Preface

Today, molecular and genomic information is informing the patient care decisions in many, if not most, areas of healthcare. Clearly, cancer diagnosis, prognosis, and treatment are driven largely by the molecular variants that drive the cancer and are the targets for new therapies. Medical genetics is moving beyond the classic single gene genetic disorders as we understand the genetic risk factors that drive the common chronic diseases that are costly to our healthcare system. While the clinical relevance of all areas of the human genome is not yet understood, our knowledge is growing rapidly and expanding well beyond the protein-coding genes to include many regulatory-coding regions, such as microRNAs and long noncoding RNAs (lncRNAs), in regions of the genome which used to be considered "junk." For infectious diseases, we are beginning to understand not only the well-known and emerging infectious agents, but that health and disease also relates to the symbiotic relationship of each patient with their microbiomes. Finally, the technologies available to the clinical molecular laboratory have advanced so the genome of individual patients can be analyzed for clinical care, even resulting in the definition of genomic critical values, which are recommended to be reported any time an exome or genome is sequenced for clinical purposes.

Molecular Pathology in Clinical Practice addresses all areas of clinical molecular pathology practice in a single textbook. This second edition has 12 new chapters, in addition to updates on the chapters from the first edition. The new chapters cover diseases not included in the first edition, plus two chapters on next-generation sequencing applications in genetics and cancer, and a proteomics chapter. The purpose of this textbook remains to provide a comprehensive reference for the practicing molecular pathologist as well as a resource for pathologists in any area of practice. The book also will continue to be used by training programs, both for Anatomic and Clinical Pathology and for Molecular Genetic Pathology trainees. This book is not meant to be a recipe book for clinical molecular tests, simply because the specifics of testing change quite rapidly in molecular pathology as new technologies emerge and are integrated into clinical molecular practice. Instead, the emphasis remains the molecular variants being detected for clinical purposes, the clinical usefulness of molecular test results, and the clinical and laboratory issues that require special attention. While this textbook focuses on molecular and genomic testing, with only a single chapter covering proteomics, the reader must understand that the genome does not drive all disease and health, but works in concert with the environment, the metabolome, the methylome, and other determinants of disease and health.

As we move toward genomic medicine, the molecular pathologist and all pathologists will play a significant role in the proper utilization of molecular and genomic tests to improve patient outcomes and the cost-effectiveness of the care we deliver. In the era of US healthcare reform, the promise of genomic medicine aligns almost perfectly with the healthcare reform goals of improving individual patient outcomes, improving the health of populations, and reducing the cost of healthcare. While much of genomic research focuses on the clinical

significance of pathogen and patient genomic variants for diagnosis and therapy, evidence of the value of genomics in clinical care also is needed, especially as we move toward population health management and global payment models.

My hope is that you apply the information in *Molecular Pathology in Clinical Practice* to the care you provide for your patients.

Burlington, VT, USA Debra G.B. Leonard

Contents

1 Basics of Molecular Biology 1
Deborah Ann Payne

2 Molecular Pathology Methods 19
D. Hunter Best, Shale A. Dames, Whitney Wooderchak-Donahue, Tracey Lewis, Kelli L. Sumner, Cecily P. Vaughn, Rong Mao, and Daniel H. Farkas

Section I Genetics

3 Genetic Counseling 55
Christine E. Miller

4 Pedigree Analysis and Risk Assessment 63
Patti Krautscheid and Danielle LaGrave

5 Bayesian Analysis 77
Robert B. Wilson and Shuji Ogino

6 Intellectual Disability and Developmental Delay: Cytogenetic Testing 91
Guangyu Gu, Reha Toydemir, and Sarah T. South

7 Developmental Delay: Gene Testing 101
Christin D. Collins, Monica J. Basehore, Kristen J. Champion, and Michael J. Friez

8 Congenital Disorders of Glycosylation 121
Melanie A. Jones and Madhuri R. Hegde

9 Neuromuscular Diseases 127
Thomas W. Prior

10 Mitochondrial Disorders 139
Renkui Bai and Jaimie D. Higgs

11 Metabolic Disorders 161
Lisa Edelmann, Yaping Yang, Amy C. Yang, and Ruth Kornreich

12 Fibroblast Growth Factor Receptor and Related Skeletal Disorders 177
Steven Sperber and Elaine Spector

13 Cystic Fibrosis 189
Lora J.H. Bean and V.M. Pratt

14 Deafness 197
A. Eliot Shearer, Robert W. Eppsteiner, and Richard J.H. Smith

15 Coagulation Disorders 203
Rajiv K. Pruthi, Michelle L. Kluge, and Aneel A. Ashrani

16 Hematologic Disorders: Hemochromatosis, Hemoglobinopathies, and Rh Incompatibility 225
Daniel B. Bellissimo and Archana Agarwal

17 Cardiovascular Disease 239
Samantha M. Baxter and Birgit H. Funke

18 Neurodegenerative Disorders 261
Maria Martinez-Lage

19 Polycystic Kidney Disease 277
Adrian Y. Tan, Jon Blumenfeld, and Hanna Rennert

20 Host Factor Pharmacogenetics for Treatment of Infectious Diseases 291
Patricia R. Slev and David R. Hillyard

21 Pharmacogenetics 301
Stuart A. Scott and Elaine Lyon

Section II Inherited Cancers

22 Inherited Breast Cancer 315
Rachel Michaelson-Cohen, Rachel Beeri, Eliahu Golomb, and Ephrat Levy-Lahad

23 Familial Adenomatous Polyposis and Turcot and Peutz–Jeghers Syndromes 329
Kandelaria M. Rumilla

24 Hereditary Nonpolyposis Colorectal Cancer and Lynch Syndrome 339
James P. Grenert

25 Multiple Endocrine Neoplasia Syndromes 351
Barbara A. Zehnbauer

26 Von Hippel-Lindau Disease 365
Catherine A. Stolle

27 Hereditary Skin Cancer 369
Dani Bercovich and Inbal Kedar

28 Li-Fraumeni Syndrome 377
Arupa Ganguly and Zhao Chen

29 Retinoblastoma 385
Arupa Ganguly and Zhao Chen

30 Hereditary Paraganglioma and Pheochromocytoma 393
Fang-Yuan Li and Lee-Jun C. Wong

Section III Solid Tumors

31 Colorectal Cancer 403
Antonia R. Sepulveda, Deqin Ma, Kathryn C. Behling, and Helen Fernandes

32 Lung Cancer 419
Dara L. Aisner, Robert C. Doebele, Marileila Varella-Garcia, and Wilbur A. Franklin

33 Breast Cancer 433
Carolyn Mies

34 Urothelial Carcinoma 447
Kevin C. Halling

35 Prostate Cancer 453
Priti Lal

36 Thyroid Cancer 471
Marina N. Nikiforova and Yuri E. Nikiforov

37 Sarcomas and Related Mesenchymal Tumors 487
Giovanni Tallini, Dario de Biase, and Pei Hui

38 Gliomas 507
Ehud Lavi

39 Molecular Detection of Circulating Tumor Cells and Cell-Free Nucleic Acids 515
Nirali M. Patel and Karen Kaul

Section IV Neoplastic Hematopathology

40 Acute Myeloid Leukemia 527
David Grimwade, Steven Knapper, and Krzysztof Mrózek

41 Acute Lymphoblastic Leukemia 561
Andrea Biondi, Carlos Alberto Scrideli, and Giovanni Cazzaniga

42 B-Cell Malignancies 579
Jennifer B. Dunlap, Guang Fan, Nicky Leeborg, and Rita M. Braziel

43 T-Cell Lymphomas 603
Jason D. Merker and Daniel A. Arber

44 Myeloproliferative Neoplasms and Myelodysplastic Syndromes 615
Albert K. Ho and Daniel M. Jones

Section V Infectious Diseases

45 Human Immunodeficiency Virus Type 1 629
Angela M. Caliendo and Colleen S. Kraft

46 Hepatitis B and C Viruses 641
Frederick S. Nolte

47 Viral Infections in Transplant Recipients 659
Raymund R. Razonable and Randall T. Hayden

48 Viral Infections of the Central Nervous System 681
Duane W. Newton and Christine C. Ginocchio

49 Bacterial Infections 695
Kevin Alby and Melissa B. Miller

50 Gastrointestinal Infections 707
Eileen M. Burd and Benjamin H. Hinrichs

51 Sexually Transmitted Diseases 735
Jeanne A. Jordan

52 Respiratory Infections 755
Christine C. Ginocchio

53 Mycobacterial Infections 779
Betty A. Forbes

Section VI Identity Testing

54 Forensic DNA Typing 793
Victor W. Weedn and David R. Foran

55 Parentage and Relationship Testing 811
Robert W. Allen and Herbert F. Polesky

56 Chimerism Testing in Allogeneic Hematopoietic Stem Cell Transplantation 823
Vivianna M. Van Deerlin and Ran Reshef

57 Specimen Identification Through DNA Analysis 849
Gregary Bocsi, Andrew Ricci, Gregory J. Tsongalis, and Vivianna M. Van Deerlin

Section VII HLA Typing

58 Molecular HLA Typing 867
Malek Kamoun, Jill A. Hollenbach, Steven J. Mack, and Thomas M. Williams

Section VIII Evolving Clinical Molecular Technologies

59 Next-Generation Sequencing: Principles for Clinical Application 889
Karl V. Voelkerding, Emily M. Coonrod, Jacob D. Durtschi, and Rebecca L. Margraf

60 Next-Generation Sequencing for the Analysis of Cancer Specimens 911
John D. Pfeifer

61 Clinical Applications of Proteomics 933
Delphine Rolland and Kojo S.J. Elenitoba-Johnson

Section IX Laboratory Management

62 Molecular Pathology Laboratory Management 945
Hanna Rennert and Debra G.B. Leonard

Basics of Molecular Biology

1

Deborah Ann Payne

Abstract

Molecular biology entails the analysis and study of the chemical organization of the cell. Molecules comprise the smallest chemical component capable of performing all the activities (structural or catalytic) of a substance. One or more atoms constitute each molecule. Many molecules comprise the various cellular and subcellular components of an organism. Molecules form not only the physical structure of the organism but communicate information between the various compartments of the cell. This communication can be the transfer of information from DNA to RNA and finally to protein or the subtle regulation of the cell's internal homeostatic processes. This communication relies on the interaction of various molecules to insure the fidelity of the message or cellular regulation. This chapter describes the physical organization of cells, cellular organelles, and molecules important in cell division, inheritance, and protein synthesis and describes how genetic information is communicated within the cell.

Keywords

Molecular biology • Genetic • Gene • Nucleic acids • DNA • RNA • Protein • Nucleotides • Amino acids • Codon • Transcription • Translation • Replication • Chromatin • Chromosomes • Complementary • Cell cycle • Hybridization • Denaturation • Mitochondria • Mutation • Ribosome • Polymerase • Exon • Intron

Introduction

Molecular biology entails the analysis and study of the chemical organization of the cell. Molecules comprise the smallest chemical component capable of performing all the activities (structural or catalytic) of a substance. One or more atoms constitute each molecule. Many molecules comprise the various cellular and subcellular components of an organism. Molecules form not only the physical structure of the organism but communicate information between the various compartments of the cell. This communication can be the transfer of information from DNA to RNA and finally to protein or the subtle regulation of the cell's internal homeostatic processes. This communication relies on the interaction of various molecules to insure the fidelity of the message or cellular regulation. This chapter describes the physical organization of cells, cellular organelles, and molecules important in cell division, inheritance, and protein synthesis and describes how genetic information is communicated within the cell.

Organization of the Cell

The cell is a mass of protoplasm surrounded by a semipermeable membrane [1]. Cells constitute the smallest element of living matter capable of functioning independently; however, within complex organisms, cells may require interaction with other cells. To function independently, cells must produce nucleic acids, proteins, lipids, and energy. In complex

D.G.B. Leonard (ed.), *Molecular Pathology in Clinical Practice*, DOI 10.1007/978-3-319-19674-9_1

organisms, these organic processes form and maintain tissues and the organism as a whole.

Genes consist of discrete regions of nucleic acids that encode proteins, and control the function of the cell. Deoxyribonucleic acid (DNA) and ribonucleic acid (RNA) comprise the two types of nucleic acids found in all cells. Chromosomes, made up of double-stranded DNA complexed with proteins, contain all the genes required for the cell to live and function.

Prokaryotic Cells

Prokaryotic cells are simple organisms lacking subcellular compartments, such as bacteria. The majority of prokaryotic nucleic acids form circular strands comprising approximately 1×10^6 base pairs (bp) (Table 1.1) [2]. Additional extrachromosomal genetic elements consist of circular plasmids also known as episomes and linear mobile genetic elements called transposable elements or transposons. Plasmids range in size from 2,686 to 500,000 bp and first gained notoriety in the 1950s by being associated with antibiotic resistance in bacteria [3, 4]. Transposons also may confer antibiotic resistance on the host bacteria. All these genetic elements exist in direct contact with the bacteria's cytoplasm.

Table 1.1 Comparison of sizes (in base pairs) of various genetic elements [2–5]

Genetic element	Size in base pairs
Human chromosome	3.3×10^9
Bacterial chromosome	$1–4 \times 10^6$
Mitochondrial chromosome	16,569
Bacteriophage	39,000
CAM plasmid	500,000
pUC19 plasmid (engineered plasmid)	2,686
Retrotransposon (i.e., SINE to LINE 1)	75–7,000
Long intergenic noncoding RNA (lincRNA)	>200
Transcribed ultraconserved regions (T-UCR)	>200
Telomeric repeat containing RNAs (TERRA)	>200
Small nucleolar RNA (snoRNA)	60–300
Promoter upstream transcripts (PROMPTs)	<200
Promoter-associated small RNAs (PASR)	22–200
Transcription start site-associated RNA (TSSa-RNA)	20–90
PIWI-interacting RNA (piRNA)	26–31
microRNA (miRNA)	22
Transcription initiation RNA (tiRNA)	17–18

Eukaryotic Cells

Cytoplasm

In contrast to prokaryotic cells, eukaryotic cells are complex, highly compartmentalized structures. The cytoplasm contains multiple membrane-bound compartments known as organelles. The cellular membrane separates the cellular cytoplasm from the external environment. The membranes consist of hydrophobic lipid bilayers. The lipid bilayer contains proteins that serve as receptors and channels.

Nucleus and Nucleolus

The nucleus of the cell contains the cell's linear chromosomes and serves as the primary locus of inherited genetic material. Inner- and outer-pore-containing membranes define the nucleus and separate the chromosomes from the surrounding cytoplasm. Further partitioning occurs within the nucleus to generate the nucleolus, which functions as the ribosome-generating factory of the cell. Instead of additional membranes, fibrous protein complexes separate the nucleolus from the rest of the nucleus. In this structure, the nucleolus organizer (a specific part of a chromosome containing the genes that encode ribosomal RNAs) interacts with other molecules to form immature large and small ribosomal subunits. Following processing, immature subunits depart the nucleolus and enter the nucleus. Eventually, mature ribosomal subunits and other molecules exit the nucleolus through the nuclear pores and enter the cytoplasm.

Mitochondria

Mitochondria are membrane-bound organelles within the cytoplasm of cells that have several cellular functions. Inheritable genetic material, independent from the nuclear chromosomes, resides in mitochondria. These maternally derived organelles contain their own circular chromosome (16,569 bp) and replicate independently from the cell and one another. As a result, not all mitochondria in a given cell have the same mitochondrial DNA (mtDNA) sequence. The genetic diversity of these organelles within and between different cells of the same organism is known as heteroplasmy. A range (approximately 39–1,283) of mitochondrial genomes are present per cell, and this number may vary with different disease states [6, 7]. Mitochondrial genes encode mitochondria-specific transfer RNA molecules (tRNA). In addition, the mtDNA contains genes that encode proteins used in oxidative phosphorylation, including subunits of the cytochrome c oxidase, cytochrome b complex, some of the ATPase complex, and various subunits of NAD dehydrogenase. Other components of the oxidative phosphorylation pathway are encoded by nuclear genes. For this reason, not all mitochondrial genetic diseases demonstrate maternal transmission. Mutations associated with mitochondrial diseases can be found at MITOMAP

(http://www.mitomap.org/MITOMAP). The higher copy number per cell of mtDNA compared with genomic DNA (i.e., approximately 100 to 1) enables the detection and characterization of mtDNA from severely degraded samples and scant samples. For this reason, mtDNA is suitable for paleontological, medical, and forensic genetic investigations. Analysis of mtDNA has applications for diagnosis of mitochondrial-inherited genetic diseases, disease prognosis, as well as forensic identification of severely decomposed bodies [6–9].

Other Cellular Organelles

Membranes not only segregate heritable genetic molecules into the nucleus and mitochondria, but also separate various cellular functions into distinct areas of the cell. The compartmentalization of cellular functions (such as molecular synthesis, modification, and catabolism) increases the local concentration of reactive molecules and improves the biochemical efficiency of the cell. This partitioning also protects inappropriate molecules from becoming substrates for these processes. One example of this segregation is the endoplasmic reticulum (ER), which consists of a complex of membranous compartments where proteins are synthesized. Glycoproteins are synthesized by ribosome-ER complexes known as rough ER (RER), while lipids are produced in the smooth ER. The Golgi apparatus possesses numerous membrane-bound sacs where molecules generated in the ER become modified for transportation out of the cell. In addition, peroxisomes and lysosomes segregate digestive and reactive molecules from the remainder of the cellular contents to prevent damage to the cell's internal molecules and infrastructure. The pathologic accumulation of large molecules within lysosomes occurs when enzymes cannot chemically cleave or modify the large molecules. Lysosomal storage and mucopolysaccharide storage diseases are associated with a variety of genetic variants and mutations. Similarly, peroxisomal diseases are associated with genetic defects in the peroxisomal enzyme pathway [1].

Biological Molecules

Carbon can covalently bond to several biologically important atoms (i.e., oxygen, hydrogen, and nitrogen) and forms the scaffold for all biomolecules. Basic subunit biomolecules can combine to form more complex molecules such as carbohydrates, nucleic acids, and amino acids.

Carbohydrates

Carbohydrates serve as energy reservoirs and are a component of nucleic acids. In addition, carbohydrates also attach to lipids and proteins. The basic unit of a carbohydrate consists of the simple sugars or monosaccharides. These molecules have carbon, oxygen, and hydroxyl groups that most commonly form ringed structures. The oxygen can react with the hydroxyl group of another simple sugar to form a chain. As a result, the formula for a simple sugar is $(CH_2O)^n$, where n represents various numbers of these linked building block units.

Two pentose sugars, deoxyribose and ribose, comprise the sugar element of DNA and RNA molecules, respectively. As the name indicates, deoxyribose ("de-," a prefix meaning "off" and "oxy," meaning "oxygen") lacks one hydroxyl (OH) group compared with ribose.

Nucleic Acids

Nucleic acids are composed of chains of nucleotides. Each nucleotide is composed of a sugar (either ribose or deoxyribose), a phosphate ($–PO_4$) group, and a purine or pyrimidine base. The nucleotides are joined into a DNA or RNA strand by a sugar-phosphate-linked backbone with the bases attached to and extending from the first carbon of the sugar group. The purine and pyrimidine bases are weakly basic ring molecules, which form N-glycosidic bonds with ribose or deoxyribose sugar. Purines are comprised of two rings, a six-member ring and a five-member ring ($C_5H_4N_4$), while pyrimidines consist of a single six-member ring ($C_4H_2N_2$). Purines (guanine, G, and adenine, A) pair with pyrimidines (cytosine, C, and thymine, T) via hydrogen bonds between two DNA molecules (Fig. 1.1). The additional hydrogen bond that forms between G and C base pairing (i.e., three hydrogen bonds) dramatically enhances the strength of this interaction compared to the two hydrogen bonds present between A and T nucleotides. This hydrogen-bonding capacity between G:C and A:T forms a pivotal molecular interaction for all nucleic acids and assures the passage of genetic information during DNA replication, RNA synthesis from DNA (transcription), and the transfer of genetic information from nucleic acids to the amino acids of proteins.

Numerous types of base modifications increase the number of nucleotides beyond the classic four types (i.e., A, T, G, and C). Although these modifications do not alter the base's hydrogen bonding characteristics, modified nucleotides serve various functions in the cell including (1) regulating gene function, (2) suppressing endoparasitic sequence reactivation, (3) identifying DNA damage, and (4) facilitating translation. Modifications such as 5-methylcytosine, 5-hydroxymethylcytosine, 5-formylcytosine, and 5-carboxylcytosine influence gene expression. Most endoparasitic sequences such as retrotransposons (e.g., long interspersed nucleotide elements [LINE 1]) are hypermethylated in normal tissue but hypomethylated in cancer tissue [10].

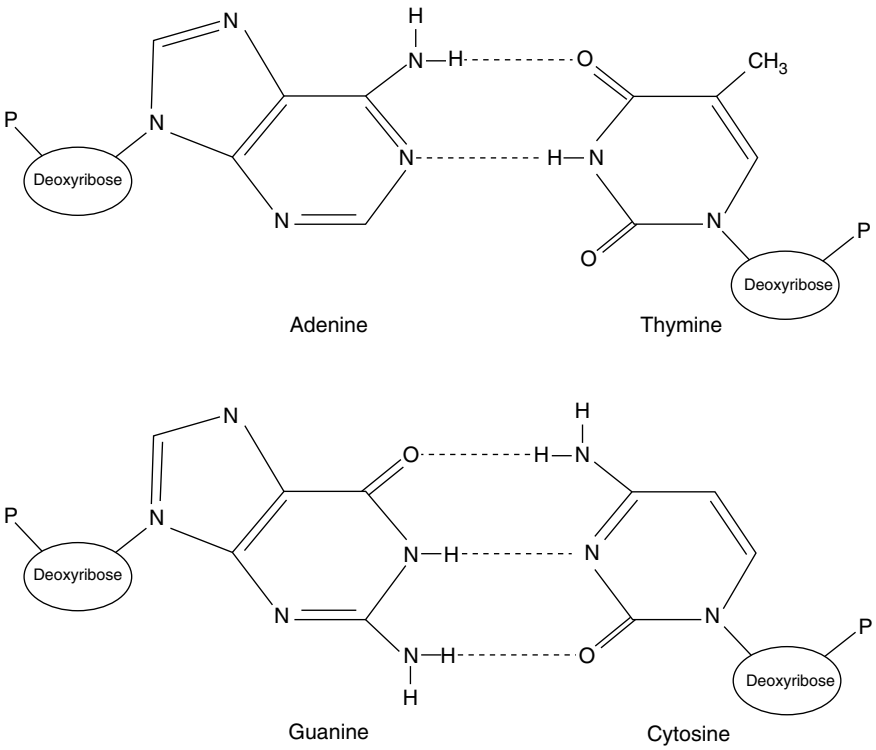

Figure 1.1 DNA base pairing. DNA nucleotides are composed of three moieties (e.g., sugar, base, and phosphate groups). The bases are either purine (adenine and guanine) or pyrimidine (thymine and cytosine). Note the difference in hydrogen bonds between adenine and thymine base pairs, with two hydrogen bonds, compared to cytosine and guanine base pairs, with three hydrogen bonds. Reprinted with permission from Leonard D. Diagnostic Molecular Pathology. 2003:1–13. Copyright Elsevier (2003)

Presumably the hypermethylation of the LINE 1 sequences prevents various insults to the host genome by inactivating the ability of these elements to transpose themselves. Methylation also regulates the phenomenon of imprinting. Methylation mechanisms include P-element-induced wimpy testis (in *Drosophila*, PIWI) proteins and PIWI-interacting noncoding RNAs (specifically, piRNA) [11]. Additionally, certain modifications such as 8-oxoguanine and 8-oxoadenine are associated with DNA damage. Base pair modifications are not limited to DNA but also influence the function of tRNAs [12]. Some of these modifications include 5-formylcytidine, queuosine, 5-taurinomethyluridine, and 5-taurinomethyl-2-thiouridine. Certain tRNA modification defects result in mitochondrial disease [13]. Modifications of rRNA include 2′-O-methylation and pseudouridylation and enable rRNA folding and stability. Such modifications result from interactions of the bases with small nucleolar ribonucleoproteins and noncoding small nucleolar RNAs [5]. With the advent of methodologies that simplify the detection of modified bases, the role of modified bases in human disease may become better understood [14].

Amino Acids

Amino acids are the building blocks of proteins. Amino acids linked together via peptide bonds form large, complex molecules. Amino acids consist of an amino group (NH_3), a carboxyl group (COO–), an R group, and a central carbon atom. The R group can be a simple hydrogen, as found in glycine, or as complex as an imidazole ring, as found in histidine. Twenty different R groups exist (Table 1.2), and determine whether an amino acid has a neutral, basic, or acidic charge. The amino group of a polypeptide is considered the beginning of the protein (N-terminus), while the carboxyl group is at the opposite end, providing directionality to the protein.

Genetic Molecules

Nucleic acids encode genetic information but also participate in additional physiological processes ranging from metabolism to energy transfer. Nucleotides constitute the monomeric units of nucleic acids (Fig. 1.1). Nucleosides consist of two components (ribose or deoxyribose in RNA and DNA, respectively, and either a purine or pyrimidine base). A nucleotide is produced from a nucleoside by the addition of one to three phosphate groups through a covalent bond with the hydroxyl group of the 5′ carbon of the nucleoside's sugar ring.

Nucleic acids consist of chains of nucleotides linked by phosphodiester bonds between the 3′ carbon of the first nucleotide's sugar ring and the 5′ carbon of the adjacent nucleotide's sugar ring. The phosphodiester linkages cause nucleic acids to have a 5′ to 3′ directionality. The alternating

The two bolded atoms in each of histidine (N–C), proline (N–C), and tryptophan (Ph–C) are covalently bonded to each other. Ph is a phenyl ring.

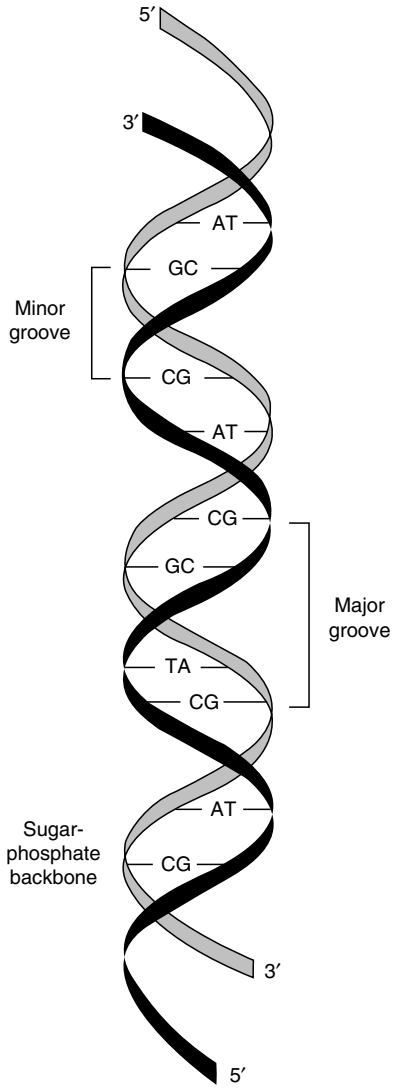

Figure 1.2 Double-stranded DNA. The two DNA strands are oriented in an antiparallel relationship, with asymmetric base pairing of two DNA strands that generates the minor and major grooves of the DNA double helix. Reprinted with permission from Leonard D. Diagnostic Molecular Pathology. 2003:1–13. Copyright Elsevier (2003)

sugar-phosphate chain forms a continuous molecule with bases extending from the 1′ carbon of each sugar. For this reason, the sugar-phosphate chain is referred to as the backbone of nucleic acids (Fig. 1.2). The phosphate groups give nucleic acids a negative charge that imparts important physiochemical properties to nucleic acids. The negative charge of DNA facilitates the binding of mammalian DNA to various proteins and allows separation of nucleic acid molecules by charge and size during gel or capillary electrophoresis.

Structure

In double-stranded DNA, the two DNA strands are held together by exact A:T and G:C hydrogen bonding between the bases of the two strands, in which case the two strands are said to be complementary. The two strands are oriented in opposite 5′ to 3′ directions, such that one strand is oriented 5′ to 3′ and the complementary strand is oriented 3′ to 5′ in an antiparallel fashion (see Fig. 1.2). In this case, "anti-" refers to the head (or 5′ end) of one DNA strand being adjacent to the tail (or 3′ end) of the opposite strand.

The molecular curves of the two DNA strands form antiparallel helices known as the DNA double helix. This double-helix form (the B form) has ten nucleotide base pairs per turn, occupying 3.4 nm. Because the bonds between the sugar and the base are not perfectly symmetrical, the strands curve slightly. The slight curve of the offset glycosidic bonds results in major and minor grooves characteristic of the B form of the double helix [15]. Many clinical molecular tests target the minor groove of DNA with sequence-specific probes known as minor groove-binding (MGB) probes. Two other forms of DNA exist as the Z and A forms. The Z form

acquires a zigzag shape, while the A form has very shallow and very deep grooves.

Thermodynamics of Nucleotide Base Pairing

Thermodynamics plays a major role in the structure and stability of nucleic acid molecules. The core mechanism of nucleic acid thermodynamics centers on the hydrogen-bonding capabilities of the nucleotides. The stability of these interactions not only influences the formation and stability of duplex (or double-stranded) nucleic acids but also impacts the structure and catalytic characteristics of single-stranded nucleic acids through intramolecular base pairing. In addition to these physiological functions, the phenomenon of complementary base pairing profoundly impacts clinical diagnostic test development. Prior to the advent of clinical molecular testing, many clinical tests required a target-specific antibody to identify or detect a target protein. The procedures for generating and validating diagnostic antibodies require extensive time and expense. The application of techniques utilizing the capability of two molecules to base pair as the basis for detection and characterization of target nucleic acids has greatly facilitated clinical molecular test development. The formation of hydrogen bonding between two pieces of nucleic acid is called hybridization, or annealing, and the disruption of the hydrogen bonds holding two nucleic acid molecules together is called denaturation, or melting. The fact that clinical molecular tests use hybridization techniques based on A:T and G:C base pairing underscores the necessity for understanding the thermodynamics of the hydrogen base pairing of nucleic acids.

Short pieces of DNA or RNA called probes, or primers, that contain a specific sequence complementary to a disease-related region of DNA or RNA from a clinical specimen are frequently used for clinical molecular tests. To achieve hybridization of a DNA or RNA probe to genomic DNA for a clinical molecular test, the two genomic DNA strands must be separated, or denatured, prior to probe hybridization. Increasing the temperature of a DNA molecule is one mechanism for disrupting the hydrogen bonds between the DNA base pairs and denaturing double-stranded DNA into single-stranded form. The temperature at which 50 % of the double-stranded DNA molecules separate into single-stranded form constitutes the melting temperature (T_m). The shorter the two complementary DNA molecules are, the easier it is to calculate the T_m. This primarily results from the decreased likelihood of nonspecific intramolecular annealing or base pairing compared to inter- and intramolecular base pairing. The simplest and least accurate formula for determining the T_m for short double-stranded DNA multiplies the sum of the G:C base pairs by 4 and multiplies the sum of the A:T base pairs by 2 and then adds these numbers together:

$$T_m = \left[4(\mathrm{G:C})\right] + \left[2(\mathrm{A:T})\right]$$

Although this is the least accurate method for calculation of the T_m of a double-stranded DNA molecule, it mathematically illustrates that G:C bonds are roughly twice the strength of A:T bonds. This formula works fairly well for short DNA molecules (i.e., <18 bp); however, as the length of the DNA molecule increases to 100 bp, the nearest neighbor T_m calculation for DNA and RNA is more accurate [16, 17]:

$$T_m = \frac{\Delta H}{\Delta S + R\ln(\mathrm{Ct})} - 273.15$$

where

ΔH = enthalpy of the nucleic acid fragment
ΔS = entropy of the nucleic acid fragment
$R = 1.987\ \mathrm{calK^{-1}\ mol^{-1}}$
Ct = total strand concentration

For longer sequences (>100 bp), the most accurate formula for calculation of T_m is as follows [18]:

$$T_m = 81.5^{\circ}\mathrm{C} + 16.6(\log_{10}[\mathrm{Na^+}]) + 0.41[\%\mathrm{GC}] - 0.65(\%\,\mathrm{formamide}) - 675/\mathrm{length} - \%\mathrm{mismatch}$$

Table 1.3 demonstrates the effect of increasing the relative amounts of G:C base pairs on the T_m using these formulas.

Intramolecular base pairing also generates complex three-dimensional forms within single-stranded nucleic acid molecules. As a result, the single-stranded nature of eukaryotic RNA molecules affords great structural diversity via intramolecular base pairing. These conformations strain the linear RNA molecule and produce chemically reactive RNA forms. Catalytic RNA molecules play pivotal roles in cellular functions and in gene-targeting therapies.

Intra- and intermolecular base pairing can negatively affect hybridizations. Dimers, bulge loops, and hairpin loops exemplify some of these interactions. Hairpins inhibit plasmid replication and attenuate bacterial gene expression [2].

Table 1.3 Melting temperature calculations for short oligomers

Total length	Number of G:C	Number of A:T	T_m[a]	%G:C[b]	A:T+G:C[c]
30	30	0	106.2	100.0	100.0

30	0	30	71.6	59.0	60.0
20	20	0	90.4	88.8	80.0
20	10	10	72.7	65.1	60.0
20	0	20	55.9	47.8	40.0

[a]Nearest-neighbor calculation of T_m [16]
[b]T_m method for sequences over 100 bases [18]
[c]4(G+C)+2(A+T) formula

These detrimental effects also may include initiation of spurious nonspecific polymerization, steric hindrance of hybridization of short stretches of nucleic acids (i.e., 10–30 base pieces of single-stranded nucleic acids, known as oligomers or primers), and depletion of probes or primers away from the specific target by either primer dimerization or other mechanisms. These interactions can result in poor sensitivity or specificity for clinical molecular tests.

Topology

The DNA and RNA molecules assume various geometric shapes or topologies that are independent of base pair interactions. Eukaryotic nucleic acids take on linear forms, in contrast to the circular forms of mitochondrial and bacterial chromosomal DNA. Transposable elements within the human genome also have a linear topology. Viral genomes occur as different forms, ranging from segmented linear to circular, and can be present in the nucleus, cytoplasm, or integrated within the human genome. Although the conformation of RNA molecules can be complex via intramolecular base pairing, the topology of messenger RNA (mRNA) molecules is primarily linear. An organism's genomic topology influences the biochemical mechanisms used during replication and the number of replication cycles a given chromosome can undertake. In contrast to circular genomes, linear genomes limit the total number of possible replication cycles due to progressive shortening of the linear chromosome. In order to mitigate the shortening of the linear chromosomes, the ends of the chromosome contain tandem guanine base-rich repeats known as telomeres.

Mammalian Chromosomal Organization

The human genome contains approximately 3.3×10^9 base pairs of DNA. At least 2.94 % of the genome encodes genes according to the GENCODE reference gene set [19]. However, more protein-encoding genes may be identified if the bioinformatic definition of a gene changes [20]. Approximately, 80.4 % of the genome engages in at least one RNA- and/or chromatin-based activity with many of these bases being located in regions possessing repeated sequences. Most of the repeated sequences are retrotransposons, including long interspersed repeat sequences 1 (LINE 1), short interspersed repeat sequences (SINE, including Alu sequences), retrotransposable element 1 (RTE-1), endogenous retroviruses, a chimeric element (SVA) composed of "SINE-R," and variable number of tandom repeats (VNTRs). The ability of retrotransposons to duplicate and insert within the genome (i.e., either autonomously or with the help of autonomous elements) has been associated with various types of genetic mutations. Mechanisms for mutations include insertional mutagenesis, unequal homologous recombination resulting in the loss of genomic sequences, and generation of novel genes. More than 100 different reports associate retrotransposons with various genetic disorders ranging from hemophilia to breast cancer [21, 22]. Retrotransposons influence transcription of microRNAs (discussed later in this chapter). Because transposable elements can replicate and cause genetic deletions with the human genome, the number of human base pairs is not static. However in germline cells, piRNAs stabilize the genome by cleaving transposable element transcripts [5].

The total DNA is contained in 46 double-stranded DNA pieces complexed with proteins to form chromosomes. The diploid human cell possesses 46 chromosomes: two of each of the 22 autosomal chromosomes, plus either two X chromosomes in females, or one X and one Y chromosome in males. Since the length of each helical turn of a double-stranded DNA molecule is 3.4 nm and consists of ten bases, the length of the total genomic DNA in each cell measures approximately 1 m in length.

For each cell to contain these long DNA molecules, the double-stranded DNA must be compressed. A complex of eight basic histones (two copies each of histone 2 [H2], H3, H4, and H5) package the DNA [23]. The histone complex contains positively-charged amino acids that bind to 146 bases of negatively-charged DNA. Histones fold the DNA either partially or tightly, resulting in compression of the DNA strand. Tight folding of the DNA condenses the DNA into heterochromatin. Following packaging and condensation, the nucleic acid strand widens from 2 to 1,400 nm, with extensive overall shortening of the nucleic acid in the metaphase chromosome. Light microscopy easily permits the visualization of condensed metaphase chromosomes.

Hypersensitivity to DNase I identifies approximately 2.9 million sites with less condensed DNA in the genome [24]. Less condensed DNA binds histone 1 (H1) proteins or other sequence-specific DNA-binding molecules. Some of these DNA-binding molecules regulate gene expression (discussed later in this chapter). In contrast, tightly condensed chromosomes lack the "open spaces" for binding of regulatory proteins and prevent gene expression from highly condensed DNA regions. These proteins also may prevent access to nucleic acid probes or primers for clinical molecular tests. Some tissue fixation methods can create covalent links between the nucleic acid and these proteins that can cause molecular testing artifacts (e.g., false-negative results). As a result, many DNA extraction protocols include a protein-digestion step to liberate the DNA from the DNA-binding proteins. Removal of the proteins facilitates hybridization with short pieces of nucleic acid, such as primers or probes.

DNA Replication

Eukaryotic DNA Replication

The replication of DNA is a complex process requiring specific physiological temperatures and a host of proteins. As mentioned previously, clinical molecular testing methods rely on the ability to denature or melt a double-stranded DNA template. Using chemical or physical conditions, separation of DNA strands can be accomplished with alkaline conditions or high temperatures (i.e., 95 °C). Under physiological conditions, dissociation of DNA strands for replication is accomplished by numerous enzymes, such as helicases and topoisomerases. The region of transition from double-stranded to separated single-stranded DNA is called the replication fork. The replication fork moves along the double-stranded DNA molecule as replication proceeds. At the replication fork, various primases, initiating proteins, and polymerases bind to the original or parental DNA strands and generate two new daughter strands. Known collectively as a replisome, these enzymatic activities generate two new nucleic acid strands that are complementary to and base paired with each of the original two template or parent DNA strands. This replication process is known as semiconservative because each resulting double-stranded DNA molecule consists of one new and one old DNA strand (Fig. 1.3).

Polymerases function to synthesize new nucleic acid molecules from nucleotide building blocks. The sequence of the new strand is based on the sequence of an existing nucleic acid molecule, and the polymerase adds nucleotides according to the order of the bases of the parent strand, using G:C and A:T pairing. The new strand is antiparallel to the parent strand and is synthesized in a 5′ to 3′ direction. Of the two parent strands of genomic DNA, one strand (called the leading strand) can be read continuously in a 3′ to 5′ direction by the polymerase, with the new strand generated in a continuous 5′ to 3′ direction. In contrast, the opposite strand (known as the lagging strand) cannot be read continuously by the polymerase. The replication fork moves along the lagging strand in a 5′ to 3′ direction, and the polymerase synthesizes only by reading the parent strand in a 3′ to 5′ direction while synthesizing the new strand in a 5′ to 3′ direction. Therefore, synthesis cannot proceed continuously along the lagging strand, which must be copied in short stretches primed from RNA primers and forming short DNA fragments known as Okazaki fragments. The new strand complementary to the lagging strand is formed by removal of the RNA primer regions and ligation of the short DNA fragments into a continuous daughter strand complementary to the lagging strand.

Discontinuous 3′ to 5′ replication results in the progressive loss of ends of the chromosomes known as telomeres in normal cells. The guanine-rich telomeres form secondary structures (or caps) that prevent chemical processes that can damage the chromosome. Apoptosis occurs when the number of uncapped telomeres reaches a critical threshold that triggers cell death. Telomerase reverse transcriptase (hTERT) and telomeric repeat containing RNAs (TERRAs) contribute to telomere homeostasis by adding bases to the 3′ end. Mutations in the hTERT and/or the telomerase RNA template (hTERC) decrease telomerase activity and are associated with dyskeratosis congenital, bone marrow failure, and pulmonary fibrosis [25–27]. Telomerase activity varies with cell type with lymphocytes experiencing more telomere length shortening than granulocytes. Telomeres shorten with age with the most prominent shortening occurring between birth and the first year of age, followed by childhood and after puberty or adulthood [28]. In contrast to these age-related changes, some malignant cells retain telomerase activity that permits the addition of these terminal telomeric sequences to the chromosomes, prolonging the life of the cell.

While replication requires many proteins, the polymerase determines the speed and accuracy of new strand synthesis. The rate that the four nucleotides are polymerized into a nucleic acid chain defines the processivity of the enzyme. The processivity of most polymerases approximates 1,000 bases per minute.

The fidelity of the polymerase refers to the accuracy of the enzyme to incorporate the correct complementary bases in the newly synthesized DNA. Incorporation of incorrect bases or other replication errors can result in cell death or oncogenesis. The error rate of polymerases varies widely from 1 in 1,500 to 1 in 1,000,000 bases (Table 1.4). DNA is susceptible to base pair changes while in the single-stranded form due to the activity of various deaminating enzymes. Many of these enzymes are induced during inflammation and have been associated with somatic hypermutation of rearranged immunoglobulin genes [32].

This DNA editing process may be a mechanism to protect the host genome from viruses replicating within the nucleus [33, 34]. To correct the erroneous incorporation of bases or other replication errors, protein complexes proofread and correct synthesis errors. In normal cells, the cell cycle pauses to facilitate error repair in the G2 phase of the cell cycle (Fig. 1.4). Malignant cells may not pause to allow for error correction, resulting in the accumulation of damaged or mutated DNA.

The complexity of the biochemical reactions necessary for replicating eukaryotic nuclear DNA demonstrates a high degree of regulation for generating two strands from one replication fork. In addition to these complexities, replication in eukaryotic cells occurs at multiple origins. These multiple sites grow progressively until the newly generated strands join to form complete chromosomal-length DNA.

Bacterial and Mitochondrial Replication

The relatively small chromosomes of bacteria (approximately 10^6 base pairs) are replicated by a simpler mechanism compared with eukaryotic chromosome replication. A single origin of replication initiates the duplication of the bacterial chromosome, and replication occurs simultaneously on both strands in opposite directions from the origin of replication. This efficient replication process depends on the circular topology of the bacterial genome.

Another unique feature of prokaryotic chromosomal replication is the mechanism by which bacterial chromosomes are protected. The lack of a protective nuclear membrane in bacteria makes the chromosome susceptible to attack by viruses (i.e., bacteriophages). As a result, many bacteria produce restriction enzymes that degrade foreign nucleic acids. These restriction enzymes recognize specific short sequences and cleave the bacteriophage DNA at those sites. However, methylation of the recognition sequences in the bacterial chromosomal DNA prevents most restriction enzymes from digesting the chromosomal DNA of the bacteria. Following replication, methylating enzymes add methyl groups to the new bacterial chromosomal DNA, preventing chromosomal degradation by the restriction enzymes. This methylation and restriction process functions as a primitive immune system by destroying foreign bacteriophage DNA before it can usurp the bacteria's replication system. Bacterial restriction enzymes are used to specifically cleave DNA in clinical molecular tests and can be used to identify genetic variations.

Additional types of replication occur in some viruses and bacteria. The rolling-circle mechanism of replication proceeds with an initial single-strand cut or nick in double-stranded circular genomes, followed by replication proceeding from the nick in a 5′ to 3′ direction. The new strand

displaces the old strand as replication proceeds. RNA viral genomes use the enzyme transcriptase for replication. In the case of retroviruses, a reverse transcriptase generates an intermediate DNA molecule, which integrates into the host chromosome and then is used for generation of progeny RNA molecules. The high error rate of human immunodeficiency virus (HIV) reverse transcriptase produces numerous mutations in the HIV viral genome during replication [31]. Some of these mutations confer resistance to antiretroviral therapies and can be identified by clinical molecular tests.

Cell Division and Cell Cycle

In eukaryotic cells, the cell cycle refers to the entire process of generating two daughter cells from one original cell, with chromosomal replication as one of the steps. The two parts of the cell cycle are called interphase and mitosis. DNA synthesis occurs during interphase and consists of three stages: gap 1 (G1), synthesis (S), and gap 2 (G2) (Fig. 1.4). Regulation of cell division depends on specific cell-cycle-dependent proteins known as cyclins and growth factors. Some of these factors cause the cycle to progress while others stop the cycle at certain stages. Checkpoints, or times when the cycle may be paused, exist at the G1/S and G2/mitosis (M) interfaces and allow the cell time to repair any DNA damage that may be present before and after replication of the DNA, respectively.

Growth factors initiate the G1 phase via cell surface receptors. Several molecular events such as the dephosphorylation of the retinoblastoma protein and cyclin binding to cyclin-dependent kinases (Cdk) transition the cell toward the G1/S checkpoint. The amount of cellular P53 protein determines whether the cell progresses beyond this checkpoint, with higher levels preventing cell cycle progression. Because various DNA-damaging events, such as ultraviolet light, radiation, carcinogens, and double-stranded DNA breaks, induce production of P53 protein, this molecule serves as a sentinel for mutated DNA. The functional failure of P53 removes this sentinel pause in the cell cycle process and results in the accumulation of genetic errors. Alternatively, downregulation of P53 pathway genes may occur through interaction with the promoter of long intergenic noncoding RNAs (specifically lincRNA-p21) [35]. Therefore, inactivation of P53 facilitates oncogenesis.

Once DNA repairs have taken place during G1 prior to replication of the DNA, the cell proceeds to S phase. DNA synthesis to create a second complete set of chromosomes occurs in the S phase, followed by the G2 phase. Replication errors occurring during the S phase are corrected in the G2 phase, called the G2/M checkpoint. This final checkpoint marks the end of interphase.

Mitosis, the process of physical division of the parent cell into two daughter cells, occurs during mitosis or M phase of the cell cycle. During mitosis, the duplicated chromosomes are physically separated so that each daughter cell receives the correct number of chromosomes. Mitosis consists of five phases: prophase, prometaphase, metaphase, anaphase, and telophase. The duplicated chromosomes condense during prophase. A structural element known as the mitotic spindle originates from two structures called centrioles, which move to opposite sides or poles of the cell and the spindle forms between the centrioles. The nuclear membrane dissipates, proteins form kinetochores on the chromosomes, and microtubules attach to the kinetochores during prometaphase. The duplicated chromosome pairs attach at central points along the spindles. The arrangement of the highly condensed chromosome pairs along an equatorial cell plane denotes metaphase. As previously discussed, highly condensed chromosomes cannot bind proteins necessary for gene expression. As a result, the cell's internal machinery focuses solely on cell division during metaphase. The centriole-derived spindle guidelines pull the duplicate chromosomes apart and drag them toward each centriole during anaphase. With the separation of the daughter chromosomes (chromatids) into opposite poles of the cell and the reformation of nuclear membranes around the two daughter sets of chromosomes, telophase begins.

Cytokinesis, or the division of the cytoplasm, is the last step in cell division. During cytokinesis, the mitochondria are randomly and potentially unevenly distributed in the daughter cells. The cell cycle can then be reinitiated by one or both of the daughter cells to generate additional cells. Alternatively, some cells become quiescent in a G0 phase (between telephase and G1) and either have a prolonged delay before initiating replication again or no longer divide.

Cell division to generate gametes (eggs and sperm) is called meiosis and consists of two divisions, meiosis I and meiosis II. Like mitosis, this process begins with the duplication of chromosomes in prophase I. During metaphase I, the maternal and paternal homologous chromosomes pair (i.e., pairing occurs between each of the pairs of the 22 autosomal chromosomes, the two X chromosomes in females and the X and Y chromosomes in males). Each pair attaches to the spindle apparatus along the equatorial plane of the cell spindle. DNA may be exchanged between the paired chromosomes by either crossing-over or recombination mechanisms during this pairing stage of meiosis I. During anaphase I, homologous chromosomes separate into daughter cells, resulting in 23 duplicated chromosomes of assorted maternal and/or paternal origin in each daughter cell. A second cell-division cycle, meiosis II, separates the duplicated

chromosomes, resulting in haploid cells (eggs or sperm) containing only one copy of each of the 22 chromosomes plus an X (egg or sperm) or Y (only sperm) chromosome.

From Gene to Protein

The genomic DNA content is the same in all cells of the same person, unless mosaicism or cell-type specific gene rearrangements are present, and encodes all the genetic information for cellular function, in combination with the mtDNA-encoded products. Encoded in the DNA are the blueprints for the RNA and protein molecules present in any type of cell. Different parts of the genetic information are used by different types of cells to accomplish each cell's specific function. DNA is used to produce RNA which in turn can be used to produce proteins by processes called transcription and translation, respectively. The regions of DNA that encode RNA for production of proteins are called genes.

Replication requires an increase in building materials for the duplicated daughter cells. Highly condensed metaphase chromatin cannot produce gene products because proteins that initiate gene expression cannot bind to the chromosomes at this phase of replication. Regulation of such processes involves some long noncoding RNAs (lncRNA) that mediate chromatin remodeling and X chromosome inactivation [36, 37]. In contrast, partially condensed or unfolded chromatin permits the binding of specific proteins (e.g., RNA polymerases) that synthesize mRNA and tRNA, which ultimately facilitate the production of gene products, specifically proteins.

Some RNA molecules function as the mediators between DNA and protein, while others have a regulatory function (discussed later in the chapter). RNA essentially is in the same language as DNA because, as nucleic acids, RNA can base pair with complementary DNA sequences. Like transferring spoken language to a written form, this process of copying information from DNA to RNA is referred to as transcription. The transcription complex, composed of proteins, must unwind the double-stranded DNA at the specific gene site to be copied into RNA, locate the polymerase binding site on one of the DNA strands, and generate a primary (1°) transcript, which is one component of heterogeneous nuclear RNA (hnRNA) by reading the DNA strand in a 3′ to 5′ direction, with RNA synthesis proceeding in a 5′ to 3′ direction. The 1° RNA transcript is processed into mRNA, and finally the DNA in the region of the gene becomes double-stranded again. Numerous DNA sequences bind RNA and proteins that regulate and coordinate gene expression. These sequences can be used to identify the locations of genes within the entire human genome sequence. Since the generation of the first draft of the human genome, the interest in understanding gene structure has increased with the goal of identifying disease-associated genes [38–40].

Gene Structure

Promoting Transcription

Processed and primary transcripts cover 62.1 % and 74.7 % of the human genome, respectively [20]. Not all transcribed sequences produce functional proteins. In fact, most transcripts serve regulatory functions with many of these being lncRNAs (http://www.lncrnadb.org/). According to the Gencode annotation v7, the genome possesses 20,687 protein encoding genes, 8,801 small RNAs (miRNA, piwiRNA, PASRs, TSSa-RNA, PROMPTs, and tiRNA [see Table 1.1]), 9,640 lncRNAs (linRNA, T-UCR and TERRAs), and 863 transcriptionally active pseudogenes from a total of 11,224 total pseudogenes. Some sequences that bind RNA polymerases in combination with transcription factors to drive and regulate the production of 1° RNA transcripts are listed in Table 1.5. Proteins and transcription factors bind to sequences located 5′, or upstream, of the gene to be expressed which

are collectively called the promoter region of a gene. Negative numbering denotes the location of these sequences upstream of the first protein-coding codon of the gene. The promoter sequence initiates (or promotes) transcription of the downstream gene and harbors conserved sequences that are recognized by the transcription complex of enzymes.

The complexity and organization of the transcription regulatory sequences of genes differ between prokaryotic and eukaryotic cells. Prokaryotes contain a simple gene structure with sequences for polymerase binding occurring at −35 and −10 for each gene. The −10 sequence contains a consensus sequence of TATAAT, while the −35 region consists of TTGACA. Variations of these sequences as well as the sequences located adjacent to the gene determine the strength of the promoter's transcriptional activity. For example, small differences such as having a TATATA sequence rather than the consensus sequence at the −10 position will decrease the promoter binding to the RNA polymerase and result in decreased production of mRNA for that gene. In bacteria, operons regulate expression of multiple genes with related functions from the same promoter.

In eukaryotic genes, various promoter sequences bind multiple proteins and/or regulatory RNA molecules, which catalytically modify and activate other bound proteins. Enhancer sequences increase the production of mRNA but are far removed from the gene. One of the pivotal proximally located sequences comprises a TATA box (TATAAA) located at −25 (Fig. 1.5). These bases initiate binding of a TATA-binding protein (TBP) within the transcription factor D complex. Following this binding, transcription factors B, H, and E bind to and open the DNA strands downstream from the promoter. Finally, transcription factor F and RNA polymerase II bind to the transcription complex. The close proximity of these proteins to RNA polymerase II permits phosphorylation of the polymerase and initiation of transcription.

In eukaryotic cells, variations in the recognition sequences alter the efficiency of transcription. These variations may be base pair changes or base modifications. As previously mentioned, consensus sequences enable the polymerase to bind and initiate transcription. The strength of the binding is determined by how closely the promoter-binding sites resemble the prototypical consensus sequence. Additionally, the presence of modified bases near or distant from the promoter region also can influence the efficiency of transcription. The two main locations for methylcytosine are CpG dinucleotide islands and regions known as CpG shores that are located approximately 2,000 bp away from the islands. Typically, hypermethylation in CpG dinucleotide islands and CpG island shores downregulate gene expression [41]. Methylation of bases in non-CpG islands and island shores also has been described and is associated with CHG and CHH sites (i.e., H indicates either A, C, or T at the position) [42]. As a result, a gene may appear to be unaltered or intact but may be transcriptionally silent due to methylated bases near to or within the promoter region. In contrast, increased transcriptional activity occurs with gene-body methylation. The proposed mechanism of enhanced methylated gene-body associated transcriptional activity suggests that elongation efficiency and prevention of spurious initiations result from genes methylated in this manner [43]. These are just a few mechanisms used to control gene expression. Additional regulatory mechanisms involve the next steps of gene expression.

Elongation and Termination of the mRNA

Once the RNA polymerase binds to the promoter, transcription begins at position +1 of the gene sequence. The polymerase reads the DNA in a 3′ to 5′ direction, while synthesis of the 1° RNA transcript proceeds in a 5′ to 3′ direction. In bacteria, the complete transcript serves as the template for translation. Transcription ends with a termination process. The mRNA must be terminated in bacteria; termination of the transcript can result from attenuation or the formation of hairpin structures. Termination occurs at several sites beyond the polyadenylation signal in eukaryotic cells and is dependent on bases near the stop codon [44]. Because the eukary-

otic cell transcripts are polyadenylated, termination of transcription by a process similar to attenuation is not necessary to regulate gene expression.

In eukaryotic cells, once the 1° RNA transcript has been produced in the nucleus, this transcript is processed to form an mRNA by splicing to remove the non-protein coding introns (intervening sequences) and join together the protein-coding exons. Introns are located between sequences called exons, which encode the protein sequence and are translated from RNA to amino acids during protein synthesis. Splicing involves a complex of ribonucleoproteins known as a spliceosome, which recognizes consensus sequences at the 5′ and 3′ ends of the intron. Genetic changes to these splice donor (A/C AG G U A/G AGU) and splice acceptor ($[U/C]_u$ N C/U AG G/A) consensus sequences may prevent the spliceosome from recognizing and catalyzing the splicing event [45, 46]. Autoantibodies directed to or alterations in the steady-state level of the spliceosome may play a role in some diseases [47, 48]. Alternate splicing may generate multiple distinct transcripts from a single gene. That is, some exons may be spliced out in one mRNA molecule but retained in another. As a result, alternate splicing generates different RNAs and proteins from the same gene and 1° RNA transcript [49, 50].

An additional mechanism of generating diversity from 1° RNA transcripts entails *trans*-splicing (initially identified in *Drosophila* cells). Essentially, two separate, unrelated transcripts form a hybrid molecule by using the splice donor from one transcript and the splice acceptor from the second transcript. Complementary intronic sequences in both transcripts facilitate the generation of the chimeric mRNA. When the process is used for gene therapy applications, normal gene function has been restored from defective genes using *trans*-splicing [51, 52]. Other therapeutic applications for catalytic RNA molecules involve innovative treatments for HIV-infected patients. In this application, synthetic ribozymes cleave drug-resistant variants of HIV [53–55]. RNA editing involving adenosine deaminases acting on tRNAs (ADATs) changes transcripts that will ultimately produce different polypeptides (i.e., by converting adenosine into inosine which can base pair with A, C, or U). For example, intestinal APOBEC1 deaminases edit a specific residue in human apolipoprotein B (apoB) by introducing a stop codon resulting in a smaller protein in the intestine compared with the liver [56].

Additional modifications of the 1° RNA eukaryotic transcript enhance the stability and transport of the mRNA. One such modification occurs immediately after the generation of the 1° transcript and involves addition of a 7-methyl guanosine linked in an unusual 5′ to 5′ linkage to the triphosphate at the 5′ end of the transcript, also known as the 5′ cap. This cap protects the transcript from degradation. Another 1° transcript modification is cleavage at a polyadenylation signal (AAUAA) near the 3′ end of the transcript, followed by the addition of 100–200 adenosine residues (poly-A tail) by polyadenylate polymerase. Mutations in the polyadenylation signal have been associated with altered transcriptional stability. In the case of the prothrombin G20210A [F2 AF4786 96.1:g.21538G>A(c.*97G>A)] variant, the change results in a more stable mRNA resulting in a gain of function [57]. The poly-A tail facilitates transportation of the mature mRNA into the cytoplasm and protection of the transcript from degradation by exonucleases. A given gene may have several polyadenylation signals, providing another level of variation for a single gene [58–60].

After the completion of a full-length mRNA, posttranscriptional regulation influences whether the message will proceed to translation. RNA interference (iRNA) is mediated by short interfering RNAs (siRNAs) and microRNAs (miRNAs). While functionally similar, miRNAs differ from siRNAs in that miRNAs are transcribed from a primary miRNA (pri-miRNA). Many miRNA promoters are found in Alu sequences [61, 62]. The 70–100-nucleotide pri-RNA transcript forms a double-stranded hairpin structure which is cleaved in the nucleus by the RNase III protein Drosha resulting in a double-stranded hairpin pre-miRNA molecule. Exportin 5 transports the pre-miRNA molecule to the cytoplasma where the dicer protein further digests the pre-miRNA into a 21–25 nucleotide double-stranded molecule. The RNase III protein Dicer removes the hairpin but its activity is influenced by the size of the hairpin loop. Dicer also acts on siRNA molecules derived from externally introduced double-stranded RNA. At this point, both siRNA and miRNA bind to the RNA-induced silencing complex (RISC). The miRNA-RISC complex aligns with the target mRNA and either translationally represses or cleaves the mRNA. The siRNA-RISC complex binds to and degrades the mRNA [63]. Changes in miRNA expression profiles are associated with the initiation and progression of oncogenesis [64]. In addition, miRNAs also are regulated by epigenetic modifications [65].

Translation

Translation is the next step in using information from the DNA gene to produce a functional protein. This process changes the genetic information from a nucleic-acid-based language into an amino-acid-based language of polypeptides and proteins. For these reasons, the term "translation" describes this complex cascade of events.

Following transportation of the mRNA into the cytoplasm, translation begins with the mRNA binding to a ribosome and requires additional nucleic acids, specifically protein-associated RNA molecules (Fig. 1.6). A ribosome is a complex of about 50 different proteins associated with

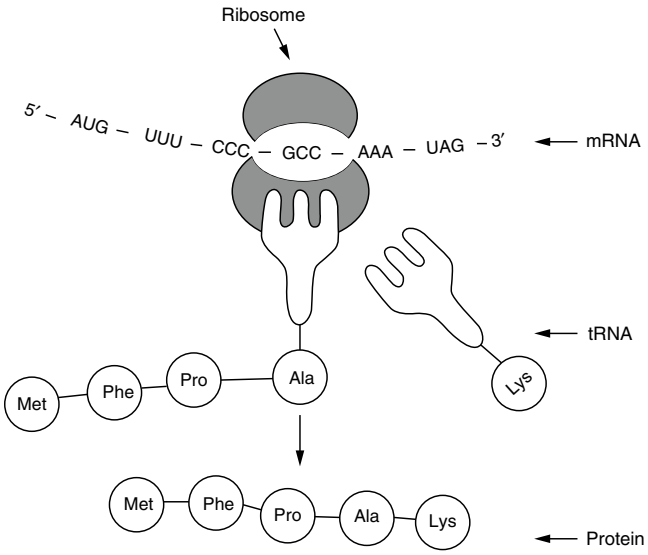

Figure 1.6 RNA translation. RNA is translated through binding events between the mRNA, a ribosome, tRNA, and amino acids, resulting in the production of a protein polypeptide chain. Reprinted with permission from Leonard D. Diagnostic Molecular Pathology. 2003:1–13. Copyright Elsevier (2003)

several ribosomal RNA (rRNA) molecules. Prokaryotic ribosomes consist of 30S and 50S subunits. Svedberg (S) units are the sedimentation rate of a particle. In bacteria, one class of small RNAs (i.e., sRNAs) produce catalytic RNAs, such as RNase P, that process tRNAs and rRNAs [66]. In eukaryotes, rRNA molecules associate with proteins in the nucleolus to form 40S and 60S subunits. Recognition of the 5′ cap of the eukaryotic mRNA by a ribosome initiates the process of translation.

Each amino acid is encoded by one or more three-nucleotide sequences, which are collectively known as the genetic code (Table 1.6). Each set of three nucleotides of an mRNA that encodes an amino acid is called a codon. As seen in Table 1.6, the first and second nucleotide positions largely determine which amino acid is encoded by the mRNA codon, while the third base has less effect on which amino acid will be incorporated. In addition to encoding amino acids, certain mRNA codons are used to initiate (START) or terminate (STOP) translation. The genetic code differs slightly between organisms and between mtDNA and eukaryotic DNA (Table 1.7). Thus, while one mRNA encodes only one protein sequence, a protein sequence can be encoded by several different mRNA sequences. This is referred to as the degeneracy of the genetic code.

Synthesis of the encoded protein begins at the initiation codon of the mRNA, the first AUG codon after the promoter, which encodes a methionine amino acid. This methionine codon establishes the reading frame of the mRNA. The next step in the translation process uses RNA molecules to bridge the information from the sequential three-nucleotide mRNA codons to the encoded amino acid in the growing polypeptide chain of the protein. Another set of RNA molecules, transfer RNAs (tRNAs), contain a sequence complementary to each mRNA codon known as the anticodon. The 3′ end of each type of tRNA binds the specific amino acid corresponding to its anticodon sequence. Base pairing of mRNA codons with complementary tRNA anticodons permits sequential alignment of each new amino acid (attached to the opposite end of the tRNA from the anticodon sequence) with the growing polypeptide chain and occurs in the small subunit of the ribosome. The large subunit of the ribosome catalyzes the covalent bonds linking each sequential amino acid to the growing polypeptide chain.

Translation ceases when the ribosome encounters a stop codon (UAA, UAG, or UGA). Release factors bound to the stop codon catalyze the addition of a water molecule rather than an amino acid, resulting in a COOH terminus to the completed polypeptide chain [67, 68]. Some factors bound to the 3′ untranslated portion of the gene also affect termination. In bacteria, small non-coding RNA (sRNA) molecules serve a quality control role. One group of sRNA are referred to as tmRNAs as they have properties common to both tRNA and mRNA. When translation stalls before reaching a termination codon (e.g., due to a rare codon), the tmRNA provides a C terminal tag which facilitates clearing of abnormal polypeptides and enables the ribosome to be released and recycled back to functional translation [69]. Additionally, some sRNA molecules regulate mRNA utilization through an antisense mechanism [66].

Structure of Proteins

Just as nucleic acids form various structures via intra- and intermolecular base pairing, proteins also assume various structures depending on the types and locations of amino acids. The primary structure of a protein is the sequence of amino acids from amino terminus (NH) to carboxy terminus (COOH) of the protein. The secondary structure refers to how amino acid groups interact with neighboring amino acids to form structures called an alpha helix or a beta sheet. The tertiary structure of a protein is created by amino acids sequentially distant from one another creating intramolecular interactions. The quaternary structure of a protein defines the three-dimensional and functional conformation of the protein. The shape that is ultimately assumed by the protein depends on the arrangement of the different charged, uncharged, polar, and nonpolar amino acids.

Posttranslational Modifications

After generation of the polypeptide chain of amino acids, additional enzymatic changes may diversify the function of the protein. These changes are termed posttranslational modifications and can include proteolytic cleavage, glycosylation, phosphorylation, acylation, sulfation, prenylation, and vitamin C- and vitamin K-mediated modifications. In addition, selenium may be added to form selenocysteine. The seleno-cysteinyl-tRNA recognizes the UGA stop codon and adds this unusual amino acid.

Mutations: Genotype vs Phenotype

Genetic information exists in the form of nucleic acids known as the genotype. In contrast, the encoded proteins function to create a phenotype, an outwardly observable characteristic. Genotypic alterations may or may not cause phenotypic alterations. Some genotype changes are called synonymous mutations because the change in the codon does not change the amino acid. Sometimes these synonymous mutations are called "silent"; however, protein function can be altered by a synonymous mutation. Some of the mechanisms

associated with deleterious synonymous mutations include exon skipping or alteration of the conformation of the protein by using codons encoding rare anticodons [70]. The mechanisms by which synonymous mutations create phenotypic changes are not clearly understood and make clinical interpretation of these mutations difficult.

Missense mutations refer to genetic changes that result in the incorporation of a different amino acid at a specific codon location. These changes may not dramatically alter the protein if the replacement amino acid is similar in size and charge to the original amino acid (for example, a hydrophobic amino acid replaces another hydrophobic amino acid). However, replacement of an amino acid with a different type of amino acid may significantly change the conformation of the protein and, thus, change its function. For example, in sickle cell anemia, a valine replaces a glutamic acid at a single position and permits the polymerization of the beta globin molecules to cause stiffening and sickling of the red blood cell under low-oxygen conditions. Different forms of proteins (known as conformers) provide the mechanism for diseases ranging from Creutzfeldt-Jacob disease to Huntington disease.

Nonsense mutations describe base changes that replace an amino-acid-encoding codon with a stop codon, which causes premature termination of translation and results in a truncated protein [71]. Truncation may result from the addition or deletion of one or two nucleotide bases, resulting in a shift in the translational reading frame. Frameshifts often result in premature termination when stop codons are formed downstream from the mutation. Alterations in splice donor or acceptor sites may either erroneously generate or prevent appropriate splicing of the 1° transcript, resulting in a frameshift mutation [72]. Genetic changes in the untranslated portions of the gene affecting the promoter, enhancer, or polyadenylation signals may affect the expression of the gene product and result in a phenotypic change. Not all genotypic changes affect the phenotype. Genetic changes affecting the third base of the codon rarely alter the gene code and, therefore, would be less likely to cause incorporation of a different amino acid.

With the sequencing of the human genome, numerous single-nucleotide variants and other types of variants have been identified, demonstrating the individual nature of human beings. Numerous studies currently target correlating genotype variations to disease phenotypes. These efforts, in combination with improved understanding of gene structure and function, promise continued improvement for diagnosis, treatment, and patient outcomes in the future.

D. Hunter Best, Shale A. Dames, Whitney Wooderchak-Donahue, Tracey Lewis, Kelli L. Sumner, Cecily P. Vaughn, Rong Mao, and Daniel H. Farkas

Abstract

Molecular pathology is based on the principles, techniques, and tools of molecular biology as they are applied to diagnostic medicine in the clinical laboratory. Molecular biology methods were used to elucidate the genetic and molecular basis of many diseases, and these discoveries ultimately led to the field of molecular pathology. As molecular research identifies the most fundamental causes and markers of disease, clinical testing of human and pathogen genetic material has become routine in laboratory medicine. Underlying mutations responsible for genetic diseases, including cancers, are being discovered and used in clinical molecular tests. In this chapter, fundamental and more advanced molecular biology techniques, as practiced in the molecular pathology laboratory, are reviewed.

Introduction

Molecular pathology is based on the principles, techniques, and tools of molecular biology as they are applied to medical practice in the clinical laboratory. These tools were developed in the research setting and perfected throughout the second half of the twentieth century, long before the Human Genome Project (HGP) was conceived. Molecular biology methods were used to elucidate the genetic and molecular basis of many diseases, and these discoveries ultimately led to the field of molecular pathology. Eventually the insights these tools provided for laboratory medicine were so valuable to the armamentarium of the pathologist that they were incorporated into pathology practice. Today, clinical molecular testing continues to grow rapidly as in vitro diagnostic companies develop new kits for the marketplace and as the insights into disease that have been gained as a result of the HGP develop into clinical laboratory tests.

Molecular pathology is a natural extension of anatomic and clinical pathology. As molecular research identifies the

most fundamental causes and markers of disease, clinical testing of human and pathogen genetic material has become routine in laboratory medicine. Underlying sequences and variations responsible for genetic diseases, cancers and infectious diseases are being discovered and used in clinical molecular tests. Some have become routine tests in molecular pathology and are described in detail elsewhere in this book.

In this chapter, fundamental and more advanced molecular biology techniques, as practiced in the molecular pathology laboratory, are reviewed. The entire field of molecular pathology is relatively new, having begun in the 1980s and matured through the 1990s. The new century has brought important advances in automated nucleic acid preparation [1–3], polymerase chain reaction (PCR), real-time PCR, deoxyribonucleic acid (DNA) sequencing, genomic microarrays, and, most recently, massively parallel sequencing of large portions of the genome. More and more, the underlying biochemistry occurring in laboratory instruments may be invisible to the user. The goal of this chapter is to describe the principles of these methods so that practitioners have adequate information for instrument troubleshooting and test interpretation.

Gene products, such as proteins and polypeptides, are molecules and could technically be classified within "molecular pathology." This chapter focuses on nucleic acid methods, including investigation of DNA and ribonucleic acid (RNA). The field will eventually move beyond genomics to proteomics. Proteomics is not addressed in this chapter since clinical proteomics is in extremely limited practice in molecular pathology today (see Chap. 61).

Basic Science Discoveries: The Foundation

Molecular pathology techniques are rooted in fundamental molecular biology discoveries of the 1940s–1980s [4]. The clinical laboratory application of molecular biology techniques would not be possible without the discovery by Griffith and Avery that nucleic acid is the genetic material. The foundation of work by Chargaff and Franklin was capitalized on by Watson and Crick, who elucidated the structure of DNA. Understanding DNA structure is seminal to understanding nucleic acid hybridization, which is central to almost all molecular methods used in the clinical molecular pathology laboratory. Additionally, work by Nirenberg (unraveling the genetic code), Wilcox, Smith, Nathans, and others (use of restriction endonucleases for DNA manipulation), Baltimore and Temin (discovery of RNA-dependent DNA polymerase or reverse transcriptase), Britten and Davis (hybridization kinetics), Kornberg and Okazaki (work on DNA polymerases and DNA replication, respectively), Southern (development of solid-phase DNA hybridization, i.e., the Southern blot), Sanger, Maxam, and Gilbert (development of DNA sequencing), Mullis (discovery of PCR for in vitro nucleic acid amplification), and their scientific collaborators and competitors led to a refined understanding of how DNA may be manipulated in vitro for research and ultimately clinical molecular testing purposes.

General Methods

Nucleic Acid Isolation

The first step of most molecular pathology tests is isolation of DNA or RNA from a patient specimen, by either manual or automated methods. Nucleic acid purification begins with lysis of the cells in the sample. Cell lysis liberates cellular macromolecules including proteins, lipids, and nucleic acids. Cell lysis can be accomplished using a detergent solution to break cell membranes and remove lipids. Proteins are enzymatically degraded with protease or selectively precipitated. Protein digestion is performed at about 56 °C which permanently denatures many proteins but does not affect nucleic acids. This process is followed by selective nucleic acid extraction that takes advantage of the physical and chemical differences between nucleic acids and other cellular molecules, forming the basis for their isolation. The nucleic acid is then purified from the soluble contaminants produced in the extraction method by precipitation in an ethanol–salt solution. Variations on this theme that combine extraction and purification are the selective adsorption of nucleic acids to silica columns under chaotropic salt conditions or magnetic bead chemistry. The isolated nucleic acid is resuspended in a dilute salt buffer, for example, 10 mM Tris/1 or 0.1 mM EDTA pH 7.6–8.0 (TE buffer).

The initial lysis step is modified according to the specimen. If the specimen is fresh or frozen solid tissue, the tissue is first homogenized in an appropriate buffer (often TE buffer). If the specimen is formalin-fixed, paraffin-embedded (FFPE) tissue, the paraffin is removed with an organic solvent such as xylenes, followed by rehydration through an alcohol series to a dilute salt buffer before protease digestion. FFPE tissue also is heated during the prolonged protease digestion step to reverse formalin cross-linking between proteins (primarily histones) and nucleic acids. Although this reduces the degree of nucleic acid shearing in subsequent vortexing or centrifugation steps, DNA longer than that packaged into a nucleosome (about 200 base pairs [bp]) is difficult to recover from FFPE tissue. Whole blood specimens may require Ficoll separation and a centrifugation step to separate the DNA-containing white blood cells (WBCs) from the erythrocytes prior to recovery of nucleic acids from WBCs because of the inhibition of PCR by hemoglobin. This blood fractionation step generally is not performed in automated nucleic acid extraction instruments.

Organic (Phenol) Extraction

Nucleic acids have a strong net negative charge because of the phosphate groups in the sugar–phosphate backbone, and thus are highly soluble in an aqueous environment. By contrast, proteins, lipids, and carbohydrates contain varying proportions of charged and uncharged domains producing hydrophobic and hydrophilic regions. This difference makes proteins entirely soluble in organic solutions or confines them to the interface between the organic and aqueous phases during an organic extraction. This characteristic forms the basis for phenol–chloroform extraction, in which phenol is added to an aqueous solution containing cellular constituents, mixed, and then centrifuged to separate the aqueous and organic phases. If the pH of the extraction is near neutral, both DNA and RNA stay in the aqueous phase, while proteins are in the phenol–chloroform phase or aqueous-phenol interface. If the pH is acidic, the phosphate groups of DNA are preferentially neutralized, driving DNA into the organic phase (or interface) and allowing RNA to be selectively extracted. This method produces high-quality nucleic acids but is relatively labor-intensive, employs hazardous chemicals, and produces liquid organic waste.

Ethanol–Salt Precipitation

Nucleic acids can be precipitated in an aqueous solution by the addition of concentrated ethanol and salt. Ethanol makes the solution hydrophobic, while salt increases the ionic strength of the solution, thereby reducing the repulsion of the negatively charged sugar–phosphate backbone of nucleic acids. Centrifugation allows the nucleic acid precipitate to be collected and resuspended in a dilute salt buffer (TE buffer).

Chaotropic Salt-Silica Column Extraction

Chaotropic salts, such as sodium iodide (NaI) or guanidinium isothiocyanate (GITC), disrupt the structure of water, promoting the solubility of nonpolar substances, such as proteins, in polar solvents, such as water. Saturated chaotropic salts also promote the adsorption of nucleic acids to glass or silica columns. Nucleic acids are purified by a series of washing steps including reducing agents, such as sodium azide, to further remove contaminants and inhibit remaining enzymes. The nucleic acids are eluted from the column with a dilute, nonchaotropic salt buffer. Since the method is simple, fast, offered in commercial kits by several manufacturers and adaptable to high-throughput robotic nucleic acid isolation, this method is widely used by clinical molecular laboratories.

Magnetic Bead Extraction

Another solid phase extraction method uses ligand-coated magnetic beads to capture nucleic acids. After cell lysis, DNA molecules are attracted to the ligands on the magnetic beads. The beads are immobilized by a magnet, allowing multiple washings of the bound nucleic acids to remove proteins and other contaminants. The nucleic acids then are eluted from the ligands on the magnetic particles with an elution buffer. Magnetic bead extraction chemistries are widely available commercially, and ideal for automation and use in high test volume settings.

RNA vs DNA Isolation

DNA is the repository of genetic information, which is then transcribed into RNA. RNA is the major constituent of ribosomes (ribosomal RNA or rRNA), forms transfer RNA (tRNA) and messenger RNA (mRNA) which are central in protein translation, and plays a regulatory role in gene expression as microRNA (miRNA) and long-noncoding RNA (lncRNA). DNA is a hardy molecule present at stable cellular levels (with the exceptions of gene amplification and deletion in tumor cells). In contrast, the level of RNA corresponding to a gene can fluctuate dramatically within a very short time in response to changes in a cell's microenvironment and functional needs. This fluctuation results from changes in both the rate of transcription and degradation of RNA species.

DNA is relatively easy to isolate and store because deoxyribonucleases (DNases) are easily denatured by heating or inhibited by sequestration of divalent cations needed for their function. RNA, by contrast, is rapidly degraded by a variety of ribonuclease (RNase) enzymes that are replete within the cell and on the skin surface. While this is necessary for cellular homeostasis, the ubiquity of RNases is problematic for the molecular analysis of RNA. RNases are very stable, active in virtually any aqueous environment, and can regain their activity after denaturation. As a result, RNA is subject to rapid degradation by RNases in most laboratory settings, making RNA a notoriously labile molecule. In addition, RNA is inherently chemically unstable under physiological conditions, primarily due to the spontaneous cleavage of the backbone phosphodiester linkages by intramolecular transesterification reactions involving the 2′-hydroxyl group of the ribose. This contrasts with DNA which lacks the reactive hydroxyl group in its deoxyribose sugar group, resulting in an inherently greater stability. The rate of degradation varies among RNA species, leading to further analytical complexity for the clinical molecular laboratory.

RNA analysis depends on successful RNA isolation and preservation. The overall techniques are similar to those described above for DNA isolation, but with the mandatory addition of steps to inhibit or degrade cellular RNases and prevent their reintroduction into the isolated RNA. RNA isolation must be performed promptly after specimen collection, particularly if RNA quantitation is desired. If RNA isolation is delayed, the sample should be stored at −80 °C, or at an

intermediary isolation point in a stable buffer with RNase inhibitors. Scrupulously clean laboratory technique is required, including careful cleansing of laboratory equipment with bleach, autoclaving of glassware, preparation of reagents with nuclease-free water, and wearing and frequently changing gloves. Addition of GITC or β-mercaptoethanol to the RNA isolation reagents inhibits or denatures RNases present in the sample. The isolated RNA is rehydrated in water or TE buffer that is nuclease free, and stored at −80 °C to further inhibit the activity of any residual RNases.

Despite these difficulties, RNA is valuable in the clinical molecular laboratory for several reasons. Many clinically significant viruses, such as human immunodeficiency virus (HIV) and hepatitis C virus (HCV), have RNA genomes. Quantitation of RNA provides an important measure of gene expression, which can be used in the diagnosis or monitoring of disease. In addition, mRNA does not contain introns, which is an advantage when analyzing neoplastic translocations with variable intronic breakpoints such as *BCR–ABL* [5]. An advancement is the availability of blood collection tubes containing a preservative solution that increases RNA stability at room temperature (PAXgene, Qiagen Valencia, CA), allowing a longer timeframe from collection to purification without RNA degradation.

Nucleic Acid Measurement for Quantity and Quality

Nucleic acid quantitation is optional for many protocols that utilize in vitro nucleic acid amplification. Some methods, however, require use of accurate quantities of nucleic acid necessitating assessment of the yield and concentration of purified nucleic acids, which is typically done using ultraviolet (UV) spectrophotometry. The absorbance of a nucleic acid solution is measured at several wavelengths. The maximal absorbance for nucleotides is at 260 nm of UV light (A_{260}), while for proteins the maximal absorbance is at 280 nm (A_{280}). Nucleic acids can therefore be quantified by the A_{260} measurement, while the A_{260}/A_{280} ratio provides an estimate of the purity of the sample. Pure DNA has an A_{260} of 1.0 at a concentration of 50 μg/ml and an A_{260}/A_{280} ratio of 1.8, while pure RNA has an A_{260} of 1.0 at a concentration of 40 μg/ml and an A_{260}/A_{280} ratio of 2.0. Lower A_{260}/A_{280} ratios indicate the presence of protein in the solution. Other contaminants can be detected by their absorbance at other wavelengths, such as phenol at A_{270} and guanidinium at A_{230}.

Ethidium bromide (EtBr) intercalates into DNA strands, causing DNA to fluoresce upon illumination with UV light. The fluorescence intensity of EtBr correlates with the number of base pairs of DNA in which the EtBr is intercalated, which is a function of both the size (length) and quantity of the DNA fragment. Therefore, by staining sample DNA with EtBr in an electrophoresis gel and comparing the brightness to mass standards in adjacent lanes, the quantity of DNA can be estimated. This provides a convenient system for estimation of post-PCR DNA quantity prior to sequencing. More importantly, the image of the EtBr-stained sample DNA can be used to assess DNA quality. High-quality, substantially intact genomic DNA forms a single band close to the well which serves as the origin of electrophoresis. In contrast, DNA degradation is apparent as a smear of EtBr-stained DNA extending downward from the well. EtBr is mutagenic and produces light background staining and, therefore, largely has been replaced in the clinical laboratory by other intercalating dyes such as SYBR Green.

Electrophoresis

In electrophoresis, an electric field is used to separate charged molecules by differential mobility in a sieving matrix that can be either liquid or solid (gel). The differential mobility is determined by the size of the molecule and its conformation, the net charge of the molecule (as modified by pH), temperature, and the pore size of the matrix. DNA, being negatively charged, migrates towards the anode (+) when an electric field is applied to an electrolyte solution. The size of DNA can be modified by restriction endonuclease digestion (see below), rendering DNA fragments small enough to be mobile in the matrix. Nucleic acid conformation can be modified with denaturing conditions prior to or during electrophoresis. Nucleic acids usually are electrophoresed at a slightly alkaline pH to ionize all phosphate groups in the backbone of the molecule, enhancing the negative charge which allows nucleic acids to be moved in the electrophoretic field.

The pore size of the matrix is determined by the composition and concentration of the polymer. For any given pore size, the mobility of a molecule through the matrix is inversely proportional to the log of its size. Therefore, for a given size difference between two molecules, the difference in the rate of migration will be substantially less if both molecules are large. The limiting mobility is defined as the rate of migration through the gel at which large molecules can no longer be separated for any given pore size. This may be related to the tendency of sections of long DNA fragments to "snake" through different pores in the gel, retarding the mobility of the fragment. The limiting mobility of gels can be overcome by using pulsed field gel electrophoresis (PFGE), in which the voltage gradient is periodically reoriented.

Polyacrylamide Gels

In clinical molecular laboratories, the matrices used most commonly are acrylamide and agarose. Polyacrylamide gels are formed by cross-linking acrylamide monomers with bisacrylamide in the same salt buffer used for electrophoresis and

pouring the solution in a thin space between two glass plates. A comb is inserted at one edge between the plates to form wells for sample insertion. After the gel has formed, the plates are mounted in a vertical electrophoresis unit such that the gel forms a bridge between two buffer chambers. Samples, controls, and sizing standards are mixed with a loading buffer containing a dye to track the progress of electrophoresis and glycerol to increase the density of the aqueous samples so the samples sink to the bottom of the wells, then loaded into the wells. Electrodes are attached to the buffer chambers and connected to a power supply providing constant voltage. After electrophoresis, the glass plates are separated and the gel is soaked in EtBr (or another intercalating agent) solution. DNA is visualized by EtBr staining under UV light. Polyacrylamide forms very small pores and is useful for high resolution of DNA fragments from 100 to 1,000 bp. However, polyacrylamide gels are thin and fragile, the glass plates are cumbersome to work with, and nonpolymerized acrylamide is a lung irritant and neurotoxin; therefore, alternatives to polyacrylamide gel electrophoresis are desirable in the clinical laboratory. Although more costly, precast acrylamide gels are commerically available to circumvent the biohazards of nonpolymerized acrylamide.

Agarose Gels

Agarose gels are formed by boiling an agarose gel powder until the agarose has completely dissolved in the same buffer used for electrophoresis, optionally adding EtBr (or another intercalating agent), then pouring the solution into a horizontal casting tray. One or more gel combs can be used to form rows of wells in the agarose. After cooling and polymerization, the gel is loaded in a horizontal electrophoresis apparatus and covered with buffer in a single chamber. DNA is mixed with a loading buffer, as described above for acrylamide gels, wells are loaded and electrophoresis performed as described above. Agarose gels have a larger pore size than acrylamide gels. Agarose gels with a concentration of 1 % are used to separate DNA fragments of 1–20 kilobases (kb), while higher concentration gels are useful to separate smaller DNA fragments. Agarose gels are thicker and more stable than polyacrylamide gels but do not provide the same degree of resolution. Agarose is safer than acrylamide but still must be handled and disposed of with care if the gel contains EtBr. Other modified agarose compounds are available that can be mixed in various ratios with standard agarose to increase the resolution of agarose gels. Like acrylamide gels, precast agarose gels are commerically available.

Capillary Electrophoresis

Capillary electrophoresis (CE) is a widely used separation technology for analysis of proteins, peptides, chemicals, natural products, pharmaceuticals, and DNA. CE systems are commercially available and generally provide more consistent and standardized results with less time and effort than gel electrophoresis. Using CE, DNA fragments are rapidly separated with a high-voltage gradient, because the capillary dissipates heat quickly. Therefore, one CE run takes approximately half an hour or less, and if 8, 16, or more capillaries are run simultaneously, the process reduces the time from standard electrophoresis, which requires 3–4 h. This is a significant time savings in the clinical laboratory for applications such as DNA sequencing. CE enables more standardized results, maximization of workforce efficiency, increased productivity and throughput, and the potential for error reduction. CE also uses smaller sample volumes. As such, CE has become the method of choice for most clinical molecular laboratories.

In CE, electrophoretic separation takes place in a capillary tube ranging in length from 25 to 100 cm and approximately 50–75 μm in diameter. Most capillary tubes are made of glass (silica) walls that often are covered with an external polyimide coating. Acid silanol groups impart a negative charge on the internal wall of the capillary. A low-viscosity acrylamide-based flowable polymer acts as the electrolyte solution and sieving matrix within the silica capillary, and is responsible for the conductivity of current through the capillary. Polymer concentration affects the pore size and movement characteristics of the DNA through the capillary.

A small section of the capillary coating is removed at one end of the capillary to create a detection window. The detection window is optically aligned with the detection system of the instrument. The detection system often includes either a diode or argon laser combined with a charge-coupled device (CCD) camera or filter wheel and photomultiplier tube. The opposite end of the capillary and electrode is used for sample injection by electrokinesis. In electrokinetic injection, the capillary and electrode are moved into the sample well. The sample enters the capillary when a voltage of 2–5 kV is applied for approximately 5–15 s. The voltage causes sample ions including DNA to migrate electrophoretically into the capillary in a flat flow profile. Electrokinetic injection produces increased resolution compared to hydrodynamic injection, which produces a laminar (curved) flow profile. After the injection, the capillary and electrode are returned to a buffer reservoir for the separation. The DNA fragments separate by size and charge during migration through the capillary (smaller fragments moving more quickly than larger fragments) and are detected through the window at the far end of the capillary.

In the clinical molecular laboratory, DNA sequencing and DNA fragment sizing and/or quantitation are the most common applications performed on CE instruments. One negative aspect of CE as opposed to older polyacrylamide gel technology is that CE is more sensitive to contaminants and DNA concentration. DNA, being negatively charged, migrates into the capillary when voltage is applied. If there

are any other charged particles in the sample, they also are injected into the capillary. For example, salt is an ionic competitor. If salt is present, the fluorescent signal intensity of the sample will be greatly reduced because of ionic competition during the brief injection. Proper sample preparation is therefore a key to successful CE.

After a post-reaction purification step, if needed for the specific CE application, DNA samples are resuspended in a sample loading solution. High-quality deionized formamide often is used as the sample loading solution. If DNA is denatured prior to CE, the formamide maintains the denatured state of DNA and provides a very stable environment for fluorescent dyes. Following the post-reaction purification and resuspension of products, the samples are ready for analysis on the CE instrument. The fragments are injected into the capillary and detected by laser-induced fluorescence, and data are generated for analysis using software supplied by the manufacturer for different CE applications.

Restriction Endonucleases

Restriction endonucleases (REs) cleave DNA at specific nucleotide recognition sequences. Restriction endonucleases are naturally occurring proteins produced by and purified from bacteria. Each bacterial species contains one or more REs, each recognizing a unique sequence of base pairs in double-stranded DNA, called recognition sites (most commonly 4–8 bp long). The natural function of REs within bacteria is to digest and inactivate foreign DNA (such as bacteriophage DNA). The frequency of recognition sites in target DNA for any given RE is inversely proportional to the size of the recognition site. Some REs do not cleave DNA when their recognition sites are methylated; this can be useful in certain clinical laboratory applications such as detection of imprinted genes in genetic diseases or promoter hypermethylation in tumors. Some mutations occur at RE recognition sites and can be detected by a change in the RE digestion pattern of a PCR product or genomic DNA. Unique DNA restriction fragment patterns are generated by digestion with different REs, creating a range of DNA restriction fragment sizes, which can be fractionated and detected using agarose gel electrophoresis. Restriction endonuclease digestion is commonly used as a component of clinical molecular tests.

Specific Methods

DNA Sequencing

The ability to sequence DNA has been essential to the field of molecular pathology because sequence information is a prerequisite for PCR, PCR alternatives, and hybridization with probes necessary for successful Southern blot analysis. The method for DNA sequencing developed by Sanger, Nicklen, and Coulson [6] is the basis for most DNA sequencing performed both in clinical laboratories and for the HGP.

The Sanger sequencing reaction uses a single DNA primer and DNA polymerase resulting in linear, rather than the exponential, PCR amplification (see below). Components essential to the Sanger sequencing reaction include: (1) DNA template that is purified and quantitated; (2) sequence-specific primers, complementary to the opposite strands and ends of the DNA region to be sequenced, which is desalted and usually purified by high-performance liquid chromatography (HPLC); (3) small proportions of dideoxynucleoside triphosphates (ddNTPs) in addition to the conventional deoxyribonucleoside triphosphates (dNTPs) used in DNA sequencing reaction; and (4) an electrophoresis technique capable of clearly distinguishing single nucleotide length differences in DNA strands dozens or hundreds of nucleotides in length. Dideoxynucleotides differ from deoxynucleotides by having a hydrogen atom attached to the 3′ carbon rather than an hydroxyl (-OH) group, which is present on the deoxynucleotide. Because the ddNTPs lack a 3′-OH group, elongation of the newly polymerized DNA chain cannot occur once a ddNTP has been incorporated (arabinonucleosides also can be used as inhibitors of elongation). The end result is a set of newly synthesized DNA chains that are complementary to the template DNA but that vary in length, with the length determined by the point at which the ddNTP was incorporated into the 3′ end of the chain.

In the original paper, four reactions were performed for each template, with the addition of a single inhibitor to each, ddGTP, ddATP, ddTTP, or araCTP [6]. The DNA chains were separated by polyacrylamide gel electrophoresis under denaturing conditions and visualized using (α-^{32}P)-dATP on a radio-autograph. The four reactions were run in consecutive lanes of the gel, and the complementary DNA sequence was determined by manual inspection based on the size of each chain, and the specific ddNTP in the reaction. As sequencing techniques evolved, radioactive labeling was replaced by fluorescent labeling. Two major categories of fluorescent labeling are used for sequencing. In dye-primer labeling, the sequencing primer is labeled, and the sequencing reaction requires four tubes differing only in the incorporation of the specific ddNTP. In dye-terminator labeling, the sequencing primer is unlabeled and instead each ddNTP is labeled with a different fluorophore, thus enabling the entire sequencing reaction to be performed in a single tube. Dye-primer labeling may be used in fragment analysis for detection of microsatellite instability, loss of heterozygosity, forensic identification, or allogeneic bone marrow transplantation monitoring using short tandem repeat polymorphisms. Automated sequencers recognize both the size of the DNA chain and the fluorescent color of the chain to assign the

nucleotide sequence, and also function as precise detectors for fragment analysis [7].

Conventional DNA sequencing with polyacrylamide gel electrophoresis (whether using manual or automated sequence detection) is time-consuming and labor-intensive. The introduction of CE facilitated the use of sequencing and fragment analysis by the clinical laboratory [8]. The sequencing reaction products are purified by ethanol precipitation or a chaotropic salt-silica column technique before injection into the CE unit to remove excess salts, dyes, and unincorporated primers that would compete for injection into the capillary. Numerous protocols and commercial kits are available for the post-reaction purification. After the post-reaction purification step, samples are resuspended in a sample loading solution containing high-quality deionized formamide to denature the DNA. Formamide also provides a very stable environment for fluorescent dyes. The fragments are injected into the capillary, detected by laser-induced fluorescence, and rendered into sequence by the analysis software. An electropherogram of the DNA sequence is generated by the detection software by correlating the fluorescent intensity of each dye wavelength corresponding to a specific ddNTP as a function of migration time.

Examples of Applications of DNA Sequencing

1. *CFTR* mutation analysis for cystic fibrosis
2. *BRCA1* mutation analysis for breast/ovarian cancer
3. *CEBPA* mutation analysis for acute myeloid leukemia (AML)
4. High-resolution human leukocyte antigen (HLA) typing for allogeneic bone marrow transplantation

Southern Blot

The Southern blot was developed by E.M. Southern in 1975 and was the first molecular biology tool to have a major impact on clinical molecular pathology. The Southern blot is in limited use, having been largely replaced by amplification methods. Development of the Southern blotting was based on prior knowledge of nucleic acid isolation, gel electrophoresis, RE digestion, and nucleic acid probe labeling for detection of DNA sequences of interest.

The Southern blot is a labor-intensive, time-consuming clinical laboratory method [9]. High-quality DNA is isolated from a patient specimen, subjected to RE digestion, and then separated by size (fractionated) by agarose gel electrophoresis. "Blotting" is the transfer of the fractionated DNA from the gel to a solid support such as a nylon membrane. A small piece of DNA complementary to the sequence of interest for the test being performed is labeled in one of a variety of ways and called a probe. The probe is hybridized to the fractionated DNA on the membrane, and then the location of the probe (and the DNA fragments relevant to the test) is detected using the probe label. This detection step allows the gene of interest to stand out from the vast background of DNA present in the sample. If the banding pattern visualized on the membrane is different from the normal pattern, this may be indicative of a mutation in the targeted sequence. As examples, a more intense probe signal indicates sequence amplification, lack of a signal indicates sequence deletion, and a shift in the band size indicates a change in a RE recognition site.

Because no amplification of target DNA occurs, Southern blot analysis requires a large mass of DNA. Because the banding pattern depends on the specific cuts made by the RE and not just random DNA breaks, the DNA must be largely intact and of high molecular weight. Therefore, electrophoresis of the isolated DNA to be used for a Southern blot test prior to analysis is important for assessing the integrity of the DNA, since only a small degree of DNA degradation is tolerable. Degraded DNA may produce false-negative results if a signal from high-molecular-weight DNA is expected, while false-positive results may occur if partially degraded DNA results in unusually sized bands. Fortunately, most tests in the clinical molecular laboratory today are based on PCR, which is less affected by DNA degradation. Polymorphisms within RE recognition sites also change banding patterns, a principle used to advantage in other molecular tests.

The physical movement of the DNA from the gel to the membrane may be accomplished by manual capillary transfer, automated vacuum transfer, or electrotransfer. DNA in the gel first is "conditioned": depurination with dilute HCl and subsequent denaturation with NaOH. Dilute and brief acid treatment causes hydrolysis of the DNA phosphodiester backbone to occur spontaneously at the sites of depurination. This acid-induced fragmentation facilitates efficient transfer of the highest-molecular-weight DNA species from the gel to the membrane, but does not alter the original size fractionation achieved by RE digestion and electrophoresis. Alkali treatment denatures double-stranded DNA (dsDNA) to single-stranded DNA (ssDNA), essential for subsequent nucleic acid hybridization with a labeled ssDNA probe. The DNA is permanently fixed to the membrane by thoroughly drying the blot in an oven or by exposing the blot to a precise amount of UV irradiation.

DNA probes are labeled before use in hybridization assays to permit visualization of probe–target binding. Note that in reverse hybridization assays, described below, unlabeled probes are immobilized and the target is labeled during the amplification step that precedes hybridization. Probe labels may be isotopic or nonisotopic. High-specific-activity DNA probes may be generated by in vitro biochemical reactions that synthesize new DNA from dNTPs, using the probe as a template. One type of the dNTPs is labeled with a

reporter molecule such as ^{32}P, biotin, or digoxigenin. When incorporated into the newly synthesized DNA, the labeled dNTP, even though it is only one of the four dNTPs in the DNA probe, is sufficient to label the entire probe for detection. The probe is used in vast molar excess relative to the target DNA in nucleic acid hybridization to drive the hybridization reaction to occur as quickly as possible.

The blot is immersed in prehybridization buffer to prepare the DNA on the blot for hybridization with a probe. Prehybridization buffer contains blocking agents included to minimize unwanted nonspecific DNA probe binding that would otherwise contribute to high background on the final image of the Southern blot used to view the results and make diagnostic conclusions. The prehybridization step equilibrates the membrane and blocks sites on the nylon membrane without DNA to prevent the probe from binding nonspecifically and increasing background nonspecific signal. A large volume of blocking agent is therefore advantageous. Addition of the labeled probe to the blot begins the hybridization phase of the Southern blot process. A small volume of buffer is used to facilitate probe and target specifically finding each other, thereby promoting hybridization. Hybridization takes several hours to overnight at an appropriate temperature determined by multiple variables: concentrations of the two species; time permitted for hybridization; complexities of the nucleic acids involved; length of the probe and its target and their complementarity to each other (or degree of mismatch); pH; temperature; and ionic strength of the buffer used.

After hybridization, the blot is washed with buffers containing sodium chloride and detergent to remove excess probe and reduce background nonspecific hybridization of the probe. Sodium chloride concentration and stringency are inversely related: the lower the sodium chloride concentration, the more stringent the wash condition. Increasingly stringent washes remove more nonspecifically bound probe. The temperature of the wash buffer and stringency are directly related: high-temperature washes are more stringent than low-temperature washes and further contribute to hybridization specificity. When appropriately stringent washing of the blot is complete, only the specific hybrids of interest should remain. Visualization of these specific hybrids, which appear as bands, is achieved by autoradiography for radioactive probes or by luminography for chemiluminescent probes. Biotinylated probes are visualized by chemical reactions, resulting in insoluble colored precipitates at the site of hybridization on the blot itself that serve as the endpoint (this is also the detection scheme used in the line probe assay; see below). Simple visual inspection of the blot or the radiograph is used for both isotopic and nonisotopic Southern blots to determine the position where the labeled probe hybridized to its target patient DNA. That position, relative to detection of appropriate controls and the distance of migration from the gel wells, allows interpretation.

Northern blotting is an extension of Southern blotting that uses RNA instead of DNA as the target of investigation. Northern blotting is as labor intensive as Southern blotting but even more problematic due to the highly labile nature of RNA. While northern blotting has been very useful in the research setting to demonstrate the selective expression of genes in various organs, tissues, or cells, it has not become a routine tool in the clinical molecular laboratory.

Examples of Applications of Southern Blotting
1. Fragile X syndrome diagnosis
2. Myotonic dystrophy diagnosis

Polymerase Chain Reaction

In the mid-1980s, Mullis and coworkers developed a method, the polymerase chain reaction (PCR), to amplify target sequences of DNA exponentially [10]. As the name suggests, the method is a DNA polymerase-mediated cyclical reaction resulting in amplification of specific nucleic acid sequences. Arguably, PCR is the single most important "invention" leading to the development of a new discipline in clinical laboratory medicine, that is, molecular pathology. Both PCR and the Southern blot are techniques used to investigate specific genomic targets. However, PCR is orders of magnitude more sensitive and rapid, permitting turnaround times from specimen receipt to report generation of 24 h or less. PCR lends itself to much higher test volumes than Southern blotting, a crucial point in its adoption in the clinical laboratory setting. Opportunity for high test volumes, excellent specificity and sensitivity, and the rapid turnaround times of PCR are the principal reasons this technology is used so widely in clinical molecular laboratories.

In PCR, a unique sequence of the nucleic acid of interest, e.g., oncogene, invading pathogen DNA, gene mutation, is chosen as the target for amplification. The inherent specificity of the ensuing reaction is provided by two short oligonucleotides (see Fig. 2.1) that serve as primers for DNA polymerase-mediated DNA synthesis using denatured target DNA as a template. The two primers are complementary to opposite strands and opposite ends of the targeted DNA template region. Usually the primers bracket the area of interest, but one type of PCR (allele-specific PCR; see below) uses primers that overlap the area of interest. Successful PCR depends on temperature cycling, and in the first step of PCR the reaction temperature is raised to 95–98 °C to denature the target DNA, and thus is called the denaturation step. After 10–60 s at this high temperature, the temperature is reduced

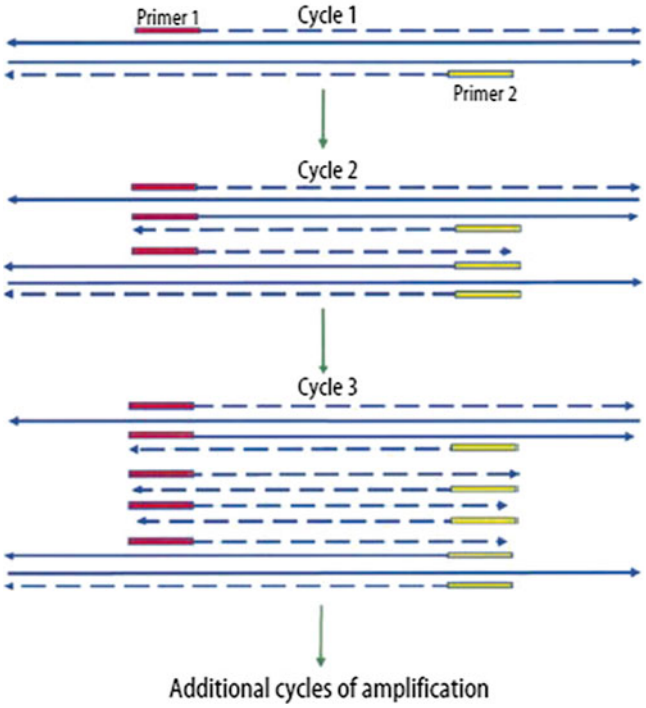

Figure 2.1 The polymerase chain reaction

to 50–70 °C, depending on the specific protocol, and held there for usually 10–60 s. This facilitates hybridization (annealing) between the denatured target DNA and the PCR primers, and is called the annealing step. This hybridization event is favored over target DNA reannealing because the PCR primers are small and present in vast molar excess, and move more rapidly in solution than larger DNA molecules.

The hybridized PCR primers form local areas of double strandedness with the template DNA, thereby serving as sites for DNA polymerase to bind and synthesize a new strand of DNA, using the target DNA as a template and dNTPS present in the reaction solution. Subsequent to the initial discovery of PCR, the opportunity for automating the temperature cycling was realized by using DNA polymerase from hot-spring living bacteria, *Thermus aquaticus* (hence the term "*Taq* polymerase"). *T. aquaticus* thrives at very high temperatures, and so its proteins do not denature at the high temperatures needed to denature DNA in the first step of PCR. Catalysis by *Taq* polymerase of a new strand of DNA proceeds at a temperature intermediate to the near-boiling temperature used for denaturation and the relatively lower temperature used for annealing. DNA polymerization occurs during this extension step, typically at 65–75 °C. Taken together, these three steps (denaturation, annealing, and extension) define one PCR cycle.

Temperature cycling is automated through the use of an instrument called a thermal cycler. Thermal cyclers hold small capped tubes (or 96- or 384-well microtiter plates for larger volume testing) containing the reagents needed for PCR, and cycle among the temperatures needed for the different steps of the PCR [11]. A single PCR tube contains template DNA (<1 ng to 1 μg), *Taq* DNA polymerase, two PCR primers (15–30 nucleotides long), all four dNTPs, Mg^{2+}, and buffer to maintain an elevated pH (8.4) optimal for *Taq* polymerase activity.

The repetition of the cycles generates exponential amplification of the target DNA because each double-stranded target DNA molecule, theoretically even if there is only one, is replicated after one PCR cycle. Both the original and replicated DNA molecules can function as templates for cycle 2, in true "chain reaction" style, generating another doubling, or four copies of the original target. Cycle 3 ends with eight molecules, and doubling continues with completion of each new cycle. This doubling plateaus in later cycles since reagents, usually dNTPs, become limiting. Additionally, the enzyme may not function at 100 % efficiency, and so true exponential amplification is theoretical, although there is a true exponential phase of amplification.

Greater than one billion copies of the original target DNA region are generated after 32 cycles of PCR: 2^{32} or more than four billion, the difference owing to the fact that unit-length amplicons are not generated until the end of the second cycle of PCR. Amplicons (PCR products) are defined as replicated target molecules created by PCR. Unit-length amplicons are those whose ends are defined by the primers. During the first cycle, the primers are extended by *Taq* polymerase using template DNA. The termination of this extension is undefined and a function of how far the polymerase moves down the template during the time allotted by the temperature cycle. The enzyme, therefore, moves beyond the ends of the primer-binding site on the complementary strand. After completion of the first cycle, therefore, the newly synthesized DNA molecules are greater in length than the sequence bracketed on each strand by the primers. In the second cycle, DNA molecules are synthesized from the products of the first cycle whose ends are defined by the two primers, thus generating unit-length or specific amplicons. While all of the above is true, the practical clinical laboratory difference between one- and four billion-fold amplification is irrelevant because either number is sufficient for detection of the target, e.g., by electrophoresis with SYBR green or EtBr used as an intercalating agent for visualization.

Several factors affect PCR specificity and sensitivity. The production of specific PCR amplicons is a function of both the complementarity of the primers to the target DNA and the annealing temperature of the PCR cycle. Heating denatures the primer and target DNA. The temperature at which a primer melts from the target DNA varies directly with the length of the primer and the guanine–cytosine (GC) content of the primer, and inversely with the degree of mismatch between the primer and the target DNA. The melting temperature (T_m)

of the primer is the temperature at which 50 % of the primer is denatured from the target DNA. If the thermal cycler is programmed to reach an annealing temperature higher than the primer T_m, the efficiency of PCR is compromised and sensitivity decreased. In contrast, if the annealing temperature is substantially less than the primer T_m, the primer can bind to both complementary and noncomplementary DNA, resulting in reduced PCR specificity as nontarget DNA is amplified (and potentially decreased sensitivity as reaction components are used nonspecifically). Therefore, the ideal annealing temperature is slightly less than the Tm of both primers, and the primers should be designed to have a very similar T_m. The annealing temperature can be decreased with subsequent cycles during PCR in a process called "touchdown" PCR. This allows the initial cycles to produce specific products at high annealing temperatures, while later cycles amplify previously generated amplicons more efficiently using lower annealing temperatures, thereby increasing sensitivity (see below the use of touchdown PCR in multiplex PCR).

Taq polymerase is very sensitive to mismatches between the primer and the target DNA at the 3′ end of the primer but can withstand considerable noncomplementarity at the 5′ end of the primer. Numerous PCR variations have been designed to take advantage of both these facts. *Taq* polymerase also requires Mg^{2+} as a cofactor for stabilization of primer annealing. Insufficient Mg^{2+} decreases PCR efficiency, while too much Mg^{2+} stabilizes nonspecific primer annealing. Primers with a high GC content may show a narrow range of tolerance for variation from ideal PCR conditions, leading to decreased amplification or nonspecific products. This may be alleviated by using PCR additives such as dimethyl sulfoxide (DMSO), betaine or glycerol, but the success and amount of these additives may need to be determined empirically for different primer pairs. Another strategy to improve specificity is the use of "hot-start" PCR, in which a crucial PCR reactant such as *Taq* is either physically or chemically sequestered from other PCR reagents until denaturation begins. This prevents the generation of nonspecific amplification products by inhibiting the activity of *Taq* at lower temperatures and until after the initial PCR denaturation step.

PCR is more sensitive than Southern blot hybridization because of the amplification of the target sequence. However, the specificity of the amplified PCR product(s) must be verified. Simple agarose gel electrophoresis coupled with intercalating agent staining may be used to observe the PCR product(s). When a clinical PCR protocol is established, such gels may be subjected the first time to blot hybridization with a specific probe complementary to the internal, non-primer sequence of the amplicon(s). This exercise proves that the PCR-generated band not only is the correct size and highly likely to be the correct target, but also is a DNA fragment that has high or perfect homology with a known probe or the correct target sequence. For example, hybridization of a particular 302 bp PCR product band detectable on an agarose gel with a defined cytomegalovirus (CMV) DNA probe confirms that the oligonucleotide primers synthesized based on the CMV sequence and used in the PCR are recognizing CMV-specific DNA and that the PCR is indeed specific for CMV sequence. An alternative method to validate the specificity of the PCR product is to sequence the PCR product. Following this one-time validation analysis, electrophoresis alone may be the assay endpoint, as opposed to blot hybridization or sequencing.

There have been significant commercial endeavors to automate or semiautomate high-volume PCR-based clinical tests. For example, denatured aliquots of completed PCRs can be added to microtiter plates with wells to which specific DNA probes are bound. In the presence of amplicon, if the patient is infected with the pathogen of interest or a specific mutation is present, the amplicons hybridize to the bound probe and are retained in the well during subsequent washing steps. Biochemical reactions are used to detect labeled moieties in the amplicons ("built in" to the PCR components), facilitating colorimetric detection of a positive patient reaction by an automated plate reader. Absence of colored product in a well indicates a negative result for that patient specimen, provided that all positive and negative controls are within tolerance limits. This scheme has gained US Food and Drug Administration (FDA) approval or clearance for clinical PCR-based detection kits for *Chlamydia trachomatis*, *Neisseria gonorrhoeae*, HCV (qualitative), and HIV [12]. (For a complete list of FDA-approved or -cleared tests, go to http://www.fda.gov/MedicalDevices/ProductsandMedicalProcedures/InVitroDiagnostics/ucm330711.htm). Subsequent generations of PCR instrumentation are available that completely automate the amplification and detection processes [13].

Another aspect of PCR that is attractive for the clinical molecular laboratory is the ability to use relatively crude DNA extractions from patient specimens rather than highly purified DNA. Cell lysis and subsequent DNA liberation accomplished by boiling or treatment with detergent may be sufficient to process a specimen in preparation for PCR [14]. Conventional PCR-based tests may be completed with turnaround times of as short as 2–4 h, while real-time PCR can be completed in 30 min, making this technique attractive for rapid clinical testing.

Examples of Applications of PCR

1. Detection of the diagnostic *BCL2–IGH* gene rearrangement in follicular lymphoma
2. Detection of *Chlamydia trachomatis* in urine

PCR Variations

PCR-Restriction Fragment Length Polymorphism Analysis

Polymorphisms are inherited differences found among the individuals in a population at a frequency >1 % of that population. The term "polymorphism" is not synonymous with the term "mutation" which is used for germline variations that are pathogenic and found less frequently in a population, or are nongermline changes in a tumor cell (somatic mutations). In the case of restriction fragment length polymorphisms (RFLP), DNA sequence differences alter RE recognition sites, manifested either as obliteration or creation of a restriction site. With obliteration of a RE site, the DNA of individuals with an RFLP exhibits a larger restriction fragment of DNA than those without the polymorphism. With creation of a new RE site, RE digestion results in two smaller fragments relative to the individual without the polymorphism. In either case, the polymorphism is detectable by creation of a new restriction fragment pattern, that is, a restriction fragment length polymorphism. In PCR-RFLP, the PCR products are digested by one or a combination of REs and electrophoresed to detect polymorphisms or mutations which are seen as changes in the DNA fragment sizes reflected by changes in the band pattern on the gel (or chromatogram).

Examples of Applications of PCR-RFLP Analysis

1. Detection of sickle-cell hemoglobin (HbS) gene mutation
2. Detection of the *Mnl*I restriction enzyme polymorphism created by the Factor V Leiden mutation [15]

Restriction-Site Generating PCR

Some DNA sequence variants create or abolish RE recognition sites and can easily be detected by PCR-RFLP. Unfortunately, most variants do not alter a RE recognition site. In restriction-site generating PCR (RG-PCR) (and a related research technique called PCR-mediated site-directed mutagenesis [PSDM]), an artificial RE recognition site is generated during PCR using a specially designed PCR primer [16, 17]. The primer contains a base mismatch to the template DNA adjacent to the variable base of the variant that creates a RE recognition site in the PCR product. The mismatched base in the primer is located near or at the 3′ end of the primer, which is near or adjacent to the variable base of the variant, and together they create a novel restriction site within either the variant or non-variant amplicon. The presence or absence of the RE recognition site is determined from the pattern of digested PCR product fragments by gel electrophoresis. Not all sequences are amenable to the generation of a restriction site, and the amplification efficiency is often decreased due to destabilization of the primer with the mismatch.

Examples of Applications of RG-PCR

1. Identification of mutations in the *CTFR* gene in cystic fibrosis
2. Identification of mutations in the *ATM* gene in ataxia–telangiectasis

Multiplex PCR

Multiplex PCR is a technique used for amplification of several discrete genetic loci with multiple PCR primer pairs in a single reaction. Multiplex PCR simultaneously answers several related questions about a specimen without the need for multiple individual PCR reactions. Multiplex PCR is commonly used for verification that amplifiable nucleic acid is present in the sample, for example, amplification of a housekeeping gene in addition to the gene sequence(s) of interest, and to check for the presence of PCR inhibitors that can prevent amplification of target nucleic acid, for example, coamplification of an exogenously added internal control. Multiplex PCR often requires painstaking optimization of PCR conditions and careful design of the multiple primer pairs to match PCR efficiencies and to prevent the generation of primer-dimers (PCR products generated by the primers alone due to complementarity between primer regions) and other nonspecific PCR products that may interfere with the amplification of specific products. Touchdown PCR can be used with multiplex PCR if the primer pairs have different annealing temperatures. Concentrations of individual primer pairs may need to be optimized to account for different amplification efficiencies and competition between the primer pairs.

Examples of Applications of Multiplex PCR

1. Detection of enterovirus and herpes simplex virus (HSV) nucleic acids in cerebrospinal fluid (CSF)
2. Detection of pathogenic enteric bacteria in stool
3. Analysis of multiple *BRCA1* loci in a breast cancer patient [18]
4. Identification of different bacteria in a respiratory infection specimen [19]
5. Amplification of multiple microsatellite loci for bone marrow engraftment analysis

Single Nucleotide Extension

Another method for a multiplexed assay is single nucleotide extension (SNE) or single base extension (SBE). In this method, either a single long-range PCR or a multiplexed PCR is used to amplify the region(s) of interest. This is followed

by a multiplexed set of extension primers of differing lengths that hybridize one base upstream to the variant(s) of interest. A second, linear amplification, similar to Sanger sequencing, adds the next nucleotide (at the variant position) using ddNTPs, with each type labeled with a different fluorophore. The products are separated by CE or mass spectrometry, and the specific fluorescent signal of the incorporated base indicates which base was added, and whether the variant is present or not. This method can be used to genotype up to approximately 20 mutations at once. SNE and SBE can be considered sequencing, but of just one base.

Examples of Applications of SNE

1. Analysis of common mutations in *GALT* for galactosemia [20]
2. Analysis of common mutations in *BTD* for biotinidase deficiency
3. Analysis of multiple mutations in the *CFTR* gene for cystic fibrosis [21]

Nested PCR

For nested PCR, two pairs of PCR primers with one set internal to the other (nested) are used to sequentially amplify a single locus. The first pair is used to amplify the locus as in any PCR assay. A dilution of the first PCR reaction then is amplified with the nested primers. Alternatively, semi-nested PCR is performed using one of the original PCR primers and one new internal primer in a second round of amplification. Both nested and semi-nested PCR generate a second PCR product that is shorter than the first one [22]. The logic behind this strategy is that if the wrong locus was amplified incorrectly or nonspecifically, the probability is very low that it would be amplified a second time by a second pair of primers. Thus, nested PCR enhances specificity while also increasing sensitivity. The problem with nested PCR is the high risk of amplicon contamination when the first-round PCR products are used to set up the second round of PCR with the nested primers (see Amplicon Carryover Contamination section below for information on PCR contamination control). For this reason, many clinical laboratories do not use nested PCR procedures.

Allele-Specific PCR

Allele-specific PCR (AS-PCR) also is referred to as amplification refractory mutation system (ARMS), PCR amplification of specific alleles (PASA) and PCR amplification with sequence-specific primers (PCR-SSP). AS-PCR is based on the principle that a 3′ mismatch between a PCR primer and the template DNA prevents PCR amplification [23]. AS-PCR is especially useful for detection of single nucleotide polymorphisms (SNPs) or mutations. For AS-PCR, target DNA is amplified in two separate and simultaneous reactions. Each reaction contains an allele-specific primer (either non-variant or variant) and a second primer common to both reactions. PCR is performed under stringent conditions, to prevent PCR amplification if a mismatch is present. Genotype is based on amplification in either one of the reactions alone (homozygous non-variant or variant) or both reactions (heterozygous). Detection of the amplicon is either by gel electrophoresis or real-time PCR technology (see below). A disadvantage of AS-PCR is that unsuspected nucleotide variants located in the DNA template at or adjacent to the 3′ binding site of the primer would prevent amplification, leading to incorrect genotyping.

AS-PCR can detect one variant allele in the presence of 40 copies of the non-variant allele. In addition, AS-PCR can be combined with multiplex PCR using multiple allele-specific primers in the same reaction tube. This technique is known as multiplex ARMS, a useful method when a single disease is caused by different mutations in one or more genes. Multiplex PCR-SSP also is commonly used in low-resolution HLA typing, in which multiple primer pairs for HLA loci are used along with control primers that amplify a housekeeping gene to verify that amplifiable DNA is present in each reaction tube.

Examples of Applications of AS-PCR

1. Detection of multiple cystic fibrosis *CFTR* mutations
2. Detection of common α-1 antitrypsin deficiency mutations
3. Detection of common phenylketonuria mutations

Allele-Specific Oligonucleotide Hybridization

Allele-specific oligonucleotide hybridization (ASOH), also known as dot-blot analysis, is used for genotyping of highly polymorphic regions of DNA. ASOH can be thought of as a variation of the Southern blot, in that patient DNA amplified by PCR is bound to a membrane and hybridized with labeled allele-specific oligonucleotide probes [24]. Reverse dot-blot analysis differs from ASOH in that unlabeled allele-specific oligonucleotide probes are spotted onto different membrane locations and hybridized with labeled PCR amplicons.

For ASOH, the PCR products are denatured and a small amount of denatured (single stranded) amplicon is spotted onto a nylon or nitrocellulose membrane. The amplicon is permanently bound to the membrane by baking under vacuum or UV cross-linking. Amplicons from different specimens can be spotted at different locations to interrogate the genotype of multiple specimens simultaneously. Duplicate membranes are made for each probe type. Each membrane is hybridized with two different labeled oligonucleotide probes (one complementary to the variant sequence and another to the non-variant sequence of the same DNA region). The membranes are washed to remove nonspecifically bound probe. Samples that hybridize strongly to only one probe indicate homozygosity for the

non-variant or variant allele; those that hybridize with both probes are heterozygous. The oligonucleotide probes are labeled and detected by radioactivity (often avoided in clinical molecular laboratories), fluorescence, colorimetry, chemiluminescence or mass spectrometry. One drawback of ASOH is the potentially ambiguous discrimination of a positive compared to a negative signal. Optimization of the assay and the use of both positive and negative controls help to define and score ASOH results.

Example of Application of ASOH
1. Low-resolution HLA typing

Oligonucleotide Ligation Assay

Oligonucleotide ligation assay (OLA) is a highly specific method for detecting well-defined alleles that differ by a single base [25, 26]. The target sequence is initially amplified using PCR and then denatured. A pair of allele-specific oligonucleotide (ASO) probes (one specific for the non-variant allele and the other specific for the variant allele), a common reporter probe (complementary to a sequence common to both alleles), and DNA ligase are added to the denatured PCR products. The ASO probes are designed to differ from one another only at the terminal 3′ base. The common reporter probe is positioned immediately adjacent to the 3′ terminal end of the ASO probes. If the ASO is complementary to the amplicon, DNA ligase can covalently join the adjacent ASO and reporter probes. If the ASO is not a perfect match to the amplicon, the 3′ base does not anneal with the template DNA, and DNA ligase cannot join the ASO and reporter probes. The ligation products are analyzed by electrophoresis. Alternatively, one of the probes can be biotinylated at the 5′ end and the other probe tagged at the 3′ end with a reporter molecule such as fluorescein or digoxigenin. If ligation occurs, the ligation product is biotinylated at one end, facilitating capture onto a streptavidin-coated microtiter plate. The opposite end contains the reporter label. Washing removes unbound label and the reporter molecule is detected.

Example of Application of OLA
1. Detection of multiple *CFTR* mutations for cystic fibrosis

High-Resolution Melting Curve Analysis

Melting curve analysis takes advantage of the principle that DNA sequences that are a perfect match will melt at a higher temperature than those that contain either a heterozygous or homozygous nucleotide variant. Typically, in genotyping by high-resolution melting curve analysis, an area of interest (approximately 50 bases, including primers) is amplified in the presence of a double-stranded DNA-intercalating fluorophore or double-stranded DNA-intercalating dye. After amplification, the temperature is decreased to the point that the DNA will reanneal. The temperature then gradually is increased while the fluorescence is monitored. Variants are identified by a change in melting curve shape as compared to a non-variant control. While the typical use of melting curve analysis is to identify single nucleotide variants of interest, it can also be used as a rapid scanning method to detect potential sequence variants in a gene of interest. Melting curve analysis can be affected by factors such as salt concentration and DNA quantity, so all samples and controls must be prepared and amplified in an identical manner to exclude this as a possible confounding factor.

Examples of Applications of Melting Curve Analysis
1. Factor V Leiden genotyping
2. *HFE*-associated hereditary hemochromatosis genotyping

Pyrosequencing

Pyrosequencing is a useful method for variant detection when analytical sensitivity (limit of detection) or quantitation is important. In pyrosequencing, amplified targets are sequenced by adding and detecting incorporation of nucleotides one at a time. First, a target region is amplified and PCR products are captured through use of a biotinylated primer, which has been included in the PCR, along with a streptavidin-coated bead. Capture of the product onto the bead via the incorporated biotin group allows purification of the specific PCR product, followed by denaturation to create a single-stranded target. A sequencing primer close to the region of interest is then annealed to the captured single-stranded DNA amplicon. Deoxynucleotides are added one at a time in the presence of four enzymes: polymerase, sulfurylase, luciferase, and apyrase. Incorporation of the nucleotide releases pyrophosphate which participates in a chain reaction with luciferin, facilitated by sulfurylase and luciferase, to generate light. The amount of light released is directly proportional to the quantity of nucleotide incorporated. Apyrase removes unincorporated nucleotides. If the complementary base is not on the strand being sequenced, then no incorporation occurs and no light is released. The next nucleotide is then added to the pyrosequencing reaction and the steps are repeated. Nucleotides may be added in cyclic fashion (ACGTACGT…) or in an order specific to the target sequence, with allowance for anticipated variants.

Compared to other methodologies, pyrosequencing is particularly useful when analytical sensitivity is of particular concern, such as in detection of somatic mutations in tumor specimens which yield both non-variant and variant DNA. Analytical sensitivity of 5 % can be achieved with pyrosequencing, as compared to approximately 20 % for Sanger sequencing and approximately 10 % for melting

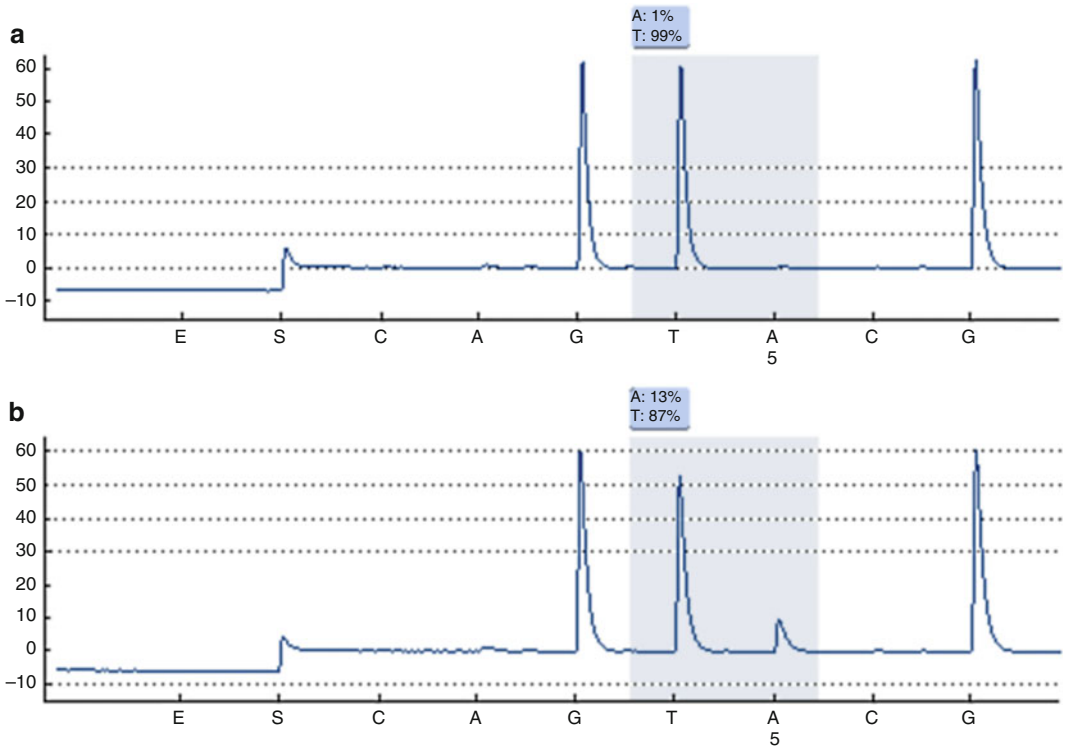

Figure 2.2 Pyrosequencing graphs for *BRAF* codon 600. Nucleotides were dispensed in the following order: CAGTACG. (**a**) Results for a non-variant sample showing the sequence GTG for codon 600. (**b**) Results for a variant sample (V600E), which has alleles with the sequence GAG, in addition to alleles harboring the normal sequence. Variant (V600E) alleles are present in this sample at 13 %.

curve analysis [27]. Quantification of mutant alleles also is provided by pyrosequencing results. Pyrosequencing is best suited for detection of variants within a targeted region. As compared to scanning methodologies, the region of interrogation may be somewhat smaller (under 100 bases, typically just multiple codons), but variants are both detected and characterized. An example of pyrosequencing results for codon 600 of *BRAF* is shown in Fig. 2.2.

Examples of Applications of Pyrosequencing
1. *KRAS* mutation detection in multiple tumor types
2. *BRAF* mutation detection in multiple tumor types
3. LINE-1 methylation

Reverse Transcription-Polymerase Chain Reaction

Reverse transcription-polymerase chain reaction (RT-PCR) may be thought of as RNA-based PCR. RT-PCR was made possible by the discovery in the early 1970s of retroviral reverse transcriptase (RT), an RNA-dependent DNA polymerase, by Baltimore and Temin [28], for which they shared the Nobel Prize in 1975. Reverse transcriptase catalyzes DNA synthesis using RNA as the template, producing a DNA strand complementary to the RNA template, called complementary DNA (cDNA). Complementary DNA is far more stable than the corresponding RNA because it is not subject to degradation by RNase. Complementary DNA can be treated like any other DNA target in subsequent PCR. Logistically, RT-PCR is trivially more time-consuming than PCR due to the extra enzymatic step of reverse transcription, but there are enzymes that combine reverse transcription and DNA polymerase activities, facilitating the use of RT-PCR in the clinical molecular laboratory. With the introduction of techniques to successfully isolate and protect RNA from ubiquitous RNases, to synthesize cDNA by reverse transcription and with the discovery of PCR, RNA analysis is virtually as rapid and sensitive as PCR-based DNA investigation. RT-PCR is a high-volume test method for the clinical molecular laboratory as used for the diagnosis and quantification of RNA viruses in human specimens, principally HIV and HCV.

Examples of Applications of RT-PCR
1. HIV and HCV viral load determinations
2. Detection of *BCR–ABL* translocation diagnostic of chronic myelogenous leukemia

Real-Time (Quantitative) PCR

Real-time (quantitative) PCR is based on the generation of a fluorescent signal by the PCR process, which is detected during PCR cycling, i.e., in real time, and reflects the amount of PCR product synthesized [29–31]. Different real-time PCR methods use alternative ways to generate a fluorescent signal during PCR. These include an intercalating dye such as SYBR Green that binds the minor groove of DNA, or an oligonucleotide used as a primer or probe and labeled with a fluorogenic dye. Instruments that combine in vitro nucleic acid amplification and real-time detection of the PCR product dramatically increased testing options for oncology, infectious diseases and genetics because of the wide range of readily available amplification primers and detection schemes, rapid turnaround time, and reduced risk of PCR amplicon contamination.

Real-time PCR is different from conventional PCR in several ways. Amplicon generation, temperature profiles and melting curves are monitored in real time, reducing the time required for post-PCR analysis. In most applications, post-amplification processing of the PCR products by gel electrophoresis or other method is eliminated. Because the reaction tubes remain closed after PCR starts, risk of amplicon carryover contamination within the laboratory is reduced. Results are more reproducible between runs since quantitation of target is based on amplification cycle threshold in the log-linear phase of amplification rather than traditional endpoint analysis in the PCR plateau phase. Real-time PCR methods have a wide dynamic range, up to 10 logs. Real-time PCR systems with intercalating dye or fluorogenic probes can be used to perform melting curve analysis, adding a check for the specificity of amplification or potentially the detection of unknown sequence variants (see below).

The simplest real-time PCR method uses intercalating dyes that insert into the stacked bases of DNA PCR products, allowing detection of amplification in real time. These dyes, for example, SYBR Green and ethidium bromide (EtBr), are nonsequence-specific dyes that increase in fluorescence when bound to double-stranded DNA. Intercalating dyes are used for melting curve analysis, qualitative and semiquantitative PCR, product discrimination and purity, and determination of primer and probe melting T_m. Intercalating dyes can be used for quantitative PCR. Results, however, are more specific and accurate with a sequence-specific probe for real time monitoring of amplicon production since fluorescence is directly proportional to the amount of specific amplicon produced which reduces the background contributed by primer-dimers or nonspecific PCR products. Intercalating dye fluorescence represents all double-stranded DNA, including primer-dimers and other nonspecific products that can be visualized with an endpoint melting curve analysis.

Most fluorogenic oligonucleotide techniques take advantage of the principle of fluorescent resonance energy transfer (FRET), in which the energy from one dye molecule (the donor) is transferred without the emission of a photon to an acceptor dye molecule when the two are in close proximity. If the acceptor is a fluorophore, a photon is emitted at a characteristic wavelength. However, if the acceptor does not emit a photon, the energy is dissipated and fluorescence from the donor is quenched. The reporter dye can be either the donor (if no FRET takes place) or the acceptor (if FRET does take place) and is defined as the one whose fluorescence correlates with the quantity of desired PCR amplicon. Several fluorogenic techniques are described below.

TaqMan

The TaqMan technique uses a short probe complementary to a non-primer internal sequence of the PCR product. The probe is labeled at the 5′ end with a reporter donor dye and at the 3′ end with an acceptor dye that quenches the reporter when the probe is intact. During the extension phase of PCR, probe bound to an amplicon is cleaved by the 5′ endonuclease activity of *Taq* polymerase, freeing the reporter dye from the quencher and resulting in fluorescence. The fluorescent signal increases proportionally to the number of amplicons generated during the log-linear phase of amplification. To ensure that hydrolysis of the probe occurs, a two-step PCR can be used with annealing and extension taking place at the same temperature (approximately 60 °C). Ideally, the TaqMan probe binding site is located near one primer and the size of the amplicon is no longer than 200–300 bases. One negative aspect of this method is that once the probe is hydrolyzed, it is unavailable for subsequent reactions or melting curve analysis, thus requiring an excess amount of probe in the reaction mix with the potential to decrease the PCR efficiency.

Molecular Beacon

A molecular beacon is a probe with a 5′ reporter dye and 3′ quencher dye, which forms a hairpin loop structure when not bound to target DNA, thereby juxtaposing the reporter and quencher dyes with quenching of fluorescence. The loop sequence is complementary to the non-primer amplicon sequence. When the loop of the molecular beacon probe hybridizes to the amplicon during the annealing step of real-time PCR, the reporter dye is separated from the quencher, resulting in fluorescence. For the molecular beacon probe to anneal to the amplicon, the amplicon-probe hybrid must be more stable than the internal base-pairing stem of the hairpin so that a fluorescent signal is generated. Generally, DABCYL is the nonfluorescent universal quencher and the other dye is a reporter fluorophore such as FAM, Cy3, TET, TAMRA, Texas Red, ROX, or Cy5.

Hybridization

Hybridization is typically a two-probe system in which one probe contains a donor dye and the other contains the reporter acceptor dye. The probes are designed to anneal to one strand of the PCR product adjacent to one another and internal to the primers. This juxtaposes the dyes, allowing FRET to occur. This probe format works well with the traditional three-step PCR with annealing at approximately 55 °C (primer specific) and extension at 72 °C, the optimal temperature for *Taq* polymerase activity. When DNA polymerase encounters the probes, they are displaced from the target strand rather than hydrolyzed and thus are available for the next round of amplification as well as endpoint melting curve analysis. In a variation of this method, a single unlabeled probe may be used in conjunction with an intercalating dye.

Uniprimer (Amplifluor, Sunrise)

Like molecular beacon probes, the uniprimer system uses a hairpin structure in the probe to quench fluorescence. The 3′ region of the fluorogenic probe is identical to a nonbinding region at the 5′ end of the reverse PCR primer. This allows the fluorogenic probe to become a primer for the newly formed amplicon by the third round of PCR. The probe is then opened in the fourth and subsequent rounds of PCR by the polymerase action of *Taq*, allowing fluorescence to occur. The advantage of this system is that the same fluorogenic probe sequence can be used in any PCR reaction (universal fluorogenic primer).

Scorpion

Scorpion also uses a hairpin structure in the probe to quench fluorescence. The fluorogenic probe is part of the reverse primer, and the nucleotides in the hairpin are complementary to the PCR amplicon sequence between the primers. The Scorpion probe unfolds and anneals to the PCR amplicon, allowing fluorescence to take place beginning in the first round of PCR.

Lux

Lux is a variation of real-time PCR that uses a single fluorophore in a primer with a hairpin loop structure. The fluorophore is quenched by the complementary structure of nucleotides in the stem of the hairpin. When the primer is incorporated into double-stranded DNA, thus opening the hairpin, fluorescence is maximal. The advantage of this system is lower production costs with the use of only one fluorophore.

The following concepts are important for understanding the use of real-time PCR in a clinical molecular laboratory. When optimizing real-time PCR, the amplification curve of the fluorescent signal vs the number of PCR cycles should be monitored to determine when optimal conditions have been achieved. The amplification curve should be sigmoidal (S shaped) with three phases: baseline (background signal or lag phase), log-linear (exponential amplification phase), and plateau. For each phase, several characteristics should be assessed. The baseline phase of the curve represents initial cycles of amplification in which accumulation of the specific signal has not yet exceeded the background signal. The fluorescent signal in this phase is from unbound probe or autofluorescing components in the reaction. The log-linear phase of the curve represents exponential amplification of the target and provides useful information about the reaction. The curve can be described by the following equation: $Tn = T_0(E)n$, where Tn is the amount of target sequence at cycle n, T_0 is the initial amount of target sequence at cycle 0, and E is the amplification efficiency of the target sequence. The crossing point represents the number of PCR cycles at which the amplification curve enters the log-linear phase. There is an inverse linear relationship between the crossing-point cycle number and the number of template copies present in a reaction.

The slope of the log-linear phase is a reflection of amplification efficiency, and the efficiency of the reaction can be determined by identifying the crossing points of known standards and plotting a line of linear regression (Fig. 2.3). The efficiency can then be determined using the following equation: $E = 10^{-1/\text{slope}}$, where E is efficiency and slope is the slope of the standard curve. Using this equation, the slope should be between -3 and -4, with -3.3 indicative of efficiency close to or at 2. The inflection point of the amplification curve is the point at which the log-linear amplification curve goes from positive to negative and begins to enter the plateau phase. If there is no inflection point, the curve may represent not amplification of DNA, but rather signal drift. Drift is characterized by gradual increase or decrease in fluorescence without amplification of product.

Plateau is defined as the phase of amplification when critical components of the PCR become rate limiting and amplicon accumulation is minimized or stops. The plateau is also the point at which incremental increase in fluorescent signal stops. As the rate of accumulation slows and enters the plateau phase, the curve levels. Since endpoint measurements often are made in conventional PCR when reaction components are limited, minor sample variations can have a relatively major effect on endpoint product production. The plateau phase can be shortened by decreasing the number of PCR cycles for reduced nonspecific amplicon production.

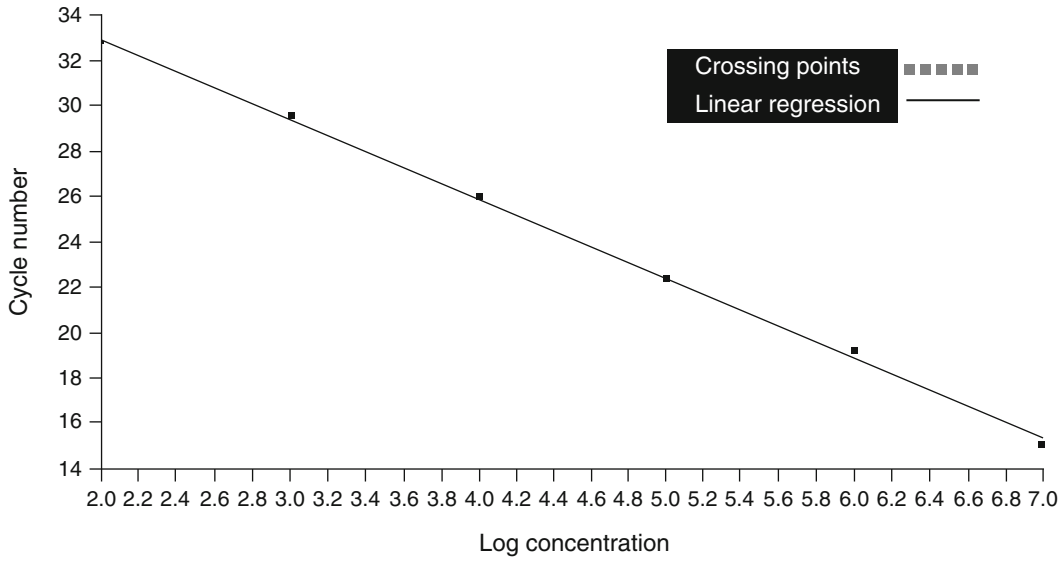

Figure 2.3 Standard curve generated from results of real-time PCR of a tenfold dilution series of a known standard

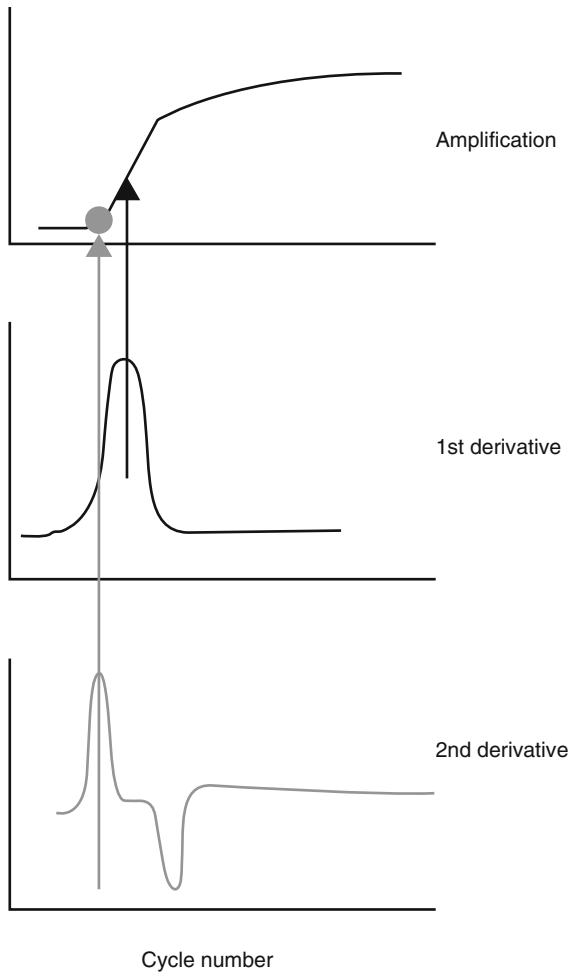

Figure 2.4 Graphical depiction of the second derivative maximum method used to identify the crossing point (*Y* axis is fluorescence value)

Several factors contribute to the plateau phase: PCR product reannealing vs primer annealing, enzyme or dNTPs becoming limiting, and amplicon buildup with resultant reaction inhibition.

In real-time PCR, the log-linear phase of the amplification curve is used for data analysis and provides a more accurate measurement than endpoint analysis. The cycle at which the curve crosses a specified threshold is called the cycle threshold (C_t), or crossing point (C_p). The C_t value can be used for qualitative or quantitative analysis. A qualitative analysis uses the defined C_t as a pass/fail measurement. A quantitative assay uses the C_t of defined standards of known template concentration to generate a standard curve. Then, the C_t values for unknown samples are used to extrapolate the concentration(s) in the unknown samples from the standard curve. Some commercial real-time PCR software allows determination of the C_t by a mathematical analysis of the amplification curve, rather than crossing at a set fluorescent signal threshold. Plotting the second derivative of the amplification curve generates a peak that corresponds to a point near the baseline of the growth curve (see Fig. 2.4). The cycle at which this peak occurs is designated as the C_t or C_p. This analysis method can provide better run-to-run reproducibility than manually setting the C_t using the primary signal.

DNA Methylation and Methylation-Specific PCR

DNA methylation is a mechanism by which the cell regulates gene expression. Methylation is an enzyme-mediated modification that adds a methyl (-CH_3) group at a selected site on

DNA or RNA. In humans, methylation occurs only at cytosine (C) bases adjacent to a guanine (G) base, known as CpG dinucleotides. CpG dinucleotides are prone to spontaneous mutation and have been selectively depleted from the mammalian genome. However, some regions of DNA contain CpG dinucleotides and are referred to as CpG islands. CpG islands are found primarily in the 5′ region of expressed genes, often in association with promoters. When the promoter CpG island is methylated, the corresponding gene is silenced and transcription does not occur. This is one method of silencing imprinted genes, as the methylation pattern and resulting transcription repression is passed on through cell divisions. Aberrant CpG island methylation of tumor-suppressor genes is frequent in cancer and appears to be an important mechanism of neoplastic transformation.

Methylated DNA can be distinguished from unmethylated DNA using sodium bisulfite treatment of DNA, which converts unmethylated C to uracil (U) but leaves methylated C intact [32]. This in vitro treatment can be assessed by one of several methods to distinguish C from U, including restriction endonuclease digestion with methylation-sensitive enzymes, sequencing, or methylation-specific PCR (MSP) [33]. In MSP of bisulfite-treated DNA, primer pairs that specifically identify either methylated or unmethylated DNA are used. The primers are designed to hybridize to regions containing one to three CpG sites concentrated in the 3′ region of the primer to increase amplification specificity, and enough non-CpG cytosines to ensure that unmodified DNA is not amplified. Gel electrophoresis is used to detect the presence or absence of the amplicon in each of the two reactions, indicating the presence of unmethylated or methylated alleles or both. A modification of quantitative MSP combines MSP with real-time PCR to distinguish the high-level CpG methylation in neoplasia from low-level methylation that can occur with aging or in nonneoplastic conditions such as metaplasia [34].

Examples of Applications of Methylation-Specific PCR
1. Analysis of imprinted genes in Prader–Willi and Angelman Syndromes
2. Clonality assessment based on X chromosome inactivation
3. Abnormal methylation in neoplasia

Mass Spectrometry

Mass spectrometry (MS) is a flexible platform for variant and target detection for clinical laboratory applications. In preparation for MS-based detection, a variety of PCR methods such as SNE can be adopted. PCR is performed to amplify the region(s) of interest, then products are enzymatically treated, diluted and/or cleaned to remove unincorporated dNTPs and reduce salts which could interfere with analysis. During MS analysis of the PCR products, samples are ionized, then separated based on their mass-to-charge ratios. The ions are detected after laser desorption with a nitrogen laser. Mass spectra of PCR products are obtained by detecting positive ions of the nucleic acids. Differences in mass due to nucleotide base changes can be detected [21]. Mass spectrometry can detect low levels of sequence variations useful for detecting mosaicism, somatic changes in a normal background and heteroplasmy in mitochondrial DNA.

Example of Application of Mass Spectrometry
1. Cystic fibrosis carrier testing

Multiplex Ligation-Dependent Probe Amplification (MLPA)

Deletions and duplications of single or multiple exons in specific genes are associated with many human diseases (reviewed in ref. 35). Although partial gene deletions or duplications account for less than 10 % of all disease-causing mutations for most hereditary conditions, some disorders can have deletion or duplication rates of 10–30 % or higher [36–44]. Multiplex Ligation-dependent Probe Amplification (MLPA, MRC Holland, Amsterdam, The Netherlands) is a semi-quantitative method used to detect abnormal copy numbers at an exon level resolution and has a high multiplexing capability [45]. The inclusion of MLPA in the clinical molecular laboratory can significantly increase the detection rate of many genetic disorders. Typically, MLPA kits contain a mixture of exon-specific probes targeted to the gene of interest and control probes that hybridize to other genomic areas.

In MLPA, DNA is denatured and incubated overnight with a mixture of probes that consist of two immediately adjacent oligonucleotides per target exon, each containing one of the PCR primer sequences (Fig. 2.5a). After hybridization, probes are ligated and the fragments are amplified by PCR using dye-tagged universal primers. Probes that are not ligated contain only one primer sequence and cannot be amplified to generate a signal. Amplification products that are typically between 130 and 480 bp in length, are separated by size using CE (Fig. 2.5a). The number of probe ligation products directly correlates to the number of target sequences in the sample. Deletions and duplications of the targeted regions are detected when the height ratios of the fluorescent peaks are lower or higher than the normal height ratio range of 0.7–1.4, respectively. An example of a large gene deletion where the deleted probes fall below the lower normal peak height ratio range of 0.7 is shown in Fig. 2.5b.

Several variations on the traditional MLPA procedure have been developed. One example is reverse transcriptase

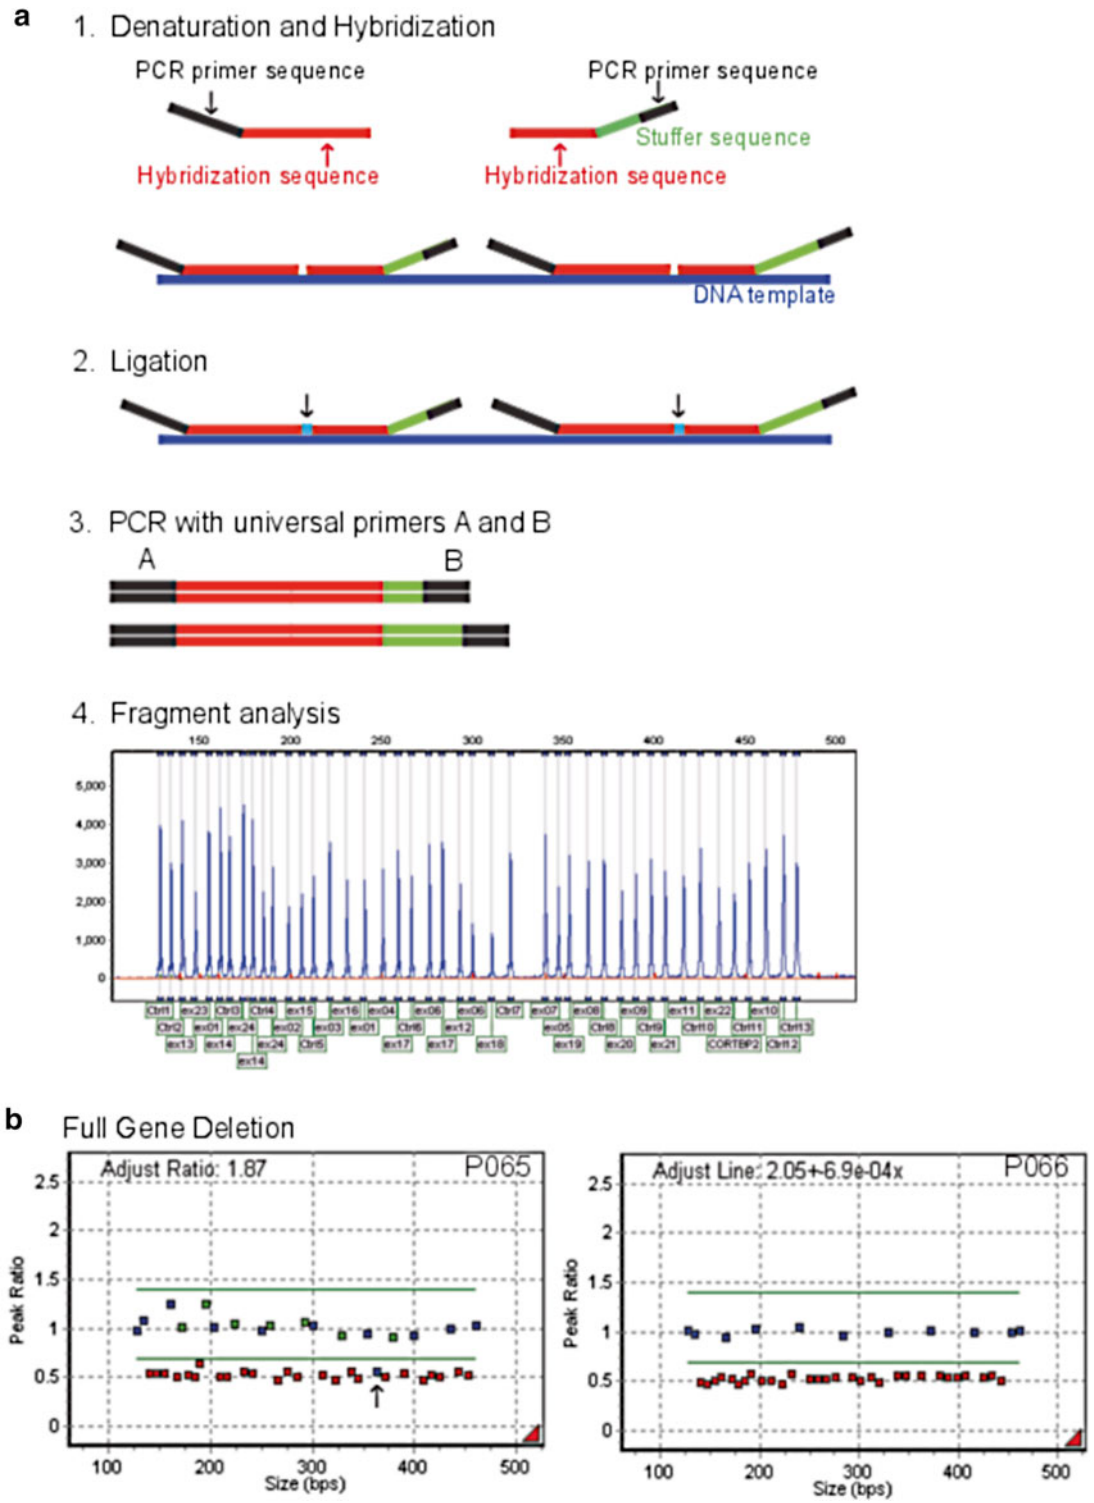

Figure 2.5 Multiplex Ligation-Dependent Probe Amplification (MLPA). In (**a**), the process of MLPA is shown. First, DNA template (*blue*) is denatured and then allowed to hybridize to exon specific probe hybridization sequences (*red*) which are targeted to the gene of interest. Adjacent probes are ligated together, and only ligated probes are amplified using universal primers A and B. Fragment analysis is used to separate the amplified fragments by size whereby the hybridization and stuffer sequences for each MLPA probe set determine the length of the amplified product. In (**b**), MLPA results of a large gene deletion are shown. Two MLPA kits (P065 and P066) were used to test for large *FBN1* gene deletions and duplications that cause Marfan syndrome. An additional control probe (*black arrow*) located 301 Kb upstream from *FBN1* exon 1 on the *DUT* (*deoxyuridine triphosphatase*) gene on chromosome 15q15-q21.1 also was deleted in this sample

MLPA (RT-MLPA) which can be used for mRNA profiling [46]. The only difference between traditional MLPA and RT-MLPA is that RT-MLPA begins with the reverse transcription of mRNA into cDNA before continuing with the typical MLPA reaction; the ligase enzyme cannot ligate probes which are bound to RNA. Methylation-Specific MLPA (MS-MLPA) is another variation that can be used to detect both copy number changes as well as the methylation status of the DNA target [47]. MS-MLPA is useful for imprinting disease testing [48–50] and the analysis of methylation aberrations in tumor samples [51, 52].

PCR Variations for Unknown Sequence Variants

Most of the techniques discussed above are used to screen for sequence variants (both mutations and polymorphisms) based on previous knowledge of the variant i.e., the sequence of the variant is either known or defined by previous scientific reports. In contrast, both research and clinical molecular pathology need methods to identify sequence variants without prior knowledge of their existence i.e., the sequence of the variant is unknown. Sequencing is the ultimate screening technique, but is costly and labor-intensive. The goal of the scanning techniques described below (denaturing gradient gel electrophoresis [DDGE], temperature gradient gel electrophoresis [TGGE], heteroduplex analysis [HA], single-strand conformation polymorphism [SSCP], denaturing high-performance liquid chromatography [DHPLC], protein truncation test [PTT], and variant screening by high-resolution melting [HRM] curve analysis) is to select DNA regions with possible variant sequences for follow up confirmation, thereby reducing costs relative to sequencing. Should an unknown variant be detected, for example by a shift in the mobility of the PCR product on a gel or capillary, the PCR product with altered mobility may be isolated and sequenced.

Denaturing Gradient Gel Electrophoresis and Temperature Gradient Gel Electrophoresis

Denaturing gradient gel electrophoresis (DGGE) [53, 54] and temperature gradient gel electrophoresis (TGGE) [55, 56] are similar methods for separating DNA fragments with similar lengths but different sequences and depends upon different mobilities within a linear gradient of increasingly denaturing conditions. In DGGE, the gradient is created with a mixture of urea and formamide, and in TGGE with a combination of water baths at different temperatures and a cooling plate under the gel. Both DGGE and TGGE exploit the markedly decreased mobility of partially melted dsDNA compared to either fully annealed dsDNA or ssDNA. Melting within a dsDNA fragment occurs within stretches of base pairs called melting domains. The point at which a domain begins to denature is referred to as the melting temperature (T_m), whether melting was induced by temperature or denaturing chemicals. In general, GC-rich sequences are more resistant to denaturation because of the three hydrogen bonds holding a GC pair together, as opposed to the two hydrogen bonds in an AT base pair. During electrophoresis, once a dsDNA fragment reaches the point at which the melting domain with the lowest T_m begins to denature, mobility of the fragment through the gel nearly ceases. Fragments that melt early in the gel can therefore be separated from those that melt later. Complete denaturation of the dsDNA can be prevented by adding a GC-rich region to the 5′ end of one of the primers (GC clamp), increasing the sensitivity for detection of sequence variants.

For DGGE and TGGE, the denaturing conditions and the time of electrophoresis are optimized such that non-variant sequences migrate to an intermediate position in the gel by the end of electrophoresis, allowing sequence variants creating either a higher or lower T_m to be identified. The denaturing gradient may be perpendicular or parallel to the electric field. Perpendicular gradient gels covering a broad range of denaturing conditions are loaded with the non-variant sequence in all lanes to find the optimal, narrower denaturing gradient (chemical or temperature) for later use in parallel gradient gels. Parallel gradients are used to assess patient samples but also to optimize the time of electrophoresis by loading the non-variant sequence in different lanes at different times. Double-gradient DGGE adds a sieving gradient, for example, 6–12 % polyacrylamide, colinear with the denaturing gradient in the gel matrix, further improving band resolution.

Both DGGE and TGGE work best with DNA fragments less than 500 bp in length. When GC-clamped fragments are analyzed, the sensitivity of detecting a SNP is close to 99 %. Following electrophoresis, specific bands can be isolated from the gel and sequenced. DNA fragments with a high GC content are not easily analyzed by DGGE, since all fragments are more resistant to melting.

Examples of Applications of DGGE or TGGE

1. *APC* gene mutation analysis for familial adenomatous polyposis [57]
2. *CTFR* gene mutation analysis for cystic fibrosis [58]
3. *TCRγ* gene rearrangements for lymphoma [59]

Heteroduplex Analysis

Heteroduplex formation results when non-variant and variant alleles are coamplified, denatured, and allowed to reanneal in a post-PCR annealing step [60]. Some of the strands pair with the complementary strand from the same allele and

form homoduplexes. However, some strands pair with a strand from the other allele and form heteroduplexes. Because the heteroduplexes have mismatched base pairs between strands, they form a partially open dsDNA sequence that migrates more slowly during electrophoresis than the fully annealed homoduplexes.

Two types of heteroduplex structures can be formed [61]. When the mismatch consists of one or more single-base mutations, small open areas of dsDNA called "bubble-type" heteroduplexes are formed. When the mismatch is formed by insertions or deletions between the two alleles, a pronounced bending of the dsDNA is produced and referred to as a "bulge-type" heteroduplex. Bulge-type heteroduplexes markedly affect the mobility of the dsDNA, whereas bubble-type heteroduplexes may be difficult to detect electrophoretically. Detection of single base-pair bubble-type mismatches can be enhanced in two ways. Electrophoresis can be performed with mutation detection enhancement (MDE) gels, an altered form of polyacrylamide used for improved resolution. Alternatively, the post-PCR introduction of a known sequence with a short deletion to form a bulge-type heteroduplex enhances the separation of sequences with base-pair mismatches in a process known as universal heteroduplex generation.

Examples of Applications of Heteroduplex Analysis
1. *HIV* subtyping
2. *CFTR* gene mutation analysis for cystic fibrosis
3. *NF1* gene mutation analysis for neurofibromatosis type 1

Single-Strand Conformation Polymorphism

The principle of single-strand conformation polymorphism (SSCP) is the differential gel electrophoretic separation of ssDNA that folds into a specific secondary structure based on its sequence [62–64]. For SSCP, the region of interest is amplified and the resulting amplicons are denatured using heat or a denaturation buffer, or both, prior to gel or capillary electrophoresis. Amplicons with different sequences will assume different folding conformations upon denaturation. Conformational differences reflecting sequence changes are detected as differences in electrophoretic mobility of the ssDNA in a nondenaturing polyacrylamide matrix. In general, a non-variant sample generates two bands, one for each of the two strands of the dsDNA product. Bands of variant ssDNA migrate to positions different from those of the non-variant ssDNA. A homozygous variant sample generates two bands, but with different migration patterns from the two non-variant bands. If a heterozygous variant is present, four bands are generated: two with non-variant mobility and two with variant mobility. Mutations also may change the conformation of only one strand but not the other in heterozygous specimens, resulting in three bands. DNA may be purified from the gel, allowing even rare somatic mutations in tumors to be sequenced.

Temperature, ionic environment and pH affect nucleic acid conformation and therefore must be held constant throughout the SSCP electrophoresis. Accurate temperature control during SSCP increases reliability and is an easily modifiable parameter in repeatable, nonisotopic tests that may increase sensitivity. SSCP is adversely affected if unincorporated primers are allowed to bind to the ssDNA during denaturing and cooling prior to electrophoresis, or if nonspecific bands are produced by low-fidelity PCR. In SSCP, electrophoretic mobility patterns of variant alleles can be difficult to distinguish from non-variant alleles. Another disadvantage of SSCP is that multiple test conditions are required for 100 % sensitivity for detection of all sequence variants.

SSCP is most sensitive when the DNA amplicon is less than 200 bp in length. Sensitivity decreases as the fragment length increases. This can be overcome by RE digestion of larger PCR products prior to electrophoresis. When RE digestion is used, the procedure is referred to as restriction endonuclease fingerprinting-single-strand conformation polymorphism (REF-SSCP). Additionally, SSCP is relatively less sensitive for G to C mutation detection; however, addition of glycerol enhances mutation detection in this circumstance.

Variations of SSCP include RNA-SSCP (rSSCP), dideoxy fingerprinting (ddF), bidirectional ddF (bi-ddF), and SSCP detection of virtually all mutations. RNA adopts more conformational structures than does ssDNA, allowing enhanced detection using rSSCP. RNA-SSCP is not widely used because of the relative difficulty in obtaining intact RNA for analysis. Dideoxy fingerprinting involves a dideoxy Sanger single-primer termination reaction (cycle-sequencing reaction; for additional information on the Sanger reaction, see the section on sequencing, above) followed by nondenaturing electrophoresis. A fingerprint bandshift is indicative of sequence changes. In bi-ddF, the dideoxy Sanger termination reaction is performed with two opposing primers in the same well or tube.

The detection of an altered SSCP pattern does not identify the exact sequence variation present in the analyzed DNA. Therefore, positive SSCP results require DNA sequence analysis to confirm and identify the sequence variation.

Examples of Applications of SSCP
1. Screening for mutations in the adenomatous polyposis coli (*APC*) gene
2. Mutation analysis of the *ATP7B* gene for Wilson disease
3. Mutation analysis in *BRCA1* for familial breast cancer
4. Pathogen identification [65]

Denaturing High-Performance Liquid Chromatography

Denaturing high-performance liquid chromatography (DHPLC) is an ion-paired, reversed-phase, liquid chromatography method used to identify variants, including SNPs and small insertions or deletions, by distinguishing between heteroduplex and homoduplex DNA [66]. DHPLC is conceptually similar to heteroduplex analysis (HA; see above). Conventional HA makes use of a gel matrix to separate homoduplex and heteroduplex species in a non-denaturing environment, whereas DHPLC uses partially denaturing conditions in a liquid chromatography column to exaggerate the separation between the two species.

For DHPLC, the gene to be tested is amplified using high-fidelity PCR to prevent the production of PCR artifacts (pseudoalleles) that could produce false-positive results. The optimal amplicon length is between 100 and 500 bp. PCR product purification usually is not necessary, as unincorporated primers, nucleotides, and genomic DNA do not interfere with the analysis. DHPLC requires heteroduplex formation, accomplished by heating and slow cooling of the PCR products. Therefore, for conditions in which only one variant allele type may be present (such as recessive diseases, X-linked conditions in males, or small tumor samples with loss of heterozygosity in all cells), PCR products from non-variant control samples and patient samples are mixed in equal proportions before heating and cooling to produce heteroduplex DNA and distinguish from homozygous non-variant alleles. The addition of non-variant PCR amplicons is not required when using DHPLC to test PCR products from heterozygous individuals, which naturally form heteroduplexes when denatured and slowly cooled.

The duplexes are injected into a DHPLC column, and the DNA binds to the stationary matrix. Binding is aided by triethylammonium acetate. Because the stability of the binding depends on the temperature, the column is optimally held at the T_m of the PCR fragment. The T_m can be calculated using a variety of proprietary or free software programs. The DNA is next eluted from the matrix using acetonitrile and DNA absorbency is measured at 260 nm. The linear gradient of acetonitrile established in the column allows separation of DNA fragments based on size or the presence of heteroduplexes, or both. All DNA fragments impart a characteristic profile when the absorbance is plotted against elution time. The peak of maximum absorbance is the retention time of that DNA sample at a given acetonitrile concentration. Heteroduplexes are less stable and thus have a lower affinity for the column. The concentration of acetonitrile required to separate heteroduplexes from the column is therefore lower, so heteroduplexes elute from the column earlier than homoduplexes.

The column temperature and gradient conditions can be optimized for the separation of any heteroduplex-homoduplex mixture. Some DNA fragments have more than one melting domain and the analysis may be performed at more than one temperature. One advantage of DHPLC is that reinjection of the same sample at different temperatures is possible. Other advantages include high detection rates of variants, rapid separation times per sample, a high degree of automation, and the ability to collect elution fractions and sequence each eluted fragment. Disadvantages of DHPLC include the need for expensive equipment and columns, high-fidelity PCR, and optimization of each reaction required to achieve the highest sensitivity of mutation detection.

Examples of Applications of DHPLC

1. *RET* and *CFTR* mutation detection [67]
2. *BRCA1* and *BRCA2* mutation analysis [68]

Protein Truncation Test

The protein truncation test (PTT) is used to identify mutations that result in premature termination of translation. Although initially developed for Duchenne muscular dystrophy testing, PTT has been applied widely [69], since protein-truncating mutations are associated with multiple types of hereditary cancer syndromes, including cancers of the breast, ovary, and colon.

In PTT, the gene segment of interest is amplified by PCR. The amplicons are used for in vitro transcription and translation in a coupled reaction. The resulting proteins are separated using sodium dodecyl sulfate (SDS) polyacrylamide gel electrophoresis. The presence of a premature termination codon is demonstrated by the visualization of a lower-molecular-weight protein band than for the non-truncated protein. Relatively large gene fragments (2–4 kb) can be analyzed using PTT.

Examples of Applications of PTT

1. Duchenne muscular dystrophy diagnosis
2. *BRCA1* and *BRCA2* mutation detection for breast cancer [70]
3. *APC* mutations for colorectal cancer [71]

Variant Scanning by High-Resolution Melting Curve Analysis

High-resolution melting curve analysis (described in detail above) can be used for variant scanning of many genes. In this method, a large region of a gene, e.g., an exon or any region that is ≤500 bp, is amplified and then melted in the presence of a non-variant control DNA. A deviant melt indicates a base change within the region and sequencing of that region must be performed in order to determine the clinical

significance of the detected variant. This method is useful for investigating genetic causes for suspected biochemical disorders found during newborn screening.

Examples of Applications of Variant Scanning by High-Resolution Melting Curve Analysis
1. Screening for Medium Chain Acyl-CoA Dehydrogenase (MCAD) deficiency mutations [72]
2. Screening for Ornithine Transcarbamylase (OTC) deficiency mutations

Other Nucleic Acid Amplification Methods

PCR is widely used in the clinical laboratory. The proprietary nature of PCR prompted the development of alternative methods for nucleic acid amplification. Several are described here: ligase chain reaction (LCR); transcription mediated amplification (TMA), strand displacement amplification (SDA), and nucleic acid sequence-based amplification (NASBA).

Ligase Chain Reaction

Ligase chain reaction (LCR) [73, 74] is initiated when a mixture of target DNA, thermostable DNA ligase, four oligonucleotide probes, and NAD^+ or ATP is heated to denature dsDNA (both target and complementary probes) in the reaction mixture. Two pairs of complementary probes are used, and, of necessity, their correct design requires knowledge of the sequence of the DNA target. After denaturation and subsequent reaction cooling, the four probes in the reaction mixture hybridize to their complementary sequences on each target DNA sister strand. The two probes that hybridize to one sister strand and the two probes that bind to the other sister strand are designed such that when hybridized, the 3′ hydroxyl end of the upstream probe is immediately adjacent to the 5′ phosphate end of the downstream probe. Thermostable DNA ligase enzymatically ligates the two bound probes, thus achieving a "doubling" of the mass of target DNA in the reaction. As the temperature cycling proceeds, a theoretical exponential amplification of the mass of target DNA in the original reaction occurs because the resultant ligated amplicons also serve as targets for probe hybridizations and ligations. In practice, amplification is less than exponential, but sufficient to achieve target DNA amplification and assessment by various methods.

Target-independent blunt-end ligation of the probes in the reaction can occur in LCR, which can cause unacceptably high levels of background signal, limiting the sensitivity and specificity of the method. This problem has been solved by use of gap LCR (G-LCR). In G-LCR, the probes are designed such that they cannot be ligated in a target-independent manner because they are not blunt ended. When G-LCR probes hybridize to target DNA, a gap of one or more bases exists between the probes hybridized to the same target strand. T his gap is then biochemically "filled" in the reaction, thus providing a suitable substrate for target-dependent ligation by DNA ligase.

Examples of Applications of LCR
1. *Chlamydia trachomatis* detection
2. *Neisseria gonorrhoeae* detection

Transcription-Mediated Amplification

Transcription-mediated amplification (TMA) uses RNA as the template, two primers, and two enzymes: reverse transcriptase (RT) and RNA polymerase. One primer contains a promoter sequence that binds RNA polymerase. As the amplification process begins, the promoter-containing primer hybridizes to the target RNA at a complementary site. Reverse transcriptase then synthesizes a cDNA copy of the target RNA template by extension of the 3′ end of the promoter-primer. The result is an RNA–DNA duplex. The RNA component is degraded by the RNase H activity inherent in RT. The other primer in the reaction mixture hybridizes to the DNA copy, and a new DNA strand is synthesized from the end of the primer by reverse transcriptase, generating a dsDNA molecule. The other enzyme in the mixture, RNA polymerase, binds the promoter sequence in the DNA template and initiates transcription. Each of the resulting newly synthesized RNA amplicons reenters the TMA cycle, serving as a template for a new round of replication and exponential expansion of the RNA target. Each DNA template can generate 10^2–10^3 copies of RNA amplicon, with the potential for 10^8- to 10^9-fold amplification in less than 1 h. The process is autocatalytic and isothermal. Acridinium ester-labeled DNA probes are added after completion of the reaction to initiate detection and quantitation based on chemiluminescence.

Examples of Applications of TMA
1. *Chlamydia trachomatis* detection [75]
2. *Neisseria gonorrhoeae* detection
3. HCV detection (qualitative) [76]

Strand Displacement Amplification

Strand displacement amplification (SDA) is an isothermal in vitro nucleic acid amplification technique [77]. Hemimodified DNA is polymerized by using three conventional dNTPs and one containing a 5′-[α-thio]triphosphate. The primer(s) is designed with an RE recognition site in the 5′

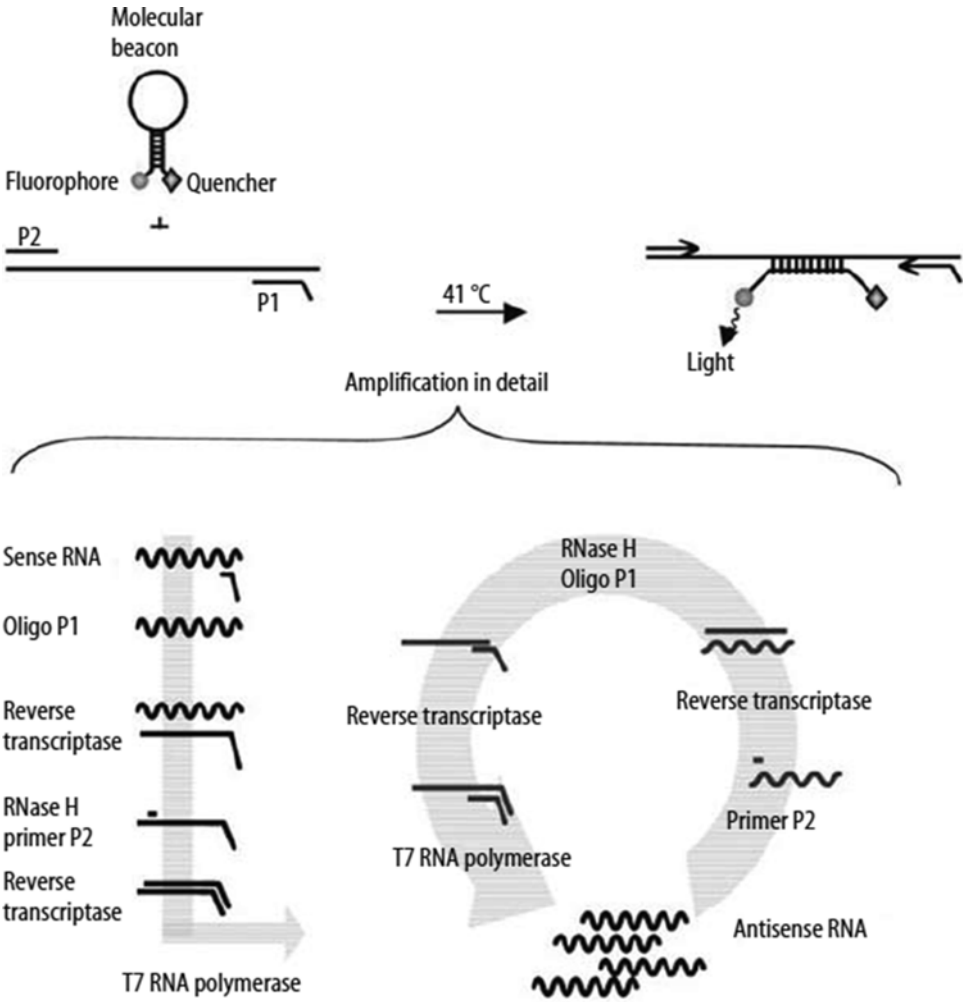

Figure 2.6 Schematic of NASBA Method. Two primers are used: P1 (antisense) and P2 (sense). The P1 overhang is a T7 RNA polymerase recognition sequence. A molecular beacon (with fluorophore and quencher, by definition) serving as probe with reporter molecules coupled to NASBA generates a real-time detection system.

overhang end. The recognition site is specific for an RE that can nick the unmodified DNA strand at a double-stranded hemiphosphorothioate recognition site, that is, when the newly synthesized strand incorporates the 5′-[α-thio]triphosphate nucleotide in the recognition sequence. DNA polymerase lacking 5′ to 3′ exonuclease activity is used to extend the 3′ end at the nick and displace the downstream strand. DNA nicking and polymerization with re-formation of the hemiphosphorothioate recognition site continuously cycle, generating complementary copies of the DNA target. Linear amplification (called target-generation SDA) occurs when a single primer is used. Exponential amplification (exponential SDA) is achieved by using two primers complementary to opposite DNA strands, with both primers containing RE recognition sites in the 5′ overhang end. Strand displacement amplification has been used in a microarray format [78].

Examples of Applications of SDA

1. *Chlamydia trachomatis* detection
2. *Neisseria gonorrhoeae* detection

Nucleic Acid Sequence-Based Amplification

Nucleic acid sequence-based amplification (NASBA) is an isothermal method for amplifying nucleic acids using two sequence-specific primers (P1, antisense, and P2, sense; see Fig. 2.6), and the coordinated activities of three enzymes: avian myeloblastosis virus reverse transcriptase (AMV-RT), RNase H, and T7 RNA polymerase [79]. A primer with a T7 RNA polymerase recognition sequence at its 5′ end is used by AMV-RT to transcribe cDNA from the RNA template. The RNA template is destroyed by RNase H. AMV-RT then extends the second primer to synthesize dsDNA. The T7 RNA polymerase binds to the recognition sequence in the dsDNA and synthesizes multiple antisense RNA transcripts, and the cycle is repeated. Generally, amplification is approximately 10^{12}-fold in 1–2 h.

In NASBA, nucleic acids serve as amplification templates only if they are single stranded and contain primer-binding regions. NASBA is performed isothermally at 41 °C, so RNA is preferentially amplified, because at this temperature genomic DNA remains double stranded and does not bind

primers, allowing RNA detection in the presence of genomic DNA without false-positive results. NASBA can be used for specific DNA amplification by introducing a DNA denaturation step before amplification.

Quantitative detection of target nucleic acids is achieved by use of an internal calibrator added during RNA isolation. The calibrator is included at a known concentration, is coamplified during the NASBA process, and is subsequently identified along with the target RNA. Quantification is based on the analysis of signals generated in real time (one color for calibrator and another for target).

Examples of Applications of NASBA
1. HIV quantitation
2. CMV detection

Amplicon Carryover Contamination

Vast numbers of target DNA copies are generated when PCR and other in vitro nucleic acid amplification methods are used. By contrast, signal amplification methods (see below) do not generate vast quantities of amplicon and do not create the potential for amplicon carryover contamination of the laboratory workspace. Amplicons from previous reactions inadvertently introduced into new amplification reactions for the same amplicon are suitable substrates for amplification. Clinical molecular laboratories therefore take precautions to prevent generation of false-positive results from amplicon carryover contamination.

Amplicon contamination and false-positive results are prevented by using physical barriers and chemical and UV light techniques to destroy amplicons or make them unsuitable for amplification. The physical barriers include performance of nucleic acid isolation, PCR setup, thermal cycling, and post-PCR analysis in separate areas of the laboratory (different rooms are ideal). Air flow is controlled such that air pressure is positive, that is, flows out of the room, in the isolation and PCR setup rooms, and is negative in the thermal cycling and post-PCR analysis rooms. Hoods are another way of providing physical separation of the different steps of amplification-based tests. Other physical separation techniques include the use of barrier pipette tips, frequent glove changes, designated laboratory coats for the pre- or post-PCR areas of the laboratory, and PCR tube openers or careful, slow opening of tubes and microtiter plates to prevent aerosolization of contents. Real-time PCR reduces the chances of amplicon contamination since the PCR product is detected and quantified without opening the real-time PCR reaction vessel.

Chemical techniques to prevent amplicon contamination include thorough cleansing with bleach of work areas and instruments before and after use. UV lights frequently are placed in hoods and work areas. UV light creates thymine dimers within amplicons, rendering the amplicons unsuitable as substrates for further amplification. The introduction of isopsoralens in PCR reactions allows DNA cross-linking of amplicons by UV light, also rendering them unsuitable for further amplification. Deoxyuridine may be used in lieu of thymidine in the reaction mixture. Use of deoxyuridine has minimal effect on amplification or product detection, but amplicons with uracil are substrates for uracil-N-glycosylase (UNG). UNG has no effect on DNA that contains only thymidine residues (new patient DNA in subsequent reactions), but digests the uracil-containing amplicons, allowing removal of contaminating amplicons before a new PCR proceeds [80]. So-called UNG sterilization is performed prior to PCR cycling to rid the reaction of any amplicon contaminants that may be present.

Signal Amplification Methods

Branched DNA Method

The branched DNA method (bDNA) [81, 82] begins with the addition of a lysis buffer to a small volume of serum, plasma, or culture supernatant containing cells or virus. The lysis reagent contains detergent to release target nucleic acid, inhibitors to prevent target degradation, and multiple capture extenders (oligonucleotides) that hybridize to specific areas of the target RNA or DNA. In the case of the HIV bDNA test, the capture extenders hybridize to multiple sequences in the viral *pol* gene. A common sequence on the capture extenders interacts with capture probes immobilized on the surface of 96-microwell plates, thereby anchoring the target nucleic acid to the plate.

Multiple target probes are added to each well that hybridize to different, conserved sequences on the target nucleic acid. In the HIV bDNA assay, more than 80 target probes covering a large portion of the 3,000 bp of the *pol* gene are used. The target probes contain key sequences that form the foundation for signal amplification, accomplished via the sequential addition of preamplifier (complementary to a region of the target probes), amplifier (complementary to a region of the preamplifier molecule), and alkaline-phosphatase-modified label probes (complementary to portions of the amplifier molecule).

Preamplifier, amplifier and label probes, as well as the preamplifier region of the binding probes, contain the non-natural nucleotides 5-methyl-2′-deoxyisocytidine (iso^{Me}C) and 2′-deoxyisoguanosine (isoG). These isomers of natural

bases can participate in Watson–Crick base pairing with each other but not with cytosine or guanine residues in probes or in natural DNA or RNA sequences. Incorporation of non-natural bases into the synthetic probe molecules increases the specificity of hybridization by decreasing nonspecific probe interactions, and increases the sensitivity of the assay since higher concentrations of probes can be used.

The series of probes results in formation of large hybridization complexes on the target RNA or DNA. For example, if each hybridization step was 100 % efficient in the HIV bDNA assay, each target molecule would be labeled with more than 10,000 alkaline phosphatase molecules. Addition of dioxetane substrate for the alkaline phosphatase results in steady-state chemiluminescent signal. The signal is proportional to the amount of target RNA or DNA present in the sample. The amount of target RNA or DNA in a specimen may be calculated by interpolation from a standard curve generated by signals produced from calibrators that contain known concentrations of the specific viral, bacterial, or cellular RNA or DNA.

Examples of Applications of bDNA method
1. HIV quantitation [83, 84]
2. Hepatitis B virus (HBV) quantitation [85–88]
3. HCV quantitation [89, 90]

Hybrid Capture

Hybrid capture (HC) is a signal amplification system based on antibody binding of RNA–DNA hybrids. The first step of HC is the hybridization of unlabeled RNA probes with denatured target DNA. The resulting RNA–DNA hybrids are captured to the surface of microplate wells by an immobilized antibody that recognizes RNA–DNA hybrids. A second anti-RNA–DNA monoclonal antibody conjugated to alkaline phosphatase is added next. Many secondary antibodies bind to each RNA–DNA hybrid. Dioxetane-based substrate is added, which is cleaved by the alkaline phosphatase, producing a chemiluminescent signal. The signal is measured using a microplate luminometer and is proportional to the amount of target DNA in the specimen [91]. The sensitivity of HC can be increased by using a precipitation buffer and high-speed centrifugation.

Examples of Applications of HC
1. Human papilloma virus detection [92]
2. CMV quantitation [93]
3. *Chlamydia trachomatis* and *Neisseria gonorrhoeae* detection [94]
4. HBV quantitation [95]

Fluorescence In Situ Hybridization

In fluorescence in situ hybridization (FISH), fluorescently tagged DNA or RNA probes are used to identify genomic sequences of interest [96, 97]. The major advantages of FISH are the utility for testing of FFPE tissue sections, correlation of probe hybridization with tissue morphology, and the increased resolution provided by FISH for identification of specific abnormalities when partnered with conventional cytogenetics. The number and location of the fluorescent signal(s) can identify chromosomal abnormalities including gene amplification, gene deletion or structural rearrangements such as translocations.

FISH is performed by sequential steps of denaturation, hybridization, and washing. Slides are prepared in the cytogenetic or histology laboratory. Fluorescently labeled probe(s) are then applied to the slide along with a nuclear counterstain and reagents to enhance denaturation and reduce background. The slides are sealed and incubated (usually overnight) in a humid environment at high temperature. These conditions denature the probe and patient DNA, allowing hybridization to occur between the probe and its complementary DNA sequence in the specimen without binding to nonspecific sites. Excess nonspecifically bound probe is washed away, and the pattern of fluorescence is observed with fluorescence microscopy. The fluorescent signal(s) can be enhanced by the use of a digital imaging system and computer software.

The specificity of FISH is largely based on probe selection. Ideally, the probe is complementary to the gene of interest; however, if the disease gene is unknown, satellite probes that identify a chromosomal region linked to the disease may be used. Labeled bacterial or yeast artificial chromosomes (BAC or YAC, respectively) are typically used as FISH probes, but short oligonucleotides also can be used with signal amplification techniques. Probes that identify individual whole chromosomes or chromosomal arms are often called "painting probes" due to the colorful patterns generated. Other probes that hybridize to a specific gene can be used for the detection of deletions or duplications and are called single-copy gene probes. Probes that hybridize to the α-satellite regions near centromeres are used in clinical cytogenetics to identify and count individual chromosomes. Probes that hybridize to the subtelomeric portions of chromosomes are used to identify cryptic telomeric abnormalities such as translocations.

Dual-color FISH (dFISH) employs two probes with different fluorescence wavelengths to identify structural chromosomal rearrangements. Each probe generates a characteristic color by itself (split signal) and a third color when the two probes are juxtaposed (fusion signal). A fusion

signal indicating chromosomal rearrangement is used to identify disease-causing mutations that predictably involve only two partner genes, for example, *BCR* and *ABL*. However, when a particular gene with multiple potential translocation partners is tested, it is more efficient to have both probes bind to the 5′ and 3′ ends of the particular gene such that the non-rearranged allele shows the fusion signal and the rearranged allele shows two split signals (so-called "break apart" probes). This is the technique used for *MLL* gene detection, which is rearranged with over 30 different partner genes in various types of leukemia.

Spectral karyotyping (SKY) and multiplex FISH (M-FISH) are modifications of conventional FISH that utilize multiple fluorochromes, specialized optics, and image analysis that can simultaneously identify all chromosomes [98]. Array-based comparative genomic hybridization (aCGH, described below), also called "copy number karyotyping," is a variation of FISH that detects relative gains or losses of the genome [99]. Array-based CGH is used to compare the ratios of patient specimen DNA, labeled with one fluorochrome, to that of control non-variant DNA, labeled with a different fluorochrome when hybridized to control chromosomes. Colorimetric probes are used in chromogenic in situ hybridization (CISH), which has the advantage that the signal does not fade with time or require fluorescence microscopy for analysis.

Examples of Applications of FISH

1. Detection of *BCR–ABL* in chronic myelogenous leukemia
2. Detection of *HER2* gene amplification for breast cancer diagnosis and prognosis
3. Detection of *MYCN* amplification in neuroblastoma [100]

DNA Arrays

In DNA arrays, the word "array" is jargon for an orderly distribution of molecules on solid supports ranging from nylon membranes to printed circuit boards to glass slides to silicon surfaces. There are macroscopic arrays, for example, reverse line blots on nylon membranes, and microarrays, for example, DNA chips. Synonyms for microarrays include gene chip, DNA chip, genome chip, biochip, gene array, DNA array, and DNA microarray. Forms of arrays currently utilized in the clinical molecular laboratory include (but are not limited to): aCGH, SNP arrays, and expression arrays.

Comparative Genomic Hybridization Arrays

First described by Kallioniemi in 1992, array-based comparative genomic hybridization (aCGH) is a technique developed for genome-wide characterization of copy number changes [101]. In its original form, differentially labeled test and reference genomic DNA were co-hybridized to normal metaphase chromosomes. The relative fluorescence ratio along the length of the chromosomes represented the relative DNA copy number. Array CGH (aCGH) is an advancement of CGH technology that uses clones, most commonly BACs or oligonucleotides, arrayed along a physical surface as the hybridization target, rather than metaphase chromosomes. The arrayed surfaces are commonly called microarrays, and the surface may hold millions of unique sequences as the hybridization targets. Much like the original CGH process, test and reference genomic DNAs are labeled with different fluorescent dyes, denatured, and then hybridized with the arrayed clones on the surface of the chip. The relative fluorescence ratios of the reference and test signals at the arrayed DNA elements provide a locus by locus measure of DNA copy number variation. In aCGH, the targets can be nonoverlapping clones evenly spaced across the genome, overlapping clones densely packed only in areas of interest, or a combination of the two approaches.

The uses of aCGH include gene discovery, cancer classification, and diagnostic assays. Analysis of DNA from mantle cell lymphomas by aCGH revealed homozygous deletions at 2q13 in 3 of the 29 samples leading to the discovery of the tumor suppressor gene BIM [102]. Since aCGH has a much higher resolution than conventional karyotyping, its use has led to the recognition of new microdeletion and microduplication syndromes such as that at 17q21.31 [103, 104]. Such discoveries are indicative of the role of aCGH in gene discovery and the development diagnostic tests.

The patterns of copy number variations detected by aCGH have led to diagnostically significant subgroup classifications of cancers. One example is that of differentiating diffuse large B-cell lymphoma types into subtypes based on copy number patterns [105]. The ABC subtype is genomically characterized by gain of 3q, 18q, and 19q and loss of 6q and 9p21, whereas the GCB subtype is genomically characterized by gain of 1q, 2p, 7q, and 12q. The subtypes have disparate biology and clinical outcomes.

As the number of unique targets on an array increases, so does the resolution. In 2005, a targeted array capable of detecting exonic level copy number variations was used to screen 162 exons of 5 genes [106]. In 2008, three groups showed the utility of CGH to detect exonic level copy number variation in the dystrophin gene [107–109]. The ability of custom-designed aCGH to detect exon copy number changes provides new opportunities for research and diagnosis.

Within the past decade, aCGH has emerged as a diagnostic tool in the clinical laboratory. Occasionally referred to as molecular karyotyping, the International Standard Cytogenomic Array Consortium recommended in 2010 genome-wide aCGH as the first-tier clinical diagnostic test for individuals with multiple congenital anomalies and

developmental delays [110]. As a result, targeted arrays are increasingly being used in the clinical laboratory for both cancer and congenital conditions.

SNP Arrays

The basic principle of the SNP array is the same as the DNA microarray. DNA is fluorescently labeled, hybridized with arrayed DNA probes, imaged, and interpreted. The difference is that for SNP arrays, the target probes are designed around single-nucleotide polymorphisms (SNPs) distributed throughout the genome. Signal intensity following hybridization is dependent on both the amount of target DNA as well as the affinity to the target. Thus, interrogating the SNP targets provides both copy number and SNP allelic information. The resolution of SNP arrays is limited by the distribution of SNPs in the human genome. The highest density SNP chips now have over four million SNP targets (Illumina Human Omnio5-Quad Bead Chip). Applications of SNP arrays include genome-wide association studies (GWAS), determination of heterozygosity, and molecular karyotyping of clinical samples.

Expression Arrays

Gene expression arrays are a powerful tool for comparing complex RNA populations. RNA is isolated from a test sample, converted to fluorescently labeled cDNA, and hybridized to a microarray. The fluorescence at each DNA element is then quantified, providing a measure of the abundance of the RNA molecules in the test sample. Detection limits are as low as 1–10 copies of mRNA per cell depending on the technology and cell type. As a means of candidate gene discovery, genome-wide expression microarrays with large densities are appropriate for analysis of differential patterns of gene expression between normal and diseased tissues while high-density, targeted expression arrays can identify novel exon skipping events and alternative splicing events [111, 112]. Expression arrays have gained acceptance in the clinical laboratory as a means of defining clinical subtypes of cancer [113]. Such arrays have demonstrated gene expression patterns which have been correlated with clinical outcomes and therapy response. Currently, five gene expression arrays are offered clinically for prognostic testing for breast cancer: Mammaprint, MapQuant Dx, OncotypeDx, PAM50 Breast Cancer Intrinsic Subtype Classifier, and Theros Breast Cancer Index.

Massively Parallel Sequencing

Massively parallel sequencing, also known as next-generation sequencing (NGS), has been widely adopted by the basic research community [114, 115]. Until recently, the use of NGS for clinical diagnostics was hindered by the relatively high cost of instruments, assay development and sequencing, as well as the bioinformatics infrastructure and expertise required for analysis. Since its introduction, advances in NGS platforms and sequencing chemistries have improved workflow, base qualities, read lengths, and total bases of sequence per experiment, all while reducing the cost per base sequenced [116]. Advances in enrichment and capture technologies have enabled the development of cost effective gene panels or exome sequencing for inherited disorders. NGS assays developed or under development include gene panels for autism, cardiomyopathies, X-linked mental retardation, the RAS pathway, among others, as well as the introduction of exome and genome sequencing in laboratories accredited by CMS under the Clinical Laboratory Improvement Act of 1988 (CLIA) [117–119]. The use of NGS for inherited disorders will supplant sequencing strategies such as Sanger sequencing or array-based genotyping when it is cost-effective and diagnostically viable. At this time bioinformatic analysis is still cumbersome and Sanger verification of putative variants of significance remains commonplace. However, improvements and standardization of bioinformatic analysis should ultimately reduce confirmatory Sanger verification and permit a high degree of certainty and reproducibility when detecting and reporting variants. (See Chap. 62 for a full discussion of NGS.)

Next Generation Sequencing Methods

The principles of NGS sequencing methodologies include sequencing by synthesis and sequencing by ligation. All platforms require the incorporation of adapters to target DNA and subsequent PCR-based generation of clonally amplified and clustered DNA. The two strategies primarily used for colony/cluster generation include in-solution emulsion PCR (emPCR) and surface bridge amplification. Once the DNA has been clonally enriched, sequencing chemistries differ depending upon platform [114, 115]. Illumina sequencing takes advantage of reversible dye-labeled terminators. Each dye terminator representing A, T, C, or G is sequentially introduced to the DNA molecule being synthesized and the surface of the flow cell is imaged. Once the complementary base has been incorporated into the extending DNA molecule, no further extension can occur until the dye is cleaved, resulting in an extendable deoxyribonucleotide triphosphate (dNTP), such that a single base is added during each cycle [114]. Technology from Roche relies upon the sequential introduction of the different dNTP bases, except the method of detection is pyrosequencing. The incorporation of a given base to the DNA being synthesized results in the release of a pyrophosphate and subsequent luciferase luminescence [120]. Since the reaction uses dNTP, single base extension does not always result, as homopolymer extension may occur during a single cycle. Technology from Life Technologies does not rely on DNA polymerase exten-

sion, rather sequencing by ligation is used. The process involves the use of multiple primers offset by one base at the 3′ end of the adapter. Fluorescently labeled interrogation probes representing two adjacent nucleotides are ligated to the primer. Once the ligation reaction has occurred and imaging is completed, the dye is cleaved off the interrogation probe, and a subsequent ligation can be performed [121]. Other methods of polymerase-mediated NGS include measuring the charge associated with nucleotide extension and the visual detection of dye-labeled nucleotide extension.

High throughput NGS platforms have made sequencing of an individual human genome in a reasonable timeframe a reality. Genome sequencing for clinical purposes is not commonplace at this time and is pursued mostly for gene discovery. Paradoxically genome sequencing is the simplest application of NGS and the most bioinformatically intensive. Because of the ease of set up, lack of need for specific assay design, and the costs associated with target-specific enrichment, genome sequencing will ultimately be performed for clinical purposes in the future [122]. However, a number of bioinformatic, regulatory, and ethical issues will need to be addressed before genome sequencing for clinical purposes will be commonplace.

Exome sequencing is a method that holds significant promise for clinical molecular laboratories. Exome sequencing can be used for gene discovery and in certain instances can be used for gene panel or pathway analysis. Because the human exome is roughly 1.5 % of the human genome, bioinformatic analysis is not as daunting as genome analysis, yielding roughly 30,000–50,000 variants [123]. Exomes from different patients can be differentially labeled using unique short sequence tags, multiplexed and sequenced in the same sequencing run, which reduces sequencing costs.

While high-throughput NGS platforms can be used to sequence genomes or multiple exomes in a single test, these instruments may not always be optimal for NGS of smaller gene panels. The use of barcodes or indexes enables pooling of multiple samples to leverage sequencing throughput, but the time required for sequencing can take days. Recently, a number of platforms have been introduced with lower throughput and faster turnaround times that facilitate the sequencing of smaller gene panels or exomes. This advancement has permitted the introduction of time-sensitive NGS-based clinical tests that are less expensive than Sanger sequencing tests, with a similar turnaround time.

Bioinformatics and Data Analysis

A typical NGS test may yield from 1 to 600 gigabytes (Gb) of sequence data. Conventional analysis pipelines and software programs developed for Sanger sequencing are totally inadequate for analysis of the large volumes of NGS data. A number of commercial and freeware software applications are available that align and perform variant calling. The steps of data analysis involve assessing the quality of the sequencing data, aligning the sequence fastq files to a reference sequence, determining the differences between the reference sequence and the patient's sequence, and collecting the data [124]. These sequence variants are bioinformatically processed to ensure the quality and accuracy of the alignment. Once the data have been processed and filtered, annotation of the variants is performed, and subsequent post-annotation filtering allows for the selection of a subset of variants of interest [116, 123, 125]. The process from raw sequence data to final variant reporting is bioinformatically intensive.

Development of bioinformatics and statistical workflows for NGS are not universal; different purposes for NGS testing require different metrics for alignment and data reporting. Public and private databases are used for annotation purposes to help determine what variants should be examined further. It is important that internal databases be developed that track areas of reproducible misalignments, miscalls, and variant frequencies to supplement public, non-clinical, and sometimes inaccurate, research-derived databases. Because of the vast amount of data associated with one test, it is not feasible to manually verify data for each variant. Tests may yield from a few to over three million variants. A paradigm shift is required for clinical laboratorians and clinicians who are accustomed to manually analyzing all variants that are reported. While graphical user interfaces are available to examine variants (should one wish to do so) clinical laboratorians and clinicians will have to rely upon the tools and pipelines developed by bioinformaticians. It is extremely important that all stakeholders are involved in pipeline development and validation to ensure that everyone involved with test interpretation understands the process and that the data reporting is accurate and useful.

Clinical Applications of Next-Generation Sequencing

NGS technologies permit sequencing of entire individual patient genomes. As the cost of NGS decreases, genome sequencing is likely to become increasingly popular as a strategy for identifying the genetic basis of diseases as it offers the potential of finding mutations in the noncoding regions, such as regulatory elements or noncoding RNAs, and the ability to detect large gene rearrangements [126, 127]. However, at present, the expense of NGS reagents and the high demand in bioinformatics makes the targeting of a subset of genome more appealing at the present time. The subset of a genome often focuses on a set of genes at different chromosomal loci which are important in a specific disease [119]. Two examples are provided by an X-Linked intellectual disability 92-gene NGS panel and a cardiomyopathy panel of 46 genes [117, 118]. This use of NGS is the

logical extension of Sanger sequencing of a panel of selected genes associated with a particular phenotype.

Exome sequencing uses a targeted selection approach to capture the majority of the protein-coding exons of genes, microRNAs and noncoding RNAs in the human genome, followed by NGS sequencing. Because the exome represents only approximately 1.5 % of the genome and contains 85 % of known disease causing mutations, exome sequencing is considered the most cost-effective method for identifying the causative mutation in rare diseases [126]. However, with a massive amount of variants detected by exome sequencing, data analysis is complicated, especially when putative causative mutations such as missense mutations are identified. Family history and pedigree segregation studies are useful to determine the causality of the mutations [128].

Conclusion

The molecular methods used in the clinical laboratory will continue to evolve and develop as researchers and instrument manufacturers develop new methods that improve on the sensitivity, specificity, cost and speed of current methods. Drivers for adoption of new technologies in the clinical laboratory include but are not limited to reduced technologist hands-on time, reduced cost, shortened turnaround time, interfacing of results to information systems to reduce human transcription errors, and improvements in the detection of analytes with clinical significance. Molecular pathology will continue to be at the leading edge of methods development, resulting in a constant stream of new test and method validations with all the required steps new tests require from a regulatory compliance perspective. While this is challenging for the molecular pathology laboratory leadership and staff, this innovation also is one of the exciting aspects of molecular pathology practice.

Genetic Counseling

3

Christine E. Miller

Abstract

Genetic counseling is a relatively new profession that began four decades ago. Genetic counselors are master level-trained individuals who have specialized knowledge in medical genetics and counseling. About 83 % work directly with patients on a daily basis, while approximately 17 % work in laboratories or other non-patient contact areas. Genetic counselors are trained to be nondirective and advocate for patient autonomy and informed consent. The genetic counseling process involves drawing a family medical pedigree, reviewing medical records, performing risk assessments, explaining medical and scientific information, discussing disease management, treatment and surveillance options, reviewing testing options, and facilitating the decision-making process. Genetic counselors believe that patients will make the best choice for themselves if their decision is made in the context of their belief systems and past experiences. Genetic counseling positions and subspecialties are rapidly evolving to meet patients' needs. Given the speed of gene discovery, genetic counselors must work to keep abreast of knowledge of specific diseases, innovative testing methods, and new disease treatments and surveillance options.

Genetic Counseling: The Discipline and the Provider

Genetic counseling is a relatively new healthcare profession rooted in a combination of medical genetics and counseling theory. The first program to train master-level genetic counselors was Sarah Lawrence College (New York) graduating its first class of eight students in 1971 [1]. Due to the increasing demand for genetic counseling services in the era of genomic medicine, by 2012, there were a total of 31 master-level genetic counseling training programs in the USA and over 2,500 practicing genetic counselors [2]. The American Board of Genetic Counseling (ABGC) provides accreditation for genetic counseling programs that meet specific educational criteria and it administers a national certification examination for genetic counselors. Thirteen states now regulate the profession of genetic counseling requiring genetic counselors to obtain licensure prior to providing this service to citizens of their state. Of the genetic counselors who provide direct patient counseling, approximately 32 % are employed in prenatal genetics, 22 % in cancer genetics, and 14 % in pediatric genetic settings. Thirty-two percent of genetic counselors have expanded into other subspecialties, including artificial reproductive technology (ART), neurology,

Table 3.1 Process of genetic counseling

Precounseling assessment	Construct medical pedigree, review pertinent medical records, and perform clinical assessment
Risk assessment	Calculate risk for occurrence using medical pedigree, test results, medical literature, and Bayesian analysis
Counsel patient, couple, or family	Explain medical and scientific information, discuss disease management, treatment and surveillance options, review various testing options, facilitate decision-making process and order appropriate genetic test(s)
Follow up	Summarize discussion in written form for referring healthcare provider and consultant(s), share information about support groups or patient-friendly information on the Internet, provide referrals to psychotherapists or family therapists, as necessary

psychiatry, cardiology, ophthalmology, and genomic and laboratory medicine. Approximately 9 % of genetic counselors work in diagnostic laboratories providing education and support to the patients and physicians who request help with genetic test selection and result interpretation [3]. Genetic counseling is a profession that actively responds to the changing landscape of medicine and matches the trends and needs in the healthcare marketplace.

Physicians with a subspecialty in genetics also provide genetic counseling services. Physician geneticists have a background in various disciplines such as obstetrics, pediatrics, and internal medicine have obtained specialty training in medical genetics and are board certified by the American Board of Medical Genetics (ABMG). As genomic medicine evolves into mainstream healthcare, all providers will need some genetic training to be able to order appropriate tests for their patients and understand the clinical significance of molecular and genomic test results.

Genetic counseling is a process whereby a genetic counselor (1) elicits a family history to construct a medical family pedigree, (2) obtains necessary records to confirm reported diagnoses, (3) determines the risk for occurrence or recurrence of a specific disorder(s), (4) communicates the natural history of the disorder(s) and risk for recurrence, and (5) explains screening, testing, or treatment options to the patient/family in a nondirective manner helping them make the best possible adjustment to the condition(s). Table 3.1 summarizes the key stages of the genetic counseling process. In 2007, the National Society of Genetic Counseling (NSGC) released an expanded scope of practice which included genetic counselors' ability to order genetic tests and perform clinical assessments in accordance with state and federal regulations [4]. The scope of practice will need continual reassessment to meet patients' needs in this rapidly evolving profession.

Clinical Genetic Counseling

Prenatal Setting

Women are referred for prenatal (and less commonly preconception) genetic counseling and prenatal diagnosis for numerous reasons including advanced maternal age (>34 years), abnormal screening test results, abnormal ultrasound findings, family history of an inherited condition, consanguinity, teratogen exposure, and multiple miscarriages or stillbirths. Although all women are at risk to have a child with a chromosome abnormality, this risk increases with maternal age. Thus, advanced maternal age remains one of the most common reasons a woman is referred for prenatal genetic counseling. In 2007, the American College of Obstetrics and Gynecology (ACOG) recommended all women be offered first- and second-trimester maternal serum screening (MSS) for Down syndrome, trisomy 18, and open neural tube defects [5]. ACOG stated that women of all ages should have the option of invasive diagnostic testing. This is a large departure from when prenatal diagnosis was mainly offered to women 35 years and older in the 1970s and early 1980s.

Amniocentesis remains the most common prenatal diagnostic technique. The procedure involves guiding a needle through the abdominal wall into the uterus and withdrawing 20 cc of amniotic fluid, which contains fetal cells, for cytogenetic and molecular analysis. Optimally, amniocentesis is performed under ultrasound guidance between 14 and 18 weeks of gestation, but can be performed safely throughout the remainder of pregnancy as well. It has been reported to be associated with a fetal loss rate of 1 in 770 by experienced practitioners [6]. Another diagnostic procedure, called chorionic villus sampling (CVS), involves removal of a small amount of chorionic villi from the placenta, either transcervically or transabdominally, to obtain fetal cells for testing. Although the miscarriage risk associated with CVS is greater than that of amniocentesis at most centers, the advantage is that CVS can be performed in the first trimester of pregnancy at 10–13 weeks of gestation [7]. A new screening test for Down syndrome, performed by isolating cell-free fetal DNA in the maternal circulation, may significantly reduce the number of invasive diagnostic procedures performed. Early publications indicate the sensitivity of this maternal blood test for Down syndrome is >98 % with a specificity of 99.8 %, which compares highly favorably to traditional maternal serum screening for Down syndrome with a sensitivity of 60–93 % and specificity of 1–5 % [8].

Given the increasing sophistication of ultrasonography equipment and its routine use in pregnancy, most fetal anomalies such as neural tube defects, holoprosencephaly, abdominal wall defects, or severe cardiac abnormalities are detected prenatally and rarely present unexpectedly in the

Table 3.2 Disorders recommended for routine screening in specific ethnic groups

Ethnicity	Disease	Carrier frequency	Recommended by
African, Mediterranean, Southeast Asian, Middle Eastern	Alpha thalassemia	1 in 3 Africans	ACOG
African, Mediterranean, Middle Eastern, Asian Indian	Sickle cell anemia	1 in 12 African Americans	ACOG
Northern African, Southern European, Asian Indian	Beta thalassemia	1 in 12 Southern Europeans	ACOG
Ashkenazi Jewish	Tay-Sachs	1 in 30	ACMG, ACOG
	Canavan	1 in 50	ACMG, ACOG
	Familial dysautonomia	1 in 32	ACMG, ACOG
	Bloom syndrome	1 in 100	ACMG
	Fanconi anemia (type C)	1 in 89	ACMG
	Gaucher	1 in 15	ACMG
	Niemann-Pick (type A)	1 in 90	ACMG
	Mucolipidosis IV	1 in 127	ACMG
All ethnicities	Cystic fibrosis	1 in 25 Caucasians	ACMG, ACOG
All ethnicities	Spinal muscular atrophy	1 in 35 Caucasians	ACMG

delivery room. Thus, prenatal genetic counselors often find themselves providing crisis counseling for individuals who have just been informed about a significant birth defect following a "routine ultrasound examination to confirm the pregnancy's dates." In fetal abnormality cases, when CVS or amniocentesis is performed, consideration is given to ordering comparative genomic hybridization (CGH) instead of just chromosome analysis since CGH can detect relatively small regions of deleted or duplicated genetic material compared with standard chromosome analysis [9].

Screening tests for single-gene disorders are recommended for expectant individuals or those planning a pregnancy in "high-risk ethnic groups" (see Table 3.2). The specific criteria used to select tests for population screening is based on a number of factors such as incidence in the population to be screened, medical knowledge of the disorder, and sensitivity and specificity of testing methods. In 2001, screening for cystic fibrosis (CF) was recommended but was controversial for the following three reasons: (1) the majority of expectant individuals would need to be offered screening; (2) the screening panel would not detect all carriers and would have variable detection rates depending on ethnicity; and (3) insufficient numbers of genetic counselors were available to provide informed consent [10]. Nevertheless, cystic fibrosis screening was successfully implemented by obstetricians and other primary care providers and couples who screened positive were referred to a genetic counselor.

In 2011, in dramatic divergence from ACOG and the American College of Medical Genetics (ACMG) testing guidelines, several direct to consumer marketing companies began promoting carrier screening tests for expectant couples for hundreds of exceedingly rare conditions, many of which were unfamiliar for most healthcare providers. Thus, providing proper informed consent for such prenatal panels was and remains difficult, at best. Furthermore, when a woman learns she is a carrier for a rare condition, a gene sequencing test may need to be offered to her reproductive partner since many of the mutations targeted on such panels represent a small percentage of the causative mutations for the specific condition. This may present two additional problems: (1) there may not be a clinical laboratory specifically performing sequence analysis for the rare genetic disorder in question, and (2) even if one succeeds in finding such a laboratory to perform sequencing, the reproductive partner may be found to have a variant of uncertain significance. This uncertainty may lead to confusion and high anxiety for a couple who thought that they were undergoing routine prenatal screening and would receive clear and clinically interpretable results.

Preimplantation genetic diagnosis (PGD) offers an alternative to prenatal testing for couples who are at risk of having a child with a genetic condition. Through in vitro fertilization (IVF), a single cell is removed from each embryo, usually on day 3 at the 8-cell stage, and tested for the specific genetic condition or familial mutation; then, the unaffected embryos are transferred back to the mother. PGD was first successfully performed in 1990 and is presently being offered for many monogenic disorders and chromosome abnormalities [11]. However, PGD is not yet routine as there are still many obstacles in the process related to the highly technical nature of the procedures and the difficulties in performing cytogenetic or molecular analysis on a single cell. The rate of pregnancy among patients undergoing IVF and PGD varies, but rarely exceeds about one third. Genetic counseling for couples considering PGD is imperative. Couples need to understand the risks and benefits of these

complex procedures and the likelihood of a successful pregnancy. Couples need to weigh these factors against those of standard prenatal diagnosis procedures. IVF and PGD are very expensive, approximately $15,000 per cycle, and are not covered by most insurance providers.

Prenatal genetic counselors explain the risks for various genetic conditions, present patients with prenatal diagnostic testing choices, and discuss management and outcome options. They help patients make informed and autonomous choices by encouraging exploration of personal, spiritual, and cultural beliefs that affect decision making [12, 13]. Genetic counselors support patients who choose to continue affected pregnancies by arranging appointments with pediatric specialists, fetal and pediatric surgeons, and neonatal intensive care physicians to help the family prepare for the delivery and offer to arrange contact with other families who have had a baby with the same condition. Genetic counselors also support patients who choose to terminate affected pregnancies by making the necessary referrals for the procedure, encouraging autopsy when the diagnosis is still in question, and providing referrals to support groups for individuals who have had a therapeutic abortion.

Pediatric and Adult Setting

Genetic conditions can occur with unique symptoms at all stages of life, from birth defects in a newborn to cognitive changes in an older adult. When a baby is born with birth defects or an individual at any age develops symptoms, the first step in clinical care is establishing an accurate diagnosis. Often medical geneticists are consulted by physicians caring for babies born with birth defects or other clinical symptoms to determine if there is one unifying syndrome or diagnosis that provides an explanation. Providing a diagnosis is helpful as it enables one to predict if the condition is associated with other problems that may develop over time, such as learning problems, behavioral disorders, cancers, or other medical conditions that are not present at the time of the examination. This may allow for early intervention, therapy and medical screening to reduce the impact of, or risk associated with, the conditions. Early diagnosis also may provide an explanation for likely causes of the condition and, therefore, potential recurrence risk for siblings or offspring of the affected individual. Up until 2010, chromosome analysis was a first line test in the evaluation of developmental disabilities, autism or multiple congenital anomalies. CGH should be the initial test for these conditions because the detection of causative deletions or duplications at 15–20 % is much higher than with chromosome analysis (3 %) [14].

Some individuals are affected with what appears to be a genetic condition, yet even after undergoing many tests, the diagnosis remains elusive. Exome sequencing has been conducted for such individuals on a research basis with a 25 % success rate in determining a diagnosis [15]. In 2012, exome sequencing also began to be offered on a clinical basis. Usually, in addition to sequencing the exome of the affected child, the exomes of the parents also are sequenced to determine if the child has de novo mutations or recessive mutations in the same gene from each parent. Analyzing such a large amount of data is very complex and requires an experienced bioinformatics specialist. Genetic counselors often are involved with developing the consent forms for exome sequencing as well as consenting the family members participating in exome sequencing research or clinical testing. Genetic counseling for exome sequencing is very time consuming because the genetic counselor, the patient, and their family members must consider what types of genetic variant information they are interested in learning about and are prepared to hear. For instance, in addition to the variants identified that may be causative for the disease in question, mutations predisposing to other conditions such as cancer, heart disease, and dementia may be detected.

When newborn screening for phenylketonuria was first available in the mid-1960s, the criteria developed to determine if a disorder should be considered for newborn screening included the following: (1) an acceptable treatment protocol is in place that changes the outcome for patients diagnosed early, (2) the condition's natural history is understood, (3) there is an understanding about who will require treatment, and (4) testing is reliable for both affected and unaffected patients and is acceptable to the public [16]. Many states screened for only a few conditions up until the late 1990s when tandem mass spectrometry (MSMS) technology was developed for newborn screening; then the number of conditions screened expanded dramatically. Now, most states screen for at least the 29 rare, mostly metabolic, conditions recommended by ACMG in 2005 [17]. Many of the new conditions being screened do not satisfy all of the criteria originally used for inclusion in newborn screening protocols. Genetic counselors often coordinate, or are heavily involved with, state newborn screening programs and provide valuable information to pediatricians or other healthcare providers caring for newborns who have a positive screen for one or more of these rare disorders.

The increasing access to and availability of genetic testing has improved the diagnostic capabilities for many disorders. Diagnosis of a genetic condition brings emotional, social, and financial burden for the patient and the family. Unlike many other areas of medicine, genetics has medical implications beyond the patient, extending to the entire family. Whether a diagnosis is made during the neonatal, pediatric, or adult years, the importance of genetic counseling remains. The goals of genetic counseling for the patient and

Table 3.3 Elements of pretest predictive genetic counseling [20]

Obtain family history and confirm diagnoses
Review natural history and inheritance of condition, as well as a priori risk
Discuss the benefits, limitations, and risks of testing, and the confidentiality of test results
Discuss motives for testing, anticipated result, psychosocial preparedness, and support system
Present alternatives to testing and assure that testing is voluntary and informed consent is provided

the family following the diagnosis of a genetic condition include: education about the natural history of the condition and medical implications; explanation of the genetic cause, mechanism of inheritance, and recurrence risks; identification of appropriate social and emotional resources; attentiveness to the patient's and the family's reactions to the diagnosis and their coping strategies; promotion of the best possible emotional adjustment for the patient and family; and facilitation of access to necessary medical and social services [18].

Genetic testing for diagnostic purposes is occurring more frequently without pretest counseling when ordered by a primary care provider or a specialist; however, once a positive test result is disclosed, patients are referred for genetic counseling to assist them with understanding the meaning and implications of the test result.

Predictive genetic testing can inform individuals, prior to the onset of symptoms, that they will develop or are at increased risk to develop a hereditary disorder. Experience with predictive genetic testing for adult-onset conditions such as Huntington disease and hereditary cancer syndromes has led to the development and strong endorsement of a multidisciplinary approach to predictive genetic testing that includes pretest and posttest genetic counseling protocols [19, 20]. This approach allows the patient to explore his or her motives for testing, expectations for testing, the risks and benefits of testing, and coping strategies prior to testing. Use of this recommended counseling process is especially important when no treatment or medical intervention is available for the disorder. Most predictive testing protocols require at least two pretest counseling visits (see Table 3.3) to allow the patient time to consider the benefits and risks of testing, develop a support network during the testing process, and ensure voluntary participation in testing. Experiences with Huntington disease testing have shown that patients are at risk for adverse outcomes after the disclosure of predictive genetic test results, whether the result is positive or negative [21]. Result disclosure should be done in person by a genetic counselor or healthcare professional knowledgeable about the disorder and the implications of the test result. Also, a support person for the patient should be present at the pre- and posttest counseling visits.

Cancer Setting

Cancer genetic counseling, which developed in the early 1990s, is now the second most common area of specialization for master level-trained genetic counselors. Genetic testing for inherited cancer syndromes can be useful for diagnosis and medical management for individuals with a tumor or cancer symptoms. For instance, women with breast cancer who have an inherited mutation in *BRCA1*, a tumor-suppressor gene, may be counseled by their oncologist to consider mastectomy and chemotherapy instead of lumpectomy and radiation. Furthermore, other at-risk family members could have targeted testing for the familial mutation and those who test positive may consider undergoing risk-reducing prophylactic mastectomy and oophorectomy. Chapters 22–30 highlight the various issues related to molecular testing for hereditary cancer syndromes, which include variable clinical utility, complex medical management options, dilemmas with molecular testing approaches, and testing in the research setting or during early transition of a test to the clinical laboratory. The potential risks and benefits associated with testing vary based on the specific hereditary cancer syndrome, as well as the patient and family history. The American Society of Clinical Oncology recommends pre- and posttest counseling for individuals referred for cancer genetic testing [22]. The genetic counselor discusses the details of the genetic testing (detection rate, clinical utility, recurrence risk, etc.), as well as early detection and prevention options for individuals with a positive test result. Often, hereditary cancer syndromes increase an individual's risk for cancer in multiple organ systems, which makes medical management, screening, and early detection more complex. For example, some individuals at risk for von Hippel-Lindau syndrome need at least annual screening for brain and spine hemangioblastomas, retinal angiomas, pheochromocytoma, renal cell carcinoma, and other tumors.

Informed Consent

In the healthcare setting, the process of informed consent is a protection for patients. Prior to diagnostic testing or therapeutic intervention, the provider explains the procedure to the patient, along with the risks, benefits, and alternatives, so that the patient can voluntarily make informed decisions about diagnostic and treatment options [23]. Depending on state law and laboratory standards, variation in informed consent requirements for genetic testing exist. Position statements and guidelines for informed consent for genetic testing are available for a growing number of conditions or groups of conditions. The majority of guidelines address issues related to predictive genetic testing. The NSGC recommends

Table 3.4 Key elements of informed consent for genetic testing

Discussion of purpose of the test and risks of procedures involved in obtaining a sample for testing
Clinical utility of the test and interpretation of all possible test results (positive, negative, uncertain, test failure)
Discussion of risks, benefits, and limitations of testing (including psychosocial, cultural, and financial)
Presentation of alternatives to genetic testing
Description of the procedure for communication of results
Confidentiality of test results
Voluntary nature of informed consent

obtaining informed consent prior to predictive genetic testing for adult-onset conditions. Guidelines for informed consent prior to genetic testing stress that this is more than having a patient read and sign a piece of paper. Informed consent should be a communication process that fosters autonomous and informed decision making by the patient [24, 25]. Presentation of the key elements of informed consent (Table 3.4) needs to be tailored to the individual patient's learning style, educational and cultural background, and family situation to optimize the usefulness of informed consent for the patient and their family. This is a time-intensive process that cannot be done by primary care physicians during a routine office visit. The informed consent process also applies to collection of tissue or body fluids for genetic or other research purposes [26].

Genetic Testing for Children and Adolescents

The benefits and harms of genetic testing need to be carefully evaluated before proceeding with testing in children who may not be able to appreciate the implications of such results. When genetic testing directly impacts medical management or treatment for a child with symptoms or clinical features of a condition, the benefits of testing are clear and the well-being of the child is being promoted. However, when genetic testing does not impact medical management, or the condition in question will occur in adulthood, the implications of testing become more complex and the benefits become less clear. The ACMG and the American Society of Human Genetics wrote "Points to Consider: Ethical, Legal and Psychosocial Implications of Genetic Testing in Children and Adolescents" [27]. The recommendations are the following:

1. Timely medical benefit to the child should be the primary justification for genetic testing.
2. Substantial psychological benefits to the competent adolescent also may be a justification for genetic testing.
3. If the medical or psychological benefits of a genetic test will not accrue until adulthood, as in the case of carrier status or adult-onset diseases, genetic testing should be deferred.
4. If the balance of benefits and harms is uncertain, the provider should respect the decision of the competent adolescent and his or her family.
5. Testing should be discouraged when the provider determines that the potential harms of genetic testing in children and adolescents outweigh the potential benefits.

Education and counseling for the parents and the child, at an appropriate level, should be provided. The benefits and harms related to medical issues, psychosocial issues, and reproductive issues need to be presented and discussed. Children and certainly adolescents have decision-making capacity. The child's competence and wishes should be assessed prior to genetic testing and carefully balanced with parental authority. This is especially true for adolescents who can articulate a specific opinion that differs from that of his or her parents [27]. Assent from the child or adolescent should be obtained in addition to informed consent from the parents.

Legal Protection

In the past decade, there was great concern about the risk for health insurance discrimination related to testing for predisposition to various familial cancer syndromes and adult onset conditions such as Huntington disease. With the passage of the Genetic Information Nondiscrimination Act (GINA) in 2008, a federal law that protects Americans from being treated unfairly because of differences in their DNA that may affect their health, this concern has largely been put to rest as GINA provides protection against health insurance and employment discrimination. Even so, GINA does not provide protection against life insurance, disability insurance, or long-term care insurance discrimination [28]. Furthermore, GINA does not provide protection for federal employees or those who are employed by companies with less than 15 individuals. Genetic counselors need to explore whether their patients are protected from health and employment discrimination and incorporate this into the discussion of risks and benefits of genetic testing.

Other Roles for Genetic Counselors

Research Testing

Genetic counseling can be valuable to individuals who are participating in research genetic testing. Research participants may have difficulty understanding the purpose, risks,

and benefits of the study. In addition, many participants have expectations of receiving research testing results and do not appreciate the limitations of reporting results in the research setting. Therefore, consent forms created by genetic counselors in language understandable to the general public are a critical component of genetic research. Disclosure of genetic research results to participants is optimally done by a professional able to provide genetic counseling. For many rare conditions, clinical testing is not available; therefore, research testing is the only option for families. When genetic testing is transitioning from research to the clinical setting, a genetic counselor can be a liaison between the participant and the laboratory and be responsible for informed consent and disclosure of results.

Genetic Counselors Working in the Laboratory

Genetic tests differ in many ways from other laboratory tests. One difference is the necessity for the laboratory to receive clinical information, including the patient's symptoms and family history, for proper interpretation of test results. Genetic counselors understand the clinical information needed by molecular laboratories to interpret specific genetic tests. Additionally, genetic counselors can review the clinical information provided to determine whether the test ordered is the most appropriate and cost-effective test given the patient's symptoms and family history. One study of genetic counselors who reviewed thousands of genetic test orders for a laboratory over a 10-month period revealed that greater than one-third of complex genetic tests were misordered [29]. Oftentimes, other healthcare providers do not understand the importance of obtaining medical records documenting a familial condition. For example, if a patient requests testing for spinocerebellar ataxia (SCA) because this condition has been diagnosed in a sibling, the specific type of SCA must be determined, as there are currently 17 causative genes and commercial testing is available for only about 9 of the 17 genes. If the individual requesting the test does not know the specific SCA type, one could order testing for all of the commercially available types; however, a negative result would not eliminate the individual's risk because the proband may have one of the SCAs not included in the testing. A genetic counselor can work with an at-risk individual to obtain the necessary family history information and documentation so that the most accurate and efficient approach to testing can be used and the interpretation of the results will be more informative. An accurate and comprehensive family history is a valuable tool in a diagnostic evaluation as it can be used as a medical screening tool, establish a pattern of inheritance, identify individuals at risk, and determine strategies for genetic testing.

Understanding the clinical validity of a genetic test result can be difficult for both healthcare providers and patients. However, the sensitivity and specificity of the test method used by the testing laboratory are paramount to the interpretation of the results [12]. Many molecular, biochemical, and cytogenetic laboratories have genetic counselors on staff who can be a useful resource for other healthcare providers and the public. They are able to provide the necessary education and information to determine the appropriate approach to genetic testing, facilitate the details of ordering a test, and help interpret and communicate test results (Table 3.5).

Table 3.5 Genetic counselors working in the laboratory

Obtain test-specific clinical information and family history to ensure that the most appropriate test is performed
Facilitate or document the informed consent process to assure that the patient's autonomy is protected
Assist referring physicians and patients with understanding the test results and implications for the patient and family members
Facilitate collection of appropriate family samples for clarifying the significance of variants of uncertain significance

Summary

The goals of genetic counseling are to address the informational and emotional needs of patients and their families [13]. For example, the explanation of risks and benefits associated with a genetic test that is tailored to a patient's educational needs as well as their family, social, and cultural background facilitates informed decision making by promoting patient autonomy and informed consent. The key goals of genetic counseling for most patient encounters include the following:

- Obtain and interpret family medical history information.
- Educate patients so that they understand the medical and genetic information (inheritance and recurrence risks) needed to make health-management decisions and understand their condition.
- Promote informed decision making and informed consent.
- Be aware of nontechnical factors (social, cultural, financial, and emotional factors) that influence patients in the decision-making process.
- Foster genetic competence in patients and families.
- Identify social and professional resources for patients.

As genetic testing expands and is incorporated into mainstream healthcare, especially for disease prevention and treatment (pharmacogenetics) for common disorders, pre- and posttest genetic counseling for every test will not be feasible. However, genetic counseling services need to be available to assist healthcare providers and patients with education and support facilitating safety in genetic testing.

Pedigree Analysis and Risk Assessment

4

Patti Krautscheid and Danielle LaGrave

Abstract

The genetic family history, or pedigree, is a valuable tool for assessment of disease risk. Use of standardized symbols and nomenclature in pedigrees is recommended to ensure accurate communication of information to end users. There are common questions which should always be asked during collection of a family health history; however, questioning is often tailored for the condition under evaluation. Pedigrees may also help assess disease transmission patterns in the family which may be Mendelian (autosomal recessive, autosomal dominant, X-linked recessive, X-linked dominant, Y-linked), chromosomal, mitochondrial, or multifactorial. When atypical patterns of inheritance are seen, consideration should be given to other factors which can influence transmission including, imprinting, uniparental disomy, unstable DNA, gene-environment interactions, mosaicism, and synergistic heterozygosity. Recognition of the mode of inheritance within a family can be useful for estimating disease risk for family members or offspring. Risk assessment also may be confounded by logistical factors, such as family dynamics and limited information, or processes such as variable expression of disease, penetrance, heterogeneity, mosaicism, lyonization, or consanguinity. Many different laboratory methods are used for direct detection of genetic mutations associated with disease. When direct mutation analysis is not feasible, gene discovery or assessing risk for disease may be facilitated by linkage analysis or genome/exome sequencing. Bayesian analysis is a statistical construct that allows for the combination of incremental contributors to risk to determine an individual's risk of developing or transmitting a disorder.

The Genetic Family History

The personal and family medical pedigree has evolved from its earliest ancestors in the fifteenth century to its current form and has become an essential tool in many aspects of the clinical genetics evaluation. Originally used primarily to display relationship information, the pedigree was used for the first time to demonstrate inheritance of traits in the mid-nineteenth century when Pliney Earl published on inheritance

of color blindness and Francis Galton described inheritance of artistic ability and genius [1].

Symbols used to document pedigree information have varied, often depending on personal, professional, or national preferences. The key to functionality for pedigrees, however, is the degree to which they are able to communicate information uniformly to all users. In 1993, a National Society of Genetic Counselors (NSGC) task force surveyed genetic counselors regarding interpretation of pedigree symbols and conformity of usage. Numerous different symbols were being used for very common scenarios, such as pregnancy and miscarriage, and it became evident that standardization was needed. The group established a recommended nomenclature for pedigrees, which has become the widely accepted standard for recording a family health history [2].

The currently recommended methods for documenting pedigree information including symbols, spatial relationships, and nomenclature for clinical/investigative status are detailed in Figs. 4.1, 4.2, 4.3, and 4.4. These standards allow recording of traditional relationships, as well as those nontraditional relationships which are developing as new technologies are applied, in a manner that meets medical-legal requirements and protects patient confidentiality. Because pedigrees contain sensitive information and may be accessed by many individuals, especially if part of the electronic medical record, care should be taken in considering what information to include in a pedigree. To ensure compliance with the Health Insurance Portability and Accountability Act (HIPAA) standards in the USA, the pedigree standardization guidelines recommend including less identifying information on the pedigree [2]. For example, for pedigrees not intended for publication, designating family members using initials or first names (instead of complete names) and listing ages or the year of birth/death (instead of exact dates of birth or death) are preferred. The current standards also serve as a baseline for future additions or modifications as the field continues to evolve.

Pedigrees now form the cornerstone for determination of diagnosis, pattern of inheritance, and recurrence risk. Visually recording elements of family and medical history in the form of a pedigree serves many purposes including: user orientation (to family relationships, source of the information included and reason for pedigree construction), improved readability, risk assessment, validation of information included, compliance with medical documentation standards, communication, and patient education. Well-constructed pedigrees also may result in cost savings by describing evaluations already performed to avoid duplicate testing, and documenting familial mutations necessary for the most cost-effective testing of family members. In addition, collection of family medical information has aided in the understanding of many unique features of hereditary disorders, including natural history, variability, and gene-gene or gene-environment interactions.

Collection of a family pedigree represents an opportunity to build a relationship with the patient and family and to learn about how the family functions. As the genetic counselor or other healthcare provider explains the purpose of obtaining family history, an atmosphere of open communication and respect can be established. This process provides a window to the social relationships and psychosocial and educational needs of patients and families. In the social sciences, genograms are used to graphically depict family dynamics that influence individual behaviors [3]. This information also is essential for successful counseling of patients in the clinical genetics setting, and while not always recorded in the same fashion, family dynamics are a vital part of the process of pedigree gathering. Observations about coping mechanisms, assumptions about disease causation, family hierarchy, key life experiences, stress levels, body language, and religious and ethnic influences all are integrated into consideration about the most effective ways to communicate information about a diagnosis, prognosis, or management plan to patients and families.

Ideally, the pedigree is collected in a face-to-face session. This is usually done prior to or at the beginning of the clinical genetics evaluation, but may be done later, particularly when evaluating a pregnancy or a newborn with an unanticipated, newly diagnosed condition. Advance notice to patients and their families about the nature of information to be collected can facilitate the accuracy and completeness of the information provided by the family. In addition, electronic tools such as the US Surgeon General's Family Health Portrait tool (http://www.hhs.gov/familyhistory) are available to engage patients in collecting their family health information.

At a minimum, a three-generation pedigree should be collected, including all first-degree relatives (parents, children, full siblings), second-degree relatives (grandparents, aunts, uncles, nieces and nephews, half-siblings, grandchildren), and, as pertinent, many third-degree relatives (cousins, great-aunts, great-uncles, great-grandparents). This group can be expanded or condensed, depending on the nature of the referral and patient responses to preliminary questioning about features relevant to the reason for referral. For example, genetic evaluations for hereditary cancer syndromes may necessitate a more extended family pedigree, while a brief, focused pedigree may suffice when discussing cystic fibrosis carrier testing.

Information that should be collected about each individual in the pedigree is listed in Table 4.1. Modifications may be needed depending on the nature of the diagnosis under investigation; recommendations from the NSGC detail additional questions appropriate for individuals being evaluated for hereditary cancer syndromes [4]. Because family medical histories change over time, pedigrees should be updated as new information is learned.

Instructions:
- Key should contain all information relevant to interpretation of pedigree (e.g., define fill/shading)
- For clinical (non-published) pedigrees include:
  a) name of proband/consultand
  b) family names/initials of relatives for identification, as appropriate
  c) name and title of person recording pedigree
  d) historian (person relaying family history information)
  e) date of intake/update
  f) reason for taking pedigree (e.g., abnormal ultrasound, familial cancer, developmental delay, etc.)
  g) ancestry of both sides of family
- Recommended order of information placed below symbol (or to lower right)
  a) age; can note year of birth (e.g.,b.1978) and/or death (e.g.,d.2007)
  b) evaluation (see Figure 4.4)
  c) pedigree number (e.g., I-1, I-2, I-3)
- Limit identifying information to maintain confidentiality and privacy

	Male	Female	Gender not specified	Comments
1. Individual	b. 1925	30y	4 mo	Assign gender by phenotype (see text for disorders of sex development, etc.). Do not write age in symbol.
2. Affected individual				Key/legend used to define shading or other fill (e.g., hatches, dots, etc.). Use only when individual is clinically affected.
			With ≥2 conditions, the individual's symbol can be partitioned accordingly, each segment shaded with a different fill and defined in legend.	
3. Multiple individuals, number known	5	5	5	Number of siblings written inside symbol. (Affected individuals should not be grouped).
4. Multiple individuals, number unknown or unstated	n	n	n	"n" used in place of "?"
5. Deceased individual	d. 35	d. 4 mo	d. 60's	Indicate cause of death if known. Do not use a cross (†)to indicate death to avoid confusion with evaluation positive (+).
6. Consultand				Individual(s) seeking genetic counseling/ testing.
7. Proband	P	P		An affected family member coming to medical attention independent of other family members.
8. Stillbirth (SB)	SB 28 wk	SB 30 wk	SB 34 wk	Include gestational age and karyotype, if known.
9. Pregnancy (P)	P LMP 7/1/2007 47,X,Y,+21	P 20 wk 46,XX	P	Gestational age and karyotype below symbol, Light shading can be used for affected; define in key/legend.

Pregnancies not carried to term	Affected	Unaffected	
10. Spontaneous abortion (SAB)	17 wks female cystic hygroma	< 10 wks	If gestational age/gender known, write below symbol, Key/legend used to define shading.
11. Termination of pregnancy (TOP)	18 wks 47,XY,+18		Other abbreviations (e.g., TAB, VTOP) not used for sake of consistency.
12. Ectopic pregnancy (ECT)	ECT		Write ECT below symbol.

Figure 4.1 Common pedigree symbols, definitions, and abbreviations. From Bennett R, French K, Resta R, Doyle D. Standardized human pedigree nomenclature: update and assessment of the recommendations of the national society of genetic counselors. J Genet Couns. 17;2008:424–33 [2]. Reprinted with permission from Springer.

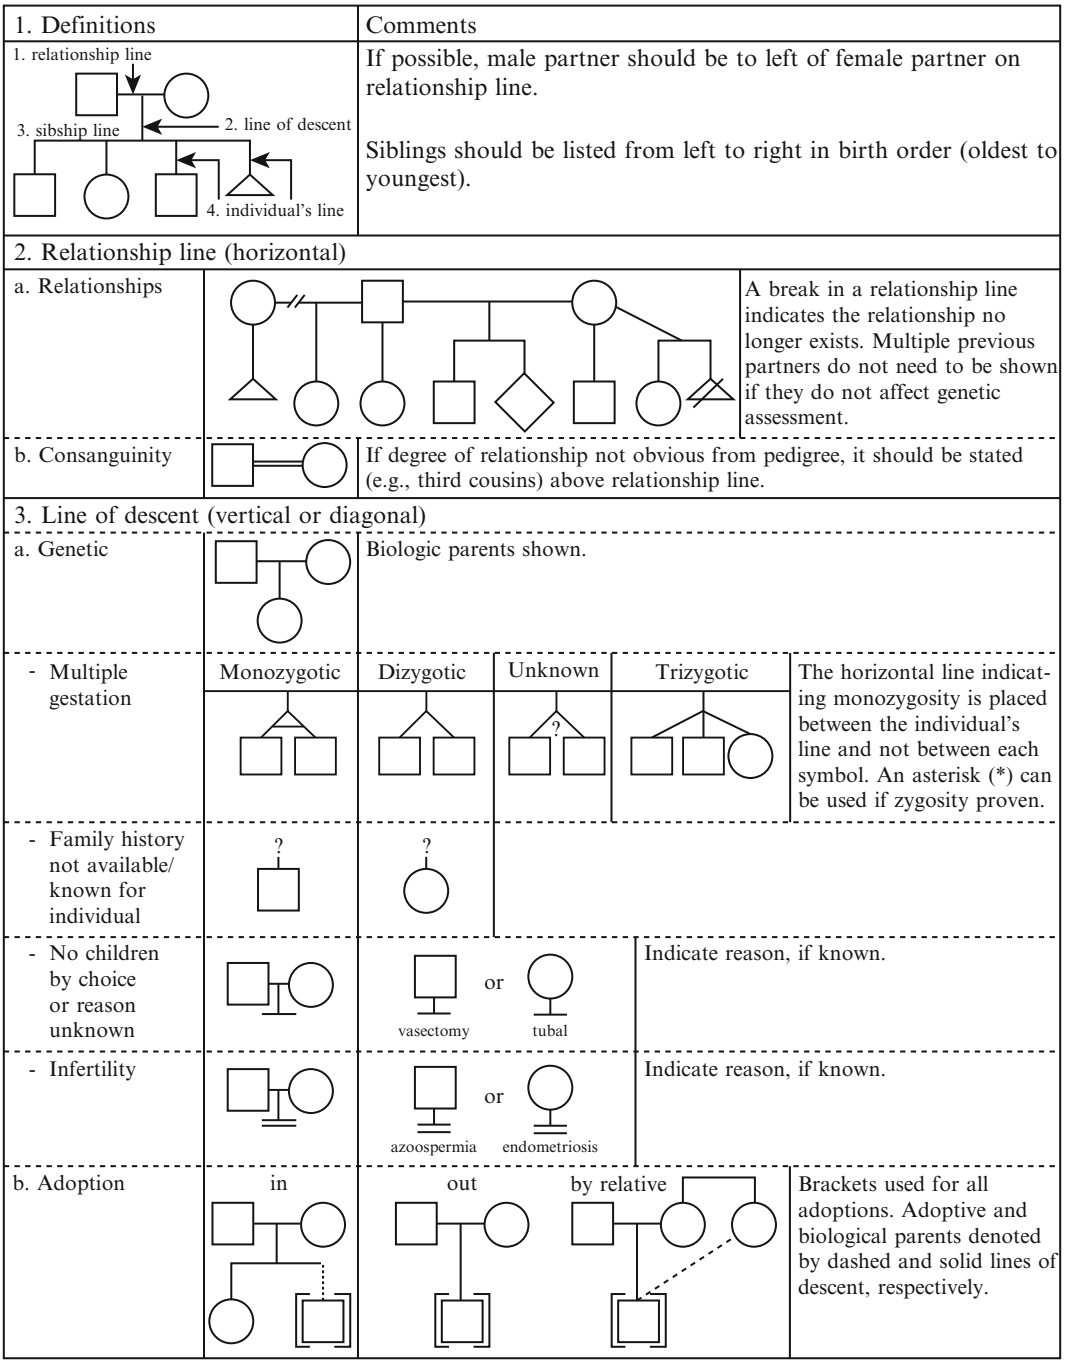

Figure 4.2 Pedigree line definitions. From Bennett R, French K, Resta R, Doyle D. Standardized human pedigree nomenclature: update and assessment of the recommendations of the national society of genetic counselors. J Genet Couns. 17;2008:424–33 [2]. Reprinted with permission from Springer

Ethnicity, consanguinity, and unique biological relationships should be recorded using standard notation. All reported diagnoses or conditions ideally should be confirmed through authorized request and review of medical records. Key records to obtain include pathology reports, test results (particularly for any genetic testing that has been performed), imaging reports, and autopsy reports. In the absence of these documents, family genealogies or death certificates may provide some degree of verification of reported information.

An important issue in the use of pedigrees for clinical evaluations and research is the issue of individual confidentiality [5]. Each member of the family has a right to expect that medical information will remain confidential.

Instructions:
- D represents egg or sperm donor
- S represents surrogate (gestational carrier)
- If the woman is both the ovum donor and a surrogate, in the interest of genetic assessment, she will only be referred to as a donor (e.g., 4 and 5)); the pregnancy symbol and its line of descent are positioned below the woman who is carrying the pregnancy
- Available family history should be noted on the gamete donor and/or gestational carrier

Possible Reproductive Scenarios		Comments
1. Sperm donor		Couple in which woman is carrying pregnancy using donor sperm. No relationship line is shown between the woman carrying the pregnancy and the sperm donor.
2. Ovum donor		Couple in which woman is carrying pregnancy using a donor egg and partner's sperm. The line of descent from the birth mother is solid because there is a biologic relationship that may affect the fetus (e.g., teratogens).
3. Surrogate only		Couple whose gametes are used to impregnate a woman (surrogate) who carries the pregnancy. The line of descent from the surrogate is solid because there is a biological relationship that may affect the fetus (e.g., teratogens).
4. Surrogate ovum donor		Couple in which male partner's sperm is used to inseminate a) an unrelated woman or b) a sister who is carrying the pregnancy for the couple.
5. Planned adoption		Couple contracts with a woman to carry a pregnancy using ovum of the woman carrying the pregnancy and donor sperm.

Figure 4.3 Assisted reproductive technology symbols and definitions. From Bennett R, French K, Resta R, Doyle D. Standardized human pedigree nomenclature: update and assessment of the recommendations of the national society of genetic counselors. J Genet Couns. 17;2008:424–33 [2]. Reprinted with permission from Springer

This becomes complicated when one considers the pedigree that may contain both reported ("hearsay") and confirmed information for numerous individuals. Those people may have willingly shared information with the patient but may not want it shared with other family members. If subsequent to an evaluation a patient requests release of his or her pedigree to another family member, a provider should carefully consider the question of ownership of the pedigree information and be attuned to the potential consequences of releasing the (identifiable) information about other family members. Current interpretation of regulations outlined by HIPAA and other medical records privacy legislation may influence how such information is shared. Professional organizations including the American Society of Human Genetics also have developed position statements on this issue [6].

Patterns of Inheritance

One key use of the carefully collected and verified pedigree is determination of the most likely mode of inheritance of a condition in a family. This will have relevance to assessing recurrence risks, approaches to testing, and in some cases even

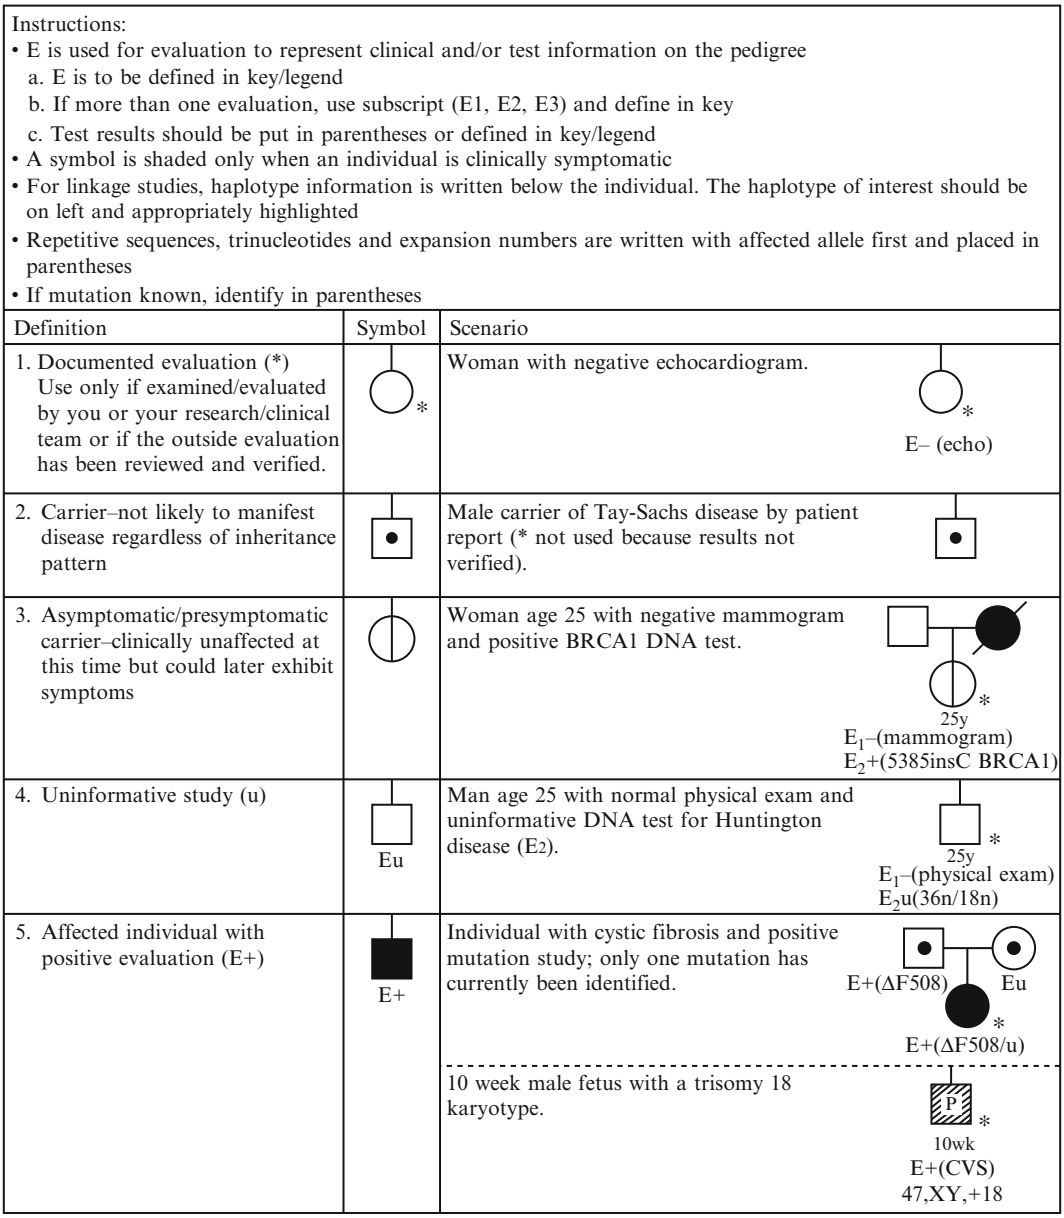

Figure 4.4 Pedigree symbols of genetic evaluation/testing information. From Bennett R, French K, Resta R, Doyle D. prognosis. The concept of patterns of inheritance extends from the seventeenth-century work of Gregor Mendel, who described transmission of traits associated with single genetic loci. Transmission of human genetic conditions and traits has proven to be more complex, involving not only the single-gene patterns first described by Mendel but also chromosomal inheritance, mitochondrial inheritance, and multifactorial inheritance. Other genetic factors which can influence transmission of disease include imprinting, uniparental disomy, unstable DNA, gene-environment interactions, mosaicism, and synergistic heterozygosity. Undoubtedly, additional factors influencing transmission and expression of inherited traits will be elucidated as our understanding of the human genome expands. As of January 2012, the Online Mendelian Inheritance in Man (OMIM), a continuously updated catalog of human genes and genetic phenotypes, listed 13,775 identified genes and 4,520 genetic disorders for which the molecular basis is known [7]. Identified genetic disorders with known patterns of inheritance are commonly inherited as autosomal, X-linked, or mitochondrial.

Table 4.1 Collection of family medical history: what to ask?

For all family members
Current age; year of birth
Exact relationship to the proband
General physical and mental health status
History of major acute or chronic illness, hospitalizations, and surgeries
History of learning problems, diagnosed disabilities, or intellectual disability
Highest grade level completed (when relevant)
Employment (when relevant)
Reproductive history, including pregnancies, miscarriages, elective terminations, infertility, and choice not to have children
Gestational age and last menstrual period for ongoing pregnancies
Consanguinity
Ethnicity
Targeted questions relevant to the reason for evaluation, for example, key symptoms or features of the condition in question, pertinent evaluations
Age at death; year of death; cause of death
For family member known to be affected by the condition in question
Diagnosis
Age at diagnosis or disease onset
Method of diagnosis
Evaluations and testing completed
Symptoms
Information about ongoing treatment or management plan
Availability of medical records for review

Mendelian Inheritance Patterns

For a summary of Mendelian inheritance patterns, see Table 4.2.

Autosomal Dominant Inheritance

In classic autosomal dominant inheritance, an affected individual has one non-functional or mutant allele at a particular locus, the presence of which causes disease. Each affected individual in a pedigree has a 50 % chance of passing the disease-associated mutation to each of his or her offspring. Additional genetic and non-genetic factors may influence the occurrence of these conditions in families. A key feature of autosomal dominant inheritance is the observance of male-to-male transmission of the condition or trait. Transmission from fathers to sons is not seen in X-linked dominant inheritance, which can be confused with autosomal dominant inheritance on first analysis. Table 4.2 lists additional features of autosomal dominant inheritance, and an example pedigree is shown in Fig. 4.5.

Table 4.2 Features of Mendelian patterns of inheritance

Autosomal dominant
Male-to-male transmission occurs; both sexes can transmit to offspring
Affected family members in multiple generations; "vertical transmission" typically showing affected descendants of affected individuals and unaffected descendants of unaffected individuals
Males and females affected, typically to comparable extent
Variability of clinical findings
Later/adult onset in some disorders
Homozygotes may be more severely affected than heterozygotes
Homozygosity may be lethal
Occurrence of new mutations
Nonpenetrance; apparent "skipping" of generations
Germline mosaicism reported
Autosomal recessive
Affected family members are usually in one generation; "horizontal" inheritance
Males and females equally likely to be affected; parental consanguinity or a small mating pool may influence disease occurrence
Disease severity is usually consistent among affected family members
Early onset of symptoms more typical
New mutations rare
May see higher frequency of disease in certain ethnic groups
X-linked dominant
No male-to-male transmission
Affected females usually have milder symptoms than affected males
Affected males have no affected sons, but all daughters will be affected
May mimic autosomal dominant inheritance
May be lethal in affected males; reflected by a paucity of males or overrepresentation of females in the pedigree
Increased occurrence of miscarriage may be observed
X-linked recessive
No male-to-male transmission
Males more frequently affected
Carrier females usually unaffected but may have mild symptoms
Affected males in a family are related through females
Y-linked
Male-to-male transmission only
Association with increased rates of male infertility
Discrepancy between chromosomal and phenotypic sex

Autosomal Recessive Inheritance

In autosomal recessive inheritance, an affected individual has two non-functional or mutant alleles at a particular locus. Carriers of autosomal recessive conditions have one nonfunctional allele at the gene locus, but usually have no symptoms as they also have one normal, functional copy of the gene. If both partners of a couple are carriers of the same autosomal recessive condition, with each pregnancy there is a one in four (25 %) chance of having an affected child, a two-in-four

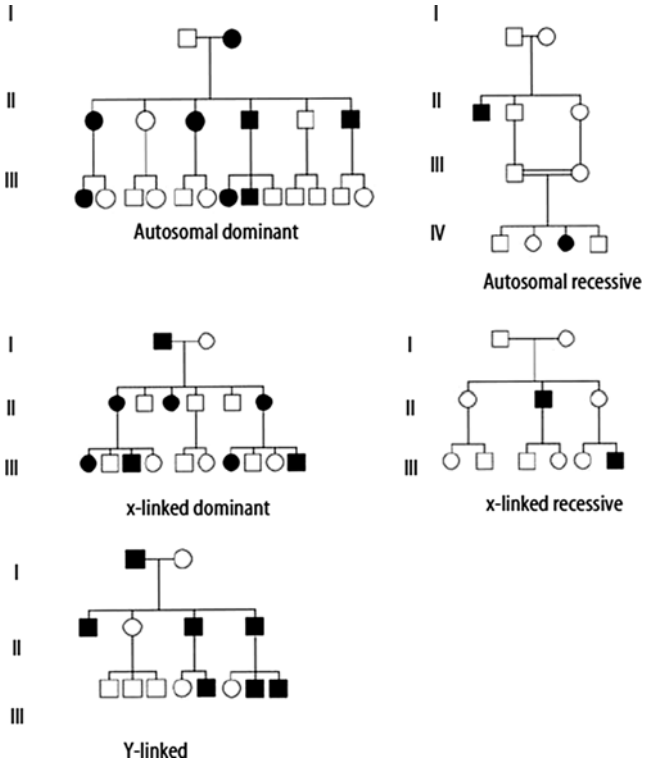

Figure 4.5 Example pedigrees for Mendelian patterns of inheritance

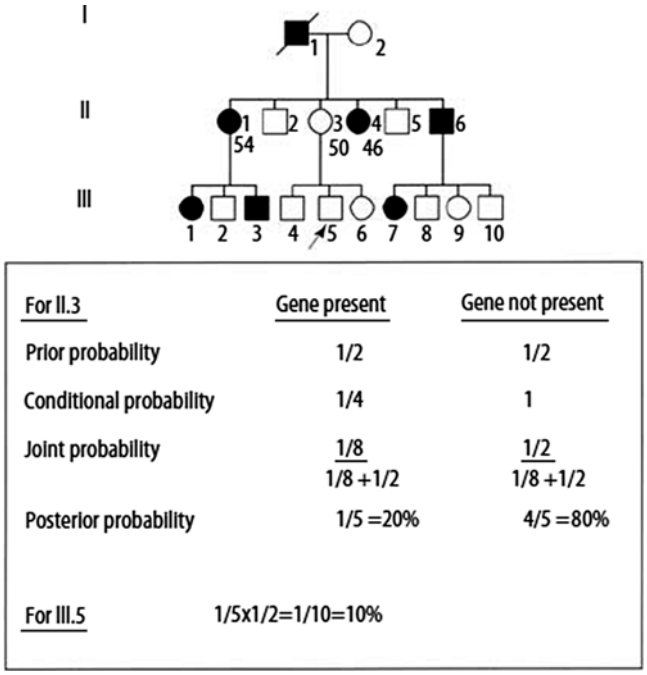

Figure 4.6 Bayesian analysis for risk assessment in an autosomal dominant, adult-onset hereditary cancer disorder. Ages of selected individuals in generation II are shown below the pedigree symbols

(50 %) chance that a child will be a carrier and a one in four (25 %) chance a child will be neither a carrier nor affected. After birth, if a child of a carrier couple is not affected by the condition in question, he or she has a two-in-three chance of being a carrier. Risk to future offspring of a known carrier depends on the likelihood that his or her partner is also a carrier. This is influenced by the frequency of the disease, which may vary among different ethnic groups or populations. Features of autosomal recessive inheritance are listed in Table 4.2, and an example pedigree is shown in Fig. 4.5.

X-Linked Dominant Inheritance

In X-linked dominant inheritance, an affected individual has one nonfunctional or mutant allele at a locus on an X-chromosome. X-linked dominant conditions can occur in either males or females. Risk for offspring of an affected female is 50 %, regardless of the sex of the offspring. Risk to offspring of affected males is sex dependent, with all daughters but no sons inheriting the gene mutation. Many of these conditions, however, are lethal in males, so pedigrees may show overrepresentation of females or increased frequency of miscarriages, presumably of affected male fetuses (see Table 4.2 and Fig. 4.6).

X-Linked Recessive Inheritance

Traditional X-linked recessive inheritance is characterized by occurrence of the condition in males having a non-functional or mutant allele for a gene on the X-chromosome. Affected males in the family will be related to each other through females. (See the pedigree in Fig. 4.5, and Table 4.2 for additional features.) Typically, carrier females are unaffected; however, due to lyonization (random inactivation of one X chromosome in each somatic cell in a female), carrier females may have mild symptoms. This occurs when, by chance, the X chromosome with the non-functional allele remains active in a majority of the cells within the critical tissue(s) for the disorder. The likelihood of symptoms in carrier females varies considerably among disorders. Risk to offspring of carrier females is 25 % overall, or 50 % for affected status if the fetus/offspring is male. Fifty percent of the female offspring of carrier females will also be carriers. Offspring of affected males will not be classically affected, but all daughters will be carriers.

Y-Linked Inheritance

In rare cases, a mutation can occur in one of a limited number of genes on the Y chromosome. This can result in disparity between chromosomal and phenotypic sex if the SRY region is involved, or can be associated with hereditary forms of male infertility. This may be identified more frequently as

reproductive technologies such as intracytoplasmic sperm injection (ICSI) are used to aid in achieving pregnancies for previously infertile males, due to Y-chromosome deletions, for example (see Table 4.2 and Fig. 4.5).

Codominant Inheritance

In codominant inheritance, two different alleles of the gene of interest are present and each is expressed. Therefore, the resulting phenotype is influenced by expression of both alleles. Traits inherited in this fashion include the ABO blood group and alpha-1-antitrypsin deficiency.

Non-Mendelian Inheritance Patterns

For a summary of non-Mendelian inheritance patterns, see Table 4.3.

Chromosomal Disorders

Chromosome abnormalities can occur sporadically or can be caused by familial transmission of duplications, deletions, or rearrangements that can result in imbalance of genetic material in the offspring. Chromosomal disorders caused by changes in the number of chromosomes (e.g., Down syndrome) occur most often due to random events during meiosis, and are typically not inherited. Copy number variants (CNVs), small deletions, or duplications of chromosomal material may be benign or disease causing, and may be inherited or de novo. Chromosomal rearrangements, such as translocations (the exchange of parts of nonhomologous chromosomes) and inversions (the breakage and reversal of a single chromosome segment), usually are deleterious when unbalanced. Unbalanced rearrangements are commonly inherited from a parent who carries a balanced version of the rearrangement. Chromosome abnormalities commonly are associated with multiple phenotypic effects as they usually cause deletion and/or duplication of many genes on the chromosomal segment(s) involved.

The classic microdeletion syndromes (e.g., DiGeorge syndrome, Williams syndrome) are clinically recognizable disorders resulting from the loss of many adjacent genes along a defined segment of a chromosome and usually result from a de novo event. The mechanism responsible for common microdeletion/microduplication syndromes is homologous recombination between stretches of nearly identical sequence that either remove or duplicate the unique intervening sequence [8]. Microdeletion/duplication syndromes are most reliably detected using array comparative genomic hybridization (aCGH) or fluorescence in situ hybridization (FISH) because the abnormalities are usually not detectable using standard cytogenetics.

Risks to offspring of individuals with chromosomal rearrangements or CNVs depend on the specific chromosome region(s) involved, size of the abnormality, and sometimes the sex of the transmitting parent. In apparently sporadic cases of unbalanced chromosomal rearrangements or disease-associated CNVs, parental testing with respect to the chromosomal abnormality should be performed to assess recurrence risk. Absence of a parental chromosome abnormality in such cases reduces the risk to future offspring. It is important to note that novel CNVs identified in an affected individual and in an unaffected parent should not be assumed to be benign; such CNVs may be disease causing but exhibit variable expressivity or reduced penetrance [9].

Table 4.3 Features of non-Mendelian patterns of inheritance

Chromosomal
Occurrence of congenital anomalies involving two or more organ systems
Occurrence of intellectual disability with dysmorphism or congenital anomalies
Multiple pregnancy losses or infertility in carriers of balanced translocations
Many occur as sporadic conditions with negative family history
Mitochondrial
Extreme variability of clinical symptoms; multiple organ systems involved
Degenerative/neuromuscular disorders predominate
Maternal transmission (fathers do not transmit disease)
Multiple generations affected (matrilineal)
Males and females equally likely to be affected
Environmental factors may influence symptoms
Multifactorial inheritance
Implicated in common adult-onset disorders
Males and females affected
The number and sex of affected relatives influence recurrence risk
Degree of relationship to affected relatives influences recurrence risk

Mitochondrial Disorders

The mitochondrial (mt) genome is a 16.5 kb circular strand of DNA located within the mitochondria. Unlike nuclear genes, the mt genome has a very high mutation rate due to lack of DNA repair mechanisms. In general, large deletions in the mtDNA arise as new mutations and confer low risk to relatives, while point mutations and duplications are commonly maternally transmitted [10]. Individuals inherit essentially all their mitochondrial DNA from their mothers; thus, transmission of mtDNA mutations is maternal. Affected males do not transmit mtDNA mutations to offspring. In each cell, including egg cell progenitors, there may be up to 1,000 mitochondria. If a mutation occurs in one of these mitochondria, as the mitochondrion divides over time, the mutation becomes present in a percentage of the overall

mitochondrial population in the cell. When the cell divides, the mitochondria are distributed stochastically to the daughter cells. The daughter cells may inherit only mutant mtDNA or no mutant mtDNA (homoplasmy), or a mix of mutant and nonmutant mtDNA (heteroplasmy). When the proportion of mutant mtDNA exceeds a critical threshold in the cell, mitochondrial dysfunction results. As the degree of heteroplasmy may differ among individuals in a family, predicting risk to offspring of affected females is difficult. The level of heteroplasmy may differ in cell populations of different organs or tissues of an affected individual; therefore, conditions caused by mtDNA mutations often result in phenotypes affecting multiple organ systems and exhibit highly variable expression. Mutations in nuclear genes which affect mitochondrial function also can result in mitochondrial diseases. Such disorders are inherited in either an autosomal or X-linked fashion and tend to have expression that more closely resembles other Mendelian disorders.

Multifactorial Disorders

Multifactorial disorders are the result of the interaction or additive effect of multiple genetic and environmental factors. The likelihood of expression of a trait or disease is based on the relative contributions of each of the factors involved. With a relatively low concentration of contributing factors, no effect will be seen. Above a critical cutoff of accumulated factors, the condition occurs. Risk to relatives of affected individuals increases as more family members are affected, presumably reflecting the presence of a higher "dose" of critical factors in the family or shared environmental factors. For multifactorial disorders that are more common in one sex, such as pyloric stenosis or neural tube defects, the risk for recurrence is higher for relatives when the affected individual is of the less commonly affected sex. Empiric risk figures for multifactorial disorders may be used for genetic counseling, but should be modified based on individual factors including number of affected relatives, relationship of affected family members to the counselee, severity of disease, and sex.

Genetic Mechanisms Influencing Transmission

For a summary of several known genetic factors which influence transmission, see Table 4.4.

Table 4.4 Genetic factors influencing transmission

Genomic imprinting
Gender of transmitting parent modifies gene/disease expression (parent-of-origin effects)
May appear to skip generations
Uniparental disomy
Single/isolated case in a family
Documentation of only one carrier parent in individuals with an autosomal recessive disease
X-linked recessive disorders occurring in 46,XX females
Unstable DNA
Anticipation (increasing severity with subsequent generations)
Gender of the transmitting parent may influence disease likelihood and severity
Synergistic heterozygosity
Unaffected, unrelated parents have multiple affected offspring
Described for genes with autosomal recessive inheritance
Implicated genes act in the same biological pathway or their proteins form complexes

Genomic Imprinting

Imprinting refers to differential expression of genes depending on the parent of origin. The process is reversible, as it affects the action of the gene but not the gene structure; genes that are passed from a male (imprinted as male) to a female are then reimprinted as female before being transmitted to the next generation, and so on. Genomic imprinting is thought to occur early in development, most likely in the germ cells [11]. Imprinting errors have been described in a number of disorders including about 3 % of individuals with Angelman syndrome and an estimated 1 % of patients with Prader-Willi syndrome. If an affected individual has a mutation in an imprinting control center, which controls gene expression by regulating methylation, recurrence risks may be as high as 50 %.

Uniparental Disomy

Uniparental disomy (UPD) is defined as both copies of a chromosome or chromosome segment being derived from the same parent. The frequency of this phenomenon is unknown. UPD can occur as heterodisomy (the presence of both copies of a chromosome from one parent) or isodisomy (two copies of the same parental chromosome). This becomes clinically relevant when males and females differentially imprint the chromosomal segment in question, or when the parent who transmits the disomic region carries a mutation for a recessive disorder in that region [11]. Some disorders which can be caused by UPD include Beckwith-Wiedemann syndrome, Angelman syndrome, and Prader-Willi syndrome. UPD has been reported as a rare cause of autosomal recessive disorders, including cystic fibrosis and sickle cell anemia, and should be considered as a mechanism for autosomal recessive disease when only one parent can be confirmed as a carrier. In addition, X-linked recessive disorders occurring in 46,XX females may be caused by UPD.

Unstable DNA

Most classic hereditary disorders are caused by static or stable mutations in one or a few genes. For trinucleotide repeat disorders (e.g., fragile X syndrome, Huntington disease, myotonic dystrophy) the causative gene alterations are unstable and consist of a variable number of copies of a tandemly repeated three-nucleotide sequence. Trinucleotide repeats are stable and usually inherited without alteration when the repeat size falls with a specific range, which is gene specific. DNA replication of the repetitive sequence may result in errors leading to expansion (additional copies of the trinucleotide sequence) or contraction (loss of copies of the trinucleotide sequence) of the number of repeat copies. With expansion, the gene segment becomes less stable and thus more likely to expand further. Intermediate lengths of expanded trinucleotide repeats are called pre-mutations, which are extremely unstable and highly likely to undergo further expansion. Individuals who carry pre-mutations typically do not have classic symptoms of the associated disorder but may show mild signs or develop associated symptoms at later ages.

If the trinucleotide repeat expands into the disease-associated size range, gene function is disrupted and symptoms occur in the individual. Disease severity typically correlates with the size of the repeated segment, with earlier age of onset and more severe symptoms with increasing repeat size. The clinical phenomenon of anticipation (earlier onset and more severe disease in subsequent generations) is explained mechanistically by the progressive expansion of the trinucleotide repeat region from one generation to the next. Sex of the transmitting parent also can influence the likelihood and degree of expansion, and is gene specific (the significant parent of origin varies by disease). Many common trinucleotide repeat disorders are associated with neurological phenotypes.

Synergistic Heterozygosity

This phenomenon can be described as the interaction of genes at multiple loci needed to express a phenotype. Heterozygous mutations in two or more distinct genes may lead to an overall decrease in function if the gene products form a complex or participate in the same developmental or metabolic pathway [12]. Examples of disorders resulting from synergistic processes include non-syndromic hearing loss resulting from heterozygous mutations in both the *GJB2* gene (encoding Connexin26) and the *GJB6* gene (encoding Connexin30). The connexins co-localize in the inner ear tissues to form gap junctions which are important for cellular communications. The presence of a heterozygous large deletion within the *GJB6* gene results in the loss of expression of *GJB2* on the same chromosome by removing a cis-acting regulatory element [13]. Thus, individuals carrying a *GJB2* mutation on one chromosome and a *GJB6* mutation on their other chromosome present with non-syndromic hearing loss. Digenic inheritance, or heterozygosity for a recessive mutation at two distinct loci, has been reported for inherited disorders including severe insulin resistance, primary congenital glaucoma, and retinitis pigmentosa. Recurrence risks for conditions resulting from synergistic heterozygosity depend on the number of loci involved, the specific genes implicated, genetic linkage of the loci, and the degree of decreased function conferred by each mutation. For classic digenic inheritance of recessive gene mutations which are not linked, risk for recurrence is expected to be 25 %.

Other Factors Affecting Risk and Risk Assessment

Understanding modes of inheritance provides a framework for risk assessment for close relatives of individuals affected by hereditary disorders; however, many factors influence the ability to clearly define patterns of inheritance in families. From a logistical perspective, family members may not know details about medical conditions in distant relatives, or relatives may not wish to share those details by providing medical records. For some, there may be stigma or guilt attached to discussion of hereditary conditions in themselves or their children. Mechanistically, there are a number of processes that may confound pedigree interpretation (Table 4.5). Variable expressivity and pleiotropy relate, respectively, to the presence of different degrees of severity of symptoms and the presence of varying phenotypic features in affected individuals. These could lead to misclassification of affected status, or failure to recognize the presence of a single clinical entity in affected family members. Further, gaps in an otherwise

Table 4.5 Factors affecting risk and risk assessment

Variable expressivity/pleiotropy
Typical age of disease onset
Penetrance
Heterogeneity
Phenocopies
Sex-influenced expression (sex-limited vs sex-influenced)
Family size/paucity of at-risk sex
Nonpaternity
Consanguinity/inbreeding
Lyonization
New mutation
Mosaicism (somatic or germline)
Modifying genes
Environmental and lifestyle effects

classic pedigree can occur due to variability in age of onset, particularly with adult-onset disease due to penetrance, or likelihood that an individual who carries the gene mutation(s) for a condition will show signs or symptoms. Some conditions show genetic heterogeneity, that is, can be caused by mutations in a number of different genes or by multiple distinct mutations at the same loci. Phenocopies, similar conditions with different genetic or nongenetic etiologies or both, also may occur within a family and lead to misinterpretations of patterns of inheritance and, thus, of risk to family members. Small family size or relatively low frequency of the at-risk sex in sex-influenced disorders (sex-limited vs sex-influenced expression) may result in failure to recognize a hereditary disorder and underestimation of risk.

Accurate reporting of relationships within a pedigree is critical. Nonpaternity, estimated at 3 % in Western industrialized nations [14], may explain transmission patterns that seem to deviate from the expected. Consanguinity, or sharing of common ancestors, is particularly important when considering transmission of autosomal recessive traits. In a consanguineous union, there is an increased chance that a gene mutation present in a common ancestor and associated with an autosomal recessive condition may be transmitted through both sides of the family and occur in the homozygous state in offspring. In general, the risk for congenital malformations or adverse medical outcomes in the offspring of consanguineous unions is increased over the general population and varies depending on the degree of relatedness of the couple [15].

Risk assessment for disorders caused by mutations in X-linked genes or for chromosomal rearrangements involving the X chromosome may be influenced by lyonization. Female carriers of X-linked recessive disorders may be symptomatic if the affected X chromosome is preferentially active while female carriers of X-linked dominant disorders may be asymptomatic if the affected X chromosome is preferentially inactivated. Spontaneous new mutations, which are not inherited from either parent but may be transmitted to offspring, are a common cause for some autosomal dominant or X-linked conditions. Parental testing may be necessary to determine if a mutation occurred sporadically and can be helpful in clarifying recurrence risk and establishing risk to family members. Somatic mosaicism, or the presence of at least two populations of cells with different genetic makeup in the same individual, may result in an atypical or mild disease phenotype depending on the type and percentage of cells affected. Mosaicism which is restricted to the egg or sperm cells (germline mosaicism) can lead to unrecognized or indefinable risk to future offspring because such individuals are asymptomatic and it is difficult to estimate the percentage of germ cells affected.

Finally, factors outside of the critical gene can influence expression of traits and thus the assessment of risk. Expression of some genes is influenced by variant forms of other so-called modifying genes. Polymorphisms or mutations in these modifying genes can change gene-gene or protein-protein interactions to affect the expression of the condition. Similarly, environmental or lifestyle factors such as dietary habits, medical screening practices and specific exposures (medications, radiation, smoke, etc.) may positively or negatively affect gene function and expression of clinical symptoms.

Each of these factors must be carefully considered in the overall diagnostic and risk assessment, initially based on collection of a family pedigree and continued through clinical evaluation, including physical examination and indicated diagnostic testing.

Direct and Indirect Mutation Analysis

The ability to directly interrogate mutations or gene regions associated with disease often provides a more definitive answer about individual risk than pedigree evaluation. Currently, there are clinical or research tests offered for over 2,500 different genetic diseases (http://www.ncbi.nlm.nih.gov/, accessed on 17 January 2012), and this list will continue to increase as additional genes are implicated in disease. Molecular methods of gene analysis vary and technologies selected by clinical molecular laboratories may be influenced by numerous factors including the number of gene(s) and sample(s) to be analyzed, size of the gene(s), gene structure, and the number and type of gene mutations to be interrogated. Sanger sequencing is considered the gold standard for DNA sequencing and is frequently used in clinical testing. Mutation scanning techniques such as conformation-sensitive gel electrophoresis (CSGE), denaturing gradient gel electrophoresis (DGGE), denaturing high-performance liquid chromatography (DHPLC), single-strand conformation polymorphism (SSCP), and high-resolution melting (Wittwer) are commonly utilized for genes which may contain a variety of disease-causing sequence alterations [16, 17]. If a sequence alteration is suspected by a scanning method, sequencing to confirm the presence of the variant can be targeted only to the suspicious gene region which makes scanning technologies economical. For analysis of a small number of defined mutations within a gene, including small insertions, deletion rearrangements, or changes in the number of repeats, polymerase chain reaction (PCR) and fragment analysis may be used [16]. For detection of defined, disease-causing single-nucleotide polymorphisms (SNPs), allele-specific PCR and fluorescent monitoring, single-nucleotide extension (SNE), or oligonucleotide ligation assays (OLA) may be used. Southern blot analysis, multiplex ligation-dependent probe amplification (MLPA), or array hybridization techniques may be utilized to identify loss or

gain of entire genes or gene segments. Southern blot analysis also may be used to identify large trinucleotide repeats.

New high-throughput sequencing technologies, collectively referred to as next-generation sequencing (NGS), use DNA synthesis or ligation processes for massively parallel sequencing of numerous DNA templates. NGS technologies have improved sequencing speed and accuracy and lowered costs of testing multiple genes for a single disease dramatically [18]. By targeting regions of the genome or genes of interest, NGS technologies are being applied to clinical molecular testing. Panels of genes associated with a particular disease phenotype (e.g., cardiomyopathy or X-linked intellectual disability) can be assembled for analysis by NGS, which is especially cost effective for diseases demonstrating genetic heterogeneity. Exome sequencing targets only the protein-encoding regions of the genome, which harbor the majority of identified disease-causing mutations, yet represent only 1 % of the entire genome. Exome sequencing is being used to identify causative mutations for Mendelian disorders difficult to identify by targeted sequencing of specific genes [19]. Genome sequencing also is being applied in clinical settings to identify rare Mendelian disorders [20]. A detailed discussion of molecular methods is provided in Chap. 2 and NGS technologies in Chap. 59 and 60.

Direct methods of identifying mutations are invaluable when the disease-associated gene is known; however, historically and even today, for many conditions the causative gene has not been identified or is not characterized adequately to allow for mutation-specific testing. The classic method for determining the causative gene for a Mendelian disorder is linkage analysis. Linkage analysis uses polymorphic genetic markers near the genomic locus of interest to assess association with the disease phenotype in the family. As linkage analysis requires samples from multiple family members, both affected and unaffected, this type of indirect mutation analysis may not be feasible for genetic assessment of very rare Mendelian disorders, sporadic cases, or unrelated cases. In addition, linkage analysis may not be an ideal method of gene discovery for conditions demonstrating diverse clinical phenotypes, those resulting from mutations in more than one gene or influenced by gene-environment interactions. Integration of exome or genome sequencing with linkage and homozygosity data can help elucidate previously unidentified causative mutations or candidate genes [19].

Bayesian Analysis Used in Risk Modification

Numerous factors, some listed above, influence the likelihood that a given individual in the family may be affected by, or a carrier of, the presenting condition. When it is not possible to do direct diagnostic testing for the condition (e.g., if the causative gene is unknown, when the affected relative is not available for testing, or for complex traits), it is possible to combine incremental contributors to risk by utilizing Bayesian analysis. Bayesian analysis is a statistical construct that uses information about the likelihood of occurrence of past events or conditions, and the current status of those events or conditions for the individual, to predict the likelihood of a future event or condition, in this case, the presence or absence of a particular gene mutation or genetic condition [12]. Some factors that may be considered in genetic risk assessment using Bayesian analysis include ethnicity, degree of relationship to affected family members, inheritance pattern, laboratory results, incidence of the disease, and natural history of the condition. The probability assigned based on past events is called the prior probability. The probability based on current information or observations is called the conditional probability. The calculated probability for each possible outcome of an event or condition is the joint probability, and the final probability of one outcome as a percentage of all possible outcomes is the posterior probability. Calculations often utilize data from multiple generations and are usually done in tabular form. The example pedigree in Fig. 4.6 demonstrates an autosomal dominant cancer predisposition syndrome affecting males and females equally. Based on Mendelian inheritance alone, the risk that individual III.5 carries the disease-causing mutation is 25 %. However, knowing that 75 % of gene carriers have been diagnosed with cancer by age 50, risk can be recalculated as demonstrated. (See Chap. 5 for a complete discussion of Bayesian analysis.)

Bayesian Analysis

5

Robert B. Wilson and Shuji Ogino

Abstract

The purpose of this chapter is to describe basic and general principles of Bayesian analysis for molecular pathologists. Analyses based on Bayes' theorem are routinely applied to calculate probabilities in a wide variety of circumstances, not limited to medicine or genetics. In molecular pathology, Bayesian analysis is commonly used to calculate genetic risk, incorporating population data, pedigree information, and genetic testing results. Bayesian analysis is introduced with two simple, concrete examples. In subsequent sections, the general principles illustrated by these examples are discussed and applied to more complex scenarios. Although the technologies for genetic testing will continue to change, Bayesian analysis and genetic risk assessment will remain fundamental aspects of genetic testing and genetic counseling.

Bayesian analysis • Genetics • Risk • Calculation • Carriers • Affected • Relationship • Prior risk • Probability • Ethnicity • Frequencies • Pedigree • Family history • Consultand

Introduction

The purpose of this chapter is to describe basic and general principles of Bayesian analysis for molecular pathologists. Thomas Bayes first described the theorem named after him in an essay on 'the doctrine of chances,' published posthumously in 1763, and republished in 1958 [1]. Analyses based on Bayes' theorem are routinely applied to calculate probabilities in a wide variety of circumstances, not limited to medicine or genetics. In molecular pathology, Bayesian analysis is commonly used to calculate genetic risk, incorporating population data, pedigree information, and genetic testing results. First, Bayesian analysis will be introduced with two simple, concrete examples. In subsequent sections, the general principles illustrated by these examples are discussed and applied to more complex scenarios. For more in-depth treatments, the reader is referred to "Introduction to Risk Calculation in Genetic Counseling" by Young [2] and "The Calculation of Genetic Risks" by Bridge [3], as well as several articles on genetic risk assessment that include advanced Bayesian analyses, particularly for spinal muscular

atrophy (SMA) [4, 5], cystic fibrosis (CF) [6–9], and autosomal dominant disorders [10].

Bayesian Analysis Using Pedigree Information

In the pedigree shown in Fig. 5.1a, the two brothers of the consultand (indicated by the arrow) have Kennedy disease (X-linked spinal and bulbar muscular atrophy, OMIM #300377), which is caused by a CAG trinucleotide repeat expansion in the androgen receptor (*AR*) gene (OMIM #310200). Because both of the consultand's brothers are affected, we can assume that the consultand's mother is an obligate carrier. Before taking into account the consultand's three unaffected sons, her carrier risk is 1/2, since there is a 1/2 chance that she inherited the mutant X chromosome from her mother. If we take into account that the consultand has three unaffected sons, how does her carrier risk change?

	Hypothesis	
	Carrier	Non-carrier
Prior Probability	1/2	1/2
Conditional Probability (of three normal sons)	1/8	~1
Joint Probability	1/16	1/2
Posterior Probability	(1/16) / (1/16 + 1/2) = 1/9	(1/2) / (1/16 + 1/2) = 8/9

Figure 5.1 (**a**) Pedigree of a family with individuals affected with Kennedy disease (see text). (**b**) Bayesian analysis for the consultand in **a**. (**c**) Schematic representation of the Bayesian analysis of **b**. Pedigrees shown in the *boxes* represent all possible disease status outcomes for the third generation of the pedigree in **a**, given the carrier or non-carrier status of the consultand. Each *small box* to the *left* represents 1/16 of the total area. (See text for full description.)

Bayesian analysis starts with mutually exclusive hypotheses. In this example, there are two: that the consultand is a carrier, and that the consultand is a non-carrier. Setting up a table with separate columns for each hypothesis facilitates Bayesian analyses, as shown in Fig. 5.1b for this case. The first row of the table comprises the "prior" probability for each hypothesis. In this example, the prior probabilities are the probability that the consultand is a carrier (1/2), and the probability that she is a non-carrier (also 1/2), *prior* to taking into account the subsequent information that she has three unaffected sons.

The second row of the table comprises the "conditional" probability for each hypothesis. The conditional probability for each hypothesis is the probability that the subsequent information would occur if we assume that each hypothesis is true. In this example, the subsequent information is that the consultand has three unaffected sons. Thus, the conditional probabilities are the probability that the consultand would have three unaffected sons under the assumption (or "condition") that she is a carrier, and the probability that she would have three unaffected sons under the assumption (or "condition") that she is a non-carrier. If we assume that she is a carrier, the probability that she would have three unaffected sons is $1/2 \times 1/2 \times 1/2 = 1/8$. This is because she would have to have passed the normal X chromosome three times in succession, each time with a probability of 1/2. If we assume that she is a non-carrier, the probability that she would have three unaffected sons approximates 1, since only in the event of a rare de novo mutation would a non-carrier have an affected son. Thus, the conditional probabilities in this example are 1/8 for carrier and 1 for non-carrier (Fig. 5.1b).

The third row of the table comprises the "joint" probability for each hypothesis, which is the product of the prior and conditional probabilities for each hypothesis. For the first hypothesis in this example, that the consultand is a carrier, the joint probability is the prior probability that she is a carrier, times the conditional probability that a carrier would have three normal sons, which in this case is $1/2 \times 1/8 = 1/16$ (Fig. 5.1b). For the second hypothesis in this example, that the consultand is a non-carrier, the joint probability is the prior probability that she is a non-carrier, times the conditional probability that a non-carrier would have three normal sons, which in this case is $1/2 \times 1 = 1/2$ (Fig. 5.1b).

The fourth row of the table comprises the "posterior" probability for each hypothesis. The posterior probability for each hypothesis is the probability that each hypothesis is true after (or "posterior" to) taking into account both prior and

subsequent information. The posterior probability for each hypothesis is calculated by dividing the joint probability for that hypothesis by the sum of all the joint probabilities. In this example, the posterior probability that the consultand is a carrier is the joint probability for the first hypothesis (1/16), divided by the sum of the joint probabilities for both hypotheses (1/16 + 1/2 = 9/16), or 1/16 ÷ 9/16 = 1/9. The posterior probability that the consultand is a non-carrier is the joint probability for the second hypothesis (1/2 = 8/16), divided by the sum of the joint probabilities for both hypotheses (1/16 + 1/2 = 9/16), or 8/16 ÷ 9/16 = 8/9. Thus, taking into account the prior family history, and the subsequent information that she has three unaffected sons, the probability that the consultand is a carrier is 1/9 (Fig. 5.1b).

The preceding example is illustrated graphically in Fig. 5.1c. The total area represents the total prior probabilities. The left half represents the prior probability that the consultand is a carrier (1/2), and the right half represents the prior probability that she is a non-carrier (also 1/2). Under the hypothesis that the consultand is a carrier, there are eight possibilities, comprising all the permutations of zero, one, two, or three affected sons. The area of the small rectangle that contains three unshaded squares (for three unaffected sons) comprises 1/8 of the left half and represents the conditional probability of three normal sons under the hypothesis that the consultand is a carrier. The area of this small rectangle is 1/16 of the total area and therefore also represents the joint probability that the consultand is a carrier (1/2), and that as a carrier she would have three normal sons (1/8), or 1/2 × 1/8 = 1/16.

Under the hypothesis that the consultand is a non-carrier, there is essentially only one possibility, which is that all three sons are unaffected. The area of the larger rectangle that contains the pedigree with three unshaded squares (for three unaffected sons) comprises all of the non-carrier half and represents the conditional probability of three normal sons under the hypothesis that the consultand is a non-carrier. The area of this larger rectangle is 1/2 of the total area and therefore also represents the joint probability that the consultand is a non-carrier (1/2), and that as a non-carrier she would have three normal sons (~1), or 1/2 × 1 = 1/2. The "reverse-L-shaped" box, which is demarcated by a bold line, represents the sum of the joint probabilities, or 9/16 of the total area.

Because the consultand has three unaffected sons, the area of the reversed-L-shaped box represents the only component of the prior probabilities needed to determine the posterior probability that the consultand is a carrier. Taking into account that all three of the consultand's sons are unaffected, Bayesian analysis allows us to *exclude* 7/16 of the prior probabilities, those that include one or more affected sons, from consideration. (Note that this explains why the joint probabilities sum to less than 1.) The posterior probability that the consultand is a carrier is therefore the area of the small rectangle with three unshaded squares (for three unaffected sons) divided by the area of the entire reversed-L-shaped box, which represents the only probabilities relevant to the consultand's risk, or 1/16 ÷ 9/16 = 1/9. Likewise, the posterior probability that the consultand is a non-carrier is the area of the larger rectangle with three unshaded squares (for three unaffected sons) divided by the area of the entire reversed-L-shaped box, or 8/16 ÷ 9/16 = 8/9.

Bayesian Analysis Using Genetic Test Results

In the second example, information from a test result modifies the prior risk. In the pedigree shown in Fig. 5.2a, the consultand is pregnant with her first child and has a family history of cystic fibrosis (CF; OMIM #219700). CF is caused by mutations in the cystic fibrosis transmembrane conductance regulator gene (*CFTR*; OMIM #602421). The consultand is an unaffected European Caucasian and her brother died years earlier of complications of CF. She undergoes carrier testing for the 23 mutations recommended by the American College of Medical Genetics (ACMG) CF screening guidelines [11–13], which detects approximately 90 % of disease alleles in European Caucasians. The consultand tests negative for all 23 mutations. What is her carrier risk after testing?

As in the first example, the two hypotheses are that the consultand is a carrier and that she is a non-carrier. The prior probability that she is a carrier is 2/3. Because the consultand is unaffected, she could not have inherited disease alleles from both parents. Thus, she either inherited a disease allele from her mother or father, or she inherited only normal alleles; in two of these three scenarios she would be a carrier (shown in Fig. 5.2b). The prior probability that the consultand is a non-carrier is 1/3 (Fig. 5.2c).

As in the first example, the conditional probability for each hypothesis is the probability that the subsequent information would occur if we assume that each hypothesis is true. In this example, the subsequent information is that the consultand tests negative for all 23 mutations. Thus, the conditional probabilities are the probability that the consultand would test negative under the assumption (or "condition") that she is a carrier, and the probability that she would test negative under the assumption (or "condition") that she is a non-carrier. If we assume that she is a carrier, the probability that she would test negative is 1/10, since the test detects 90 % of European Caucasian disease alleles or carriers. If we assume that she is a non-carrier, the probability that she would test negative approximates 1. Thus, the conditional probabilities in this example are 1/10 and 1 for the carrier and non-carrier hypotheses, respectively (Fig. 5.2c).

(**d**) Schematic representation of the Bayesian analysis of **c** (see text)

As in the first case, the joint probability for each hypothesis is the product of the prior and conditional probabilities for that hypothesis. For the first hypothesis in this example, that the consultand is a carrier, the joint probability is the prior probability that she is a carrier (2/3) multiplied by the conditional probability that a carrier of European Caucasian ancestry would test negative (1/10), or $2/3 \times 1/10 = 1/15$ (Fig. 5.2c). For the second hypothesis in this example, that the consultand is a non-carrier, the joint probability is the prior probability that she is a non-carrier (1/3) multiplied by the conditional probability that a non-carrier would test negative (1), or $1/3 \times 1 = 1/3$ (Fig. 5.2c).

Finally, the posterior probability is calculated for each hypothesis by dividing the joint probability for that hypothesis by the sum of all the joint probabilities. In this example, the posterior probability that the consultand is a carrier and tests negative for 23 CF mutations is the joint probability for the first hypothesis (1/15) divided by the sum of the joint probabilities for both hypotheses ($1/15 + 1/3 = 2/5$), or $1/15 \div 2/5 = 1/6$ (Fig. 5.2c). The posterior probability that the consultand is a non-carrier and tests negative for 23 CF mutations is the joint probability for the second hypothesis (1/3) divided by the sum of the joint probabilities for both hypotheses (2/5), or $1/3 \div 2/5 = 5/6$ (Fig. 5.2c).

The preceding example is illustrated graphically in Fig. 5.2d. The total area represents the total prior probabilities. The left 2/3 represents the prior probability that the consultand is a carrier, and the right 1/3 represents the prior probability that the consultand is a non-carrier. Under the hypothesis that the consultand is a carrier, there are two possibilities for the test result: positive or negative. The area of the small rectangle on the lower left comprises 1/10 of the 2/3 carrier region and represents the conditional probability of a normal test result under the hypothesis that the consultand is a carrier. The area of this small rectangle is $1/10 \times 2/3 = 1/15$ of the total probabilities area and therefore also represents the joint probability that the consultand is a carrier (2/3) and that as a European-Caucasian carrier she would test negative for all 23 mutations (1/10), or $2/3 \times 1/10 = 1/15$ (Fig. 5.2d).

Under the hypothesis that the consultand is a non-carrier, there is essentially only one possibility for the test result, which is negative. The area of the rectangle that comprises all of the 1/3 non-carrier region represents the conditional probability of a negative test result under the hypothesis that the consultand is a non-carrier. The area of this rectangle is 1/3 of the total area and therefore also represents the joint probability that the consultand is a non-carrier (1/3), and that as a non-carrier she would test negative (~1), or $1/3 \times 1 = 1/3$. The "reverse-L-shaped" box, which is demarcated by a bold line, represents the sum of the joint probabilities, or 2/5 (=1/3 + 1/15) of the total area.

Because the consultand tested negative, the area of the reverse-L-shaped box represents the only component of the prior probabilities needed to determine the posterior probability that the consultand is a carrier. Taking into account that she tested negative, Bayesian analysis allows us to *exclude* 3/5 of the prior probability, that portion comprising a positive test result, from consideration. (Note, again, that this explains why the joint probabilities sum to less than 1.) The posterior probability that the consultand is a carrier is therefore the area of the small rectangle at the lower left divided by the area of the reverse-L-shaped box, which represents the only probabilities relevant to the consultand's risk, or $1/15 \div 2/5 = 1/6$. Likewise, the posterior probability that the consultand is a non-carrier is the area of the larger rectangle on the right divided by the area of the reverse-L-shaped box, or $1/3 \div 2/5 = 5/6$.

Simple Bayesian Analyses Generalized: Carrier vs Non-carrier

The preceding Bayesian analyses can be generalized as in Table 5.1. Note that if the correct prior and conditional probabilities can be determined, the rest is simple calculation. Setting up a spreadsheet, as in Table 5.1, facilitates clinical Bayesian analyses.

A very common application of Bayesian analysis in molecular pathology is to calculate carrier risk after a negative test result, as in the second example above. The need to calculate carrier risk in this scenario stems from the fact that the sensitivity of most carrier tests is, at present, less than 100 %; therefore, a negative test result decreases, but does not eliminate, carrier risk. Hypothesis 1 in this scenario is that the consultand is a carrier, and Hypothesis 2 is that the consultand is a non-carrier (Table 5.1). The prior carrier probability ("A" in Table 5.1) depends on whether there is a family history, and if so, the relationship of the consultand to the affected family member as shown by the family pedigree. In the absence of a family history, the prior carrier probability is the population carrier risk for that disease. In the case of cystic fibrosis (CF) and some other diseases, the appropriate population risk depends on the ethnicity of the consultand. The conditional probabilities ("C" and "D" in Table 5.1) are one minus the test sensitivity for the carrier hypothesis, and the test specificity for the non-carrier hypothesis, respectively. The remainder of the table is completed through calculation, with the posterior probabilities ("G" and "H" in Table 5.1) representing one minus the negative predictive value, and the negative predictive value, respectively. This is shown schematically in Fig. 5.3.

For illustration, suppose in the second example above (Fig. 5.2) that the consultand's husband is Ashkenazi Jewish, that he has no family history of CF, and that he tests negative for all 23 mutations in the ACMG screening guidelines panel. What is his carrier risk? The carrier risk in Ashkenazi Jewish populations, and therefore the husband's prior carrier risk in the absence of a family history, is approximately 1/25 ("A" in Table 5.1). Thus, his prior probability of being a non-carrier is 24/25 ("B" in Table 5.1). The ACMG screening guidelines panel of 23 mutations detects 94 % of CF mutations in Ashkenazi Jewish populations [11–13], so the conditional probability of a negative test, under the hypothesis that he is a carrier, is 6 % = 3/50 ("C" in Table 5.1). Under the hypothesis that he is a non-carrier, the conditional probability of a negative test approximates 1 ("D" in Table 5.1). (This is generally the case in genetic testing, since non-carriers by definition lack mutations in the relevant disease gene and hence, unless there are technical problems, essentially always should test negative.) The Bayesian analysis table for this example is shown in Table 5.2. The joint probabilities ("E" and "F" in Table 5.1) are the products of the prior and conditional probabilities, and the posterior probabilities ("G" and "H" in Table 5.1) derive from each joint probability

Table 5.1 Simple Bayesian analyses generalized

	Hypothesis	
	1	2
Prior probability	A	B = 1 − A
Conditional probability	C	D
Joint probability	E = AC	F = BD
Posterior probability	G = E/(E + F)	H = F/(E + F)

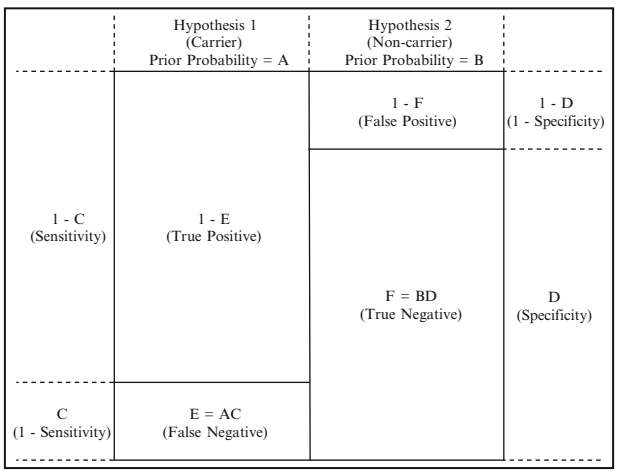

Figure 5.3 Schematic representation of the generalized Bayesian analysis shown in Table 5.1, for the case of a negative carrier test. The *small boxes* represent true positive, false positive, true negative, and false negative rates for a particular consultand, i.e., the prior probabilities are influenced by factors such as family history or signs and symptoms, and the sensitivity and specificity of the test are influenced by factors such as ethnicity. For a negative carrier test, the posterior carrier probability (one minus the negative predictive value) is the false negative rate divided by the sum of the false and true negative rates, or E/(E + F).

Table 5.2 Bayesian analysis for an Ashkenazi Jewish individual without a family history of CF who tests negative for the ACMG screening guidelines panel of 23 *CFTR* mutations

	Hypothesis	
	Carrier	**Non-carrier**
Prior probability	1/25	24/25
Conditional probability (of negative test result)	3/50	1
Joint probability	3/1,250	24/25
Posterior probability	(3/1,250)/(3/1,250 + 24/25) = 1/401	(24/25)/(3/1,250 + 24/25) = 400/401

Table 5.3 Bayesian analysis for the consultand in Fig. 5.2a after testing of the parents (see text)

	Hypothesis	
	Carrier	**Non-carrier**
Prior probability	2/3	1/3
Conditional probability (of negative test result)	1/2	1
Joint probability	1/3	1/3
Posterior probability	(1/3)/(1/3 + 1/3) = 1/2	(1/3)/(1/3 + 1/3) = 1/2

Table 5.4 Alternative Bayesian analysis for the consultand in Fig. 5.2a after testing of the parents (see text)

	Hypothesis		
	Carrier		
	Carrier with paternal (detectable) mutation	**Carrier with maternal (undetectable) mutation**	**Non-carrier**
Prior probability	1/3	1/3	1/3
Conditional probability (of negative test result)	0	1	1
Joint probability	0	1/3	1/3
Posterior probability	0	1/2	1/2

divided by the sum of the joint probabilities. The husband's posterior carrier risk after the negative test result is 1/401.

What is the risk that the fetus of the mother (consultand) in Fig. 5.2 and the father from Table 5.2 is affected with CF? Prior to testing, the risk was the prior probability that the mother was a carrier (2/3), times the prior probability that the father was a carrier (1/25), times the probability that the fetus would inherit two disease alleles (1/4), or $2/3 \times 1/25 \times 1/4 = 1/150$. After testing, the risk is the posterior probability that the mother is a carrier (1/6), times the posterior probability that the father is a carrier (1/401), times the probability that the fetus would inherit two disease alleles (1/4), or $1/6 \times 1/401 \times 1/4 \cong 1/9{,}600$.

Often, testing is performed on additional family members and genetic risks need to be modified accordingly. In the example above, testing of both parents of the mother (consultand) would affect her carrier risk calculations. Detection of mutations in both parents using the same mutation test panel would essentially rule out carrier status for the mother, since we would then know that the sensitivity of the test for the mutations she is at risk of carrying is essentially 100 %. Alternatively, if the test results for the mother's parents only are positive for one of her parents (for example, her father) and negative for the other parent (her mother), then the sensitivity of the test for the mutations she is at risk of carrying is essentially 50 %. The Bayesian analysis for the mother, modified from Fig. 5.2c, is shown in Table 5.3. The conditional probability of a negative test under the hypothesis that she is a carrier has changed from 1/10 to 1/2, which increases the posterior probability that she is a carrier to 1/2. Taken together with her husband's carrier risk of 1/401 (Table 5.2), the risk that the fetus is affected with CF can be modified to $1/2 \times 1/401 \times 1/4 \cong 1/3{,}200$.

Another way of conceptualizing the Bayesian analysis described above is to separate the carrier hypothesis into two sub-hypotheses as shown in Table 5.4. (See also Sect. "Bayesian Analyses with More Than Two Hypotheses" below.) The two sub-hypotheses are (1) that the consultand is a carrier with a paternal (detectable) mutation and (2) that she is a carrier with a maternal (undetectable) mutation. The prior probability of each hypothesis is 1/3; i.e., half of 2/3. The conditional probability of a negative test result, under the sub-hypothesis that she is a carrier of a detectable paternal mutation, is 0. The conditional probability of a negative test result, under the sub-hypothesis that she is a carrier of an undetectable maternal mutation, is 1. As in the generalized Bayesian analysis shown in Table 5.1, the joint probability for each hypothesis is the product of the prior and conditional probabilities for that hypothesis, and the posterior probability for each hypothesis is the joint probability for that hypothesis divided by the sum of all the joint probabilities. The posterior probability that she has a detectable paternal mutation is 0, and the posterior probability that she has an undetectable maternal mutation is 1/2 (Table 5.4).

Simple Bayesian Analyses Generalized: Affected vs Unaffected

Another common application of Bayesian analysis in molecular pathology is to calculate the risk that a patient is affected with a particular disease after a negative test result. Again, the need to calculate risk in this scenario stems from the fact that the sensitivities of many genetic tests are less than

Table 5.5 Bayesian analysis for a child with clinically typical type III SMA who tests negative for homozygous deletions of the *SMN1* gene

	Hypothesis	
	Affected	**Unaffected**
Prior probability	0.87	0.13
Conditional probability (of negative test result)	0.06	~1
Joint probability	0.052	0.13
Posterior probability	0.29	0.71

Table 5.6 Bayesian analysis for a child with clinically typical type III SMA who has one copy of the *SMN1* gene by dosage analysis

	Hypothesis	
	Affected	**Unaffected**
Prior probability	0.87	0.13
Conditional probability (of one-copy test result)	0.06	0.021
Joint probability	0.052	0.0027
Posterior probability	0.95	0.05

100 %. Hypothesis 1 (in Table 5.1 and Fig. 5.3) in this scenario is that the patient is affected, and Hypothesis 2 is that the patient is unaffected. The prior probability ("A" in Table 5.1 and Fig. 5.3) usually derives mostly from signs and symptoms, but also may depend on aspects of the patient's history, including family history in diseases with a genetic component. As in the CF example above, the conditional probabilities ("C" and "D" in Table 5.1 and Fig. 5.3) are one minus the test sensitivity for the affected hypothesis, and the test specificity for the unaffected hypothesis, respectively. The remainder of the analysis is accomplished by calculation, with the posterior probabilities ("G" and "H" in Table 5.1) representing one minus the negative predictive value, and the negative predictive value, respectively.

For example, suppose that a Caucasian child with clinically typical type III spinal muscular atrophy (type III SMA; Kugelberg-Welander disease; OMIM #253400) tests negative for the homozygous deletion of the *SMN1* gene found in most affected individuals. What is the probability that the child is affected with *SMN1*-linked SMA? The Bayesian analysis for this scenario is shown in Table 5.5. Wirth et al. found that 17 of 131 individuals with clinically typical type III SMA lacked mutations in both *SMN1* alleles (and therefore were considered to have diseases unrelated to *SMN1*) [14]; hence the prior probability that the child is affected with *SMN1*-linked type III SMA is 114/131 or 0.87. Approximately 6 % of individuals with *SMN1*-linked type III SMA have a deletion of one *SMN1* allele and a subtle mutation, undetectable by simple PCR testing for a homozygous deletion, in the other *SMN1* allele [15]; hence, the conditional probability of a negative test result under the hypothesis that the child is affected is 6/100 or 0.06. Homozygous deletions of *SMN1*, when present, are highly specific for *SMN1*-linked SMA; hence the conditional probability of a negative test result under the hypothesis that the child is unaffected with *SMN1*-linked SMA approximates 1. Following the simple calculation rules in Table 5.1, the posterior probability that the child is affected with *SMN1*-linked type III SMA is approximately 0.29 (Table 5.5).

Suppose that *SMN1* dosage analysis is performed on the child's DNA (i.e., the SMA carrier test), and the result is that the child has one copy of the *SMN1* gene. What is the probability that he or she is affected with *SMN1*-linked SMA? The Bayesian analysis for this scenario is shown in Table 5.6. Again, the prior probability that the child is affected with *SMN1*-linked type III SMA is 0.87. Because approximately 6 % of individuals with *SMN1*-linked type III SMA have a deletion of one *SMN1* allele and a subtle mutation in the other *SMN1* allele that is detectable as a single copy by dosage analysis [15], the conditional probability of a one-copy test result under the hypothesis that the child is affected is again 0.06. However, the carrier frequency for SMA in the Caucasian population is approximately 1/47 [16]; hence, in this scenario, the conditional probability of a single-copy test result under the hypothesis that the child is unaffected with *SMN1*-linked SMA is 1/47 or 0.021. Following the simple calculation rules in Table 5.1, the posterior probability that the child is affected with *SMN1*-linked type III SMA is approximately 0.95 (Table 5.6).

Suppose instead that the result of the *SMN1* dosage analysis is that the child has two copies of the *SMN1* gene. What is the probability that the child is affected with *SMN1*-linked SMA? The Bayesian analysis for this scenario is shown in Table 5.7. Again, the prior probability that the child is affected with *SMN1*-linked type III SMA is 0.87. Only approximately 9 in 10,000 individuals with *SMN1*-linked type III SMA would be expected to have two subtle, non-deletion mutations, detectable as two copies by dosage analysis [15]; hence, the conditional probability of a two-copy test result under the hypothesis that the child is affected is approximately 0.0009. Because approximately 6.9 % of unaffected Caucasian individuals have three copies of the *SMN1* gene, and approximately 2.1 % of unaffected Caucasian individuals have one copy of the *SMN1* gene, for a total of 9 % of unaffected Caucasian individuals without two copies of *SMN1* [16], the conditional probability of a two-copy test result under the hypothesis that the child is unaffected with *SMN1*-linked SMA is 91/100 or approximately 0.9. Following the simple calculation rules in Table 5.1, the posterior probability that the child is affected with *SMN1*-linked type III SMA is only approximately 0.006 (Table 5.7).

Profiling by proteomics, RNA microarrays, and/or analysis of single-nucleotide polymorphisms (SNPs) is likely to play an important role in molecular pathology, and clinical test results will be reported, in many cases, as probabilities or

Table 5.7 Bayesian analysis for a child with clinically typical type III SMA who has two copies of the *SMN1* gene by dosage analysis

	Hypothesis	
	Affected	**Unaffected**
Prior probability	0.87	0.13
Conditional probability (of two-copy test result)	0.0009	0.9
Joint probability	0.00078	0.12
Posterior probability	0.006	0.994

Table 5.8 Bayesian analysis for a consultand with a 20 % lifetime risk of developing a disease and a proteomic profile 16 times more common in those who develop the disease than in those who do not

	Hypothesis	
	Affected eventually	**Never affected**
Prior probability	0.2	0.8
Conditional probability (of profiling result)	16	1
Joint probability	3.2	0.8
Posterior probability	0.8	0.2

relative risks. For example, suppose that a consultand has a 20 % lifetime risk of developing a particular disease (based on family history, physical examination, and/or clinical laboratory test results) and that his or her proteomic profile is 16 times more common in those who go on to develop the disease than in those who do not. What is his or her lifetime risk of developing the disease? The Bayesian analysis for this scenario is shown in Table 5.8. Hypothesis 1 (from Table 5.1) is that the consultand will develop the disease, and Hypothesis 2 is that the consultand will not develop the disease. The prior probabilities are 0.2 and 0.8 for Hypotheses 1 and 2, respectively. Because the conditional probability of the proteomic profiling result is 16 times more likely in those who develop the disease than in those who do not, the conditional probabilities ("C" and "D" in Table 5.1) are 16 and 1, respectively. Following the simple calculation rules in Table 5.1, the posterior probability that the consultand will develop the disease is 0.8 (Table 5.8).

Note that because posterior probabilities are normalized joint probabilities, the absolute values of the conditional probabilities are unimportant, as long as the ratio (i.e., the odds ratio) between them is correct. This also is true of prior probabilities. For example, in the scenario above, prior probabilities of 1 and 4 can be substituted for 0.2 and 0.8 and the same answer is obtained. Likewise, in the first example of this chapter (Fig. 5.1a), prior probabilities of 1 and 1 can be substituted for 1/2 and 1/2, and conditional probabilities of 1 and 8 can be substituted for 1/8 and 1, and the same answer is obtained. Hence, relative risks are easily incorporated into Bayesian analyses.

Bayesian Analyses with More Than One Conditional Probability

Often there is more than one test result, and/or pedigree information, that can be incorporated as conditional probabilities in a single Bayesian analysis. For example, consider the pedigree in Fig. 5.4a, in which the two maternal great uncles of the consultand were affected with Duchenne muscular dystrophy (DMD; OMIM #310200), a severe X-linked recessive disease caused by mutations in the *DMD* gene (OMIM

	Hypothesis	
	Carrier	Non-carrier
Prior Probability	1/8	7/8
Conditional probability (of negative genetic test result)	1/3	1
Conditional Probability (of normal CPK result)	1/3	19/20
Conditional Probability (of three normal sons)	1/8	1
Joint Probability	1/576	133/160
Posterior Probability	0.002	0.998

Figure 5.4 (**a**) Pedigree of a family with individuals affected with DMD (see text). (**b**) Bayesian analysis for the consultand in **a**, taking into account her normal carrier test result, her normal CPK test result, and her three normal sons

#300377). Her maternal grandmother's carrier risk was 1/2, her mother's carrier risk was 1/4, and therefore her prior carrier risk is 1/8. Suppose that her carrier testing is negative using a highly specific test (an analysis for heterozygous deletions in the *DMD* gene) that detects 2/3 of carriers. Suppose also that her serum creatine phosphokinase (CPK), which is elevated in 2/3 of carriers, is within normal limits. Taking into account her prior probability of 1/8, her normal molecular and CPK test results, and, in addition, her three normal sons, what is the probability that she is a carrier?

The Bayesian analysis for this scenario is shown in Fig. 5.4b. Each conditional probability is given its own line. Because the genetic test detects 2/3 of carriers and is highly specific, the conditional probabilities of a negative genetic test result under the hypotheses that she is a carrier and non-carrier are 1/3 and 1, respectively. Because serum CPK is elevated in 2/3 of carriers, the conditional probability of a normal serum CPK for the hypothesis that she is a carrier is 1/3. Because 5 % of non-carrier women have an abnormal serum CPK (i.e., the normal range is defined as comprising 95 % of normal individuals), the conditional probability of a normal serum CPK under the hypothesis that she is a non-carrier is 95 % or 19/20. Finally, as in Fig. 5.1b, the conditional probabilities of three normal sons under the hypotheses that she is a carrier and non-carrier are 1/8 and 1, respectively. The joint probabilities for each hypothesis are the products of the prior probability, and all conditional probabilities, for each hypothesis (Fig. 5.4b). Calculation of posterior probabilities then proceeds exactly as in Table 5.1. In this scenario, taking into account her normal test results and her three normal sons, the consultand's carrier risk is lowered from 1/8 to 0.002, or approximately 1/500.

Bayesian Analyses with More Than Two Hypotheses

In some Bayesian analyses, more than two hypotheses must be considered. For example, consider the pedigree in Fig. 5.5a, in which a child with clinically typical type I spinal muscular atrophy (type I SMA; Werdnig–Hoffmann disease; OMIM #253300) lacks both copies of the *SMN1* gene. By dosage analysis, the child's (unaffected) mother has one copy of the *SMN1* gene and, therefore, carries one copy of the *SMN1* gene on one chromosome 5, and zero copies of the *SMN1* gene on the other chromosome 5, called the "1+0" genotype. However, the child's (unaffected) father has two copies of the *SMN1* gene and therefore could have one of three possible genotypes: (1) two copies of the *SMN1* gene on one chromosome 5 and zero copies of the *SMN1* gene on the other chromosome 5 (the "2+0" genotype), (2) one copy of the *SMN1* gene on one chromosome 5 and a subtle mutation in the *SMN1* gene on the other chromosome 5 (the "$1+1^{D}$" genotype, where "1^{D}" stands for a "one-copy-disease" allele), or (3) one copy of the *SMN1* gene on each chromosome 5 (the "1+1" non-carrier genotype), in which case he passed a *de novo* deletion of the *SMN1* gene to his affected child. The relative frequencies of the various *SMN1* alleles in several major ethnic groups are known [16], which allows the corresponding genotype frequencies to be calculated [15]. The paternal and maternal de novo deletion rates are also known ($\mu_p = 2.11 \times 10^{-4}$ and $\mu_m = 4.15 \times 10^{-5}$, respectively) [15]; thus, the probability that the father is a carrier can be calculated, which obviously has important implications for recurrence risk.

Posterior Probability	0.68	0.32	0.00014

Figure 5.5 (**a**) Pedigree of a family with an individual affected with type I SMA, with the SMA carrier test results indicated below each individual (see text). (**b**) Bayesian analysis for the father of the affected child in **a**, assuming Asian ethnicity

Assuming Asian ethnicity for the father, the Bayesian analysis for the father's carrier risk is shown in Fig. 5.5b. There are three hypotheses for the father's genotype: 2+0, 1+1, and $1+1^{D}$. The prior probabilities are the relative frequencies for these genotypes in Asian populations [16]. The conditional probabilities are the probabilities that the father passes a 0-copy allele to his child under each hypothesis. For the 2+0 genotype, the conditional probability of passing a 0-copy allele is 0.5, whereas for the 1+1 and $1+1^{D}$ genotypes, the conditional probability of passing a 0-copy allele is the de novo deletion rate of μ_p. As in the generalized Bayesian analysis shown in Table 5.1, the joint probability for each hypothesis is the product of the prior and conditional probabilities for that hypothesis, and the posterior probability for each hypothesis is the joint probability for

that hypothesis divided by the sum of all the joint probabilities. The father's carrier risk is the sum of the posterior probabilities of the first (2+0) and third ($1+1^D$) columns, or approximately 0.68. The third column contributes little to the carrier risk because the frequency of the $1+1^D$ genotype is low and the conditional probability of a de novo deletion is also low. In contrast, although the frequency of the 2+0 genotype is much lower than that of the 1+1 genotype, this is counterbalanced by the higher conditional probability of passing a 0-copy allele under the former hypothesis.

Suppose that the father's parents, the paternal grandfather and grandmother of the affected child, are tested and found to have three copies and one copy of the *SMN1* gene, respectively (Fig. 5.6a). What is the father's carrier risk? The Bayesian analysis for this scenario is shown in Fig. 5.6b. Again, there are three hypotheses for the father's genotype: 2+0, 1+1, and $1+1^D$. However, in this scenario, the father's prior probabilities derive from the prior and conditional probabilities of his parents. Because the grandfather has three copies of the *SMN1* gene, his genotype is either 2+1 (columns A and C) or $2+1^D$ (columns B and D), and his prior probabilities are the relative frequencies for these genotypes in Asian populations [16]. Because the (unaffected) grandmother has one copy of the *SMN1* gene, her genotype is 1+0, and her prior probability is the relative population frequency of the 1+0 genotype for type I SMA in Asian populations, which is the carrier frequency of 1/64 (1.57×10^{-2}) [15]. (Note that because the grandmother must have a 1+0 genotype, simply a prior probability of 1 could be used; as noted above, the absolute values of the conditional probabilities are unimportant, as long as the ratio between them is correct.) The four columns (A through D) show the four possible permutations of grandparental genotypes (prior probabilities) with passage of particular alleles to the father (conditional probabilities) so that he would have a two-copy SMA carrier test result. Under the hypothesis that the father has a 2+0 genotype, he could have inherited a two-copy "allele" (two copies of *SMN1* on one chromosome 5) from the grandfather (2+1) at a probability of 0.5 and a 0-copy allele from the grandmother (1+0) at a probability of 0.5 (column A), or he could have inherited a two-copy allele from the grandfather ($2+1^D$) at a probability of 0.5 and a 0-copy allele the grandmother (1+0) at a probability of 0.5 (column B). Under the hypothesis that the father has a 1+1 genotype, he could have inherited a one-copy allele from the grandfather (2+1) at a probability of 0.5 and a one-copy allele the grandmother (1+0) at a probability of 0.5 (column C). Under the hypothesis that the father has a $1+1^D$ genotype, he could have inherited a 1^D allele from the grandfather ($2+1^D$) at a probability of 0.5 and a one-copy allele the grandmother (1+0) at a probability of 0.5 (column D).

The father's prior probabilities are the products of the prior and conditional probabilities for the grandparents for each column/permutation. Under the hypothesis that the father is 2+0, the conditional probability of passing a 0-copy allele to his child is 0.5 (columns A and B), whereas under the hypothesis that the father has a 1+1 or $1+1^D$ genotype, the conditional probability of passing a 0-copy allele to his child is the de novo deletion rate of μ_p (columns C and D). As in the generalized Bayesian analysis shown in Table 5.1, the joint probability for each column is the product of the prior and conditional probabilities for that column, and the posterior probability for each column is the joint probability for that column divided by the sum of all the joint probabilities. The father's carrier risk is the sum of the posterior probabilities of columns A (2+0), B (2+0), and D ($1+1^D$), or approximately 0.999. The father's increased carrier risk in this scenario derives almost entirely from the probability that he has the 2+0 genotype; this is unsurprising since the grandfather's three-copy test result demonstrates the presence of a two-copy allele in the family. (Note that because the grand-

mother's prior and conditional probabilities are the same in every column, excluding her data from the analysis will not change the result.)

Suppose instead that the father's parents, the paternal grandfather and grandmother of the affected child, are tested and both are found to have two copies of the *SMN1* gene (Fig. 5.7a). What is the father's carrier risk? The Bayesian analysis for this scenario is shown in Fig. 5.7b, again assuming Asian ethnicity. Again, there are three hypotheses for the father's genotype: 2+0, 1+1, and $1+1^D$. However, in this scenario, the number of possible permutations of grandparental genotypes (prior probabilities) with passage of particular alleles to the father (conditional probabilities) is dramatically increased. This is because each grandparent could have either a 2+0, 1+1, or $1+1^D$ genotype, and the father could have received a two-copy allele, a 0-copy allele, a one-copy allele, or a 1^D allele from either grandparent, in most cases by direct Mendelian inheritance and in some cases from de novo deletions. The organization of the Bayesian analysis in Fig. 5.7b is guided by the possible genotypes of the father, which determine the grandparental genotype permutations that need to be considered. Under the hypothesis that the father has the 2+0 genotype, he could have received a two-copy allele from one [2+0] grandparent and a 0-copy allele from the other [2+0] grandparent, both by direct inheritance (columns A and B), or he could have

Figure 5.7 (continued)

received a two-copy allele from one [2+0] grandparent by direct inheritance and a de novo deletion allele from the other [1+1 or $1+1^D$] grandparent (columns C, D, E, and F). Under the hypothesis that the father has the 1+1 genotype, he must have received a one-copy allele from each [1+1 or $1+1^D$] grandparent (columns G, H, I, and J). Under the hypothesis that the father has the $1+1^D$ genotype, he must have received a one-copy allele from one [1+1 or $1+1^D$] grandparent and a 1^D allele from the other [1+1 or $1+1^D$] grandparent (columns K, L, M, and N).

More specifically, under the hypothesis that the father has the 2+0 genotype, column A shows the prior probability that the grandfather has a 2+0 genotype (7.87×10^{-4}), the conditional probability that he passes a two-copy allele to the father (0.5), the prior probability that the grandmother has a 2+0 genotype (7.87×10^{-4}), and the conditional probability that she passes a 0-copy allele to the father (0.5). Under the hypothesis that the father has the 1+1 genotype, column G shows the prior probability that the grandfather has a 1+1 genotype (0.89), the conditional probability that he passes a one-copy allele to the father (1), the prior probability that the grandmother has a 1+1 genotype (0.89), and the conditional probability that she passes a one-copy allele to the father (1). Under the hypothesis that the father has the $1+1^D$ genotype, column K shows the prior probability that the grandfather has a 1+1 genotype (0.89), the conditional probability that he passes a one-copy allele to the father (1), the prior probability that the grandmother has a $1+1^D$ genotype (3.78×10^{-4}), and the conditional probability that she passes a 1^D allele to the father (0.5).

Again, the father's prior probabilities are the products of the prior and conditional probabilities for the grandparents for each column/permutation. Under the hypothesis that the father has a 2+0 genotype, the conditional probability of passing a 0-copy allele to his child is 0.5 (columns A through F), whereas under the hypothesis that the father has a 1+1 or $1+1^D$ genotype, the conditional probability of passing a 0-copy allele to his child is the de novo deletion rate of μ_p (columns G through L). As in the generalized Bayesian analysis shown in Table 5.1, the joint probability for each column is the product of the prior and conditional probabilities for that column, and the posterior probability for each column is the joint probability for that column divided by the sum of all the joint probabilities. The father's carrier risk is the sum of the posterior probabilities of columns A through F (2+0), and K through N ($1+1^D$), or approximately 1/622. Relative to the previous scenario (Fig. 5.6), in which the father also had two copies of *SMN1* but the grandparents had different *SMN1* copy numbers, the father's dramatically decreased carrier risk in this scenario derives from the much lower

probability that a two-copy allele is present in his family, and illustrates the importance of integrating all available genetic testing information into risk assessment calculations.

The use of one comprehensive Bayesian analysis table incorporating all necessary information allows simultaneous calculations of the carrier risks of the father, grandfather, and grandmother. Such a comprehensive approach is necessary because the two-copy test results for the grandparents influence the carrier risk of the father, and the two-copy test result for the father influences the carrier risks of the grandparents. Using Fig. 5.7b, the posterior carrier risk of the grandfather is the sum of the posterior probabilities of columns A through D, F, I, J, and L through N, or approximately 0.0014 (1/720), and the carrier risk of the grandmother is the sum of the posterior probabilities of columns A, B, D through F, H, J, K, M, and N, or approximately 0.0016 (1/640). The posterior probability that all three of them are carriers is the sum of the posterior probabilities of columns A, B, D, F, M, and N, or approximately 0.00092 (1/1,085).

From carrier testing more than 72,000 individuals for SMA, Sugarman et al. showed that SMA allele frequencies differ significantly by ethnicity; in particular, they found that 27.5 % of alleles in the African-American population are two-copy, which is dramatically higher than in other ethnic groups [16]. If we repeat the Bayesian analysis shown in Fig. 5.7b, assuming African American, rather than Asian, ethnicity, the result is very different (Fig. 5.7c); specifically, the father's carrier risk (again, the sum of the posterior probabilities of columns A through F [2+0], and K through N [$1+1^{D}$]) is approximately 1/16. The reason the carrier risk is so much higher in this case is that, because of the higher two-copy allele frequency in the African-American population compared to Asian populations, the prior probability that the grandparents are 2+0, rather than 1+1 or $1+1^{D}$, is many fold higher. Thus, as in the case of CF, the appropriate population risk depends on the ethnicity of the consultand, and the consultand's family, and must be taken into account in genetic risk assessment for SMA.

Concluding Remarks

Bayesian analysis plays a central role in genetic risk assessment, and those who offer genetic testing should be proficient. Genetic risk should be assessed as accurately as possible, using all available information at a particular point in time, including the most up-to-date estimates of carrier and allele frequencies, information from the pedigree, and results of laboratory testing. Although the technologies for genetic testing will continue to change, Bayesian analysis and genetic risk assessment will remain fundamental aspects of genetic testing and genetic counseling.

Intellectual Disability and Developmental Delay: Cytogenetic Testing

6

Guangyu Gu, Reha Toydemir, and Sarah T. South

Abstract

Intellectual disability/developmental delay (ID/DD) is not a specific diagnosis, but a description of certain conditions in which intellectual functioning shows significant limitations when compared to the expected level for age. This chapter discusses the methods for evaluating an individual for ID/DD. In addition, advantages, limitations, and interpretation challenges are discussed.

Keywords

Intellectual disability • Developmental delay • Comparative genomic hybridization • Array • Chromosomes • Copy number variants • Deletions • Cytogenetic • Microdeletion • Microduplication • Microarray

Introduction

Intellectual disability and developmental delay (ID/DD) is not a specific diagnosis. It is rather a description of certain conditions in which intellectual functioning or at least two areas of adaptive performance show significant limitations when compared to the expected level for age. The adaptive areas include gross or fine motor skills, speech or language, cognition, social or personal, and activities related to daily living. A significant delay is described as two or more standard deviations from the age and cultural norms. The prevalence of ID/DD is approximately 3 % [1] with some studies suggesting up to 16 % of children referred to pediatric clinics have some developmental problems [2].

Clinical Utility

Early identification of the underlying etiology of ID/DD is critical for treatment planning, prognosis, and family planning. Although fairly common, the cause of ID/DD remains mostly unknown. This is due in part to the highly heterogeneous etiology of ID/DD. Both genetic causes and environmental factors affect the development of the brain. The development of the brain requires the orchestrated action of many genes. In fact, 86 % of human genes are involved in the formation and differentiation of the human brain [3]. As chromosomal aberrations are considered a major cause of non-syndromic ID/DD [4, 5], cytogenetic studies are recommended for all children with ID/DD when an etiology has not been determined [6, 7].

Available Assays

Over the past few decades, many exciting advances in cytogenetics and molecular cytogenetics have allowed the identification of genomic imbalances related to ID/DD in an increasing number of both mild and severe cases. Conventional cytogenetics techniques, such as G-banding, have been widely used to detect numerical and structural chromosomal

D.G.B. Leonard (ed.), *Molecular Pathology in Clinical Practice*, DOI 10.1007/978-3-319-19674-9_6

abnormalities, including deletions, duplications, and translocations. The development of fluorescence in situ hybridization (FISH) methods has enabled the identification of many microdeletion and microduplication syndromes and subtelomere rearrangements that are generally undetectable by conventional banding techniques [8, 9]. Most recently, chromosomal microarray analysis (CMA), including array-based comparative genomic hybridization (aCGH) and single-nucleotide polymorphism (SNP) arrays, has become a standard cytogenetic diagnostic test for the identification of copy number variations (CNVs) in patients with DD [10, 11].

G-Banded Karyotyping

In cases of DD with and without dysmorphic features, G-banded karyotyping is still a valuable technique that allows for analysis of chromosomes from a tissue of interest to identify large-scale genomic aberrations. This conventional cytogenetic approach may detect aneuploidy, chromosomal mosaicism, and many other structural abnormalities (Fig. 6.1). The limit of resolution of G-banding is between 5 and 10 Mb and depends on the region of the genome and the length of chromosomes. The rearrangements of chromosome segments smaller than 5 Mb cannot reliably be detected. Likewise, the chromosomal origin of a small marker chromosome may not be identified by G-banded karyotyping.

Fluorescence In Situ Hybridization

FISH approaches were first described in 1986 [12] and have become essential for many comprehensive cytogenetic analyses. Most any DNA segment can be used as a FISH probe. For clinical use, most probes are between 100 and 500 kb. This provides a resolution far greater than that of G-banding for the identification of deletions, insertions and translocation breakpoints. The types of probes include (1) painting probes, which are used to identify the chromosomal origin of a DNA segment and are useful for distinguishing translocations; (2) centromere probes that hybridize to alpha-satellite DNA located at the centromere of each chromosome, which are used to identify aneuploidy of specific chromosomes or to identify the chromosomal origin of marker chromosomes; (3) beta-satellite probes, which are used to

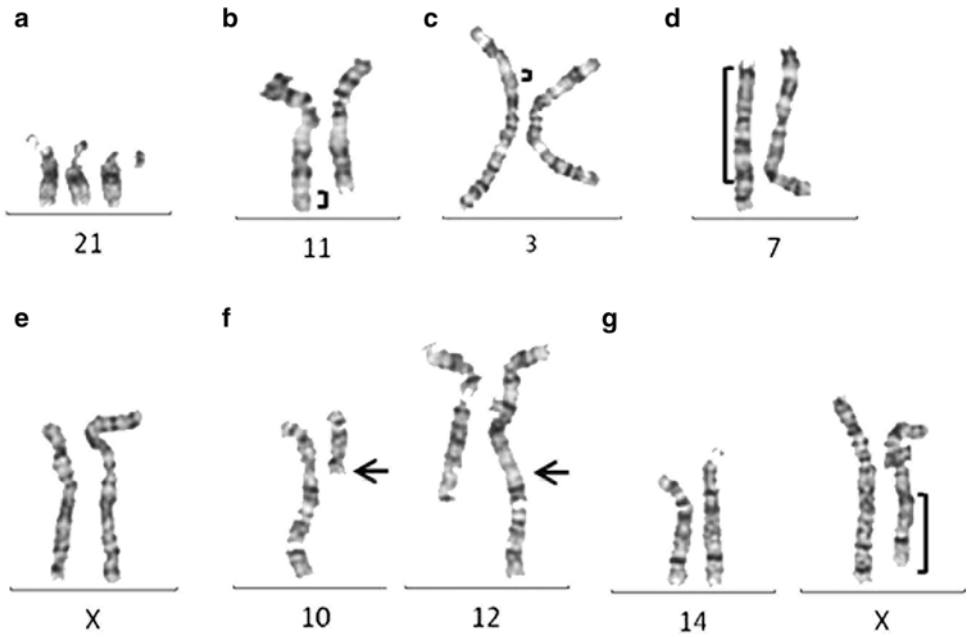

Figure 6.1 Common types of chromosome abnormalities detected by standard chromosome analysis (G-banded karyotyping). (**a**) Aneuploidy, defined as the loss or gain of an entire chromosome, shown as trisomy 21. (**b**) Terminal deletion, shown as a deletion of distal 11q (normal chromosome 11 on *left*, with deleted region *bracketed*, and deleted 11 on *right*). (**c**) Interstitial deletion, shown within 3p (normal chromosome 3 on *left*, with deleted region *bracketed*, and deleted 3 on *right*). (**d**) Inversion, shown as a pericentric inversion of chromosome 7 (normal chromosome 7 on *left* with inverted region *bracketed*, and inverted 7 on *right*). (**e**) Isochromosome, defined as the loss of one chromosome arm with duplication and mirror image of other arm, shown as isochromosome Xq (normal X on *left* and isochromosome Xq on *right*). (**f**) Balanced translocation, shown between 10q and 12q (with normal 10 and 12 on *left* of each pair and translocated 10 and 12 on *right with arrows* marking breakpoints of the translocation). (**g**) Unbalanced translocation, shown between 14q and Xq with two normal 14 chromosomes, one normal X, and one X with a deletion of part of Xq and replacement with gain of 14q region bracketed, leading to partial 14q trisomy and partial Xq monosomy.

identify beta-satellite regions on the short arm of acrocentric chromosomes; (4) subtelomeric probes, which are used to detect subtelomeric rearrangements of chromosome arms; and (5) locus-specific probes, which hybridize to unique gene sequences and are used to identify contiguous gene syndromes and other microdeletion or microduplication syndromes (Fig. 6.2).

FISH allows the determination of the frequency and location of specific DNA sequences in cells in any state of the cell cycle and in archived formalin-fixed, paraffin-embedded tissues. However, FISH can only detect deletions, duplications, and rearrangements of the chromosomal region complementary to the probe. Clinically, suspicion of a syndrome with known cytogenetic etiology is normally required to run a FISH study. Also, the number of probes that can be mixed and used in a single FISH assay is limited and depends on the number of fluorochromes available for probe labeling; in most clinical applications, this is limited to three unique regions probed per hybridization.

Chromosomal Microarray Analysis

Chromosomal Microarray Methodology

CMA allows for the detection of loss or gain at multiple loci at a much higher resolution than either conventional chromosome analysis or FISH. For CMA testing using aCGH, the patient's genomic DNA and control genomic DNA are labeled with different fluorochromes and co-hybridized onto DNA substrates immobilized on a solid support (Fig. 6.3). Several aCGH platforms have been developed for diagnostic purposes. Initially, bacterial artificial chromosomes (BACs, between 80 and 200 kb) were used as array targets (Fig. 6.4) [13]. Oligonucleotide arrays (25–85 bp) were subsequently constructed to allow for higher resolution [14, 15].

Arrays that target clinically meaningful regions of the genome have been used for postnatal and prenatal cases with normal chromosome analysis results and for general screening purposes [16–20]. The whole genome designed array

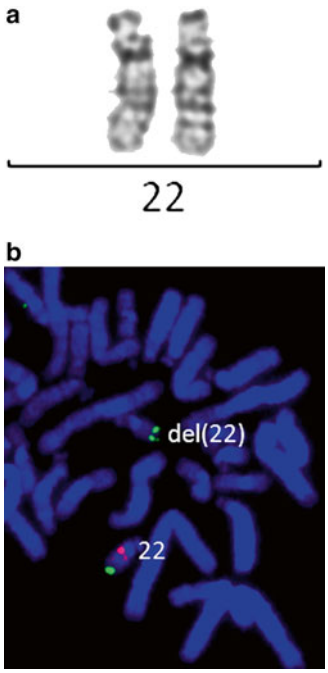

Figure 6.2 Chromosomally cryptic 22q11.2 deletion detected by FISH, but not by G-banded karyotyping. (**a**) Normal banding pattern for each chromosome 22. (**b**) FISH with a specific probe to the *TUPLE1* gene in *red* and control probe in *green* show a deletion of one copy of this gene on one chromosome 22

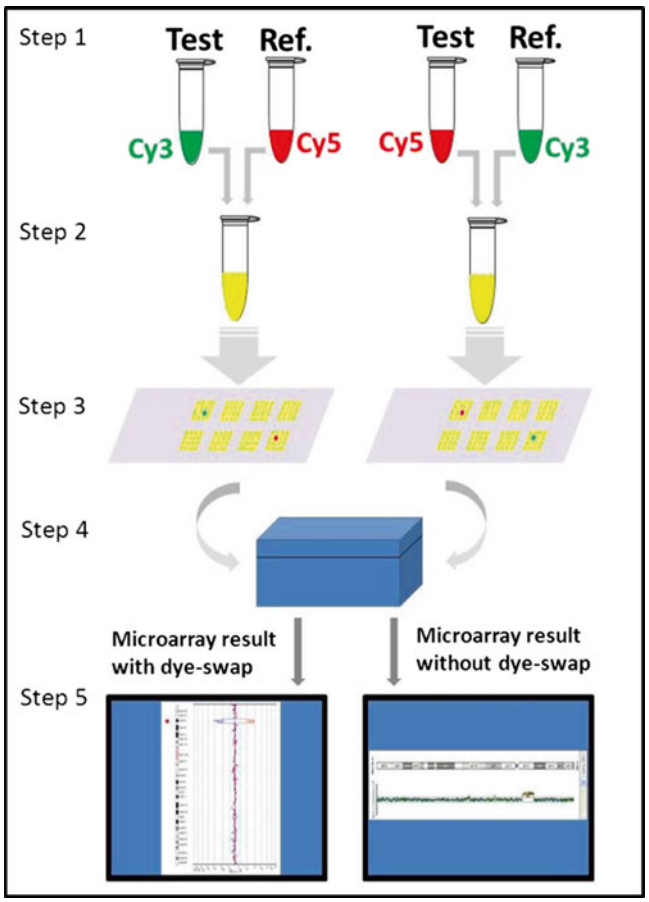

Figure 6.3 Steps in aCGH procedure. *Step 1*: Test and reference DNA are fragmented and labeled with fluorescent dyes, Cy3 and Cy5. *Step 2*: Equal amounts of labeled test and reference DNAs are mixed together. *Step 3*: The combined labeled test and reference DNAs are applied to the microarray and compete to hybridize to the target DNA (segments of the human genome) on the microarray. *Step 4*: Fluorescent signals are measured in the microarray scanner. *Step 5*: Analysis software generates data linking signal to relative copy number of test DNA compared to reference DNA for each probe on the microarray. To confirm the result, this process is repeated with the fluorochromes switched between the test and reference DNAs (called a dye-swap), so that a true loss or gain would have the opposite fluorescent signal in the repeat test. In lieu of a dye-swap repeat, multiple independent probes adjacent in the genome but separate on the microarray showing a contiguous loss or gain increases confidence in the accuracy of result.

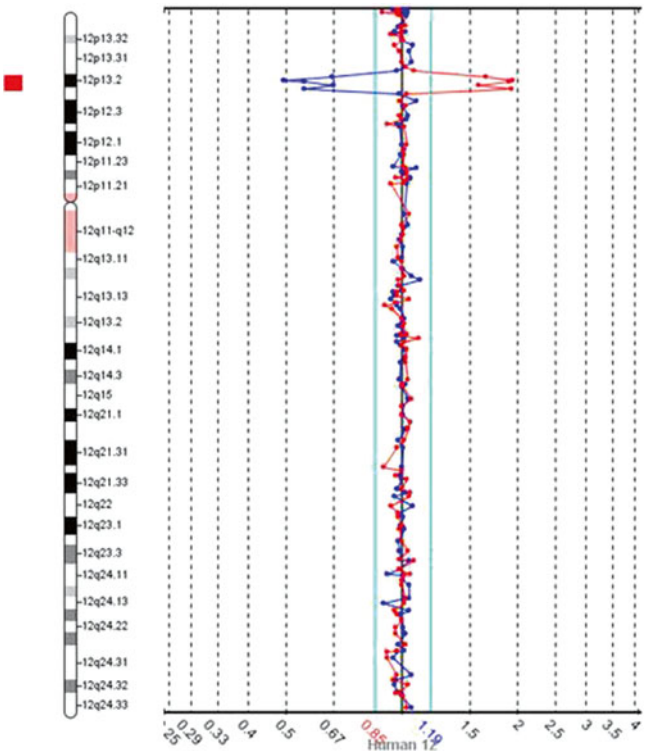

Figure 6.4 Example of a deletion detected by the original aCGH with the dye-swap repeat using BAC-based targets. Data from chromosome 12 with each dot representing a BAC probe mapping approximately every one megabase across chromosome 12. In both runs, less of the labeled test DNA hybridized to the BACs in region 12p13 when compared to the reference DNA, as represented by the reciprocal deviation from the *central black line* (representing zero) on the *Y*-axis and the *red bar to the left* of the schematic chromosome 12 (for this software, when equal hybridization of test and reference DNAs occurs, the *dots map* within the *aqua lines* near the *central black line*)

offers full coverage of the genome as the technology and genomic architecture allows. The copy number of some regions of the genome cannot be accurately evaluated by this technology, notably repetitive regions and small deletions and duplications. Whole-genome design is important for the discovery of new chromosomal syndromes [21, 22] and detection of recently discovered syndromes that may have occurred since the design of a targeted array. Many platforms in clinical use are currently a combination of both whole-genome coverage and enrichment of targets at known clinically relevant regions.

The SNP array is another type of oligonucleotide array. SNPs are DNA sequence variations in which a single nucleotide in the sequence of the oligonucleotide differs between individuals or between paired chromosomes in an individual. Similar to aCGH, SNP arrays contain probes that can detect imbalances at thousands of loci in the genome. In contrast to aCGH, SNP arrays also can be used for detecting long contiguous stretches of homozygosity, which may be caused by either consanguinity or uniparental disomy (UPD) of a genomic interval (Fig. 6.5). Both consanguinity and UPD increase the risk of autosomal recessive conditions. In addition, UPD of specific chromosomal regions is associated with imprinting defects, such as UPD of chromosome 15 in patients with Prader-Willi syndrome and Angelman syndrome.

Advantages of CMA Testing

Compared with G-banded karyotyping, CMA analyzes chromosomes for genomic gains and losses at a much higher resolution, which allows the detection of smaller or cryptic abnormalities (Figs. 6.6 and 6.7) and provides better definition of cytogenetic abnormalities (Fig. 6.8). The detection of abnormalities by CMA is usually more detailed, automatable, and less subjective than G-banded karyotyping. Furthermore, archived or non-growing tissue can be used for CMA, but not G-banded karyotyping. CMA also may provide information on the mechanism of the genetic aberration. For example, depending on the observed pattern of imbalance in the proband and the parents, the proband may be predicted to have an unbalanced segregation of a translocation or inversion which is present in a balanced form in either parent. Also, analysis of the flanking regions of the imbalance allows determination of whether the rearrangement is mediated by non-allelic homologous recombination [25]. Information about the likely mechanism then informs the likelihood of recurrence in subsequent pregnancies.

The diagnostic yield of a G-banded karyotype in individuals with ID/DD is approximately 3 %. FISH analysis of subtelomeric regions may provide a diagnosis in another 2–3 % of cases [26]. Several large cohort studies have shown that CMA has the highest yield as a single diagnostic test for individuals with ID/DD [5, 11, 27–29]. The detection rate varies between studies, likely due to differences in platform design, populations studied, and interpretation methods (see below); however, these studies still demonstrated between a 10 and 28.9 % detection rate for pathogenic aberrations in patients with ID/DD, and less than 0.6 % of cases with probable disease-causing balanced de novo aberrations remained undetectable. Thus, CMA has been recommended as a "first-line test" in the initial evaluation of patients with nonsyndromic ID/DD by the American College of Medical Genetics (ACMG) Practice Guidelines [10].

Limitations of CMA Testing

CMA alone cannot detect balanced rearrangements (such as translocations, inversions, and point mutations) and some cases of mosaicism (depending on the platform, size, direction, and percentage of mosaicism of imbalance [30–32]). Also, arrays will not detect CNVs in the regions of the genome that are not on the array platform, and, therefore, the resolution of the array is dependent both on the design and the genomic architecture. The array will not identify the

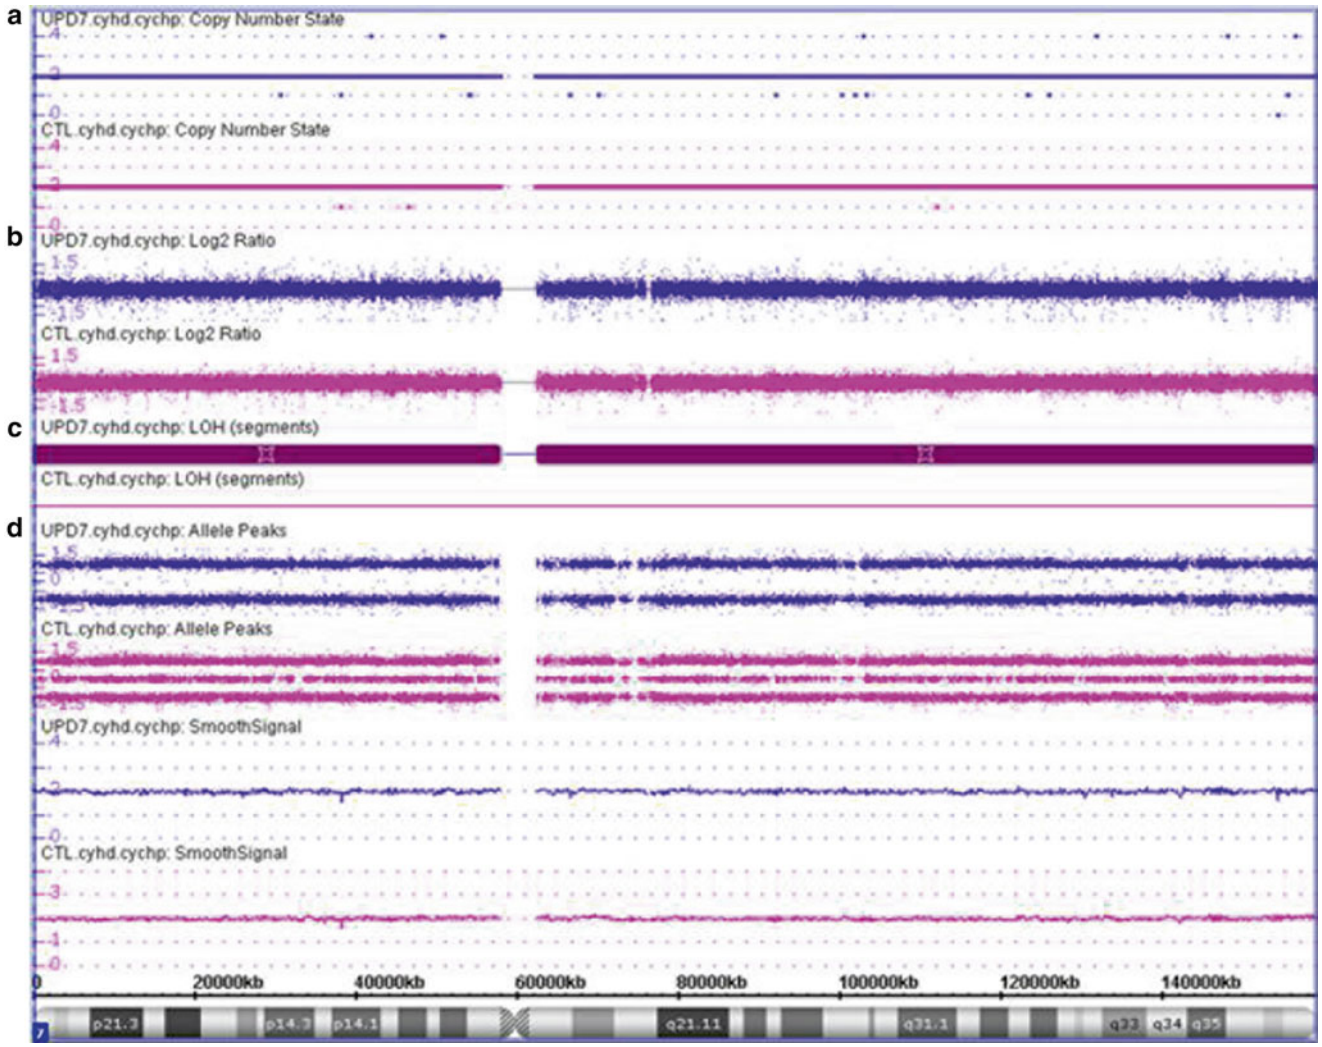

Figure 6.5 CMA finding consistent with uniparental isodisomy of chromosome 7. UPD7 case shown in *purple* and a normal case shown in *pink* for comparison. (**a**) The copy number state is determined to be 2 (normal diploid) across the vast majority of the chromosome both for the UPD7 and normal cases (CTL). (**b**) Estimation of the copy number state based on the log2 ratio of the hybridization of the patient DNA to the control DNA, with signal centered at zero. (**c**) Loss of heterozygosity is noted across the entire chromosome for the UPD7 case (*maroon bar*) due to the allele peak pattern which shows only values at 1.0 and −1.0; whereas the normal case shows normal heterozygosity (*no maroon bar*) with values at 1.0, 0, and −1.0. These values are determined by assigning each allele a value of 0.5 and then plotting A–B. Therefore a locus with AA is $(0.5+0.5)-0=1$; a locus with AB is $0.5-0.5=0$; and a locus with BB is $0-(0.5+0.5)=-1$. (**d**) For the UPD7 case, all of chromosome 7 shows no evidence of any AB loci, suggestive that both chromosome 7 s are 100 % identical. Maternal UPD7 is associated with Russell-Silver syndrome; whereas paternal UPD7 has not been associated with a specific clinical consequence. Additionally, recessive disorders mapping to chromosome 7, such as cystic fibrosis, should be considered for this child. Although this example shows isodisomy for all of chromosome 7, also note that UPD may have parts of the affected chromosome showing isodisomy whereas other parts of the same chromosome still show heterodisomy due to crossing over between the homologous chromosomes.

genomic location of gained material and this may be relevant as duplications with a single breakpoint within a gene may or may not disrupt the open reading frame of that one copy of the gene, depending on the orientation and location of the duplicated material.

Finally, the detection of CNVs of unknown clinical significance is challenging for interpretation due the current lack of published data on these variations (Fig. 6.9). This is an expanding field and reevaluation of the clinically uncertain findings at a later date may result in the reclassification of some of these results.

CMA Interpretation for Patients with ID/DD

ACMG published guidelines for the interpretation and reporting of CNVs detected in the postnatal and constitutional setting [34]. Some of the major points are summarized here,

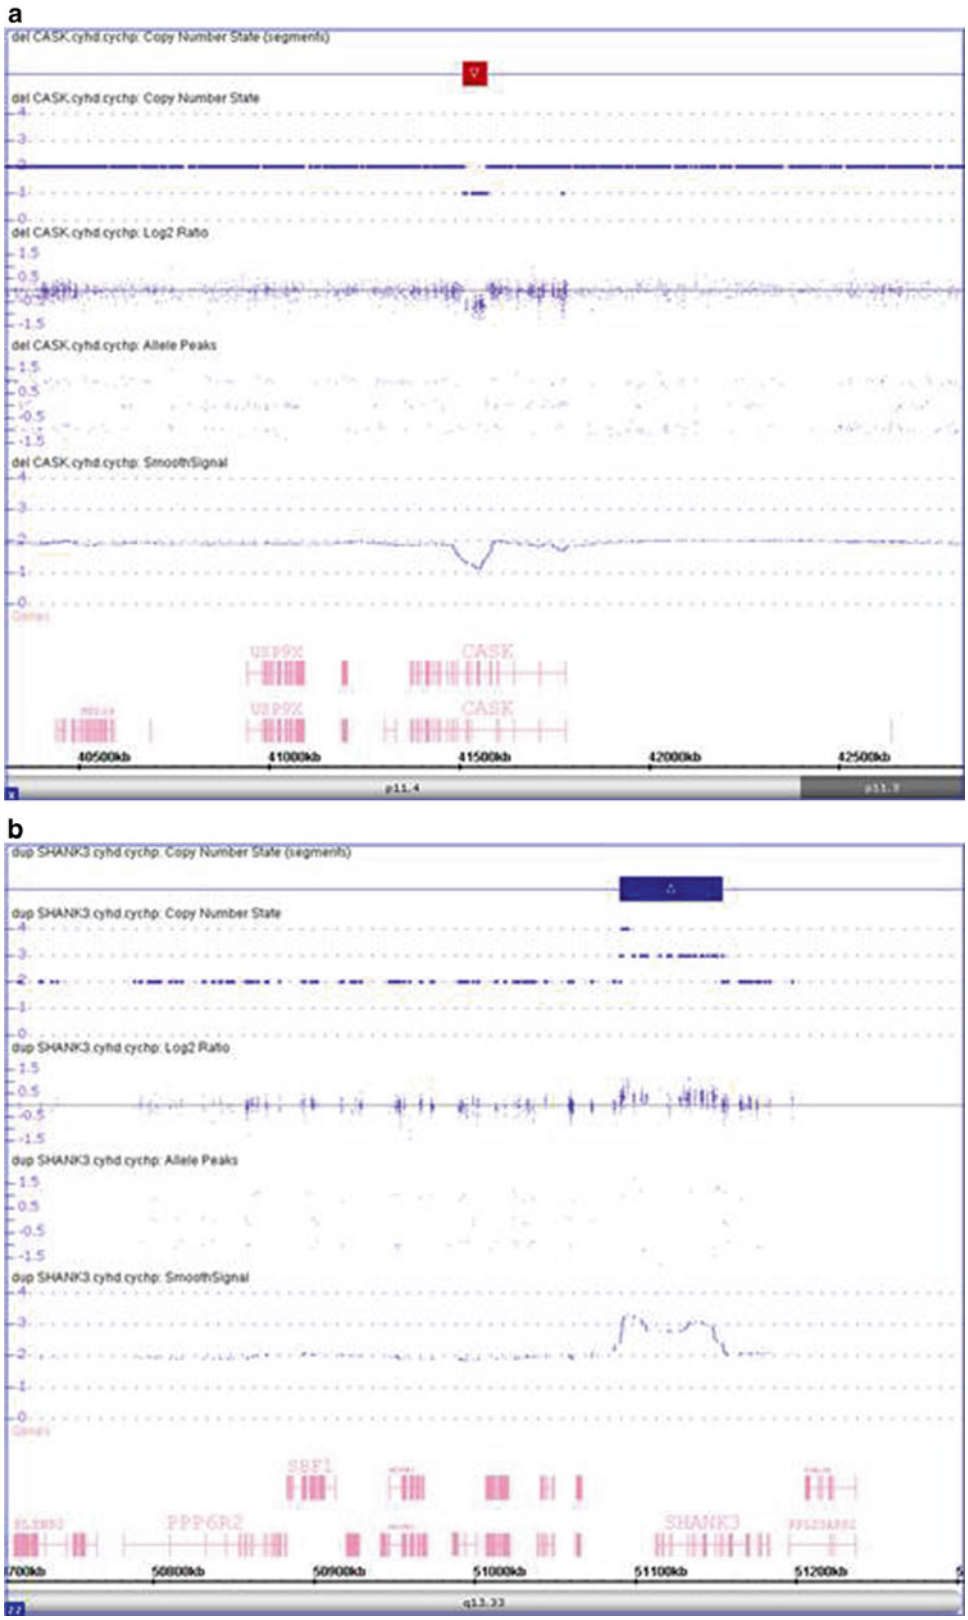

Figure 6.6 Detection of intragenic loss and small gain using CMA. (**a**) The CMA shows a 63 kb deletion within Xp11.4 in a female patient (region *highlighted by red bar at top*). This deletion involves three exons of the gene *CASK*. Deletions of *CASK* have been found in female and male patients with X-linked cognitive disability, optic atrophy, brainstem and cerebellar hypoplasia, microcephaly, and dysmorphic facial features [23]. (**b**) The CMA shows a 64 kb gain within 22q13.33, indicating trisomy for this region (region *highlighted by blue bar at top*). This duplication has a breakpoint within the *SHANK3* gene. Disruption of *SHANK3* has been reported in patients with global developmental delay [24].

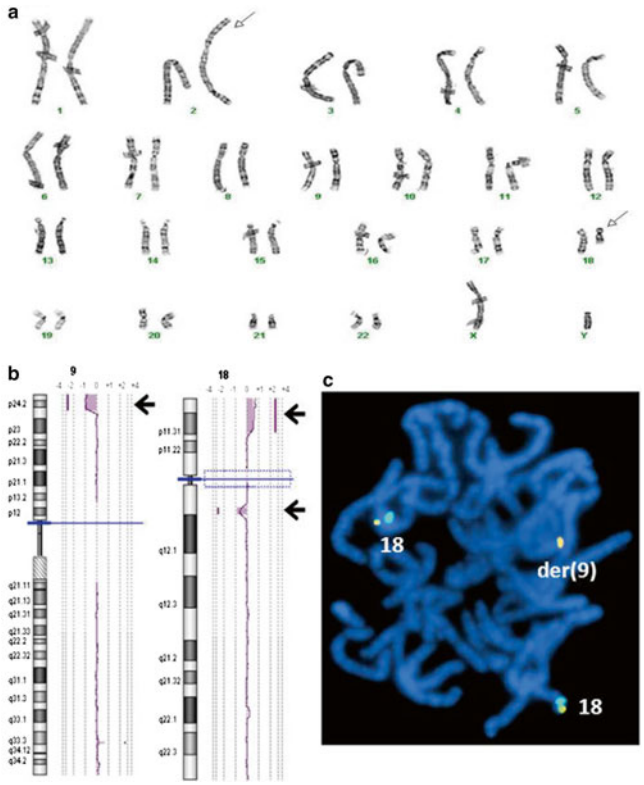

Figure 6.7 Identification of cryptic abnormality by CMA in addition to a visible chromosome abnormality by G-banded karyotype. (**a**) Chromosome G-banding shows a translocation between 2q and 18q (*arrows*). (**b**) Genomic microarray shows a 1.2 Mb interstitial deletion at the 18q breakpoint, but also a 5.9 Mb terminal deletion of 9p and a 6.0 Mb terminal duplication of 18p (*arrows*). (**c**) FISH with the 18p subtelomere probe (fusion signal) shows additional signal is on the derivative 9, consistent with an unbalanced translocation not detected in chromosome analysis

though the guideline provides more comprehensive recommendations. Many detected CNVs already may be described in the medical literature and their pathogenic or benign nature be well understood; however, many other detected changes may represent rare variations. Assessing the clinical significance of an identified CNV can be challenging due to the presence of benign CNVs within the genome, the potential for incomplete penetrance and variable expressivity, and the continual discovery of new associations of clinical conditions with genetic alterations.

A number of databases are available to assist with the interpretation of CMA results including PubMed, OMIM (currently at http://www.omim.org), GeneReviews (currently at http://www.ncbi.nlm.nih.gov/sites/GeneTests/), DECIPHER [35], the International Standard Cytogenetic Array Consortium (ISCA) database housed by dbVar (currently available at http://www.ncbi.nlm.nih.gov/dbvar/studies/nstd37/), and the Database of Genomic Variants [36]. New microdeletion and microduplication syndromes are identified regularly. The pathogenic nature of some recurrent microdeletion and microduplication regions may not yet be clear; therefore, frequent literature reviews are important to assess newly defined phenotypic associations.

A primary consideration for interpretation of results is the functions and density of the genes within the variant interval. For example, regions with very few genes, or primarily containing repetitive elements or pseudogenes, may be less likely of clinical significance than similar regions that are very gene rich. When assessing the gene content, the impact of gene dosage on the function of the genes in the interval should be considered. Factors to consider include gene dosage in control populations, the focal nature of the alterations in the literature, the associated phenotype, other reported findings in the described patient(s) that may contribute to the phenotype, the molecular mechanism of the mutation (i.e., loss of function vs gain of function vs unknown), and the inheritance pattern (i.e., dominant vs recessive effect and issues of penetrance). For deletions, primary consideration will be on the evidence for the phenotypic effect of haploinsufficiency of the region. For duplications, primary consideration will be on the triplosensitivity of the region; however duplication breakpoints within a gene may or may not disrupt the function of the gene.

Additional considerations for identified CNVs within a gene will be the exonic vs intronic nature of the alteration as well as if the gene exists in multiple isoforms, and whether the CNV in question does or does not involve all isoforms. Comparison of the identified CNV to control and patient populations is of significant value in predicting the pathogenicity of the variant. Finally, investigation of the established contiguous gene syndromes and microdeletion or microduplication syndromes associated with the interval is important because these may not be identified simply by a literature search focused on the genes within the interval.

Laboratory Issues

Based upon the technical performance and probe density of the microarray platform being used for clinical testing, size restrictions may be established for copy number calls, which can differ based on the type of variation. Different thresholds may be established for deletions, duplications, for regions of the genome well associated with clinical conditions, and for uncharacterized regions of the genome. Such size thresholds should not be set based on assumptions regarding an association between size and clinical significance because relatively large copy number changes can be benign and relatively small copy number changes can be clinically significant.

Parental studies may be considered as part of the interpretation of an identified CNV; however, due to issues of incomplete penetrance and variable expressivity, the finding of a

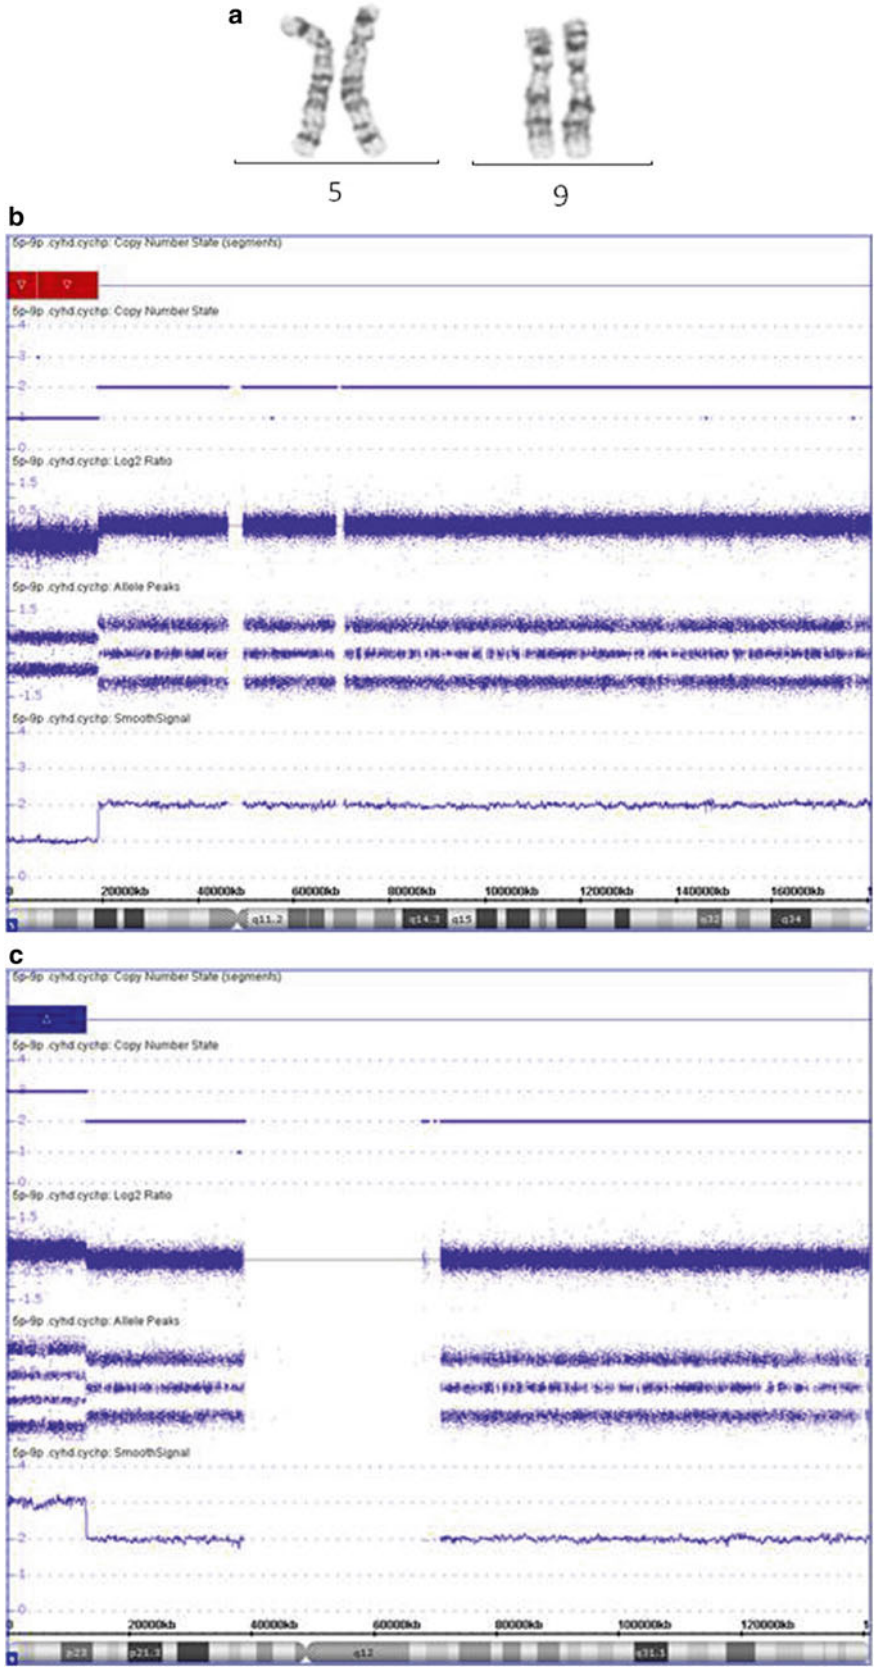

Figure 6.8 CMA often provides a better definition of a chromosome abnormality, leading to better genotype-phenotype correlation and recurrence risk estimation. (**a**) Chromosome analysis shows a terminal deletion on the short arm of chromosome 5 (abnormal chromosome on *right*) with two normal appearing chromosome 9 s. (**b** and **c**) The CMA analysis indicates that there is a 19.0 Mb terminal deletion of 5p (**b**), and a 12.8 Mb terminal duplication of 9p (**c**), suggesting an unbalanced translocation involving 5p and 9p. This abnormality is associated with the Cri-du-Chat syndrome and 9p duplication syndrome separately, so this patient is likely to have a clinical phenotype with features of both syndromes. In addition, there is a higher probability of a parent carrying a balanced rearrangement of 5p and 9p then if this was only a 5p deletion. This increases the urgency for parental testing for recurrence risk determination.

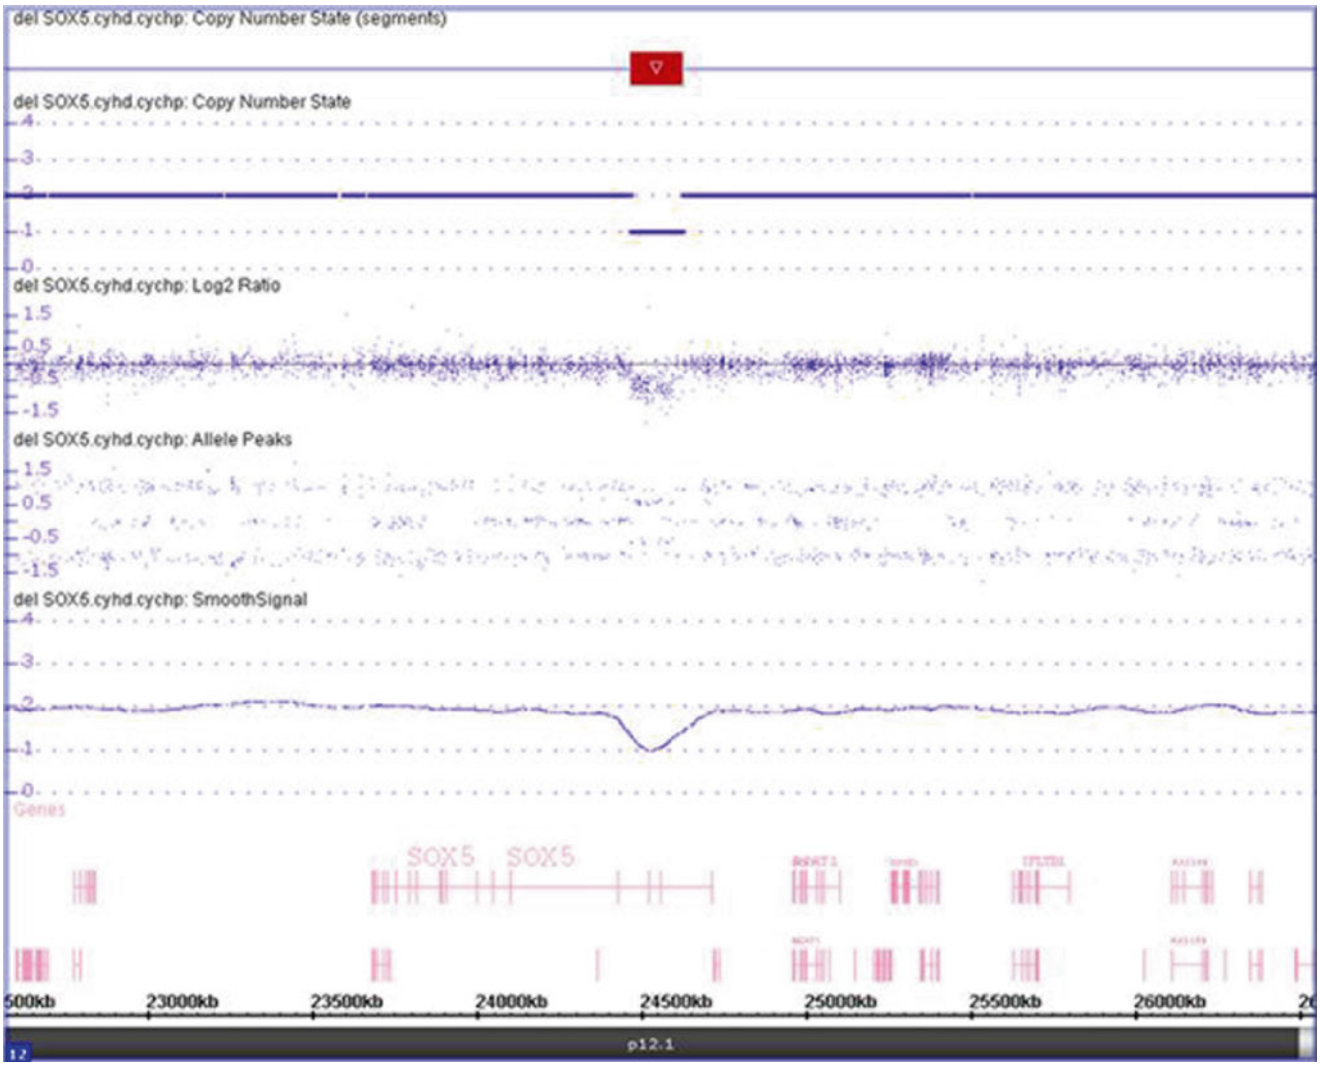

Figure 6.9 CMA detection of an abnormality of unknown clinical significance. CMA result from a 16-year-old female with behavior/conduct disorder, epilepsy, hydrocephaly, multiple congenital anomalies, and gait abnormalities. The CMA shows a 156 Kb deletion involving 12p12.1 (indicated by *red bar at top*). This deletion is within the gene *SOX5* and includes two untranslated exons in the 5′ untranslated region of one of the *SOX5* transcripts. Due to absence at the time of the patient's test results of publications associating disruption of *SOX5* with human disease, this deletion was reported as an abnormality of unknown clinical significance. Subsequently, a study showed that haploinsufficiency of *SOX5* at 12p12.1 is associated with speech delay, intellectual disability, behavior abnormalities, and dysmorphic features [33], allowing reclassification of this finding as likely pathogenic.

CNV in a clinically normal parent may not rule out a causal relationship between the alteration and the phenotype of the patient [37, 38].

Conclusions and Future Directions

ID/DD is a common medical condition, and determining the etiology can be challenging. Even though it is still an evolving field, the diagnostic success of cytogenomic microarray technology has exceeded that of conventional cytogenetic techniques. As more medical specialists utilize this technology, understanding of the pathogenesis of ID/DD will improve.

Developmental Delay: Gene Testing

7

Christin D. Collins, Monica J. Basehore,
Kristen J. Champion, and Michael J. Friez

Abstract

Although the classic childhood phenotypes of many developmental disorders have been established for some time, only recently have the genetic etiologies of some of these disorders been identified. Understanding the genetic basis of these disorders allows for molecular confirmation of the clinical diagnosis in an individual which can then be utilized for risk counseling and prenatal testing. This chapter reviews the molecular basis, clinical utility, testing strategy, and interpretation of clinical molecular tests for single-gene causes of developmental delay, which include fragile X syndrome, Angelman syndrome, Rett syndrome, Noonan spectrum disorders, and X-linked intellectual disability.

Keywords

Developmental delay • Fragile X syndrome • Angelman syndrome • Prader-Willi syndrome • Uniparental disomy • Rett syndrome • X-linked intellectual disability • Noonan syndrome • Mosaicism • De novo • Permutation • Trinucleotide repeat expansion

Introduction

Although the classic childhood phenotypes of many developmental disorders have been established for some time, only recently have the genetic etiologies of some of these disorders been identified. Investigations of the molecular basis of these conditions have resulted in the identification of new genes, leading to insights into the function of new proteins and biochemical pathways. This chapter reviews the molecular basis and testing strategy of single-gene causes of developmental delay (DD) and/or intellectual disability (ID), which include fragile X syndrome, Angelman syndrome, Rett syndrome, Noonan spectrum disorders, and X-linked intellectual disability.

Fragile X Syndrome

Molecular Basis

Named for its association with a chromosomal fragile site observed in many patients (*FRAXA* chromosomal locus Xq27.3), fragile X syndrome (FXS) is the most common cause of inherited ID. FXS results from loss or severe reduction of the protein FMRP, encoded by the *FMR1* (fragile X mental retardation) gene [1]. All patients with FXS have mutations in *FMR1*, as no mutations leading to FXS have been identified in other genes. Both males and females may

D.G.B. Leonard (ed.), *Molecular Pathology in Clinical Practice*, DOI 10.1007/978-3-319-19674-9_7

be affected with FXS, but females are typically less severely affected. Thus, FXS is considered to be X-linked dominant with reduced penetrance in females [2].

The *FMR1* gene encompasses 38 kilobases (kb) of genomic DNA and has 17 exons [3]. The major *FMR1* messenger RNA produced in most tissues is approximately 4 kb, although several protein isoforms are generated by alternative splicing toward the 3′ end of the mRNA in some tissues. While FMRP can be detected in the nucleus, the majority of the protein associates with translating ribosomes in the cytoplasm, functioning as a negative translational regulator. FMRP also has a role in neuronal synapse maturation and plasticity. Autopsy samples from FXS patients have shown failure of dendritic spines to assume a normal mature size, shape, and distribution.

The molecular genetics of *FMR1* are complex given the presence of a trinucleotide repeat region in the 5′ untranslated region of exon 1. This repeat sequence is composed primarily of CGG repeats and ends 69 base pairs upstream of the translational ATG start codon. The *FMR1* repeat region is naturally polymorphic, with variation of the CGG repeats in normal (i.e., stably inherited) alleles ranging from 5 to 44 repeats, with the vast majority of individuals in the general population having 20–40 repeats. Intermediate alleles containing 45–54 repeats occasionally have minor variations of a few repeats when transmitted from parent to child, producing no clinical consequences. However, in rare instances, transmission of intermediate alleles may result in expansion of the CGG repeat to form pathological alleles. *FMR1* alleles with 55 repeats up to 200 repeats are considered to be premutations because of their potential instability. Individuals with a premutation allele do not have typical characteristics associated with FXS; however, they are at risk of repeat expansion when maternally transmitted and are associated with a later onset fragile X tremor/ataxia syndrome characterized by progressive intention tremor and cognitive decline [4]. Primary ovarian insufficiency is another phenotype that presents in approximately 20 % of females that carry an *FMR1* premutation allele [5].

Almost all mutations (>99 %) that cause FXS occur as a result of instability of the trinucleotide repeat causing dramatic expansion of the repeat segment (>200 to a few thousand CGG repeats). Rarely, deletions and point mutations in *FMR1* account for the remaining mutations found in patients with FXS. The mechanism of repeat instability in *FMR1* is believed to be DNA polymerase slippage during DNA replication. AGG repeats, spaced at about ten repeat intervals within the CGG repeat segment, may mitigate potential repeat instability through disruption of higher order molecular structures formed during DNA replication. These secondary structures contribute to polymerase slippage, and alleles that lack interrupting AGG repeats are at higher risk of expansion. Since FXS occurs strictly through maternal inheritance, individuals with full mutations (>200 CGG repeats) may inherit a similarly sized allele from their mothers or, alternatively, their mothers may have a premutation-sized allele. With repeat expansion to a full mutation, hypermethylation of the CpG dinucleotides within the *FMR1* promoter region almost always occurs, resulting in decreased or completely absent transcription and the concomitant loss of FMRP. Patients with partial methylation of a full mutation (methylation mosaics) may have some FMRP expression, resulting in a less severe phenotype. In addition, patients with a mixture of cells having either a premutation or full mutation (premutation/full mutation size mosaics) frequently are identified during molecular testing. These patients usually have ID but may perform at the lower end of normal intellect (IQ >70). Because methylation is not an all-or-none phenomenon within *FMR1*, the FXS phenotype may encompass a spectrum of possible affectations from mild to severe. Table 7.1 summarizes the classification of *FMR1* alleles.

Table 7.1 Normal and pathological *FMR1* allele types

Allele type	Repeat range	Methylation status
Normal	5–44	Not methylated
Intermediate/gray zone	45–54	Not methylated
Premutation	55–200	Not methylated
Full mutation	>200	Methylated
Methylation mosaic	>200	Variable methylation
Premutation/full-mutation mosaic (repeat size mosaic)	Mixed premutation and full mutation	Full mutation may be methylated

Clinical Utility of Testing

Due to the presence of unrecognized *FMR1* alterations in unaffected carrier mothers, the first indication of FXS within a family is usually the diagnosis of an affected child. Unfortunately, many families do not learn the FXS diagnosis for long periods after first concerns about their child's development or behavior, and many have subsequent pregnancies before diagnosis for their first child. Such situations highlight the importance of diagnosing FXS so that children and families can receive the benefits of genetic counseling and early intervention services. Other than the infrequent deletion or point mutation, which often are spontaneous and not inherited from a parent, mothers of *all* FXS patients are either premutation or full mutation carriers. In turn, at least one of the mother's parents has an *FMR1* alteration. Consequently, *FMR1* mutations may be present in siblings of an affected individual as well as other extended family members. It is important to remember that each daughter of unaffected males with a premutation (transmitting males) is an obligate carrier of a premutation, and that their offspring are

at risk for FXS. Many extended families have been documented in which an *FMR1* mutation has been transmitted through numerous generations and into family branches unknown to one another.

For DD children, *FMR1* molecular testing is diagnostic, as FXS affects development from infancy; however, the nonspecific nature of FXS during early development makes the testing approach one of ruling out FXS in most situations. The hallmark finding in almost all patients with FXS is ID, but the physical and behavioral features of males with FXS are variable prior to puberty. Physical features not readily recognizable in preschool-age boys and become more obvious with age: long face, prominent forehead, large ears, prominent jaw, and enlarged testicles (macroorchidism). Motor milestones and speech are frequently delayed, and temperament often is affected (e.g., hyperactivity, hand flapping, hand biting, temper tantrums, and occasionally autism). Females with FXS usually have milder manifestations and as a result are more difficult to diagnose clinically. FXS always should be suspected in males with mild to moderate ID and females with mild ID until shown otherwise by negative *FMR1* analysis.

Women who are full-mutation or premutation carriers have a 50 % risk of transmitting their abnormal allele in each pregnancy. While transmission of a full mutation always leads to a child with a full mutation, the risk of a premutation transmission resulting in an affected offspring with a full mutation is proportional to the maternal allele size. Empirically, the 50 % risk of a female carrier producing an affected male child is reduced to 7 % if the premutation contains 56–59 repeats, 10 % for 60–69 repeats, 29 % for 70–79 repeats, 36 % for 80–89 repeats, and 47 % for 90–99 repeats; it reaches the maximum, 50 %, when a premutation has >100 and up to 200 repeats. Because females have approximately 50 % penetrance, the risk of having an affected female child is half that of having an affected male child in any premutation repeat interval category.

Prenatal testing for *FMR1* mutations is available in some clinical molecular laboratories. Genomic DNA isolated from amniocytes obtained during amniocentesis at 16–18-week gestation or from chorionic villus sampling (CVS) at 10–12-week gestation can be used for testing. Prenatal molecular analysis proceeds in much the same fashion as that performed on DNA obtained from adult peripheral blood. However, the DNA analysis of CVS may be more complex, as chorionic villi are extraembryonic. Hypermethylation in CVS may be incomplete and not representative of the true *FMR1* methylation status in fetal tissues; therefore, a follow-up amniocentesis occasionally may be required to resolve ambiguous CVS test results.

General population screening for *FMR1* mutations has been proposed but remains controversial. In comparison to most disorders already screened for in the newborn period, FXS is more prevalent and testing is highly reliable; however, before population screening is practical for newborns and women of reproductive age, the relatively high costs and the technical complexities of testing must be resolved. Several recent studies demonstrate that higher throughput testing for population-screening purposes is becoming increasingly possible, both from a cost and a time perspective [6, 7]. Protein testing of FMRP may also be useful for screening populations with ID.

Available Assays

Routine clinical testing for *FMR1* mutations includes molecular assessment of both the trinucleotide repeat number and the *FMR1* methylation status. Traditional approaches to this testing include two concurrent analyses: (1) double-digest Southern blot analysis using a methylation-sensitive restriction enzyme such as *Eag*I, *Bss*HII, or *Nru*I along with a methylation-insensitive restriction enzyme such as *Eco*RI or *Hind*III [8]; and (2) polymerase chain reaction (PCR) assays specific for the CGG repeat segment of *FMR1* (Fig. 7.1) [9]. When used in conjunction with PCR, Southern blot analysis provides a more complete inspection of the trinucleotide repeat region by detecting multiple possible molecular events, including repeat expansion, DNA methylation, and the relatively rare *FMR1* deletions. Specialized fragile X chromosome cytogenetic analysis, using special culture techniques to induce fragile sites, is no longer used for diagnosis of FXS due to low sensitivity. While only a very few FXS patients with point mutations in *FMR1* have been identified, clinical molecular testing does not routinely investigate this gene for point mutations, deletions, insertions, or inversions downstream of the repeat segment.

In most clinical laboratories, PCR is used to size normal and smaller premutation-sized alleles with a typical sensitivity of up to approximately 120 repeats. PCR product yield is inversely proportional to the number of trinucleotide repeats such that with traditional PCR methods, little or no product can be obtained when larger repeats are present. Since the inception of diagnostic testing for FXS, different testing strategies to facilitate the transition away from Southern blots have been met with limited success. Although some PCR-based testing protocols have higher sensitivity regarding detection of larger repeats, most laboratories have been reluctant to adopt these practices due to technical difficulties. The ability to rapidly identify trinucleotide expansions in an efficient and cost-effective manner has been revisited in recent years and several very similar protocols to address this challenge have been developed [6, 10–13]. Each of these new methods relies on a triplet repeat-primed PCR reaction to separate alleles with apparent CGG expansions from those without expansions. Typically, this is based on a threshold of

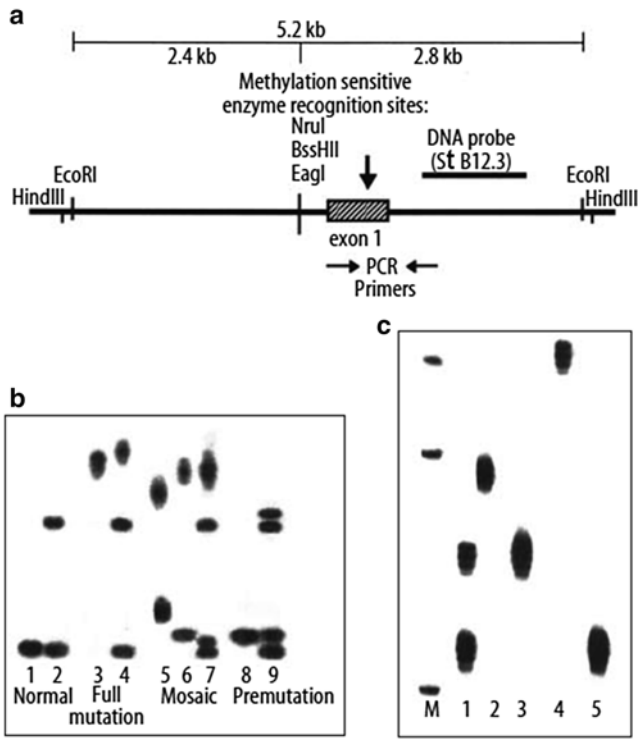

Figure 7.1 Repeat expansion and methylation in *FMR1*. (**a**) Restriction enzyme map of *FMR1*, with locations of restriction enzyme sites, DNA probe, and PCR primers used in molecular testing. *Top line* indicates DNA fragments generated using *Eco*RI and *Eag*I as depicted in the Southern blot analysis in **b** (2.8 kb and 5.2 kb fragments are detected by the DNA probe StB12.3). The *vertical arrow* indicates the location of the CGG repeat in exon 1. (**b**) Southern blot analysis of *FMR1*. Only the 2.8 kb fragment is detected in normal males (*lane 1*), while both the 2.8 kb and 5.2 kb fragments are detected in normal females (*lane 2*) due to methylation associated with normal X-inactivation that prevents cutting of the inactivated methylated allele with the methylation-sensitive restriction enzyme *Eag*I, *Bss*HII, or *Nru*I. Completely methylated full mutations are depicted in *lane 3* (affected male with full mutation) and *lane 4* (affected female with full mutation contained on one of her X chromosomes; normal allele on her other X chromosome). Smeary signals occur due to variable repeat expansion within peripheral lymphocytes used for DNA isolation. Mosaic patterns are illustrated in *lane 5* (male with partial methylation of full mutation), *lane 6* (male with premutation/full-mutation mosaicism), and *lane 7* (female with premutation/full-mutation mosaicism). *Lane 8* illustrates a transmitting male with a premutation and *lane 9* illustrates a female with a premutation. Both premutations contain approximately 75 repeats. (**c**) PCR analysis of *FMR1* repeats from five individuals separated on a 6 % polyacrylamide gel. *Lane 1* contains PCR products from a female with 20 and 30 repeats, respectively, contained within her two normal alleles. *Lanes 2, 3*, and *5* are males with normal repeat alleles (40, 30, and 20 repeats, respectively), while *lane 4* illustrates a male with a 65-repeat premutation allele. Smeary signals result from DNA polymerase stuttering during the PCR amplification.

55 trinucleotide repeats; however, the threshold can be adjusted according to the needs of the user (Fig. 7.2). Patients with expanded alleles detected by this PCR screening test then can be reflex tested by Southern blot analysis for further evaluation of expansion size and methylation status. This considerable advancement in testing allows the opportunity to significantly reduce the number of Southern blots needed, thereby significantly decreasing the turnaround time for most samples tested. Although only routinely performed in a few clinical laboratories, protein-based testing for FMRP can be utilized. Since severity of the FXS phenotype appears to inversely correlate with FMRP expression, assessment of FMRP production in patients with methylation mosaicism may be a useful prognostic indicator of disease severity [14].

Interpretation of Test Results

Because *FMR1* appears to be the only disease-causing gene for FXS, test specificity is 100 %. Using both Southern blot analysis and PCR specific for the *FMR1* locus, test sensitivity for repeat expansion can be estimated to be nearly 99 %, as only rare point mutations, small deletions/insertions remote from the repeat segment, or gene inversions would be missed. Non-repeat expansion molecular alterations may be under-ascertained in *FMR1* since gene regions downstream of the repeat segment in exon 1 are rarely investigated. When identified, the presence of cellular mosaicism, in either repeat size or methylation status, presents potential problems for the prediction of FXS severity. Essentially all patients with mutations resulting in reduction of FMRP are impaired, but expression of variable amounts of FMRP may allow some individuals to function at a higher level than expected; therefore, these individuals may occasionally have higher intelligence quotients (IQ>70). Prognostication of severity based on testing of a young child should be predicated with great caution during genetic counseling, because no long-term study exists following the development of individuals with methylation mosaicism.

Laboratory Issues

If the etiology of ID in an individual is unknown, DNA analysis for FXS should be performed as part of a comprehensive genetic evaluation that includes routine cytogenetic analysis (see Chap. 6), since cytogenetic abnormalities have been identified at least as frequently as *FMR1* mutations in individuals with ID. In addition, the use of Southern blotting on DNA isolated from amniocytes for prenatal *FMR1* analysis, with typical 2- to 3-week turnaround times, may lead to stressful situations on occasion regarding the timing of possible pregnancy termination. Utilization of CVS specimens provides additional time for possible pregnancy termination, but equivocal results sometimes occur due to incomplete methylation when a full mutation is present, requiring follow-up amniocentesis.

PCR-based kits used to estimate repeat copy number are available through some commercial vendors but not widely utilized. Many laboratories use laboratory-developed methods for both *FMR1* Southern blot analysis and PCR. Patient

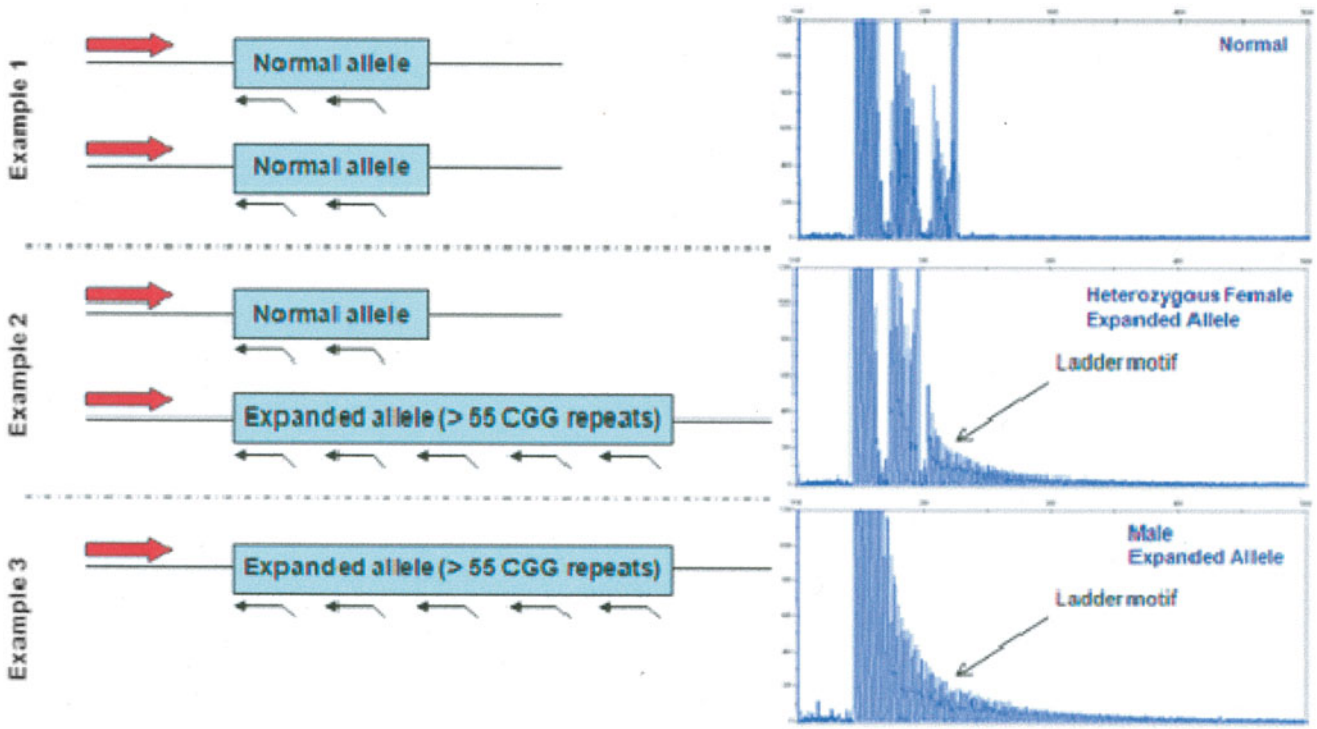

Figure 7.2 Triplet repeat-primed *FMR1* PCR screening test for fragile X alleles. The forward PCR primer is located upstream of the *FMR1* CGG region while the fluorescently-labeled reverse primer randomly binds inside the *FMR1* CGG repeat region. These PCR primers generate different sized amplicons depending on the size of the CGG repeat region present. The presence or absence of a trinucleotide "ladder" can be easily identified and a threshold of 55 CGG repeats typically is used to define expanded *FMR1* alleles. Example 1 shows the trace for a female with two normal alleles, neither of which results in the characteristic ladder motif present for expanded alleles. Example 2 illustrates the typical pattern for a female with one normal allele and one expanded allele while Example 3 illustrates the typical pattern for a male with an expansion at the *FMR1* locus. From Basehore MJ, Marlowe NM, Jones JR, Behlendorf DE, Laver TA, Friez MJ. Validation of a screening tool for the rapid and reliable detection of CGG trinucleotide repeat expansions in FMR1. Genet Test Mol Biomarkers. 2012 Jun;16(6):465–70. doi: 10.1089/gtmb.2011.0134. Epub 2012 Jan 6. Reprinted with permission from Mary Ann Liebert, Inc.

control cell lines may be purchased from the Coriell Institute (http://coriell.umdnj.edu/). Testing for FXS is routinely included in proficiency tests administered by the College of American Pathologists.

Angelman Syndrome and Prader-Willi Syndrome

Molecular Basis

Angelman syndrome (AS) is a neurodevelopmental disorder characterized by severe DD/ID, gait ataxia, microcephaly, seizures, and a happy demeanor that includes frequent laughing, smiling, and excitability [15]. AS is caused by deficient expression of the maternally inherited copy of the *UBE3A* (ubiquitin-protein ligase E3A) gene which can result from one of several different genetic abnormalities involving the proximal part of the long arm of chromosome 15 (15q11–q13). This two megabase (Mb) region of chromosome 15 contains multiple imprinted genes, meaning that their expression is dependent on the parent of origin. Within this region of chromosome 15, the *MKRN3*, *MAGEL2*, *NECDIN*, and *SNURF–SNRPN* genes, as well as a cluster of C/D box small nucleolar RNAs (snoRNAs) are paternally expressed, while the *UBE3A* and *ATP10C* genes are maternally expressed. Imprinting of genes in this domain is coordinately controlled by a bipartite imprinting center (IC) which overlaps the *SNRPN* promoter and extends approximately 35 kb upstream. Flanking this imprinted region are several low-copy repeats that predispose the region to chromosomal rearrangement by unequal crossing over.

Imprinted *UBE3A* expression is tissue specific, displaying predominantly maternal expression in the human fetal brain and adult frontal cortex but biparental expression in other tissues. *UBE3A* encodes a protein that is involved in the ubiquitination pathway which targets certain proteins for degradation [16]. Four known genetic mechanisms cause loss of *UBE3A* expression, and explain 85–90 % of AS cases [17]. A 4 Mb deletion of the maternal chromosome 15q11–q13 region occurs sporadically in 65–70 % of cases and is due to unequal crossing over. Paternal uniparental disomy

(UPD) of chromosome 15 is detected in about 7 % of cases and is likely to be postzygotic in origin. Approximately 3 % of AS cases involve an imprinting defect caused by microdeletions of the IC and result in lack of expression of the maternally inherited *UBE3A* gene in the brain. Point mutations within *UBE3A* (mostly truncating mutations) are found in approximately 11 % of cases [17]. Currently, approximately 10 % of patients with a clinical diagnosis of AS have no identifiable chromosomal or molecular abnormality, most likely due to an undetected abnormality affecting the *UBE3A* gene or a mutation in another gene within the ubiquitination pathway.

While the AS phenotype results from loss of expression of maternally expressed *UBE3A*, another developmental disorder, Prader-Willi syndrome (PWS), is due to loss of expression of *paternally* expressed genes within this 15q11–q13 region. PWS is characterized by infantile hypotonia, hypogonadism, dysmorphic appearance, small hands and feet, hyperphagia and obesity, DD, and ID. Approximately 70 % of PWS cases involve a 4 Mb deletion of the paternal chromosome 15q11–13, while 20 % of PWS cases are due to maternal UPD of chromosome 15. Another 1–5 % of cases are thought to be due to an imprinting defect. Recent evidence suggests that loss of expression of one or more of the C/D box snoRNAs, including SNORD116, encoded within the *SNRPN* locus may cause the PWS phenotype [18, 19]. The following section reviews the available diagnostic testing for AS, as well as PWS, since the primary testing method used to diagnose AS also will diagnose PWS.

Clinical Utility of Testing

Infants with AS commonly present with non-specific findings such as DD and/or seizures. These findings may result in a broad differential diagnosis, which can include inborn errors of metabolism, mitochondrial encephalopathy, cerebral palsy, and other neurodevelopmental syndromes including Rett syndrome, Christianson syndrome, and Pitt-Hopkins syndrome, which will be reviewed later in this chapter. Analysis of parent-specific DNA methylation imprints in the 15q11–q13 chromosome region is typically the first test that is ordered as it will detect approximately 80 % of individuals with AS, including those with a deletion, paternal UPD, or an IC defect. This analysis also is used to diagnose PWS and will detect nearly 100 % of those cases. Methylation analysis for AS/PWS typically investigates the methylation status of CpG dinucleotide sites within the promoter region of the *SNRPN* gene. Once the diagnosis of AS (or PWS) is established through an abnormal DNA methylation pattern, the specific genetic mechanism involved can be investigated for the purposes of genetic counseling. Fluorescent in situ hybridization (FISH) or array-based comparative genomic hybridization (aCGH) analysis can be used to detect a deletion, while DNA microsatellite analysis can be performed to investigate the presence of UPD. For patients with an AS phenotype but normal DNA methylation, sequence analysis of the *UBE3A* gene can be used for further evaluation of the diagnosis. Collectively, molecular testing for AS through DNA methylation studies and sequencing of *UBE3A* will identify an alteration in approximately 90 % of individuals with clinical AS/PWS.

The recurrence risk for AS in a family and the type of prenatal testing that is available will vary according to the chromosome or molecular defect that is ultimately detected in the proband. For this reason, prenatal diagnosis should be undertaken only after the specific genetic mechanism in the proband has been determined and the parents have received genetic counseling. In cases where de novo deletions or UPD have been demonstrated, recurrence risk will be low, although prenatal testing may be offered for reassurance purposes. For cases of IC and *UBE3A* mutations, recurrence risk can be as high as 50 %. Since germline mosaicism has been reported in mothers of AS patients with *UBE3A* mutations, prenatal testing should be offered even if a mutation is not identified in the mother. Because methylation status within the promoter region of the *SNRPN* gene is established in early embryonic development, DNA methylation analysis on cells obtained from CVS is theoretically possible; however, most clinical molecular laboratories currently performing prenatal methylation testing prefer to use amniocytes for testing due to the relative hypomethylation of cells derived from the placenta [15]. Prenatal testing is appropriate for families without a previous child with AS if a deletion of chromosome 15q11–q13 is suspected on chromosome analysis of CVS or amniotic fluid, or if trisomy 15 is noted on CVS but a normal karyotype is found on amniotic fluid, which would suggest that a trisomy rescue event may have occurred (possibly resulting in UPD). Prenatal testing also would be indicated if either a de novo chromosome 15 translocation or a supernumerary marker chromosome is found by karyotype analysis.

Parents of patients with deletions, specifically the mothers of AS patients, should be tested by chromosome and FISH analysis to determine if they carry balanced chromosome rearrangements or deletions which are not expressed as an abnormal phenotype in that parent. Chromosome analysis is appropriate for parents of patients with UPD combined with a Robertsonian translocation to determine whether the translocation is inherited or de novo. Parents also should be tested for mutations that are identified in the proband, such as IC deletions or *UBE3A* mutations. If a parent of an AS patient is found to be a carrier of a mutation or a chromosomal translocation, then the siblings of that parent should be offered testing.

Available Assays

DNA Methylation Analysis

Standard molecular techniques for the methylation analysis of CpG sites within the *SNRPN* gene promoter region include (1) double-digest Southern blot analysis using a methylation-sensitive enzyme such as *Not*I along with a methylation-insensitive enzyme such as *Xba*I [20]; (2) PCR amplification of the *SNRPN* promoter region following either *Not*I or mcrBC digestion; and (3) methylation-specific PCR (MS-PCR) which is based on modifying DNA with bisulfite, which converts unmethylated cytosine (C) to uracil (U), followed by amplification using primers specific for the unmethylated and methylated alleles [21].

Methylation-specific multiplex ligation-dependent probe amplification (MS-MLPA) provides a method to simultaneously semiquantitatively analyze copy number changes and DNA methylation status at numerous sites across the 15q11–q13 region. Oligonucleotide probes specific to the *SNRPN* gene are utilized, of which a subset contain a *Hha*I restriction site. After hybridization and ligation, the methylation-sensitive restriction enzyme *Hha*I is used to digest the unmethylated DNA. PCR amplification using a universal primer is performed, followed by separation of the amplification products by capillary electrophoresis. If the site is not methylated, the *Hha*I digestion will prevent amplification of the MS-MLPA probe. If the CpG sites are methylated, the *Hha*I enzyme is unable to digest the DNA, and PCR products are generated and detected. Individuals with AS will have two unmethylated (maternal) alleles and accordingly no MS-MLPA signal will be present. Individuals with no methylation abnormality will show a 50 % reduction in the MS-MLPA signal due to the presence of both a methylated and an unmethylated allele. Individuals with PWS will have two methylated (paternal) alleles and will show a 50 % increase in the MS-MLPA signal compared to normal controls.

Pyrosequencing is a quantitative method available to assess the CpG methylation status of the *SNRPN* gene [22]. As in MS-PCR, the genomic DNA is treated with bisulfite to convert unmethylated C to U, whereas methylated cytosine (^{m}C) will remain unchanged. During PCR amplification of the bisulfite-treated DNA, the U will be amplified as thymine (T) and the ^{m}C will be amplified as C. Pyrosequencing, which is a "sequencing-by-synthesis" method based on the luminometric detection of a pyrophosphate release that occurs upon the incorporation of nucleotides into the sequence, is then utilized to discriminate C and ^{m}C by the presence of a T or C at each CpG site analyzed, respectively. This information is used to determine the percent methylation at each CpG site, which will be approximately 50 % for normal individuals who have both a methylated (paternal) and unmethylated (maternal) allele. Individuals with AS will have 0 % methylation at each site, and individuals with PWS will have 100 % methylation at each site.

Uniparental Disomy Analysis

For individuals who exhibit methylation abnormalities but are negative for a deletion by FISH or aCGH, DNA microsatellite analysis to test for whole or segmental UPD of chromosome 15 is available for further evaluation of the diagnosis. UPD analysis requires DNA from the proband as well as both parents. Polymorphic repetitive regions (microsatellites) along chromosome 15 are analyzed to determine if the proband's genetic constitution reflects contribution from both parents at all loci tested (biparental) or from only one parent (UPD). Paternal UPD of chromosome 15 is consistent with AS while maternal UPD of chromosome 15 is consistent with PWS. Alternatively, SNP-based arrays can be used to detect segmental and whole chromosome UPD, but may not identify all cases of UPD, because the segment of UPD may be too small to be detected by SNPs designed to evaluate UPD of larger chromosomal regions. Abnormal methylation studies and biparental inheritance of chromosome 15 is suggestive of an imprinting center defect.

Targeted *UBE3A* Analysis

When DNA methylation testing is normal, *UBE3A* sequence analysis should be considered. The majority of mutations identified in the *UBE3A* gene are protein truncating mutations [23, 24]. These mutations must be present on the maternal allele in order to be pathogenic since *UBE3A* expression occurs only from the maternal allele. In some cases, small intragenic deletions of *UBE3A* have been detected, so gene-specific deletion and duplication testing should be considered for individuals who test negative for *UBE3A* gene sequencing [25, 26].

Interpretation of Test Results

If the methylation pattern or methylation-specific amplification is characteristic of only paternal inheritance in the individual tested, then a diagnosis of AS is confirmed (Fig. 7.3, lane 8). Conversely, a methylation pattern characteristic of only maternal inheritance is diagnostic for PWS (Fig. 7.3, lane 7). Methylation assays detect virtually all cases of PWS and AS that are caused by large deletions, UPD, and IC defects; however, they will not detect rare small deletions that do not involve the *SNRPN* locus or sequence alterations within the *UBE3A* gene. Therefore, methylation analysis will detect approximately 80 % of AS cases. Sequencing of the *UBE3A* gene will detect another 11 % of cases. Approximately 10 % of AS cases will not be detected with the currently available tests.

Laboratory Issues

If the etiology of DD in a patient is unknown, DNA analysis should be performed as part of a comprehensive genetic evaluation that includes assessment of single gene disorders

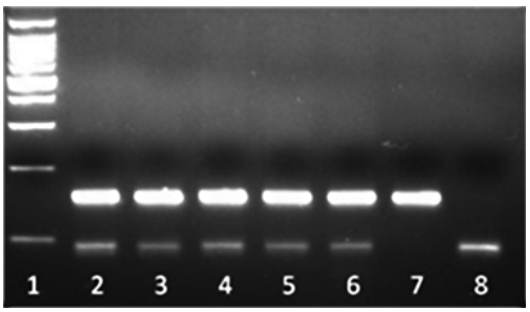

Figure 7.3 Methylation-sensitive PCR (MS-PCR) analysis of *SNRPN* DNA of patient samples referred to a clinical molecular laboratory. PCR products are amplified from the methylated and unmethylated alleles of the *SNRPN* locus. Normal individuals exhibit a biparental inheritance pattern (both upper methylated and lower unmethylated allele PCR products present; *lanes 2–6*), whereas patients with PWS show a pattern of only maternal inheritance (only upper methylated allele PCR product present; *lane 7*) and patients with AS show a pattern of only paternal inheritance (only lower unmethylated allele PCR product present; *lane 8*). Molecular weight ladder present in *lane 1*.

by molecular and cytogenetic approaches. Although every laboratory does not need to provide all testing methods, a smooth progression through the various tests may be necessary to determine the genetic mechanism causing AS. Testing is facilitated by a clinical molecular laboratory that is able to offer DNA methylation, FISH, UPD analysis and sequencing of the *UBE3A* gene, as well as gene-specific deletion/duplication testing. Mutation analysis of the IC is available only on a research basis.

The *SNRPN* probe for Southern blot analysis is available from American Type Culture Collection (http://www.atcc.org). Caution should be exercised when interpreting MS-PCR results, as allele dropout has been reported [27]. Because of the risk of allele dropout, multiple MS-PCR primer sets should be considered to minimize the possibility of a false-positive result. An MS-MLPA kit is available from MRC-Holland (http://www.mrc-holland.com). A pyrosequencing kit to evaluate methylation status of the AS/PWS critical region is available from Qiagen (http://www.qiagen.com). There are many microsatellite markers available for testing of the 15q11–q13 region, but caution should be exercised because some previously used markers are now considered problematic, such as *DS15S113* and *D15S817* [28, 29].

Rett Syndrome and Other *MECP2*-Related Disorders

Molecular Basis

Rett syndrome is an X-linked neurodevelopmental disorder that almost exclusively affects females. In the classic form of the disease, affected girls appear to develop normally until the age of 6–18 months followed by a characteristic pattern of regression, which includes deceleration of head growth leading to acquired microcephaly, autistic features, loss of speech and purposeful hand use, irregular breathing patterns, stereotypical hand wringing, and seizures [30]. There are well-documented criteria for the clinical diagnosis of Rett syndrome which include the clinical features that are considered as either necessary or supportive for the diagnosis [31]. The frequency of classic Rett syndrome is approximately 1 in 10,000 females [32]. In 1999, mutations in the methyl-CpG-binding protein 2 (*MECP2*) gene located at Xq28 were reported to be the underlying cause for Rett syndrome [33]. Since that time, a broader range of clinical phenotypes have also been associated with mutations in *MECP2* [34]. This section focuses on *MECP2* variants causing Rett and atypical-Rett syndromes which are X-linked dominant conditions. The other *MECP2*-related phenotypes primarily affect males and are considered to be X-linked recessive disorders.

Since being associated with *MECP2*, the field of Rett syndrome research has focused attention on determining the function of the MECP2 protein to better understand the underlying pathophysiology of the condition. The current perspective of MECP2 function is complex and is based on its apparent involvement as both a transcriptional repressor and activator [35]. MECP2 binds preferentially to methylated DNA via its methyl-CpG-binding domain, and silences transcription by recruiting corepressor complexes through its transcriptional repression domain. More recent studies have demonstrated that loss of MECP2 leads to reduced expression of numerous genes, implying a role in upregulating gene expression, although the mechanisms involved are not well understood [36]. This is an area of great interest given that Rett syndrome is not associated with any sort of gross anatomic abnormalities of the brain. MECP2 clearly affects transcriptional regulation more dramatically in certain regions of the brain than other regions. The physiologic significance of these differences needs to be understood in order for individuals affected by Rett syndrome to benefit from promising new therapeutic options in the future.

Clinical Utility of Testing

Independent studies have confirmed *MECP2* as the major causative gene for Rett syndrome by the identification of pathogenic mutations in approximately 95 % of classic cases. Approximately 85 % of classic Rett patients have either point mutations or small insertions/deletions within the *MECP2* coding region, while larger deletions have been identified in approximately 10 % of classic cases [37]. Nearly 50 % of Rett patients have one of eight recurrent point mutations, while most of the remainder has one of the many other described

pathogenic alterations. It should be noted that greater than 99 % of mutations in individuals with classic Rett syndrome are de novo, with the large majority occurring on the paternally inherited allele [38]. Mutations also have been found in atypical mild variant cases and in severe early-onset cases of Rett syndrome. In addition, *MECP2* mutations have been documented in patients with an Angelman-like presentation and in individuals with autistic phenotypes. Affected males with variable phenotypes ranging from lethal neonatal encephalopathy to uncharacterized ID have been shown to be caused by *MECP2* mutations. The presentation of Rett syndrome also has been documented in males with Klinefelter (47, XXY) syndrome, as well as those with mosaic *MECP2* mutations [39]. Definitive genotype-phenotype correlations have not been consistent, although several findings related to specific mutations appear to be reproducible [40]. Some studies have investigated multiple individuals with the same mutation but variable degrees of clinical severity, demonstrating that additional factors beyond the specific *MECP2* alteration play significant roles in the presentation of Rett syndrome [41]. In males, larger duplications of Xq28 that include *MECP2* have a consistent set of clinical features that include hypotonia, severe ID, absence of speech, seizures, and recurrent respiratory infections that often lead to death at an early age [42]. Given the spectrum of neurodevelopmental phenotypes associated with *MECP2* mutations, the clinical utility of molecular testing is significant.

Available Assays

The *MECP2* gene is composed of four exons, which give rise to two distinct MECP2 isoforms [43]. Diagnostic testing for Rett syndrome should begin with DNA sequence analysis of the entire *MECP2* coding region given the profile of known mutations. In the past, mutation scanning using denaturing high performance liquid chromatography (DHPLC) was used, but very few laboratories still utilize this method given the relative ease of sequencing *MECP2*. Sanger sequencing with capillary electrophoresis continues to be considered the gold standard for point mutation detection. Approximately 85 % of classic Rett syndrome patients have mutations that are detectable by sequencing of *MECP2*, which is performed by numerous clinical molecular laboratories (http://www.genetests.org/).

To increase the overall mutation detection for the *MECP2* gene, additional testing is available for larger *MECP2* dosage alterations, present in approximately 10 % of classic Rett patients. Deletions and duplications involving all or part of the gene have been identified by dosage-sensitive testing methods such as multiplex ligation-dependent probe amplification (MLPA), quantitative real-time PCR analysis, and targeted aCGH.

Interpretation of Test Results

Rett syndrome is commonly considered in females with DD, making the volume of *MECP2* testing performed worldwide significant. Molecular confirmation of Rett syndrome is straightforward when one of the eight common *MECP2* mutations is present. Interpreting other less common alterations can be assisted by use of available mutation databases. RettBASE, the database dedicated to *MECP2* (http://mecp2.chw.edu.au/), and the Human Gene Mutation Database (HGMD) are currently the most comprehensive resources. Some of the changes reported in the databases are not clinically correlated, leaving their pathogenicity uncertain. When other novel variants are identified, evaluation of additional family members to determine the segregation pattern may allow the clinical significance of an alteration to be interpreted with greater certainty. For females with variants of unknown clinical significance, the most common strategy is to test both parents. Alterations that are shown to be de novo are normally accepted as pathogenic mutations. In some rare cases, two de novo alterations are present with uncertainty which change is pathogenic, or whether their collective impact on protein function is causative of the symptoms. A variant of unknown significance inherited from the father is interpreted as not being clinically significant given the expectation that the variant would have an even greater phenotypic consequence in a male with a single X chromosome. When variants are inherited from the mother, the interpretation becomes more challenging and typically requires additional testing which often includes both X-inactivation testing of the mother and variant analysis of additional family members. If the proband and her mother carry the same alteration and both have normal/random X-inactivation patterns, the variant typically is interpreted as a benign variant with no clinical significance. Testing of extended family members has the potential to identify the change in a phenotypically normal male which also confirms that the change is not clinically relevant. When testing males, the interpretation issues change to some degree and the strategy for these will be discussed later in the X-linked intellectual disability section of this chapter.

Laboratory Issues

One of the issues encountered in sequence-based clinical testing is the interpretation of novel sequence variations, particularly alleles of uncertain pathogenic significance. A valuable resource for laboratories and referring clinicians is provided by the American College of Medical Genetics, which has issued updated recommended standards and guidelines for interpretation of sequence variations [44]; the recommendations are available at http://www.acmg.net. Another current issue pertaining to molecular testing for Rett syndrome is the

value of two-tier testing (sequencing followed by dosage analysis) to provide comprehensive mutation analysis of *MECP2*. Identification of the mutation in the proband facilitates prenatal testing in subsequent pregnancies, although the majority of *MECP2* point mutations are de novo and of paternal origin, with extremely low rates of recurrence. Prenatal testing should be offered to females who are known to carry a point mutation or large rearrangement in *MECP2*. In cases where the mother is not a carrier, prenatal testing may be sought for parental reassurance due to rare reports of germline mosaicism [45]. The current focus on point mutation analysis within the coding region by sequence analysis does not rule out potential mutations in regulatory elements or other important noncoding regions of *MECP2*. Equally important to consider are the other conditions that phenotypically overlap with Rett syndrome and should be given further consideration when clinical testing for *MECP2* is negative. Several of these syndromes and their respective gene associations are discussed in the following section.

Angelman/Rett Syndrome Second-Tier Testing

Molecular Basis

AS and Rett syndromes are clinically similar conditions that often present with numerous overlapping phenotypic features. Clinicians with significant clinical experience typically can distinguish the two conditions, but in many cases clinical diagnosis can be challenging. As discussed earlier, AS and Rett syndromes are caused by disruption or loss of normal gene function of the *UBE3A* and *MECP2* genes, respectively. Testing for these conditions is common given their prevalence and the number of individuals with DD suggestive of one or both of these diagnoses. Accordingly, many patients have clinical presentations that mimic AS and Rett syndrome and have normal clinical test results for both disorders. In these instances, additional testing of genes causing diseases with overlapping phenotypes may provide the molecular diagnosis needed. Some of the most common conditions that should be considered in the differential diagnosis for AS and Rett syndrome for which diagnostic testing is available are discussed in this section. The syndromes detailed in this section are not meant to be an all-inclusive list, but rather as a starting point for second tier testing for patients with features in this clinical spectrum of ID/DD.

Clinical Utility of Testing

The molecular confirmation of a clinical diagnosis allows the physician to provide recurrence risks and genetic counseling, as well as prenatal diagnosis, to the proband and additional family members. Once the presence of a causative mutation has been established in an individual, targeted analysis of fetal samples is available for prenatal testing, as well as for other family members.

Molecular Genetic Testing

CDKL5 Gene

Mutations in the *CDKL5* (cyclin-dependent kinase-like 5) gene have been identified in individuals with early-onset infantile spasms and clinical features that overlap other neurodevelopmental disorders, such as AS and Rett syndromes [46]. Subsequently, mutations in *CDKL5* (also known as Serine Threonine Kinase 9 or *STK9*) have been associated with an atypical variant of Rett syndrome, which includes ID and other severe neurological symptoms including severe early-onset seizures, regression of communication and skills, and global developmental delay. Rett-like stereotypies such as hand-wringing have been identified in individuals with *CDKL5* mutations, further indicating a shared clinical differential.

Mutations identified in *CDKL5* show haploinsufficiency, including missense and splicing mutations, small deletions and insertions, as well as nonsense mutations. De novo mutations and evidence of germline mosaicism have been reported, suggesting that the presence of an affected proband in a family is sufficient to consider prenatal diagnosis. Large deletions have also been detected, thus deletion and duplication testing should be considered if an individual tests negative for sequence mutations.

FOXG1 Gene

Point mutations and deletions in the *FOXG1* (forkhead box G1) gene are associated with a developmental disorder known as the congenital variant of Rett syndrome. This disorder exhibits features of classic Rett syndrome, but with an earlier onset within the first months of life. Reports of individuals with mutations in the *FOXG1* gene show a clinical profile consisting of postnatal microcephaly, apraxia, absent language, stereotypical hand and mouth movements, seizures, poor sleep, and hypoplasia of the corpus callosum with decreased white matter volume [47–49]. Unlike Rett syndrome, individuals with a *FOXG1* mutation do not have periods of normal development; thus regression is not usually a feature.

In addition to sequence mutations, deletions and duplications have been reported in the *FOXG1* gene. Deletions have been identified in a cohort of patients with severe mental retardation, microcephaly, absent language, and/or brain anomalies [50]. Duplications have been associated with epilepsy, mental retardation, and speech impairment [51]. For patients suspected to have the congenital variant of Rett syndrome, sequence analysis is recommended as the first step in mutation identification. For patients in whom mutations are

not identified by gene sequencing, deletion/duplication testing is appropriate.

SLC9A6 Gene

Mutations in the *SLC9A6* (solute carrier family 9, member 6) gene are found in Christianson syndrome, an X-linked condition associated with ID, microcephaly, seizures, ataxia, and absent speech [52]. Individuals with *SLC9A6* mutations may exhibit an apparently happy disposition, with laughter and excessive smiling, that is reminiscent of AS [53]. Additional reports suggest that individuals have deceleration of head growth in the first year of life, epilepsy, and a thin body habitus [52]. The clinical spectrum caused by mutations in SLC9A6 resembles AS in younger individuals and should be considered as part of the differential. The clinical spectrum of carrier females can range from ID to absence of symptoms [52, 54].

TCF4 Gene

Mutations in the *TCF4* (transcription factor 4) gene are found in Pitt-Hopkins syndrome. Haploinsufficiency mutations are causative of disease, which also include deletions of the *TCF4* gene [55]. In cases where parental samples were available, de novo occurrence of the mutation was established [56, 57]. Pitt-Hopkins syndrome is characterized by ID, intermittent hyperventilation and apnea, and a characteristic facial gestalt that includes a wide mouth [58]. Additional clinical features seen in individuals with Pitt-Hopkins may include clubbing of the fingers and toes, thick lips, prominent nose, and epilepsy.

Available Assays

Sequence-based tests are considered the gold standard for point mutation detection, with deletion/duplication testing increasing the yield of identifiable mutations. Standard sequencing protocols and custom primer designs are utilized for gene-specific analysis. Targeted aCGH and MLPA assays can be designed for interrogation of deletions and duplications. With the implementation of next-generation sequencing (NGS) in the clinical molecular laboratory setting, testing for multiple genes causative of disorders with similar phenotypes is increasingly available. Testing for single gene disorders that share a clinical presentation feature, such as DD, may be offered as a single test panel inclusive of the many genes associated or with a DD or ID phenotype. Additional comments regarding NGS and targeted gene panels can be found in the XLID section later in this chapter and in Chap. 59.

Interpretation of Test Results

The identification of sequence alterations is standard in many clinical laboratories. The interpretation of the clinical significance of identified variants is dependent upon the identification of the change in individuals with disease, familial segregation of the variant with the disease phenotype, clinical suspicion, conservation, protein prediction, presence in the general population, and functional evidence that the change is disease causing.

Laboratory Issues

Large deletions and duplications, mutations in the promoter region, mutations in some regulatory regions, as well as deep intronic mutations will likely not be detected by traditional Sanger sequencing methods. Deletion/duplication testing for the gene of interest may be appropriate to identify larger dosage alterations not detected by traditional sequencing methods.

Noonan Syndrome and Related Disorders

Molecular Basis

Noonan syndrome (NS) is a clinically and genetically heterogeneous congenital disorder with an estimated prevalence of 1 in 1,000–2,500 live births [59]. First described by the pediatric cardiologist, Jacqueline Noonan in 1968 [60], NS is characterized by distinctive facial features, short stature, congenital heart defects, variable cognitive deficits, and an increased risk of specific cancers [60, 61]. Until recently, the diagnosis of NS was based solely on clinical findings; however, genetic mutations now are identifiable in approximately 60–80 % of patients with a clinical diagnosis of NS.

NS is a Mendelian trait transmitted in an autosomal dominant manner with a significant but unclear percentage of cases due to de novo mutations. In 1994, linkage analysis of a large NS family was used to definitively establish the first NS locus in the chromosome 12q22-qter interval which led to the subsequent identification of the first causative gene, protein tyrosine phosphatase nonreceptor type 11 (*PTPN11*) [62–64]. There are currently nine genes (*PTPN11*, *SOS1*, *RAF1*, *KRAS*, *BRAF*, *SHOC2*, *NRAS*, *MAP2K1*, and *CBL*) that have been causally related to NS and more are likely to be discovered (Table 7.2) [64–74]. Interestingly, all of these genes encode components of the same molecular pathway, the RAS-mitogen activated protein kinase (RAS-MAPK) signal transduction pathway, which mediates many diverse cellular functions including proliferation, migration, survival, cell fate determination, differentiation, and senescence. In addition to NS, there are several other clinically related disorders also linked to germline mutations within the RAS-MAPK pathway (Table 7.2) [70, 75–81]. These disorders include LEOPARD syndrome, Costello syndrome, cardiofaciocutaneous (CFC) syndrome, neurofibromatosis

Table 7.2 Genetic syndromes of the RAS-MAPK pathway

Syndrome	Gene	Chromosome location	Protein
Noonan	*PTPN11*	12q24.1	SHP2
	SOS1	2p22.1	SOS1
	RAF1	3p25.1	CRAF
	KRAS	12p12.1	KRAS
	BRAF	7q34	BRAF
	SHOC2	10q25	SHOC2
	NRAS	1p15.2	NRAS
	MAP2K1	15q22.31	MEK1
	CBL	11q23.3	CBL
LEOPARD	*PTPN11*	12q24.1	SHP2
	RAF1	3p25.1	CRAF
	BRAF	7q34	BRAF
Costello	*HRAS*	11p15.5	HRAS
Cardiofaciocutaneous	*BRAF*	7q34	BRAF
	MAP2K1	15q22.31	MEK1
	MAP2K2	19p13.3	MEK2
	KRAS	12p12.1	KRAS
Neurofibromatosis 1	*NF1*	17q11.2	Neurofibromin
Legius	*SPRED1*	15q14	SPRED1

type 1 and Legius syndrome. Collectively, this group of developmental disorders has come to be referred to as the RASopathies or alternatively, the neurocardiofacialcutaneous syndrome (NCFCS) family.

The RAS-MAPK pathway is activated in response to cytokine, hormone, and growth factor stimulation, and is a major mediator of early and late developmental processes, including morphology determination, organogenesis, synaptic plasticity, and growth. Dysregulation of the RAS-MAPK pathway, specifically enhanced activation, has been well established as one of the primary causes of many types of cancer. RAS-MAPK pathway genes are found to be somatically mutated in approximately 20 % of all malignancies [82]. Only relatively recently has this pathway also come to be known for its role in developmental disorders such as NS. Similar to the somatic mutations that are involved in cancer, germline mutations responsible for NS and related disorders are almost exclusively gain-of-function missense mutations.

Functionally, these mutations have been demonstrated to result in increased signal transduction through the RAS-MAPK pathway leading to the clinical manifestations of NS and other disorders, although the exact cellular mechanism remains unclear. Given the role of the RAS-MAPK pathway in oncogenesis, it is not surprising that, the NCFCS family of disorders share an increased risk of malignancy, with the exception of CFC syndrome. In general, the germline mutations that cause these developmental disorders are distinct from the somatic mutations observed in cancer, and it has been hypothesized that the mutations capable of surviving in the germline may be less strongly activating than those involved in cancer [83].

Clinical Utility of Testing

Due to variability in the phenotypic manifestations of NS, as well as significant clinical overlap with other disorders, establishing a diagnosis of NS by clinical examination alone can be difficult. Therefore, diagnostic testing is increasingly being used to confirm or establish a diagnosis of NS, especially in patients presenting without a prior family history. The disorders that have considerable clinical overlap with NS include not only other conditions within the NCFCS family, but also Turner syndrome, Aarskog syndrome, fetal alcohol syndrome, mosaic trisomy 22, and Baraitser-Winter syndrome, among others. A molecular diagnosis of NS is established through the detection of a pathogenic mutation in one of the nine known NS genes. Identifying the disease-causing mutation not only provides the patient with a definitive diagnosis of NS, but also allows the clinician to provide the family with an accurate recurrence risk. If the mutation was inherited from an affected parent, then the couple has a 50 % chance of having another child affected with NS. However, if the mutation is determined to be de novo in the proband, then the recurrence risk for the couple would be <1 %, allowing for the rare possibility of germline mosaicism. Furthermore, identification of the causative mutation allows the couple the option of having prenatal or preimplantation genetic diagnosis (PGD) for subsequent pregnancies. Prenatal testing for NS may be warranted even without prior identification of a disease-causing mutation in the family, based on abnormal ultrasound findings. Though not specific for NS, prenatal features associated with NS that may be detected on ultrasound examination include polyhydramnios, cardiac defects, cystic hygroma, and increased nuchal translucency. Of fetuses with normal chromosomes, 1–3 % of cases with nuchal edema detected in the first trimester and 10 % of second-trimester fetuses with a cystic hygroma will be diagnosed with NS [84, 85]. Lastly, establishing a definitive diagnosis of NS through molecular testing is important to provide the patient and their family with accurate information regarding prognosis, cancer risk, and potential therapeutic options, because this information varies considerably depending on the specific disorder.

Available Assays

When NS is clinically suspected, a karyotype and/or aCGH should be performed to rule out Turner syndrome, mosaic

trisomy 22, or other chromosomal alterations. Provided the patient has a normal karyotype, molecular analysis of the nine genes known to cause NS should be performed. The order in which these genes are tested and the molecular technology used to detect mutations within these genes may vary. As gain-of-function missense mutations are the primary type of mutation associated with NS, Sanger sequencing of the entire coding region of each gene is typically considered the standard testing approach. Genotype/phenotype correlations have been reported in NS and may be used to determine the specific order in which the NS genes should be tested. For patients with a classic NS presentation, a sequential approach typically is taken, starting with sequencing of the *PTPN11* gene followed by sequencing of the remaining eight genes in the following order: *SOS1*, *RAF1*, *KRAS*, *SHOC2* (targeted analysis for the recurrent p.S2G mutation), *BRAF*, *MAP2K1*, *NRAS*, and *CBL*. This approach will identify a disease-causing mutation in approximately 60–80 % of individuals with a clinical diagnosis of NS. Mutations in the *PTPN11* gene are detected in approximately 50 % of individuals with NS and are more common in familial cases. *PTPN11* mutations are more common in patients with a classic facial presentation and pulmonary valve stenosis or atrial septal defect, and are less common in patients with hypertrophic cardiomyopathy (HCM) [86]. Importantly, patients with *PTPN11* mutations are at an increased risk for bleeding diathesis and juvenile myelomonocytic leukemia. Individuals with *SOS1* mutations (10–13 % of individuals with a clinical diagnosis of NS) are more likely to have ectodermal features including keratosis pilaris, sparse hair, curly hair, or sparse eyebrows, and are less likely to have short stature or cognitive deficits [66]. The majority of individuals with *RAF1* mutations have HCM, and the *SHOC2* p.S2G recurrent mutation has been associated with a distinctive hair phenotype called loose anagen hair in which the hair is extremely fine in texture, grows very slowly and can be easily plucked from the scalp [67, 68, 71].

As an alternative to sequential testing, simultaneous testing of all nine NS genes can be performed using Sanger sequencing, microarray-based sequencing, or NGS. A simultaneous approach may allow for faster test results and may or may not offer a potential cost reduction compared to sequential testing. Currently, the clinical utility of copy number analysis of the NS genes is unclear, since deletion/duplication of these genes is not a commonly observed disease mechanism; although gene duplications involving the *PTPN11* gene have been reported in individuals with clinical NS [87, 88].

Laboratory Issues

As with other sequence-based molecular testing, the major potential laboratory issue associated with molecular testing for NS is the detection of variants of unknown or uncertain clinical significance. When a sequence variant is unable to be classified as benign or pathogenic, testing of the proband's parents and/or other family members can be used to further assess the pathogenicity of the variant. Because disease-causing mutations associated with NS are almost invariably missense mutations, intronic sequence variants or variants of other mutation classes generally are considered less likely to be pathogenic. Additionally, the results of laboratory testing should be interpreted in the context of the patient's clinical features to ensure that the appropriate clinical diagnosis is ultimately made because other conditions are known to be allelic with NS (i.e., LEOPARD syndrome and CFC syndrome). Another important issue to consider when testing for NS is that negative testing of the known NS genes cannot rule out a clinical diagnosis of NS. Approximately 20–40 % of NS patients will not have a pathogenic mutation identified with currently available testing. Presumably this percentage will decrease as more genes causative of NS are identified.

X-Linked Intellectual Disability

Molecular Basis

Conditions that present with ID as the predominant phenotypic feature and are caused by defects of an X-linked gene are collectively referred to as X-linked intellectual disability (XLID). Although the primary clinical feature is ID, other serious and complicated physical, neurological and muscular features may also be present in patients with XLID [89–91]. As of early 2012, approximately 100 X-linked genes have been associated with ID and therefore are considered to be authenticated XLID genes. Even though the current number of genes is significant, many additional XLID genes likely exist because there are families with multiple affected males and a clearly X-linked pattern of inheritance that cannot be explained by mutations in the current list of associated genes [92]. Recently, new molecular technologies have accelerated the pace of genotype-phenotype discoveries and continued progress in the field of XLID is expected in the years ahead.

Beyond the unifying presentation of ID, individuals with one of the many XLID conditions can have a diverse array of additional clinical features. For classification purposes, XLID is divided into two general categories: syndromal and nonsyndromal. Syndromal XLID encompasses those conditions that present with additional phenotypic features that allow them to be differentiated from one another clinically. The majority of the syndromal XLID conditions have consistent clinical presentations that can include dysmorphic features, neurodevelopmental delays and possibly other physical manifestations. While an experienced clinician can identify some of these syndromes by their presentation, many of the

XLID syndromes have features that overlap to such a degree that they are difficult to differentiate. In some cases, the associated phenotype is known to evolve over time, potentially making the diagnosis more problematic in adults than in children. Adding interest to syndromal XLID conditions is the fact that some genes display phenotypic heterogeneity and are associated with more than one clearly defined syndromal presentation.

In contrast, individuals with a nonsyndromal form of XLID have no additional consistent clinical findings beyond ID, making diagnosis much more complicated at the molecular level. Roughly two-thirds of XLID is believed to be nonsyndromal, which reinforces the importance of having testing options that adequately address this XLID group. Both nonsyndromal and syndromal presentations have been attributed to the same gene, further complicating XLID molecular diagnosis. Furthermore, for many of the XLID genes, only a small number of families with mutations have been identified, making genotype-phenotype correlations difficult. On the other hand, a number of well-described XLID syndromes have been diagnosed in many patients throughout the world, allowing these conditions to be more distinct and recognizable [93].

Correlating with the broad spectrum of phenotypic presentations associated with XLID, the known genes causative of XLID have a wide range of functions and are not simply intermediates of a particular signaling, biochemical, or functional pathway, as noted with the RASopathies in the previous section. The following cellular activities are interrupted by mutations in at least one XLID gene: regulation of transcription, enzymatic function, energy production, myelination, cellular structure, lysosomal function, regulation of cell cycle activities, RNA binding, neuronal migration, cell adhesion, peroxisomal transport, phosphatase activity, kinase signaling, ion channel/exchange function, deacetylase activity, ubiquitin-related activity, nonsense-mediated decay, vesicular transport, and protease activity. A complete list of XLID conditions organized by the year of gene discovery, gene function and method used for discovery is available at http://www.ggc.org/images/documents/genes-involved-in-xlmr.pdf. As stated earlier, advances in molecular methods available to the clinical molecular laboratory, such as NGS, will continue to improve the diagnostic testing available for XLID [94].

Clinical Utility of Testing

FXS is the most common XLID condition, and the clinical utility of testing for this disorder, as discussed earlier in this chapter, applies in general to the entirety of XLID [95]. There are caveats that make FXS unique in some regards due to the trinucleotide repeat expansion that underlies nearly all cases of this condition. Details of FXS and *FMR1* testing will not be reiterated here; however, another XLID condition caused by a trinucleotide expansion is much less common and known as FRAXE (or ID associated with fragile site FRAXE). FRAXE is caused by expansion of a CCG repeat in the 5′ untranslated region of *AFF2* (previously known as *FMR2*). For the remainder of the XLID conditions, more traditional Mendelian alterations, such as point mutations, small insertions/deletions, and other larger scale deletions and duplications, account for the mutational spectrum [96, 97]. For some genes, the mutational diversity is minimal, while for others, it is quite extensive with large numbers of pathogenic alterations documented in the literature and in the HGMD. In most clinical settings, FXS is one of the first genetic tests requested for individuals with ID/DD, given the relative prevalence of FXS and especially in younger children when the clinical presentation may not be fully developed. Once FXS and other cytogenetic rearrangements have been ruled out, a testing strategy appropriate for the affected individual is developed.

As therapeutic options are generally limited and related to early interventions, the benefit to affected individuals is limited at the present time. One of the greatest benefits to identifying the specific XLID gene and mutation is providing reproductive information for the extended family. In many cases, families have multiple affected males prior to reaching a confirmed XLID diagnosis, which emphasizes the need for earlier clinical diagnosis and testing. Females that are heterozygous for a pathogenic XLID mutation most often are phenotypically normal, making prediction of carrier status virtually impossible in the absence of molecular testing. This uncertainty can lead to great angst for properly counseled females who have a 50 % chance that each pregnancy will result in the transmission of the X chromosome that carries the pathogenic alteration. This translates to 50 % of male offspring inheriting the abnormal X chromosome and being affected, while 50 % of female offspring will be carriers. For some XLID conditions, carrier females can present with features that are clinically recognizable, albeit, less severe in comparison to classically affected males.

X-inactivation (XI) is another genetic mechanism that plays a role in XLID. Carrier females often exhibit preferential inactivation of the X chromosome that carries a pathogenic mutation which serves as a protective factor. Some XLID conditions almost always are associated with skewed or nonrandom XI in carrier females, while other conditions have not been linked to biased inactivation of the X chromosome. In some XLID families, some carrier females have random (i.e., normal) XI, while other females with the same change have completely skewed XI, suggesting that other factors play a role in this complex biological process.

Available Assays

Due the high prevalence of FXS as a cause of ID/DD, FXS is the only XLID condition for which testing is available in most clinical molecular laboratories. Given the frequency of ID/DD in the general population, FXS testing is a more frequently ordered test in comparison to most other molecular studies performed for inherited disorders. For the remainder of XLID conditions, clinical testing has historically targeted the most common syndromes and has been offered by a limited number of laboratories. More recently, the paradigm of single gene testing for conditions with genetic heterogeneity is being supplemented with newer testing options such as targeted gene panels performed by NGS. Targeted NGS requires that the genomic DNA first be enriched for the regions of interest using one of several different technologies that are based either on PCR that is multiplexed at high orders of magnitude or by in-solution hybridization methods that have been developed to complement the newest sequencing platforms. XLID became one of the first targeted applications of NGS to be offered diagnostically, making comprehensive testing for individuals with a suspected X-linked disorder a reality. Even though a targeted panel for known XLID genes represents a major advancement in the field, single gene testing likely will continue to be an important option, evolving to targeted gene panels, and eventual transition to exome or genome sequencing, as these options become practical and cost effective in the clinical laboratory setting.

In addition to investigating genes by sequencing, either single genes or a gene panel, the possibility of larger scale deletions or duplications not detected by sequencing should be considered. Deletions in X-linked genes should be detected in males by a loss of amplification (or enrichment) and subsequent lack of sequence data. Duplications are not typically detectable by sequencing, so other technologies are necessary for detection. MLPA and aCGH have been the two principal methods for assessing dosage, each with its own benefits and limitations (not discussed in detail here) [98].

Interpretation of Test Results

Whether interpreting results from single-gene studies or from larger XLID gene panels, common issues are encountered. Clearly pathogenic alterations (nonsense, frameshift, consensus splice site) are not difficult to interpret as being clinically significant. Other novel variants such as missense, synonymous and intronic changes can be more challenging to resolve [99]. The most helpful method for determining the pathogenicity of a variant of unknown clinical significance often comes in the form of further testing of appropriate family members. Confirming the carrier status of the proband's mother is the first priority, especially in cases where there may not be a definitive X-linked family history. De novo mutations in known XLID genes are expected to be pathogenic in nearly all cases, but some rare exceptions to this rule may exist. For variants that are proven to be maternally inherited, the next step is ascertaining the availability of additional family members for testing. In principle, this becomes an exercise of segregation testing of the maternally related males that are available and willing to participate. The presence of a variant of unknown significance in a phenotypically normal male allows the change to be interpreted as a benign variant. In larger pedigrees, clear segregation of the abnormal allele only in affected males and the normal allele in unaffected males increases the likelihood that the variant is pathogenic, although. In such families the alteration may be a benign variant that is in linkage disequilibrium with the genuine disease-causing mutation. For some of the XLID genes, there may be an enzymatic/functional assay or biomarker that can be utilized to help substantiate the pathogenicity of a change that appears to be clinically relevant. RNA analysis also can be very helpful in determining if certain changes lead to altered splicing that affects the final transcript for the gene, but in general this analysis is not a clinically available service. The interpretation of molecular XLID test results has a variety of recurring themes that always need to be considered in the context of the individual patient/family being tested.

Laboratory Issues

Many of the laboratory issues discussed earlier in this chapter also apply to XLID testing. The newest area of issues pertaining to XLID and other targeted panels relates to the use of the most recently developed technologies for enrichment and sequencing. Significant effort is required to develop and validate targeted NGS gene panels that are designed to address a specific clinical condition, and then updating these gene panel tests as new genes are identified. This will continue to be an ongoing issue for some time, but will likely be overcome as targeted panels are replaced by exome and/or genome sequencing. Another issue pertaining to NGS-based testing relates to the current common practice of confirming novel changes using Sanger sequencing. The need for this as a routine procedure will likely diminish as NGS technologies become more standardized. Another issue that may become more common is the identification of alterations that appear to be mosaic. NGS allows for lower levels of mosaicism to be detected compared to Sanger sequencing, thus making secondary confirmation by Sanger sequencing a potentially difficult challenge for clinical laboratories. Lastly, bioinformatics and data management are significant issues that require attention as clinical laboratories shift away from single-gene testing towards use of NGS for targeted panels and exome or genome sequencing.

Conclusions and Future Directions

Much progress has been made in identifying individual genes and causative mutations for ID/DD. Some tests, such as FXS repeat testing or methylation analysis for AS/PWS are widely available in clinical laboratories; however, testing genes for less prevalent syndromes is performed in only those laboratories which have sequencing capabilities and expertise. As the field moves towards NGS platforms, new genes will be discovered and shown to be associated with ID/DD and incorporated into clinical tests. Challenges will remain with interpretation of variants of uncertain clinical significance, but as testing becomes more widely available, understanding of the molecular basis for these disorders will increase.

Congenital Disorders of Glycosylation

8

Melanie A. Jones and Madhuri R. Hegde

Abstract

Glycosylation is the addition of sugars (glycans) to proteins and lipids and is the most frequent modification of both secreted and membrane-bound proteins. Defective synthesis, assembly or processing of glycans results in a group of disorders known as congenital disorders of glycosylation (CDG). Biochemical testing assesses the level of glycosylation on glycoproteins, such as transferrin, as well as the structure of *N*-linked or *O*-linked glycans released from glycoproteins. Molecular CDG single gene and gene panel testing is clinically available for more than 30 CDG-associated genes. An exome sequencing approach is being used to identify the gene defect in individuals with unknown types of CDG (CDG-Ix and CDG-IIx), and can lead to the identification of new CDG genes. Identification of the molecular mechanisms for new subtypes of CDG will provide important building blocks for the development of new treatments and therapies for individuals affected with CDG.

Glycosylation • Congenital disorders • *N*-glycosylation • *O*-glycosylation • Lipids • Serum transferrin

Introduction

Glycosylation is the addition of sugars (glycans) to proteins and lipids and is the most frequent modification of both secreted and membrane-bound proteins [1]. Two types of protein glycosylation occur, *N*-linked and *O*-linked, which differ in the linkage of the oligosaccharide to protein.

Approximately 50 % of all proteins in the human genome are *N*-glycosylated [2]. In *N*-glycosylation, an oligosaccharide is assembled, beginning in the cytosol and continued in the endoplasmic reticulum (ER). The sugar chain precursor is assembled on a lipid dolichol pyrophosphate carrier in the ER membrane and consists of two *N*-acetylglucosamine residues, nine mannose residues, and three glucose residues. Once the assembly process is complete, the oligosaccharyltransferase complex transfers the oligosaccharide to specific asparagine residues on nascent polypeptide chains in the lumen of the ER. After linkage, modification of the glycan begins with the trimming of sugar chains in the ER, and further modification of these sugar chains takes place in the Golgi apparatus. This pathway is well described, and many enzymes are involved in both the assembly and the post-linkage processing of the glycan chain [3]. *N*-glycosylated proteins are important for a variety of biological processes, including intracellular targeting, cell-cell recognition, protein folding and stability, and immune response [1].

In contrast, *O*-linked-glycosylation occurs in the Golgi apparatus with sugars added sequentially to serine or threonine amino acids of proteins. *O*-glycosylated proteins provide a barrier against pathogens, serve as lubricants, provide cushioning and physical integrity to the extracellular matrix, and function as co-receptors for a number of growth factors [1].

Glycosylation of lipids begins within the cytosol and continues in the ER and Golgi apparatus. Glycosylated lipids are involved in signaling, membrane diffusion, and sorting [4]. Hence, the proper development and functioning of multiple organ systems are dependent upon normal glycosylation of proteins and lipids.

Molecular Basis of Disease

An impaired *N*-glycosylation biosynthesis pathway, due to mutations in genes that encode proteins that function within this pathway or are involved in intracellular protein or nucleotide sugar trafficking between the endoplasmic reticulum and Golgi apparatus, affects multiple organ systems including the brain, heart, bone, endocrine system, immune system, liver, gastrointestinal tract, and vision [1]. Defects within the *O*-glycosylation pathway mainly affect muscle, bone, cartilage, and the extracellular matrix [1]. Defects in lipid glycosylation primarily affect the nervous system [5, 6].

Defective synthesis, assembly or processing of glycans results in a group of disorders known as congenital disorders of glycosylation (CDG) [1]. The majority of individuals with CDG have symptoms that began in infancy. These symptoms can include severe developmental delay, ataxia, seizures, liver fibrosis, cardiac dysfunction, retinopathy, skeletal abnormalities, and coagulopathies. The liver and intestine are most affected in CDG because these organs consume the most mannose for glycoprotein synthesis. Approximately 20 % of children do not survive beyond 5 years of age due to widespread organ dysfunction and severe infections. Worldwide occurrence of CDG has an estimated prevalence as high as 1 in 20,000. The great variability of symptoms and severity of disease across individuals with CDG makes the diagnosis of these disorders challenging to pediatric health care providers. The majority of CDG types are due to autosomal recessive inheritance. The exceptions include an X-linked *N*-glycosylation defect and two autosomal dominant *O*-glycosylation defects.

CDG patients are classified as having either Type I, Type II, or combined Type I and Type II defects, which is defined by serum transferrin analysis. This designation is based on whether the *N*-glycosylation defect results in either hypo- or mis-glycosylation [7]. Type I CDGs are caused by defects in genes that create the sugar chain precursors or in genes that attach these precursors to proteins and lipids. These defects result in a glycan structure that is partially or totally missing. Type II CDGs are caused by defects in genes that modify the sugar chains after they are attached to proteins and lipids. These defects result in a structurally altered glycan. Combined Type I and Type II defects have recently been reported, making an accurate diagnosis in these patients even more challenging. Most CDG subtypes have been described in only a few individuals; therefore, an understanding of phenotypes for these CDG subtypes is limited.

Currently, efficient treatment is only available for one subtype of CDG, MPI-CDG (CDG-Ib), caused by mutations in the phosphomannose-isomerase (*MPI*) gene [8]. The defect in MPI-CDG is the inability to convert fructose-6 phosphate to mannose-6-phosphate. The enzyme hexokinase can form mannose-6-phosphate from the administration of oral mannose, thereby bypassing the defect. Two other CDGs that can respond to treatment include SLC35C1-CDG (CDG-IIc) in which fucose is an effective treatment for recurrent infections with hyperleukocystosis, and PIGM-CDG in which butyrate upregulates PIGM transcription, thereby controlling seizures [9, 10]. Only supportive therapy and symptom-based treatment is available for all other CDG subtypes.

Clinical Utility of Testing

Due to the multisystem involvement of CDG, subtype diagnosis based on the clinical phenotype often is not possible. A combination of biochemical and molecular testing is used to identify the CDG subtype. Confirmation of the specific gene defect is important because some life-threatening phenotypes (i.e., cardiac dysfunction) have presented in only certain subtypes of CDG and may develop at any time. Confirmation of the defect allows for close monitoring of different organs for dysfunction and complications that may arise due to coagulation abnormalities. A growing number of individuals have a biochemical diagnosis of CDG without identification of a disease-causing mutation in a known CDG gene. Although molecular testing may miss some mutations in deep intronic or promoter regions of CDG-associated genes, many individuals with negative testing likely have mutations in genes not yet associated with CDG.

Genotype-phenotype correlations are not well described for many subtypes of CDG because only a few individuals have had mutations detected in the majority of CDG-associated genes [11]. Even in the most common CDG subtype, PMM2-CDG (CDG-Ia), individuals with the same mutation have variable severity of the clinical symptoms [12]. Identification of both disease-causing mutations in the affected individual allows carrier and prenatal testing of other family members.

Available Assays

Biochemical Assays

The standard screening for individuals with symptoms of CDG is biochemical testing to assess the level of glycosylation on glycoproteins, such as transferrin, and the structure

of *N*-linked or *O*-linked glycans released from glycoproteins [13]. Transferrin is an iron-binding protein that is synthesized and metabolized mainly in the liver and is the most sensitive serum glycoprotein marker for CDG. Glycosylation of transferrin can be analyzed using isoelectric focusing (IEF), electrospray ionization mass spectrometry or matrix-assisted laser desorption/ionization–time-of-flight mass spectrometry. Transferrin contains two biantennary *N*-glycan chains with a total of four terminal sialic acid residues. A normal IEF profile of transferrin isomers consists predominantly of four sialic acids (tetrasialotransferrin). For type I CDG, an abnormal profile is observed with a decreased amount of tetrasialotransferrin and increased amounts of asialo- and disialotransferrin due to some transferrin molecules lacking either one or both *N*-glycan chains. For type II CDG, an abnormal profile consists of an increase of tri-, di-, mono-, or sometimes asialotransferrin due to a portion of the glycan chains being incomplete. Serum transferrin analysis is relatively of low cost and is available in many clinical laboratories. Transferrin testing is a rapid screen for CDG, but does not identify the specific gene defect.

Serum transferrin screening for CDG has limitations. Several CDG subtypes including MOGS-CDG (CDG-IIb), SLC35C1-CDG (CDG-IIc), and SLC35A1-CDG (CDG-IIf) present with a normal transferrin pattern [1]. Some patients with PMM2-CDG (CDG-Ia) may have a normal transferrin pattern later in life, and analysis of PMM2 enzyme activity may be needed to confirm the diagnosis [14]. These examples demonstrate that a normal transferrin pattern does not necessarily exclude an individual from having CDG, with approximately 25 % of CDG cases estimated to have a normal transferrin pattern [15]. False-positive results can be observed in individuals presenting with liver disease, other metabolic disorders including galactosemia and fructosemia, or alcoholism [16–18]. Transferrin analysis also is not accurate in children less than 6 months of age and may give false-negative results [7]. Transferrin analysis also is reported to have false-positive results in infants less than 3 weeks of age [19].

MALDI-TOF-MS can be used for analysis of *N*- and *O*-linked glycan structures. This technique protects glycans from fragmentation and allows for the structural detail of *N*- and *O*-linked glycans to be analyzed. This technique has been used to characterize a number of subtypes of CDG that could not be detected by IEF of transferrin and is particularly useful for characterizing Type II defects, combined Type I and Type II defects, and multiple glycosylation defects [20]. Caution needs to be exercised with interpretation of *O*-glycan MALDI-TOF-MS profiles from patients with cancer or diabetes because these conditions can alter *O*-glycans at the cellular level [21]. This analysis is available only in a few clinical laboratories.

Enzyme activities of phosphomannomutase (PMM) and phosphomannose isomerase are assessed in patient fibroblasts or leukocytes if the patient is suspected to have a Type I CDG [13]. This will diagnose or rule out two common CDGs, PMM2-CDG (CDG-Ia) (700 individuals worldwide), and MPI-CDG (CDG-Ib) (20 individuals worldwide). Analysis using leukocytes is preferred, especially for PMM enzyme activity, because rapidly dividing fibroblasts can give high PMM residual activity levels [22]. Enzyme activity assays are clinically available only for these two CDG subtypes, and performed by several laboratories worldwide.

Molecular Assays

Since serum transferrin analysis can only determine whether the patient has Type I or Type II CDG, follow up with molecular testing is needed to determine the specific gene defect and to direct testing of additional family members, as needed. If individuals have reduced PMM or MPI enzyme activity, PCR amplification and sequencing of the respective genes can be performed to determine the disease-causing mutations. Single gene testing is currently available for more than 30 genes associated with CDG (Table 8.1). Only a few laboratories provide molecular testing for the more rare CDG subtypes. A comprehensive clinical CDG next-generation sequencing panel is available for comprehensive mutation detection in 38 CDG-associated genes when it is unclear what defect an individual with CDG may have based on phenotype [23]. Array-based comparative genomic hybridization (aCGH) also can be used to detect exon and gene deletions and duplications in these CDG-associated genes.

For the most common CDG, PMM2-CDG (CDG-Ia), over 90 mutations have been identified [8]. The most common mutation is p.Arg141His that leads to almost complete inactivation of the enzyme [12]. This amino acid substitution is seen in about 40 % of compound heterozygous individuals. Another mutation, p.Phe119Leu, is frequently found in affected Northern Europeans with the compound heterozygote genotype (p.Arg141His and p.Phe119Leu), and represents 72 % of mutations in *PMM2*. Due to the limited number of individuals with defects in the other CDG genes, no common mutations have been identified across individuals.

Interpretation of Results

The majority of mutations identified in CDG patients are missense and nonsense mutations, and small insertions and deletions. Since only a few patients have been identified with defects in each of the CDG genes, the list of mutations in Human Gene Mutation Database is very limited for many

Subtypes with an asterisk indicate that clinical testing is available

CDGs; therefore, a conservative approach should be taken for novel variants identified in CDG genes that have not been previously reported. Interpretation of duplications identified by array CGH is difficult because the duplication may or may not disrupt the function of the encoded protein. The presence of one known disease-causing mutation in a specific CDG gene can assist with the interpretation of aCGH results. Parental studies can be useful in determining whether two variants identified in a single gene are on the same or opposite alleles.

Laboratory Issues

Serum transferrin analysis is prone to both false-positive and false-negative results; therefore, if a patient has a strong clinical indication of CDG, follow-up with additional biochemical or molecular testing is recommended. If biochemical testing indicates an individual has CDG, molecular testing is used to confirm the diagnosis and to identify the disease-causing mutations. Testing for the majority of CDGs is provided by only a few laboratories worldwide. A list of laboratories that test for each CDG subtype is provided on the GeneTests website (http://www.ncbi.nlm.nih.gov/sites/GeneTests/).

Conclusions and Future Directions

Due to the wide spectrum of symptoms and variable severity of CDG, pediatric physicians should be educated to consider glycosylation disorders in patients presenting with multi-organ dysfunction and symptoms that include developmental delay, failure to thrive, liver dysfunction, or neurological involvement. As testing for CDG continues, the number of

patients that lack a molecular diagnosis will likely increase, highlighting the need for broader molecular testing to identify the causative gene in these patients. Greater than 40 % of CDG patients are estimated to have an unknown type of CDG (CDG-Ix or CDG-IIx) and lack a molecular diagnosis, with the majority of unsolved cases being CDG-IIx. Approximately, 250–500 genes are estimated to be involved in the process of glycosylation, with the likelihood that defects in a number of these genes will result in CDG. CDG is an ideal candidate syndrome for exome sequencing, and this approach already has successfully identified the gene defect in a previous CDG-Ix patient [24]. New CDG genes identified from exome or genome sequencing can be added to the clinical CDG next-generation sequencing panel to provide a more comprehensive test.

Improved molecular diagnosis of CDG will reduce the number of patients lacking genetic characterization, shorten a patient's time to diagnosis, facilitate genetic counseling, improve patient management, and facilitate carrier or prenatal testing for other family members. Molecular diagnosis of additional patients with CDG will provide an estimate of the prevalence of each subtype and a greater understanding of the spectrum of phenotypes associated with each subtype. The clinical outcome and natural course for each CDG subtype will also be elucidated. As more patients are identified, the study of genotype/phenotype correlations can be assessed. Identification of new genes also will provide insight into new pathways that are linked to glycosylation. Furthermore, identification of new genes associated with CDG will provide important building blocks for the development of new treatments and therapies for individuals afflicted with different subtypes of CDG.

Neuromuscular Diseases

9

Thomas W. Prior

Abstract

This chapter describes clinical manifestations, pathology, and the molecular diagnosis of selected neuromuscular disorders which are commonly tested for in the molecular pathology laboratory. Neuromuscular function can be impaired as a result of defects in the nervous system, muscle, or both. The disorders described are all heritable. However the disorders have different patterns of inheritance and are caused by different types of mutations. The molecular assay utilized is determined by the type of mutation to be identified. The molecular testing allows for more accurate diagnostic, carrier, predictive, and prenatal testing. The clinical utility, interpretation, and laboratory issues will be described for each disorder.

Keywords

Neuromuscular disease • Duchenne • Becker • Muscular dystrophy • X-linked • Myotonic dystrophy • Spinal muscular atrophy • SMA • Mitochondrial encephalomyopathies • Kearns-Sayre syndrome • Mitochondrial encephalomyopathy with lactic acidosis and stroke-like episodes • MELAS • Myoclonic epilepsy with ragged-red fibers • MERRF • Kennedy disease • Spinobulbar muscular dystrophy

Introduction

This chapter describes clinical manifestations, pathology, and the molecular diagnosis of selected neuromuscular disorders which are commonly tested for in the molecular pathology laboratory. Neuromuscular function can be impaired as a result of defects in the nervous system, muscle, or both. The disorders described in this chapter are all heritable. However the disorders often have different patterns of inheritance and are caused by different types of mutations. The molecular assay utilized is determined by the type of mutation to be identified. The molecular testing allows for more accurate diagnostic, carrier, predictive, and prenatal testing. Furthermore, by better understanding the pathogenesis of the disease, new therapeutic strategies will be developed in the future. The clinical utility, interpretation, and laboratory issues will be described for each disorder.

Duchenne and Becker Muscular Dystrophies

Molecular Basis of Disease

Duchenne and Becker muscular dystrophies (DMD and BMD) are X-linked, allelic, neuromuscular diseases characterized by progressive muscular weakness and degeneration of skeletal muscle. DMD is the most common X-linked recessive lethal disease, with an incidence of approximately 1 in 3,500 newborns, and approximately one-third of cases are the result of new mutations [1, 2]. Affected children are usually wheelchair bound by the age of 12 years. As the disease progresses, contractures increasingly develop, leading to asymmetrical spinal deformities. Most patients die at

D.G.B. Leonard (ed.), *Molecular Pathology in Clinical Practice*, DOI 10.1007/978-3-319-19674-9_9

about 20 years of age due to pneumonia, related to chronic respiratory insufficiency. The allelic disorder BMD has a milder clinical course and slower disease progression. BMD occurs approximately one-tenth as frequently as DMD, with an incidence of about 1 in 35,000. The majority of patients with BMD initially experience difficulties between 5 and 15 years of age, although an onset in the third or fourth decade or even later can occur. By definition the affected patients remain ambulatory until 16 years of age or later, thus allowing clinical distinction from patients with DMD.

The *DMD* gene is the largest human gene isolated, spanning more than 2,000 kilobases (kb) of genomic DNA, and is composed of 79 exons that encode a 14 kb transcript, which is translated into a protein named dystrophin [3, 4]. Dystrophin is a 427 kilodalton (kDa) cytoskeletal protein consisting of four domains: (1) an amino terminus that associates with actin or an actin-like protein; (2) a rod domain consisting of long, flexible rows of 24 alpha helical repeats; (3) a cysteine-rich region; and (4) a unique carboxy terminus [5]. Dystrophin has been shown to be tightly associated with a large oligomeric complex of sarcolemmal glycoproteins through its cysteine-rich domain and carboxy terminus, while the amino-terminal domain interacts with actin or an actin-like protein.

By immunohistochemistry, dystrophin localizes to the cytoplasmic face of the muscle cell membrane and at postsynaptic membrane specializations in neurons. Dystrophin makes up only 0.002 % of total muscle protein but up to 5 % of the membrane skeleton. Dystrophin is found in skeletal muscle, smooth muscle, cardiac muscle, and brain. There are slightly different forms of dystrophin messenger RNA (mRNA) in different tissues due to different transcription start sites and alternative splicing. The function of dystrophin is not known for certain, but proposed functions include important roles for the organization and stabilization of the sarcolemma and in protection of muscle fibers from contraction-induced injury. Patients with DMD have very little or no detectable dystrophin, whereas BMD patients have an altered size and/or quantity of dystrophin [6]. However, the disease etiology may be more complex than a simple loss of dystrophin, because several of the dystrophin-associated proteins that interact with dystrophin also are absent. The dystrophin-associated proteins may be involved directly with the calcium flux in the dystrophic fibers. Thus, the loss of dystrophin may be the first of many steps that ultimately lead to muscular dystrophy.

Testing, utilizing complementary DNA (cDNA) probes derived from the 14 kb mRNA and multiplex polymerase chain reaction (PCR) analysis, has shown that approximately 65 % of the DMD/BMD cases are due to deletions in the dystrophin gene [7, 8]. The deletions are nonrandomly distributed and occur primarily in the center (~80 %) and less frequently near the 5′ end (~20 %) of the gene. The 200 kb region covering intron 44, exon 45, and intron 45 is the major deletion breakpoint region of the gene. The majority of the larger deletions initiate at the 5′ end of the gene.

The size or location of the deletion does not clearly correlate with the severity and progression of the disease. One of the largest deletions (35 exons) identified is in a mild BMD patient. Furthermore, sequences deleted in DMD patients often overlap with deletions in BMD patients. However, a theory was proposed that if a deletion disrupts the translational reading frame of the dystrophin mRNA triplet codons, then little or no dystrophin will be synthesized, most often resulting in the more severe disease, DMD [9]. In the milder disease, BMD, the deletion maintains the translational reading frame, and a partially functional protein is produced. The reading frame hypothesis explains the phenotypic differences observed in about 92 % of the DMD/BMD cases. One major exception to the reading frame hypothesis has been the identification of BMD patients with an out-of-frame deletion of exon 3 through exon 7. An alternate splicing mechanism or new cryptic translational start site may account for the production of an altered dystrophin protein and the milder phenotype in these patients. A small number of DMD patients with in-frame deletions also have been identified. The more severe phenotype in these patients may be due to the overall effect of the deletion on the protein conformation or may be the result of mRNA instability. Phenotypic variability even has been observed in several patients who share identical gene deletions. Deletion of exon 45, the most commonly observed DMD deletion, also has been associated with the BMD phenotype. Some genetic variability may be due to other molecules involved in destruction of damaged muscle fibers, in muscle regeneration, or in the cellular response to different hormones.

The large gene size, particularly of the introns, which average 35 kb, may account for part of the high deletion rate; however, in addition to size, other factors must be involved. The observed nonrandom deletion pattern may reflect domain-associated variation in chromosomal stability. For instance, complications related to the maintenance of replication, correct transcription, and proper splicing of such a large gene may play an extremely important role. Partial gene duplications have been identified in 5–8 % of patients. Unlike the deletion distribution, approximately 80 % of the duplications are located at the 5′ end of the gene and only 20 % in the central gene region. Out-of-frame duplications occur in DMD patients and in-frame duplications in BMD patients, thus suggesting that the reading-frame genotype-phenotype hypothesis also holds true for duplications.

Small mutations (point mutations and small deletions and duplications) in the dystrophin gene also have been identified in DMD patients [10]. The majority of these mutations have been unique to individual patients and have resulted in a truncated dystrophin protein lacking part or all of the C-terminus. The truncated proteins are presumably unstable, and little or

no dystrophin is produced. Therefore, these types of mutations provide little information on structural/functional relationships in the dystrophin protein. The identification of DMD mutations that do not cause protein truncation may provide further insight into the function of dystrophin, as well as defining the essential regions and conformations necessary for dystrophin stability. A DMD missense mutation was found in the actin-binding domain [11]. The patient was shown to have correctly localized dystrophin, thus indicating that an intact actin-binding domain is essential for protein function and not just protein localization. The distribution of small mutations is fairly random throughout the gene sequence; however, whereas less than 5 % of the gene deletions are found upstream of exon 55, more than 40 % of the small mutations are located in this same region of the gene [12].

Clinical Utility of Testing and Available Testing

The most important impact of DNA testing for DMD/BMD has been on presymptomatic diagnosis and the correct diagnosis of patients with DMD/BMD-like symptoms, as well as for carrier detection and prenatal diagnosis. The western immunoblot is a sensitive protein test for the diagnosis of DMD or BMD, but requires a muscle biopsy from the patient. Proteins from the muscle biopsy specimen are separated by electrophoresis, transferred to a membrane, and incubated with antibodies against specific dystrophin domains. Dystrophin from unaffected patients is 427 kDa in size. The complete absence of dystrophin is very specific for the diagnosis of DMD, whereas the presence of an altered molecular weight form or reduced amount of dystrophin, or both, is consistent with BMD. It must be emphasized, however, that the clinical diagnosis and phenotype predictions should never be made exclusively on the basis of dystrophin western blot analysis. Patients with markedly reduced dystrophin levels may have the milder BMD phenotype. Furthermore, western blot analysis is generally not sensitive enough to detect female carriers. Lastly, a muscle biopsy, which some families may view as traumatic, is not necessary if a molecular diagnosis is secured first.

The genetic test methods commonly used to identify large rearrangements in the dystrophin gene are: Southern blot, multiplex PCR and multiplex ligation-dependent probe amplification (MLPA). Southern blot analysis using a full-length dystrophin cDNA clone as a probe detects deletions as well as gene duplications. The cDNA probes detect the site of the mutation, so meiotic recombination events are irrelevant. Therefore, the chance of diagnostic error is greatly reduced. Diagnostic strategies are based on initially identifying deletions/duplications in the affected patient [13]. The deletions are simply detected by examination of Southern blots for the presence or absence of each exon containing genomic restriction fragments, which hybridize to the cDNA probe, whereas duplications are detected as an increased intensity of the restriction fragment. From a practical perspective, Southern blot analysis requires the use of a radioisotope, is labor intensive, and is time consuming. Therefore most laboratories perform a deletion/duplication screen using either multiplex PCR [14] or MLPA [15].

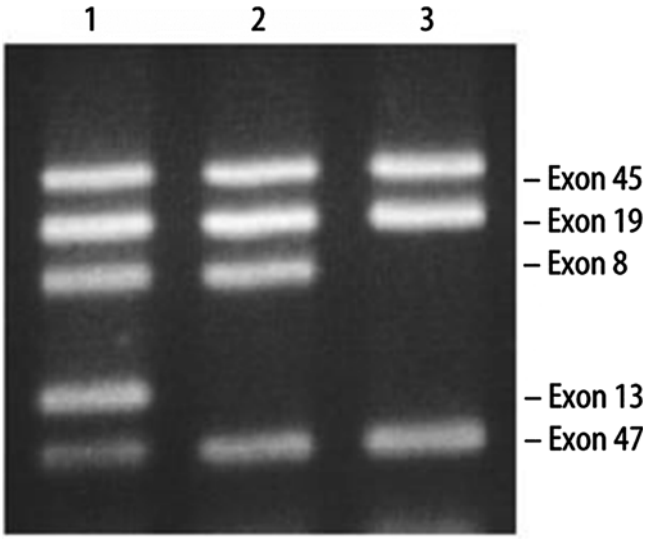

Figure 9.1 Multiplex DNA amplification of DMD exons 8, 13, 19, 45, and 47. *Lane 1*: normal control; *lane 2*: DMD patient with exon 13 deletion; *lane 3*: DMD patient with exon 8 and 13 deletions.

Multiplex PCR simultaneously amplifies specific deletion prone exons within the *DMD* gene. Deletion of specific exons from a patient's sample results in absence of the corresponding ethidium bromide-stained amplification products by gel electrophoresis analysis (Fig. 9.1). Multiplex PCR, using primer sets for about 20–25 different exons, detects approximately 98 % of the deletions in the *DMD* gene. In contrast to Southern blot analysis, which may require several cDNA hybridizations and take several weeks to complete, multiplex PCR testing can be completed in one day. This makes the technique ideal for prenatal diagnosis, when time is critical. Additional refinements of the multiplex PCR assays have enabled the quantitative analysis of the DMD gene exons, allowing for the detection of duplications in males as well as deletions and duplications in carrier females.

Testing using MLPA has been utilized for both DMD deletion/duplication detection and carrier dosage determinations. The MLPA analysis has been shown to reproducibly generate each of the 79 DMD exons and their sizes should correspond to each probe pair. MLPA technology not only accurately detects deletions but also quantifies the copy number of each exon and therefore can be used for duplication and carrier determinations. Using capillary electrophoresis for analysis of the MLPA products, computer-aided scoring is a sensitive method to normalize the peak height or area of each PCR product to an endogenous two-copy control locus

product. A heterozygous deletion should give a ratio of approximately 0.5 whereas an elevated copy number should give a reference value greater than 1.5. MLPA technology has been shown to exhibit a high degree of accuracy for the quantitative detection dystrophin exons, a high degree of reproducibility, and a capacity for testing a large number of samples simultaneously. One major limitation of MLPA technology is that DNA polymorphic sequence variants located under the probe-binding sites may interfere with probe hybridization and may result in false-positive results.

The identification of a deletion in a DMD patient not only confirms the diagnosis but also allows accurate carrier testing for other family members. Carrier status is determined by gene dosage analysis, which is used to assess whether a female at risk of being a carrier exhibits no reduction or 50 % reduction in band intensity for bands that are deleted in the affected male relative. A 50 % reduction (single-copy intensity) for the deleted band or bands indicates a deletion on one of her X chromosomes and confirms her carrier status. Southern blot, quantitative multiplex PCR, or MLPA can be used for gene dosage analysis. Dosage determinations permit direct carrier analysis and eliminate the inherent problems of linkage testing (recombinations, noninformative meioses, unavailability of family members, and spontaneous mutations). This is important since, unlike affected males, carrier females are generally asymptomatic, and creatine phosphokinase is elevated in only approximately two-thirds of known carriers.

As previously described, large genomic deletions and duplications have been identified in approximately two-thirds of the DMD/BMD population. The other mutations are due to smaller types of mutations within the dystrophin gene which require a sequence-based testing strategy. In most clinical molecular laboratories, these mutations have gone undetected because sequencing the entire gene is both expensive and labor intensive. With the advances in DNA sequencing technology, point mutation analysis of exons in the *DMD* gene is now feasible. The identification of these mutations is not only important for the confirmation of the diagnosis, but also important for the determination of carrier status. Due to the high mutation rate in the dystrophin gene, carrier testing based on indirect linkage results often is limited for extended family members of isolated cases of the disease. Knowledge of the exact causative mutation allows for the determination of the origin of the mutation in families with simplex cases of the disease.

Interpretation of Test Results

The analysis of gene mutations and protein determinations has greatly improved diagnosis, carrier detection, and prenatal counseling. Amplification techniques will confirm the clinical diagnosis in approximately 65 % of the DMD and BMD patients and should be performed as the initial molecular test due to the relatively common occurrence of deletions and duplications. If the patient tests negative by deletion/duplication analysis, gene sequencing of the coding regions and intron/exon boundaries should be performed. By gene sequencing, detection rates can be increased to greater than 90 %; however, even with sequencing, not all mutations are identified. Some of the undetected mutations may reside in the large dystrophin introns or in regulatory regions. Furthermore, genetic heterogeneity in the DMD phenotype may be another reason for less than 100 % sensitivity of testing. If there is any question of the diagnosis after negative results by molecular testing, western blot analysis of the dystrophin protein should be performed on a muscle biopsy specimen.

When gene dosage testing indicates that the mother does not have the deletion present in the affected child, she still has an uncertain risk of carrier status, due to the possibility of germline mosaicism [16]. Cases of germline mosaicism in DMD have been reported, in which a deletion is transmitted to more than one offspring by a mother who shows no evidence of the mutation in her somatic cells. Cases of germline mosaicism have important counseling implications. First and most obvious is the need to perform carrier studies on all female siblings of affected males, regardless of the outcome of testing for the mother. Furthermore, a negative deletion result in a mother does not rule out a recurrence risk for future pregnancies, and prenatal diagnosis still should be offered. The exact recurrence risk in germline female carriers is unknown because the risk is related to the percentage of the mutant clone in the mosaic mother. In these cases, the recurrence risk for subsequent pregnancies is significantly higher than a new mutation with a low recurrence risk. Mothers of apparently sporadic DMD cases have an estimated 15 % recurrence risk in future pregnancies.

Linkage analysis can provide valuable information but is limited by the possibility of recombination between the polymorphic marker and the unknown mutation, the presence of sporadic mutations, and unavailability of family members. The intragenic recombination rate over the entire length of the *DMD* gene is estimated to be as high as 12 %. The high recombinational error rate can be partially overcome by using microsatellite markers throughout the gene. Linkage analysis results often are extremely limited for extended family members of isolated cases of DMD/BMD, due to the possibility of the occurrence of a new mutation. Linkage analysis indicates only whether the female at risk inherited the same X chromosome as the affected male, not whether she is a carrier of a defective gene. Furthermore, since the gene mutation remains unidentified, a correct clinical diagnosis is essential. This is extremely important with patients presenting with the milder BMD phenotype, since this phenotype can overlap with other neuromuscular disorders.

Laboratory Issues

As a result of the discovery of the *DMD* gene and elucidation of the disease mutation spectrum, clinical diagnostic testing for DMD and BMD has significantly improved.

Until an effective treatment is found to cure or arrest the progression of the disease, prevention of new cases through accurate diagnosis, and carrier and prenatal testing is of the utmost importance. Furthermore, molecular therapies (such as antisense oligonucleotides, antibiotics, or chimeric RNA/DNA) are being applied according to the specific dystrophin mutation. This requires a comprehensive mutation analysis and identification of all types of dystrophin mutations. Although the majority of laboratories offer testing for dystrophin deletions and duplications, sequencing of the entire gene becomes necessary for all patients who are negative for the deletion/duplication screen. Proficiency testing for both *DMD* deletion/duplication testing and carrier testing is currently offered through the College of American Pathologists (CAP), and proficiency specimens are sent to participants twice per year.

Myotonic Dystrophy

Molecular Basis of Disease

Myotonic dystrophy type I (DM1) is the most common inherited form of muscular dystrophy affecting adults, with an incidence of approximately 1 in 8,000 individuals. DM1 is an autosomal dominant, multisystem disorder characterized by progressive muscle weakness, myotonia, intellectual impairment, cataracts, and cardiac arrhythmias. The diagnosis can be problematic because of the wide range and severity of symptoms. Often, affected individuals have children before they are diagnosed. A severe congenital form of DM results in mental retardation, respiratory distress, hypotonia, and in many cases death due to respiratory complications shortly after birth. Those that survive the neonatal period initially follow a static course, eventually learning to walk but with significant mental retardation. The congenital form is most often observed in the offspring of women who are themselves affected, although the disease in a mother may not be diagnosed until after the birth of a congenitally affected child [17].

The myotonic dystrophy protein kinase gene (*DMPK*) at chromosome 19q13.3 is the only known gene associated with DM1. The DM1 mutation involves an expanded CTG trinucleotide repeat, located at the 3′ untranslated region (UTR) of the *DMPK* gene [18–20]. The number of CTG triplets varies in the normal population from 5–34 repeats, and within this range the alleles are stably transmitted. Individuals with 35–49 repeats (premutation alleles) do not have symptoms but their children are at an increased risk of inheriting larger repeats and having symptoms. When the number of repeated CTGs exceeds 50 (in some patients up to several thousands), the allele becomes unstable and results in the DM1 phenotype. There is a significant correlation between the number of CTG repeats and the age of onset and clinical severity. Mildly affected patients have 50–100 repeats, and these patients may only have cataracts. More classically affected patients have 100–1,000 repeats and congenital cases often have 1,000–6,000 repeats. Somatic mosaicism of the CTG repeat occurs and results in patients with similar repeat sizes having different severity of symptoms, which calls for caution in genetic counseling. The trinucleotide repeat region is mitotically and meiotically unstable, with a bias towards length increase in the next generation, accounting for the clinical phenomenon of "anticipation" (increasing severity in successive generations of the same family, with earlier age of onset). Although repeat expansions occur through both maternal and paternal transmissions, the larger repeat expansions observed in congenital cases are almost exclusively due to maternal transmissions.

The CTG repeat is located within the 3′ UTR of the *DMPK* gene that encodes a protein kinase, named myotonin protein kinase. Since protein kinases are involved in signal transduction pathways in all cells in the body, a defective protein kinase was considered as a mechanism in which a single-gene defect could result in the diverse symptoms characteristic of DM1; however, since the repeat is not in the protein-coding region of *DMPK*, the molecular mechanism by which the mutation exerts its dominant expression is difficult to explain. One theory is that the myotonin kinase mRNA with long CUG repeats, and not the protein, results in a gain-of-function RNA pathogenesis [21, 22]. Novel RNA-binding proteins that specifically bind to CUG repeats may be depleted by excessive CUG repeats in the DM1 transcripts. Muscleblind-like protein (MBNL1) and CUG-binding protein (CUGBP1) are two RNA-binding proteins proposed to be involved in the pathogenesis. The depletion of these CUG-binding proteins causes splicing alterations of the chloride channel gene (*CLC1*) and the insulin receptor genes (*IR*), resulting in myotonia and insulin resistance, phenotypes that are related to the clinical features of DM1.

Clinical Utility of Testing and Available Testing

The majority of clinically significant mutations can be identified by Southern blot analysis; however, PCR is essential for the detection of smaller CTG expansions (<100 repeats). Although the PCR test is less expensive and faster than Southern blot analysis, longer repeats often are not reliably amplified. Southern blot analysis can be performed using *Hind*III restriction digestion and the probe pMDY1 [19], which spans the repeat region (Fig. 9.2). The probe pMDYI detects a *Hind*III polymorphism with normal alleles of 8.5 and 9.5 kb, the frequencies of which are approximately 0.6 and 0.4, respectively. The polymorphism is due to a 1 kb insertion telomeric to the CTG repeat, and is almost in complete linkage disequilibrium with the CTG repeat mutation in most populations [20]. The mutation is found on the larger 9.5 kb allele, suggesting that there were a limited number of

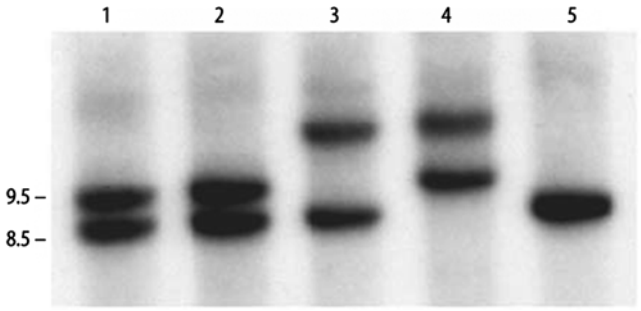

Figure 9.2 Autoradiogram of a Southern blot for myotonic dystrophy. Normal alleles are 8.5 and 9.5 kb. *Lanes 1*, *2*, and *5*: unaffected individuals; *lanes 3* and *4*: expanded and normal alleles in DM patients with repeat expansions

ancestral mutations that occurred on a chromosome having the 1 kb insertion. Alternatively, the larger allele may be predisposed to DM1 mutations. Typical increases in the range of 1–4 kb are observed on Southern blots in the DM1 population. Many of the larger expansions are detected as smears, indicating somatic cell heterogeneity of the expanded alleles. Background signal may interfere with the detection of larger expanded alleles since expanded alleles often appear as diffuse smears due to the somatic instability of the mutation. The efficiency of the detection of these somatically variable expansions is increased by use of a restriction enzyme with a recognition sequence which occurs relatively infrequently in the human genome, which will generate a larger restriction fragment containing the expansion. (*Eco*RI creates a large 9–10 kb fragment.) The larger fragment lengths reduce the smearing effect of the somatic variability of the unstable repeats. Decreasing the electrophoretic migration also improves the detection of larger somatic mosaic expansions. Molecular testing can identify individuals who are asymptomatic or exhibit equivocal symptoms, such as cataracts. These smaller expansions are detected using alternate restriction enzymes which reduce the normal size fragment, such as *Bam*HI, or by PCR amplification across the repeat region. The most efficient approach for identifying expansions is a combination of different restriction enzymes and variation in electrophoretic duration. PCR amplification across the repeat region is used to exclude DM1 by demonstrating the presence of two different normal size alleles (8.5 and 9.5 kb). Since the heterozygosity frequency for the CTG repeats is approximately 75 % in the normal population, approximately 25 % of unaffected individuals will be homozygous for one normal allele. Therefore, the presence of a single PCR band does not confirm a diagnosis of DM1. All single bands require a Southern blot confirmation.

Several cases of reverse mutations have been reported in DM1, whereby there is a spontaneous correction of a deleterious expansion mutation upon transmission to an unaffected offspring. The mechanism for the DM1 reverse mutations remains unknown. A gene conversion mechanism, whereby the normal parental allele replaces the expanded allele, may best account for the reversion events in DM. The reversions may provide an explanation of the lack of penetrance observed in some DM families.

Interpretation of Test Results

PCR and/or Southern blot analysis for the *DMPK* CTG repeat region is used for symptomatic confirmatory diagnostic testing. Onset in adulthood typically presents with muscle weakness and myotonia. *DMPK* testing can be particularly useful in individuals for whom DM1 is part of a wider differential diagnosis, such as infants with muscular hypotonia. Prenatal problems, with congenital DM1, may be suspected when reduced fetal movements and polyhydramnios are observed on ultrasound. The testing also is helpful in identifying individuals who are asymptomatic or exhibit equivocal symptoms, such as cataracts. No new mutations have been described for DM1, which is consistent with the linkage disequilibrium data. To account for the maintenance of the mutation in the population, the theory developed that there is a high incidence of minimally expanded alleles in DM1 families which produce few symptoms and are stably transmitted over several generations [23]. For counseling purposes, testing can be used to identify the side of the family carrying the mutation, which is important for appropriate genetic counseling.

The triplet repeat size does correlate with muscular disability and is inversely related with the age of onset of the disease. However, there is a significant overlap of repeat size in patients with differing severity. When comparing unrelated affected individuals with small to moderate differences in repeat sizes, it is generally difficult to accurately predict the severity of the disease in each case. This is due to the overlap of triplet repeat size in patients with differing severity of the disease and the sometimes lack of a correlation between organ involvement and repeat size. As a result of the somatic heterogeneity observed in DM1, genotype/phenotype associations derived from leukocytes may not be as accurate as the measurement of the repeat size in the affected tissues (muscles, heart, others) [24]. Within a family, when a child has a significant increase in allele size compared to the parent, prediction of an earlier age of onset and more severe disease is more certain. Genetic counseling is very important not only for the affected patient, but also for other at-risk interested family members. DM1 testing can be used for prenatal diagnosis using either amniotic fluid cells or chorionic villus samples. Molecular testing has largely replaced muscle biopsy, muscle enzyme studies, and electromyography as the first diagnostic procedure.

Myotonic dystrophy type 2 (DM2, MIM 602668), previously termed proximal myotonic myopathy is due to a CCTG expansion located in intron 1 of the zinc finger protein 9 (*ZNF9*) gene on chromosome 3q21 [25]. Individuals affected

with DM2 also have a complex clinical presentation that is similar to DM1, including myotonia, cardiac involvement, insulin insensitivity, and histological abnormalities in skeletal muscle. Patients with DM2 often can be distinguished from DM1 by more proximal muscle weakness and sparing of facial muscle involvement. Further distinguishing characteristic features of DM2 include muscle pain, the absence of congenital cases, and milder course of the disease without significant mental involvement.

Laboratory Issues

Many molecular pathology laboratories offer DNA testing for DM1. The majority of laboratories are using a combination of PCR and Southern blot testing. Although the PCR test is less expensive and faster than Southern blot, longer repeats are not reliably amplified. The availability of DNA testing has reduced the use of invasive (muscle biopsy) and noninvasive (electromyography) tests for the diagnosis of DM1. The combination of PCR and Southern blot analysis can detect all DM1 mutations. Proficiency testing is offered through the College of American Pathologists and proficiency specimens are sent to participants twice per year.

Spinal Muscular Atrophy

Molecular Basis of Disease

The autosomal recessive disorder proximal spinal muscular atrophy (SMA) is a severe neuromuscular disease characterized by degeneration of alpha motor neurons in the spinal cord, which results in progressive proximal muscle denervation and atrophy resulting in the symptoms of weakness and paralysis. SMA is the second-most common fatal autosomal recessive disorder after cystic fibrosis, with an estimated prevalence of 1 in 10,000 live births [26]. Childhood SMA is subdivided into clinical groups on the basis of age of onset and clinical course. Type I SMA (Werdnig-Hoffmann disease) is characterized by severe, generalized muscle weakness and hypotonia at birth or within the first 3 months after birth. Death from respiratory failure usually occurs within the first 2 years of life. Children affected with Type II SMA are able to sit, although they cannot stand or walk unaided, and survive beyond 4 years of age. Type III SMA (Kugelberg-Welander syndrome) is a milder form, with onset during infancy or youth, and patients may walk unaided. Type III SMA is further subdivided into two groups, type IIIa (onset before 3 years of age) and type IIIb (onset at age ≥3 years). Cases presenting with the first symptoms of the disease at the age of 20–30 years are classified as type IV, or proximal adult-type SMA. The described classification is based on age of onset and clinical course, although SMA demonstrates a continuous range of severity.

SMA is caused by mutations in the survival motor neuron (*SMN1*) gene which has nine exons [27]. Two almost identical *SMN* genes are present on 5q13: the telomeric *SMN1* gene that is the SMA-causing gene, and the centromeric *SMN2* gene. Exon 7 of the *SMN1* gene is deleted in approximately 95 % of affected patients, while small, more subtle mutations have been identified in the majority of the remaining affected patients. The genotypic explanation for the phenotypic variability results from variability in the number of *SMN2* gene copies, which influences the severity of the disease [28–30]. The number of *SMN2* gene copies varies from 0–3 copies in the normal population, with approximately 10 % of unaffected individuals having no gene copies of *SMN2*. However, milder patients with type II or III SMA on average have more gene copies of *SMN2* than do type I SMA patients. The extra *SMN2* gene copies are thought to arise through gene conversions, whereby the *SMN2* gene is copied either partially or totally into the telomeric *SMN1* locus.

SMA is caused by low levels of SMN protein rather than by a complete absence of the protein. Complete loss of SMN protein function results in loss of viability of a fetus and in utero death. SMA is possible because *SMN2* can partially replace the lost function of *SMN1*. Five base pair differences exist between *SMN1* and *SMN2* transcripts, and none of these differences change amino acids. The normal *SMN1* gene produces predominately a full-length transcript, whereas the *SMN2* gene produces predominately an alternate, exon-7-deleted product with only 10–20 % of transcripts being full-length. The inclusion of exon 7 in *SMN1* transcripts and exclusion of this exon in the majority of *SMN2* transcripts is caused by a single nucleotide difference at +6 in *SMN* exon 7, which alters splicing efficiency by disrupting an exonic splicing enhancer and results in absence of exon 7 in the majority of *SMN2* transcripts. The SMN exon 7 region encodes a highly conserved tyrosine-glycine (Y-G) dodecapeptide motif which is crucial for the oligomerization and function of the SMN protein [31]. SMA arises because the levels of full-length SMN protein from the *SMN1* gene are lost, and only partially rescued by the low number of full-length SMN protein from the *SMN2* gene. The *SMN2* gene cannot completely compensate for the lack of SMN protein; however, the small amounts of full-length transcript generated by *SMN2* are able to prevent in utero lethality. Additional copies of the *SMN2* gene result in greater amounts of full-length SMN protein and produce a milder type II or III phenotype.

SMN plays a role in small nuclear ribonucleoprotein (snRNP) biogenesis and function [32]. The SMN protein is required for pre-mRNA splicing. Immunofluorescence studies using a monoclonal antibody to the SMN protein demonstrate that the SMN protein is localized to novel nuclear structures called "gems," which display similarity to and

possibly interact with coiled bodies, which are thought to play a role in the processing and metabolism of snRNAs. SnRNPs and possibly other splicing components require regeneration from inactivated to activated functional forms. SMN functions in the reassembly and regeneration of these splicing components. Mutant SMN, such as that present in SMA patients, lacks the splicing-regeneration activity of wild-type SMN. SMA may be the result of a genetic defect in spliceosomal snRNP biogenesis in motor neurons. Consequently, the motor neurons of SMA patients may be impaired in their capacity to produce specific mRNAs and as a result become deficient in proteins that are necessary for the growth and function of these cells. Possibly, the altered splicing of a unique set of premessenger RNAs results in deficient proteins, which are necessary for motor neuron growth and survival. In addition to its role in spliceosomal ribonucleoprotein assembly, SMN may have other functions in motor neurons. A subset of SMN complexes are located in axons and growth cones of motor neurons and may be involved in some aspects of axonal transport and localized translation of specific mRNAs.

Clinical Utility of Testing and Available Testing

The molecular diagnosis of SMA consists of the detection of the absence of exon 7 of the *SMN1* gene (Fig. 9.3). Although the gene region contains many repetitive elements and the centromeric *SMN2* copy is almost identical to the *SMN1* gene, an exonic base pair difference allows distinction of *SMN1* and *SMN2* PCR products using restriction-site generating PCR (RG-PCR) followed by restriction enzyme digestion. The absence of detectable *SMN1* exon 7 in SMA patients is utilized to diagnose SMA, with a sensitivity of approximately 95 %.

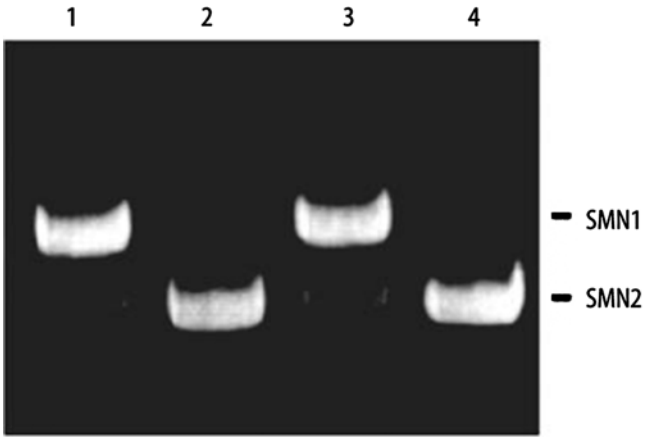

Figure 9.3 Restriction enzyme digestion of RG-PCR products distinguishes *SMN1* from *SMN2* exon 7 PCR products. *Lanes 1* and *3*: normal controls with *SMN1* present and *SMN2* deletion; *lanes 2* and *4*: SMA patients with *SMN1* deletion and *SMN2* present. *RG-PCR* restriction-site generating polymerase chain reaction.

Although the absence of both copies of exon 7 of the *SMN1* gene is a very reliable and sensitive test for SMA, about 5 % of affected patients have other types of mutations in the *SMN1* gene that will not be detected by homozygous exon 7 deletion testing. Due to the high deletion frequency, and according to the Hardy-Weinberg equilibrium, most of these patients will be compound heterozygotes, with one *SMN1* allele being deleted and the other allele containing a point mutation or other types of small mutations. Determination that a SMA patient has only a single copy of *SMN1* supports the diagnosis of SMA, with the possibility that the remaining *SMN1* gene contains a more subtle mutation, including nonsense mutations, missense mutations, splice site mutation insertions, and small deletions. These mutations have been essential in defining important structural and functional domains of the SMN protein. Many of the same intragenic mutations have been reported in unrelated patients [33, 34].

Since SMA is one of the most common lethal genetic disorders, with a carrier frequency of 1 in 40–60, carrier testing is useful to many families. *SMN1* dosage testing is used to determine the *SMN1* copy number and detect SMA carriers. Most carriers have one *SMN1* copy and most non-carriers will have two *SMN1* copies, or less frequently three *SMN1* copies. Carrier detection for the heterozygous state was initially shown to be more technically challenging because the SMA region is characterized by the presence of many repeated elements. In addition, the *SMN2* copy number varies with approximately 10–15 % of non-carriers lacking any *SMN2* copies, whereas many of the more mildly affected SMA patients have more *SMN2* copies. Thus, a straightforward dosage assay using the *SMN2* gene as the internal control would not be reliable. A number of techniques have been developed for the detection of SMA carriers. Quantitative PCR and MLPA assays are most often used for the identification of SMA carriers by determination of the number of copies of the *SMN1* gene as well as for the *SMN2* gene [35, 36].

Interpretation of Test Results

The presence of *SMN1* exon 7 does not entirely exclude a diagnosis of SMA. Although the absence of both copies of the *SMN1* gene is a very reliable and sensitive assay for the majority of SMA patients, about 5 % of affected patients have other types of mutations in the *SMN1* gene that will not be detected by PCR deletion testing. Most of these patients will be compound heterozygotes, with one *SMN1* allele deleted and the other allele with a point mutation or other small insertion or deletion. If the clinical suspicion remains high after a negative deletion test, then dosage carrier testing to determine whether there is a single copy of *SMN1* should be considered. If a patient with a SMA phenotype possesses only a single copy of *SMN1*, the remaining copy most likely contains a more subtle mutation, including

nonsense mutations, missense mutations, splice site mutation insertions, and small deletions. A dosage testing result of two copies of the *SMN1* gene for a patient with an SMA phenotype greatly reduces the likelihood of SMA, although very rare cases of SMA can be due to two non-deletion mutations of *SMN1*.

The SMA carrier test has two limitations. First, approximately 2 % of SMA cases arise as the result of de novo mutation events, which is high compared to most autosomal recessive disorders [37]. The high rate of de novo mutations in *SMN1* may account for the high carrier frequency in the general population despite the genetic lethality of the type I disease. The large number of repeated sequences around the *SMN1* and *SMN2* locus likely predisposes this region to unequal crossovers and recombination events and results in the high de novo mutation rate. Second, the copy number of *SMN1* can vary on a chromosome; about 5 % of the normal population possess three copies of *SMN1* [28]. A carrier may have one chromosome 5 with two *SMN1* copies and the other chromosome 5 with zero *SMN1* copies, resulting in a two-copy carrier test result for a carrier. Using haploid conversion technique, which allows for single-chromosome analysis, Mailman et al. identified a parent of an affected child with two *SMN1* genes on one chromosome [38]. The finding of two *SMN1* genes on a single chromosome has serious genetic counseling implications, because a carrier with two *SMN1* genes on one chromosome and an *SMN1* deletion on the other chromosome will have the same dosage result as a non-carrier with one *SMN1* gene on each chromosome 5. Thus, the finding of normal two *SMN1* copy dosage significantly reduces the risk of being a carrier; however there is still a residual risk of being a carrier, and subsequently a small recurrence risk of future affected offspring for individuals with two *SMN1* gene copies. Risk assessment calculations using Bayesian analysis are essential for the proper genetic counseling of SMA families. A report has shown that there are significant differences among different ethnic groups in carrier frequencies and the two-copy chromosome genotypes [35]. The results from this study provide adjusted detection rates based on ethnicity, and thus allow for more accurate Bayesian risk estimates.

Laboratory Issues

Many molecular pathology laboratories offer testing for the homozygous deletion of *SMN1*. Most laboratories use PCR amplifications of exon 7 and exon 8 in two separate reactions, with restriction enzyme digestion to differentiate *SMN1* from *SMN2* PCR products, and report results for both *SMN1* exons 7 and 8. Some laboratories only test for exon 7 deletion. As a consequence of the *SMN1* gene being relatively small, and given the uniform spectrum of mutations, sequencing of the SMN1 gene is relatively straightforward and can identify mutations in patients who are negative for the diagnostic homozygous deletion test. However, it is necessary to verify that the intragenic mutation has occurred in the *SMN1* gene and not the *SMN2* gene. As an initial screen, primers that do not distinguish between *SMN1* and *SMN2* often are used to amplify each exon for direct DNA sequencing. If variants or mutations are identified, *SMN1*-specific long-range PCR amplification is followed by either direct DNA sequencing of that long-range product or nested PCR sequencing. Carrier testing is performed by a fewer number of clinical molecular laboratories. Proficiency testing for the homozygous *SMN1* deletion is offered by the CAP. These proficiency specimens are sent to participants twice per year. External proficiency testing is not available for carrier testing, so proficiency testing most often is achieved by specimen exchange between laboratories performing carrier testing.

Mitochondrial Encephalomyopathies

Molecular Basis of Disease

Mitochondria are semiautonomous replicating cellular organelles containing genetic material. Each mitochondrion contains multiple copies of the mitochondrial DNA genome (mtDNA), with replication, transcription, and translation machineries separate from these cellular functions. Human mtDNA encodes 13 polypeptides of the respiratory chain subunits, 28 ribosomal RNAs (rRNAs), and 22 transfer RNAs (tRNAs) in a circular double-stranded genome of approximately 16.5 kb.

Unlike nuclear DNA, in which each cell contains pairs of chromosomes, one of maternal and the other of paternal origin, mtDNA is inherited exclusively from the mother. This type of transmission is called maternal inheritance, since the sperm's mitochondria do not contribute to the zygote. Although both sexes are equally affected by mitochondrial diseases, inheritance of the disorder is from the mother. Mitochondrial mutations are often present in only some of the mtDNA molecules of a cell (heteroplasmy). Heteroplasmy occurs because mitochondria segregate randomly into daughter cells during mitosis, which results in cells containing both mutant and wild-type mtDNA. Thus, the proportion of heteroplasmic mutation may vary widely between different tissues or even between different cells of the same tissue. The proportion of mutant to wild-type mtDNA plays a role in determining the clinical variability and severity often observed in the mitochondrial disorders. The phenotype-genotype correlation in the mitochondrial disorders is complex and influenced by age, the type and extent of respiratory chain disruption caused by the mutation, and the tissue-specific threshold for the pathogenic effect.

The term "mitochondrial encephalomyopathies" is used to describe mitochondrial disorders in which both muscle and

the central nervous system are affected. These disorders affect multiple systems, with diverse clinical features due to defects in the mitochondrial function. Mitochondrial diseases are individually uncommon, but collectively pose a significant burden to human health. This chapter is restricted to those disorders in which the mutation event involves mtDNA, in contrast to the many nuclear genetic disorders that result in mitochondrial pathology. This occurs when the nuclear encoded protein functions in the mitochondria, which are described in Chap. 10. This chapter discusses Kearns-Sayre syndrome (KSS), mitochondrial encephalomyopathy with lactic acidosis and stroke-like episodes (MELAS), and myoclonic epilepsy with ragged-red fibers (MERRF).

Kearns-Sayre Syndrome

The common features of KSS include progressive external ophthalmoplegia (PEO), pigmentary degeneration of the retina, and defects of cardiac conduction [39]. The typical affected patient presents before the age of 20 years with PEO and pitosis, followed by development of pigmentary retinal degeneration and cardiac conduction block. Other features of the disorder may include ataxia, deafness, dementia, and diabetes mellitus. The most common type of mutation found in KSS is a deletion in the mtDNA (Fig. 9.4), and almost of all these deletions occur sporadically [40]. Approximately one third of KSS cases are due to a common 4,977 bp deletion, which is associated with direct repeats at the deletion junction. The severity of KSS depends on the extent of heteroplasmy and the tissue distribution of structurally altered mtDNA. An extreme KSS phenotype occurs when the frequency of deleted mtDNA in muscle cells is greater than 85 %. In contrast, when lower levels of heteroplasmy for the deletion are present, then PEO may be the only symptom.

Mitochondrial Encephalomyopathy with Lactic Acidosis and Stroke-Like Episodes

Patients with MELAS are usually normal at birth but develop stunted growth, intermittent vomiting, seizures, and recurrent cerebral insults resembling strokes during the first years of life [41]. An episodic course follows, with recurrent stroke-like episodes, only partial recovery, and eventual deterioration, with death from respiratory failure often before 20 years of age. Milder adult-onset cases have been reported. Approximately 80 % of all MELAS cases are the result of an m.3243A>G point mutation in the mtDNA gene encoding mt-tRNA(Leu) [42]. The point mutation alters the normal structural conformation of the tRNA, thereby impairing protein synthesis. The m.3243A>G mutation occurs in the heteroplasmic state, with variation among different tissue types. When the mutation is present in greater than 90 % of the mtDNA of the muscle tissue, there is increased likelihood of recurrent strokes and classic MELAS manifestations. However, when the heteroplasmy of the mutation is less than 90 %, later onset and more moderate symptoms may occur.

Figure 9.4 Autoradiogram of a Southern blot of muscle mitochondrial DNA. *Lane 1*: Kearns-Sayre patient with heteroplasmic deletion; *lanes 2* and *3*: unaffected individuals. The normal allele is 16.5 kb and the deleted allele fragment is indicated by the *asterisk*.

Myoclonic Epilepsy with Ragged-Red Fibers

MERRF is a rare mitochondrial disorder with symptoms including muscle weakness, myoclonus, generalized seizures, ataxia, and deafness [43]. The hallmark morphologic change seen in the muscle biopsy is the ragged-red fibers. The term "ragged-red fibers" refers to large clumps of abnormal mitochondria that accumulate beneath the sarcolemma and stain red with the Gomori trichome stain. The majority of MERRF cases are the result of a point mutation (m.8344A>G) in the mt-tRNA(Lys) gene. The MERRF mutation, like the MELAS mt-tRNA(Leu) mutation, diminishes overall mitochondrial protein synthesis. Similar to the other mitochondrial disorders, a more classic MERRF phenotype is observed when the mutation is present at higher levels in the muscle and nerve.

Clinical Utility of Testing and Available Testing

The symptoms of the mitochondrial disorders often are nonspecific and are common to many other neuromuscular diseases. The diversity of clinical syndromes allows mitochondrial disease to appear in the differential diagnosis of almost any neurological condition, from stroke to myopathy. As a result, the mitochondrial diseases often are considered only after many other diagnoses have been excluded. However, genetic testing for mitochondrial diseases is becoming increasingly available. Southern blot analysis or long-range PCR is used to detect the deletions observed in KSS, using DNA from a muscle biopsy. PCR-RFLP testing is used for the common tRNA point mutations found in MERRF and MELAS. Patients with MERRF have high levels of the mutant mtDNA in the blood, and therefore blood is an appropriate specimen for testing. In contrast, patients with the MELAS mutation often have low levels of the mutation in the blood, leading to false-negative results when blood is used for testing, such that DNA from a muscle biopsy is preferred for testing.

Interpretation of Test Results

If clinical suspicion is strong and the blood results are negative, then mtDNA from a muscle biopsy should be tested. Since the disorders are highly clinically heterogeneous and there is considerable phenotypic overlap, the classic MERRF and MELAS point mutations and the KSS deletions frequently are ordered together and tested as a mitochondrial test panel. The m.8344A>G MERRF mutation is associated with other phenotypes, including Leigh syndrome, myoclonus or myopathy with truncal lipomas, and proximal myopathy. The m.3243A>G MELAS mutation can result in milder phenotypes, including sensorineural deafness with diabetes. Furthermore, these mutations sometimes are found in asymptomatic relatives of the index case.

Laboratory Issues

If the common mtDNA mutations are not detected, more extensive testing for rarer mutations may be useful for diagnosis. Sequencing of the mtDNA is available from several clinical molecular laboratories, which may identify a novel mutation; however, since the mtDNA is very polymorphic, novel mutations must be verified for functional effects.

Kennedy Disease

Molecular Basis of Disease

Spinal and bulbar muscular atrophy (SBMA), or Kennedy disease, is a rare X-linked, slowly progressive, adult-onset motor neuropathy [44]. The age of onset is usually 30–50 years of age and is characterized by muscle cramps, proximal and bulbar weakness, and fasciculation. Endocrine abnormalities, including gynecomastia and testicular atrophy, are common. The disease is caused by a CAG trinucleotide repeat expansion in the coding region of the androgen receptor gene (*AR*) [45]. The CAG repeat found within the first exon of *AR* is polymorphic in normal populations, and ranges in length from 10–36 repeats. Patients with SBMA have a CAG repeat expansion that does not overlap with the normal population and ranges from 40–62 repeats. Similar to other trinucleotide repeat disorders, the number of CAG repeats correlates with disease severity and inversely with age of onset. Considerable variability in age of onset is seen among family members with similar CAG repeat lengths, suggesting that factors other than just the size of the repeat modulate the onset and severity of the disease. While CAG repeats in the unaffected range are stably transmitted, expanded CAG repeats are transmitted less stably and tend to increase in size by paternal transmission.

The pathogenic mechanism of SBMA expansion involves gain of a toxic function of the protein product. The mutant allele is both transcribed and translated, arguing against a loss of function mechanism. Individuals with mutations producing a loss of AR protein function have testicular feminization and do not have the motor neuropathy seen in SBMA patients. The exact mechanism by which the expanded polyglutamine tract in the AR protein produces the neuropathy of SBMA is uncertain.

Clinical Utility of Testing and Available Testing

Despite distinct clinical features, SBMA is often misdiagnosed due to the heterogeneity of manifestations and lack of full expression in some family members. Many of the cases are sporadic, and some patients have only mild signs of motor neuron disease and mild gynecomastia. Amyotrophic lateral sclerosis, type III SMA, hereditary motor and sensory neuropathy, limb-girdle muscular dystrophy, and facioscapulohumeral muscular dystrophy are included in the differential diagnosis for some patients affected with SBMA [46]. PCR amplification of the repeat sequence within the first exon of the *AR* gene accurately determines the number of CAG repeats and is used for the diagnosis of SBMA. In addition, carrier females and young asymptomatic males may be identified by molecular testing for a repeat expansion with implications for genetic counseling and potential early treatment.

Interpretation of Test Results

The definitive diagnosis of SBMA is by the analysis of the CAG repeat in the *AR* gene from a blood or buccal specimen without the need for a muscle biopsy. All patients with SBMA have a CAG repeat expansion, and no other related mutations in the *AR* gene have been identified. Some studies have described a correlation between repeat size and age of onset, but interfamilial and intrafamilial variation is large for any given repeat length [46].

Laboratory Issues

Several clinical molecular laboratories offer DNA testing for SBMA. The PCR test is accurate and requires only a blood sample. PCR with electrophoretic analysis of the PCR products allows for accurate assessment of the repeat size. External proficiency testing currently is not available for SBMA.

Mitochondrial Disorders

10

Renkui Bai and Jaimie D. Higgs

Abstract

Mitochondrial disorders, also known as mitochondrial respiratory chain (RC) disorders, or oxidative phosphorylation (OXPHOS) disorders, are a heterogeneous group of disorders resulting from primary dysfunction of the mitochondrial respiratory chain or ATR synthesis. Mitochondrial disorders may affect a single organ, but many involve multiple organ systems particularly those that are highly dependent on aerobic metabolism (brain, skeletal muscle, heart, kidney, and endocrine system). This chapter describes mitochondrial diseases resulting from OXPHOS deficiency and genes directly and/or indirectly involved in the respiratory chain and ATP synthesis.

Keywords

Mitochondria • Oxidative phosphorylation • Leber Hereditary Optic Neuropathy, LHON • Kearns–Sayre syndrome • Chronic progressive external ophthalmoplegia, CPEO • Mitochondrial encephalomyopathy with lactic acidosis and stroke-like episodes, MELAS • Myoclonic epilepsy with ragged-red fibers, MERRF • Neurogenic weakness with ataxia and retinitis pigmentosa, NARP • Leigh syndrome • Mitochondrial neurogastrointestinal encephalopathy • MNGIE • Alpers syndrome

Introduction

Mitochondria are DNA-containing intracellular organelles with multiple functions. The major function of mitochondria is production of adenosine triphosphate (ATP) through oxidative phosphorylation (OXPHOS), which includes the oxygen-consuming respiratory chain (RC) and ATP synthesis that provides about 90 % of the energy needed by the cell. In addition, mitochondria also are home to many other metabolic pathways, including the tricarboxylic acid cycle, protein import, fatty acid and amino acid oxidation, apoptosis, and biosynthesis of ketone bodies, pyrimidines, heme, and urea. Mitochondrial disorders, also known as mitochondrial RC disorders, or OXPHOS disorders, are a heterogeneous group of disorders resulting from primary dysfunction of the mitochondrial RC or ATP synthesis. Mitochondrial disorders may affect a single organ, but many involve multiple organ systems, particularly those that are highly dependent on aerobic metabolism (brain, skeletal muscle, heart, kidney, and endocrine system). Patients may present at any age. Some affected individuals exhibit clinical features that fall into a discrete clinical syndrome, such as Leber Hereditary Optic Neuropathy (LHON), Kearns–Sayre syndrome (KSS), chronic progressive external ophthalmoplegia (CPEO), mitochondrial encephalomyopathy with lactic acidosis and stroke-like episodes (MELAS), myoclonic epilepsy with ragged-red fibers (MERRF), neurogenic weakness with ataxia and retinitis pigmentosa (NARP), Leigh syndrome (LS), mitochondrial neurogastrointestinal encephalopathy (MNGIE), or Alpers syndrome (progressive neuronal degeneration of

children with liver disease). However, often the clinical features are highly variable and nonspecific, and many affected individuals do not fit well into one particular category. Common features of mitochondrial disorders may include, but are not limited to, ptosis, external ophthalmoplegia, proximal myopathy, exercise intolerance, cardiomyopathy, gastrointestinal reflux, liver failure, sensorineural deafness, optic atrophy, pigmentary retinopathy, diabetes mellitus, encephalopathy, seizures, migraines, stroke-like episodes, ataxia, spasticity, chorea, and dementia. The prevalence of mitochondrial disorders has been estimated at 1 in 5,000 to 8,500 [1–4].

This chapter describes mitochondrial diseases resulting from OXPHOS deficiency and genes directly and/or indirectly involved in the RC and ATP synthesis. This chapter does not include other pathways in the mitochondria, such as pyruvate dehydrogenase metabolism, fatty acid beta-oxidation, the urea cycle, the methionine metabolism pathway, and other mitochondrial functions.

Molecular Basis of Mitochondrial Disorders

Mitochondrial disorders result from dysfunction of one or more of the OXPHOS complexes. The OXPHOS system consists of about 90 structural proteins (subunits) assembled into five multiprotein enzyme complexes (Complex I to V) embedded in the inner mitochondrial membrane. Thirteen of the structural protein subunits are encoded by the mitochondrial genome (referred to as mtDNA), and the rest are encoded by nuclear genes. Complex I (NADH dehydrogenase, also called NADH:ubiquinone oxidoreductase) consists of approximately 46 structural protein subunits, seven encoded by mtDNA and approximately 39 encoded by nuclear genes. Complex II (succinate dehydrogenase or SDH) consists of four protein subunits: SDHA, SDHB, SDHC, and SDHD, all encoded by nuclear genes. Complex III (cytochrome bc1 complex) consists of 11 subunits, 1 encoded by mtDNA and the rest encoded by nuclear genes. Complex IV (cytochrome c oxidase) consists of 13 protein subunits, three encoded by mtDNA and the rest encoded by nuclear genes. Complex V (ATP synthase) consists of approximately 18 subunits, two encoded by mtDNA and the rest encoded by nuclear genes. In addition to the structural subunits of the OXPHOS system, many nuclear gene-encoded proteins are involved in the biosynthesis, maintenance, transcription, and translation of mtDNA, and in the assembly of the OXPHOS complexes. The two ribosomal RNAs (rRNAs) (12S and 16S) and 22 transfer RNAs (tRNAs) encoded by mtDNA also are involved in the translation processes of the mitochondrial genome.

Mitochondrial disorders can be caused by mutations in mtDNA, as well as mutations in nuclear genes. Approximately 29 % of patients (approximately 15–20 % pediatric and approximately 40 % adult) with primary mitochondrial disorders are caused by mutations in mtDNA, and the remainders likely are caused by nuclear defects [5–8]. Most of the nuclear gene-encoded proteins are synthesized in the cytoplasm and imported into mitochondria. Although there are more than 1,000 proteins in the mitochondria, only approximately 77 nuclear gene-encoded proteins are structural subunits of the five OXPHOS complexes [9], and only 200–300 proteins are directly or indirectly involved in the buildup and primary function of the OXPHOS complexes [10]. The rest of the proteins, which are not involved in the composition or primary function of the OXPHOS system, are components of the numerous other mitochondrial pathways. Although mutations in genes encoding proteins not involved in the OXPHOS functions do not cause a primary mitochondrial OXPHOS disorder, the diseases caused by mutations in non-OXPHOS genes may have features that overlap with those of primary mitochondrial disorders, or may cause secondary dysfunction of the mitochondrial RC system [11–13]. Disorders due to nuclear gene mutations that affect mitochondrial function may be inherited in an autosomal dominant, autosomal recessive, or X-linked manner.

Mutations in the Mitochondrial Genome

Human mtDNA encodes for two rRNAs, 22 tRNAs, and 13 proteins that are part of the respiratory chain. Mutations in mtDNA are either maternally inherited or arise de novo. In most cases, mtDNA point mutations are inherited, whereas gross deletions arise de novo [14]. Each mitochondrion has multiple copies of mtDNA and there are hundreds to thousands of mitochondria per cell, which varies based on the cell type. Usually, mutations affect only a fraction of the mtDNA; the coexistence of normal and mutant mtDNA is called heteroplasmy. In general, the disease severity correlates with the level of mutant mtDNA. When the percentage of mutant mtDNA (mutation load) reaches a certain threshold that varies by tissue type, age, and specific mutation, the function of that tissue is impaired [14]. As the mutation load varies within and between tissues, the manifestation of mitochondrial disease may reflect tissue-specific mutation load [2]. In certain tissues, like blood, there may be selection against some of these mutations, so that cells with normal mtDNA are selectively retained. For some mutations, the mutation load in the peripheral blood may decrease with age. Mutations in mtDNA may only be identified in specific tissues, particularly those with a lower rate of cell division such as skeletal muscle, heart, and brain [14].

During oogenesis, only a small subset of mtDNA molecules from the mother is passed into the germ cells that will become the next generation (bottleneck effect): therefore, the inheritance of mitochondrial DNA disorders within

families is difficult to predict. A mother can pass on a small proportion or a high proportion of mutant mtDNA to her children, making the difference between a child being born without disease and another having a very severe form of the disease, respectively. The types of mtDNA mutations include quality defects (point mutations, deletions, duplications, and complex rearrangements) and quantity defects (mtDNA copy number changes including depletion and over-replication). To date, more than 400 definitive or likely pathogenic point mutations and more than 120 single deletions/duplications or complex rearrangements have been reported in the mtDNA mutation database Mitomap (www.mitomap.org).

MtDNA Point Mutations

MtDNA point mutations account for approximately 80 % of patients with primary mtDNA disorders [1]. Of the over 400 point mutations with disease associations in the Mitomap database (www.mitomap.org), about 58 (or approximately 14 %) are recurrent, definitive mutations and account for 70–80 % of patients with mitochondrial disorders associated with primary mtDNA point mutations [1]. The rest either are seen in a single family or lack solid evidence of the pathogenicity of the mutation. Overall, these point mutations, either definitive or reported, can be divided into three major classes [15]: (1) mutations in the protein-coding genes associated with LHON; (2) mutations in the protein-coding genes associated with other phenotypes; and (3) mutations in tRNA and rRNA genes associated with various multisystem disorders.

The LHON mutations have been subclassified into two main categories [15]. The first category includes well characterized and causative mutations designated the primary LHON mutations. This group includes the three most common LHON mutations (m.3460G>A, m.11778G>A, and m.14484T>C) and accounts for approximately 95 % of LHON patients. The second category includes mutations that have been reported in a single family and thus require additional independent reports to confirm their causal association with LHON (www.mitomap.org). These mutations usually appear to be homoplasmic, although heteroplasmic mutations are seen in a small percentage of patients and family members [16]. LHON mutations usually are associated with reduced penetrance; only about 50 % of males and 10 % of females harboring a primary pathogenic mutation suffer visual loss, and the severity of visual loss among members of the same family is highly variable [17, 18]. This marked incomplete penetrance, gender bias, and intra-family variability could be due to the level of heteroplasmy of the mutation, additional mitochondrial and/or nuclear genetic factors modulating the phenotypic expression of LHON, or environmental factors contributing to the onset of visual failure [19].

Of the mtDNA mutations in the protein-coding genes associated with other phenotypes, the m.8993T>G and m.8993T>C mutations (in the *ATP6* gene) associated with maternally inherited Leigh syndrome (MILS) and NARP are the most common [20]. Approximately 10–20 % of individuals with LS have either the m.8993T>G or m.8993T>C *MT-ATP6* mutation, while approximately another 10–20 % of patients with LS have mutations in other mitochondrial genes, e.g., other mutations in the mitochondrial genes *MT-ATP6*, *MT-TL1*, *MT-TK*, *MT-TW*, *MT-TV*, *MT-ND1*, *MT-ND2*, *MT-ND3*, *MT-ND4*, *MT-ND5*, *MT-ND6* and *MT-CO3* [20]. Of individuals with NARP, greater than 50 % likely have a detectable mutation at m.8993T, with the m.8993T>G mutation being the most common although the m.8993T>C mutation has also been described. The m.9176T>G mutation in the *ATP6* gene and the m.13513G>A mutation in the *ND5* gene each accounts for 1–5 % of patients with LS. Mutations in this category usually are more deleterious to the function of their associated protein than are LHON mutations and can cause OXPHOS complex deficiency.

Mutations in the mitochondrial tRNAs and rRNAs affect protein synthesis. Commonly, a pathogenic tRNA mutation leads to a combined OXPHOS defect, in part through a decreased overall rate of mitochondrial protein synthesis. Depending on which tRNA is mutated and the percentage of the corresponding amino acid in the different electron transport chain (ETC) complex subunits, the effects on the individual ETC complexes could be different. Mutations in the tRNAs also have been reported to cause isolated OXPHOS complex deficiency [8, 21, 22]. Many different pathogenic mechanisms lead to defective translation caused by a tRNA mutation, including impaired transcription termination, impaired tRNA maturation, defective posttranscriptional modification of the tRNA, impaired tRNA folding and stability, reduced aminoacylation, decreased binding to the translation factor mtEFTu or the mitochondrial ribosome, and altered codon decoding [23, 24]. Among the more than 30 definitive mutations in mitochondrial tRNAs recorded in Mitomap (www.mitomap.org), m.3243A>G in the mitochondrial *tRNALeu* (*UUR*) gene (*MT-TL1*) and m.8344A>G in the mitochondrial *tRNALys* gene (*MT-TK*) are the most common. The m.3243A>G mutation is present in approximately 80 % of patients with MELAS [14], in approximately 2–7 % of patients with maternally inherited diabetes and deafness (MIDD) [25], in approximately 10 % of Finnish patients with hypertrophic cardiomyopathy [25], and in association with LS [14]. The m.8344A>G mutation is present in over 80 % of MERRF patients [26].

A list of 58 common mtDNA point mutations that account for approximately 60–70 % of mtDNA point mutation-associated primary mitochondrial disorders is summarized in Table 10.1.

Table 10.1 Common mitochondrial DNA mutations and their associated disorders

mtDNA mutations	Gene	Associated disorders
m.583G>A	*MT-TF*	MELAS, mitochondrial myopathy and exercise intolerance [27]
m.1494C>T	*MT-RNR1*	Maternally inherited deafness or aminoglycoside-induced deafness [27]
m.1555A>G	*MT-RNR1*	Account for majority of patients with mitochondrial non-syndromic hearing loss and aminoglycoside induced hearing loss [28]
m.1606G>A	*MT-TV*	Ataxia, myoclonus and deafness [27]
m.3243A>G	*MT-TL1*	MELAS (m.3243A>G present in ~80 % of cases) [14]; MIDD (m.3243A>G present in ~2–7 % of patients) [25]; LS [14]; Hypertrophic cardiomyopathy (m.3243A>G present in ~10 % of Finnish patients) [25]; Sensorineural hearing loss, focal segmental glomerulosclerosis, cardiac plus multi-organ dysfunction [27]
m.3271T>C	*MT-TL1*	MELAS (m.3271T>C present in ~7.5 % of cases) [29]
m.3256C>T	*MT-TL1*	MELAS [27]
m.3260A>G	*MT-TL1*	Maternal myopathy and cardiomyopathy [27]
m.3291 T>C	*MT-TL1*	MELAS, myopathy, deafness plus cognitive impairment [27]
m.3302A>G	*MT-TL1*	Mitochondrial myopathy [27]
m.3303C>T	*MT-TL1*	Maternal myopathy and cardiomyopathy [27]
m.3460G>A	*MT-ND1*	LHON (together m.3460G>A, m.11778G>A, and m.14484T>C account for 95 % of patients) [27, 30]
m.3635G>A	*MT-ND1*	LHON [27]
m.3697G>A	*MT-ND1*	MELAS/LS/LHON and dystonia [27]
m.3700G>A	*MT-ND1*	LHON [27]
m.3733G>A	*MT-ND1*	LHON [27]
m.3733G>C	*MT-ND1*	LHON [31]
m.3890G>A	*MT-ND1*	Progressive encephalomyopathy/LS/optic atrophy [27]
m.4171C>A	*MT-ND1*	LHON [27]
m.4298G>A	*MT-TI*	Chronic progressive external ophthalmoplegia/multiple sclerosis [27]
m.4300A>G	*MT-TI*	MICM [27, 30]
m.4308G>A	*MT-TI*	Chronic progressive external ophthalmoplegia [27]
m.4332G>A	*MT-TQ*	Encephalopathy/MELAS [27]
m.5537AinsT	*MT-TW*	LS [27]
m.5650G>A	*MT-TA*	Myopathy [27]
m.5703G>A	*MT-TN*	Chronic progressive external ophthalmoplegia/mitochondrial myopathy [27]
m.7445A>G	*MT-CO1*	Sensorineural hearing loss [27]
m.7472insC (=C7471CC)	*MT-TS1*	Progressive encephalopathy/ataxia, myoclonus and deafness/motor neuron disease-like [27]
m.7497G>A	*MT-TS1*	Mitochondrial myopathy/exercise intolerance [27]
m.7511T>C	*MT-TS1*	Sensorineural hearing loss [27]
m.8344A>G	*MT-TK*	MERRF (m.8344A>G present in over 80 % of patients) [26, 27]
m.8356T>C	*MT-TK*	MERRF [26, 27]
m.8363G>A	*MT-TK*	MERRF [26]; MICM [26, 27]
m.8993T>G	*MT-ATP6*	LS (~10–20 % of patients have either m.8993T>G or m.8993T>C) [20, 27]; NARP (mutation at nucleotide 8993 estimated to be present in 20 % to >50 % of patients. m.8993T>G is more common than m.8993T>C.) [20, 27]
m.8993T>C	*MT-ATP6*	LS (~10–20 % of patients have either m.8993T>C or m.8993T>G) [20]; NARP (mutation at nucleotide 8993 is estimated to be present in 20 % to >50 % of patients. m.8993T>C is less common than m.8993T>G.) [20, 27]
m.9176T>G	*MT-ATP6*	LS (present in ~1–5 % of patients) [20, 27]; NARP (present in ~1–5 % of patients) [20, 27]
m.9176T>C	*MT-ATP6*	LS (1–5 % of patients) [27, 32–34]
m.9185T>C	*MT-ATP6*	LS/ataxia syndromes/NARP-like disease [27]
m.10010T>C	*MT-TG*	Progressive encephalopathy [27]

LHON Leber hereditary optic neuropathy, *LS* Leigh syndrome, *MELAS* mitochondrial encephalomyopathy, lactic acidosis, and stroke-like episodes; *MERRF* myoclonic epilepsy and ragged red muscle fibers; *MICM* maternally inherited hypertrophic cardiomyopathy; *MIDD* maternally inherited diabetes and deafness; *NARP* neurogenic weakness with ataxia and retinitis pigmentosa.

Single Large-Scale Rearrangements

More than 120 single deletions, duplications and complex rearrangements associated with a primary mtDNA disorder have been published and recorded in the mtDNA mutation database, Mitomap (www.mitomap.org). The size of disease-causing mtDNA single deletions varies from several base pairs to 10 kb. The large-scale single deletions (>1 kb) are the most common rearrangements and account for approximately 97 % of the reported pathogenic deletions of the mtDNA and >99 % of patients with mtDNA deletion associated diseases. Greater than 80 % of deletions are associated with direct repeats of 3–13 bp in length (www.mitomap.org). The most common large-scale deletions are between a 13 bp direct repeat from m.8470 to m.8482 in the *ATPase8* gene and from m.13447 to m.13459 in the *ND5* gene. Large duplications of mtDNA almost always coexist with large-scale single deletions and have been observed in a subset of patients who harbor large-scale mtDNA single deletions [41–45]. MtDNA duplications alone are not disease causing, although they may have modifying effects on the phenotype caused by mtDNA deletions [42, 43]. In about 20 % of patients with primary mtDNA disorders, the disorder is caused by large-scale single deletions in mtDNA [1].

Patients with large-scale single deletions usually have one of the three mitochondrial DNA deletion syndromes: Pearson syndrome, KSS, or progressive external ophthalmoplegia (PEO). The clinical features of the major mtDNA deletion syndromes are described in Table 10.2. In Pearson syndrome, mtDNA deletions are usually more abundant in blood than in other tissues. In PEO, mtDNA deletions are confined to skeletal muscle. In KSS, approximately 90 % of patients have a large-scale (i.e., 1.1–10 kb) mtDNA deletion. Deletions are usually present in all tissues of individuals with KSS, and may be identified in blood leukocytes. However, in many cases, the level of heteroplasmy of the deletion is too low in blood cells to be detected, and a muscle biopsy may be necessary [41]. Pearson syndrome patients who survive infancy may develop KSS at a later age [46]. An individual may have a large-scale mtDNA deletion abundant in blood and undetectable in muscle at an early age and have Pearson syndrome. If this individual survives, the same deletion can be abundant in muscle and undetectable in blood at a later age and cause KSS.

Copy Number Changes (Depletion or Over-Replication)

Abnormal amounts of mtDNA, either decreases of copy number (depletion) or increases of copy number (over-replication), can be indicative of mitochondrial dysfunction. MtDNA depletion syndrome is a group of mitochondrial disorders characterized by a reduced amount of mitochondrial DNA in tissues. The disorders associated with mtDNA depletion syndrome generally involve neurological symptoms that occur during infancy or childhood. Symptoms may include muscle weakness, hypotonia, exercise intolerance, developmental delay, lactic acidosis, encephalopathy, hepa-

Table 10.2 Characteristics of mitochondrial DNA deletion syndromes [1, 41]

mtDNA deletion syndrome	Disease characteristics	Characteristics of mtDNA deletions
KSS	A triad of (1) onset <20 yo, (2) pigmentary retinopathy, and (3) PEO, plus at least one of the following: cardiac conduction block, cerebrospinal fluid protein concentration greater than 100 mg/dL, or cerebellar ataxia.	~90 % have a large-scale 1.1–10 kb deletion usually present in all tissues, but most abundant in muscle, and often undetectable in blood cells. A deletion of 4,977 bp is the most common. Over 120 deletions have been associated with KSS. Large-scale duplications have also been reported.
PEO	Ptosis, ophthalmoplegia, variably severe proximal limb weakness; relatively benign, may be the early sign of KSS.	Deletion/duplication analysis is estimated to identify a deletion in approximately 50 % of patients. Deletions are confined to skeletal muscle.
Pearson syndrome	Sideroblastic anemia, exocrine pancreas dysfunction, usually fatal in infancy. Children who survive the disease usually go on to develop KSS.	Deletions are usually more abundant in blood than other tissue types. Deletion load gradually decreases in blood and increases in muscle as it evolving to PEO and KSS.

KSS Kearns–Sayre syndrome, *PEO* progressive external ophthalmoplegia

topathy, or myopathy. MtDNA depletion syndrome is usually caused by mutations in the nuclear genes involved in mtDNA biosynthesis or maintenance, such *POLG*, *TYMP*, *C10ORF2*, *DGUOK*, *MPV17*, etc.

Mitochondrial over-replication can be a cellular response to mitochondrial dysfunction and is characterized by ragged red fibers in the affected muscle specimens of patients with mtDNA mutations in tRNA genes or with large-scale mtDNA deletions [47, 48]. Over-replication of mtDNA also has been reported in a later-onset, mild KSS patient with a high heteroplasmy (92 %) for a deletion in the mtDNA [49].

Mutations in the Nuclear Genes

Nuclear genes encode the structural protein subunits that are components of the mitochondrial OXPHOS complexes, as well as proteins involved in biosynthesis, maintenance, transcription and translation of the mitochondrial DNA, proteins involved in the assembly of the OXPHOS complexes, and cofactors of the electron transport chain that are indirectly involved in the primary function of the OXPHOS system. Proteins needed for the assembly of an OXPHOS complex, referred to as assembly factors, are not usually components of the final structure. Fewer than 100 nuclear genes have been associated with disease-causing mutations for a primary mitochondrial OXPHOS disorder. These nuclear genes encode proteins from all the above categories. Although most of these nuclear gene-encoded proteins are synthesized in the cell cytoplasm and imported into the mitochondria, some of these proteins have dual localization (located in both mitochondria and cytoplasm), such as ISCU and LRPPRC, and some are localized in the cytoplasm but not localized in mitochondria, such as the small subunit of P53-inducible ribonucleotide reductase encoded by the *RRM2B* gene and thymidine phosphorylase encoded by the *TYMP* gene. As mtDNA genes also are involved in the structure and/or function of mitochondria, relevant mtDNA genes are discussed with nuclear genes in this section.

Genes Encoding OXPHOS Complex Structural Subunits or Assembly Factors

Complex I (CI) deficiency is the most common cause of mitochondrial disorders and accounts for about one-third of patients with primary mitochondrial disorders [50, 51]. Mutations in the mtDNA account for about 29 % of patients with confirmed isolated CI deficiency, while the rest are considered to be due to nuclear gene defects [8]. Mutations have been identified in 17 of the 39 nuclear genes encoding the structural subunits and in 10 nuclear genes encoding the assembly factors for CI (see Table 10.3). Mutations in these genes have been seen in approximately 20 % of patients with isolated CI deficiency [8]. Each gene accounts for less than 5 % of patients with CI deficiency [52]. The diseases resulting from these mutations range from severe lethal infantile mitochondrial disease, congenital lactic acidosis, encephalocardiomyopathy, and LS to adult onset muscle weakness, exercise intolerance, liver dysfunction, ataxia, and progressive neurodegeneration [52, 53]. Some genes with mutations expected to cause combined (multiple) OXPHOS deficiency, such as *MT-TL1*, *MT-TS2*, and *MT-TW* in the mtDNA, and *POLG*, *SUCLA2*, *C10ORF2*, and *TAZ* in the nuclear genome, can be associated with an isolated complex deficiency (Table 10.3). In contrast, patients with mutation(s) in CI subunit genes (either mtDNA or nuclear), can present with combined Complex I and III deficiency [54, 55], likely due to supercomplex formation of the respiratory chain [56–58].

Although Complex II (CII) has four known genes (*SDHA*, *SDHB*, *SDHC* and *SDHD*) encoding the structural subunits and two known genes (*SDHAF1* and *SDHAF2*) encoding the assembly factors, only two genes, *SDHA* and *SDHAF1*, have

been associated with CII deficiency, and present as LS or mitochondrial encephalopathy (see Table 10.3). The rest of the genes, *SDHB*, *SDHC SDHD*, and *SDHAF2*, are considered tumor suppressor genes, with mutations associated with hereditary paraganglioma and pheochromocytoma syndromes only, suggesting that mutations in these genes are involved in tumorigenesis [59].

Complex III (CIII) deficiency is relatively rare and accounts for only about 7 % of patients with an OXPHOS complex deficiency [51, 60]. Of the 11 structural subunits of CIII, mutations have been reported in the only subunit encoded by the *MT-CYB* gene in the mtDNA and 4 (*UQCRB*, *UQCRC2*, *UQCRQ* and *CYC1*) of the 10 subunits encoded by nuclear genes (Table 10.3). More than 20 pathogenic mutations in the *MT-CYB* gene account for the vast majority of known pathogenic mutations in the CIII subunits and most of these mutations are located outside of the transmembrane domain of the protein [61]. The *UQCRB*, *UQCRQ* and *UQCRC2* genes each have one homozygous pathogenic mutation described in a single family and the *CYC1* gene has two different homozygous pathogenic mutations identified in two unrelated patients. In addition, mutations in two genes (*BCS1L* and *TTC19*) encoding CIII assembly factors are associated with primary mitochondrial disorders due to CIII deficiency (Table 10.3). More than 20 pathogenic mutations in the *BCS1L* gene are in the human gene mutation database (HGMD) (www.hgmd.org) and account for the majority of patients with CIII deficiency. Clinical features range from mild congenital sensorineural hearing loss and distorted hair (pili torti), the hallmarks of Björnstads syndrome, tubulopathy alone or combined with cholestasis, and/or encephalopathy to GRACILE syndrome (growth retardation, amino aciduria, cholestasis, iron overload, lactic acidosis, and early death) [62–64].

Complex IV (CIV; Cytochrome c oxidase or COX) is the terminal component of the respiratory chain catalyzing the reduction of molecular oxygen to water. COX is composed of three catalytic subunits encoded by mtDNA genes and ten accessory subunits encoded by nuclear genes. The accessory subunits are involved in structural stabilization, assembly of the complex, and modulation of COX catalytic activity. Disease-causing mutations occur in all three mtDNA genes (*MT-CO1*, *MT-CO2* and *MT-CO3*) encoding catalytic subunits of COX, but almost all the mutations were seen in a single family and are considered "private" mutations. Of the ten genes encoding accessory subunits of COX, only *COX6B1* and *COX4I2* (Table 10.3) have pathogenic mutations. In addition, mutations occur in nine nuclear genes (*SURF1*; *SCO1*; *SCO2*; *COX10*; *COX14* [*C12ORF62*]; *COX15*; *COX20*; *LRPPRC*; *COA5* [*C2orf64*]) encoding COX assembly factors that are not themselves components of the final COX structure, and account for the majority of patients with isolated COX deficiency (Table 10.3). The *SURF1* gene represents the most common gene accounting for 25–75 % of LS associated with COX deficiency [65]. Furthermore, mutations in *ETHE1*, *FASTKD2*, and *TACO1* also are associated COX deficiency (Table 10.3).

Complex V (ATP synthase) deficiency most commonly is caused by mutations in the mtDNA encoded ATP6 and ATP8 proteins, and as described earlier in this chapter, m.8993T>G and m.8993T>C are the most common mutations (Table 10.1). The severity of disease caused by these mutations depends on mutation load: a low mutation load is asymptomatic; an intermediate mutation load causes NARP; and a high mutation load causes MILS [66, 67]. Only two of the approximately 16 nuclear genes encoding the subunits of complex V (*ATP5E*) and two genes encoding the assembly factors, *ATPAF2* (*ATP12*) and *TMEM70*, have mutations which cause ATP synthase deficiency (Table 10.3). The presentation of patients with isolated ATP synthase deficiency caused by mutations in nuclear genes is remarkably homogeneous with neonatal onset, lactic acidosis, hypertrophic cardiomyopathy, psychomotor retardation, and, in most cases, 3-methyl-glutaconic aciduria. These patients usually have diminished content of ATP synthase and lack striatal brain involvement [68].

Genes Encoding Proteins Essential for MtDNA Biosynthesis and/or Maintenance

Although mtDNA resides in mitochondria, its biosynthesis (replication), maintenance, transcription, and translation are controlled by proteins encoded by nuclear genes, synthesized in the cytoplasm, and imported into mitochondria [171]. The mtDNA copy number is related to energy demand, i.e., tissues with the highest respiratory demand, such as muscle, liver, heart, and brain, have the greatest number of mtDNA copies per cell. Normal mtDNA replication and maintenance is important for both the quality and quantity of mtDNA and requires normal function of the mtDNA replisome as well as normal mitochondrial deoxynucleoside triphosphate (dNTP) pool maintenance. Major proteins or enzymes involved in mtDNA replication include DNA polymerase gamma (with its catalytic subunits encoded by the *POLG* gene and its accessory subunit encoded by the *POLG2* gene) and Twinkle helicase encoded by the *C10ORF2* gene (also known as *PEO1*). Major proteins involved in the maintenance of the large dNTP pool are encoded by genes including *TK2*, *TYMP*, *DGUOK*, *RRM2B*, *SUCLA2*, *SUCLG1*, etc [24]. Mutations in genes involved in mtDNA replication or dNTP pool maintenance may cause quality or quantity defects of mtDNA. To date, disease-causing mutations have been identified in many genes involved in mtDNA replication or dNTP pool maintenance (Table 10.4). Mutations in *POLG* are the most common and account for approximately 25 % of all patients with mitochondrial disease presentations [172, 173]. Mutations in *POLG*, *POLG2*, *ANT1*, *C10ORF2*, *RRM2B*, and *OPA1* have been reported to be associated with autosomal-dominant external ophthalmoplegia (adPEO) with multiple mtDNA deletions (Table 10.4). Mutations in

adPEO autosomal dominant external ophthalmoplegia, *arPEO* autosomal recessive progressive external ophthalmoplegia, *CI* Complex I, *CII* Complex II, *CIII* Complex III, *CIV* Complex IV, *CV* Complex V (ATP synthase), *COXPD* combined OXPHOS deficiency, *MELAS* mitochondrial encephalomyopathy, lactic acidosis, and stroke-like episodes, *mtDNA* mitochondrial DNA

POLG, *C10ORF2* (*PEO1*), *RRM2B*, and *SLC25A4* (*ANT1*) account for approximately 45 %, 15–35 %, 9 %, and 4–15 % of familial PEO with multiple deletions, respectively. Mutations in *POLG2* are rare and account for less than 2 % of adPEO [173, 174]. Mutations in *POLG* and *RRM2B* are associated with autosomal-recessive external ophthalmoplegia (arPEO) with multiple mtDNA deletions (Table 10.4). Mutations in *POLG*, *C10ORF2*, *RRM2B*, *DGUOK*, *MPV17*, *TK2*, *SUCLA2*, *SUCLG1*, and *TYMP* are associated with different types of mtDNA depletion syndromes (Table 10.4). Approximately 69 % of patients with myopathic mtDNA depletion syndrome and more than 84 % of patients with hepatocerebral mitochondrial DNA depletion syndrome harbor mutations in one of these nine genes [175]. Mutations in genes involved in mtDNA biosynthesis and maintenance account for approximately 40 % of patients with combined OXPHOS deficiency [176].

Genes Encoding Mitochondrial Translational Machinery

The 13 proteins encoded by mtDNA are synthesized in mitochondria using a nonuniversal genetic code as follows: UGA codes for tryptophan (W) instead of a stop (X) codon; AGA & AGG codes for a stop (X) codon instead of arginine (R); and AUA codes for methionine (M) instead of isoleucine (I). The mitochondrial translational machinery consists of two rRNAs and 22 tRNAs encoded by mtDNA and approximately 100 proteins encoded by nuclear genes, including initiation, elongation, and termination translation factors; up to 81 mitochondrial ribosomal proteins (MRPs); and approximately 19 mitochondrial aminoacyl-tRNA synthetases and methionyl-tRNA transformylase [177, 178]. Theoretically, mitochondrial protein synthesis deficiency can be caused by mutations in any of the components of the mitochondrial translational machinery and can result in OXPHOS deficiency affecting theoretically all complexes containing mtDNA-encoded subunits (CI, CIII, CIV, and CV).

To date, in addition to the two rRNAs and 22 tRNAs encoded by mtDNA with many disease-causing mutations reported to be associated with combined (multiple) complex deficiency (www.mitomap.org), pathogenic mutations associated with combined OXPHOS deficiency also have been reported in many nuclear genes encoding components of the mitochondrial translational machinery, including two genes involved in tRNA modification (*PUS1* and *TRMU*), three genes encoding elongation factors (*GFM1*, *TUFM*, and

TSFM), ten genes encoding aminoacyl-tRNA synthetase (*AARS2*, *DARS2*, *EARS2*, *FARS2*, *HARS2*, *LARS2*, *MARS2*, *RARS2*, *YARS2*, and *SARS2*), and one gene encoding peptide release factor (*C12orf65*) (Table 10.4). Of all the 81 human MRPs, mutations have been found in only four: *MRPS16*, *MRPS22*, *MRPL3* and *MRPL44* (see Table 10.4). Mutations in both *MRPS16* and *MRPS22* genes result in a marked decrease in the 12S rRNA transcript level, probably caused by impaired assembly of the mito-ribosomal small subunit, generating unincorporated and instable 12S rRNA [137, 138]. Similarly, mutations in both *MRPL3* and *MRPL44* genes result in a marked decrease in the 16S rRNA transcript level [135, 136].

Genes Involved in Mitochondrial Dynamics

Mitochondrial fusion and fission (collectively termed mitochondrial dynamics) are important for mitochondrial inheritance and for the maintenance of mitochondrial functions [179]. Three nuclear-gene encoded proteins are required for mitochondrial fusion: Mitofusins 1 and 2 (Mfn1 and Mfn2) for outer membrane fusion, and Opa1 for inner membrane fusion [180]. Dynamin-related protein Drp1 is required for mitochondrial division (fission) [181, 182]. *OPA1* mutations cause autosomal-dominant optic atrophy [183, 184]. In most cases, this disease specifically involves degeneration of retinal ganglion cells. However, more diverse *OPA1*-related phenotypes have been described recently, and they include disorders of mtDNA maintenance [180]. Mutations in the *MFN2* gene cause the autosomal-dominant Charcot–Marie–Tooth disease type 2A, which is a peripheral neuropathy caused by degeneration of axons in long sensory and motor nerves of the distal extremities [185]. A mutation in the *DNM1L* gene has been reported in a patient with lethal encephalopathy due to defective mitochondrial and peroxisomal fission. The patient presented in the first days of life with microcephaly, abnormal brain development, optic atrophy and hypoplasia, and lactic acidemia, and died at age 37 days. Overexpression of the mutant DNM1L from the patient in fibroblasts from control subjects induced aberrant mitochondrial and peroxisomal phenotypes, indicating that the mutation acted in a dominant-negative manner [186].

Genes Involved in CoQ10 Biosynthesis or Metabolism

Coenzyme Q10 (CoQ10), or ubiquinone, is a mobile lipophilic electron carrier critical for electron transfer by the mitochondrial inner membrane respiratory chain from Complex II and I to Complex III. Intracellular synthesis is the major source of CoQ10, although a small proportion is acquired through diet. CoQ10 is synthesized in the mitochondrial inner membrane. At least 12 genes are involved in COQ10 biosynthesis [187]. Primary CoQ10 deficiency is a rare, clinically heterogeneous autosomal recessive disorder with six major phenotypes [187, 188]: (1) an encephalomyopathic form with seizures and ataxia; (2) a multisystem infantile form with encephalopathy, cardiomyopathy, and renal failure; (3) a predominantly cerebellar form with ataxia and cerebellar atrophy; (4) LS with growth retardation; (5) an isolated myopathic form; and (6) nephrotic syndrome. Typical CoQ10 deficiency has relatively normal isolated Complex I, II, and III activity, but deficient I + III and II + III activity. Mutations in any of the genes involved in COQ10 biosynthesis may cause CoQ10 deficiency. To date, mutations in six nuclear genes, *COQ2*, *ADCK3* (*CABC1*, *COQ8*), *COQ6*, *COQ9*, *PDSS1*, and *PDSS2* have been reported to be associated with primary CoQ10 deficiency (Table 10.4). CoQ10 levels also can be affected by other genetic defects (such as mutations of mtDNA, *ETFDH*, *APTX*, and *BRAF* genes) that are not directly related to the CoQ10 biosynthetic process (see Table 10.4). CoQ10 deficiency can be treated by supplementation with CoQ10.

Genes Indirectly Affecting OXPHOS Function

Although not involved in the structure and assembly of the OXPHOS system, both *SLC25A4* (*ANT1*) and *SLC25A3* (*PHC*) are important for the major function of the OXPHOS system-ATP synthesis. The mitochondrial phosphate carrier (PHC), encoded by *SLC25A3*, transporting inorganic phosphate into the mitochondrial matrix, is essential for the aerobic synthesis of ATP. A homozygous *SLC25A3* mutation has been identified in two siblings with lactic acidosis, hypertrophic cardiomyopathy, and muscular hypotonia who died within the first year of life. Functional investigation of intact mitochondria showed a deficiency of ATP synthesis in muscle [99]. ANT1 encoded by the *SLC25A4* gene determines the rate of ADP/ATP flux between the mitochondrion and the cytosol and is an important regulator of oxidative energy metabolism. Mutations in the *SLC25A4* gene have been reported in patients with autosomal dominant progressive external ophthalmoplegia with mtDNA deletions, and in patients with familial hypertrophic cardiomyopathy (Table 10.4).

The *TIMM8A* gene, located on the X chromosome, encodes the mitochondrial import inner membrane translocase subunit Tim8 that acts in a complex together with the Tim13 protein in a chaperone-like manner to facilitate the import of nuclear-encoded precursor proteins into the mitochondrial inner membrane. Mutations in *TIMM8A* cause deafness-dystonia-optic neuropathy (DDON) syndrome (also known as Mohr-Tranebjaerg syndrome), a rare neurodegenerative disease with early-onset deafness, dystonia and other neurological abnormalities including cortical blindness, spasticity, dementia and mental retardation [189].

The mitochondrial iron-sulfur cluster assembly enzyme, ISCU, is important for normal mitochondrial function [190]. Mutations in the *ISCU* gene have been reported to be associated with hereditary myopathy with lactic acidosis, and combined OXPHOS deficiency (Table 10.4).

The mitochondrial disulfide relay system (DRS) drives the import of cysteine-rich proteins into the intermembrane space via an oxidative folding mechanism. Proven substrates of the DRS include many proteins relevant to COX biogenesis, thus connecting the DRS to the OXPHOS system. Mutations in the *GFER* gene, encoding the DRS protein, GFER, are associated with autosomal recessive progressive mitochondrial myopathy with cataract and combined respiratory chain deficiency (Table 10.4).

The *SPG7* gene encodes paraplegin, a component of the m-AAA protease. The m-AAA protease is an ATP-dependent proteolytic complex of the mitochondrial inner membrane that degrades misfolded proteins and regulates ribosome assembly [191]. Mutations in the *SPG7* gene are associated with autosomal recessive spastic paraplegia [192, 193]. Patients with *SPG7* mutations show typical signs of mitochondrial OXPHOS defects [194].

The *NFU1* and *BOLA3* genes each encode a protein that plays an essential role in the production of iron-sulfur (Fe-S) clusters for the normal maturation of ipoate-containing 2-oxoacid dehydrogenases and for the assembly of the mitochondrial RC complexes [169]. Mutations in *NFU1* and *BOLA3* are associated with an autosomal recessive fetal mitochondrial disease: multiple mitochondrial dysfunctions syndrome [169]. Patients with mutations in *NFU1* have abnormalities of the glycine-cleavage system, the branched-chain alpha-keto acid dehydrogenase, and a significant reduction in activity of mitochondrial respiratory chain complexes [195]. Patients with mutations in *BOLA3* have decreased activity of the pyruvate dehydrogenase complex, the branched-chain alpha-keto acid dehydrogenase, and the mitochondrial RC complexes [195]. The above data suggest that mitochondrial dysfunction can result from a multitude of mechanisms other than direct impairment of the components of the OXPHOS system.

Common Mitochondrial Diseases with Highly Heterogeneous Underlying Molecular Defects

Some affected individuals exhibit clinical features that fall into a discrete clinical syndrome with underlying molecular defects confined to a specific gene(s) in the mitochondrial genome, such as, LHON, KSS, MELAS, MERRF, NARP, and MILS. MNGIE is mostly caused by mutations in *TYMP* [196] or *POLG* [197]. For the majority of patients with a mitochondrial disorder, the causative mutation can be in the mtDNA or in one of the many nuclear genes important for normal mitochondrial function. Therefore, predicting the causative gene from the clinical presentation can be difficult.

Chronic Progressive External Ophthalmoplegia

CPEO is a disorder characterized by slowly progressive paralysis of the extraocular muscles. Patients usually experience bilateral, symmetrical, progressive ptosis, followed by ophthalmoparesis months to years later. Ciliary and iris muscles are not involved. CPEO can be caused by mtDNA rearrangements (1.1–10 kb large-scale single deletions and duplications) (www.mitomap.org); mtDNA point mutations (m.3243A>G, m.4274T>C); or mutation(s) in many different nuclear genes (*C10ORF2* [*PEO1*], *OPA1*, *POLG* [*POLG1*], *POLG2*, *RRM2B*, *SLC25A4* [*ANT1*], and *TYMP*).

Optic Atrophy

Hereditary optic atrophy is a generic term referring to a heterogeneous group of genetic disorders that affect retinal ganglion cells and the optic nerve, leading to impaired vision. The most common forms of these disorders are autosomal dominant optic atrophy (ADOA; MIM#165500) and LHON (MIM#53500). Almost all LHON patients have mutations in the mtDNA, which account for approximately 10 % of patients suspected of having a hereditary optic atrophy. The clinical features of LHON may overlap with those caused by mutations in the nuclear genes. Mutations in *OPA1* account for 30–40 % of patients with suspected hereditary optic atrophy and approximately 40–50 % of patients with hereditary optic atrophy due to mutations in the nuclear genes [198, 199]. Mutations in many other genes have also been reported to be associated with hereditary optic atrophy, including *AUH*, *C12ORF65*, *CISD2* (*WFS2*), *NDUFS1*, *OPA3*, *POLG* (*POLG1*), *SPG7*, *TIMM8A* (*DDP1*), *TMEM126A*, and *WFS1* (Table 10.5). Almost all of these genes are important for normal mitochondrial function.

Leigh Syndrome

LS is an early-onset progressive neurodegenerative disorder with a characteristic neuropathology consisting of focal, bilateral lesions in one or more areas of the central nervous system, including the brainstem, thalamus, basal ganglia, cerebellum, and spinal cord. The lesions are areas of demyelination, gliosis, necrosis, spongiosis, or capillary proliferation. Approximately 30–40 % of patients with LS are due to mutations in the mtDNA, while the rest are due to mutations in the nuclear genes. Mutations in about 50 nuclear genes have been reported to be associated with LS or Leigh-like syndrome (Table 10.5).

Table 10.5 Genes with pathogenic mutations for common mitochondrial disease syndromes or with overlapping clinical features

Disease or features	Associated genes with disease-causing mutations

Mitochondrial Encephalopathy

The clinical features of mitochondrial encephalopathy may overlap that of LS. Mutations in more than 50 nuclear genes important for normal mitochondrial function have been reported to be associated with mitochondrial diseases with encephalopathy as one of the major clinical features (Table 10.5).

Lactic Acidosis

Lactic acidosis or elevated lactate in blood or cerebrospinal fluid is one of the clinical features in 50–87 % of patients with primary mitochondrial disorders [200, 201]. To date, mutations in more than 80 nuclear genes have been reported to be associated with mitochondrial disorders with lactic acidosis or elevated lactate levels (Table 10.5).

Cardiomyopathy Due to Mitochondrial OXPHOS Dysfunction

Up to 40 % of pediatric patients with mitochondrial disorders have cardiomyopathy as one of the major features [200, 202]. To date, many mutations in the mtDNA (www.mitomap.org) and mutations in more than 20 nuclear genes are associated with primary mitochondrial disorders with cardiomyopathy (Table 10.5).

Genotype and Phenotype Correlation of Mitochondrial Disorders

Mitochondrial disorders are clinically and genetically highly heterogeneous in a number of ways. The same disease syndrome can be caused by mutations in mtDNA, or mutations in different nuclear genes involved in the function of different mitochondrial complexes. Mutations in the same gene or even the same mutation can cause different disease syndromes. Mutation(s) in genes theoretically involved in a single OXPHOS complex may actually cause deficiency of multiple OXPHOS complexes. Mutation(s) in genes involved in multiple OXPHOS complexes may cause deficiency of a single OXPHOS complex. Finally, the phenotypes resulting from different complex deficiencies overlap with each other. Therefore, genotype–phenotype correlations for mitochondrial disorders are not well established.

Clinical Utility of Testing

While the diagnosis of mitochondrial disorders is usually suspected clinically [203], biochemical and/or molecular evaluations often are necessary to confirm a specific diagnosis. Since biochemical testing is not definitive and may not be reliable and reproducible [204], molecular genetic confirmation is important, when possible, to confirm the diagnosis, provide guidance on management and prognosis, and

permit accurate recurrence risk counseling. For mitochondrial disorders that result from mutations in nuclear genes, identification of the specific familial mutation(s) facilitates prenatal testing.

Identification of a specific disease-causing mutation for mitochondrial diseases has several major clinical utilities. First, diagnostic testing confirms a clinical diagnosis of a specific mitochondrial disease syndrome, distinguishes between primary and secondary mitochondrial disorders, establishes the genetic cause of a primary mitochondrial disorder, and provides prognostic information. A specific diagnosis is used to guide selection of optimal treatment for the affected patient. Test results can inform genetic counseling, recurrence risk determination, and family planning. Predictive testing for asymptomatic family members of a proband with a known mitochondrial disease-causing mutation enables clinical monitoring, follow-up, and optimal treatment of family members with a positive result, and reduces anxiety and foregoing clinical monitoring for family members with a negative test result. Identification of known, pathogenic nuclear gene mutations can be used for prenatal testing of the fetus in at-risk pregnancies. An example of genetic test results used for therapeutic decision-making is patients with Alpers-Syndrome and other POLG-related disorders, due to homozygous or compound heterozygous mutations in the *POLG* gene, should avoid valproic acid which induces or accelerates liver disease in these patients. Another example is patients with CoQ10 deficiency due to mutations in genes involved in the biosynthesis of CoQ10 can be treated by supplementation of CoQ10.

Available Assays

Testing MtDNA

Testing Common MtDNA Point Mutations

To date, more than 50 definitive disease-causing point mutations of mtDNA have been reported (www.mitomap.org). These point mutations account for 70–80 % of patients with primary mtDNA disorders associated with mtDNA point mutations. Many testing methods are used for detection of common mtDNA point mutations including polymerase chain reaction-allele specific oligonucleotide hybridization (PCR-ASO), PCR-restriction fragment length polymorphism (PCR-RFLP), pyrosequencing, real-time amplification-refractory mutation system quantitative PCR (real-time ARMS-qPCR), Sanger sequencing, or next-generation sequencing (NGS). Each method has advantages and disadvantages compared to other methods. The lowest level of heteroplasmy detectable varies from 0.1–1 % by real-time ARMS-qPCR, to 20–25 % by Sanger sequencing (Table 10.6).

Deletion/Duplication Testing of MtDNA

Large-scale mtDNA single deletions can be detected by Southern blot analysis, array-based comparative genomic hybridization (aCGH), or long-range PCR. Both Southern blot analysis and aCGH can detect large-scale single deletions with heteroplasmy of about 15 % or higher [209]. Southern blot analysis may be able to detect multiple deletions of mtDNA, usually in muscle specimens [210]. Long-range PCR is more sensitive in detecting large-scale single deletions and multiple deletions; however, as mtDNA dele-

Table 10.6 Comparison of methods for mtDNA common point mutation analysis

Method	Advantages	Disadvantages	Lowest level of heteroplasmy detectable
PCR-RFLP	Roughly quantitative	Not sensitive; incomplete digestion may result in false positive or false negative results; the adjacent sequences may affect enzyme site.	5–10 % [205, 206]
PCR-ASO	Sensitive; not affected by the adjacent variants	Not quantitative; need radioactive isotope	2 % [205, 206]
Pyro sequencing	Roughly quantitative	Need specific instrument; reliability affected by the adjacent nucleotide sequences.	1–5 % [207]
ARMS-qPCR	Quantitative; sensitive; not affected by the adjacent variants	Need real-time PCR machine; accurate	0.1–1 % [208]
Sanger sequencing	Can detect many variants in a fragment simultaneously	Labor-intensive	20–25 %
Next-generation sequencing	Can analyze many genes and many variants simultaneously	Need expensive instrument	~2 %

ARMS amplification refractory mutation system, *ASO* allele-specific oligonucleotide hybridization, *PCR* polymerase chain reaction, *RFLP* restrictive fragment length polymorphism

tions accumulate with age, false-positive results can occur because some low-level age-related deletions of mtDNA do not have clinical significance.

Sequence Analysis of Entire Mitochondrial Genome

Sequence analysis of the entire mitochondrial genome can be done by using Sanger sequencing of 24–50 overlapping PCR amplicons covering the entire mitochondrial genome or by using NGS. Sanger sequencing can detect mutation heteroplasmy of 20–25 % or higher. NGS can detect mutation heteroplasmy as low as 1–2 %. NGS can use either multiple over-lapping amplicons covering the mitochondrial genome, or two whole mitochondrial genome amplicons overlapping at the D-loop (noncoding) region (GeneDx unpublished data). The latter method also detects large-scale single deletions in the mtDNA which account for about 20 % of patients with a primary mitochondrial DNA disorder [1], in addition to point mutations and small insertions or deletions which account for about 80 % of patients with a primary mitochondrial DNA disorders. Although this method cannot detect large duplications of mtDNA, large duplications usually coexist with large-scale mtDNA single deletions and are seen in a subset of patients with KSS [42, 43]. NGS using two whole mitochondrial genome amplicons overlapping at the D-loop (noncoding) region can detect almost all of the primary disease-causing quality defects of mtDNA (see Table 10.7).

Real-Time PCR Analysis of mtDNA to Determine Depletion or Over-Replication

The mtDNA content in muscle or liver tissue can be quantified using real-time PCR for mtDNA and nuclear genes. By comparing the patient result with tissue- and age-matched controls, mtDNA depletion or over replication can be determined [211].

Testing Nuclear Genes

Sequence Analysis of Single Nuclear Genes

Currently, the majority of clinical molecular laboratories offer sequencing of individual nuclear genes. Because mutations in the *POLG* gene are considered to be responsible for

Table 10.7 Comparison of methods for testing entire mitochondrial genome

Disease-causing quality defects in mtDNA				**Methods**				
Type		Information and comments		Sanger sequencing	Southern blot	aCGH	NGS with multiple partial mtDNA amplicons	NGS with two whole mtDNA amplicons
		Primary or secondary mutations	% Primary mtDNA disorders					
Point mutations		Primary	~80 %	Y	N	N	Y	Y
Lowest heteroplasmy (point mutations) detectable		~10 % patients positive for some point mutations with <5 % mutant in blood, but ≥30 % in muscle; ≥25 % mutant could cause disease		≥25 %	NA	NA	~2 %	~2 %
Deletions	≤20 bp (rare)	Primary	~20 %	Y	N	N	Y	Y
	>20–1,000 bp (Rare)	Primary		Y	N	N	Some	Y
	1 kb (account for >99 % patients with MDS)	Primary		N	Y	Y	N	Y
Large duplications (seen only in a subset of KSS patients with LSDs)		Primary	Always coexist with LSDs	NA	Some	Y	N	N
Multiple deletions (due to mutations in nuclear genes)		Secondary	0 %	N	Some	N	N	Some
Lowest heteroplasmic LSDs detectable		~99 % of the LSDs are de novo; all reported disease-causing LSDs are >15 %		NA	~1 %	~15 %	NA	~15 %
% of patients with primary mtDNA disorders diagnosed				<80 %	~20 %	~20 %	~80 %	>99 %

aCGH array-based comparative genomic hybridization, *KSS* Kearns–Sayre syndrome, *LSD* large single deletion, *MDS* mtDNA deletion syndromes, *mtDNA* mitochondrial DNA, *N* no, *NA* not applicable, *NGS* next-generation sequencing, *Y* yes

up to 25 % of patients with mitochondrial disorders, sequencing of this gene is often a good first testing option. Mutations in several other genes (*C10ORF2*, *DGUOK*, and *MPV17*) are known to be responsible for more than 50 % of patients with hepatocerebral mtDNA depletion syndrome, and therefore also are good candidates for single gene sequencing. For the vast majority of other genes, the positive detection rate is very low, and the overall cost of sequencing multiple single genes is very high.

Sequence Analysis of Multiple Genes

For patients with diseases that fall into a specific category, such as CI deficiency, or CIV deficiency, mutations in many different nuclear genes could be causal. For the more than 20 nuclear genes with known disease-causing mutations for CI deficiency, no single gene is responsible for more than 5 % of the patients [52]. Therefore, sequencing the multiple genes individually is neither time-efficient nor cost-effective. NGS can analyze many genes simultaneously at a cost that is often less than sequencing multiple single genes individually and is therefore more suitable for testing of diseases with many candidate genes, such as CI deficiency, CIV deficiency, LS, and other mitochondrial diseases (see Tables 10.3, 10.4, and 10.5). Multi-gene panels that sequence the majority of genes known to cause mitochondrial disease are the best testing approach at this time.

NGS is not optimal for detection of large deletions or duplications in the nuclear genome, and many laboratories rely on aCGH for clinical testing for these types of variants.

Interpretation of Results

Positive Result

A positive result indicates that a disease-causing mutation was identified that confirms the diagnosis of a particular type of mitochondrial disorder and provides valuable information to the physician and family members about treatment, prognosis, and recurrence risk. For mtDNA mutations, it is difficult to provide prognosis and recurrence risk for most of the patients because of the uncertainty of the degree of heteroplasmy by tissue type. For patients with disease-causing nuclear gene mutations, all first-degree relatives (e.g., children, siblings, and parents) can be offered predictive genetic testing with appropriate genetic counseling before and after the testing is performed. If a family member is found to be positive for the familial mutation(s), this individual is also at risk to develop the specific mitochondrial disorder or may be at risk to have children with the specific mitochondrial disorder. Of note for genetic counseling is the fact that mitochondrial diseases are highly variable in the symptoms, age of onset, severity, and response to therapeutic agents, even among members of the same family who have the same genetic mutation(s).

Negative Result

A negative result in an individual suspected of having a mitochondrial disorder does not rule out a genetically inherited mitochondrial disease. Possible reasons for a false-negative result are that the patient has a mutation in a gene not included in the testing panel, or located in a part of a mitochondrial disease gene not covered by the test. A true negative result is expected if the patient does not have a heritable type of mitochondrial disease. A negative result obtained by a specific genetic test for an individual with a definite mitochondrial disorder indicates that predictive testing of asymptomatic family members will not be informative and is not warranted. However, family members of a clinically affected individual with negative test results may still be at risk for mitochondrial disease and thus should be evaluated by a specialist in mitochondrial medicine, as indicated. If an asymptomatic individual is negative for a mutation identified in a family member with a definitive mitochondrial disorder, the result is considered a true negative. This indicates that the individual is not at increased genetic risk for the familial mitochondrial disorder and instead has the same risk as a person in the general population to develop a mitochondrial disorder. Specific clinical monitoring for the development of a mitochondrial disorder is not necessary in individuals with a true negative result.

Variant of Unknown Significance

One of the most difficult results to interpret is the finding of a variant of unknown clinical significance (VUS). This situation indicates that the pathogenic role of the variant cannot be clearly established. In some cases, testing of other family members may help clarify the clinical significance of a VUS. If other relatives with mitochondrial disease are found to have the same variant, it is more likely that the variant is disease causing. The greater the number of affected family members who carry the VUS, the greater is the likelihood that the VUS is pathogenic. Likewise, if an individual has an apparently sporadic mitochondrial disorder, the finding that a VUS is de novo (arose new in that individual and was not inherited from a parent) indicates that the variant is likely disease causing.

Test Sensitivity

Technical Sensitivity

As discussed above and in Table 10.6, for mtDNA point mutations, the lowest level of heteroplasmy of mutations detectable

by different methods varies from 0.1–1 % by real-time ARMS-qPCR [208] to 20–25 % by Sanger sequencing. For large-scale single deletions, both Southern blot analysis and aCGH can detect large-scale single deletions with heteroplasmy of approximately 15 % or higher [209]. Sanger sequencing can detect point mutations, small deletions, and small insertions in both mtDNA and nuclear genes.

Clinical Sensitivity

Depending on the method used and how many genes are tested, the clinical sensitivity of genetic testing for different diseases varies significantly. See Tables 10.2, 10.3, 10.4, and 10.5 for details.

Laboratory Issues

Many laboratories offer molecular genetic testing for mitochondrial disorders. Most laboratories offer common mtDNA mutation testing by using PCR-ASO, PCR-RFLP, real-time ARMS-qPCR, pyrosequencing, Sanger sequencing, or other methods. A patient with a disease-causing mutation with heteroplasmy of <5 % in the blood may have >50 % heteroplasmy in the muscle tissue or other tissues. More than 10 % of patients positive for the m.3243A>G mutation have a level of heteroplasmy less than 5 % in the blood specimen [212]. Since blood samples are still the most common sample sent for clinical molecular testing for mitochondrial disorders, it is important to use a technology that is able to detect low heteroplasmic mtDNA mutations. For NGS testing of large numbers of nuclear genes, some laboratories use PCR-based sequence enrichment, while other laboratories use capture (hybridization)-based enrichment. Compared to capture based-enrichment, PCR-based enrichment is more sensitive, easier to use, and is highly reproducible for targeted NGS testing [213]. Approximately 25 % of human genes in the genome have pseudogenes (www.pseudogene.org). PCR-based sequence enrichment selectively amplifies only the genes of interest, thus avoiding many pseudogene/homologous sequence problems inherent to hybridization-based sequence enrichment (target capture) methods that can cause both false-positive and false-negative results.

Metabolic Disorders

11

Lisa Edelmann, Yaping Yang, Amy C. Yang, and Ruth Kornreich

Abstract

Inborn errors of metabolism represent a highly diverse group of genetic disorders. Although individually the disorders are rare, collectively they are estimated to affect as many as 1 in 600 individuals. This chapter discusses the molecular mechanisms of disease and the available genetic testing for selected metabolic disorders. Mutations in many of the metabolic diseases are genetically heterogeneous and diagnoses are still widely dependent on biochemical testing. DNA testing is critical for confirmatory studies, genetic counseling, carrier and prenatal testing, and genotype-phenotype correlation, and is widely used for carrier screening for metabolic disorders in certain populations that have a high frequency of specific mutations due to founder effects. With increasing use of next-generation sequencing technologies in the clinical laboratory, DNA testing for confirmatory studies of all newborn screening positive results likely will be available in the near future.

Keywords

Inborn errors of metabolism • Molecular testing • Newborn screening • Phenylketonuria • Medium-chain acyl CoA dehydrogenase deficiency • Maple syrup urine disease • Ornithine transcarbamylase deficiency • Lysosomal storage disorders • Tay-Sachs disease • Gaucher disease • Galactosemia • Hereditary fructose intolerance • Glycogen storage diseases • von Gierke disease • Pompe disease • Cori disease • Andersen disease • Very-long-chain acyl-CoA dehydrogenase deficiency • X-linked adrenoleukodystrophy • Canavan disease

Introduction

Inborn errors of metabolism represent a highly diverse group of genetic disorders. Individually the disorders are rare. The most prevalent disorder, phenylketonuria (PKU), affects approximately 1 in 10,000 individuals. However, because numerous metabolic disorders exist, collectively they are estimated to affect as many as 1 in 600 individuals. The clinical consequences of such disorders are broad and can be severe, with progressive neurological impairment, intellectual disability (ID), organomegaly, and high morbidity. The mode of inheritance is usually autosomal recessive but also can be X-linked. Metabolic disorders result from defects in the individual enzymes of pathways that govern many different aspects of metabolism in distinct compartments within the cell.

The onset of disease is most often after birth with the appearance of an apparently normal infant, but in some classes of metabolic disorders, multiple congenital anomalies also exist. For most metabolic disorders, disease symptoms begin in early infancy or childhood, but in less severe cases, adolescent or adult onset may occur. Therefore, early recognition with prompt therapeutic intervention when possible is critical for reducing damage due to the metabolic defect. For those diseases that are prevalent and for which early detection and intervention would have a beneficial outcome, neonatal screening is performed in the USA and in several countries around the world. In the USA, each state and the District of Columbia determine the diseases for which newborns are screened and the methods used for screening. With respect to metabolic disorders, all states now screen for PKU, congenital hypothyroidism, galactosemia, maple syrup urine disease, (MSUD), homocystinuria, biotinidase deficiency, congenital adrenal hyperplasia, and tyrosinemia. Since the American College of Medical Genetics and Genomics (ACMG) Newborn Screening Expert Group's recommendation in 2006, tandem mass spectrometry has been added to newborn screening programs in all states and can detect more than 20 metabolic disorders, including medium-chain acyl CoA dehydrogenase (MCAD) deficiency. DNA testing is currently used as a follow-up to an initial positive screen for certain disorders, such as MCAD deficiency and PKU.

This chapter discusses the molecular mechanisms of disease and the available genetic testing for selected metabolic disorders. The choice of disorders reflects population prevalence and current availability of molecular testing, as the mutations in many of the metabolic diseases are genetically heterogeneous and diagnoses are still widely dependent on biochemical testing. DNA testing often is critical for confirmatory studies, genetic counseling, carrier and prenatal testing, and genotype-phenotype correlation, and is widely used for carrier screening for metabolic disorders in certain populations that have a high frequency of specific mutations due to founder effects. With increasing use of next-generation sequencing technologies in the clinical laboratory, DNA testing for confirmatory studies of all newborn screening positive results likely will be available in the near future.

Amino Acidopathies

Amino acids derived from protein sources within the diet are metabolized via specific pathways. Enzyme deficiencies within these pathways lead to distinct clinical manifestations of amino acidopathies, such as PKU and MSUD.

Phenylketonuria

Molecular Basis of the Disease

PKU is an autosomal recessive disorder caused by the inability of the body to convert phenylalanine to tyrosine. PKU is the most common metabolic disease in Caucasians, with an incidence of 1 in 10,000 individuals. About 98 % of PKU cases are caused by defects in the phenylalanine hydroxylase (*PAH*) gene, which encodes the rate-limiting enzyme of the pathway. The other 2 % are caused by defects in the biosynthesis or regeneration of the cofactor of PAH, 6(R)-L-ERYTHRO-TETRAHYDROBIOPTERIN (BH4). Accumulation of phenylalanine can damage the development of the central nervous system and result in ID. PKU has a spectrum of phenotypes ranging from classic PKU, which is the most severe type with the least tolerance to dietary phenylalanine, to moderate PKU, mild PKU, and mild hyperphenylalaninemia (MHP). Patients with MHP have no clinical symptoms and do not require dietary treatment.

PKU is included in newborn screening programs in all 50 states and is a classic example of a genetic disease that meets the criteria for newborn screening: relatively high occurrence, availability of fast and economical screening methods, and therapeutic options. With early diagnosis and intervention, including a low-phenylalanine diet, the major disease phenotypes of ID and growth retardation can be prevented.

The *PAH* gene is located on 12q23.2 and spans a genomic region of 90 kilobases (kb). The coding region is about 4 kb with 13 exons. More than 600 mutations in *PAH* have been reported to date, of which approximately 81 % are point mutations, 14 % are small deletions or insertions and the remaining 5 % are gross deletions or duplications affecting one or multiple exons or even the entire gene (HGMD® Professional 2011.4) [1]. While the majority of the mutations are private mutations, seven of the most prevalent European mutations, p.R408W (31 %), c.1315+1G→A (11 %), c.1066-11G→A (6 %), p.I65T (5 %), p.Y414C (5 %), p.R261Q (4 %), and p.F39L (2 %), account for approximately two-thirds of all mutations [2].

Clinical Utility of Testing

Molecular testing for PKU serves several purposes, including assisting prognosis, confirmation of clinical and newborn screening results, carrier testing, prenatal diagnosis, and information for genetic counseling.

Available Assays

Several methods are currently used for the molecular detection of mutations in *PAH* associated with PKU. These methods include the following:

- Testing of a panel of common mutations detects up to 50 % of mutations, depending on the number of mutations included as well as the ethnic backgrounds of the patients.

- Denaturing high-performance liquid chromatography (DHPLC) detects approximately 96 % of mutations with scanning of the entire coding region of *PAH* [3]. However, the claimed detection rate is based on limited numbers of variants and does not necessarily reflect the real detection rate for each exonic position in the gene.
- Sanger sequencing, which is considered the gold standard for detecting small nucleotide changes, is utilized much more widely than DHPLC in clinical testing of the *PAH* gene. With high sensitivity and lower cost, Sanger sequencing should be the method of choice for mutation screening of the entire code region of the gene.
- Gross deletions and duplications, which usually cannot be detected by Sanger sequencing, have been reported in the *PAH* gene (HGMD® Professional 2011.4) [1]. The most commonly used methods to detect these types of mutations are array-based comparative genomic hybridization (aCGH), multiplex ligation-dependent probe amplification (MLPA), and quantitative PCR (qPCR). Finally, when molecular analysis fails to detect one or both mutant alleles, linkage studies using polymorphic markers within or very closely linked to the *PAH* gene may be considered.

Interpretation of Test Results

The variant interpretation guidelines from ACMG [4] should be followed, and include assessment of the evidence from in vitro studies, familial segregation data, or population data before a missense variant is classified as deleterious. Genotype may not be a good predictor of phenotype since environmental factors and/or modifier genes also can play a role in the clinical manifestations of the disease. For patients with mild mutations in the BH4 cofactor-binding region (p.V190A, p.R241C, p.A300S, p.A313T, p.E390G, p.A403V, and p.P407S), overloading with BH4 may increase PAH activity and may be used as an alternative to dietary restriction [5].

Maple Syrup Urine Disease

Molecular Basis of the Disease

MSUD is an autosomal recessive disorder characterized by a maple syrup odor in the urine and cerumen, and elevated branched-chain amino acids (leucine, valine, isoleucine, allo-isoleucine) in the blood. MSUD is caused by a deficiency of the branched-chain alpha-ketoacid dehydrogenase (BCKAD) complex. While it is relatively rare in the general population with an incidence of about 1 in 185,000 live births, due to founder effects, select populations such as the Ashkenazi Jewish and the Amish-Mennonites have a much higher incidence (1 in 26,000 and 1 in 380, respectively).

The BCKAD complex is comprised of four subunits; E1a, E1b, E2, and E3. Mutations in E1a (*BCKDHA*), E1b (*BKDHB*), or E2 (*DBT*) that give rise to MSUD are biochemically identical. Because the subunit E3 (*DLD*) also is shared with the pyruvate dehydrogenase and alpha-ketoglutarate complexes, a pathological defect in E3 also will cause lactic and/or metabolic acidosis, abnormal urine organic acids, and Leigh syndrome-like neuropathology, which are features not typically seen in MSUD. E3 deficiency also is called lipoamide dehydrogenase (LAD) deficiency and occurs at a higher frequency in the Ashkenazi Jewish population with two founder mutations.

Based on residual enzyme activity, an affected individual can be phenotypically classified as having classic, intermediate, or intermittent MSUD. Classic MSUD usually presents neonatally with poor feeding, lethargy, dystonia, and seizures. Intermediate types usually present with milder symptoms and later onset with developmental delays or ID. Intermittent types can have normal early development with acute, episodic mental status changes and/or psychosis during times of illness or stress. The treatment goal of protein and branched-chain restrictive diets is to maintain leucine, valine, and isoleucine at a therapeutic level and thus prevent neurotoxic effects from elevated metabolites. Liver transplantation is now a curative treatment for MSUD, with effective normalization of the branched-chain amino acid levels without dietary therapy. MSUD is included in newborn screening programs in all 50 states.

Table 11.1 shows the four genes implicated in MSUD, the protein involved, and notable pathological alleles. The p.T438N mutation on E1a has a carrier frequency of about 1 in 10 in the Amish-Mennonite population. The three common mutations on E1b found in the Ashkenazi Jewish population (p.R183P, p.G278S, and p.Q372X) have a combined carrier frequency of approximately 1 in 80 [6]. A pathological allele for LAD deficiency (p.G229C) has a carrier frequency of 1 in 94 in Ashkenazi Jews [7]. Excluding those with LAD deficiency, 45 % of patients have mutations in the *BCKDHA* gene, 35 % in the *BCKDHB* gene, and 20 % in the *DBT* gene [8].

Clinical Utility of Testing

Molecular testing for MSUD confirms clinical and newborn screening results. Carrier screening for the Mennonite and Ashkenazi Jewish populations is available and allows for preconceptual and prenatal genetic counseling and for immediate treatment of an affected infant after birth.

Available Assays

Targeted mutation analysis of the common alleles via multiplex PCR is a cost-effective and quick method for the Mennonite and Ashkenazi Jewish populations, with a mutation detection rate of over 98 % for *BCKDHA* and

Table 11.1 Genes, protein subunit, and founder alleles associated with MSUD

Gene	MSUD type	Locus	Size	Protein subunit	Exons	Founder mutations
BCKDHA	Ia	19q13	28 kb	E1a	9	p.T438N
BCKDHB	Ib	6q14	240 kb	E1b	11	p.R183P, p.G278S, p.Q372X
DBT	II	1p31	56 kb	E2	11	
DLD	III (aka. LAD deficiency)	7q31	30 kb	E3	14	p.G229C

BCKDHB, respectively [8]. For the general population, exon sequencing and deletion analysis of *BCKDHA*, *BCKDHB*, and *DBT*, and *DLD* are available.

Interpretation of Test Results

Mutations in *BCKDHA*, *BCKDHB*, and *DBT* do not have clear phenotype correlations, and treatment modality is essentially the same, regardless of the degree of biochemical phenotype. In a small study of 13 Ashkenazi Jewish families affected with LAD deficiency, homozygosity for the p.G229C allele appeared to be associated with a milder and later-onset disease, with no neurological manifestations [7].

Urea Cycle Disorders (Ornithine Transcarbamylase Deficiency)

Molecular Basis of the Disease

Defects in the urea cycle constitute a rare group of disorders resulting in the accumulation of urea precursors, mainly ammonium and glutamine. Ornithine transcarbamylase (OTC) deficiency, the most common inborn error of ureagenesis, is an X-linked disorder. Affected hemizygous males typically present in the neonatal period or later in childhood, with symptoms that include vomiting, lethargy, hypothermia, and apnea due to hyperammonemia, leading to coma or death. Recurrent episodes of metabolic crisis can result in ID. The only available treatment after an acute metabolic episode is liver transplantation, which should be performed as early as possible to prevent brain damage. In 15–20 % of carrier females, symptoms are evident. Symptomatic carrier females typically have a later onset but the disease can be fatal, presumably due to an unfavorable pattern of X-inactivation in the liver [9].

OTC is a homotrimeric mitochondrial matrix enzyme that catalyzes the synthesis of citrulline from ornithine and carbamyl phosphate, and is found almost exclusively in the liver and intestinal mucosa. Loss of OTC activity results in high plasma glutamine and ammonium, low plasma citrulline, and an excess of orotic acid in the urine, a combined metabolic profile that is diagnostic for OTC deficiency. However, a direct assay of OTC activity performed on tissue isolated from a liver biopsy specimen may be necessary to obtain unequivocal biochemical results.

The *OTC* gene is located on Xp21 and spans a region of 73 kb that contains ten exons and encodes a protein of 354 amino acids. The overall prevalence of the disease is estimated at 1 in 50,000 in the USA, with similar statistics reported in Japan. Mutations have been identified in all ten exons; however, disease-causing mutations are less frequent in exons 1 and 7, the least conserved exons, most likely reflecting their lesser relevance to the function of the enzyme [10].

Clinical Utility of Testing

Diagnosis of OTC deficiency by molecular testing is preferable to the more invasive liver biopsy that is necessary for the enzymatic test. Molecular screening for *OTC* mutations identifies approximately 80 % of mutations, while the remaining undetected mutations are expected to affect promoter function or splicing [11]. The *OTC* gene has an approximately 50:1 sperm-to-egg mutation rate ratio [9]. From 66–93 % of male probands inherit the mutation from their mothers, while only 20 % of manifesting females inherit the mutation, taking into account differences in new mutation rates between sperm and eggs, and lyonization effects for a female to manifest symptoms. Thus, a woman who has a son with OTC deficiency has a much higher chance of harboring the mutation than a woman who has an affected daughter. Due to the inheritability and the severity of the disease with the limited treatment available, molecular screening of at-risk couples for the purpose of prenatal testing may be beneficial. Additionally, mutation identification may be of prognostic value in OTC deficiency (see "Interpretation of Test Results" below).

Available Assays

Molecular testing using bidirectional sequencing of the entire coding region and intron-exon boundaries of the *OTC* gene is available in a number of clinical molecular laboratories. In addition, MLPA is used to detect large *OTC* coding region deletions/duplications. High-resolution aCGH can be used to detect exonic deletions/duplications or larger rearrangements that include the *OTC* gene as part of a contiguous gene deletion syndrome [12]. Approximately 300

mutations have been reported (http://www.cnmcresearch.org/OTC/). Most mutations (86 %) in the *OTC* gene are point mutations, with G to A transitions accounting for 34 % and C to T transitions accounting for 21 % of the total. Approximately one-third of all point mutations are at CpG dinucleotides, and 15 % are at splice junctions. Although the CpG sites are recurrent mutation sites, none accounts for more than 4 % of the total single-base substitutions.

Interpretation of Test Results

In general, the genotypic spectrum correlates with the severity of the phenotype, and mutations that result in complete loss of function or amino acid changes near the active site of the protein result in neonatal onset of disease. In contrast, amino acid changes that are not close to the active site and result in protein with residual enzymatic activity are associated with later onset and a milder disease course [12].

Lysosomal Storage Disorders

Lysosomal storage disorders are a group of diverse inherited metabolic diseases that result from the disruption of the lysosomal system and catabolism of macromolecules (for review, see Ref. 13). Mutations in genes encoding hydrolyzing enzymes, activator proteins, lysosomal membrane proteins, or proteins involved in the posttranslational modification or transport of lysosomal proteins can cause such storage disorders. More than 40 lysosomal storage disorders are known, and they have a collective incidence of approximately 1 in 5,000–8,000 live births in the USA. Most of the genes responsible for lysosomal storage disorders have been cloned, permitting molecular testing once a diagnosis is established by biochemical analyses. This information is valuable for genotype-phenotype correlation, selection of therapy, and genetic counseling. In this section, two lysosomal storage disorders are discussed: Tay-Sachs disease (TSD), which serves as a model for population screening, and Gaucher disease (GD), for which much effort has been concentrated on genotype-phenotype correlations.

Tay-Sachs Disease

Molecular Basis of the Disease

TSD is a neurodegenerative disorder resulting from deficiency of the lysosomal enzyme hexosaminidase A (HEX A), resulting in accumulation of the cell membrane glycolipid G_{M2} ganglioside within lysosomes (for review, see Refs. 14, 15). The clinical course of TSD is characterized by normal development for the first few months of life followed by progressive loss of motor skills, macrocephaly, seizures, blindness, and death usually before 4 years of age. Infantile TSD always is fatal and there is no effective treatment. Later-onset forms of TSD have slower disease progression. TSD is an autosomal recessive disease and has a carrier frequency of approximately 1 in 30 among Ashkenazi Jewish individuals and 1 in 250–300 in most other populations. Genetically isolated populations such as the French Canadians of Quebec, Cajuns from Louisiana, and the Amish in Pennsylvania also have carrier frequencies similar to the Ashkenazi Jews. The first carrier screening programs began in 1970 and used the measurement of HEX A activity in serum, leukocytes, or tears. When the *HEXA* gene encoding HEX A was cloned in 1987, disease-associated mutations were identified. Current testing for TSD utilizes both biochemical and molecular testing by various methods.

Clinical Utility of Testing

Carrier screening for TSD, which began in the 1970s and was later endorsed by the American College of Obstetricians and Gynecologists (ACOG) and the ACMG, has been a model for population screening programs. As a result, there has been a 90 % reduction in the incidence of TSD in the North American Ashkenazi Jewish population, such that the incidence of TSD is now three- to fourfold higher in non-Jews by comparison.

Available Assays

Clinical laboratories use several strategies to incorporate mutation testing into their screening programs. Some laboratories initially screen by enzyme analysis followed by molecular testing for individuals with a result in the carrier or inconclusive ranges. Other laboratories use molecular testing alone for selected populations. Molecular tests are performed using a variety of methods, including PCR amplification followed by allele-specific primer extension analysis, allele-specific oligonucleotide (ASO) hybridization or restriction enzyme digestion, allele-specific amplification, TaqMan probe technologies, or ligation chain reaction amplification. In Ashkenazi Jewish individuals, two common mutations in *HEXA* are associated with infantile TSD and one associated with an adult-onset form of the disease. A four-base pair insertion (c.1274_1277dupTATC) in exon 11 accounts for approximately 80 % of mutant alleles in the Ashkenazi Jewish population, and a splice defect in intron 12 (c.1421+1G>A; IVS12) accounts for another 15 %. A missense mutation, p.G269S, leads to an adult-onset form of TSD and accounts for approximately 2 % of carriers.

Interpretation of Test Results

A pseudodeficiency allele, p.R247W, is present in approximately 2 % of Ashkenazi Jewish individuals who are carriers by the enzymatic assay. The p.R247W variant

decreases the activity of HEX A for the artificial substrate used in the laboratory but does not cause TSD since it does not affect HEX A activity for its natural substrate, GM2 ganglioside. About 36 % of non-Jewish individuals who are carriers by enzyme analysis have a pseudodeficiency allele (32 % p.R247W and 4 % p.R249W). In addition, screening for the three common Ashkenazi Jewish mutations and an additional mutation (c.1073+1G>A; IVS9) will identify approximately 95 % of Ashkenazi Jewish carriers, but only 40–50 % of disease-causing alleles in the non-Ashkenazi Jewish populations. Other populations who are at high risk, such as the French Canadians, Cajuns, and Pennsylvania Dutch, have their own common alleles. Therefore, the mutations included for population screening must target the specific mutations of the ethnic background of the individuals being tested.

Gaucher Disease

Molecular Basis of the Disease

GD is another prevalent autosomal recessive lysosomal storage disorder that is found with higher incidence in the Ashkenazi Jewish population. The carrier frequency is 1 in 15 in the Ashkenazi Jewish population and 1 in 100 in other populations [16] (for comprehensive review on GD, see Ref. 17). A defect in the enzyme glucocerebrosidase leads to the accumulation of glucocerebrosides in lysosomal compartments in macrophage/monocyte-derived cells, particularly in the liver, bone marrow, spleen, and lung. Several forms of GD exist. Type 1 GD has a wide range of clinical presentations, from asymptomatic to symptoms including bone disease, hepatosplenomegaly, anemia, and thrombocytopenia, but without primary central nervous system involvement. Types 2 and 3 have primary central nervous system involvement that varies by age of onset and rate of disease progression. Type 2 GD patients usually have an earlier age of onset than type 3 patients, with acute disease progression and death by approximately 2 years of age. Type 3 patients have onset in early childhood to adolescence and survive into their first to fourth decade of life. A perinatal-lethal form of GD also can occur, as well as a cardiovascular form characterized by aortic and mitral valve calcification, ophthalmologic abnormalities, and hydrocephalus.

The glucocerebrosidase gene (*GBA*) and its transcribed pseudogene (ψ*GBA*) are located on chromosome 1q21. Approximately 200 mutations causing GD have been identified. Many of the mutations are most likely due to gene conversion events with the pseudogene.

Clinical Utility of Testing

The demonstration of deficient glucocerebrosidase activity in leukocytes establishes a diagnosis of GD but is unreliable for carrier detection. Therefore, molecular testing is useful for carrier identification, prenatal testing, and genetic counseling.

Available Assays

Four mutations (p.N409S, c.115+1G>A, c.84dupG, p.L483P) are responsible for approximately 95 % of disease-causing alleles in Ashkenazi Jewish individuals and 50 % of disease-causing alleles in non-Ashkenazi Jewish individuals [16]. Most clinical molecular laboratories performing GD molecular testing assess at least these four mutations. Several factors must be considered when designing molecular testing for GD. Primers must be selected that avoid amplification of the pseudogene which is located 16 kb downstream and is approximately 96 % identical to the functional gene. Recombinant alleles, which are thought to result from unequal crossovers between exons 9 and 10 of the functional gene and pseudogene, contain two or more point mutations, including p.L483P. If p.L483P alone is tested, misdesignation of the genotype may occur. This may be important, as the recombinant allele is typically associated with a more severe genotype. Mistyping also is possible when a 55 base pair (bp) deletion in exon 9 (c.1263_1317del), is present in combination with the common p.N409S allele. Homozygosity of p.N409S would be observed even though the true genotype is p.N409S/55 bp deletion. Therefore, the 55 bp deletion should be analyzed in patients who are found to be homozygous for p.N409S.

Interpretation of Test Results

Genotype-phenotype correlations have been widely investigated in GD [18]. While overlaps occur, some generalizations can be made. The presence of a p.N409S allele is predictive of type 1 disease. Individuals with p.L483P in the presence of a null allele will usually have type 2 GD, while homozygosity for p.L483P typically results in type 3 GD. Homozygosity for the p.D448H allele has been associated with the rarer cardiovascular form of GD.

Disorders of Carbohydrate Metabolism

Galactosemia, fructosemia, and the glycogen storage diseases are discussed in this section, which addresses disorders of carbohydrate metabolism.

Galactosemia

Molecular Basis of the Disease

Galactosemia is an autosomal recessive disorder caused by deficient or absent activity of one of three enzymes involved in the metabolic pathway to convert galactose to glucose: galactokinase (GALK), galactose-1-phosphate uridyl transferase (GALT), and UDP-galactose 4′-epimerase (GALE). Classic

galactosemia is due to a severe reduction or absence of the GALT enzyme, and has an incidence of 1 in 40,000–60,000 in European newborns (for review, see Ref. 19).

The symptoms of classic galactosemia in neonates include poor feeding, vomiting, failure to thrive, lethargy, jaundice, occasionally diarrhea, and *E. coli* sepsis. The symptoms in an affected newborn can be obviated if a lactose-free diet is initiated within the first 2 weeks of life. Newborn screening for galactosemia is included in all 50 states. Newborns with a positive screen are followed up with immediate dietary treatment and confirmatory biochemical analysis.

The *GALT* gene is located at 9q13, is about 4 kb in length, and consists of 11 exons. More than 150 mutations in the *GALT* gene have been reported, most of which are private mutations [20]. The p.Q188R mutation is the most frequent mutation associated with classic galactosemia in many populations, and accounts for 64 % of disease alleles in Europeans, 60–70 % in Americans, and 50–58 % in Mexican Hispanics [20, 21]. Ethnic-specific mutations include p.K285N, p.S135L, c.253-2A>G, and a 5 kb deletion in Caucasian, African-American, Hispanic, and Jewish patients, respectively.

Clinical Utility of Testing

Molecular testing is used for confirmation of diagnosis, carrier detection, prenatal diagnosis, prognosis, and genetic counseling. Because the detection rate of molecular testing is less than 100 % and biochemical testing is highly accurate, mutation detection is carried out in parallel with biochemical analysis.

Prenatal diagnosis for galactosemia can provide the opportunity for immediate dietary restriction of the newborn. Although galactosemia is considered "treatable," symptoms such as ID, growth delays, speech dyspraxia, abnormal motor function, and premature ovarian failure in women may still occur even with early intervention and lifetime dietary restrictions. These long-term phenotypes often are associated with specific mutations; for example, p.Q188R can cause premature ovarian failure and speech dyspraxia. Genetic counseling is very important for parents of affected fetuses before a choice regarding pregnancy outcome is made.

Available Assays

Initial molecular testing for the diagnosis of galactosemia focuses on the most prevalent mutations or the p.N314D mutation associated with Duarte galactosemia (Duarte-2) by quick and cost-effective methods, such as multiplex PCR followed by restriction enzyme digestion [22]. If only one mutation or no mutations are found, screening of all 11 exons and exon-intron boundaries by DNA sequencing can be performed [22]. A detection rate of 96 % can be achieved by a combination of testing for prevalent mutations and DNA sequencing [23]. Gross deletions and duplications are detected by aCGH or MLPA.

Interpretation of Test Results

Genotype-phenotype associations have been established for some mutations [20]. For example, p.Q188R, p.K285N, and p.L196P alleles have undetectable GALT activity and are associated with severe phenotypes, whereas p.S135L and p.T138M are less severe and are usually associated with a good prognosis. In addition to the classic form of galactosemia, which has less than 5 % of the normal GALT activity, the Duarte-2 variant associated with the p.N314D variant has 50 % of the normal GALT activity. The p.N314D allele is in linkage disequilibrium with four polymorphisms, c.329-27G>C, c.378-24G>A, c.507+62G>A, and c.-119_-116delGTCA. The symptoms of Duarte-2 patients are mild compared to the classic type, but Duarte-2 still results in long-term phenotypes such as ID and growth delays, speech dyspraxia, abnormal motor function, and premature ovarian failure in women.

Hereditary Fructose Intolerance

Molecular Basis of the Disease

Hereditary fructose intolerance (HFI) is an autosomal recessive disorder caused by deficient or absent activity of aldolase B. The aldolases are a group of tetrameric enzymes that are highly conserved and involved in the cleavage of fructose-1,6-biphosphate. Aldolase B also cleaves fructose-1-phosphate, and thus is a key player in fructose metabolism, as well as in gluconeogenesis and glycogenolysis. Aldolase A is found predominantly in muscles, whereas aldolase B is found predominantly in the liver, kidney, and intestine, and aldolase C is predominantly in the brain. Severe reduction or absence of only the aldolase B enzyme causes HFI, and has an incidence of 1 in 20,000–30,000 in European newborns (for review, see Ref. 24).

Typically in HFI, symptoms do not arise until an infant is exposed to fructose, sucrose, or sorbitol-containing foods, usually at the weaning of breast milk and introduction of table foods. Acute ingestion of the offending sugar can result in a variable presentation of abdominal pain, vomiting, progressive liver dysfunction, hypoglycemia, uric and lactic acidosis, and renal tubulopathy, depending on the dose of the sugar ingested, and timing and length of exposure. Chronic, low-dose ingestion of fructose-containing foods can cause a subacute picture of hepatomegaly and failure to thrive. Affected individuals typically have an aversion to sweets. The acute and chronic symptoms are, for the most part, reversible, if a fructose-free diet is initiated. Once on treatment, the prognosis is good with a normal life expectancy.

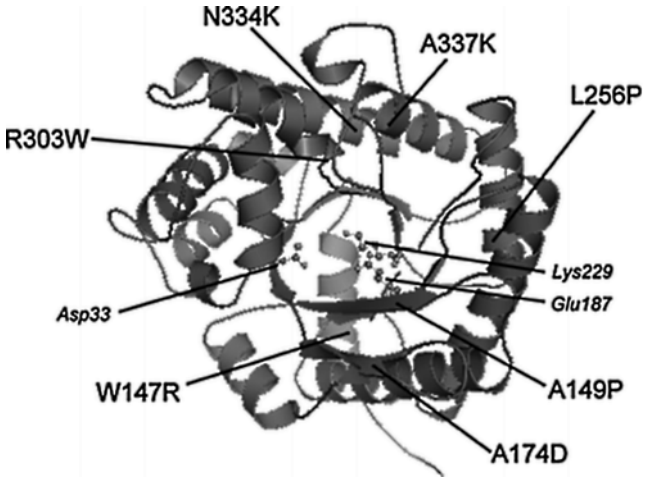

Figure 11.1 Location of some naturally occurring aldolase B mutations, shown on the crystal structure of human aldolase B (based on Protein Data Bank [PDB] structure file 1QO5, chain A) [26]. Only one monomer is shown for clarity. Active site residues are shown in a *ball and stick* representation and labeled in *italics*. Reprinted from Bouteldja N, Timson DJ. The biochemical basis of hereditary fructose intolerance. J Inherit Metab Dis 2010;33(2):105–12 [24], by permission of Springer

The *ALDOB* gene is located at 9q22.3, is about 14 kb in length, and consists of nine exons, eight of which are translated. More than 40 mutations have been identified (http://www.bu.edu/aldolase/HFI/hfidb/hfidb.html). The most common allele, p.A149P, accounts for 50–65 % of all mutations in the European population, and together with two other common mutations, p.A174D and p.N334K, account for more than 80 % of mutant alleles in the European population [25]. Most of the missense mutations are located in exons 5 and 9. Studies show that the p.A149P decreases the thermal stability of the enzyme. Figure 11.1 illustrates the locations of the most common variants in the aldolase B protein structure.

Clinical Utility of Testing

Molecular testing is used for confirmation of diagnosis, carrier detection, prenatal diagnosis, and genetic counseling. Enzymatic testing of aldolase B activity can only be performed from liver, kidney, or intestinal tissue. Thus, molecular testing is now the preferred method. Prenatal diagnosis for HFI can provide the opportunity for early dietary restriction and prevention of acute symptoms and liver disease.

Available Assays

Targeted mutation analysis of the common alleles using multiplex PCR is a cost effective and rapid method for the European population [27]. If only one mutation or no mutations are found, DNA sequencing of the entire coding region and exon-intron boundaries should be performed. For those not of European descent, DNA sequencing should be performed as a first-line method.

Interpretation of Test Results

Genotype-phenotype correlations are not clear. HPI patients with the same genotype have varied presentations and reactions to ingestion of fructose.

Glycogen Storage Diseases

Molecular Basis of the Disease

Glycogen storage diseases (GSD) are a group of heterogeneous genetic disorders characterized by the accumulation of glycogen in tissues and have an overall incidence of 1 in 20,000–25,000 live births [28]. Fourteen types of GSD that vary significantly in clinical phenotypes, age of onset, and affected organs have been identified (www.omim.org). They are caused by defects in one of 18 genes in glycogen metabolism. A summary of the 14 GSD types is presented in Table 11.2. The most common and severe types, GSD I, II, III, and IV, are discussed below.

GSD I (von Gierke disease) is characterized by hepatomegaly, kidney enlargement, growth retardation, hypoglycemia, hyperuricemia, and hyperlipidemia. GSD I has two major subgroups, GSD1a and GSD1b. The subgroup GSD1a has a deficiency of glucose-6-phosphatase (G6Pase), which converts glucose-6-phosphate to glucose and phosphate, the last step in glycogenolysis. The *G6PC* gene encoding G6Pase is located on 17q21. The subgroup GSD1b has a deficiency in glucose-6-phosphate translocase, encoded by *SLC37A4* gene located on 11q23. Common mutations vary in different ethnic groups [20]. The prevalent mutations for GSD1a in different ethnic groups are: p.R83C and p.Q347X in Caucasians; p.R83C in Ashkenazi Jews; c.459insTA and p.R83C in Hispanics; p.V166G in Muslim Arabs; p.R83H and p.G727T in Chinese; and p.G727T in Japanese. For GSD1b, two common mutations, p.G339C and c.1211delCT, are present in whites, while p.W118R is prevalent in Japanese.

GSD II, also known as Pompe disease, is a lysosomal storage disease caused by the inability to degrade glycogen due to defects in acid α-1,4-glucosidase. The phenotypes range from the most severe infantile disorder to juvenile- and late-onset adult myopathy. Patients with the infantile form usually die from cardiomyopathy before 2 years of age. Acid α-1,4-glucosidase is encoded by the gene *GAA* located at 17q25, and different forms of the protein are obtained by different proteolytic processing. Common mutations have been identified in different ethnic groups.

Patients affected with GSD III, also known as Cori disease, have symptoms similar to but milder than those associated with GSD I. GSD III is caused by mutations in the

Table 11.2 Glycogen storage disease types and subgroups

Disorder(s)	Defective enzymes	Gene symbol	Gene location	Inheritance pattern
GSD I (von Gierke disease)	GSD1a: Glucose-6-phosphatase, catalytic	*G6PC*	17q21.31	AR
	GSD1b: Solute carrier family 37 (glycerol-6-phosphate transporter), member 4	*SLC37A4*	11q23.3	AR
GSD II (Pompe disease)	Glucosidase, alpha acid	*GAA*	17q25.3	AR
GSD III (Cori disease)	Amylo-1,6-glucosidase, 4-alpha-glucanotransferase	*AGL*	1p21.2	AR
GSD IV (Andersen disease)	Glucan (1,4-alpha-) branching enzyme	*GBE1*	3p12.2	AR
GSD V (McArdle disease)	Phosphorylase, glycogen (muscle)	*PYGM*	11q13.1	AR
GSD VI (Hers disease)	Phosphorylase, glycogen (liver)	*PYGL*	14q22.1	AR
GSD VII	Phosphofructokinase, muscle	*PFKM*	12q13.11	AR
GSD IX (GSD VIII)	Phosphorylase kinase alpha 1 (muscle)	*PHKA1*	Xq13	XR
	Phosphorylase kinase alpha 2 (liver)	*PHKA2*	Xp22.13	XR
	Phosphorylase kinase, beta subunit	*PHKB*	16q12.1	AR
	Phosphorylase kinase, testis/liver, gamma 2	*PHKG2*	16p11.2	AR
GSD X	Phosphoglycerate mutase 2, muscle	*PGAM2*	7p13	AR
GSD XI	Lactate dehydrogenase A	*LDHA*	11p15.1	AR
GSD XII	Aldolase A	*ALDOA*	16P11.2	AR
GSD XIII	Enolase 3 (beta, muscle)	*ENO3*	17p13.2	AR
GSD XIV	Phosphoglucomutase 1	*PGM1*	1p31.3	AR

amylo-1-6-glucosidase (*AGL*) gene. GSD IV, also known as Andersen disease, is caused by deficiencies of the glycogen-branching enzyme encoded by the *GBE1* gene, resulting in abnormal and insoluble glycogen. Intracellular glycogen accumulations occur in the liver, brain, heart, skeletal muscles, and skin fibroblasts. Neonates with GSD IV appear normal at birth but develop hepatomegaly and failure to thrive in the first year of life. Patients develop progressive cirrhosis and usually die of liver failure by 2–5 years of age.

Clinical Utility of Testing

Due to the complex nature of molecular testing for GSD (large genes with numerous mutations), enzyme assays are usually used for the diagnosis of GSD. However, for prenatal diagnosis of GSD I, gene-based mutation testing or linkage analysis is the preferred method, since the enzymes are not present in amniocytes or chorionic villi, requiring a liver biopsy to obtain tissue containing the relevant enzyme. For prenatal diagnosis of other types of GSD, DNA testing can be used to complement and confirm biochemical results. Therapy for GSD I, II, III, and IV includes dietary management, and for GSD II, enzyme replacement is available (for complete review on treatment for GSD, see Refs. 28, 29).

Available Assays

Sanger sequencing tests are available clinically for all the GSD genes.

Fatty Acid Oxidation Disorders

During periods of fasting or prolonged aerobic exercise when glycogen stores are depleted, fatty acids become a main energy source by β-oxidation in the liver, and skeletal and cardiac muscles, via synthesis of acetyl-CoA and ketone bodies. The pathway for fatty acid oxidation occurs in the mitochondria and is complex, involving many steps. A number of disorders involving different enzymes in the pathway have been identified. Although the symptoms of the disorders have phenotypic overlap, several biochemical measurements can aid in the diagnosis of these disorders, including plasma carnitine levels which are usually low, plasma acylcarnitines, and urine acylglycines (for review, see Ref. 30). The most common of these disorders is medium-chain acyl-CoA dehydrogenase (MCAD) deficiency. Since the addition of the acylcarnitine profile to newborn screening, the prevalence for very-long-chain acyl-CoA

dehydrogenase (VLCAD) deficiency is thought to be more common, and a new role for clinical molecular testing for VLCAD is emerging. At present, all 50 states within the USA employ tandem mass spectrometry in their newborn screening program, which allows detection of the abnormal plasma acylcarnitine profile characteristic of MCAD and VLCAD deficiencies.

Medium-Chain Acyl-CoA Dehydrogenase Deficiency

Molecular Basis of the Disease

MCAD is an intramitochondrial enzyme that is encoded by a nuclear gene. The normal function of MCAD is the initial dehydrogenation of acyl-CoAs with chain lengths of 4–12 carbons. Defective function leads to the accumulation of metabolites of the medium-chain fatty acids, mainly the dicarboxylic acids, acylglycine in urine, and acylcarnitine in plasma. These metabolites are at their highest concentration in the blood in the first few days of life, making the newborn period the ideal time for detection. Accordingly, the specificity of the newborn screening test is 100 %, as no false negatives have been reported. MCAD enzymatic activity also can be assayed in several different tissue types.

Because fatty acid oxidation fuels hepatic ketogenesis, the symptoms of MCAD deficiency appear after periods of prolonged fasting or intercurrent infections and include hypoketotic hypoglycemia, lethargy, seizures, coma, and, without treatment, death. Complications of the disease can include hepatomegaly, acute liver disease, and brain damage. The disease typically presents before 2 years of age but after the newborn period. However, individuals have been described who present with symptoms within the first few days of life as well as those who present as adults.

MCAD deficiency is an autosomal recessive disorder that is prevalent in individuals of northwestern European ancestry, with the highest overall frequency of 1 in 4,900 in northern Germany. The incidence in the USA is somewhat lower and is estimated to be 1 in 15,700. The MCAD gene, *ACADM,* spans a 44 kb region on chromosome 1p31 and contains 12 exons encoding a protein of 421 amino acids. A single founder mutation in exon 11, 985A>G, which results in the substitution of the acidic amino acid, glutamate, for the basic amino acid, lysine (p.K304E), represents 90 % of all alleles in the northern European population. However, recent studies of the US population, attributable to the expansion of newborn screening for MCAD deficiency, indicate that this mutation accounts for 79 % of the total mutant alleles in the US population (Table 11.3) [31]. The discrepancy between the two results is presumably due to the greater ethnic diversity of the US population.

Table 11.3 Genotypes of 57 MCAD-deficient newborns detected

Using MS/MS to screen more than 1.1 million newborns (Neo Gen Screening, Pittsburgh, PA, USA)	
Mutation position and type	**Number of patients identified**
c. 985 A→G/985 A→G	35
c. 985 A→G/199T→C (exon 3)	8

c. 489T→G (exon 7)	
IVS 5+1G→A	
IVS 8+6G→T	

Clinical Utility of Testing

Molecular testing for *ACADM* mutations usually is offered as confirmatory testing after the initial diagnosis of MCAD deficiency by biochemical testing. In addition, carrier testing for MCAD deficiency cannot be performed using biochemical metabolite profiles and must be done by molecular testing or by direct assay of MCAD activity in cultured fibroblasts.

MCAD deficiency is a disease that can be treated if promptly diagnosed in the early postnatal period. Precautions, such as avoidance of fasting and saturated fats and ingestion of carbohydrates prior to bedtime, can eliminate the symptoms and related complications of the disease. Although prenatal diagnosis on chorionic villus sampling or cultured amniocytes using biochemical or molecular testing, or both, is possible, with the inherent risks of the procedures, prenatal testing may offer no advantage to postnatal testing of acylcarnitines and other metabolites characteristic of the disease. Therefore, genetic counseling and discussion of the issues related to this disease are warranted when prenatal testing is being considered.

Available Assays

Initial molecular testing usually focuses on the high-prevalence p.K304E allele and is performed by PCR amplification followed by restriction enzyme digestion or other methods that can discriminate between single nucleotide changes, such as ASO hybridization or ligation chain reaction amplification. Clinical testing for this mutation is widely available. When an affected individual is found to be heterozygous for the p.K304E mutation or in the rare instance when an affected individual is negative for the mutation, all 12 exons of the *ACADM* gene are sequenced; however, relatively few laboratories offer *ACADM* gene sequencing. Additional mutations

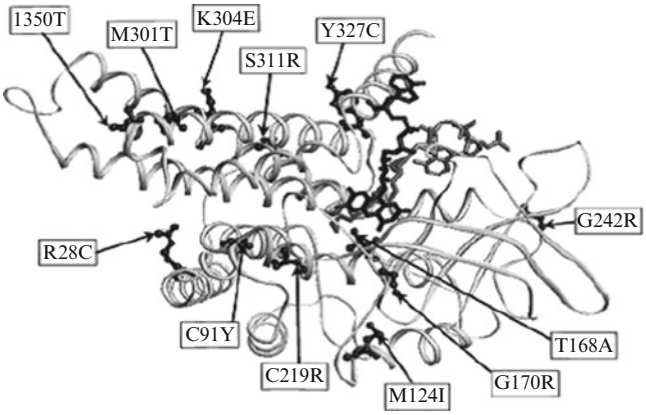

Figure 11.2 Schematic representation of a human MCAD monomer based on the crystal structure with cofactor flavin adenine dinucleotide (FAD) (*black*) and bound C8-CoA substrate (*darker gray*). The side chains for residues in which missense mutations have been published are shown in ball-and-stick representation. Only one of these mutations (T168A) is located in close proximity to the active site, forming a hydrogen bond to the flavin N(5) of FAD. Reprinted from Gregersen N, Andresen BS, Corydon MJ, et al. Mutation analysis in mitochondrial fatty acid oxidation defects: exemplified by acyl-CoA dehydrogenase deficiencies, with special focus on genotype-phenotype relationship. Hum Mutat 18(3):169–89 [32], by permission of Wiley-Liss, Inc., a subsidiary of John Wiley & Sons, Inc., ©2001

have been identified throughout the gene with no obvious mutation hotspot.

Interpretation of Test Results

The majority of mutations identified in *ACADM* are missense mutations located away from the active center of the enzyme, and are thought to affect the overall stability of the protein by affecting proper protein folding (Fig. 11.2) [32]. Most patients exhibit the classic MCAD phenotype; however, a small subset of patients has been identified that is compound heterozygous for the p.A304E mutation or for two other mutations, where at least one mutation is present that does not eliminate MCAD activity. These patients are much less likely to experience metabolic decompensation; however, even mildly symptomatic patients should avoid circumstances that could precipitate a metabolic crisis, since there is variability in age of onset even with classic MCAD deficiency.

Very-Long-Chain Acyl-CoA Dehydrogenase Deficiency

Molecular Basis of the Disease

VLCAD is an inner mitochondrial membrane enzyme encoded by the nuclear gene, *ACADVL*. VLCAD initiates the first reaction in β-oxidation of long, straight-chained acyl-CoAs of 14–20 carbons in length. Since the majority of dietary and endogenous fats are long chains, VLCAD function is an early crucial step for energy and ketone production from fat metabolism. Like MCAD deficiency, defective VLCAD activity leads to the accumulation of abnormal metabolites, mainly long-chain fatty acids and their conjugated moieties in the urine and plasma. Again, these metabolites are at their highest concentration in the first few days of life, due to the stressful and catabolic early neonatal period.

Because long-chained fats are the primary source of energy for the heart and during sustained skeletal muscle activity, the primary features of VLCAD deficiency, besides fasting hypoketotic hypoglycemia, are cardiomyopathy and skeletal myopathy with three main phenotypes. The severe, infantile-onset form presents with cardiomyopathy and arrhythmias which can lead to sudden death, hypotonia, and hepatomegaly. The childhood-onset form presents primarily with fasting hypoglycemia and liver disease, and rarely with cardiomyopathy. The late-onset form is mostly myopathic in presentation, with exercise intolerance, muscle cramping, and intermittent rhabdomyolysis during physical stress or times of illness. Patients are treated with a low-fat diet with supplemental medium-chain triglycerides, avoidance of fasting, intravenous glucose during hypoglycemic episodes, and intravenous fluids for rhabdomyolysis.

VLCAD deficiency is an autosomal recessive disorder with a prevalence of approximately 1 in 30,000. The VLCAD gene, *ACADVL*, is located on chromosome 17p13, is 5.4 kb in length, and contains 20 exons, encoding a protein of 701 amino acids. Unlike MCAD deficiency, there does not appear to be a prevalent mutant allele among a specific population. Mutations in all 20 exons have been reported.

Clinical Utility of Testing

An elevated C14:1-carnitine on the newborn screen taken at 48–72 h of life is highly indicative of VLCAD deficiency. However, borderline high levels can be equivocal in determining affected individuals from healthy carriers and normal neonates [33]. In addition, C14:1-carnitine levels can normalize with time, and attempts to confirm an abnormal acylcarnitine profile after 5 days can lead to a false-negative diagnosis [34]. Thus, molecular testing for *ACADVL* mutations is now offered as confirmatory testing of positive newborn screening results. VLCAD enzyme activity in lymphocytes or fibroblasts also is available. If two pathological *ACADVL* mutations are found, the diagnosis of VLCAD deficiency is confirmed. If only one mutation is found, an enzyme test using lymphocytes or fibroblasts is recommended.

Once diagnosis is confirmed, VLCAD deficiency is a disease that can be treated promptly in the early postnatal period

to avoid cardiomyopathy, liver disease, and sudden hypoglycemic coma. With an identified *ACADVL* mutation, genetic counseling and carrier and prenatal testing can be made available to the patient and family, and genotype-phenotype correlations can be deduced (see below).

Available Assays

Because mutations causing VLCAD deficiency are heterogeneous, molecular testing is done through sequencing and deletion/duplication analysis. Sequencing of all 20 exons has a mutation detection rate of 85–93 % for individuals with clinical disease [35].

Interpretation of Test Results

Deleterious mutations identified in *ACADVL* include missense mutations, deletions, insertions, and splice-site changes. Mutations that lead to a null mutation, as in a truncation of protein or a premature stop codon, result in elimination of enzyme activity, while missense or single-amino acid deletions can still confer residual enzyme activity. The presence of two null mutations correlates with the severe infant-childhood phenotype. Conversely, patients with a milder disease phenotype more frequently have missense or single-amino acid deletions [36].

Peroxisomal Disorders (X-Linked Adrenoleukodystrophy)

Genetic disorders of peroxisomal biogenesis and function have severe phenotypic consequences that often result in death in early childhood. A number of important metabolic processes, including β-oxidation of long- and very-long-chain fatty acids and the degradation of peroxide (H_2O_2), take place in the unique microenvironment of the single-membrane-bound matrix of the peroxisome. Whereas the symptoms of most metabolic diseases manifest after birth, disorders of peroxisome biogenesis, such as Zellweger syndrome, are associated with multiple congenital anomalies (for review, see Ref. 37). In this section, X-linked adrenoleukodystrophy (X-ALD) is highlighted, as it is the most common disorder.

Molecular Basis of the Disease

X-ALD is a severe, often fatal, disease that manifests in a progressive demyelination of the central nervous system, dysfunction of the adrenal cortex, and testicular dysfunction in hemizygous males. The most common form has an early onset that typically appears at 4–8 years of age and results in a progressive irreversible dementia and often death. Less severe presentations of the disorder include adrenomyeloneuropathy (AMN), which has a later age of onset, neurological complications that are limited to the spinal cord and peripheral nerves, and frequently includes adrenal insufficiency [38]. Although the disease is inherited in an X-linked recessive manner, up to 20 % of carrier females manifest late onset neurological symptoms similar to AMN. More than 93 % of X-ALD patients inherit mutations from their mothers, while the remaining 5–7 % carry de novo mutations; mosaicism has been reported in less than 1 % of patients [39]. The primary biochemical defect is impaired peroxisomal β-oxidation of fatty acids with the subsequent accumulation of very-long-chain fatty acids (VLCFAs), most notably C26, in the plasma and tissues. Therefore, X-ALD is not a disorder of peroxisomal biogenesis, but rather a specific defect of peroxisomal function. The accumulation of VLCFAs and the accompanying inflammatory response are thought to mediate the severity of the disease phenotype. In the great majority of hemizygous males (99 %) and approximately 85 % of carrier females, the plasma concentration of VLCFAs is elevated, a measurement that can be used as a diagnostic marker for the disease [40].

Defects in the peroxisomal membrane protein, ALDP, a member of the ATP-binding cassette family of molecular transporters, cause the severe juvenile form of X-ALD and its milder associated forms. The X-ALD gene, *ABCD1*, is located on Xq28, spans 19 kb, contains ten exons, and encodes a protein of 745 amino acids. The overall incidence of X-ALD and all variant forms is 1 in 15,000, making X-ALD the most common genetic determinant of peroxisomal disease. More than 1,000 different mutations have been found in the *ABCD1* gene, with the vast majority being point mutations, although deletions and duplications also have been identified (http://www.x-ald.nl/). In addition, mutations in all ten exons have been reported. No genotype-phenotype correlations are apparent, and wide phenotypic variation has been reported within families.

Clinical Utility of Testing

Molecular testing is most useful for determining the carrier status of at-risk women and for prenatal diagnosis, since 15 % of carrier females will not have elevated VLCFA levels and therefore will have a false-negative result by biochemical methods.

Available Assays

Molecular testing of the *ABCD1* gene is clinically available with many of the mutations identified as private mutations specific to a particular family. PCR amplification and SSCP or direct sequencing of all ten exons successfully identifies mutations in the majority of cases [41], whereas Southern blotting and MLPA can be used to assess deletion and duplication status. Complications can arise during PCR amplification due to the presence of paralogous gene segments of *ABCD1* spanning exons 7–10 on chromosomes 2p11, 10p11,

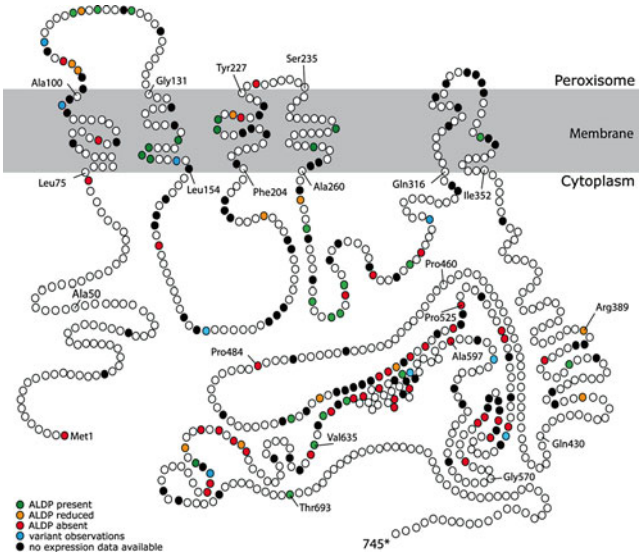

Figure 11.3 A hypothetical model of ALDP is shown. Individual amino acids are represented by *circles*. Missense mutations may affect the stability of ALDP. The effect of a missense mutation on ALDP stability by means of immunofluorescence (IF) in primary fibroblasts was investigated for >200 independent (non-recurrent) missense mutations. The results are presented in this figure. *Green circles* indicate missense mutations that do not affect protein stability; *red circles* those that result in no detectable ALDP (see remark below); *orange circles* represent mutations that result in reduced ALDP expression; *blue circles* indicate amino acid residues at which multiple missense mutations have been reported that result in different outcomes. The *black circles* indicate amino acids at which a missense mutation was identified, but for which no expression data are available. Overall, 69 % of all missense mutations result in reduced levels or absence of detectable ALDP [42]. All other mutations, including in-frame amino acid deletions and truncations near the carboxy terminus, result in the absence of detectable levels of ALDP. Reproduced from the Web site http://www.x-ald.nl/, with permission ©J. Berger and S. Kemp

16p11, and 22q11, but can be overcome by primer design that avoids amplification from the other chromosomes [41]. Although mutations have been identified throughout the entire *ABCD1* gene, a 2 bp AG deletion in exon 5 was found in 10.3 % of families with X-ALD and is therefore the most common mutation identified in the *ABCD1* gene [42]. Interestingly, this mutation, which is associated with all X-ALD phenotypes, does not represent a founder allele and is therefore a mutation hotspot within the *ABCD1* gene.

Interpretation of Test Results

The majority of mutations in *ABCD1* are missense mutations (61 %), with frameshifts and nonsense mutations accounting for 20 % and 10 % of mutation alleles, respectively, and amino acid insertions and deletions and whole exon deletions accounting for 4.6 % and 4 %, respectively. A recent study of the effects of missense mutations on ALDP stability demonstrated that approximately 70 % resulted in absent or reduced ALDP, indicating that most mutations in *ABCD1* result in complete loss of protein function (Fig. 11.3) [42]. These findings are consistent with the observed lack of genotype-phenotype correlation and lend support to the existence of additional genetic and environmental factors that modify the X-ALD phenotype.

Leukodystrophies (Canavan Disease)

The leukodystrophies are a group of degenerative metabolic diseases that involve the white matter of the brain, resulting predominately from disruption in the synthesis, transport, or catabolism of myelin. Examples include Krabbe disease and metachromatic leukodystrophy which affect lysosomal function and degradation of myelin, and Pelizaeus-Merzbacher disease, which is due to the abnormal synthesis of proteolipid protein. Another example, discussed in detail below, is Canavan disease, characterized by loss of axonal myelin sheaths and spongiform degeneration of the brain. Neurological deterioration in most leukodystrophies occurs after a period of normal development, and therapy is usually limited to the alleviation of symptoms.

Molecular Basis of the Disease

Canavan disease (CD) is an autosomal recessive disorder found mainly in Ashkenazi Jewish families and is caused by deficiency in the activity of the enzyme aspartoacylase (for review, see Ref. 43). The pathophysiologic relationship between the loss of this enzymatic activity and the development of CD remains to be elucidated. Diagnosis usually is established by the demonstration of increased levels of the substrate N-acetylaspartic acid in urine because enzymatic studies have been shown to be quite variable. Clinical symptoms associated with CD include macrocephaly, hypotonia, severe developmental delay, optic atrophy, poor head control, and death in childhood.

The gene encoding aspartoacylase (*ASPA*), located on the short arm of chromosome 17, is relatively small, with six exons spanning 30 kb of genomic sequence. Two point mutations, p.E285A and p.Y231X, are responsible for more than 97 % of mutant alleles in Ashkenazi Jews. Mutations in non-Jewish individuals are more heterogeneous; however, a panethnic mutation, p.A305E, accounts for 40–48 % of non-Jewish European alleles [44].

Clinical Utility of Testing

The genes responsible for many of the leukodystrophies have been cloned and characterized. Because the mutations in most of these genes are diverse, biochemical testing is still widely used for diagnosis, although molecular testing may be performed for carrier and subsequent prenatal testing. CD, however, occurs at increased frequency in the Ashkenazi Jewish population and screening for a limited number of specific mutations is feasible.

CD population screening of Ashkenazi Jewish individuals has demonstrated a carrier frequency of 1 in 40–59 (Refs. 45, 46 and our unpublished data). The carrier frequency for non-Jewish individuals has not been determined adequately, but it is far lower than that seen in the Ashkenazi Jewish population. As the carrier frequency is so high in the Ashkenazi Jewish population and the sensitivity of the assay is well above 90 %, ACOG and the ACMG recommended in 1998 that carrier screening for CD be performed preconceptually on couples with Ashkenazi Jewish ancestry.

Available Assays

A number of laboratories test for the two common Ashkenazi Jewish mutations, while some also test for p.A305E. A few laboratories also test for the less frequent non-Jewish mutation, c.433-2A>G. Testing methods commonly used for the detection of these mutations include PCR followed by ASO hybridization or restriction enzyme digestion, or allele-specific amplification. Miami Children's Hospital Research Institute holds a patent on the *ASPA* gene and CD testing, and requires laboratories to obtain a license, with a royalty fee for each test performed.

Interpretation of Test Results

If carrier screening indicates that both partners are carriers, prenatal testing should be offered. The preferred method of testing is DNA analysis of known mutations. For couples in which one partner is shown to be a carrier and the other partner is negative by targeted molecular testing, particularly if they are not Jewish, biochemical testing by measurement of the substrate in amniotic fluid is possible when the fetus has been shown to carry the one identified parental mutation.

Laboratory Issues

As discussed in this chapter, molecular genetic testing for metabolic disorders is used primarily as a follow-up to biochemical analyses for confirmation of findings, prognosis, carrier screening, or prenatal testing. Readers interested in learning which clinical laboratories perform individual tests should refer to the Genetic Test Registry (http://www.ncbi.nlm.nih.gov/gtr/). As testing for many of these disorders is performed in only a few laboratories, commercial test kits and proficiency testing is limited. Proficiency testing for TSD is available through the California Tay-Sachs Disease Prevention Program. For other disorders, interlaboratory exchange of samples is common practice. Several companies have developed assays for a panel of Ashkenazi Jewish disorders that include TSD, CD, and GD, among others. Although a large number of clinical laboratories offer Sanger sequencing and additional dosage sensitive methods for metabolic disorders, next-generation sequencing will allow assessment of large panels of genes related to metabolic disorders, though improved genotype-phenotype correlation will be needed before sequencing will replace biochemical testing as a first-line test.

Fibroblast Growth Factor Receptor and Related Skeletal Disorders

12

Steven Sperber and Elaine Spector

Abstract

Osteochondrodysplasias are a heterogeneous group of disorders. To date, more than 450 skeletal conditions have been characterized. Many of the skeletal dysplasias arise during the prenatal period and are able to be diagnosed by ultrasonography. Fibroblast growth factor (FGF) signaling, including the ligands and their receptors, plays an important role in the function of chondrocytes and osteocytes that contribute to bone patterning. Two of the most common types of skeletal dysplasias are achondroplasia and thanatophoric dysplasia, emphasizing the importance of FGF signaling in skeletal development. This chapter focuses on the many distinct skeletal disorders arising from mutations in the FGF receptor (FGFR) family of genes that are responsible for forms of syndromic and non-syndromic craniosynostosis and chondrodysplasias.

Keywords

Osteochondrodysplasias • Skeletal dysplasia • Fibroblast growth factor • FGF • Fibroblast growth factor receptor • FGFR • Achondroplasia • Thanatophoric dysplasia • Craniosynostosis • Chondrodysplasias

Introduction

Osteochondrodysplasias are a heterogeneous group of disorders. To date, greater than 450 skeletal conditions have been characterized [1–3]. Many of the skeletal dysplasias arise during the prenatal period and can be clinically diagnosed by ultrasonography. The perinatal prevalence of skeletal dysplasias is conservatively suggested to be 2.3 in 10,000 with estimates as high as 1 in 4,000–5,000 births [4, 5]. Fibroblast growth factor (FGF) signaling, including the ligands and their receptors, play an important role in the function of chondrocytes and osteocytes that contribute to bone patterning. Two of the most common types of skeletal dysplasias are achondroplasia and thanatophoric dysplasia, emphasizing the importance of FGF signaling in skeletal development [6]. Since mutations found in the FGF receptor (FGFR) genes result in some of the most common types of skeletal dysplasias, genetic testing is an effective diagnostic tool for determination of the type of skeletal dysplasia and establishing recurrence risks. This chapter focuses on the many distinct skeletal disorders arising from mutations in the FGFR family of genes that are responsible for forms of syndromic and non-syndromic craniosynostosis and chondrodysplasias.

Fibroblast Growth Factor Signaling

The FGF signaling pathway plays a prominent role in the growth and shaping of the skeletal system through regulation

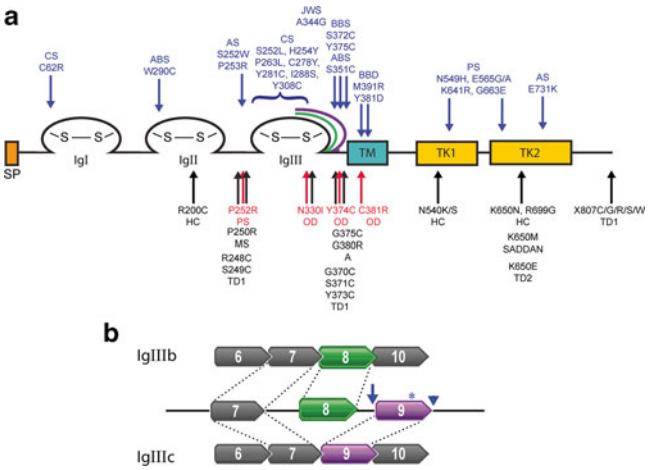

Figure 12.2 FGFR protein structure. (**a**) Common FGFR protein structure showing the signal peptide domain (SP, *orange*), the three immunoglobulin loops (IgI, IgII, and IgIII) with cysteine–cysteine disulfide bonds (S–S), the transmembrane domain (TM, *blue*), and the bifurcated tyrosine kinase domain (TK1 and TK2, *yellow*). The alternatively spliced carboxy-region of IgIII is illustrated as *green* and *purple lines*. Locations of selected mutations in *FGFR1* (*red*), *FGFR2* (*blue*), and *FGFR3* (*black*) are indicated by *arrows*, with the associated disease above or below the mutation. *A* achondrodysplasia, *ABS* Antley-Bixler syndrome, *AS* Apert syndrome, *BBD* bent bone dysplasia, *BSS* Beare-Stevenson syndrome, *CS* Crouzon syndrome, *HC* hypochondrodysplasia, *JWS* Jackson-Weiss syndrome, *MS* Muenke syndrome, *OD* osteoglophonic dysplasia, *PS* Pfeiffer syndrome, *TD1* and *TD2* thanatophoric dysplasia type 1 and 2, respectively. (**b**) Alternative splicing of exons 8 and 9 that code for the IgIII carboxy-terminal region. Isoform FGFR-IIIb (*top*) includes exon 8 (*green*). Isoform FGFR-IIIc (*bottom*) includes exon 9 (*purple*). Examples of *FGFR2* splicing mutations are shown: c.940-2A>G (*arrow*), c.1032G>A (A344A) (*asterisk*); and c.1084+3A>G (*arrowhead*)

of chondro- and osteoblastogenesis [7]. Twenty-three known FGF family members act as ligands to the FGFRs to influence cellular proliferation and differentiation. The FGF ligands interact with four high-affinity receptors (*FGFR1* through -4). Signaling is initiated by a FGFR monomer that binds to a FGF ligand, which requires heparin sulfate proteoglycan to facilitate the interaction [9]. FGF ligands bind to the FGFRs with different affinities and specificities [8]. Ligand binding induces homodimerization of the receptors and autophosphorylation of the tyrosine residues located in the cytoplasmic domain to propagate the intracellular signal [10, 11].

FGF Receptors

FGFRs are membrane-bound receptor tyrosine kinases. Of the four receptors, only mutations in *FGFR1*, *-2*, and *-3* (OMIM *136350, *176943, *134934) result in skeletal disorders (Fig. 12.1). The structures of the FGFR paralogs are very similar (Table 12.1). The FGFR paralogs share the same organization consisting of three immunoglobulin-like extracellular domains denoted as IgI, IgII, and IgIII, a membrane traversing hydrophobic region, and a bifurcated intracellular tyrosine kinase domain that propagates the signal to downstream pathways (Fig. 12.2a). The three immunoglobulin-like regions are stabilized by cysteine-cysteine disulfide bonds. The *FGFR1-3* genes produce alternative splicing of the IgIII domain, which generates two isoforms that exhibit tissue-specific expression. The amino aspect of the IgIII region is referred to as IgIIIa. The carboxy half of the IgIII loop contains one of two alternate exons (Fig. 12.2b) denoted as IgIIIb and IgIIIc that code for the C-terminal region of the IgIII domain [12, 13]. The two isoforms preferentially bind to particular FGF ligands and are differentially expressed in epithelial and mesenchymal tissues during development [14]. Studies indicate that it is the FGFR2c and FGFR3c isoforms, expressed in the mesenchyme, that are particularly involved in proper bone patterning [15].

Molecular Basis of Disease

Mutations in the *FGFR1*, *-2*, and *-3* genes account for approximately 15–20 % of all craniosynostosis and chondrodysplasias. FGFR-related skeletal anomalies are a result of gain-of-function variants that constitutively activate the receptor function [16–18]. Activated FGFRs receptors cause increased cellular proliferation and premature osteoblast differentiation [19–21]. The FGFR constitutive activation is by either a FGF ligand-dependent or -independent mechanism. Ligand-dependent mechanisms arise due to mutations that improve binding of FGF ligands and dimerization of the receptors prolonging signaling activity [22]. Alternatively, ligand-independent mechanisms include the following: (1) enhancement of receptor dimerization due to an immunoglobulin domain structural change such as a gain or loss of a cysteine residue within the loops; (2) augmentation of dimerization due to intramembrane domain changes in amino acid charge that increases hydrogen bonding; and (3) alterations in the kinase domain causing constitutively active phosphorylation [23–25].

Mutations causing FGFR-related craniosynostosis and/or chondrodysplasia tend to cluster in specific domains of the receptors (Fig. 12.2a). These clusters illustrate the importance of the domains in receptor function. Analogous mutations found in each of the different FGFRs tend to mirror phenotypic effects between the receptors. However, distinctions between analogous mutations in the different receptors and their phenotypes reveal their independent roles during normal skeletogenesis.

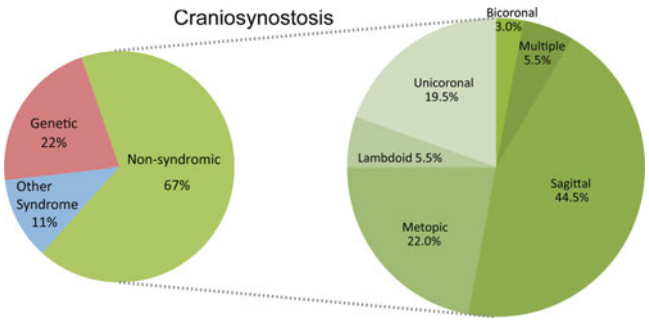

Figure 12.4 The prevalence of different forms of craniosynostosis derived from analysis of a 215-patient cohort affected with syndromic and nonsyndromic forms of craniosynostosis (*left*). Phenotypic categorization of nonsyndromic cases based upon affected sutures (*right*) (adapted with permission from Wilkie et al. 2010 [32])

Craniosynostosis and Chondrodysplasia

Craniosynostosis

Craniosynostosis arises from the premature fusion of one or more of the cranial sutures resulting in a dysmorphic skull. Distortions of the skull arise from uneven growth patterns between the sutures and depend on the location and timing of the fusion events [26]. The cranial sutures are the leading edges of the growing intramembranous bones that comprise the skull vault or calvaria. The calvaria consists of the left and right frontal, squamous occipital, squamous temporal, and the left and right parietal bones that will form the neurocranium (Fig. 12.3). At birth, the frontal bones are separated by the metopic suture. The coronal suture separates the frontal bones from the left and right parietal bones. The lambdoid suture separates the parietals from the occipital bone. The suture leading edges function as ossification centers. The calvaria of the neurocranium that forms the desmocranium ossifies as intramembranous bone forming the vault of the neurocranium. Normally, the metopic suture begins to close after the first year and closure is completed by the seventh year, generating the frontal bone [27]. The sagittal, coronal, and lambdoidal sutures generally complete fusion between 20 and 40 years of age. *De novo* or autosomal dominantly inherited mutations in the *FGFR1–3* genes that enhance signaling result in the inhibition of the osteogenic proliferation program, thereby causing premature fusion of cranial sutures [28]. Mutations associated with isolated nonsyndromic forms of craniosynostosis have been found in each of the *FGFR1–3* genes [29–31].

Nonsyndromic or isolated single-suture forms of craniosynostosis are more common than syndromic and number 1 in 2,100–3,000 live births [17]. Sagittal synostosis is the most common, followed by coronal, metopic, and then lambdoid suture synostosis (Fig. 12.4) [32, 33]. Nonsyndromic craniosynostosis is heterogeneous and many of the causes remain unknown. Often full sequencing of the *FGFR* genes may be requested to rule out the receptors and potentially detect *de novo* mutations.

Chondrodysplasias

In addition to influencing the growth of the neurocranium, FGF signaling also participates in the development of the skeletal system exemplified by its role in the growth of the long bones of the appendicular skeleton. Dominantly inherited and *de novo* gain-of-function mutations result in varying degrees of dwarfism as illustrated by particular *FGFR3* mutations that cause hypochondroplasia and achondroplasia. Observed in both craniosynostosis and chondrodysplasia cases, germline mutations due to advanced paternal age are a significant contributor to these disorders [34, 35].

Clinical Utility of Testing

Syndromic forms of *FGFR*-related craniosynostosis and chondrodysplasia are diagnosed clinically, based on their well-described phenotypes. Three-dimensional ultrasonography is able to detect early skeletal anomalies, including short bones, premature skull fusion, and other characteristic syndromic features [6, 36]. Molecular testing is performed to confirm the diagnosis and provide recurrence risks in pregnancies with either suspected germline mosaic transmission in families with a history of a previously affected fetus, or in families with an affected parent and a 50 % probability of passing on the deleterious allele. In such cases of inheritance, examination of the contributing parent may reveal a mild phenotype. For severe cases, *de novo* mutations occurring in the male germline may be responsible. Advanced paternal age is known to increase the risk of having affected offspring. Generally, targeted mutation analysis is sufficient to confirm a well-characterized phenotype and is the first tier of testing. Sequencing of all the exons may be performed if no mutation is found initially.

Available Assays

Different methods have been developed to identify mutations within the *FGFR* genes. The vast majority of mutations are missense and nonsense, with splicing and in-frame small insertions and deletions being much rarer. Detection methods include targeted mutation analysis, scanning of specific exons, and sequencing of all the coding regions as well as their intron/exon boundaries. Targeted analysis is based on testing the patient's DNA for previously described mutations. Using restriction fragment length polymorphism (RFLP) methods, regions of interest within the coding sequences can be amplified by polymerase chain reaction (PCR) and digested with restriction endonucleases that would characteristically identify specific mutations based on altered banding patterns observed by gel electrophoresis and staining (Fig. 12.5). Incomplete digestion of a restriction site may lead to aberrant results and an incorrect heterozygosity interpretation; therefore, both positive and negative digestion controls are essential for RFLP analysis. Alternatively, allele-specific oligonucleotide PCR with primers targeted to wild-type alleles and previously characterized mutations may be performed, resulting in identifiable amplicon patterns. The drawback to targeted analysis is that mutations outside the scope of the assay will be missed.

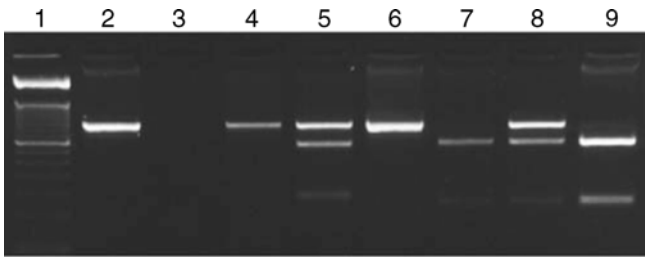

Figure 12.5 Thanatophoric dysplasia type 2 restriction fragment length polymorphism (RFLP) assay. Amplification of the *FGFR3* exon 15 and digestion of patient and control DNA give characteristic banding patterns diagnostic for the p.Lys650Glu mutation. *Lane 1*, 50 base pair (bp) size marker; *lane 2*, undigested 450 bp amplicon; *lane 3*, no DNA template PCR control; *lanes 4–6*, restriction digest with *Bsm*AI; *lanes 7–9*, digest with *Bbs*I. *Lanes 4, 6, 7,* and *9*, control DNA. *Lanes 5* and *8*, patient DNA. *Lanes 4–6* show a gain of a *Bsm*AI restriction site in the patient DNA (*lane 5*). *Lanes 7–9* demonstrate loss of a *Bbs*I digest site in the patient's DNA (*lane 8*)

Mutation scanning by denaturing high-performance liquid chromatography (DHPLC) has been employed to screen the exons of the FGFR genes whereby patient's profiles suggest potential mutations in comparison to unaffected and affected controls. Issues arise in scanning techniques such as DHPLC as well as high-temperature melting profiles and single-stranded conformational polymorphism in their inability to identify specific mutations or distinguish between known mutations and rare polymorphisms. Unique profiles identifying potential mutations must then be directly sequenced. Sequence analysis of the coding exons is the most comprehensive of the methods ensuring that any point mutation and small deletions and duplications will be identified within the amplified regions. Massively parallel sequencing, using next-generation sequencing platforms, also offers the option to perform sequence analysis on many samples concurrently through barcoding of individual patient's DNA and using bioinformatics to separate the reads by patient and analyze the sequence data.

Deletion/duplication analysis may be performed by multiplex ligation-dependent probe amplification or exon level array-based comparative genomic hybridization and then confirmed by quantitative PCR. These methods measure the relative amounts of each exonic region where probes are placed, comparing the quantitative results to internal controls, usually housekeeping gene(s) found on other chromosomes.

Interpretation of Test Results

The majority of *FGFR* mutations causing skeletal dysplasia are point mutations. Interpretation of novel missense variants is becoming easier as the knowledge base grows. To date, there are approximately 155 known mutations within the *FGFR1-2-3* that cause skeletal dysplasias. Current lists of mutations are available in the Human Gene Mutation Database (www.biobase-international.com/product/hgmd). Databases that include polymorphisms, such as dbSNP (www.ncbi.nlm.nih.gov/projects/SNP/), the 1000 Genomes Project (www.1000genomes.org/), and exome sequencing projects (Exome Aggregation Consortium [ExAC], exac.broadinstitute.org; Exome Variant Server, http://evs.gs.washington.edu/EVS/), provide information on the genetic variants and their frequencies in the general population [37, 38]. Variants of unknown significance can be evaluated using predictive algorithms that may provide insight into whether they are benign or pathogenic. These predictions take into consideration the biochemical properties of the amino acid change, including size, charge, polarity, steric constraints, and evolutionary conservation of the residue within the protein domain. Internet-based predictive tools, including PolyPhen2, SIFT, and Mutation Taster, provide analysis of the probable functional consequences of missense variants [39–41]. The results of these prediction tools have to be considered as one piece of evidence.

Rare splicing mutations causing skeletal dysplasia have been documented. Mutations, such as the synonymous change p.Ala344Ala (c.1032G>A) in the immunoglobulin IIIc (IgIIIc) domain of *FGFR2*, activate a cryptic splice donor site (Fig. 12.2b) [42]. Conversely, weakening the endogenous donor site (c.1084+3A>G and c.1084+1G>A) induces exon skipping and preferential splicing of the IgIIIb isoform [43–45]. Similarly, *FGFR2* mutations causing Pfeiffer syndrome affect the IgIIIc acceptor site (c.940-2A>G or A>T) [46]. Unknown variants found in the intronic regions of the gene can be analyzed through splicing algorithms, such as the Human Splice Finder (www.umd.be/HSF/) [47] and Netgene2 (www.cbs.dtu.dk/services/NetGene2/) [48], to predict their influence on the precursor mRNA.

Laboratory Issues

Commercial test kits for analyzing the *FGFR* genes are not available, so testing is performed using laboratory developed tests. Test development and validation may be achieved using cell lines obtained from the Coriell Cell Repository (http://ccr.coriell.org). Proficiency testing is available through the College of American Pathologists Molecular Genetics Laboratory sequencing surveys. Additionally, interlaboratory sample exchanges and internal repeat testing of blinded samples can be used to meet the proficiency testing requirements.

FGFR-Related Skeletal Syndromes

Apert Syndrome

Apert syndrome (OMIM#101200), also known as acrocephalosyndactyly, is characterized by craniosynostosis, facial hypoplasia, broad thumbs and great toes, and digit fusion of the hands and feet (syndactyly) described as a "mitten-hand" malformation. As the most common of the craniosynostosis syndromes, Apert syndrome accounts for approximately 4.5 % of all cases with an occurrence estimated as 1 in 65,000 to 80,000 [49, 50]. The majority of cases result from *de novo* mutations attributed to increasing paternal age [51].

The majority of cases (99 %) are caused by one of two point mutations in the *FGFR2* gene [52]. The common mutations are p.Ser252Trp, which accounts for approximately two-thirds of the cases, and p.Pro253Arg accounting for one third of cases. These mutations, located at the IgII-IgIII linker region, enhance ligand binding affinity [9]. Rarer mutations have been observed surrounding these two mutations in the linker region. Diagnostic testing can be performed by targeted Sanger sequencing.

Apert syndrome is clinically diagnosed. Identification of the specific mutation helps in determining the potential risk for further affected pregnancies due to germline mosaicism. With an affected parent, there is a 50 % probability that a pregnancy will result in an affected child.

Pfeiffer Syndrome

Patients presenting with Pfeiffer Syndrome (OMIM#101600) exhibit brachycephaly, hypertelorism, ocular proptosis, a flat midface, broad thumbs, and medially deviated great toes, and occasionally with hearing loss and variable cutaneous syndactyly [17]. Pfeiffer syndrome is a genetically heterogeneous disorder. Mutations have been found in both *FGFR1* and *FGFR2*. *FGFR2* mutations account for 95 % of patients' mutations. One activating mutation, p.Pro252Arg in the *FGFR1* gene, accounts for approximately 5 % of the diagnosed patients. Mutations in *FGFR2* are found in the IgIIIa and IgIIIc regions as well as the tyrosine kinase domain, and tend to be phenotypically more severe than the *FGFR1*-derived phenotype.

Crouzon Syndrome With or Without Acanthosis Nigricans

Crouzon syndrome (OMIM#123500) patients have multiple suture fusions or coronal fusions causing brachycephaly, trigonocephaly, and rare reports of cloverleaf skull malformation also known as kleeblattschädel [53, 54]. Attributes

typically include hypertelorism, a small midface, beaked nose and protrusion of the eyes. Hands and feet are generally normal. Heterozygous mutations in the *FGFR2* gene show high penetrance and variability of the phenotype within families. Approximately half of the cases are inherited and the other half arise from *de novo* mutations. Increasing paternal age is a contributing factor for *de novo* mutations [35]. The prevalence is estimated as 1 in 65,000 live births [55].

Patients with Crouzon syndrome with acanthosis nigricans (OMIM#612247) are typically female, display hyperpigmentation of the skin, hyperkeratosis, and other skin findings. A specific *FGFR3* heterozygous mutation, p.Ala391Glu, has been identified and is located in the transmembrane domain [56].

Muenke Syndrome

Muenke syndrome (OMIM#602849) displays incomplete penetrance and a variable phenotype even within families [57]. Prevalence in the population is estimated to be 1 in 30,000 live births. Sporadic and familial cases have been reported. Characteristics include bi- or unicoronal synostosis, midfacial hypoplasia, ptosis, and downslanting palpebral fissures. Some affected individuals have additional features that may include sensorineural hearing loss, developmental delay, brachydactyly, and coned epiphyses in the hands and feet. Muenke craniosynostosis is a result of a specific heterozygous mutation, p.Pro250Arg, found in the linker region between domains IgII and IgIII of *FGFR3* [58–61]. Targeted testing may be performed by sequencing the seventh exon of *FGFR3* or by RFLP analysis using the *Msp*I endonuclease.

Beare-Stevenson Syndrome

Beare-Stevenson (OMIM#123790), also known as cutis gyrate syndrome of Beare and Stevenson, is a rare and severe disorder. Patients characteristically have body-wide skin furrows (cutis gyrate), acanthosis nigricans, skin tags, bifid scrotum, and anogenital anomalies. The craniosynostosis may be severe and present as a cloverleaf skull with hypertelorism, a broad nasal bridge, cleft palate, and hypodontia. Two heterozygous point mutations in the *FGFR2* gene, p.Ser372Cys and p.Tyr375Cys, account for 50–60 % of cases, suggesting locus heterogeneity. The resulting cysteine residues are thought to increase ligand-independent dimerization. These *de novo* mutations are analogous to the mutations in *FGFR3* causing thanatophoric dysplasia. An intragenic deletion, c.1506del63, has recently been described and is proposed to alter gene splicing in favor of the IgIIIb isoform of *FGFR2*. Loss of the 21 amino acids encoded by exons 8 and 9 is suggested to cause aberrant expression of *FGFR2b* [62].

Jackson-Weiss Syndrome

Jackson-Weiss Syndrome (OMIM#123150), inherited in an autosomal dominant manner, has been most prominently described in an extended Amish family with a p.Ala344Gly mutation in the IgIIIc domain of *FGFR2* [63–66]. Fully penetrant with variable severity, the characteristics of the syndrome include craniosynostosis with facial anomalies, broad great toes, and webbing of the second and third toes [67]. A few reports suggest mutations in *FGFR2* and *FGFR1* exhibit phenotypic traits similar to Jackson-Weiss syndrome indicating that Crouzon, Jackson-Weiss, and Pfeiffer syndromes may represent a spectrum of craniosynostotic and digit malformations [68, 69].

Antley-Bixler Syndrome Type 2

Antley-Bixler syndrome (ABS; trapezoidocephaly-synostosis syndrome) is a rare and severe heterogeneous disorder with mutations found in both the *FGFR2* gene (autosomal dominant; type 2; OMIM#207410) and the cytochrome P450 oxidoreductase (*POR*) gene (autosomal recessive; type 1; OMIM#201750). ABS type 2 is characterized by craniosynostosis of the coronal and lambdoid sutures, midfacial hypoplasia, radiohumeral and digit fusions, exophthalmos, and arachnodactyly [70, 71]. The mutations associated with ABS include p.Trp290Cys and p.Ser351Cys, both found in the IgIII domain of the *FGFR2* gene [72]. Mutations at these positions also have been associated with the milder phenotype of Crouzon syndrome [73].

Osteoglophonic Dysplasia

Osteoglophonic dysplasia (Fairbank-Keats syndrome; OMIM#166250), a very rare disorder, is typified by variable craniosynostosis and rhizomelic dwarfism with a "hollowed-out" appearance of the tubular bones on radiographs, depression of the nasal bridge, unerupted teeth, frontal bossing, and prognathism similar to achondroplasia. Mutations in *FGFR1* are found in the conserved amino acids clustered in the C-terminal region of the IgIII immunoglobulin domain, the linker region, and the transmembrane domain. The *FGFR1* p.Tyr372Cys mutation is analogous to both the *FGFR2* p.Tyr375Cys mutation that causes Beare-Stevenson syndrome and the p.Tyr373Cys *FGFR3* mutation that causes thanatophoric dwarfism type 1, indicating the importance of that amino acid position in the functional role of the receptors [74].

Achondroplasia

Achondroplasia (OMIM#100800) arises from mutations in the *FGFR3* gene that inhibit chondrocyte proliferation within the endochondral growth plate resulting in the shortening of long bones. Achondroplasia is the most common form of FGFR-related short-limbed dwarfism [75, 76], with an occurrence of 1 in 10,000 to 30,000 live births [4, 5]. Two common variants, c.1138G>A (~98 %) and c.1138G>C (1–2 %), result in a p.Gly380Arg mutation in the transmembrane domain of *FGFR3* [77]. The achondroplasia mutation is the most common *de novo* disease-causing mutation known. There is a strong paternal origin for the mutation, mostly in fathers over the age of 35 years [34]. A second mutation, described in several published accounts, suggests that p.Gly375Cys also causes achondroplasia [78–80].

Testing for the c.1138G>A mutation may be performed by RFLP digestion of exon 10 with the *Sfc*I restriction enzyme. It has been noted, however, that complete digestion is not consistently observed for the assay and other molecular methods may be required to differentiate between the G>A and the G>C mutations, the heterozygous form, and the lethal homozygous form [81–83].

Severe Achondroplasia, Developmental Delay, and Acanthosis Nigricans (SADDAN)

Severe achondroplasia, developmental delay and acanthosis nigricans (SADDAN; OMIM#187600), is caused by a c.1949A>T mutation (p.Lys650Met) in *FGFR3*. The substitution of a methionine residue at position 650 differentiates SADDAN from type 2 thanatophoric dysplasia, which arises from a glutamic acid substitution at the same position (c.1948A>G; Lys650Glu). The SADDAN amino acid change induces constitutive kinase activity that is threefold greater than normal [84].

Hypochondroplasia

Hypochondroplasia (OMIM#146000) is clinically diagnosed as a mild form of skeletal dysplasia. Clinical diagnosis is usually by short limbs detected on ultrasonography, which prompts diagnostic testing. The *FGFR3* c.1138G>A mutation that causes achondroplasia has been found in about 5 % of hypochondroplasia cases. *FGFR3* mutations account for only 50–70 % of cases, suggesting genetic heterogeneity. Of those mutations in *FGFR3*, 70 % are a recurrent p.Asn540Lys amino acid change located in the tyrosine kinase 1 domain (TK1), while others are rarer. Testing may be performed by RFLP analysis of an exon 13 PCR product, which will detect the two c.1659C>A/G, p.N540K mutations. A *Bsp*MI restriction site is abolished by the c.1620C>A mutation, and the c.1620C>G mutation creates a novel *Alu*I restriction site [85]. The other known mutations may be detected by sequencing exons 10, 13, and 15 of *FGFR3*.

Thanatophoric Dysplasia

Thanatophoric dysplasia (TD) is the most common lethal condition of short-limbed skeletal dysplasia with a distorted head and has an estimated incidence of 1 in 20,000 to 50,000 live births. Two types of TD are clinically diagnosed based on ultrasound and radiographic findings [86–88]. Type 1 (OMIM#187600) patients have prominently curved femurs, while type 2 (OMIM#187601) patients typically have a severe form of craniosynostosis often referred to as a cloverleaf skull and a small chest [89].

Several different gain-of-function mutations in *FGFR3* cause TD type 1. Mutations p.Arg248Cys, p.Ser249Cys, p.Ser371Cys, and p.Tyr373Cys create novel cysteine residues in the extracellular and intramembranous domains, while other mutations causing TD type 1, such as p.Ter807Arg, p.Ter807Cys, p.Ter807Gly, p.Ter807Ser, and p.Ter807Trp, obliterate the stop codon resulting in extension of the intracellular domain by an additional 141 amino acids [90, 91].

TD type 2 is caused by the *FGFR3* transition mutation c.1948A>G, coding for p.Lys650Glu [92, 93]. The mutation causes multiple cranial sutures to fuse prematurely resulting in a cloverleaf skull malformation. The importance of the lysine 650 codon, situated in the tyrosine kinase-domain activation loop of FGFR3, is emphasized by the wide range of clinical phenotypes observed based, on the different amino acid substitutions and their ability to influence kinase activity. Similar to the previously mentioned SADDAN p.Lys650Met mutation, substitution of the lysine 650 for a glutamine or asparagine residue is associated with a milder hypochondrodysplasia phenotype [94].

Bent Bone Dysplasia: FGFR2 Type

Bent bone dysplasia-FGFR2 type (OMIM#614592) has recently been attributed to two heterozygous mutations in the FGFR2 transmembrane domain, c.1172T>G (p.Met391Arg) and c.1141T>G (p.Tyr381Asp) that reduce its localization to the plasma membrane [95]. A phenotype of perinatal lethality with hypertelorism, midface hypoplasia, micrognathia, prematurely erupted prenatal teeth, low-set posteriorly rotated ears, and clitoromegaly in females. Distinct radiological findings include coronal craniosynostosis with poorly mineralized calvaria, curved appendicular skeletal defects, and clavicle hypoplasia. The nuances of the genotype-

phenotype correlations are observed in the mutation of the tyrosine 381 residue to asparagine (p.Tyr381Asn, c.1141T>A) that causes Crouzon syndrome [96]. These studies suggest a spectrum of severity for altered FGFR2 activity.

Other *FGFR*-Associated Disorders

In addition to the activating mutations resulting in craniosynostosis and chondrodysplasia, loss-of-function mutations in the *FGFR* genes cause a variety of different syndromes.

CATSHL Syndrome

Dominantly inherited, camptodactyly, tall stature, scoliosis, and hearing loss (CATSHL; OMIM#610474) is caused by a *FGFR3* p.Arg621His heterozygous missense mutation residing within the tyrosine kinase domain generating a loss-of-function that promotes endochondral bone growth [97]. Recently, a novel homozygous *FGFR3* c.1167C>A p.Thr546Lys, mutation has been described as also causing skeletal overgrowth [98].

Kallmann Syndrome

Hypogonadotropic hypogonadism, also known as Kallmann syndrome (OMIM#308700), is a heterogenic disorder with mutations found most commonly in the *KAL* gene (KAL1, X-linked; OMIM *300836) as well as *FGFR1* (KAL2, OMIM#147950). Other genes that account for 5 % or less of cases include *PROKR2*, *PROK2*, *CHD7*, and *FGF8*, while an additional five genes are known to account for the autosomal recessive form. Sensitivity of testing for clinically diagnosed Kallmann syndrome is approximately 30 % for the aforementioned genes [99]. Loss-of-function mutations in *FGFR1* account for approximately 10 % of cases of type 2 Kallmann Syndrome with deletions being rare contributors to the disorder. Kallmann syndrome exhibits a 5:1 male to female ratio with an incidence of approximately 1 in 8,000 to 10,000 in males and 1 in 40,000 to 50,000 in females [100, 101]. Patients characteristically have olfactory bulb dysgenesis (anosmia) and hypogonadotropic hypogonadism, with boys also having micropenis and cryptorchidism. Mutations in the *FGFR1* gene also may result in cleft lip and/or palate, agenesis of the teeth, and digital malformations [102].

LADD Syndrome

Lacrimo-auriculo-dento-digital (LADD) syndrome (OMIM#149730; Levy-Hollister syndrome) is a dominant, heterogeneous disorder with mutations found in the *FGF10* gene as well as the tyrosine kinase domains of *FGFR2* (p.Ala648Thr, p.Ala628Thr) and *FGFR3* (p.Asp513Asn) [103–105]. Variants in the receptor kinase domain associated with LADD syndrome reduce phosphorylation activity [106]. Affected individuals typically exhibit hypoplasia/aplasia of the tear and salivary ducts, malformed ears and deafness, hypodontia, and digital anomalies mostly affecting the thumbs [107–109].

Cystic Fibrosis

13

Lora J.H. Bean and V.M. Pratt

Abstract

Cystic fibrosis (CF) is one of the most common lethal autosomal recessive diseases in whites, with an estimated incidence of 1 in 2,500–3,300 live births. CF, caused by mutations in the *CFTR* gene, is a complex multisystem disease, affecting the respiratory tract, pancreas, intestine, male genital tract, hepatobiliary system, and exocrine system. Recurrent infections that lead to respiratory failure are the major cause of morbidity. Due to the high frequency of CF, *CFTR* mutation analysis is useful for a variety of clinical indications, including newborn screening, diagnostic testing, carrier screening, and fetal diagnosis for at-risk pregnancies. A relatively small number of mutations account for the majority of CF alleles. The American College of Medical Genetics and the American Congress of Obstetricians and Gynecologists recommend first-tier *CFTR* mutation analysis using a panethnic panel of 23 mutations that occur at a frequency of >0.1 % in any of the major US ethnic groups. Commercial test kits are available to perform this testing. Reporting of CF results is complex because the detection in a targeted mutation assay is less than 100 %. The interpretation and subsequent recommendations are dependent on the indication for the test and the ethnicity and family history of the individual being tested, and may require consultation with a medical geneticist or genetic counselor.

Cystic fibrosis • *CFTR* • Diagnostic testing • Carrier screening • Prenatal testing • Molecular testing

Introduction

Cystic fibrosis (CF) is one of the most common lethal autosomal recessive diseases in whites, with an estimated incidence of 1 in 2,500 to 1 in 3,300 live births. CF, caused by mutations in the *CFTR* gene, is a complex multisystem disease, affecting the respiratory tract, pancreas, intestine, male genital tract, hepatobiliary system, and exocrine system. Recurrent infections that lead to respiratory failure are the major cause of morbidity. Due to the high frequency of CF, *CFTR* mutation analysis is useful for a variety of clinical indications, including newborn screening (NBS), diagnostic testing, carrier screening, and fetal diagnosis for at-risk pregnancies. A relatively small number of mutations account for the majority of CF alleles. The American College of Medical Genetics (ACMG) and the American Congress of Obstetricians and Gynecologists (ACOG) recommend a panethnic panel of 23 mutations that occur at a frequency of >0.1 % in any of the major US ethnic groups be used for first-tier *CFTR* mutation analysis. Commercial kits are available to perform this testing. Reporting of CF results is complex because the detection in a targeted mutation assay is

less than 100 %. The interpretation and subsequent recommendations are dependent on the indication for the test and the ethnicity and family history of the individual and may require consultation with a geneticist or genetic counselor.

Molecular Basis of Disease

CF is one of the most common lethal autosomal recessive diseases in Caucasians, with an estimated incidence of 1 in 2,500 to 3,300 live births. Approximately 30,000 children and adults in the USA are affected and approximately 1,000 individuals are newly diagnosed annually, the majority less than 1 year old. For a current, comprehensive review of clinical CF and molecular diagnostics for this disorder, see ref. 1.

The gene mutated in CF, the cystic fibrosis transmembrane conductance regulator (*CFTR*), spans approximately 230 kilobases (kb) on chromosome 7q31.2, contains 27 coding exons, produces a 6.5 kb mRNA product, and encodes a CFTR protein of 1,480 amino acids with a mass of approximately 170,000 Da. The CFTR protein is in the ATP-binding cassette family of transporter proteins, containing five domains: two membrane-spanning domains, a regulatory domain, and two nucleotide-binding domains that interact with adenosine triphosphate. Mutations that lead to an abnormal CFTR protein cause defective electrolyte transport in the apical membrane of epithelial cells resulting in complex multisystem disease affecting the respiratory tract, pancreas, intestine, male genital tract, hepatobiliary system, and exocrine system.

CF is characterized by viscous mucus secondary to faulty transport of sodium and chloride, which leads to salt loss, and affects water content of the extracellular space. CF has a highly variable presentation and clinical course. The clinical features of "classic" CF are dominated by pulmonary disease. The median age of diagnosis is 6–8 months, and nearly two-thirds of affected individuals are diagnosed by the age of 1 year; however, the advent of NBS for CF is enabling earlier diagnosis of presymptomatic individuals. Respiratory failure, often with recurrent respiratory infections, is the major cause of morbidity and mortality. Approximately 90 % of CF patients die from pulmonary complications with an overall median survival into the late 30s. Approximately 85 % of CF patients have pancreatic insufficiency as a result of obstruction of the pancreatic ducts and subsequent scarring and destruction of exocrine functions. Neonatal meconium ileus, which can present prenatally as echogenic bowel (EB), occurs in approximately 15 % of newborns with CF. Other manifestations include chronic sinusitis, nasal polyps, liver disease, pancreatitis, and, in males, congenital bilateral absence of the vas deferens (CBAVD) resulting in azoospermia.

Treatment for individuals with CF is palliative and includes chest percussion and use of inhaled medications or hypotonic saline to clear lung secretions, control of infections by antibiotic therapy, and improvement of nutritional status through dietary managements and pancreatic enzyme replacement. The goals of therapy are maintenance of adequate nutritional status, prevention of pulmonary and other complications, encouragement of physical activity, and provision of adequate psychosocial support. Although the development of new therapies for CF based on correction of electrolyte transport is a major research focus, there is currently no cure for CF. While lung transplantation can be used in selected CF patients with severe respiratory compromise, the success is not sustained and lung transplant does not address the other end-organ disease of CF [2].

A diagnosis of CF in a symptomatic or at-risk individual is suggested by clinical presentation and confirmed by a sweat test. In the presence of clinical symptoms (e.g., recurrent respiratory infections), a sweat chloride level above 60 mmol/L is diagnostic for CF. Although the results of this test are valid in a newborn as young as 24 h, collecting a sufficient sweat sample from a baby younger than 3 or 4 weeks old is difficult and must be performed by an experienced, Cystic Fibrosis Foundation-accredited sweat testing center. The sweat test also confirms the diagnosis in older children and adults but is not useful for carrier detection.

Since the identification of the *CFTR* gene, more than 1,800 mutations have been identified; a complete list can be found at www.cftr2.org/. A relatively small number of mutations account for the majority of CF alleles. The most frequent mutation is c.1521_1523delCTT (p.Phe508del), commonly known as deltaF508. This mutation is a 3-base pair deletion that accounts for approximately 70 % of CF chromosomes worldwide; thus, approximately half of CF patients are homozygous for deltaF508. The mutations and their frequency vary by ethnic group.

CFTR gene mutations and variants that reduce but do not destroy CFTR protein function are associated with "non-classic CF," the clinical spectrum of which includes chronic respiratory problems such as rhinosinusitis, chronic pancreatitis, and isolated CBAVD. The presence of a variant with less impact on CFTR protein function on one chromosome, in combination with a classic CF mutation on the opposite chromosome (in *trans*), may lead to non-classic clinical features of CF (Fig. 13.1). Males with CBAVD have an increased frequency of mutations in one or both *CFTR* alleles or an incompletely penetrant mutation (the intron 8-variant c.1210-12T[5T], commonly known as the 5T allele) in a noncoding region of *CFTR*. These men usually have no pancreatic disease and may have normal, borderline, or elevated sweat electrolytes. Small subsets of individuals with non-classic CF have chronic *Pseudomonas* bronchitis, normal pancreatic function, and normal or

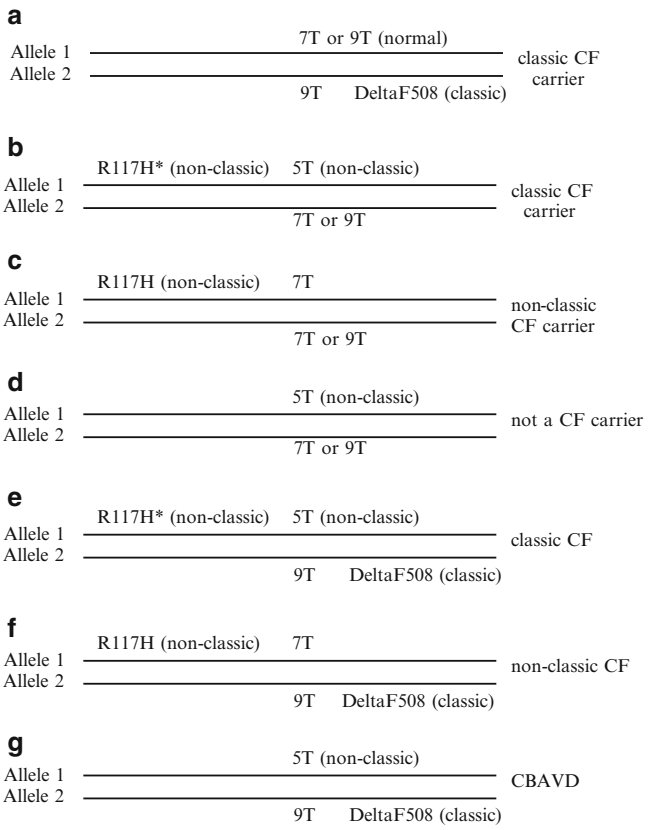

Figure 13.1 Examples of allelic configurations and their interpretations in carrier testing (**a**–**d**) and diagnostic testing (**e**–**g**) when classic or non-classic mutations are detected. *c.350G>A (p.R117H) and c.1210-12T (intron 8 5T/7T/9T) are the most frequently occurring non-classic *CFTR* gene variants. Other non-classic variants detectable by sequence analysis have been described

intermediate sweat electrolytes. Asymptomatic infants identified by NBS with an elevated immunoreactive trypsinogen (IRT), one classic *CFTR* gene mutation, and a borderline sweat test are given the diagnosis *CFTR*-related metabolic syndrome (CRMS) until it is known whether they will manifest clinical features of CF.

Clinical Utility of Testing

Due to the high frequency of CF, *CFTR* mutation analysis is useful for a variety of clinical indications, including NBS, diagnostic testing, carrier screening, and prenatal diagnosis for at-risk pregnancies. Biochemical testing is used to augment molecular methods for NBS and diagnostic testing. Carrier and prenatal testing relies solely on molecular testing.

Newborns with CF tend to have elevated levels of blood IRT. Although these levels fall within a few weeks after birth, elevated IRT is a reliable biochemical marker to identify newborns at increased risk for CF. NBS is performed in all states and many foreign countries using IRT alone or in combination with molecular testing. If IRT alone is used, a second sample is typically collected and those newborns with two elevated IRT results are called screen positive and are referred for further testing (IRT-IRT model). In a model where *CFTR* mutation analysis is performed on the original sample for those with an elevated IRT (IRT-DNA model), infants with one or two *CFTR* mutations identified are called screen positive, and those with two mutations have a presumptive diagnosis (for review, please see the CLSI Approved Guidelines for Newborn Screening for Cystic Fibrosis [3]). Diagnosis of infants with presymptomatic CF leads to better management and long-term outcomes, a fact underscored by a recommendation from the ACMG to include CF as one of their 29 recommended "core conditions" for uniform NBS in the USA [4].

In a symptomatic individual, the identification of two classic *CFTR* mutations is sufficient to establish a diagnosis for CF; however, sweat testing remains the diagnostic gold standard as recommended by the CF Foundation [5]. In the majority of classic CF cases, both mutations can be identified by a panel of common mutations. For symptomatic individuals in whom two of the common mutations are not identified, full *CFTR* gene sequencing and, if necessary, *CFTR* gene deletion/duplication analysis are useful to determine the likelihood that the individual's clinical features are part of a *CFTR*-related disorder. The availability of both biochemical and molecular diagnostic tests is particularly useful for individuals with non-classic clinical presentations and normal or borderline sweat tests, at-risk newborns from whom it is difficult to collect sufficient quantities of sweat, and individuals in whom one classic *CFTR* mutation and one *CFTR* variant of uncertain or unknown clinical significance have been identified. Identification of familial mutations is useful for testing at-risk relatives.

In 1997, a National Institutes of Health Consensus Development Conference recommended CF carrier testing for all couples planning a pregnancy, regardless of family history. However, at that time, there was no standardization of CF testing among laboratories and no commercially available reagents or kits. The largest challenges to standardize mutation panels were the ethnic diversity and admixture of the US population, which complicated the selection of mutations for a standardized screening panel. The ACMG and the ACOG recommended a panethnic panel of 23 mutations (which was revised from an original 25 mutations) that occur at a frequency of >0.1 % in any of the major US ethnic groups, plus reflex testing for four additional sequence variants under specified conditions (Table 13.1) ([6–8], revised 2011). These organizations developed and distributed an educational document entitled "Preconceptual and Prenatal Carrier Screening for Cystic Fibrosis" to the members of ACMG and ACOG, and established CF carrier screening as a standard of care in the USA.

Vendor	**Abbott/Celera**	**Autogenomics**	**Elucigene/GenProbe**	**Luminex**	**Hologic**	**Innogenetics**	**GenMarkDx**	**Illumina, Inc. (San Diego, CA)**
Platform	PCR target amplification, OLA, and capillary electrophoresis	PCR target amplification, and hybridization to BioFilmChip microarray	ARMS target amplification, ARMS, and capillary electrophoresis	PCR target amplification, allele-specific primer extension, hybridization to universal tags, and sorting on Luminex 100 analyzer	PCR and signal amplification and FRET detection	PCR target amplification and reverse ASO	PCR target amplification, chip hybridization, and detection on an electronic microarray	Sequencing by synthesis
Product or platform name	Oligonucleotide Ligation Assay 16-capillary CEGA	INFINITI™ CFTR31	Elucigene CF-EU	TAG-IT CF39, TAG-IT CF60, TAG-IT CF71	InPlex	Inno-LiPA CFTR	eSensor® Cystic Fibrosis Genotyping Test	MiSeqDx Cystic Fibrosis 139-Variant Assay, MiSeqDx Cystic Fibrosis Clinical Sequencing Assay
Regulatory status	US FDA cleared	Research use only/CE marked	CE marked (not available in the USA)	US FDA cleared	US FDA cleared	Research use only	US FDA cleared	FDA-cleared

ARMS amplification refractory mutation system, *ASO* allele-specific oligonucleotide, *CEGA* capillary electrophoresis genetic analyzer, *FRET* fluorescence resonance energy transfer, *OLA* oligonucleotide ligation assay, *PCR* polymerase chain reaction

Prior to the cloning of the *CFTR* gene, couples learned that both parents were CF carriers upon the birth of an affected child. No robust assays were available to assess a subsequent pregnancy with a 1 in 4 risk of CF. Now, the most common indication for mutation analysis is direct heterozygote detection for carrier risk revision for a couple either for pregnancy planning or screening.

The ACMG/ACOG panel is not designed for diagnostic testing for individuals with clinical features of classic or non-classic CF or men with CBAVD, although the panel is often used as an initial screen in these clinical settings. A larger mutation panel provides increased detection for symptomatic individuals.

Analysis is used for fetal testing of pregnancies with a 1 in 4 risk for which both mutations have been identified in the two carrier parents. Fetal or prenatal testing often is offered in lower risk pregnancies presenting in the second trimester on ultrasound with fetal EB. EB is associated with an increased risk for CF (2–20 %) in the absence of a positive family history. Mutation analysis of the parents of a fetus with EB may reveal that both are carriers, but often neither or only one parent carries a common *CFTR* mutation. Fetal diagnosis can determine that a heterozygous parent has transmitted an identified mutation, but there is no additional testing offered to further clarify the fetal CF status. In such cases of EB, Bayesian analysis is used to modify the risk.

Furthermore, some clinicians submit a fetal sample without testing the parents, and formal genetic counseling may not be offered to the couple until the laboratory testing has been completed.

Available Assays

Currently, there are several available testing platforms. Technical standards and guidelines for CF mutation testing have been published by the ACMG ([6], revised 2011) and are available at www.acmg.net. These guidelines address the technology platforms used with commercial kits and reagents for laboratory-developed tests (LDTs) for CF mutations. Currently available commercial kits and reagents for LDTs are summarized in Table 13.2. All are robust and include at least the ACMG/ACOG minimum core mutation panel, but vary considerably with respect to criteria that laboratories consider for platform adoption: reagent/royalty costs, footprint of instrumentation, throughput, flexibility, and data analysis.

Reflex testing for the c.1210-12T (intron 8 5T/7T/9T) sequence variation is specifically recommended by ACOG/ACMG for individuals with an identified c.350G>A (R117H) mutation, since 5T vs 7T or 9T *in cis* increases CF severity in a compound heterozygote with a second CF mutation. Note that some assay platforms may only reveal the c.1210-12T (intron 8 5T/7T/9T) results if a c.350G>A (R117H) mutation is identified. Since some methodologies do not distinguish between c.1521_1523delCTT (deltaF508) and other alterations in close proximity, a second reflex to three exon 10 sequence variants [c.1516A>G (I506V), c.1519A>G (I507V), c.1523T>G (F508C)] is recommended when an unexpected homozygous c.1521_1523delCTT (deltaF508) or c.1519A>G (I507V) mutation is detected to avoid reporting of false-positive results due to interference by these surrounding polymorphisms. Most available kits or reagents include these nonpathogenic exon 10 reflex sequence variants.

The Abbott/Celera platform offers both semiautomated and automated detection and data analysis and requires capital purchase of an instrument with a relatively large footprint. The automated assay format is useful for high-volume testing.

The Innogenetics assay is a reverse allele-specific oligonucleotide test that can be semiautomated using a customized instrument. The assay is amenable to low and high test volumes. Manual analysis of the strip data is required.

The Elucigene assay features capillary electrophoresis detection of sequence-specific primer amplicons and provides an expanded mutation panel specific to European populations. This platform is not available in the USA.

The Luminex assays incorporate multiplex PCR and multiplex allele-specific primer extension with a proprietary universal tag sorting system (xTAG® Technology) on the Luminex 100/200 Analyzer. This is a high-throughput assay that incorporates automated software analysis for genotype calls.

The Autogenomics and GenMarkDx systems are microarray assays that are partially amenable to automation. With lower throughput than some other assays, these assays may be optimal for laboratories with small test volumes. Both platforms also have flexibility to use other non-CF reagents on the same system.

The Hologic assay only requires manual pipetting steps which can be automated using a liquid handler. Thus, this assay is potentially of low cost, requiring only a fluorescent plate reader. The assay is unique among CF assays by combining limited cycles of PCR with signal amplification using the Invader® FRET technology. Because this assay format cannot be multiplexed, the detection steps are performed on a custom "InPlex" card, in which reaction products are distributed to wells of dried-down reagents, each specific for the detection of a single-mutant allele.

DNA sequencing and deletion/duplication analyses are laboratory-developed tests validated and performed in high-complexity laboratories in the USA. *CFTR* gene sequencing refers to DNA sequencing of the *CFTR* exons and intronic borders. Newer sequencing technologies' cost is decreasing to perform the assay. In an affected individual, if two mutations are not identified by targeted mutation analysis and gene sequencing, or if unexpected homozygosity for a rare mutation is identified, deletion/duplication testing may be warranted. Commercial reagents are available (MRC-Holland, Amsterdam, the Netherlands) for laboratory-developed deletion/duplication testing.

Interpretation of Test Results

The majority of *CFTR* gene mutations can be detected by targeted mutation analyses, which have only three possible results: detection of no, one, or two mutations. However, reporting of CF results is complex because the mutation detection rate in a targeted mutation assay is less than 100 %. The interpretation and subsequent recommendations are dependent on the indication for the test and the ethnicity and family history of the individual. In cases where *CFTR* gene sequencing or deletion/duplication analysis is warranted, interpretation of test results is more complex and should be performed in a laboratory with experience in interpretation of these test results in collaboration with a medical geneticist or genetic counselor.

In the majority of CF NBS programs, infants with an elevated IRT NBS test result are tested for a panel of classic

CFTR mutations. An infant with two classic *CFTR* mutations is presumed to have a diagnosis of CF; however, confirmatory studies such as a sweat testing and molecular testing on a new blood sample are standard practice to assure proper identification of the infant specimen. Infants with one mutation identified are at an elevated risk for CF (approximately 1 in 10). In infants with an elevated IRT and one *CFTR* mutation, a normal sweat test confirms carrier status and an abnormal sweat test confirms a diagnosis of CF; however, a borderline sweat test may indicate non-classic CF. If the sweat test results indicate classic or non-classic CF, *CFTR* gene sequencing is indicated to identify rare or private *CFTR* gene mutations and variants. Infants with an elevated IRT and no classic *CFTR* mutation are presumed to be NBS false positives, but should be referred for further evaluation if symptoms of CF develop. It is important to note that infants with meconium ileus tend to have normal IRT levels and therefore a normal CF NBS.

For individuals with symptoms of CF, finding of two *CFTR* mutations confirms a diagnosis of CF. However, genotype-phenotype relationships are not adequately established to make prognostic interpretations for the many possible homozygous and compound heterozygous genotypes. The interpretation of one or no detected mutations for a symptomatic individual must include a statement of limitations of the targeted assay, a recommendation for *CFTR* gene sequencing and/or deletion/duplication analyses, and consultation with a CF specialist. Referrals for CF diagnostic testing may include older children and adults with features of non-classic CF, for example chronic respiratory problems, isolated pancreatitis, or male infertility. In such cases a *CFTR* classic mutation panel is unlikely to fully explain the clinical symptoms (Fig. 13.1), but identification of a single mutation would be a strong indicator that full gene sequencing and/or deletion/duplication analysis are warranted.

Since the publication of the ACMG/ACOG recommendations, more than 95 % of all DNA testing for CF is for carrier screening in a prenatal or pregnancy setting. Although the finding of one mutation in a couple is straightforward, the majority of these pregnancy planning carrier-screening tests are negative, with no mutations detected. In the setting of a negative test result, the physician must be informed that the revised carrier risk, while reduced from the prior risk, is not eliminated because the mutation detection is incomplete. As shown in Table 13.3, both the prior and revised carrier risks are dependent on individual ethnicity and family history. Prior carrier risks are based on pedigree analysis. For example, risks for a non-Hispanic Caucasian individual vary from a high of 2 in 3 for an individual with an affected sibling to approximately 1 in 25 for an individual with no family history.

Prior carrier risks for individuals without a family history of CF are calculated from the ethnic frequency of CF, which is highest among non-Hispanic Caucasians (1 in 25), lower in Hispanics (1 in 46) and non-Hispanics of African descent (1 in 62), and lowest among Asians (1 in 90). Revised risks also are based on the frequency of the tested mutations in the individual's ethnic group. The frequency of mutation detection using the ACMG/ACOG panel ranges from 97 % for individuals of Ashkenazi Jewish descent to 57 % for Hispanics, and 49 % for Asians. Risk revision is even more complicated for individuals of mixed heritage.

Table 13.3 Prior and residual CF risks for individuals with a negative carrier test for Caucasian, European: 90 % detection

Affected relative	Prior risk	Revised risk
No affected relative	1 in 25	1 in 241
Sibling	2 in 3	1 in 6
Niece/nephew/half-sibling	1 in 2	1 in 11
Aunt/uncle	1 in 3	1 in 21
First cousin	1 in 4	1 in 31

Responsible reporting for *CFTR* mutation test interpretation should include a clear statement of test limitations. Often, samples are referred for testing without individual ethnicity information provided to the testing laboratory for calculation of risk; therefore, a table of residual risks for Ashkenazi Jewish, Caucasian, Hispanic, African American, and Asian individuals for the test performed should be provided. Such a table is also useful for individuals of mixed ancestry since their residual risk would be intermediate between two or more groups. For individuals with a family history of CF a recommendation for a medical genetics consultation or genetic counseling is appropriate since a more precise risk assessment can be made if the familial mutations are known.

The published ACMG/ACOG recommendations include model laboratory reports for detection of no or one mutation in a carrier-screening context for individuals with a negative personal and family history [7]. These model reports also are included in the educational materials that have been distributed to the members of ACOG and ACMG. They contain a field for patient ethnicity, but the interpretation is not patient specific. In the model mutation-negative report, the prior and revised carrier risks for all ethnicities are presented in the interpretation field in a tabular format.

Laboratories can anticipate the most common reporting formats and prepare standard template reports. This approach accommodates high test volumes while maintaining reporting standards. Each report should contain a statement that the carrier risk of the consultant is reduced but that the risk for having a child affected by CF is also a function of the partner's carrier status. In this way, the non-zero value of the revised risk for a negative test is emphasized as well as the interplay of the genotypes of both parents.

Although the ACMG/ACOG mutation panel is designed for carrier screening of individuals without a family history of CF, individuals with an affected relative often are referred for carrier risk testing, and the same screening mutation panel is used. Often the affected family member has not been tested and the familial mutations are not known, or the mutation has been identified but the information is not available to the at-risk relative. Reports should clearly state that the intended use of the mutation panel is for individuals without a family history of CF to alert the physician that residual carrier risk after a negative test is modified by this history. Table 13.3 illustrates the benefit of identifying familial mutations, thereby allowing a yes or no answer to carrier status, vs not identifying the familial mutation and relying on risk reduction alone even when the affected individual is more distantly related. The report also may include a recommendation that the physician refer individuals with a positive family history for genetic counseling and Bayesian calculation of revised carrier risk (see Chap. 5). If a laboratory has the expertise and sufficiently reliable clinical information, individual-specific revised risks may be reported. All such reports should include an individual-specific revised risk calculation, a recommendation for genetic counseling and a statement that the residual risk would be significantly modified if the familial mutations are known.

Reporting for most of the possible positive results in a carrier test is straightforward and, as recommended by ACMG/ACOG, should always contain a recommendation for genetic counseling and a comment that at-risk relatives also may benefit from genetic counseling and mutation analysis for carrier risk revision. As recommended by ACMG/ACOG, interpretation of positive results for the c.350G>A (R117H) mutation should always be made in the context of the individual's genotype for the c.1210-12T (intron 8 5T/7T/9T) sequence, since expression of the c.350G>A (R117H) mutation in a compound heterozygous child is variable, depending on the specific genotypic combination (Fig. 13.1). The c.350G>A (R117H) mutation is most severe when on the same allele as the 5T variant. The reflex of an unexpected c.1521_1523delCTT (deltaF508) homozygous result in a healthy adult to testing for other exon 10 sequence variations [c.1516A>G (I506V), c.1519A>G (I507V), c.1523T>G (F508C)] is necessary to prevent false-positive results, since some detection platforms (e.g., probe hybridization) do not discriminate the c.1521_1523delCTT (deltaF508) mutation from these polymorphisms.

For fetal testing, laboratories may request or require CF carrier screening results of both partners. Parental results influence the interpretation of fetal results particularly when one or both are found to be carriers. Partners often have different last names, they may be tested at different times or in different laboratories, or the laboratory volume can be high enough that partners are not recognized during CF testing. The nongeneticist physician usually can communicate a 1 in 4 risk to couples who are both carriers, but may not have the experience to provide a fetal risk assessment when only one partner is a CF carrier and the other does not carry a common mutation. Effective ways to communicate the results and interpretations of a complex genetic test to a nongeneticist physician, enabling him or her to make appropriate management decisions, is an area of ongoing research [9, 10]. Successful carrier testing for CF depends on many factors, the most important of which is physician education to react appropriately to the complex scenarios that occur in patients and couples.

Laboratory Issues

Targeted mutation panels are designed to test for the most common variants, but rare variants can interfere with the assay and cause false results, for example due to allele drop-out. In some cases, the variants may occur under primers and probes and present as homozygosity for rare mutations or amplicons may fail to amplify. Laboratories often provide disclaimers on reports indicating the possibility of such rare events. In cases of homozygosity for rare mutations, follow-up by DNA sequencing and/or duplication/deletion analysis or family studies to establish biparental inheritance may be warranted. Additional family members also can be tested, if available, and may provide useful information for interpretation of results in the proband.

Predicting a genotype-based phenotype is imprecise and is not recommended as there are often additional variants or modifiers of mutations present. For example, two (or more) variants may be present on the same chromosome (in cis) and are often referred to as "complex alleles." Parental studies may be needed to confirm if complex alleles are present. A relatively common example is c.1210-12T (intron 8 5T/7T/9T) and c.350G>A (p.R117H).

Reference materials and controls are important for assay validation and quality control. Although kits and reagents for targeted CF mutation testing are commercially available, most do not include positive controls for all of the mutations. Commercially available controls can be obtained from several sources (www.cdc.gov/dls/genetics/rmmaterials). One source is Maine Molecular Quality Controls, Inc. (Scarborough, ME) that offers a variety of synthetic *CFTR* mutation panel control reagents, one of which includes the 23 ACMG/ACOG recommended mutations. In addition, the Coriell Cell Repository (Camden, NJ) offers a set of DNAs that contains a complete set of verified mutations in the ACMG/ACOG panel. The Coriell Cell Repository also has verified reference materials for several other CF mutations. The Centers for Disease Control and Prevention Newborn Screening Quality Assurance Program (NSQAP) provides reference materials for IRT-level testing and consultation

and training for laboratories offering NBS for CF (www.cdc.gov/labstandards/nsqap).

Proficiency testing or external quality assessment programs for CF testing ensure the quality of the testing laboratory. For molecular testing, the College of American Pathologists (CAP), jointly administered by the ACMG and CAP, and European CF-EQA provide such programs. For NBS, NSQAP oversees proficiency testing for IRT and DNA tests.

Deafness

14

A. Eliot Shearer, Robert W. Eppsteiner,
and Richard J.H. Smith

Abstract

Deafness is the most common sensory deficit in humans. Genetic diagnosis has traditionally been difficult due to extreme genetic heterogeneity and a lack of phenotypic variability. For these reasons multi-gene screening panels have been adopted. While these methods make comprehensive genetic testing possible, interpretation of the many variants is difficult, specifically, differentiating novel benign variants from novel deafness-causing variants. This chapter describes methods for the genetic diagnosis of deafness with particular attention to multi-gene screening panels.

Keywords

Hearing loss • Deafness • Genetic testing • Massively parallel sequencing • GJB2

Introduction

Deafness is the most common sensory deficit in humans, affecting 1 of 500 newborns [1]. The relative contributions of syndromic and non-syndromic deafness to the total deafness genetic load vary with age of ascertainment. About 70 % of congenital hereditary deafness is non-syndromic (non-syndromic hearing loss, NSHL) with the remaining 30 % accounted for by a large number of different syndromes (SHL). In developed countries, most NSHL (80 %) is due to a genetic cause. Because syndromes are generally straightforward to recognize, most are identified at birth with the notable exceptions of Usher syndrome and Pendred syndrome. With both of these common recessively inherited types of SHL, deafness is the only immediately apparent phenotype.

Comprehensive genetic testing for deafness has been difficult because of significant genetic heterogeneity: 57 NSHL genes have been identified since the first gene was cloned in 1995 (http://www.hereditaryhearingloss.org) and more than 1,100 causative allelic variants have been reported in these genes (http://www.deafnessvariationdatabase.org). Traditionally, hereditary deafness is distinguished from non-genetic causes of deafness (often referred to as acquired deafness) by medical and family history, physical examination, and audiologic testing, in some cases aided by ancillary tests such as temporal bone imaging, urinalysis, thyroid function studies, and electrocardiography. However, even using this test battery, an unequivocal distinction between heritable and environmental causes of deafness can be difficult. If comorbid conditions are identified, deafness may fall into one of more than 400 recognized types of SHL, but if hearing is the only abnormality, the basis for the diagnosis of hereditary deafness is often exclusionary in the absence of some type of genetic testing.

This paradigm is shifting rapidly with the use of massively parallel sequencing methods, which provide the ability to screen thousands or millions of DNA base pairs simultaneously. Genetic testing for NSHL is uniquely suited to take advantage of these technologies due to its genetic heterogeneity, which makes multi-gene screening panels the logical default option. Today, genetic testing for apparent NSHL is the first test that should be ordered after history,

physical examination, and audiometry. This comprehensive genetic testing can unequivocally diagnose hereditary hearing loss, provide prognostic information, and help dictate further patient management.

While these technologies hold the promise of personalized genomic medicine, they are accompanied by specific challenges with respect to assay design and implementation, the interpretation of results, and the ethical issues that may arise. Particularly challenging is differentiating variants of unknown significance (VUS) or novel variants predicted to be pathogenic but without an established record of pathogenesis from true disease-causing mutations. With these technologies, the testing focus is heavily shifted towards data interpretation rather than data generation. At present, screening of a single gene, *GJB2*, using Sanger sequencing remains a cost-effective option and is prudent in patients with apparent congenital autosomal recessive NSHL (ARNSHL) prior to embarking on a multi-gene screen. For this reason, testing of this single gene is discussed separately from multi-gene screening strategies.

Molecular Basis of Disease

In 1994, Guilford et al. mapped the first locus for ARNSHL to chromosome 13q12-13 and named it DFNB1, nonsyndromic hearing loss and deafness (Online Mendelian Inheritance in Man [OMIM; database online] #220290) [2]. Three years later, the deafness-causing gene at this locus was identified as *GJB2* [3]. Of relevance to genetic testing, mutations in *GJB2* are causative in up to 50 % of individuals with severe-to-profound congenital ARNSHL in several worldwide populations. No other gene makes up such a significant proportion of genetic deafness [4].

Since the discovery of *GJB2*-related deafness, our understanding of the biology of hearing and deafness has advanced tremendously through the identification of genetic pathologies that lead to deafness in animal models and humans. Mutations have been identified that affect almost every part of the organ of Corti: the cellular cytoskeleton, including actins (*ACTG1*) and actin-associated genes (*TRIOBP* and *RDX*); myosins (*MYO7A*, *MYO15A*, *MYO6*, *MYO1A*, *MYH9*, *MYH14*); cell-cell junctions (*OTOA*, *CLDN14*); cell-cell attachments (*CDH23*, *PCDH15*); gap-junctions (*GJB2*, *GJB6*); transporters (*SLC26A4*); and ion channels (*KCNQ4*).

Clinical Utility of Testing

The primary goals in obtaining a molecular diagnosis of apparent NSHL are (1) to preclude unnecessary diagnostic testing (for example, CT scanning of the temporal bones) and define possible medical comorbidities (for example, visual problems that will develop in Usher syndrome); (2) to provide families with genetic counseling and allay parental/family concerns; and (3) in the future to guide treatment options to remediate the hearing loss [5–7].

Available Assays

GJB2 Single-Gene Screening

Historically, a number of mutation detection strategies have been used to screen *GJB2* for nucleotide changes, including restriction enzyme digestion, allele-specific polymerase chain reaction, single-strand conformation polymorphism (SSCP), heteroduplex analysis (HA), denaturing high-performance liquid chromatography, and Sanger sequencing. Of these methods, SSCP and HA were among the first and most commonly used methods because of their simplicity and cost-effectiveness. However, the gold standard is bidirectional Sanger sequencing.

Although *GJB2* is a small gene with only a single coding exon, more than 100 different allele variants are associated with both ARNSHL and autosomal dominant NSHL (ADNSHL). These variants, scattered throughout the gene, make mutation screening of the entire coding sequence essential. Phenotypic-genotypic studies of *GJB2*-associated deafness have provided important insights that are invaluable for genetic counselors. For example, cross-sectional analyses of *GJB2* genotypes against audiometric data from 1,531 persons with ARNSHL ranging from mild-to-profound identified a total of 177 different genotypes. The degree of hearing loss associated with biallelic truncating mutations was significantly more severe than the hearing loss associated with biallelic non-truncating mutations. Several common mutations (M34T, V37I, L90P) were associated with mild-to-moderate hearing loss (median 25–40 decibels [dB]), and two genotypes [35delG/R143W (median = 105 dB) and 35delG/del(GJB6-D13S1830) (median = 108 dB)] had significantly more severe hearing loss than 35delG homozygotes [8].

The identification of a single deafness-causing allele variant in *GJB2* is not uncommon and implies the presence of a "missed" variant in a noncoding region or coincidental carrier status in a person with deafness of another etiology. These types of challenges are multiplied when more comprehensive multi-gene panels are used for diagnosis and stress the need for phenomic approaches to the interpretation of genomic data.

Multi-Gene Panels

Massively parallel sequencing (MPS, also called next-generation sequencing or NGS) identifies many genetic variants and the interpretation of these variants is key to

rendering a genetic diagnosis. As a bridge between Sanger sequencing of a single gene and exome or genome sequencing, targeted genomic enrichment (TGE) isolates a subset of genes from genomic DNA for more targeted sequencing. TGE is especially well suited to multi-gene screening panels and has been quickly adopted for several diseases, including deafness, because of a relatively low-cost but high-yield result. During library preparation, molecular barcodes can be added to an individual's DNA sample to ensure that data are correctly matched with a specific patient. Barcoding also allows multiple samples to be pooled in a single sequencing run, which improves the cost-effectiveness of the testing.

An alternative technology that has been used for genetic testing for deafness is resequencing arrays. While these arrays are cost effective, they are limited by the number of base pairs that can be sequenced on a single array. For deafness testing, no arrays are available that interrogate every base pair of every gene implicated in NSHL. In contrast, TGE followed by MPS provides a comprehensive genetic assessment for deafness.

MPS is extremely reliant on bioinformatic analysis of the sequencing data. Following TGE and sequencing, a typical workflow involves de-multiplexing sequencing reads, mapping reads to the human reference genome, and then identifying and annotating variants. Variants are then prioritized to determine the variant(s) most likely to cause deafness. Use of both publicly available databases (i.e., 1000 Genomes, dbSNP) and laboratory-developed databases is essential for variant filtering. A freely available central repository of variants specific to deafness is available at http://www.deafnessvariationdatabase.org.

Interpretation of Results

GJB2 Single-Gene Screening

Several databases of *GJB2* deafness-causing variants exist and should be consulted for interpretation of results (Connexin-deafness homepage http://davinci.crg.es/deafness/; http://www.deafnessvariationdatabase.org). The carrier rate for pathogenic *GJB2* variants is high enough that a single mutation is not diagnostic of *GJB2*-related deafness. If the full sequencing of *GJB2* (exon 1, coding regions, splice sites, and upstream deletions) does not identify two disease-causing variants, then testing with a multi-gene panel is recommended. Multi-gene panel testing also should be considered in instances of obvious *GJB2* genotype-phenotype discordance.

Table 14.1 Evaluation of targeted genomic enrichment assays: a sample summary of variants

Sample evaluation—targeted genomic enrichment	
Sample ID	112111-3
Phenotype	High-frequency SNHL
Exons targeted	1,357
Bases targeted	351,522 base pairs
Metric	**Result (reference range)**
Total reads	28.2 million (14–32 million)
% Reads mapped	97.2 % (94.3–98.7 %)
% Reads overlapping target	61.0 % (58.1–63.9 %)
Targets covered at 1×	98.8 % (98.6–98.9 %)
Targets covered at 10×	98.2 % (97.5–98.2 %)
Total variants identified	335 (300–400)
Rare variants (≤1 %)	87 (60–100)
Exonic or splice site variants	19 (10–30)
Non-synonymous/indel/splice site variants	7
Variants of unknown significance	4
Known disease-causing mutations	0
Candidate mutations for deafness	2

Multi-Gene Panels

Evaluation of the quality of the targeted enrichment and the sequence reads is essential. Typical metrics to consider are overall sequence data generation, read quality, percent of reads that map to the human genome, percent of reads that overlap the targeted genes, and the depth of coverage of the targeted regions (Table 14.1).

Variants are typically annotated with the following: gene, location (exonic/intronic/splice site/intergenic/noncoding RNA), nucleotide change, amino acid change, presence in publicly available databases (1000 Genomes, dbSNP), and scores in pathogenicity prediction algorithms (Polyphen, PhyloP, SIFT). Variants are then prioritized to identify those most likely to be disease causing; variants previously reported as disease-causing mutations (DCMs) are most likely to be causative. In general, if no DCMs are identified, the prioritization strategy adheres to two generally accepted tenants of human disease genetics: (1) DCMs will be rare; and (2) DCMs will have a significant functional impact on the protein. An algorithm for variant prioritization is included in Fig. 14.1.

Determining the population frequency of a variant is greatly facilitated by dbSNP and the 1000 Genomes Project, where millions of genomic variants from large sequencing projects are publicly available. Of particular importance are well-curated, locus-specific databases and laboratory-developed variant databases, which can provide significant

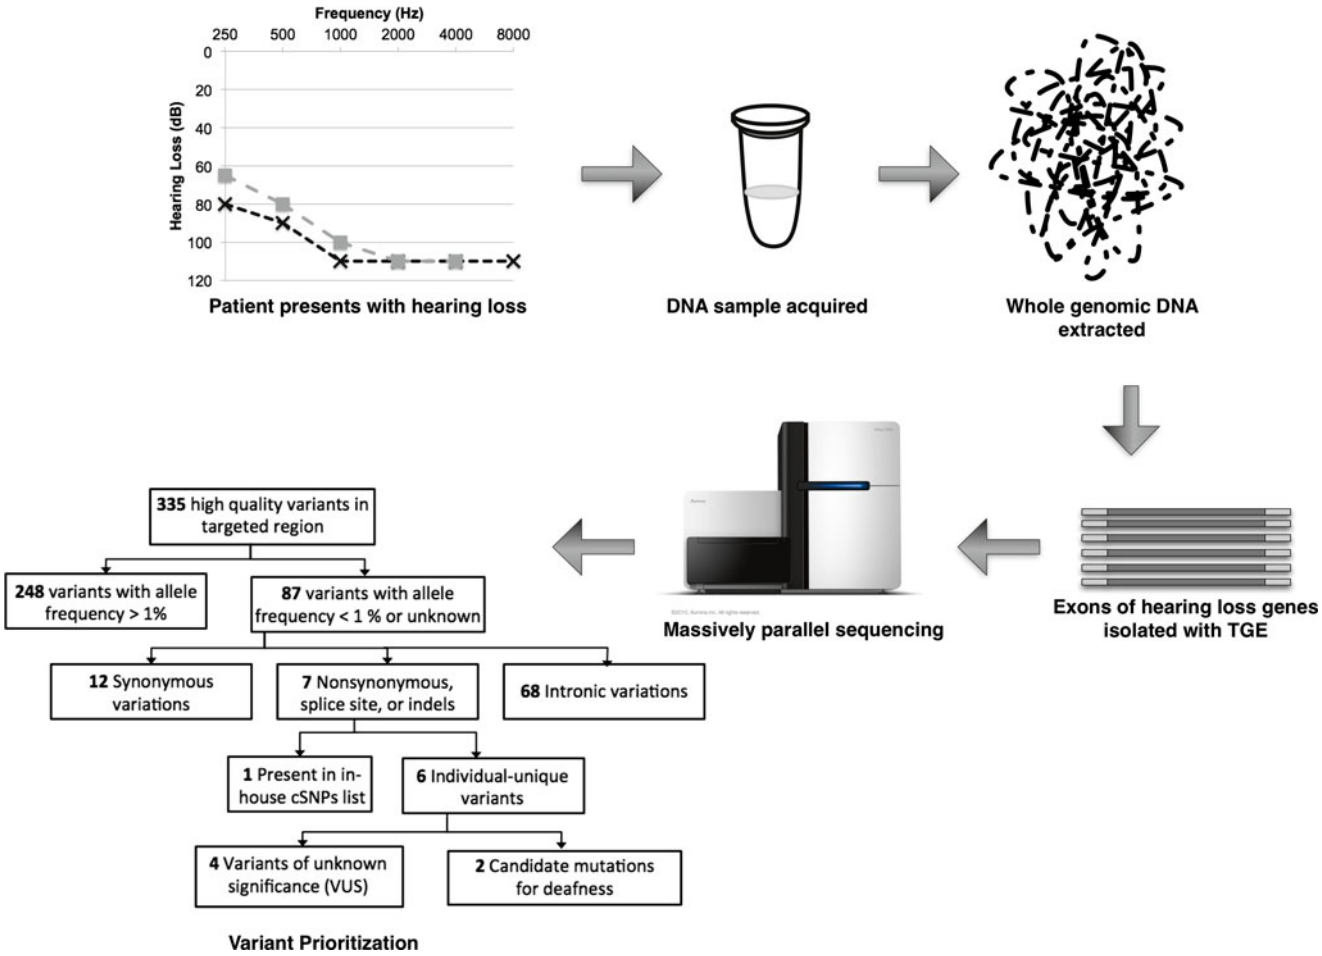

Figure 14.1 Overview of multi-gene screening panel for deafness using targeted genomic enrichment (TGE). After DNA is isolated, exons of interest (every exon of every known hearing loss gene) are isolated via TGE. Massively parallel sequencing yields millions of sequencing reads that are assessed for quality and aligned to the reference human genome. Variants are compared to the reference genome for annotation and prioritization to identify those changes that are most likely to be deafness causing, as described in detail in the text

data on variant frequency for TGE assays. The functional effect of a genetic variant is most easily interpretable when it is non-synonymous, affects a splice site, or is an insertion/deletion that causes a frameshift. Variants located outside the coding sequence are more difficult to interpret.

Frequently, several rare variants cannot be further prioritized based on database comparison and gene effect assessment. In silico pathogenicity algorithms can be used to predict the significance of these variants. For example, evolutionary conservation of the variant location (BLOSUM), comparison of the physical characteristics of the most common and the variant amino acids (Align-GVGD), and protein-specific annotation and functional consequence of changes (SIFT and PolyPhen) can provide insight into the possible pathogenicity of VUS. These in silico methods do not replace in vitro or in vivo experimentation, but provide the only mechanism to assess the large numbers of variants expeditiously. When these four specific methods are concurrent on pathogenicity, the positive predictive value is >94 % [9]. The alternative, to invest significant time and effort completing functional assays, would reduce the clinical usefulness of genetic testing in many instances.

A complementary technique for filtering is based on the patient's phenotype. In the case of NSHL, particularly ADNSHL, audiograms can be used to filter variants. For example, DCMs in *WFS1* are associated with an audio profile characterized by low-frequency NSHL; DCMs in *KCNQ4*, in contrast, cause high-frequency NSHL. Prioritizing the significance of identified variants based on a patient's clinical characteristics will play an increasingly large role as more genotype-phenotype correlation data are available.

Laboratory Issues

GJB2 Single-Gene Screening

Determination of *GJB2*-related deafness is dependent on the identification of mutations in the DNA of affected individuals. Sequencing of only exon 2 of *GJB2* by any technique is

incomplete because there are several common noncoding, noncomplementary DFNB1-causing mutations that must be considered in persons heterozygous for a known *GJB2* deafness-causing variant. These mutations include those found in intron 1 and a few large deletions involving *GJB6* [DFNB1B (MIM 612645)] or both *GJB2* and *GJB6* that are easily detectable by sequencing across the breakpoint fragments or by MPS of a multi-gene panel for deafness. Based on the relative frequency of *GJB2* allele variants in the general population, the frequency of noncoding *GJB2* variants associated with deafness, and phenotype-genotype correlations, ongoing studies of *GJB2*-related deafness have confirmed the existence of at least one additional variation associated with the DFNB1 phenotype that lies outside the coding region of *GJB2* [10].

Multi-Gene Panels

Due to the capacity of next-generation sequencers, bar-coded genomic libraries from several individual patients frequently are pooled prior to sequencing. Due to the large output associated with these assays, data storage and the documentation and maintenance of the bioinformatics infrastructure are issues that must be addressed in any clinical laboratory using this testing method. Due to the speed at which genomics is advancing, annotation and prioritization methods must be updated frequently to ensure that variants are reported correctly. Laboratories must consider whether to implement processes to modify earlier reports as new data are generated that potentially change the interpretation of the previous report. Examples include the addition of new genes to these platforms and the inclusion of intronic and promoter regions to allow the identification of noncoding deafness-causing variants. One important advance already realized has been the ability to complete comprehensive copy-number variant analysis of the genes included on the multi-gene panels currently in use. This type of analysis can detect *GJB2* and *GJB6* deletions and has implicated deletions of *STRC* as a very frequent cause of mild-to-moderate ARNSHL.

Laboratories must determine through their validation process whether DCMs will be validated by an alternative method such as Sanger sequencing to confirm the MPS results that are predicted to be clinically significant. If possible, limited segregation analysis should be completed. Laboratories also must have procedures that define which data will be stored and for what length of time. Screening controls to determine the population carrier frequency of identified variants is no longer necessary due to the prevalence of publicly available data. Processes for reporting of VUS results to healthcare providers, patients, and families also should be defined by the laboratory in collaboration with the healthcare providers.

Conclusions and Future Directions

Inherited deafness is uniquely suited to TGE and MPS because of its extreme genetic heterogeneity. Over the last 5 years, these technologies have transformed genetic testing for deafness from a gene-by-gene approach to a comprehensive and all-inclusive test. For the short term, initial screening of persons with severe-to-profound presumed ARNSHL for variants in *GJB2* is an acceptable option, with a negative result triggering a multi-gene screen. However, the capacity of MPS is rapidly expanding and costs are decreasing, making single-gene methods of very limited use. The currently used TGE platform for deafness is sufficiently flexible that more genes can be easily added with follow-up validation, ensuring a continually up-to-date platform. As clinicians become more comfortable with genomic medicine, comprehensive genetic testing for hearing loss will be an integral part of the clinical evaluation of patients and become the test of choice for a diagnosis of NSHL.

Coagulation Disorders

15

Rajiv K. Pruthi, Michelle L. Kluge, and Aneel A. Ashrani

Abstract

The vascular system is a series of interconnected biologic conduits filled with fluid moving under pressure. This system is subject to injury, with exsanguination avoided by the functions of the hemostatic system. Normal hemostasis is a reparative process and consists of three major mechanisms: (1) vasospasm, (2) platelet plug formation, and (3) the procoagulant system. While inherited or acquired disorders of all three mechanisms can cause clinically abnormal bleeding, this chapter reviews the molecular basis of the more commonly inherited disorders of the procoagulant system (e.g., hemophilia A and B, and von Willebrand disease) associated with abnormal bleeding.

Introduction

Reduced to its simplest form, the vascular system is a series of interconnected biologic conduits filled with fluid moving under pressure. This system is subject to injury, with repair required to avoid exsanguination. This latter function is provided by the hemostatic system. Thus, normal hemostasis is a reparative process and consists of three major mechanisms: (1) vasospasm, which is the main mechanism for controlling bleeding after transection/avulsion injuries of large arteries, arterioles, and veins; (2) platelet plug formation; and (3) the procoagulant

system. The procoagulant system consists of mechanisms by which fluid blood is converted into an insoluble hemostatic thrombus. While inherited or acquired disorders of all three mechanisms can cause clinically abnormal bleeding, this chapter reviews the molecular basis of the more commonly inherited disorders of the procoagulant system (e.g., hemophilia A (HA), hemophilia B (HB), and von Willebrand disease (VWD) associated with abnormal bleeding. Inherited vascular and platelet disorders associated with abnormal bleeding are not discussed.

Consider also that, once activated, the reparative (e.g., hemostatic) response to injury must be constrained such that the thrombus is limited to the site of injury, and is downregulated such that the conversion of fluid blood to solid thrombus does not propagate throughout the lumen of the vessel. This latter function is provided by the anticoagulant and fibrinolytic systems. Inherited disorders (deficiencies) of the anticoagulant system (e.g., familial thrombophilia) are associated with venous thromboembolism (VTE) and complications of pregnancy. In addition, inherited abnormalities of selected procoagulant proteins are associated with VTE. Although biologically plausible, the association between familial thrombophilia and arterial thrombosis is unproven and will not be reviewed.

Inherited Bleeding Disorders

The initial hemostatic response to endothelial injury is platelet adhesion to exposed subendothelial matrix. Platelets circulate preferentially along the vessel luminal surface, as opposed to circulating evenly distributed throughout the blood. Thus, platelets can be viewed as a "surveillance" blood cell that is "searching" for sites of endothelial injury. Platelet adhesion at an injury site is mediated by the ligand, von Willebrand factor (VWF). VWF tethers platelets to the site of injury by binding to collagen within the subendothelial matrix exposed by the injury, and to the constitutively active platelet receptor, glycoprotein (GP)-Ib-IX-V complex. Firm platelet adhesion at the injury site is mediated by subsequent binding of the platelet GP-$\alpha_2\beta_1$ collagen receptor to subendothelial matrix collagen. VWF binding to platelet GP-Ib-IX-V generates transmembrane signals that activate platelets, converting the constitutively inactive platelet fibrinogen receptor, GP-$\alpha_{IIb}\beta_3$ (GP IIb/IIIa), to the fibrinogen-binding conformation. Subsequent platelet-to-platelet cohesion is mediated by fibrinogen or VWF binding to platelet GP-$\alpha_{IIb}\beta_3$. In addition, a scramblase protein within the platelet membrane phospholipid bilayer flips negatively charged phospholipids from the inside to the outside membrane bilayer leaflet. The newly exposed negatively charged phospholipids support assembly of the plasma procoagulant factors on the platelet membrane. Finally, platelets release contents of the dense granules (adenosine diphosphate [ADP], serotonin, etc.) and α-granules (fibrinogen, VWF, factors V and XI, etc.), which feed back to stimulate further platelet activation and support the plasma procoagulant system.

The plasma procoagulant system has been characterized as a "cascade" of amplifying enzymatic reactions leading to the activation of the final serine protease enzyme, thrombin from prothrombin. This cascade is initiated by exposure of the coagulation activator, tissue factor, to circulating blood. Tissue factor, located within the vascular walls and normally sequestered from the circulation, is exposed to blood after blood vessel injury. Exposed (or expressed) tissue factor binds to circulating factor VII_a ($FVII_a$) to form a "Factor X-ase" activation complex which either cleaves ("activates") FX to FX_a directly or activates FIX to FIX_a (Fig. 15.1). Factor IX_a binds $FVIII_a$ to form a second Factor X-ase activation complex. Factor X_a binds FV_a to form the "prothrombinase complex" that activates prothrombin (FII) to thrombin (FII_a). The X-ase and the prothrombinase complexes assemble on negatively charged phospholipids within the outer membrane of activated platelets. Thrombin produces a hemostatic thrombus by cleaving fibrinogen (factor I) to form fibrin monomers, by activating platelets, and by activating FXIII to $FXIII_a$ which cross-links strands of fibrin monomers to form an insoluble hemostatic thrombus. In a feedback amplification loop, thrombin also increases its own production by activating FV, FVIII, and FXI.

Hemophilia A

Overview

HA is an X-linked recessive bleeding disorder due to a deficiency in coagulation factor VIII (FVIII). HA affects approximately 1 in 10,000 live male births, among all ethnic populations. Approximately 30 % of cases result from new mutations occurring in families in whom there is no apparent family history of HA. The diagnosis of HA is established based on reduced or absent FVIII activity (FVIII:C) and is classified into severe (<1 %), moderate (1–5 %), or mild (>5–40 %) disease, with estimated prevalence of 43 %, 26 %, and 31 %, respectively [1].

Molecular Basis of Disease

The factor VIII gene (*F8*) is located on the long arm of the X chromosome (Xq28) (Fig. 15.2). *F8* is 186 kilobase pairs (kbp) with 26 relatively short exons, ranging from 69 to 262 base pairs (bp), and two long exons, exon 14 (3,106 bp) and exon 26 (958 bp). The resulting messenger RNA (mRNA) is approximately 9 kb, of which the coding sequence is 7,053 nucleotides. The intron/exon boundaries roughly correlate with the FVIII domains (Fig. 15.3). The introns are large (14–23 kb) with intron 22 being the largest (32 kb). A CpG island in intron 22 acts as a bi-directional promoter for two additional genes (Fig. 15.2). The first, termed *F8*-associated gene

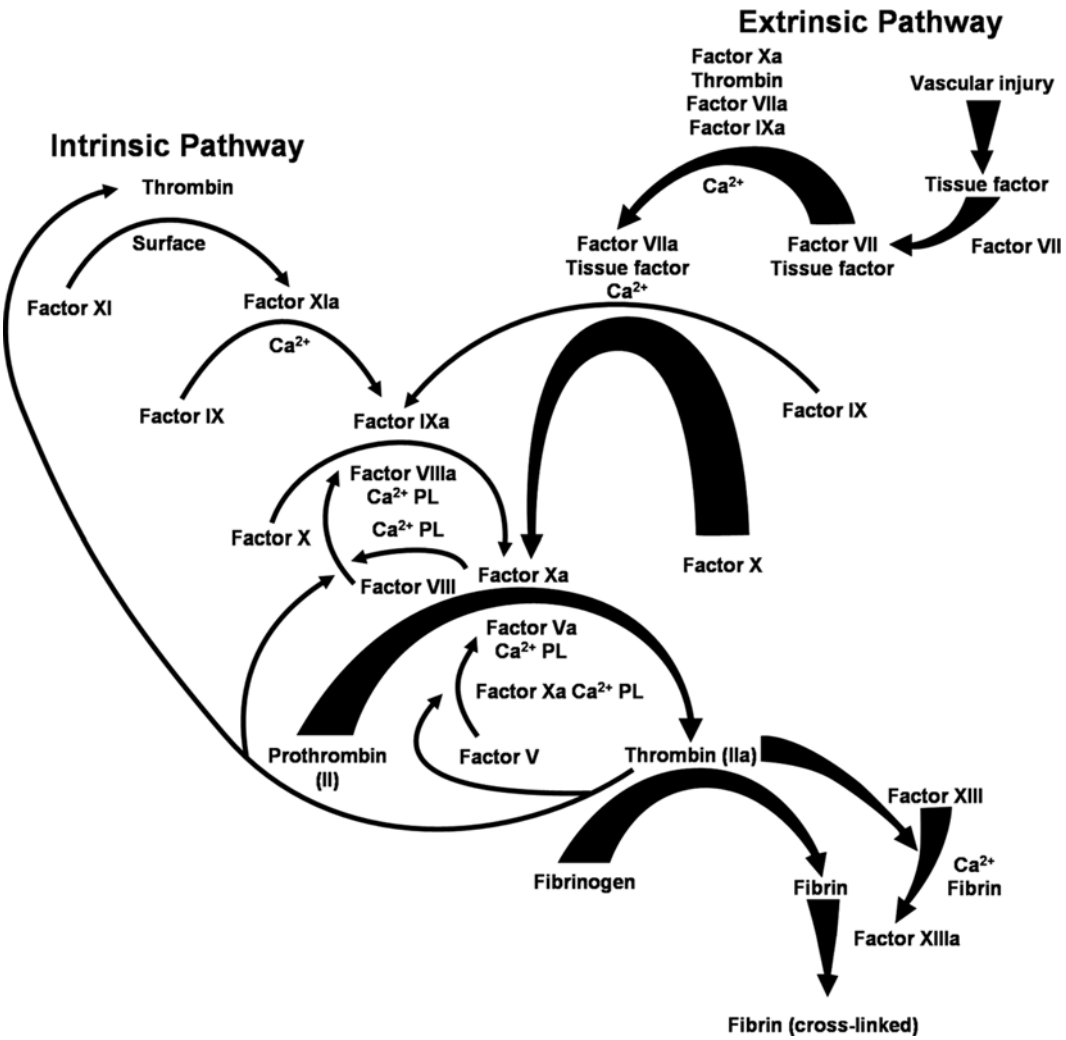

Figure 15.1 The Coagulation Cascade: *a* activated factor; *Ca2+* calcium; *PL* phospholipid. Reprinted with permission from Davie EW, Fujikawa K, Kisiel W. The coagulation cascade: initiation, maintenance and regulation. Biochemistry. 1991;30:10363. Copyright 1991 American Chemical Society

A (*F8A* or *Int22h-1*), is an intronless gene approximately 2 kb long and is transcribed in the opposite direction to *F8*. The second *F8*-associated gene B (*F8B*) is 2.5 kb long and transcribed in the same direction as *F8*. The *F8A* and *F8B* transcripts originate within 122 bases of each other and the functions of their potential protein products are unknown. The *F8A* sequence is replicated at least twice, approximately 500 kb telomeric to the *F8* gene and close to the tip of the X chromosome termed Int22h-2 (proximal) and Int22h-3 (distal). Int 22h-2 and -3 are about 100 kb apart and transcribed in the same direction as the *F8* gene. These three homologous repeats are involved in the intron 22 inversion mutation which is a frequent rearrangement of the *F8* gene, resulting in severe HA (Fig. 15.4). The putative promoter region is located 300 nucleotides 5′ to the gene and although a TATA box is not essential for transcription, liver-enriched transcription factors (e.g., HNF1, NFkB, C/EBPa, and C/EBPb) interact with the *F8* promoter region. The *F8* gene encodes a precursor protein of 2,351 amino acid residues consisting of a 19 amino acid leader peptide followed by 2,332 amino acids in the mature protein. The mature protein can be divided into several homologous domains termed A1-A2-B-A3-C1-C2 and is predominantly expressed in the liver.

Factor VIII is activated to FVIIIa via proteolytic cleavage, by either thrombin (FIIa) or factor Xa in the presence of phospholipid surfaces (Fig. 15.3). Although cleavages at amino acid positions 740 or 1,721 have no effect on coagulant activity, the cleavages at amino acid position 372 or 1,689 are important for FVIII procoagulant activity. Cleavage at 1,689 releases FVIII from VWF, permitting FVIII interaction with phospholipids and platelets. Missense mutations affecting these cleavage sites have been found in patients with HA and result in a form of hemophilia called "cross-reacting material positive (CRM+)-HA" with normal levels of FVIII antigen but low activity (1–7 %). Although missense mutations have been found in the A2 domain in HA and its value to FVIII coagulant activity has been confirmed by in vitro studies, the exact role of the A2 subunit remains unknown.

The B domain is cleaved during proteolytic activation and is not directly required for procoagulant activity of FVIII. However, it may have a role in intracellular processing and/or secretion of FVIII as B-domain-deleted FVIII molecules are expressed at five- to ten-fold higher levels than non B-domain-deleted FVIII. Mutations in this region have been reported in HA.

VWF-bound FVIII is protected from inactivation by activated protein C (APC). The putative VWF-binding region on FVIII is felt to be at the N-terminus of the light chain of

FVIII and in the C2 domain. The binding site for FIXa has been localized to the A2 domain and regions of the light chain. In addition, the binding site to FX is localized to the C-terminus of the A1 domain. Binding to phospholipids, which is important for FX activation by FIXa and FVIIIa, occurs in the C1 and C2 domains of the light-chain FVIII. No deleterious mutations in HA patients have been identified in the inactivation cleavage sites of FVIII.

Deleterious Mutations in *F8* Gene

Deleterious mutations and polymorphisms are cataloged in an international database available on the Internet and updated periodically: http://hadb.org.uk. References for the amino acid numbering system used below can be accessed at this website.

Mutations have been found in the promoter and all coding regions of the *F8* gene. Of the approximately 1,492 unique reported mutations, missense mutations account for approximately 46 %, small deletions (<50 bp) 18 %, large deletions (>50 bp) 11 %, nonsense mutations 10 %, and splice-site mutations and insertions 7 % each. However, approximately 40 % of severe HA patients have an inversion mutation at the tip of the X chromosome that disrupts the *F8* gene [2]. Homologous recombination can occur when the *F8A* gene (Inth22-1) in intron 22 of *F8* pairs with one of the two homologous regions (Int22h-2 or Int22h-3) that are telomeric to the *F8* gene probably as a result of folding over of the tip of the X chromosome (Fig. 15.4). Upon unfolding, exons 1–22 are inverted and placed approximately 500 kb upstream of exons 23–26 and oriented in the opposite direction. Depending on which repeat the *F8A* pairs with, the inversion may be termed type I (distal) or type II (proximal). Rarely type III inversion mutations occur in patients with a third extragenic copy of *F8A*. Given that the majority of inversions originate in male meiosis, almost all mothers of patients with the inversion mutation are carriers. An additional inversion of exon 1 of the *F8* gene affecting up to 5 % of patients with severe HA has also been described [3].

Genotype-Phenotype Correlations

The types of *F8* mutations correlate with the severity of hemophilia and the risk of developing FVIII inhibitors. In addition to the inversion mutations, certain missense, insertion, and deletion mutations result in severe disease (<1 % FVIII activity). However, specific deletions of 156 bp of exon 22 or the 294 bp of exons 23 and 24 are associated with moderate disease, likely due to in-frame splicing of exon 21 to exon 23, or exon 22 to exon 25. Patients with large deletions are susceptible to formation of FVIII inhibitors (antibodies) in response to therapy with FVIII concentrates. In an analysis of the HA

database, up to 40 % of patients with deletions develop FVIII inhibitors, whereas up to 60 % of patients with single-base pair changes resulting in nonsense mutations and 15 % of patients with single-base pair changes resulting in missense mutations developed inhibitors [4]. More recently, a meta-analysis of 30 studies involving over 5,000 patients concluded that the pooled odds ratios (OR) of inhibitor development in large deletions and nonsense mutations were 3.6 (95 % CI 2.3–5.7) and 1.4 (95 % CI 1.1–1.8), respectively, compared to intron 22 inversion mutations, with the remaining mutations (e.g., intron 1 inversions and splice-site mutations) posing an equivalent risk as an intron 22 inversion [5].

Single-base pair changes that result in missense mutations are spread throughout the *F8* gene. Although the structure-function relationships of some of the missense mutations are known or can be deduced (e.g., alteration of VWF-binding site, thrombin cleavage site), the structural consequences of most such mutations remain undefined.

Although HA predominantly affects males, some female carriers have reduced FVIII:C and may have clinically significant bleeding. The molecular basis of symptomatic females includes lyonization of the normal X chromosome and Turner syndrome (XO karyotype) where the dominant mutant *F8* gene is responsible for production of the abnormal FVIII. Rarely, a female known to be a carrier may have children with a known hemophilia patient; in this circumstance, each child regardless of gender has a 50 % chance of being affected.

Polymorphisms in the *F8* Gene

Polymorphisms present within the *F8* gene (intragenic) or outside the *F8* gene (extragenic) have been used to assign haplotypes (combination of polymorphisms) for linkage analysis. The putative defective *F8* gene can be tracked with polymorphisms that are closely linked to the gene. The carrier frequency of such polymorphisms varies with the ethnicity of the study population and needs to be considered when studying patients of diverse ethnic origin. A complete listing of polymorphisms is available in the *F8* mutation database at http://hadb.org.uk.

Clinical Utility of Testing

In a male patient suspected of being affected, the diagnosis of HA is established by assaying plasma FVIII:C. Given that FVIII relies on binding to VWF for its normal survival, all patients with a low FVIII:C should have VWB excluded. In addition, FVIII is a labile factor resulting in a potential artifactual loss of up to 15 % of FVIII:C with delayed processing of plasma specimens. Thus, mild reductions in FVIII:C should prompt repeat testing with careful attention to timely specimen processing.

In at-risk females, while reduced FVIII:C typically confirms carrier status, a normal FVIII:C does not exclude the possibility of carrier status. Given that FVIII:C may be normal in carriers and the fact that FVIII is an acute-phase reactant, it can be elevated with acute or chronic inflammation, liver disease, vasculitis, estrogen therapy, or pregnancy. Thus, molecular genetic testing would be the only option for diagnosis.

Knowledge of the causative *F8* mutation in the proband does not alter clinical management but may be useful in predicting the risk of developing FVIII inhibitors [4]. The causative mutation can be useful for carrier testing of family members. Asymptomatic females with no access to their familial *F8* genotype information will need their entire *F8* gene analyzed for carrier testing. This is not an uncommon situation for adopted females. For carriers, prenatal diagnosis during pregnancy provides useful information for management of labor and delivery and, occasionally, pregnancy termination. Advances in reproductive technology may permit preimplantation genetic diagnosis and circumvent the need for prenatal testing [6].

Available Assays

Several laboratories offer genetic testing for HA. A complete listing of clinical laboratories performing HA testing that have registered with GeneTests can be found on their website (www.genetests.org). An alternative source is the NCBI Genetic Testing Registry (http://www.ncbi.nim.nih.gov/gtr). In general, testing can be divided into direct mutation analysis and indirect testing based on haplotype, and selected laboratories offer prenatal testing.

Direct DNA Analysis

Direct DNA analysis for the intron 22 and 1 inversion mutations is typically performed by restriction digestion and Southern blot method. This detects the more common types: I and II inversions and the rare type III inversion. Polymerase chain reaction (PCR)-based assays also can be used [3, 7, 8]. Detection of hemizygous gene or exonic deletions in the *F8* gene in at-risk carriers by PCR amplification of individual exons may not be diagnostic given that the normal copy of the gene may be amplified. For this situation, linkage analysis may be required; however, the role of multiplex ligation-dependent probe amplification (MLPA) is evolving [9]. Different laboratories utilize varied approaches, including initial screening or direct sequencing of all the relevant regions of the *F8* gene [10]. The large size of the *F8* gene with 26 exons makes this a labor-intensive test. Thus alternate strategies have been utilized on a research basis which involves analysis of *F8* mRNA by RT-PCR [11] or other SSCP-based screening techniques [12].

Indirect DNA Analysis (Linkage Analysis)

The principle underlying genetic linkage analysis is the tendency for alleles close together on the same chromosome to be transmitted together as an intact unit through meiosis.

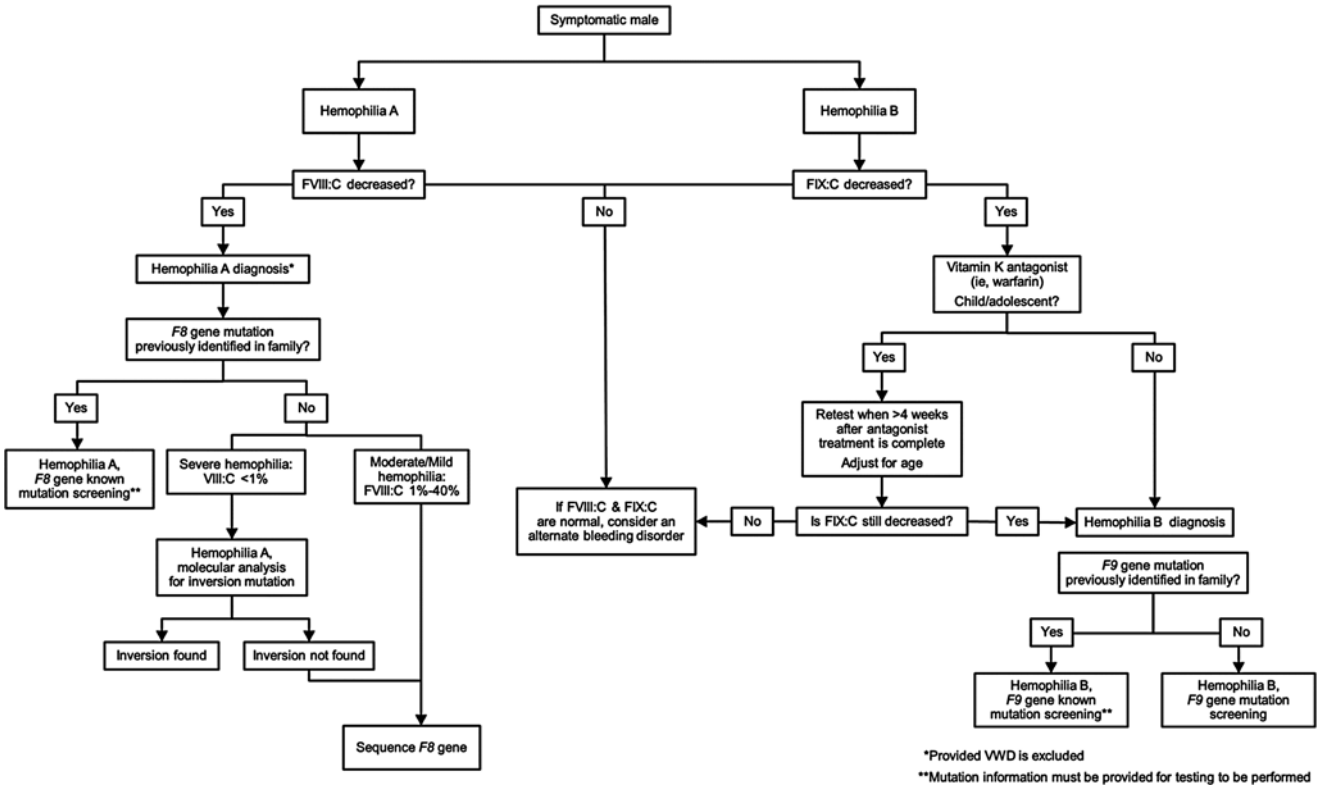

Figure 15.5 Hemophilia testing algorithm: symptomatic male. FVIII:C, FVIII activity; FIX:C, FIX activity; *F8*, FVIII gene; *F9*, factor IX gene. By permission of Mayo Foundation for Medical Education and Research. All rights reserved

Polymorphisms, within the *F8* gene (intragenic) or outside the *F8* gene (extragenic), are typically single-base pair changes or simple sequence repeats (CA^n repeats). Disadvantages of linkage analysis include the need for DNA samples from the proband and both parents, and the requirement that the proband's mother be heterozygous and thus "informative" for the polymorphism. A polymorphism is informative if the DNA sequence at a locus differs on the maternally inherited and paternally inherited chromosomes. Most families (up to 90 %) are informative with one or more DNA polymorphisms if both intragenic and extragenic polymorphisms are analyzed. The distance between the disease-causing mutation and the polymorphism increases the risk of recombination, which may lead to false-positive or false-negative results. This risk is lowest if intragenic markers are used. Rarely, families will only be informative for extragenic polymorphisms: misdiagnosis can occur in up to 6 % of carriers as a result of linkage disequilibrium. When an intragenic polymorphism is used for the diagnosis of carrier or affected status, the chance of an error is less than 1 %. A major drawback with linkage analysis is the possibility of identifying nonpaternity in the tested family. A complete listing and frequency of polymorphisms is available in the *F8* mutation database.

HA Testing Algorithms

HA genetic testing should be accompanied by pretest and posttest counseling, which is described below. For questions regarding any laboratory's sample requirement, testing, and reporting process, direct communication with the laboratory is critical. Most laboratories have a genetic counselor available for testing guidance. In general, genetic testing for hemophilia is ordered by healthcare providers familiar with the diseases, inheritance patterns, and testing options, but also is ordered by primary care providers who may not be familiar with testing options and counseling. Algorithms for testing symptomatic males and at-risk females are illustrated in Figs. 15.5 and 15.6 and described below.

For a symptomatic male, the diagnosis of HA is established based on plasma FVIII:C, which also classifies the disease as severe (<1 %), moderate (1–5 %), or mild (>5–40 %) (Fig. 15.5). In patients with a history of a bleeding disorder but who have normal FVIII:C, alternative bleeding disorders should be considered, e.g., HB (X-linked recessive) or VWD (autosomal dominant or recessive). If the specific *F8* mutation has been identified in an affected family member, the documentation of the specific familial mutation should be provided to the laboratory and testing should concentrate on identifying the presence or absence of the familial

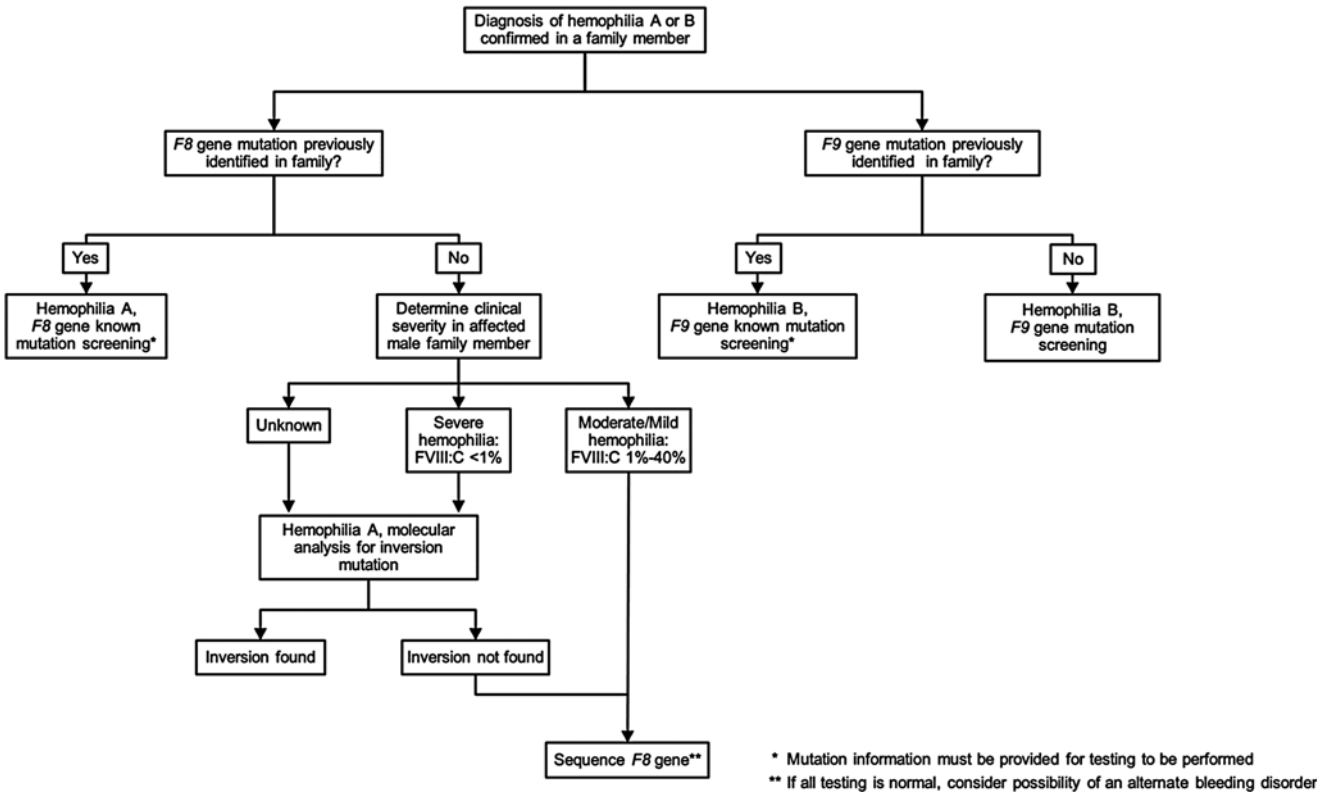

Figure 15.6 Hemophilia carrier testing algorithm: FVIII:C, FVIII activity; FIX:C, FIX activity; *F8*, FVIII gene; *F9*, factor IX gene. By permission of Mayo Foundation for Medical Education and Research. All rights reserved

mutation; typically, testing laboratories offer focused testing generically termed "known mutation analysis." If the familial mutation has not been identified, for symptomatic males with severe HA, initial testing is focused on the *F8* intron 22 inversion mutation and, if negative, the intron 1 inversion. For those with no detectable inversion mutation and for probands with moderate or mild HA, full gene analysis is required.

For at-risk females, a reduced FVIII:C confirms carrier status; however, a normal FVIII does not exclude HA carrier status, for which molecular testing is required. As with testing male patients, if the familial mutation is known, this information should be provided to the laboratory and testing should focus on the familial mutation (Fig. 15.6). For at-risk females without a known familial mutation, determining the clinical severity of hemophilia in an affected male family member will aid in a rational testing approach. Information on severity of the hemophilia may not be known to the at-risk female (especially if the proband was a distant relative). Communication with the local comprehensive hemophilia center that provided hemophilia care to the proband may be useful. For families with severe HA, initial testing is focused on the *F8* intron 22 inversion, and if negative, the intron 1 inversion. For those with no detectable inversion mutation and for families with moderate or mild HA, full *F8* gene analysis is required.

Identification of a causative mutation confirms the disease in symptomatic males, and carrier status in at-risk females. This carrier status confers a 50 % risk of each male child being affected with and a 50 % risk of each female child being a carrier for HA. All biological daughters of an affected male are obligate carriers. Lack of a detectable mutation in an at-risk female excludes carrier status if the familial mutation is known, but not if the familial mutation is unknown. Posttest counseling for a discussion on the aforementioned issues is vital in ensuring that the patient understands his or her own risk and the risk for offspring to be carriers of or affected with HA.

Interpretation of Test Results

Reduced FVIII:C is virtually diagnostic of HA, provided VWD and specimen artifact (see above) have been excluded. Rare instances of other genetic disorders that can have low FVIII activity include VWD type 2N (see section on VWD) and rare combined deficiencies of FV and FVIII. The latter occurs as a result of mutations in ERGIC-53, which is a protein necessary for efficient transport of FV and FVIII from the endoplasmic reticulum to the Golgi. FV and FVIII levels are typically in the 10–15 % range [13].

Detection of the presence of a deleterious mutation in a symptomatic male establishes the familial mutation and

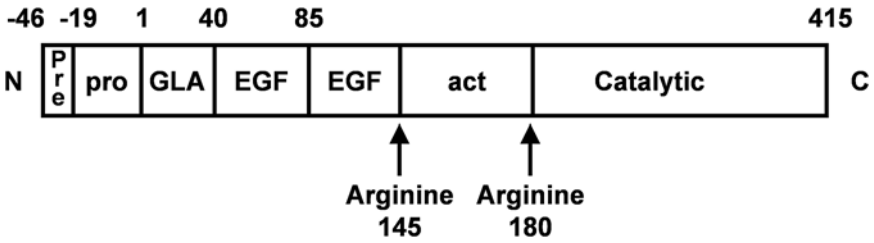

Figure 15.7 Factor IX peptide showing domains: *N* N-terminus, *C* C-terminus, *Pre* pre-propeptide, *pro* propeptide, *GLA* glutamic acid-rich domain, *EGF* epidermal growth factor domain, *act*, activation peptide

confirms carrier status in the at-risk female. Certain well-defined mutations (e.g., inversion, deletions, insertions, splice junction mutations, and nonsense mutations) have obviously deleterious effects. Determining the deleterious nature of previously uncharacterized missense mutations poses a challenge. However, identification of a variant of uncertain significance in hemizygous genes (*F8* and *F9*) in males without additional mutations provides reasonable evidence of its deleterious nature. Other criteria typically considered include genotype-phenotype correlation in the family if other family members are affected and tested, analysis of the degree of conservation of the respective residue among other species, and presence of a similar mutation in other patients. The best evidence of deleterious nature of a missense mutation is in vitro confirmation of its effect on protein function.

Laboratory Issues

As with any genetic test performed on peripheral blood leukocyte genomic DNA, high-quality DNA extracted from whole blood is essential. The specimen needs to be clearly identified and, given that testing is performed on peripheral blood leukocyte genomic DNA, history of allogeneic bone marrow or peripheral blood stem cell transplant needs to be provided. For testing performed on cord blood samples, a maternal peripheral blood sample should also be submitted for exclusion of maternal cell contamination of the cord blood which can cause incorrect test results.

Hemophilia B

Overview

HB is an X-linked recessive bleeding disorder due to a deficiency of FIX and is clinically indistinguishable from HA. HB affects 1 in 30,000 live male births across all ethnic groups. As with HA, up to 30 % of HB cases occur in families with no prior family history of HB. The diagnosis is established based on plasma FIX activity (FIX:C), which permits classification of HB disease severity as severe (<1 %), moderate (1–5 %), or mild (>5–40 %).

Molecular Basis of Disease

The factor IX gene (*F9*) is located on the long arm of the X chromosome (Xq27.1) and is 38 kb long with eight exons of varying lengths (25–1,935 bp). The *F9* mRNA is approximately 3 kb in length with a coding sequence of 1,390 nucleotides. The intron/exon boundaries roughly correlate with the FIX domains and bear a high degree of homology to members of the vitamin K-dependent protein family (FVII, FX, and protein C) (Fig. 15.7). The *F9* gene encodes a precursor protein of approximately 454 amino acids consisting of a propeptide followed by a glutamic acid-rich (Gla) domain, two epidermal growth factor domains, an activation peptide, and a catalytic domain.

Activation of FIX to FIXa occurs by cleavage by factor VIIa (FVIIa)-tissue factor (TF) and activated factor XI (FXIa). Cleavage releases the activation peptide, resulting in circulating light and heavy chains connected by a disulfide bond. Numerous posttranslational modifications are necessary for the normal function of FIXa, including tyrosine sulfation, serine phosphorylation, and *O*- and *N*-linked glycosylation. The relatively small size of the *F9* gene allows complete molecular testing, and mutations are catalogued in a database accessed at http://www.factorix.org.

Mutations in the *F9* Gene

The majority of *F9* mutations are single-base pair changes that result in missense, frameshift, or nonsense mutations. Short deletions (<30 nucleotides) account for approximately 7 %, larger deletions approximately 3 %, and insertions approximately 2 % of mutations. Many of the single-base pair changes occur at CpG doublets that are "hotspots" for mutation. However, a subset of recurrent mutations is due to a founder effect, which typically results in mild disease. Mutations have been detected in all regions of the *F9* gene, including the poly(A) signal.

Genotype-Phenotype Correlation

The numbering system for FIX peptide has evolved. The former numbering system was based on the Yoshitake numbering system [14] which is termed the legacy system in the FIX mutation database. An alternate and increasingly used system is the Human Genome Variation Society numbering

system. The numbering system utilized in this chapter is the legacy system.

Missense mutations account for the majority of mutations that typically result in mild disease unless the mutations occur in residues critical for normal FIX function. Selected mutations in the promoter region of the *F9* gene result in a unique phenotype termed hemophilia B Leyden. This phenotype is characterized by severe disease at birth with progressive amelioration of severity through adolescence and puberty. However, some promoter mutations (e.g., Brandenburg mutation at −26) in the *F9* promoter result in lifelong severe disease. Nonsense mutations in the signal peptide and propeptide regions lead to severe HB. Selected missense changes, that lead to retention of FIX within hepatic cells (e.g., p.Ile-30 and p.Ile-19) or prevent cleavage of the propeptide, result in a dysfunctional FIX molecule (e.g., p.Arg-4) and result in hemophilia of varying severity (mild, moderate, or severe) depending on the amino acid substitution.

Mutations in the Gla domain disrupt γ-carboxylation (posttranslational modification) that is important for normal FIXa binding to collagen, activated platelets, and endothelial cells. Mutations in the EGF domains result in disruption of FIX binding to calcium that is essential for procoagulant activity, as well as impaired binding to its cofactor FVIII. Mutations in the catalytic domain typically disrupt the catalytic triad (p.His221, p.Asp269, and p.Ser365) essential for FIXa protease function.

An unusual FIX variant, due to mutation at p.Ala10, is characterized by normal baseline FIX:C. However, warfarin therapy results in a severe and disproportionate reduction in FIX:C (typically <1 %) and causes bleeding in patients being treated with warfarin who have an apparently therapeutic International Normalized Ratio. An indication of such a situation is a disproportionate prolongation of the activated partial thromboplastin time which should prompt testing for FIX:C levels. A second unusual variant, p.Arg338Leu (termed FIX Padua), results in a marked increase in FIX:C of up to 700 % of normal. In one case report, this mutation resulted in early-onset and recurrent VTE [15].

Polymorphisms in the *F9* Gene

Eight common polymorphisms that do not cause HB have been described in different ethnic populations of European and African descent. These polymorphisms, however, are much less common in Asian and other populations. The most informative polymorphism documented in the Asian population is what is termed the *Hha* I polymorphism (rs3117459 allele frequency = 0.17) located approximately 8 kb 3′ to *F9*. Recent reports [16] have described additional polymorphic loci in these populations, facilitating molecular diagnosis of non-Caucasian carriers and patients with HB. A polymorphism within the FIX-coding region, p.Ala148Thr, occurs within the activation peptide. This does not correlate with FIX activity or antigenic levels. The Thr allele occurs with a frequency of 0.3 in the Caucasian population; however, it is much less frequent in the African-American (0.053–0.15) and Asian (<0.01) populations.

Clinical Utility of Testing

The diagnosis of HB in a symptomatic patient is established by FIX:C testing, rather than by genetic testing. Given that FIX is a vitamin K-dependent protein, all patients with mild-to-moderate reductions in FIX activity should have vitamin K deficiency excluded. In addition, healthy normal children have a lower FIX activity that reaches adult reference ranges at puberty.

For the symptomatic male, knowledge of *F9* genotype does not alter clinical management of HB patients; however, the specific genotype may predict the risk of developing FIX inhibitors and anaphylaxis in response to FIX concentrate therapy [17]. Although knowledge of the proband's genotype information is important for carrier testing of at-risk female family members, the smaller size of the *F9* gene allows routine use of sequence analysis to identify the specific *F9* mutation causing HB. A reduced FIX:C in at-risk females typically confirms HB carrier status, provided that vitamin K deficiency has been excluded. However, normal FIX:C does not exclude the patient being a carrier. In this circumstance, molecular genetic testing would be the only option for diagnosis. See Fig. 15.5 for a recommended diagnostic testing algorithm for HB patients and Fig. 15.6 for recommended testing algorithm for HB carriers.

Available Assays

A listing of laboratories offering HB genetic testing that have registered with GeneTests can be found on their website (www.genetests.org). An alternative source is the NCBI Genetic Testing Registry (http://www.ncbi.nlm.nih.gov/gtr/). In general, testing can be divided into direct and indirect testing and selected laboratories offer prenatal testing.

Direct DNA Analysis

Generally, most patients with HB have mild disease. Since approximately 25 % of mild HB Caucasian patients have one of the three founder mutations (p.Gly60Ser, p.IIe397Thr, and p.Thr296Met) [18], a logical first step is to perform limited testing for these founder mutations. For symptomatic patients without one of the founder mutations, for severely affected patients, and for individuals at risk of being an HB carrier, the logical next step is *F9* gene mutation screening or sequencing regions of functional significance in the *F9* gene. Although the majority of HB patients have one deleterious mutation, approximately 1 % of HB patients have two mutations. Additional limitations of molecular testing as described in the section above on HA also apply for HB.

Indirect DNA Analysis (Linkage Analysis)

As discussed above for HA, indirect DNA analysis of an HB proband does not identify the familial mutation. Linkage analysis does assign a haplotype which identifies the abnormal *F9* gene and is useful for carrier testing of family members. Given the small size of the *F9* gene, direct sequencing is also feasible for carrier testing when the HB mutation is not a large *F9* gene deletion. As discussed in the section on HA, such mutations may be detected by MLPA.

Testing Algorithm

Pre- and posttest genetic counseling is critical for overall patient management. See section on HA above. A reduced, age-appropriate, FIX:C confirms the diagnosis of HB, provided that vitamin K deficiency or use of vitamin K antagonists (e.g., warfarin) can be excluded. The FIX:C level allows classification of the severity of disease as severe (<1 %), moderate (1–5 %), or mild (>5–40 %). If FIX:C is not reduced, consider testing for an alternate bleeding disorder, such as HA or VWD.

The preanalytical issues regarding knowledge of the familial mutation, as discussed in the section on HA above, also apply to HB. Thus, for probands or at-risk carriers with an identified familial mutation, focused testing is reasonable. If the familial mutation is not known or not available, *F9* gene sequencing is the most appropriate approach.

Interpretation of Test Results

See section on HA above.

Laboratory Issues

See section on HA above.

von Willebrand Disease

Overview

VWD is an autosomal dominant or recessive disorder characterized by a deficiency of VWF. VWD is the most commonly recognized congenital bleeding disorder, with a prevalence of 0.82–2 % [19]. Diagnosis is established based on a personal and family history of abnormal clinical bleeding and reduced plasma VWF antigen levels and/or functional activity (ristocetin cofactor activity), and analysis of the size distribution of the VWF multimers.

Molecular Basis of Disease

The *VWF* gene is located near the end of the short arm of human chromosome 12, spans 180 kb, and consists of 52 exons. The intron-exon boundaries roughly correlate with the VWF domains. The presence of an unprocessed partial pseudogene located on chromosome 22q11.2 corresponds to exons 23–34 of the *VWF* gene. VWF is synthesized in endothelial cells and megakaryocytes and is secreted from its storage sites (platelet alpha granule and endothelial cell Weibel-Palade bodies) into plasma. VWF is a 2,813-amino acid peptide consisting of a 22-amino acid signal peptide, a 741-amino acid propeptide, and a mature 2,050-amino acid VWF protein (Fig. 15.8). After removal of the signal peptide, the pro-VWF dimerizes by disulfide bonds at the C-terminal

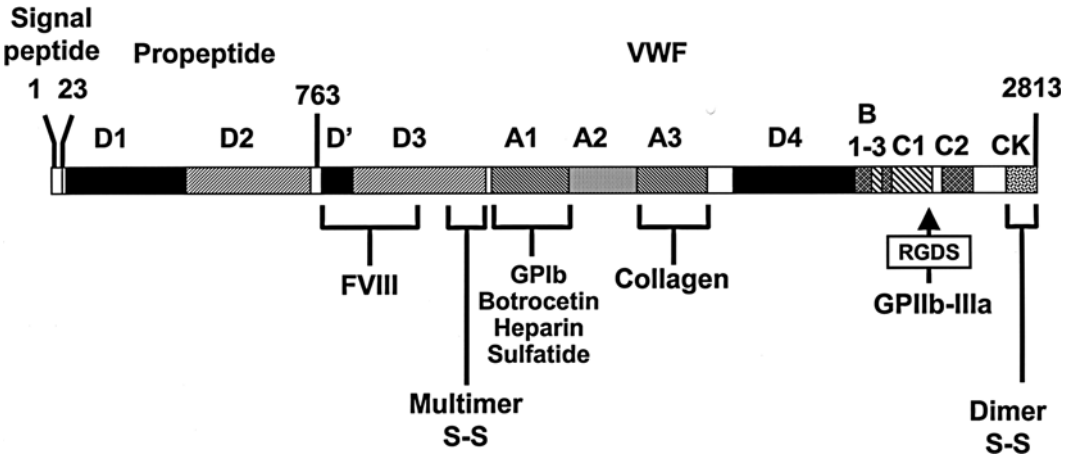

Figure 15.8 von Willebrand peptide domains: *FVIII* factor VIII, *S-S* disulphide bridge, *GPIb* glycoprotein Ib, *VWF* von Willebrand factor, *GPIIb–IIIa* glycoprotein IIb–IIIa, *RGDS* arginine (R), glycine (G), aspartic acid (D), serine (S)-binding sequence. Copyright 2001 McGraw-Hill

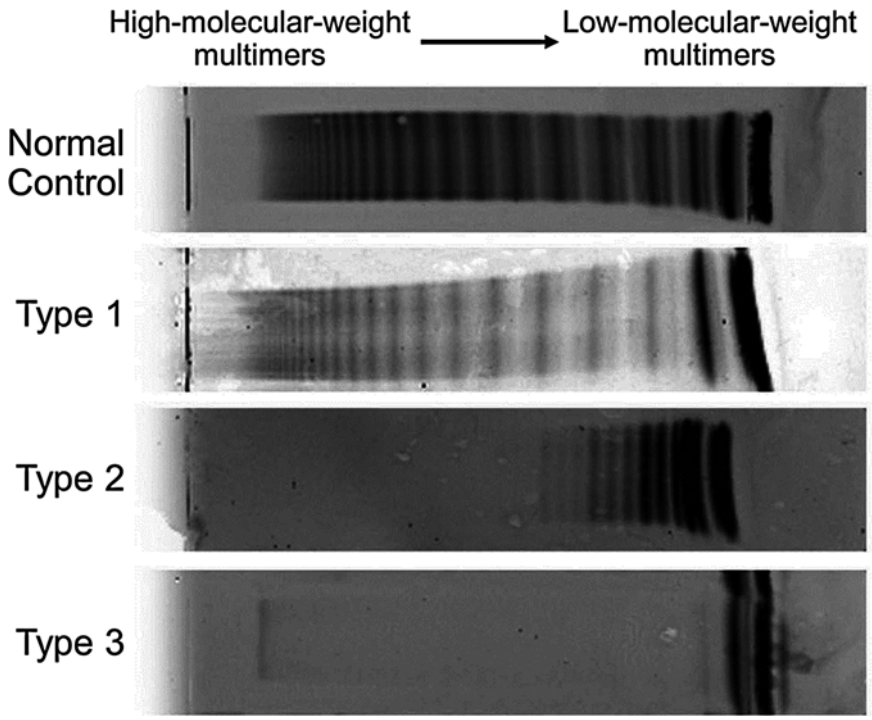

Figure 15.9 VWF multimer distribution: The protein gel demonstrates the size distribution of VWF multimers in a normal control and the three types of VWD. Type 1 has reduced multimers of normal size distribution, type 2 has reduced highest and intermediate molecular weight multimers, and type 3 lacks all multimers

ends and further polymerizes between the N-terminal ends resulting in multimers ranging in size from 500 kDa to over 10 million daltons. Binding sites for various ligands have been localized to different domains of the VWF subunit.

VWD can be divided into two broad categories based on quantitative (types 1 and 3) or qualitative (type 2) abnormalities of plasma VWF. Quantitative abnormalities include a mild reduction of qualitatively normal VWF (type 1) or absent VWF (type 3). Type 2 VWD is characterized by plasma VWF with defective structure and function, and typically results in the absence or reduction of the larger VWF multimers (Fig. 15.9).

Previously identified mutations and polymorphisms in the *VWF* gene are available in an international database at http://www.sheffield.ac.uk/VWF/.

Type 1 von Willebrand Disease

Type 1 VWD, which accounts for approximately 85 % of VWD cases in the USA, is typically autosomal dominant. Diagnosis is established by assays of VWF demonstrating proportionate reduction in plasma VWF antigen (VWF:Ag), ristocetin cofactor activity (VWF:RCo), and factor VIII activity (FVIII:C) with a normal distribution of VWF multimers. Although the most commonly diagnosed variant of VWD, the molecular pathogenesis of type 1 continues to be elucidated. Currently, apart from a few sporadic reports, few clearly deleterious *VWF* mutations have been identified in type 1 VWD. Although type 1 VWD appears to be linked to the *VWF* locus, animal data suggests locus heterogeneity as an explanation for the mild quantitative deficiency of VWF associated with type 1 VWD, e.g., defects in glycosylation of the VWF protein [20]. Selected patients with type 1 VWD are a result of heterozygous inheritance of a VWD type 3 defect which includes nonsense, frameshift, or deletion mutations; however, emerging information demonstrates a completely different mutation spectrum from VWD type 3, discussed below. A unique variant, type 1 Vicenza, is characterized by the presence of ultralarge VWF multimers with increased clearance from the circulation, and is due to a unique mutation p.Arg1205His in the D3 domain.

Type 1 VWD has heterogeneous clinical manifestations with variable penetrance that may be due to concordant or discordant reductions in platelet VWF. Some pedigrees are characterized by significant reductions in VWF levels which may be due to defects in multimer synthesis or secretion.

Type 3 von Willebrand Disease

Type 3 VWD, which accounts for approximately 5 % of VWD cases in the USA, is autosomal recessive and characterized by a severe reduction in VWF:Ag, VWF:RCo, and a concordant reduction in FVIII:C resulting in a more severe bleeding phenotype. Deleterious mutations include frameshifts, deletions, and nonsense mutations. Although most patients are typically compound heterozygous for such VWF mutations, homozygosity has been demonstrated in a few consanguineous families. Although most patients with type 3 VWD have two defective *VWF* alleles, many have clinically unaffected parents. Assays of VWF may be normal or exhibit

only mild abnormalities. Full gene analysis would be required to document heterozygous carrier state. This poses a challenge in providing genetic counseling, due to the possibility of new mutations.

The prevalence of type 3 VWD is 0.5–3 per million and based on the Hardy-Weinberg equilibrium, heterozygotes should occur at an expected frequency of at least 1,400–3,500 per million population. However, the currently estimated prevalence of symptomatic type 1 VWD is at least tenfold lower. This discrepancy may be due to a distinct molecular pathogenesis of type 1 VWD compared to type 3 VWD (outlined above) or variable phenotypic expression of type 1 VWD. Although VWF levels may be lower in parents of patients with type 3 VWD, there is a variable expression with most parents being asymptomatic.

Type 2 von Willebrand Disease

Type 2 variants of VWD, which account for approximately 10 % of VWD cases in the USA, are characterized by qualitatively abnormal VWF with defective stability, function, or multimer distribution and include types 2A, B, N, and M. In general, mutations are well characterized and may disrupt dimerization, multimerization, impaired secretion, or increased susceptibility to proteolysis.

Type 2A von Willebrand Disease

Type 2A VWD is autosomal dominant and accounts for approximately 75 % of all type 2 VWD. There is a variable reduction in VWF antigen, with a discordant reduction in VWF:RCo, indicative of a qualitative VWF abnormality. The higher and intermediate plasma VWF multimers are reduced or absent, and the lower molecular weight multimers are relatively increased or have an abnormal infrastructure. Plasma and platelet multimer abnormalities may be concordant or discordant depending on the underlying molecular defect.

Missense mutations resulting in type 2A VWD occur predominantly in the A2 domain of VWF and result in abnormal VWF patterns by two distinct mechanisms. The first mechanism includes impairing the assembly and secretion of normal VWF multimers, resulting in decreased higher molecular weight VWF multimers in both plasma and platelets. The second mechanism includes normal assembly and secretion of VWF; however, the mutant VWF has an increased sensitivity to proteolytic degradation in plasma resulting in decreased plasma high-molecular-weight multimers but a normal platelet VWF multimer pattern.

Type 2B von Willebrand Disease

Type 2B VWD is autosomal dominant and accounts for approximately 20 % of all type 2 VWD. Type 2B is characterized by a variable reduction in the VWF:Ag, a discordant reduction in VWF:RCo with a loss of the higher and intermediate plasma VWF multimers, but normal distribution of platelet VWF multimers. Type 2B is distinguished from type 2A VWD by the presence of mild-to-moderate thrombocytopenia. This occurs as a result of an increased affinity of VWF for platelet GPIb, resulting in spontaneous binding of VWF to platelets and rapid clearance of the platelet-bound larger multimers from plasma. In addition, platelet aggregation in response to ristocetin demonstrates an exaggerated response. The few cases described of normal multimer distribution with hyperresponsiveness to ristocetin appear to represent a mild form of the type 2B defect. Causative missense mutations are found in the A domain of VWF and result in a dominant gain-of-function phenotype. Mutations in this region likely disrupt a regulatory site that normally inhibits the binding of the A1 domain to platelet GPIb.

Type 2B VWD must be distinguished from a pseudo-VWD or platelet-type VWD, which is similar in presentation. The latter group of patients has a primary platelet defect resulting from mutations in the platelet GPIb/IX receptor.

Type 2M von Willebrand Disease

In type 2M VWD, although the VWF:Ag and the distribution of VWF multimers are normal, the VWF:RCo is reduced, reflecting a functional defect of the VWF multimers. Mutations in the A1 domain of VWF can result in decreased binding affinity for platelet GPIb and thus a reduced VWF:RCo. However, not all reduced VWF:RCo represents VWD. A recent description of a polymorphism in the A1 domain, p.Asp1472His, found in 63 % of the African-American normal control population and 17 % of the Caucasian normal control population, results in a lower VWF:RCo in carriers of the mutation compared to non-carriers. Carriers of this mutation did not have bleeding symptoms [21].

Type 2N (Normandy) von Willebrand Disease

Mutations in the FVIII-binding domain of VWF result in suboptimal binding of FVIII to VWF. This binding defect results in a shorter half-life of plasma FVIII and thus plasma FVIII:C is reduced. Levels of VWF:Ag and VWF:RCo are normal as is the plasma VWF multimer distribution. This subtype mimics mild HA; however it is distinguished by an autosomal recessive pattern of inheritance rather than the X-linked recessive pattern of HA. In a recent international survey, type 2N VWD was detected in 4.8 % (58/1,198) of patients previously diagnosed as having mild HA. Three *VWF* gene mutations (p.Thr791Met, p.Arg816Trp, and p.Arg854Gln) accounted for 96 % of type 2N patients [22]. Type 2N VWD should be considered in patients with a diagnosis of "mild HA" with a non-X-linked inheritance pattern. Typically, heterozygotes have normal FVIII:C and homozygotes have reduced FVIII:C. However, apparent heterozygotes

with low FVIII:C typically have inherited a second allele resulting in type 1 VWD (compound heterozygotes).

Clinical Utility of Testing

Currently, the most significant impact on clinical management and genetic counseling is the differentiation of type 2N VWD and mild HA. Both have a mild-to-moderate reduction in FVIII with normal levels of VWF:Ag and VWF:RCo. The autosomal inheritance pattern and the need for use of VWF concentrates in patients with VWD2N, rather than pure FVIII concentrates, make this an important distinction.

Differentiation of type 2A from 2B VWD alters clinical management, since therapeutic use of vasopressin (DDAVP) is contraindicated in patients with type 2B VWD given the potential for worsening the thrombocytopenia. Patients with type 2B VWD can have variable degrees of thrombocytopenia, such that a clear distinction between types 2A and 2B is not always possible based on platelet levels alone.

Currently, genetic testing is not useful for type 1 VWD, given its mild phenotype, the lack of well-characterized mutations, and the implication of locus heterogeneity. In contrast, type 3 VWD has well-characterized mutations and a severe phenotype. Although genotyping the index patient of a family would likely not affect their clinical management, the genotype would be useful for genetic counseling and prenatal diagnosis of the parents in anticipation of future pregnancies.

Available Assays

Functional assays that measure FVIII binding to VWF are available in selected laboratories and are considered the initial test of choice. Molecular testing confirms the genotype, but mutations are not consistently found in all patients with binding defects. Tests available include assays for determining the molecular basis of type 2N, and types 2A and 2B. Methods include restriction fragment length polymorphism analysis or direct sequencing. Indirect testing is available for VWD; however it is rarely indicated except for severe type 3 VWD. The laboratories offering such testing are listed with GeneTests and can be found on their website (genetests.org). An alternative source is the Genetic Testing Registry at http://www.ncbi.nim.nih.gov/gtr.

Interpretation of Test Results

Detection of mutation(s) in the FVIII-binding domains of *VWF* in a homozygous state is good evidence of the deleterious effect on protein function and presence of type 2N VWD. However, not all mutations have been characterized at a structural level and thus need to be viewed with caution. The presence of a heterozygous mutation in the setting of a low FVIII:C could reflect the presence of a second mutation in *VWF* (compound heterozygote). Although most known mutations in type 2A and 2B VWD are clustered within exon 28 of the *VWF* gene, type 2 variants with mutations outside this domain have been described.

Laboratory Issues

The large size of the *VWF* gene precludes efficient, cost-effective screening or sequencing on a clinical basis. In addition, (co)amplification of the unprocessed pseudogene, homologous to exons 23–34 of *VWF* gene, complicates mutational analysis of PCR products amplified from genomic DNA. However, use of primers designed specifically to amplify the *VWF* gene and not the pseudogene reduces this risk. Mutation analysis of mRNA on a research basis has been performed, but likely is not practical for clinical testing given the instability of mRNA in transported specimens; however current availability of stabilizing agents may make this a viable option. At the present time, mRNA-based sequencing is not available for clinical testing.

Inherited Thrombophilias

The term "thrombophilia" refers to hereditary or acquired disorders or clinical circumstances that are risk factors for venous or arterial thrombosis. Broadly speaking, within the coagulation system, predisposition to thrombosis can be caused by deficiencies of the anticoagulant and fibrinolytic components or unbridled activity of the procoagulant system. The known hereditary thrombophilia disorders are well-established risk factors for venous thrombosis and its complication, pulmonary embolism, which together are called VTE; however, although biologically plausible, the association of the hereditary thrombophilia disorders with arterial thrombosis is less well established.

The recognized plasma components of the anticoagulant system include antithrombin (AT), protein C (PC), and protein S (PS); the fibrinolytic system includes plasminogen and its activating proteins, plasminogen activator inhibitors 1 and 2 (PAI-1 and -2), as well as alpha-2 antiplasmin. The procoagulant system consists of members of the coagulation cascade (Fig. 15.1). Two key hemostasis regulatory proteins, factors V (FV) and VIII (FVIII), once activated to FV_a and $FVIII_a$, function as cofactors that markedly accelerate the rate of thrombin generation and fibrin thrombus formation. Thus, inactivation of these cofactors markedly downregulates thrombin generation (Fig. 15.10).

PC, a vitamin K-dependent zymogen, circulates in an inactive form and, for its anticoagulant activity, requires activation to activated protein C (APC). This activation occurs by the thrombin-thrombomodulin complex. Thrombomodulin is an integral membrane protein on the luminal surface of endothelial cells that binds circulating thrombin and changes its substrate specificity such that thrombin no longer cleaves fibrinogen nor activates platelets. Instead, thrombomodulin-bound thrombin activates PC to APC, which in turn exerts its

anticoagulant activity by inactivating (via enzymatic cleavage) FV_a and $FVIII_a$ in the presence of PS.

AT is a serine protease inhibitor (SERPIN) and acts as a pseudo-substrate to irreversibly inhibit thrombin and procoagulant factors IX_a, X_a, XI_a, and XII_a by covalently binding the enzymatic active sites. AT anticoagulant activity is markedly enhanced by glycosaminoglycans (e.g., heparin).

Activated Protein C Resistance Due to Factor V Leiden Mutation

Molecular Basis of Disease

APC inactivates FV_a by cleavage at two sites on FV. Described using legacy nomenclature (amino acid numbering starts 28 amino acids after standard HGVS nomenclature), an initial cleavage at arginine (R) 506 of FV_a facilitates subsequent cleavage at positions R306 and R679 (in the presence of phospholipid and PS) resulting in inactivation of FV_a (Fig. 15.11). Hereditary resistance to inactivation of FV_a by APC, termed activated protein C resistance (APCR), is an autosomal dominant condition and occurs as a result of a single-point mutation, guanine (G) to adenine (A) at the 1,691 nucleotide (G1691A) within exon 10 of the *F5* gene [called factor V Leiden (FVL), *F5* rs6025] on chromosome 1 (1q21-25) [23]. HGVS nomenclature describes the factor V Leiden mutation as *F5*:c1601G>A, p.Arg534Gln (p.R534Q).

This mutation encodes for substitution of a glutamine (Gln, Q) for arginine (Arg, R) at amino acid position 506 within the heavy chain of FV, one of the three APC-cleavage sites (R306, R506, R679). FVL promotes thrombosis by impaired downregulation of thrombin generation and by inhibition of fibrinolysis.

FVL is a founder mutation, arising between 21,000 and 34,000 years ago and after the evolutionary divergence of Africans from non-Africans and of Caucasoid from Mongoloid subpopulations. Worldwide, the FVL carrier frequency ranges from 2 % in Southern Europe to 15 % in Southern Sweden, and generally declines in native populations as one moves from west to east toward Asia, Africa, and Australasia. In the USA, about 3–7 % of asymptomatic white populations of northern European or Scandinavian ancestry are heterozygous carriers. FVL is much less common in other US populations, with a carrier frequency of 1.2 % in African Americans, 2.2 % in Hispanics, 1.2 % in Native Americans, and 0.45 % in Asian Americans.

Clinical Utiltity of Factor V Leiden Testing

Most patients with FVL go through their lives with no clinical events. For those developing clinical sequelae, VTE is the most common clinical presentation. The initial observations of an association with pregnancy-related complications, such as recurrent fetal loss, preeclampsia, and abruption, are currently being questioned [24].

Guidelines on FVL testing continue to evolve [25–27]. Currently, FVL testing is not recommended as a newborn or general population screen, nor is it indicated in asymptomatic prepubescent children, in patients with arterial thrombotic events, or as a risk stratification tool for deciding on type and duration of thromboprophylaxis. Routine testing prior to pregnancy or oral contraceptive use was not found to be cost effective [27]; however, in contrast to no testing, testing was felt to be cost effective prior to hormonal replacement therapy in postmenopausal women, but impact on overall patient management needs to be considered [27].

Testing for FVL may impact clinical management in patients with a history of recurrent VTE; a first VTE before 50 years of age; a first unprovoked VTE at any age; a first VTE at an unusual anatomic site such as the cerebral, mesenteric, portal, or hepatic veins; and a first VTE at any age in a subject with a first-degree family member with a VTE before age 50 years. However, a careful analysis of the impact on patient management should be considered.

Testing for FVL is controversial in young (age <50 years) women smokers with a myocardial infarction; older patients (age >50 years) with a first provoked VTE in the absence of cancer or an intravascular device; or a first VTE related to selective estrogen receptor modulators (SERMs).

After appropriate counseling, testing for FVL may also be indicated in asymptomatic adult family members of probands with known FVL, especially those with a strong family history of thrombosis at a young age (<50 years) and asymptomatic female family members that are pregnant or are considering oral contraceptives or pregnancy.

Available Assays

In most circumstances, a functional assay of plasma APCR is the preferred initial test. In the most commonly used assay, the patient's plasma is first mixed with FV-deficient plasma that contains a heparin neutralizer. The addition of the FV-deficient plasma corrects for deficiencies of other coagulation proteins and may dilute the effect of some lupus-like anticoagulants. The assay is essentially 100 % sensitive and specific for FVL and accurately distinguishes heterozygotes from homozygotes. This assay is unaffected by heparin or warfarin anticoagulation; however, it may still not be diagnostic if the baseline aPTT (after mixing with FV-deficient plasma) still is prolonged due to a lupus anticoagulant or a specific factor inhibitor. Moreover, the assay will miss patients with acquired APCR. Each laboratory must establish the normal range for this assay based on their patient population.

Direct DNA-based testing for FVL is widely available for diagnosis. Commonly used molecular methods involve PCR amplification of the region surrounding the mutation, followed by RFLP analysis, allele-specific PCR amplification, or allele-specific hybridization. Semiautomated assay methods include fluorescence detection of PCR products with allele-specific hybridization probes, and non-PCR signal amplification methods based on either enzymatic hybridization mismatch recognition using fluorescent allele-specific probes or linked fluorescent allele-specific pyrophosphorolysis-kinase reactions [26]. Each laboratory must insure that its method can distinguish FVL from an uncommon polymorphism A1696G.

Counseling Issues and Management

Pre- and post-test counseling should take into account the indications for testing and the potential impact on patient management. VTE is the most common known clinical consequence of APCR due to FVL. Given that VTE is a multifactorial disease, specific issues to review in women are the interaction of the FVL with oral contraceptives, pregnancy, hormonal replacement therapy, and use of SERM therapy (e.g., tamoxifen, raloxifene). Other environmental risk factors that interact with FVL include hospitalization (with or without surgery), nursing home care, trauma, malignant neoplasms (with or without chemotherapy), central venous catheterization, or a transvenous pacemaker, and serious neurologic disease with extremity paresis or paralysis [28].

Incidence of Venous Thromboembolism

The annual incidence of VTE in the general population (noncarriers of FVL) is approximately 1 per 1,000 person-years (0.1 % per year) and increases with age [28]. FVL prevalence

among incident VTE cases varies from 12 to 50 %. In addition, individuals who are heterozygous for FVL have an eight-fold relative increased risk of VTE, while individuals with homozygous FVL have an 80- to 100-fold increased risk. In absolute terms, the data can be summarized as follows: individuals who are FVL heterozygous have a lifetime probability of developing VTE by age 65 years from 2.4 % [29] to 6 % [30] and the annual VTE incidence is 0.45 % [25].

VTE Risk with Oral Contraceptive Use

Depending on the study design, the relative increased risk of VTE is reported to vary from approximately 5- to 30-fold among women who are FVL heterozygous and taking oral contraceptives [27]. In absolute terms, the incidence of VTE among women of childbearing age who are not carriers of FVL and are not on oral contraceptives is approximately 1 per 10,000 woman-years [31], and that risk is increased about three-fold (to an incidence of 3 per 10,000 woman-years) among women taking oral contraceptives. Among women of childbearing age who are FVL heterozygous, the incidence of VTE is about 6 per 100,000 woman-years, and increased to approximately 30 per 100,000 woman-years when also taking oral contraceptives. While this represents a 30-fold relative risk, the incidence is still only 0.3 % per year (i.e., 99.7 % of carriers on oral contraceptives will not develop VTE during that year). In more recent studies, the annual absolute risk of VTE has been approximated to 0.35 per 100 person-years [32]. The acceptability of this mild increase in risk compared to the benefits of oral contraceptive use will vary with each patient.

VTE Risk During Pregnancy and Postpartum Period

The OR for VTE during pregnancy and the postpartum period is approximately 8-fold for women who are FVL heterozygous and 34-fold for women who are FVL homozygous [27]. This translates to an absolute annual incidence of 1.97 per 100 pregnancy-years for women who are heterozygous for FVL, compared to an annual incidence of 0.73 per 100 pregnancy-years for women without FVL [32].

Interaction with Postmenopausal Hormone Replacement Use

Postmenopausal women heterozygous for FVL had an OR for VTE of up to 15-fold higher when receiving estrogen replacement therapy. Given the baseline increased risk of VTE with age, this translated into an annual incidence of >1 % in this population of patients.

Interaction with Age

The incidence of VTE among individuals with FVL also varies by age, ranging from 2–3 per 1,000 person-years for ages 15–30 years to 7–11 per 1,000 person-years for age 60 years and older.

Impact on Patient Management

Empiric anticoagulation therapy is not recommended for asymptomatic FVL carriers; however, appropriate prophylaxis should be prescribed for medical and surgical hospitalizations [33–35]. The indication and type of VTE prophylaxis should not be based on results of thrombophilia testing. FVL carriers with acute VTE should receive standard anticoagulation therapy [36]. Given that VTE recurs frequently, with an estimated cumulative recurrence of 30 % by 10 years [28], research efforts are focused on determining predictive recurrence risk factors. Independent predictors of recurrence include older age, obesity, malignant neoplasm, and extremity paresis or paralysis. The recurrence risk in the presence of hereditary thrombophilia varies by study and thrombophilia type.

Although studies are conflicting, individuals who are FVL heterozygous are not felt to be at increased risk of recurrent VTE compared to non-carriers; however, this risk is significantly increased for individuals who are both heterozygous FVL and heterozygous prothrombin G20210A, and in individuals who are homozygous FVL. Recommendations on short- and long-term management of VTE have recently been reviewed [36].

Pre- and posttest counseling and the decision to perform thrombophilia testing in eligible women prior to prescribing oral contraception or hormone replacement therapy require a detailed discussion with the patients regarding their comfort level with the risk of VTE which needs to be balanced against the benefits of the prescribed hormones. Currently, FVL testing is not advised for pregnancy-associated complications other than VTE [24]. Prophylactic anticoagulation in pregnant, asymptomatic FVL carriers with no prior history of VTE is not routinely recommended. Decisions about providing prophylaxis should be individualized based on the FVL genotype (heterozygous vs homozygous) and coexisting risk factors. Asymptomatic women who do not receive anticoagulation should be followed closely throughout pregnancy and given prophylaxis during the postpartum period.

Prothrombin G20210GA Mutation

Molecular Basis of Disease

The prothrombin G20210A (*F2* G20210A, HGVS: c.*97G>A) mutation is a relatively common mutation that affects the 3′ terminal nucleotide of the 3′ untranslated region of *F2* [37]. The *F2* G20210A mutation causes a gain of function due to increased recognition of the polyadenylation cleavage signal, increased 3′ end RNA processing, mRNA accumulation, and increased protein synthesis [38]. A family-based study has shown close linkage between a quantitative trait locus determining plasma prothrombin activity and the *F2* G20210A mutation [39]. Plasma prothrombin concentration is a major determinant of plasma thrombin

generation potential; thus, thrombin generation is increased in the plasma of individuals either heterozygous or homozygous for the *F2* G20210A mutation. High plasma prothrombin levels also inhibit APC-mediated inactivation of procoagulant factor V_a, further augmenting thrombin production. Although carriers of the *F2* G20210A mutation have higher median plasma prothrombin levels compared to non-carriers, there is considerable overlap of the range of prothrombin levels; thus, molecular testing is the only option for diagnosis of this thrombophilia disorder.

Based on haplotype analyses, the *F2* G20210A mutation also appears to be a founder mutation, arising 20,000–30,000 years ago and after the divergence of Africans from non-Africans and of Caucasoid from Mongoloid subpopulations. In Europe, the overall carrier frequency is 2 %, ranging from 1.7 % in northern Europe to 3 % in southern Europe. In the USA, the estimated overall carrier frequency is 1–2 %. The mutation is uncommon among African Americans and rarely seen among Asian Americans and Native Americans [40].

Clinical Utility of F2 G20210A Testing

As with FVL, the majority of patients with *F2* G20210A will go through their lives with no clinical events. For those developing clinical sequelae, the most common clinical presentation is VTE. Although initial studies suggested an association with pregnancy-related complications, e.g., recurrent fetal loss, preeclampsia, and abruption, currently this association is being questioned and testing is not recommended [24]. Recommendations for *F2* G20210A mutation testing and patient management are essentially the same as for FVL.

Available Assays

Although *F2* G20210A carriers have statistically higher plasma prothrombin activity, the normal range for plasma prothrombin activity is quite broad. Thus, plasma prothrombin activity cannot accurately distinguish *F2* G20210A carriers from non-carriers. Direct DNA-based testing for the specific mutation is required for diagnosis. Molecular testing methods available for the *F2* G20210A mutation are essentially the same as for FVL. Each laboratory must ensure that its method can distinguish the *F2* G20210A from an uncommon polymorphism at nucleotide *F2* C20209T, which is prevalent among the African-American population but is not associated with VTE.

Counseling Issues and Management

Issues pertaining to *F2* G20210A mutation and interactions with environmental risk factors for VTE are similar to those with FVL (see above). The *F2* G20210A mutation is a weaker risk factor for VTE, so the risk estimates and incidence of VTE are lower. Selected unique features of *F2* G20210A are as follows. Female *F2* G20210A carriers receiving oral contraception have an approximate 6-fold increased risk for deep vein thrombosis or VTE [27], and a 150-fold increased risk of cerebral vein thrombosis. The available data suggests that the absolute risk of VTE with oral contraceptive use or pregnancy is similar to that with FVL. No detailed studies are available on the risk of VTE in association with hormone replacement therapy; however the risks are likely similar to those for FVL.

Impact on Patient Management

Issues pertaining to patient management in carriers of *F2* G20210A are similar to those for FVL (see above).

Deficiencies of Anticoagulant Proteins

Molecular Basis of Disease

Genetic deficiencies of plasma AT, PC, or PS activity to approximately half of normal plasma activity are strongly associated with VTE. Altogether, deficiency of AT, PC, or PS is found in less than 10 % of patients with VTE. Comparing family members with inherited AT, PC, or PS deficiency to family members with no defect, the lifetime relative VTE risk is increased about seven- to eight-fold. Individuals who are homozygous or compound heterozygous for PC or PS mutations may develop severe full-thickness dermal and limb thrombotic infarction as neonatalis (called purpura fulminans neonatalis). Homozygous AT deficiency appears to be incompatible with life except for mutations that impair heparin binding to AT.

The AT gene, *SERPINCI*, is located at chromosome 1q23-q25, and mutations lead to type I (reduced antigen and activity) or type II (reduced activity and normal antigen) AT deficiency. Type II can be subdivided into reactive site (RS) mutations, heparin-binding site (HBS) mutations, and pleiotropic effect (PE) mutations. Reported mutations are catalogued in the AT mutation database at http://www.hgmd.cf.ac.uk/ac/index.php.

Mutations in the PC gene, *PROC*, located on chromosome 2q13-q21, lead to type I and II defects, as with AT deficiency. Reported *PROC* mutations are catalogued in the PC mutation database at http://www.hgmd.cf.ac.uk/ac/index.php.

The gene encoding PS, *PROS1*, is located on chromosome 3p11.1-q11.2. A homologous pseudogene, (*PROSP*) is approximately 95 % homologous to the *PROS1* gene. PS deficiency is classified into type 1 (reduced free and total PS antigen and activity), type II (normal total and free PS antigen and reduced PS activity), and type III (normal total reduced free PS antigen).

Clinical Utility of Testing

Although rare, patients with deficiency of PC, PS, or AT are at high lifetime risk of VTE with approximately 50 % of patients developing VTE by 50 years of age. Once symptom-

atic VTE has occurred, such patients are at a high lifetime risk of recurrent VTE (approximately 10 % per year) in the absence of anticoagulation. Testing patients who are young, have a strong family history of VTE, or experience a recurrent VTE is useful.

Avazilable Assays

Mutations causing impaired expression or function of AT, PC, or PS are rare and spread throughout their respective genes. Moreover, there are few data correlating specific mutations with a unique clinical thrombosis phenotype. Thus, for diagnosis, functional testing of plasma activities of AT, PC, or PS is preferred over genetic testing. Selected laboratories may offer gene sequencing on a research basis.

Recommendations for Testing

Given that knowledge of genotype-to-phenotype correlation is still developing, at the present time, genetic testing for PC, PS, and AT deficiency is not routinely recommended. Functional and antigenic assays for the proteins (AT, PC, and PS) should be the initial tests. It is important to remember that these proteins are produced in the liver; thus, patients with advanced liver diseases will have reduced levels. In addition, reference ranges for neonatalis are lower than those for adults. Finally, given that PC and PS are vitamin K-dependent proteins, levels are typically reduced in patients with vitamin K deficiency and those on vitamin K antagonists (warfarin).

Counseling Issues and Management

Asymptomatic family members who are tested as part of family screening have an annual risk of incident VTE that ranges from 0.7 to 1.7 per 100 person-years, a risk that is higher than with FVL or the *F2* gene mutation [32]. In addition, these patients have an annual risk of recurrent VTE that approaches approximately 10 % [41]. The annual risk of VTE in users of oral contraceptives approaches 4.6 per 100 person-years; thus oral contraceptive use is generally discouraged in patients with PC, PS, or AT deficiency.

Hyperhomocysteinemia

Molecular Basis of Disease

Homocysteine is an intermediary amino acid formed during metabolism of methionine to cysteine (Fig. 15.12) which is formed by intracellular demethylation of dietary methionine. Homocysteine is then converted to cysteine in a two-step transsulfuration pathway that requires initial condensation of homocysteine with serine to form cystathionine. The latter reaction is catalyzed by cystathionine-β-synthase (CBS) and requires the essential cofactor, pyridoxal 5-phosphate (vitamin B_6). In the second step, catalyzed by cystathionine γ-lyase, cystathionine is hydrolyzed to α-ketobutyrate and cysteine. Homocysteine can be remethylated to methionine via two pathways. In the first, a methyl

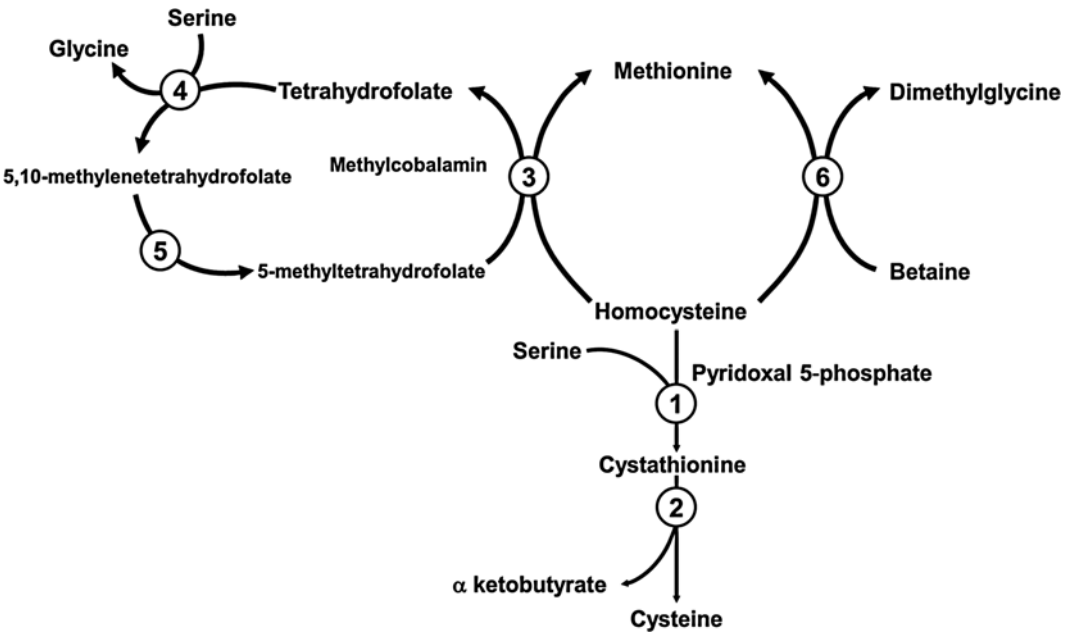

Figure 15.12 Homocysteine metabolism pathway. (*1*) Cystathionine β synthetase (CBS); (*2*) cystathionine γ ligase; (*3*) methyltetrahydrofolate-homocysteine methyltransferase; (*4*) serine-glycine hydroxymethyltransferase; (*5*) 5,10-methylenetetrahydrofolate reductase (MTHFR); (*6*) betaine-homocysteine methyltransferase

group is donated by 5-methyltetrahydrofolate in a reaction catalyzed by methyltetrahydrofolate-homocysteine methyltransferase and requiring methyl-cobalamin (vitamin B_{12}). Tetrahydrofolate (folic acid) is remethylated to 5-methyltetrahydrofolate in a reaction that includes the intermediary 5,10-methylenetetrahydrofolate and requires the enzymes serine-glycine hydroxymethyl transferase and 5,10-methylenetetrahydrofolate reductase (MTHFR). In the second pathway, betaine (trimethyl-glycine) donates a methyl group to remethylate homocysteine to methionine in a reaction requiring betaine-homocysteine methyltransferase. Remethylation is primarily responsible for regulation of fasting homocysteine levels, while transsulfuration mainly regulates higher homocysteine levels as occur in the postprandial state or after methionine loading [42].

Homocystinuria is a rare inherited disorder affecting 3–5 per million of the general population, and usually is caused by severe deficiency of cystathionine β synthase (CBS). Most patients are homozygous or compound heterozygous for one or more of the three mutations (c.833T>C, c.919G>A, c.1224-2A>C) within the *CBS* gene located in the subtelomeric region of 21q22. CBS mutation heterozygotes often have normal basal plasma homocysteine levels, but develop hyperhomocysteinemia after a methionine load [42].

While rare, severe MTHFR deficiency due to mutations in the *MTHFR* gene also cause homocystinuria. Individuals who are homozygous for the common *MTHFR* C677T mutation (HGVS: c.665C>T) and become folate deficient may develop mild hyperhomocysteinemia. This mutation encodes p.Ala223Val. Approximately 1.5 % and 30 % of the US population are homozygous and heterozygous for the *MTHFR* C677T mutation, respectively. The role of a second commonly tested *MTHFR* variant, A1298C (HGVS: c.1286A>C), in the diagnosis and management of VTE is still being defined.

Clinical Utility of Testing

Testing for the *MTHFR* C677T and A1298C variants, in the presence of a normal plasma homocysteine level, provides little clinical utility. Patients with homocystinuria are at markedly increased risk for both atherosclerotic arterial occlusive disease and VTE. About 25 % of patients with homocystinuria develop a thrombotic vascular occlusive event by age 16 years, and about 50 % develop such an event by age 29 years [43]. Of these, about half are arterial occlusive events (e.g., stroke, myocardial infarction, or peripheral artery thrombosis), and the remainder are venous thromboembolic events. The event rate is significantly reduced by vitamin therapy in B_6-responsive patients [42].

Homocystinuric patients generally have plasma homocysteine levels of 100–300 μmol/L. Multiple case-control studies have found that milder hyperhomocysteinemia (e.g., 15–100 μmol/L) is a risk factor for both arterial occlusive disease and VTE, with OR of about 2.2–3.0 [42]. However, there is concern that these studies may have been confounded because plasma homocysteine levels may be elevated after thrombotic vascular events. Indeed, although fewer in number, prospective studies have provided conflicting results. Thus, hyperhomocysteinemia appears to be a weak risk factor for thrombotic arterial occlusive disease, while the risk for VTE remains uncertain. Individuals heterozygous for the *MTHFR* C677T mutation are not at risk for hyperhomocysteinemia, thrombotic arterial occlusive disease, or VTE. While individuals homozygous for the *MTHFR* C677T mutation are at increased risk for hyperhomocysteinemia, homozygosity for the *MTHFR* C677T mutation in the absence of hyperhomocysteinemia is not an independent risk factor for either arterial or venous thrombosis. There are no studies showing that reduction in plasma homocysteine levels by therapy with vitamins B_6, B_{12}, or folic acid reduces the risk for arterial or venous thrombosis. Testing for hyperhomocysteinemia is recommended for patients with documented atherosclerotic arterial occlusive disease (e.g., coronary artery, cerebrovascular, or peripheral vascular), while testing patients with VTE remains controversial. Genotyping for the *MTHFR* C677T mutation may provide insight into the etiology of hyperhomocysteinemia, but does not influence therapy or warrant family testing. Recently the American College of Medical Genetics released practice guidelines recommending that providers not order *MTHFR* polymorphism genotyping for a thrombophilia or recurrent pregnancy loss clinical evaluation. In addition, genotyping should not be conducted for at-risk family members [44].

Available Assays

Clinical assays for plasma homocysteine include HPLC and immunoassay [42]. Each laboratory should determine local gender and population-specific reference ranges. The basal plasma homocysteine level should be determined first, and, if elevated, further investigation regarding the potential cause as well as therapeutic intervention should be considered. The need for an overnight fast prior to testing plasma homocysteine levels is unclear. Because plasma homocysteine levels can be elevated for several months after myocardial infarction or stroke, testing should be postponed accordingly. In addition to vitamin deficiency, impaired renal function and hypothyroidism are other common causes of hyperhomocysteinemia. It is particularly important to exclude vitamin B_{12} deficiency prior to beginning therapy with high-dose folic acid which can precipitate acute B_{12} neuropathy. If the basal homocysteine level is normal, methionine loading (0.1 g/kg body weight or 3.8 g/m^2 body surface area with measurement of plasma homocysteine 4–6 h after the load) should be considered since 25–40 % of symptomatic patients develop hyperhomocysteinemia only after methionine loading. Therapy includes folic acid (0.5–1.0 mg/day), vitamin B_{12} (400–1,000 μg/day), and/or vitamin B_6 (20–50 mg/day) [42].

Hematologic Disorders: Hemochromatosis, Hemoglobinopathies, and Rh Incompatibility

16

Daniel B. Bellissimo and Archana Agarwal

Abstract

Hereditary hemochromatosis (HHC) is a disorder of iron metabolism and has been classified into six types having similar phenotypes but caused by mutations in different genes involved in the regulation of iron stores. Two allelic variants of the *HFE* gene, p.C282Y (c.845G>A) and p.H63D (c.187C>G), are significantly correlated with HHC, and most clinical studies have focused on these variants. Diagnosis of HHC is based on clinical, biochemical, histological, and molecular studies, specifically tests such as transferrin saturation, ferritin concentration, evaluation of iron stores by liver biopsy, and genotyping for p.C282Y and p.H63D mutations in *HFE*. Hemoglobinopathies are the most common single-gene diseases in the world. Approximately 5–7 % of the world's population is a carrier for one of the hemoglobin disorders. Two copies of the alpha (α) globin genes are present (α1 and α2) on each chromosome 16. The beta and beta-like chains (ε, Gγ, Aγ, and δ) are clustered on chromosome 11. The hemoglobinopathies are commonly divided into two broad categories: structural variants, and thalassemias that are characterized by reduced rates of production of α or β chains. Sickle hemoglobin results from a single nucleotide substitution (GAG→GTG) that changes codon 6 of the β-globin gene from a glutamic acid to a valine (Glu6Val). Homozygosity for this mutation causes sickle cell disease (SD), an autosomal recessive disorder. SD is a major cause of morbidity and mortality in Africa and in populations with individuals of African descent. The α-thalassemias are most commonly caused by deletions while the β-thalassemias are most likely due to single nucleotide substitutions or frameshift mutations. Single nucleotide changes causing either structural variants or thalassemias can be easily diagnosed by targeted mutation analysis or by sequencing. Gap-PCR or multiplex ligation dependent probe amplification assays are the common methods to detect deletions. The Rh antigen system is clinically important because antibodies to Rh antigens are involved in hemolytic transfusion reactions, autoimmune hemolytic anemia, and hemolytic disease of the fetus and newborn. The Rh antigens are expressed on proteins encoded by two distinct but highly homologous genes, *RHD* and *RHCE*, on chromosome 1p34.3-36.1. The D antigen is expressed from *RHD* and the C/c and E/e antigens are expressed from *RHCE*. Rh incompatibility cases require both phenotypic and genotypic testing of parental samples.

Introduction

Hemochromatosis

Hereditary hemochromatosis (HHC) is a disorder of iron metabolism resulting from excess iron storage in the liver, skin, pancreas, heart, joints, testes, and pituitary gland. It is a disorder of iron metabolism and has been classified into six types having similar phenotypes but caused by mutations in different genes involved in the regulation of iron stores. Two allelic variants of the *HFE* gene, p.C282Y (c.845G>A) and p.H63D (c.187C>G), are significantly correlated with HHC, and most clinical studies have focused on these variants. These mutations are most common in populations of European descent. Diagnosis of HHC is based on clinical, biochemical, histological, and molecular studies, specifically tests such as transferrin saturation, ferritin concentration, evaluation of iron stores by liver biopsy, and genotyping for p.C282Y and p.H63D mutations in *HFE*, when necessary. These mutations can be accurately detected by polymerase chain reaction-restriction fragment length polymorphism (PCR-RFLP), allele-specific PCR (AS-PCR), allele-specific oligonucleotide (ASO) hybridization, single-nucleotide primer extension, and real-time PCR methods.

Hemoglobinopathies

Hemoglobinopathies are the most common single-gene diseases in the world; approximately 5–7 % of the world's population is a carrier for one of the hemoglobin disorders. There are two copies of the alpha (α) globin genes (α1 and α2) on each chromosome 16. The beta (β) and β-like chains (ε, Gγ, Aγ, and δ) are clustered on chromosome 11. The hemoglobinopathies are commonly divided into two broad categories: structural variants, and thalassemias that are characterized by reduced rates of production of α or β chains. Sickle hemoglobin results from a single nucleotide substitution (GAG→GTG) that changes codon 6 of the β-globin gene from a glutamic acid to a valine (Glu6Val). Homozygosity for this mutation causes sickle cell disease (SD), an autosomal recessive disorder. SD is a major cause of morbidity and mortality in Africa and in populations with individuals of African descent. The α-thalassemias are most commonly caused by deletions while the β-thalassemias are most likely due to single nucleotide substitutions or frameshift mutations. Single nucleotide changes causing either structural variants or thalassemias can be easily diagnosed by targeted mutation analysis or by sequencing the gene. Gap-PCR or multiplex ligation dependent probe amplification (MLPA) assays are the common methods to detect deletions.

Rh Incompatibility

The Rh antigen system is clinically important because antibodies to Rh antigens are involved in hemolytic transfusion reactions, autoimmune hemolytic anemia, and hemolytic disease of the fetus and newborn (HDFN). HDFN results from the alloimmunization of a mother to a paternally inherited fetal alloantigen. The most common cause for alloimmunization is fetomaternal hemorrhage. The severity of HDFN is variable; mild cases require either no treatment or phototherapy, while more severe cases require exchange transfusion at birth, or possibly intrauterine transfusion, and may result in fetal hydrops. The Rh antigens are expressed on proteins encoded by two distinct but highly homologous genes, *RHD* and *RHCE*, on chromosome 1p34.3-36.1. The most common RHD-negative allele results from the total deletion of *RHD*; however, there are a number of *RHD*-negative haplotypes that are positive for at least portions of the *RHD* gene. The c.307T>C, p.Ser103Pro, variation is responsible for the C and c antigens expressed from the *RHCE* gene. The assay formats are predominantly AS-PCR and real-time PCR with hydrolysis probes.

Hemochromatosis

Molecular Basis of Disease

HHC is a disorder of iron metabolism resulting from excess iron storage in the liver, skin, pancreas, heart, joints, testes, and pituitary gland. If left untreated, life-threatening complications such as cirrhosis, diabetes, liver cancer, and cardiomyopathy may result. Iron overload and the resulting clinical complications can be avoided by early diagnosis and periodic phlebotomy to reduce the body's iron stores. Extensive reviews on the *HFE* gene and HHC are available [1–4].

Table 16.1 Hereditary hemochromatosis classification

Type	OMIM#	Gene	Chr.	Protein	Inheritance	Age of onset
1	235200	*HFE*	6p22.2	Hereditary Hemochromatosis Protein	Autosomal recessive	Adult
2A	602390	*HJV*	1q21.1	Hemojuvelin	Autosomal recessive	Child to young adult
2B	602390	*HAMP*	19q13.12	Hepcidin	Autosomal recessive	Child to young adult
3	604250	*TFR2*	7q22.1	Transferrin Receptor Protein 2	Autosomal recessive	Young adult to adult
4A	606069	*SLC40A1*	2q32.2	Solute carrier family 40 member 1 (Ferroportin)	Autosomal dominant (LOF)	Adult
4B	606069	*SLC40A1*	2q32.2		Autosomal dominant (GOF)	Adult

GOF gain of function, *LOF* loss of function

Table 16.2 *HFE* genotype frequencies and their contribution to hereditary hemochromatosis

Genotype	Population frequency (%)	Pooled odds ratio	95 % CI	% HHC cases
p.C282Y/p.C282Y	0.4	4,383	1,374–>10,000	77.5
p.C282Y/p.H63D	2.0	32	18.5–55.4	5.3
p.H63D/p.H63D	2.0	5.7	3.2–10.1	1.5
p.C282Y/+	9.2	4.1	2.9–5.8	3
p.H63D/+	23	1.9	1.5–2.5	3

Source: Data are from Refs. 2, 7

HHC has been classified into six types that have similar phenotypes but are caused by mutations in different genes involved in the regulation of iron stores (Table 16.1). Types 1–3 are autosomal recessive disorders with mutations in genes that result in defective expression of the hepcidin (*HAMP*) gene. Hepcidin regulates iron homeostasis by binding SLC40A1, also known as ferroportin, causing degradation of this iron-transporting protein resulting in reduced iron export from enterocytes. Type 4 is an autosomal dominant disorder with mutations in the *SLC40A1* gene. The gain-of-function mutations in type 4B cause defective down regulation in response to hepcidin. The loss-of-function mutations in type 4A result in iron retention in monocytes and macrophages and cause a distinctly different phenotype than the other types of HHC. HHC typically has an age of onset in adults; however, types 2A and 2B are juvenile forms of HHC. Except for *HFE*-related HHC (type 1) which is the most common form of HHC, the other types of HHC are rare.

The HFE protein, a 343 amino acid transmembrane protein, is homologous to major histocompatibility class I molecules and associates with β_2-microglobulin. The HFE protein is found predominantly in hepatocytes. At the cell surface, HFE complexes with the transferrin receptor protein 1 (TfR1) and competes for binding of iron-loaded transferrin. Under conditions of high iron, HFE is displaced from TfR1 and binds to transferrin receptor protein 2 (TfR2). Although the mechanism is not understood, the HFE-TfR2 complex is believed to create an intercellular signal to increase hepcidin expression. The role of *HFE* in HHC and iron homeostasis is supported by the fact that an *HFE* knockout mouse develops iron overload similar to that seen in human HHC [5].

Two allelic variants of the *HFE* gene, p.C282Y (c.845G>A) and p.H63D (c.187C>G), are significantly correlated with HHC, and most of the clinical studies have focused on these variants [6]. These two variants are usually not found on the same chromosome. The p.C282Y mutation abolishes a conserved disulfide bond which disrupts secondary structure required for HFE-binding to β_2-microglobulin and subsequent transport to the cell surface. The p.C282Y HFE protein remains in the Golgi rather than being transported to the cell surface. The p.H63D protein product is expressed on the cell surface, but likely has an altered interaction with the transferrin receptor. Several other *HFE* allelic variants have been described, but little is known regarding their phenotypic effects. The p.S65C mutation has been implicated in HHC but its clinical significance is still unclear [2].

The frequency of the p.C282Y and p.H63D mutations in different ethnic groups has been reviewed [2]. These mutations are most common in populations of European descent. A pooled analysis of several Caucasian population studies found that the frequency of p.C282Y homozygosity was 0.4 % and heterozygosity was 9.2 % (Table 16.2). The frequency of p.H63D homozygosity was 2 % and heterozygosity was 23 %. Compound heterozygosity (p.C282Y/p.H63D) was 2 %. The frequency of *HFE* genotypes in HHC cases was 77.5 % for p.C282Y/p.C282Y, 5.3 % for p.C282Y/p.H63D, and 1.5 % for p.H63D/p.H63D. The pooled odds ratio (OR) for each *HFE* genotype indicated that individuals with the p.C282Y/p.C282Y and p.C282Y/p.H63D genotypes have the highest risk for iron overload with an OR of 4,383 and 32, respectively [7]. Individuals with the p.H63D/p.H63D and p.C282Y heterozygote (p.C282Y/+) gen-

otypes are not considered to be at elevated risk for developing iron overload. The high frequency of HHC patients with the p.C282Y/p.C282Y genotype suggested that the penetrance for this genotype was very high. However, additional studies designed to estimate the penetrance suggested that the majority of p.C282Y homozygotes would not develop clinical disease resulting from iron overload. In a large prospective study, the proportion of p.C282Y homozygotes with documented iron-overload was 28.4 % for men and 1.2 % for women [8]. Currently, the estimates of the penetrance range from 1 % to 50 %. The penetrance of the p.C282Y/p.H63D genotype is much lower, ranging from 0.3 % to 1.4 %.

Clinical Utility of Testing

Diagnosis of HHC is based on clinical, biochemical, histological, and molecular studies, specifically tests such as transferrin saturation, ferritin concentration, evaluation of iron stores by liver biopsy, and genotyping for p.C282Y and p.H63D mutations in the *HFE* gene. Due to the reduced penetrance of p.C282Y/p.C282Y, the even lower penetrance of p.C282Y/p.H63D, and the presence of other mutations within *HFE* or in other genes related to HHC, the diagnosis or rule out of HHC cannot be made with a molecular test alone. However, in patients with clinical and biochemical symptoms of iron overload, molecular testing can be useful in confirming the diagnosis of HHC and may eliminate the need for liver biopsy. Typically, molecular testing is warranted in patients with transferrin saturation of >45 %. A genotyping result of p.C282Y/p.C282Y or p.C282Y/p.H63D is considered to confirm a diagnosis of HHC. A small number of cases (<5 %) will be identified as p.C282Y heterozygotes. It is possible these patients have other mutations in *HFE* or mutations in other genes involved in iron overload (Table 16.1).

Molecular testing also is used for carrier analysis and to identify relatives at risk for HHC. After the diagnosis of HHC is made in the proband, testing may be appropriate for other family members who may be at higher risk than the general population for developing iron overload. The iron status of these individuals can be monitored as appropriate. The *HFE* genotyping test can be used to identify individuals with the same genotype as the proband; these individuals would be at higher risk for developing iron overload than family members who did not inherit the mutations present in the proband. Requests for prenatal testing for HHC are highly unusual since HHC is a treatable adult onset disorder with low penetrance.

Soon after the identifications of the role of *HFE* mutations in iron overload, population screening for p.C282Y and p.H63D was considered. Since simple phlebotomy can prevent iron overload and its severe clinical complications, early identification of individuals at risk would be beneficial. However, given the low penetrance of the *HFE* genotypes, the majority of individuals identified with *HFE* mutations would be unlikely to develop clinical symptoms associated with HHC and yet might be subject to stigmatization and/or genetic discrimination as a result of the testing. At this time, population screening for HHC is not recommended due to these limitations.

Available Assays

As the p.C282Y and p.H63D mutations are single nucleotide polymorphisms (SNPs), they can be accurately detected using a variety of methods. As with all SNP assays, careful consideration must be given to the known sequence variants that may affect the assay method. The first method described for these mutations was an oligonucleotide ligation assay [6]. The primers described by this group to amplify the regions of the *HFE* gene have been used in a variety of assays. However, polymorphisms in one primer binding site sequence has been described and has the potential to result in a diagnostic error [9, 10]. Using primers that do not include the polymorphisms eliminates this potential error. The possible interference of the p.S65C mutation with the detection of p.H63D also should be considered in assay design. A number of additional assay methods for these mutations have been described, including PCR-RFLP, AS-PCR, ASO hybridization, single-nucleotide primer extension, and real-time PCR methods [11].

A simple method for detection of p.C282Y and p.H63D is PCR-RFLP. p.C282Y is detected by digestion of the PCR product with *Rsa*I, and H63D is detected by using *Bcl*I or *Mbo*I. The digested PCR products are analyzed by gel electrophoresis. The advantage of this method is that optimization is relatively straightforward and expensive equipment is not required. The disadvantage is a longer turnaround time for testing. AS-PCR assays distinguish the normal and mutant alleles directly with only gel electrophoresis of the PCR products, so the post-PCR processing is reduced. The AS-PCR reactions require careful optimization, and multiple reactions are required to determine the genotype.

Real-time PCR methods that couple PCR with detection of hybridization probes are commonly used to detect single nucleotide polymorphisms. These techniques are rapid, sensitive, have a wide dynamic range, and require no additional processing after PCR. A variety of chemistries are available such as FRET hybridization probes with melt curve analysis, hydrolysis probes, and molecular beacons. For each method, the appropriate negative and positive controls are required to demonstrate the specificity of the assay. A melting curve of the hybridization probe fluorescence is used to detect changes in thermal stability and therefore discriminate single base mutations in a single reaction (Fig. 16.1). An additional advantage of real-time PCR is that new sequence variations in the probe regions are detected. For example, the probe for

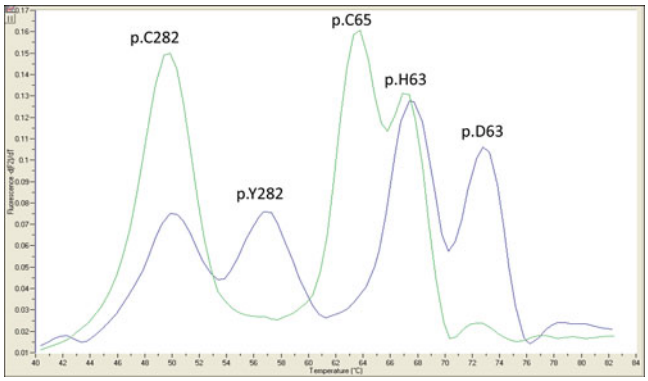

Figure 16.1 PCR-FRET hybridization probe with melt curve analysis for p.Cys282Tyr (p.C282Y) and p.His63Asp (p.H63D) alleles of the *HFE* gene. One set of probes distinguishes the p.C282Y alleles and the other set p.H63D alleles. The probes for p.H63D also overlap the p.S65C allele so it can also be identified. Each allele has a specific melting temperature. Since the melting temperatures of the probes do not overlap, this assay can be performed using a single fluorophore. An example of a p.C282Y/p.H63D compound heterozygous sample (*blue trace*) and a sample negative for p.C282Y and p.H63D and positive for p.S65C (*green trace*) are shown

p.H63D also detects the p.S65C mutation [12]. In cases where testing is indicated for additional *HFE* mutations or HHC types 2–4, *HFE*, *HJV*, *HAMP*, *TFR2*, and *SLC40A1* are analyzed by DNA sequencing.

Interpretation of Test Results

The analytic sensitivity for detecting these mutations should be >99 %. False positives and false negatives are rare. However, sequence variations in primers, probes, and restriction sites have the potential to lead to a diagnostic error. A polymorphism reported at the 3′ end of one of the primers described in the original publication [6] was later reported to prevent the amplification of wild-type p.C282Y alleles with some assay methods [9].

Interpretations should be made in the context of all clinical information and account for the reduced penetrance and variable expression observed with HHC. In individuals with biochemical evidence of iron overload, a genotype of p.C282Y/p.C282Y or p.C282Y/p.H63D confirms a diagnosis of *HFE*-related HHC. Up to 5 % of these individuals will be heterozygous for p.C282Y. Testing for other *HFE* mutations or mutations in other iron-related genes may be indicated. Individuals who test negative for p.C282Y are a heterogeneous group with other genetic causes of HHC or iron overload caused by liver disease or a metabolic disorder. Unaffected individuals with the p.C282Y/p.C282Y genotype have an increased risk of HHC with a penetrance of 1–50 %. p.C282Y heterozygotes may have elevated iron levels but rarely develop complications of iron overload.

Genetic counseling should be recommended when p.C282Y and p.H63D are identified in a family. Molecular testing will be useful in identifying carriers, homozygous individuals, and those who did not inherit the at-risk genotype. Most parents of the proband will be p.C282Y heterozygotes so the risk to siblings of a proband is 25 % but could be as high as 50 % if one of the parents is homozygous. The risk assessment should include the most current estimates of the disease penetrance.

Laboratory Issues

Proficiency testing for p.C282Y and p.H63D mutations in the *HFE* gene is available through the College of American Pathologists (CAP) Molecular Genetics Laboratory (MGL) survey. Cell-line controls can be purchased from Coriell Cell Repositories (http:/ccr.coriell.org/).

Hemoglobinopathies

Molecular Basis of Disease

Hemoglobinopathies are the most common single-gene diseases in the world; approximately 5–7 % of the world's population is a carrier for one of the hemoglobin disorders. The extensive study of these disorders has led to much of our knowledge regarding protein structure and function, mutational mechanisms, gene expression during development, and evolution. Extensive reviews of these disorders are available [13, 14]. A list of the numerous characterized mutant alleles is available at the Globin Gene Server (http://globin.cse.psu.edu) and the Human Gene Mutation Database (http://www.hgmd.cf.ac.uk/ac/index.php).

Hemoglobin (Hb) functions as an oxygen carrier in vertebrate red cells. The protein is a tetramer consisting of two α and two β chains. Each subunit contains a heme prosthetic group that is responsible for the oxygen-binding capacity of the protein. These chains are highly homologous to one another at the primary sequence level as well as in three-dimensional structure. Six different globin chains (α, β, γ, δ, ε, ζ) are found in normal human hemoglobins at various times during development [13–15]. The α and β chains are encoded by separate genetic loci (Fig. 16.2). The α and α-like chains (ζ, Ψζ, Ψα) are clustered on chromosome 16. In addition, two copies of the α-globin genes, α_1 and α_2, are located on each chromosome 16. The β and β-like chains (ε, Gγ, Aγ, Ψβ, δ) are clustered on chromosome 11.

The developmental regulation of these genes is important to the understanding of many of the hemoglobin disorders. The gene order in each cluster is identical to the order of expression during development. In each developmental stage, there is an equimolar production of α and β chains. Hb Gower 1 ($\zeta_2\varepsilon_2$), Hb Gower 2 ($\alpha_2\varepsilon_2$), and Hb Portland

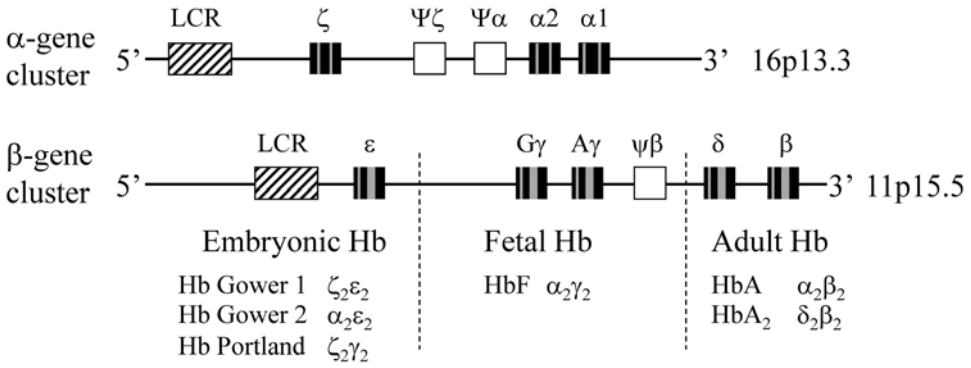

Figure 16.2 Genomic organization and developmental expression of the α- and β-globin gene clusters. The *boxes* identify the locus control region (LCR; *diagonal*), pseudogenes (*white*), exons (*black*), and introns (*gray*). The developmental time periods for the expression of the β-globin genes are indicated by the *dashed lines*. (Adapted from Stamatoyannopoulos G, Nienhuis AW. Hemoglobin switching. In: Stamatoyannopoulos G, Nienhuis AW, Majerus PW, Varmus H, eds. *The molecular basis of blood diseases*. Philadelphia: W.B. Saunders, 1994:107–55)

($\zeta_2\gamma_2$) are expressed in embryos. In the fetal stage, the Hb is predominantly $\alpha_2\gamma_2$ (HbF). In normal adults, the Hb is comprised of approximately 96 % $\alpha_2\beta_2$ (HbA), 2.5 % $\delta_2\beta_2$ (HbA2), and approximately 1 % $\alpha_2\gamma_2$ (HbF). In addition to promoters and enhancer elements, the locus control region (LCR) is responsible for developmental expression of these genes. The LCR for the β locus is approximately 20 kb upstream of the ε-globin gene and the LCR for the α locus is approximately 40 kb upstream from the ζ-globin gene. The LCR is required for expression of all the globin genes at the locus [13].

The difference in gene dosage and expression patterns between α and β genes is significant. Each diploid genome encodes four copies of the α gene and two copies of the β gene. Since γ globin is expressed during fetal life and shortly after birth, β globin mutations do not exert their deleterious effects during the prenatal period. In contrast, since α chains are expressed during fetal and postnatal life, mutations in the α chain can cause severe disease during both developmental stages.

The hemoglobinopathies are commonly divided into two broad categories: structural variants, and thalassemias that are characterized by reduced rates of production of α or β chains [13]. These categories are not exclusive, as structural variants, which result in unstable hemoglobins, can be associated with both α- and β-thalassemia phenotypes. Although an extensive number of abnormal hemoglobins have been described, this chapter focuses on two of the most common structural variants, sickle hemoglobin (HbS) and HbC, and the more common forms of α- and β-thalassemia.

Sickle hemoglobin results from a single nucleotide substitution (GAG→GTG) that changes codon 6 of the β-globin gene from a glutamic acid to a valine (p.Glu6Val). Using standard nomenclature this variant should be reported as p. Glu7Val; however, the extensive literature uses the numbering of the mature protein in which the first methionine is cleaved. Homozygosity for this mutation causes SD, an autosomal recessive disorder. SD is a major cause of morbidity and mortality in Africa and in populations with individuals of African descent such as the Mediterranean area, the Middle East, and India [13]. Under the condition of low oxygen tension in the microvasculature, HbS polymerizes into fibers that cause the erythrocytes to sickle. The poor deformability of the sickle red cells and their defective passage in the micro-circulation causes the vasoocclusive events that are the hallmark of SD. The shortened survival of these red cells leads to a chronic hemolytic anemia. The frequency of SD is 1 in 600 in African Americans; the heterozygote frequency in African Americans is approximately 8 %, but the frequency in Africa can be much higher [13]. The frequency of the HbS allele, as well as alleles causing thalassemia, is maintained by their protective effect against malaria. The heterozygous state, sickle cell trait, is clinically normal but may be at risk for vasoocclusive events when exposed to low oxygen tension such as flying at high altitude in an airplane with reduced cabin pressure.

The sickling disorders also include compound heterozygous states with the HbS mutation in association with another β-globin variant such as HbC, or β-thalassemia. Similar to HbS, HbC also has an amino acid substitution at position 6 of the β-globin gene (Glu6Lys). HbC is less soluble than HbA and leads to reduced deformability of the red cells and a mild hemolytic anemia. The allele is frequent in persons of African descent; approximately 3 % of African Americans are carriers [13]. Individuals with $\beta^S\beta^C$ have sickle cell hemoglobin (SC) disease. SC disease is a milder hemolytic disorder than SD and therefore may go unrecognized until a serious complication occurs.

The thalassemias result from the reduced synthesis or stability of either the α- or β-globin chain. The chains in excess due to the α:β imbalance precipitate within the red blood cells, leading to membrane damage and red cell destruction. The defect produces a hypochromic, microcytic anemia. The population distribution of thalassemia

includes the Mediterranean, Middle East, portions of Africa, India, and Southeast Asia; however, the migration of these populations has resulted in the worldwide occurrence of these diseases [13].

The most common forms of α-thalassemia are caused by deletions. The genetics of α-thalassemia are complicated by the fact that each normal chromosome has two α genes and that there are haplotypes with either the loss of one (-α) (α+ thalassemia) or both (--) (α^o thalassemia) copies of the α gene. In addition to the normal genotype, four additional genotypes are possible: silent carrier (αα/-α), α-thalassemia trait (-α/-α or --/αα), HbH (β_4) disease (-α/--), and hydrops fetalis, Hb Barts: γ_4 (--/--). Individuals with HbH disease have a moderately severe hemolytic anemia, while the inheritance of no copies of the α gene (Hb Barts) is incompatible with life. Carriers of α-thalassemia trait have only a mild hypochromic microcytic anemia, but couples with these genotypes are at risk for having a fetus with hydrops fetalis or a child with HbH disease. The (--) genotype, and therefore the risk of hydrops fetalis, is largely restricted to Southeast Asia, while in other groups the (-α) genotype is more common [13, 14]. Distinguishing these two carrier states is important for accurate genetic counseling. The most widely occurring single α-globin gene deletions are $-\alpha^{3.7}$ and $-\alpha^{4.2}$. The double α-globin gene deletions $\alpha\text{-}^{SEA}$, $\alpha\text{-}^{FIL}$, and $\alpha\text{-}^{THAI}$ are common in Southeast Asia while $\alpha\text{-}^{MED}$ and $-(\alpha)^{20}$ are more common in the Mediterranean area. Nondeletion α-thalassemia alleles are rare, but the $\alpha^{Constant\ Spring}$, a mutation in the termination codon of the α_2 gene, is frequently present in Southeast Asia.

The β-thalassemias are mainly inherited in an autosomal recessive manner, although there are some dominant forms. Heterozygotes are asymptomatic but with recognizable hematologic parameters including an elevated HbA_2. Homozygotes and compound heterozygotes of HbE develop a severe anemia within the first year of life as the switch from γ to β chains occurs. In contrast to α-thalassemia, β-thalassemias are heterogeneous at the molecular level. The molecular mechanism of the mutations is equally varied. Most mutations are single-nucleotide substitutions or frameshift mutations. More than 200 disease-causing mutations have been identified in the β-globin gene; however, within each at-risk population there is a set of 4–10 mutations that account for the majority of disease-causing alleles (Table 16.3) [15]. HbE is a β-globin variant (Glu26Lys) that can cause a mild thalassemia phenotype. It is one of the most common Hb variants, and the frequency is high in Southeast Asia. Although HbE homozygotes are asymptomatic, compound heterozygotes with another β-thalassemia allele will have an abnormal phenotype [13]. Although deletions are rare, a 619 base pair (bp) deletion involving the 3′ end of the β-globin gene is common in India and Pakistan, accounting for approximately 30 % of the β-thalassemia alleles [13]. β-Thalassemia also may result from deletion of part of the globin gene cluster (e.g., 5P-thalassemia) or from deletions that start 50–100 kilobases (kb) upstream from the globin gene cluster and extend 3′ into the cluster (εγδβ-thalassemia). Some of these deletions lead to hereditary persistence of fetal hemoglobin. In addition, there are fusion chain variants such as Hb Lepore, a $\delta\beta^+$ thalassemia. Mutations either completely (β°-thalassemia) or partially (β^+-thalassemia) abolish β-chain production. Milder phenotypes have been recognized that can be explained at the molecular level by homozygosity or compound heterozygosity for mild or silent mutations, coinheritance of α-thalassemia, or coinheritance of a genetic determinant that increases the production of the γ chain.

Clinical Utility of Testing

Sickle cell disease and α- and β-thalassemias and their carrier states can be diagnosed using standard red-cell indices such as Hb, red blood cell number, mean corpuscular volume, and red cell distribution, along with Hb electrophoresis, high-performance liquid chromatography (HPLC) and isoelectric focusing (IEF). The main application of molecular testing is for prenatal diagnosis and genetic counseling. When a carrier is identified by abnormal hematologic analysis, the carrier's partner can be screened for carrier status. Molecular testing can be used to identify the disease-causing mutations. Prenatal molecular testing can be offered to couples whose gene mutations have been identified. Testing also can be used to identify mutations in partners with borderline or normal hematologic values when one partner is clearly a carrier, since these couples are at risk for having a fetus with thalassemia. This testing model has been successfully used in population screening to reduce the incidence of thalassemia.

In states where testings for hemoglobinopathies are included in the newborn screen, HbH disease or hydrops fetalis can be diagnosed by the presence of Hb Barts on HPLC, or IEF analysis. However, molecular confirmation might be necessary in these conditions to make a definitve diagnosis and also to know about the specific deletions for genetic counseling purposes. For α-thalassemia, prenatal diagnosis predominantly is used in situations where both members of the couple are carriers of the double α-gene deletion or one member has one α gene deletion and the other has double α gene deletions, as only these couples are at risk for having a fetus with hydrops fetalis and HbH disease, respectively. Although the α^o-gene is found almost exclusively in the Southeast Asian population, molecular testing can be used to identify and distinguish the two distinct types of α-thalassemia carrier states (-α/-α vs --/αα) because HPLC analysis is not helpful in these conditions. As these carrier states can present with microcytic anemia, the diagnosis is important in differentiating them from iron deficiency states to avoid unnecessary iron intake.

[a]Nonstandard variant designations in common use

[b]DNA nucleotide change designations follow current nomenclature guidelines

In addition to prenatal testing for β-thalassemia, molecular testing can be used to predict the clinical phenotype by identifying mild and silent alleles and for presymptomatic diagnosis of at-risk family members. HbE disorders are now becoming increasingly recognized in the US population due to migration. A β-thalassemia major phenotype also could be due to compound heterozygosity for a beta zero mutation and HbE disease. Molecular testing is the only way to make a definitive diagnosis in these cases. Molecular testing also may be useful in recognition of complex heterozygotes in populations where multiple hemoglobinopathies are common.

Available Assays

HbS and HbC are caused by single-base substitutions, so a number of methods are suitable as long as the mutations can be distinguished from one another. One of the most common methods is PCR-RFLP [16]. Modified primers are used to introduce restriction sites so the β^A, β^S, and β^C alleles can be identified using *Ava*I and *Sty*I restriction enzymes. A real-time PCR method using hybridization probes also has been described that can readily identify the β^E allele in addition to the β^A, β^S, and β^C alleles [17].

The conventional method for detecting α-gene deletions has been Southern blot using probes to the ζ- and α-globin genes. The ζ-globin probe is useful for detecting deletion breakpoint fragments because the α-globin probe will fail to hybridize to the α fragment in an α^o-thalassemia fetus [16]. A number of PCR-based methods including a gap PCR method which is widely used, have been described that detect the seven most common α^o and α+ deletions [18]. Since these deletions either partially or completely remove the α2 globin gene, its detection by PCR indicates heterozygosity when a deletion allele is present. The PCR assays are faster, less expensive, and easier to interpret than Southern blot, although the PCR has to be carefully optimized to faithfully amplify the GC-rich sequences at this locus. The remaining deletions not detected by this common deletion testing by PCR can be detected by MLPA [19]. If

all these tests are negative, non-deletion mutations can be identified by α globin sequencing.

Since the mutations causing β-thalassemia are mainly single-nucleotide substitutions, assays using ASO hybridization, AS-PCR, PCR-RFLP [19], and real-time PCR with hybridization probes have been described [20]. These assays target population-specific mutations. If mutations are not identified by these methods, then direct sequencing of the β-globin gene including known 5′ promoter and 3′ polyadenylation site mutations can be performed. The size of the β-globin gene, about 1.6 kb containing three exons, is amenable to DNA sequencing. The advantage of DNA sequencing is that virtually all β-globin mutations can be detected. Deletions of the β-globin gene cluster can be detected by MLPA or gap PCR.

Interpretation of Test Results

Hematologic screens are more than 95 % accurate, with occasional problems detecting carriers with mild phenotypes. The analytic sensitivity for detecting gene mutations should be greater than 99 %. False positives and false negatives are rare. However, sequence variations in primers, probes, and restriction sites have the potential to lead to a diagnostic error. The mutation resulting in HbC occurs at 1 bp from the HbS mutation. There is the potential for a diagnostic error with a test that does not clearly distinguish these two mutations.

The mutation detection rate for α- and β-thalassemia will depend on the mutations in the panel and the patient's ethnicity. For α-thalassemia, greater than 95 % of the mutations are deletions; the majority of these deletions can be detected in the current assays. For β-thalassemia, if a mutation is not detected in a patient with symptoms, then DNA sequencing should be considered to identify the mutation. The detection rate using DNA sequencing for β-thalassemia is approximately 99 % depending on the actual coverage of the gene sequence. Deletions larger than the PCR product size or ones that abolish the PCR primer sites will not be detected by DNA sequencing. When interpreting the molecular analysis in relation to the clinical phenotype, the possible coinheritance of genetic determinants that could influence the phenotype must be considered. For example, inheritance of an α-thalassemia allele, silent or mild β-thalassemia allele, HPFH allele, or HbS allele would modify the phenotype. Family studies are useful in sorting out complex genotypes.

The possibility of maternal contamination should be considered in interpreting the molecular test result done for prenatal diagnosis. The contamination with maternal cells of both direct and cultured amniotic fluid and chorionic villus sampling (CVS) is well documented and therefore represents a potential source of error in prenatal diagnosis. Prenatal samples should be tested in parallel with a maternal sample, or both samples should be used to perform a separate analysis for maternal contamination using microsatellite markers, to rule out error due to maternal cell contamination. Laboratories should understand how their testing methods are affected by the presence and the amount of maternal cell contamination. The mutation status of one or both parents, as appropriate, should be tested prior to testing of fetal specimens, preferably within the same laboratory.

Laboratory Issues

Proficiency testing is available for HbS and HbC through the CAP MGL survey. Proficiency testing for α- and β-thalassemia usually can be accomplished through a sample exchange with another laboratory that performs the testing. DNA and cell-line controls for many of the hemoglobinopathies can be purchased from Coriell Cell Repositories (http://ccr.coriell.org/). Commercial kits for the HbS, HbC, and the common α- and β-thalassemia mutations are available from Bio-Rad Laboratories (Hercules, CA).

Rh Incompatibility

Molecular Basis of Disease

The Rh antigen system is clinically important because antibodies to Rh antigens are involved in hemolytic transfusion reactions, autoimmune hemolytic anemia, and HDFN. HDFN results from the alloimmunization of a mother to a paternally inherited fetal alloantigen. For example, an RhD-negative mother may make antibodies to the D antigen if the fetus inherits the *RHD* gene from the father. The most common cause for alloimmunization is fetomaternal hemorrhage. Other causes include unrecognized miscarriage, amniocentesis, CVS, cordocentesis, and transfusion. In subsequent pregnancies, these antibodies cross the placenta and may destroy the red blood cells of an antigen-positive fetus leading to hemolytic disease. The severity of HDFN is variable; mild cases require either no treatment or phototherapy, while more severe cases require exchange transfusion at birth, or possibly intrauterine transfusion, and may result in fetal hydrops. HDFN can occur when fetomaternal incompatibilities exist in several red cell antigen systems, including the RHD, C/c, E/e, Kell, Kidd, Duffy, and M. Anti-D accounts for the majority of HDFN cases followed by anti-K, anti-c, and anti-E [21]. The frequency of Rh-negative individuals, those at risk for making anti-D, is 15 % in Caucasians, 5 % in African Americans, 8 % in Hispanics, and low in Inuit, Native Americans, Japanese, and Asians.

The Rh antigens are expressed on proteins encoded by two distinct but highly homologous genes, *RHD* and *RHCE*, on chromosome 1p34.3-36.1 [22]. The *RHD* and *RHCE* genes are arranged in tandem and likely arose through duplication of a single ancestral gene (Fig. 16.3a) [23]. The D

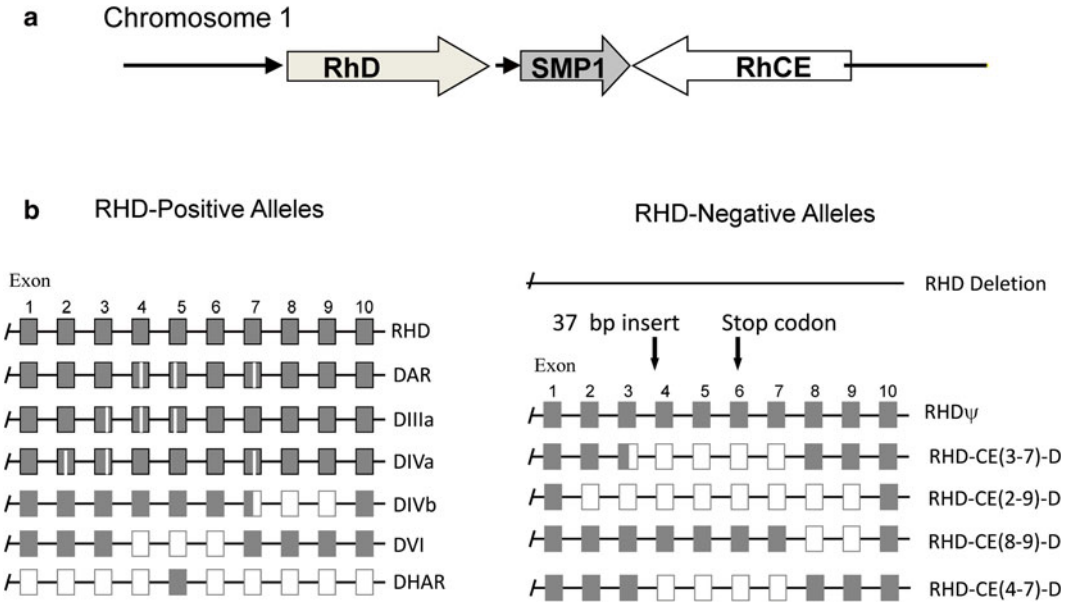

Figure 16.3 (**a**) Genomic organization of the RHD and RHCE genes on the short arm of chromosome 1. The RHD gene is flanked by two highly homologous Rhesus boxes (*black arrowheads*). (**b**) The listing of the most common *RHD* variant alleles illustrates why *RHD* genotyping assays require multiple targets within the *RHD* gene. Most variants are *RHD–RHCE* hybrid genes. *RHD* exons are indicated by the *square boxes*. *Grey boxes* indicate *RHD*-specific sequences and white indicates *RHCE*-specific sequences. The *RHDΨ* and *RHD-CE*(3-7)-*D* are frequently seen in the African-American population and may lead to false-positive results if not specifically targeted and detected. ((**b**) Used with kind permission of Springer Science+Business Media from Diagnostic molecular pathology in practice: a case based approach, 2011, Chap. 9, Rh Incompatibility by DB Bellissimo)

antigen is expressed from *RHD* and the C/c and E/e antigens are expressed from *RHCE*. The alleles from the *RHD* and *RHCE* are inherited as a haplotype. The eight possible haplotypes in order of frequency in the Caucasian population are DCe, dce, DcE, Dce, dCe, dcE, DCE, and dCE where d is the designation for the RHD-negative allele. The *RH* genes are more than 95 % homologous at the nucleotide sequence level and both genes consist of ten exons spanning over 75 kb. A number of sequence variations can be used to distinguish these two highly similar genes. However, it is important to be aware of a number of variant alleles that exist in this genetic system as the result of gene conversion events between the *RHD* and *RHCE* genes and from point mutations (Fig. 16.3b). Databases of these variants are available: Blood Group Antigen Gene Mutation Database (http://www.ncbi.nlm.nih.gov/projects/rbc) and the Rhesus Site (http://www.uni-ulm.de/~wflegel/RH/).

These hybrid *RHD-CE-D* alleles may result in either *RHD*-positive or *RHD*-negative haplotypes. Most variant *RHD*-positive alleles encode proteins that do not express all the RHD epitopes. Although an RHD-negative mother can be alloimmunized by a partial D antigen, hemolytic disease in these cases is rare. However, a mother with a partial D antigen can still be alloimmunized by the normal D antigen. The frequency of these variant alleles is low in the Caucasian population, but in some ethnic groups these alleles can be common [24]. The DAR allele is found in 17 % of South-African blacks, and DIIIa has been found in 18 % of blacks in New York and 28 % of blacks from Brazil.

The most common *RHD*-negative allele results from the total deletion of *RHD*; however, there are a number of *RHD-negative* haplotypes that are positive for at least portions of the *RHD* gene (Fig. 16.3b). In the African population, there are two *RHD*-positive, antigen D-negative alleles that are common and must be considered in any genotyping strategy. *RHDΨ* is present in 66 % of RHD-negative Africans and 24 % of African Americans and contains a 37 bp insertion at the junction of intron 3 and exon 4 that disrupts the reading frame and leads to a stop codon [25]. There are additional sequence variations in exon 4, 5, and 6 that distinguish *RHDΨ* from *RHD*. The Cde^{s} allele (RHD-CE(3-7)-D) is a hybrid allele containing exons 1 and 2, part of exon 3 from *RHD*, exons 3–7 from *RHCE* and exons 8–10, including intron 7, from *RHD*. Cde^{s} is found in 15 % of RHD-negative Africans. In addition, a significant percentage of RHD-negative Asians (27 %) are positive for the *RHD* gene.

The c.307T>C, p.Ser103Pro, sequence variation is responsible for the C and c antigens expressed from the *RHCE* gene. Genotyping for the *RHc* allele is straightforward, but the identification of the *RHC* allele is complicated by the fact that exon 2 of the *RHC* allele is identical to exon 2 of *RHD*. A 109 bp insertion found in intron 2 of the *RHC* allele can be used for genotyping [26]. The *Cdes* allele discussed above does express a C antigen but this allele will

give a false-negative result with this intron 2 assay since the intron 2 is of *RHD* origin. The identification of *RHD* and *RHCE* sequences in exon 3 will indicate the possible presence of this variant allele. The c.676C>G, p. Pro226Ala, sequence variation is responsible for the RhE and Rhe antigens of the *RHCE* gene. Rare allelic variants involving exon 5 have been described that would lead to erroneous typing of the E/e polymorphism.

Clinical Utility of Testing

Algorithms for managing a first sensitized pregnancy and patients with a previously affected fetus or newborn have been described [27]. Maternal antibody titers, ultrasound, middle cerebral artery (MCA) Doppler, cordocentesis, and molecular testing are used to monitor these pregnancies. MCA Doppler has a sensitivity of 88 % and specificity of 82 % for the detection of severe hemolytic disease [28]. MCA Doppler has largely replaced the use of amniotic fluid ΔOD_{450} which requires serial amniocentesis and puts these patients at risk for additional alloimmunization. Molecular testing plays an important role in the proposed algorithms for the management of HDFN. The algorithms seek to identify fetuses at risk for HDFN and monitor the severity of the disease while minimizing invasive procedures that may increase maternal exposure to fetal red cells and worsen the sensitization. The main utility of molecular testing is to determine paternal zygosity and fetal genotype, and to characterize variant alleles.

Paternal zygosity is used to predict the risk of HDFN in each pregnancy. If the paternal sample is homozygous for the alloallele then the fetus is predicted to be positive for the alloallele and the fetus can be appropriately monitored and invasive procedures may be avoided. Prenatal testing of the fetus may still be indicated if non-paternity is a possibility. If the paternal sample is heterozygous, fetal DNA testing through amniocentesis, CVS, or the testing of free fetal DNA in maternal plasma can be used to determine whether the fetus is positive or negative for the alloallele. Zygosity determination is straightforward by serological or molecular methods in most biallelic antigen systems except for *RHD*. *RHD* zygosity can be predicted by the Rh phenotype and haplotype frequencies. However, the predictions are not reliable in some ethnic groups, especially African Americans. *RHD* zygosity is most accurately determined using molecular methods.

Genotyping assays for *RH* also can help identify variant alleles that may or may not be identified in the immunohematology laboratory or blood bank by their usual phenotypic characteristics. Some individuals will be typed as RhD-negative by serology, yet may have a weak or partial D that is not detected by the antibody reagent being used. Molecular testing is useful in detecting these variants and may help identify patients that require Rh immune globulin treatment. There are a number of examples in the literature describing the loss or weakening of RhD expression, particularly in cancer patients [22]. In some instances this has been caused by deletion of the *RHD* gene or loss or abnormalities involving chromosome 1. Molecular assays can confirm the loss of genetic material encoding the *RHD* gene. In addition, molecular assays are useful in predicting blood group phenotype in the transfused patient [29].

Available Assays

The assay formats are predominantly AS-PCR and real-time PCR with hydrolysis probes. Both methods are well suited for detecting single base pair polymorphisms; however, the sensitivity of real-time assays is beneficial when the amount of DNA from a prenatal sample is limiting. Testing for two or more regions of the *RHD* gene is required for identification of allelic variants. Assays must distinguish the *RHD* gene from *RHCE*. A number of assays have been described using the various sequence differences between the genes in exons 3–7 and 9, introns 4 and 7, and the 3′ untranslated region of exon 10 [26, 30, 31]. Detection of the *RHDΨ* also should be included in all genotyping assays [25]. Targets for *RHDΨ* include a 37 bp insertion in exon 4 as well as single nucleotide variants in exons 5 and 6. Although exon 10 is a very sensitive marker for the *RHD* gene due to the unique sequence in this exon, it is important to be aware of possible false positives and false negatives caused by variant alleles. However, exon 10 is useful in recognizing the Cde^s haplotypes in RhD-negative individuals.

Molecular assays for *RHE/e* take advantage of polymorphisms within exon 5 that are specific to the *RHCE* gene [26]. *RHc* is detected directly using the C307 polymorphism, while the 109 bp intron 2 insertion is used to detect the *RHC* allele. Multiplex genotyping assays for *RHD* and *RHCc* also have been described [25]. The sensitivity for detecting the RHC allele can be improved by using an assay that detects the *RHC* allele associated Cde^s haplotype [26]. Although laboratory-developed tests are most commonly used, CE-marked kits for *RHCE* and *RHD* including partial and variant alleles are available from Bag Healthcare (Lich, Germany). A number of assays are being developed for genotyping patients and blood donors for red cell antigens [32]. Their use of these assays for prenatal testing has not been assessed.

The precise site of the *RHD* deletion has been defined, making detection of the deletion possible with a PCR-based assay [24]. Although the deletion is the most common *RHD-negative* allele in whites and African Americans, this assay will not correctly determine zygosity in RhD-negative alleles that contain RHD gene sequences such as Cde^s and *RHDΨ*. Real-time PCR assays or fragment analysis of fluorescently labeled PCR products potentially can be used for determining zygosity, as long as more than one region of the *RHD*

gene is detected and the assay design takes into account possible genetic variants. A quantitative fluorescent PCR technique has been described that detects *RHD* exons 5 and 7 using *RHCE* exon 7 as an internal two copy control [33]. The presence of common Rh variants in Caucasians and African Americans is recognized when the *RHD* exon 5 copy number is discordant with exon 7. The exon 5 primers are specific for the *RHD* gene, such that *RHDΨ* is not detected. The exon 7 primers detect both the *RHD* and *RHDΨ* genes.

These methods are suitable for testing fetal DNA as well as genomic DNA from blood. Fetal DNA sources are typically amniotic fluid or chorionic villi, using either direct or cultured samples. Since fetal DNA preparations can be potentially contaminated with maternal DNA, laboratories must understand how maternal contamination will affect the assay results and have methods to determine the extent of contamination. Testing of variable number of tandem repeats (VNTR) or microsatellite loci in fetal and maternal DNA samples can be used to determine whether maternal cells contaminate the fetal sample.

Another potential source of fetal DNA is maternal plasma. Fetal DNA accounts for approximately 3 % of the total cell-free DNA in maternal plasma during the second trimester and increases throughout pregnancy. Since this method avoids invasive techniques that cause risk to the fetus, and prevents further sensitization of the mother, the method is of significant interest. Laboratories outside the USA have successfully performed these tests for almost 10 years. However, due to intellectual property issues, the maternal plasma assays have only recently become available in the USA. Several studies have demonstrated that fetal DNA in maternal plasma can be used to determine a fetal genotype using real-time PCR or mass spectrometry [31, 34, 35].

Interpretation of Test Results

Using a multiplex strategy, the sensitivity for detecting the *RHD* gene should be >99 % and the false-positive rate <1 %. However, the performance characteristics may vary with different testing strategies in different ethnic groups. The rate of false-positive results and positive predictive values for different PCR strategies in the European population has been described [30]. One rare *RHD* allele, DHar, would be missed by many genotyping assays as it contains only exon 5 of the *RHD* gene (*RHCE-D(5)-CE*). The frequency of variant *RHD* alleles is much greater in other ethnic groups, especially Africans (Fig. 16.3b). The most common RhD-negative variants are *Cdes* and *RHDΨ*. In most assay designs, the presence of a variant allele is identified by a missing or altered PCR product.

In a typical HDFN case, an Rh-D negative mother has developed an anti-D titer. *RHD* zygosity testing on a paternal sample determines whether the fetus is at 50 % or 100 % risk of inheriting an *RHD* allele. An example *RHD* genotyping assay that targets exon 7 and intron 4 in one reaction and exon 4 and intron 7 in a second reaction is shown (Fig. 16.4a). The size of the exon 4 band indicates whether RHDΨ is present. The maternal sample has only the control bands as expected for a *RHD*-negative sample. The exon 4 products in the paternal sample indicate the presence of the *RHD* gene and *RHDΨ*. The results indicate the fetus is RHD-positive and is at risk for HDFN. Figure 16.4b illustrates two more complex HDFN cases. In the first case, fetus F1 is positive for *RHD* but the maternal sample (M1) is also *RHD*-positive despite a D-negative phenotype. Unless the maternal variant can be identified, it cannot be determined whether the fetus has inherited the maternal or paternal *RHD* allele or both. Zygosity testing on the fetal sample can be used to determine whether the fetus has inherited one or two copies of *RHD*. If the fetus is homozygous, then the fetus inherited the paternal *RHD* and is at risk for HDFN. If the fetus is heterozygous, the test is inconclusive. The fetus should be consider at risk for HDFN with a 50 % chance of being RhD-negative. The second case involves an RhD-positive mother that has developed anti-D. Genotyping of the maternal sample (M2) indicates the absence of exon 7 most likely due to a *DAR* or *DIVa* allele (Fig. 16.3b). The fetus F2 genotypes as *RHD*-positive. The presence of the exon 7 band indicates the fetus inherited the paternal *RHD* gene and is at risk for HDFN.

These examples illustrate the importance of testing maternal and paternal samples. The detection of variant alleles by discrepancies between parental serotypes and genotypes will reduce the risk of false-negative and false-positive results. Variants easily will be identified in RhD-negative mothers that test positive for the *RHD* gene. As discussed above, if the mother is positive for only parts of the *RHD* gene, it still may be possible to tell if her fetus inherited a paternal *RHD* gene. Allelic variants can go undetected by serology and genotyping in paternal samples by the presence of a "normal" *RHD* allele. If the masked allele with an altered pattern of *RHD* products is detected, the genotype may not allow certain prediction whether the fetus will have an RhD-positive phenotype. In these cases, the fetus should be considered at risk for HDFN.

As discussed earlier, allelic variants of the *RHC* are common in individuals of African ancestry. In RHD-negative Africans, the *Cdes* allele will result in a 15–20 % false-negative result since intron 2 is of *RHD* origin. Clearly, in this ethnic group, testing a paternal sample for the presence of the *RHC* allele is important, especially in a C-negative fetus. The *DHar* allele (*RHCE-D5RHCE*) may cause a false negative for Rhe since exon 5, the location of the *RHE/e* polymorphism, is of *RHD* origin. Other rare alleles in the *RH* system may be misidentified in DNA typing assays. When maternal and paternal samples are not available, interpretation should include the possibility of a false-positive or false-negative result as relevant to the population being tested.

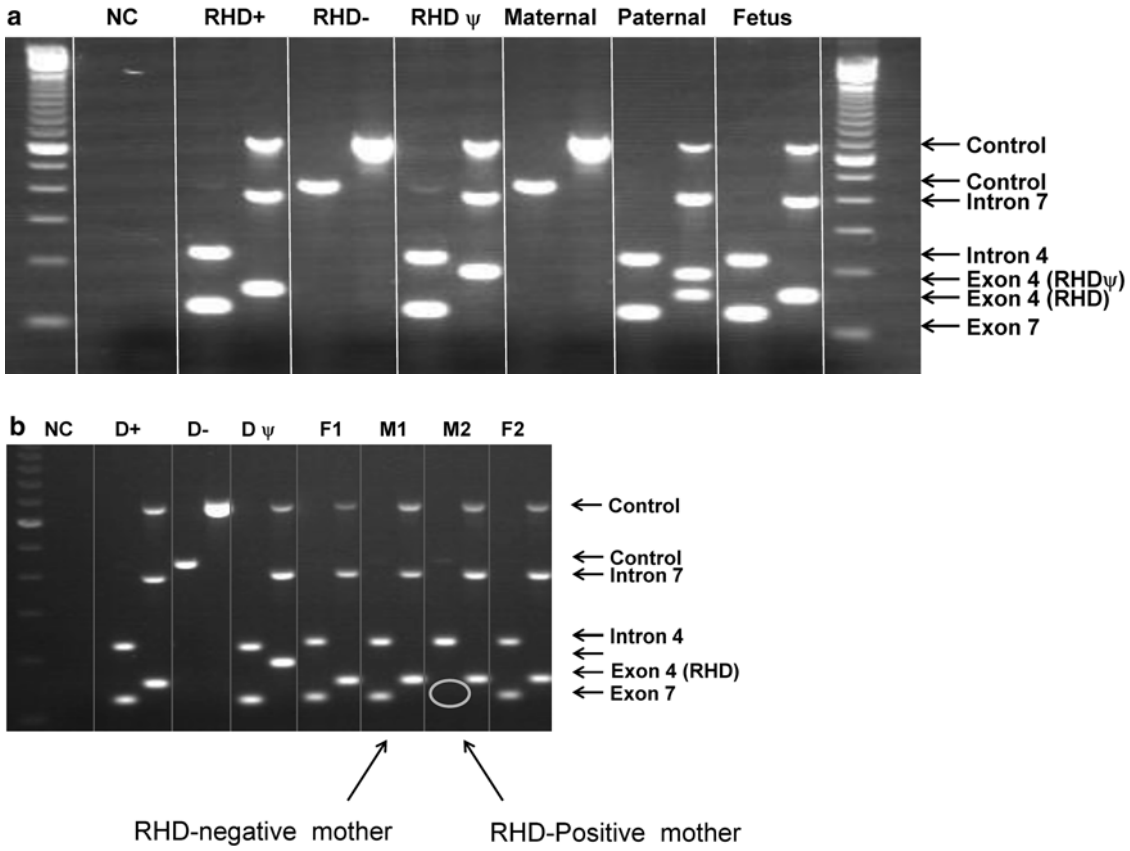

Figure 16.4 (**a**) *RHD* multiplex genotyping assay. There are two reactions per sample. The first reaction detects exon 7 and intron 4. The second reaction detects exon 4 and intron 7. If the *RHDΨ* is present, the size of the exon 4 PCR product is increased by 37 bp. Each PCR reaction also contains primers to a control gene. The control products for reactions 1 and 2 are of different sizes. The PCR products are identified by the *arrows*. (**b**) Complex HDFN cases with variant *RHD* alleles. Fetus (F1) is positive for *RHD* but the maternal sample (M1) is also *RHD*-positive despite a D-negative phenotype. M2 is RhD-positive with anti-D; exon 7 is absent (*circle*) most likely due to a DAR or DIVa allele (Fig. 16.3b). The fetus (F2) genotypes as *RHD*-positive. The presence of the exon 7 band indicates the fetus inherited the paternal *RHD* gene and is at risk for HDFN. Laboratory Issues

Many Rh incompatibility cases will require both phenotypic and genotypic testing of parental samples. Laboratories need to work in conjunction with an immunohematology laboratory, which is able to provide phenotypic data and assist in the analysis of variant alleles. Only simple *RHD* controls are available from Coriell Cell Repositories (http://ccr.coriell.org/). The immunohematology laboratory or blood bank are the best source of ethnic-specific assay controls. These tests are typically developed and validated by the laboratory. Proficiency testing for *RHD* is available in the CAP MGL survey but this survey does not challenge the laboratory's ability to identify variant *RHD* alleles. Proficiency testing can be accomplished through a sample exchange with another laboratory that performs the testing.

The key laboratory issue is understanding the sensitivity and specificity of the test and how this will be affected by ethnic group and if one or both of the parental samples are not available for testing. This is especially true for maternal plasma testing. Despite the high sensitivity and specificity of these assays, there is still a significant level of false-positive, false-negative, and inconclusive results compared to conventional testing [34]. The fetal DNA represents a minority of the total DNA in maternal plasma and the fetal copy number is variable. Internal controls are important to demonstrate that fetal DNA is present in sufficient quantity. This is especially true when the test result is *RHD*-negative. Y chromosome-specific sequences can be used when the fetus is male but other paternal-specific polymorphisms, dose, or fetal-specific markers may be required to provide the necessary internal control [36]. Finally, the laboratory needs to be aware whether the test on the fetus is being requested to determine if they are at risk for HDFN or soley predict the fetal blood type. Typically, Rh-negative blood is used when a fetus requires an intrauterine transfusion for HDFN. However,

if multiple red cell antigen antibodies are present, the antigen-negative blood needed may be quite rare. Finding blood will be easier if the fetus is known to be RhD-positive and can be transfused with Rh-positive blood. A false-positive result in these instances has quite different medical management implications. In the fetus at risk for HDFN related to anti-D, a false-positive result will lead to increased monitoring of the fetus, whereas a false-positive result for transfusion could lead to an RhD-negative fetus being transfused with RhD-positive blood. When predicting red cell antigen phenotypes by genotyping, it is important to work with experts in transfusion medicine.

Cardiovascular Disease

17

Samantha M. Baxter and Birgit H. Funke

Abstract

During the last decade, techniques and advances in molecular genetics and genomics have yielded profound insights into the fundamental mechanisms and genetic underpinnings for many heritable cardiovascular diseases. The availability of clinical genetic testing has resulted in dramatic changes in our ability to: (1) identify preclinical/presymptomatic individuals by molecular testing, (2) characterize/clarify clinical diagnoses with phenotypic and genotypic overlap, and (3) in some cases, provide gene-specific or gene-targeted therapy including primary prevention in genotype-positive/phenotype-negative individuals. Sudden cardiac death (SCD) consumes more lives than any other medical condition in developed countries, with 1,000 SCDs occurring each day in the USA. Coronary artery disease (CAD) is the major cause of SCD, while other heritable diseases including cardiomyopathies and channelopathies also predispose to fatal ventricular arrhythmias. Characteristic hallmarks of most inherited cardiovascular diseases discussed in this chapter include a high degree of locus heterogeneity (many genes) as well as allelic heterogeneity (many different mutations within a gene). Multiple modes of inheritance usually exist and reduced penetrance and variable expressivity are common. All these factors can complicate the interpretation of genetic test results and highlight the critical importance of interpreting identified mutations in the context of an individual's clinical features as well as family history.

provide gene-specific or gene-targeted therapy including primary prevention in genotype-positive/phenotype-negative individuals. Cardiology has embraced new genetic discoveries. Sudden cardiac death (SCD) consumes more lives than any other medical condition in developed countries, with 1,000 SCDs occurring each day in the USA. Coronary artery disease (CAD) is the major cause of SCD, while other heritable diseases including cardiomyopathies and channelopathies also predispose to fatal ventricular arrhythmias. For example, over 4,000 deaths per year are attributed to long QT syndrome (LQTS) and in 10 to 15 % of those cases sudden death is the first symptom a patient experiences [1]. In this chapter, we review the current understanding of heritable cardiovascular diseases with a focus on the molecular pathogenic mechanisms and status of molecular testing for cardiomyopathies, channelopathies/arrhythmias, CAD, and congenital heart disease or defects (CHD), most of which of which render an individual susceptible to SCD.

Cardiomyopathies have a combined estimated prevalence of 1 in 390 individuals [2]. Many causal genes have been identified and extensively studied in individuals with hypertrophic cardiomyopathy (HCM), dilated cardiomyopathy (DCM), arrhythmogenic right ventricular cardiomyopathy (ARVC), restrictive cardiomyopathy (RCM), and isolated left ventricular non-compaction (LVNC) [3]. Cardiac channelopathies may account for a significant proportion of SCD and are characterized by a structurally normal heart, defined as no abnormalities seen at autopsy [4]. The main channelopathies/arrhythmias include congenital LQTS, Brugada syndrome (BrS), idiopathic ventricular fibrillation, and catecholaminergic polymorphic ventricular tachycardia (CPVT) [3]. CAD is a common disease with a complex interaction of many genetic susceptibility loci and environmental factors. Much progress has been made towards understanding genetic risk factors for CAD; however, clinical genetic testing is not yet within reach. Several rare monogenic diseases such as familial hypercholesterolemia predispose to CAD and provide a stepping stone to understand the common, complex form [5]. Finally, isolated CHDS are the most common birth defect with an estimated incidence of approximately 6 in 1,000 live births. While much of the genetic etiology of various types of CHD (such as Tetralogy of Fallot or various septal defects) is thought to be complex, monogenic forms exist and disease genes lending themselves to genetic testing have been identified [6].

Many genetic syndromes, such as Noonan syndrome and Marfan syndrome, have cardiovascular involvement. As with many of the diseases mentioned in this chapter, use of molecular testing has increasingly informed the clinical diagnosis of these syndromes, and helped characterize their phenotypic spectrum [7, 8]. Syndromes with cardiac involvement are discussed further in other chapters.

Characteristic hallmarks of most inherited cardiovascular diseases discussed in this chapter include a high degree of locus heterogeneity (many genes) as well as allelic heterogeneity (many different mutations within a gene). Multiple modes of inheritance usually exist and reduced penetrance (not everyone with a pathogenic mutation will present with disease in their lifetime) and variable expressivity (those with the mutation can present at various stages of life and with different symptoms) also are common. All of these factors can complicate the interpretation of genetic test results and highlight the critical importance of interpreting identified mutations in the context of an individual's clinical features as well as family history.

Expert Opinions and Guidelines on Genetic Testing for Inherited Cardiac Disease

Several expert opinions and practice guidelines on clinical management as well as genetic testing for inherited cardiomyopathies and channelopathies have been published over the last few years [3, 9–11]. General recommendations include obtaining a detailed family history of at least three generations, clinically screening at risk relatives, counseling for a possible heritable basis and considering genetic testing of the most clearly affected person in a family. It is recognized that the evidence implicating cardiomyopathy and channelopathy genes varies tremendously and that the level of evidence for a given gene correlates directly with a test's clinical validity (its ability to correctly detect the condition). Recent guidelines from the Heart Rhythm Society (HRS) and European Heart Rhythm Association (EHRA) based recommendations on the diagnostic, prognostic, and therapeutic impact of genetic testing [3]. Despite the availability of gene panels of rapidly increasing size, comprehensive testing is currently recommended only for a relatively small number of genes, which have high detection rates and/or strong genotype–phenotype correlations. One of the main benefits of genetic testing is the ability to test at-risk family members, when a pathogenic mutation is identified. The presence of a clearly pathogenic mutation in a presymptomatic relative enables implementation of lifestyle changes to avoid sudden death, while disease risk in mutation negative relatives is reduced to the general population risk. However, because genetic testing for inherited cardiovascular disease is still a relatively young discipline, the risk for identifying uninterpretable mutations, often referred to as variants of unknown significance (VUS), is still relatively high compared to other disease areas, reducing the clinical utility of currently available tests [3].

Genetic Testing for Inherited Cardiac Disease in the Era of Genomic Medicine

Until recently, the high cost of Sanger sequencing made comprehensive genetic testing challenging for genetically heterogeneous diseases. Gene panels were of limited size and usually did not include genes with low detection rates. With the advent of next-generation sequencing (NGS) technologies this limitation has been removed. A prime example is the titin (*TTN*) gene, which encodes the largest human protein. Due to its enormous size (383 exons), only with the clinical use of NGS testing is this gene now being sequenced in patients, which has led to the discovery that *TTN* is one of the most frequently mutated genes in DCM [12]. Gene panels covering tens to hundreds of genes are beginning to be broadly available in molecular testing laboratories. These comprehensive tests greatly facilitate the genetic testing process as they eliminate the costly and lengthy testing odysseys of one gene at a time that has dominated genetic testing for inherited cardiovascular disease for a decade. Although still costly and therefore not yet broadly available, exome or genome sequencing (ES/GS) is beginning to enter clinical practice though still mostly in the setting of clinically complex cases [13–15]. An important advantage of these large scale sequencing tests is that while the assay assesses all genes, the interpretation can focus on a clinically relevant subset of genes relevant to the patient's disease or symptoms. Despite obvious advantages, testing large gene sets has some important limitations. In the past, the limited size of gene panels provided a natural selection for well-established disease genes. With the ability to sequence virtually every gene it is critical to carefully review the evidence available for a published disease-gene association. It is not uncommon that a gene (particularly if disease-causing mutations are rare) is supported by a single or very small number of studies providing limited evidence. The inclusion of genes that have not yet been firmly associated with disease can lead to an inflation of VUS, which limit the clinical utility of large gene panels if no clear pathogenic mutation is detected.

Inherited Cardiomyopathies

Cardiomyopathies are diseases of the heart muscle that have traditionally been defined based solely on clinical features including ventricular morphology and function. While HCM, DCM, ARVC, and LVNC are generally recognized as distinct clinical entities, phenotypic overlap is increasingly recognized. For example, end stage HCM can resemble DCM [16]. Similarly, there is phenotypic overlap between DCM and ARVC, which can manifest with ventricular dilation [17]. Finally, features of LVNC can overlap with HCM, DCM, and RCM [18, 19]. With the characterization of the underlying genetic etiologies came the recognition of substantial and increasing genetic overlap (Table 17.1, reviewed in Refs. 3 and 20). Genes encoding proteins of the sarcomere, the contractile unit of myocytes, were first identified in patients with HCM but more recently also in patients with DCM, LVNC, and RCM [21–23]. Similarly, Z-disk genes have been implicated in DCM as well as HCM [24]. A growing number of genes have been associated with both DCM and ARVC. Genes encoding desmosomal proteins were initially only implicated in ARVC, but recent evidence suggests that mutations in these genes also cause DCM [25, 26]. The phenotypic spectrum of mutations in the desmin gene includes DCM, RCM, and recently also ARVC [27–29]. Finally, mutations in the *TTN* gene recently were shown to be a frequent cause of DCM [12] and emerging evidence also implicates the *TTN* gene in ARVC [30].

The amount of phenotypic overlap combined with genetic overlap has challenged the traditional paradigm of configuring test content strictly by clinical diagnosis. The large number of genes that can now be screened simultaneously has enabled test configurations that remove the need for sequential testing for those patients where the phenotype is not clearly defined.

Hypertrophic Cardiomyopathy

HCM is the most common inherited cardiomyopathy and affects approximately 1 in 500 individuals [3]. Asymmetric left ventricular hypertrophy (LVH) occurs in the absence of identifiable causes (e.g., uncontrolled hypertension), with myocyte hypertrophy, disarray, and interstitial fibrosis as the hallmark histological features of this disease [31, 32]. HCM typically follows an autosomal dominant mode of inheritance, although autosomal recessive forms have been identified (Table 17.1). Clinical manifestations are variable, ranging from an asymptomatic or mildly symptomatic course to severe heart failure and SCD [33]. HCM commonly manifests between the second and fourth decades of life but can manifest at the extremes of age [34, 35]. SCD can be the tragic sentinel event in children, adolescents, and young adults. Storage diseases such as Fabry disease and Danon disease also can present with apparently isolated LVH [36, 37]; however, these typically present with concentric LVH and, in males, are accompanied by other symptoms such as reduced sweating (Fabry disease) or cognitive impairment (Danon disease). In severe cases, HCM can progress, causing cell remodeling and an end stage phenotype that can resemble DCM [38, 39].

Table 17.1 Genes implicated in the etiology of inherited cardiomyopathies

Gene	Spectrum of clinical features						MOI	Location/function
	HCM	DCM	ARVC	RCM	LVNC	Other

Detection rates of >5 % in at least one study are detailed and highlighted

Molecular Basis of Disease

HCM is considered to be primarily a disease of the sarcomere, the contractile unit of myocytes. Disease-causing mutations have been identified in most sarcomere genes, with two genes (*MYH7* and *MYBPC3*) contributing almost 80 % of disease causing mutations [40]. Genes encoding Z-disk proteins, mitochondrial genes, and metabolic genes also have been implicated, though these are less frequently mutated. The majority of mutations are private (only seen in one family), and there is a high prevalence of missense mutations acting in a dominant negative fashion. Mutations leading to loss of function are less frequent but are prevalent in the *MYBPC3* gene. The known HCM-causing genes are listed in Table 17.1. Interestingly, very few genotype–phenotype correlations have been identified. Some general associations have emerged through analysis of case studies, though these are broad, usually are defined at the gene level, and may not be applicable to everyone with mutations in those genes. For example, HCM caused by mutations in *TNNT2* has been associated with a wide variety of clinical presentations and is usually associated with a reduced disease penetrance, a mild degree of hypertrophy, but a high incidence of SCD and more extensive myocyte disarray, although some mutations are associated with hypertrophy without risk of arrhythmias [41–43]. *MYBPC3*-related HCM has been associated with a reduced penetrance, relatively mild hypertrophy, a low incidence of SCD, late onset of clinical manifestations, and good prognosis before the age of 40 [44–46]. *PRKAG2* related HCM is associated with concentric hypertrophy and Wolff–Parkinson–White syndrome [47, 48]. Finally, *MYH7* mutations appear to be associated with severe LVH and an increased risk of heart failure and SCD [10].

Recent studies have shown that approximately 5 % of individuals with HCM have two pathogenic mutations, typically one inherited from each parent [49, 50]. Multiple mutations typically lead to a more severe presentation and an earlier age of onset than those seen with only one mutation [50].

Clinical Utility of Testing

One of the most important uses of genetic testing for HCM is the ability to identify asymptomatic family members who may be at risk to develop HCM. Multiple modes of inheritance have been described in HCM and knowing the genetic cause of an individual's disease allows for more accurate genetic counseling of family members. Since genotype–phenotype correlations for HCM are minimal, prognostic use of genetic testing is limited. Distinguishing the different genetic causes of heart muscle thickening is extremely important, as the treatment for HCM differs markedly from the treatment of other conditions. Fabry disease can present as isolated LVH in men and women and recent studies have suggested that approximately 6 % of males with late onset HCM had low α-Gal A enzyme activity [51, 52]. Identifying a pathogenic mutation in the *GLA* gene can provide a definitive diagnosis and enable lifesaving enzyme replacement therapy. Additionally, studies are emerging regarding therapeutic guidance for patients with sarcomeric HCM. Experimental studies and clinical trials of interventions (including diltiazem and angiotensin receptor/aldosterone blockade) show promise in delaying disease onset [53–55].

Available Assays

Clinical molecular testing for the HCM genes listed in Table 17.1 is currently available through several laboratories (www.genetests.org). The majority of testing for HCM is done by NGS using a targeted gene panel.

Interpretation of Test Results

Over 50 % of individuals with a clinical diagnosis of idiopathic HCM and up to 70 % of familial HCM will have a

mutation in one of the genes listed in Table 17.1 [3, 20]. Therefore, a negative test result reduces but does not eliminate the likelihood that the individual carries a causative mutation. Copy number variants (CNVs), such as large deletions leading to loss of function, are generally suspected to exist in genes with a high prevalence of other loss-of-function variants (e.g., nonsense and frameshift variants). HCM genes that fit this description include *MYBPC3* and *LAMP2*. Deletion mutations have been described [56] but are thought to be rare. However, Sanger sequencing does not detect large deletions and thus, their prevalence will only emerge as technologies which can detect large deletions are more widely used for clinical testing. Methods of NGS data analysis are being developed to simultaneously detect small mutations as well as CNVs, which will provide a more accurate estimate of the prevalence of CNVs related to HCM and other inherited disorders.

Genetic studies have revealed that approximately 25 % of tested patients have a mutant allele but do not manifest a HCM phenotype (genotype-positive/phenotype-negative HCM) [57]. The variability in phenotypic expression of the mutations could be due to environmental influences (differences in lifestyle, risk factors, and exercise) or genetic modifiers. VUS are common and difficult to interpret and should not be used for predictive testing for at-risk family members. Genetic testing laboratories typically offer targeted testing of family members to establish whether a variant identified in the index family member segregates with the disease. These concordance studies can be helpful in clarifying the clinical significance of VUS. Functional tests, such as the investigation of a possible splice mutation, exist but are currently difficult to incorporate into routine clinical testing so are largely confined to research laboratories.

Laboratory Issues

The majority of molecular genetic testing for inherited cardiac diseases is done by sequencing the exons and splice sites of one or several disease genes because allelic heterogeneity is the norm for all diseases covered in this chapter. Similarly, the assays that are commonly used to detect small deletions or duplications (e.g., multiplex ligation-dependent probe amplification [MLPA] or array-based comparative genomic hybridization) are not unique to any given gene or disease; hence, the laboratory issues common to all genetic CVD testing are reviewed at the end of this chapter.

Dilated Cardiomyopathy

DCM is characterized by ventricular dilation and impaired systolic function affecting approximately 1 in 2,500 individuals ([58]; www.genereviews.org). The spectrum of clinical manifestations includes dyspnea, orthopnea, fatigue, edema, and ultimately heart failure. DCM is most commonly an end stage manifestation of acquired causes, such as ischemic injury from myocardial infarction, viral myocarditis, or thyroid disease, that damage the myocardium. DCM also is caused by environmental insults including drug related side effects or alcohol abuse.

Idiopathic DCM (IDC) is diagnosed when all other known causes have been ruled out. A molecular basis for IDC was first postulated after clinical studies demonstrated familial inheritance in 20–35 % of cases when first-degree relatives are screened carefully [59, 60]. Today, over 40 genes have been implicated in the genetic etiology of DCM (Table 17.1). The onset of clinical manifestations is age related, with only 20 % of gene mutation carriers under the age of 20 years of age manifesting the disease phenotype. Nearly two thirds of familial DCM has an autosomal dominant inheritance pattern with an isolated cardiac phenotype [61]. However, other modes of inheritance are known and include autosomal recessive, mitochondrial (maternal), and X-linked inheritance.

DCM also presents with arrhythmias and/or muscular involvement and can be the initial and/or predominant feature of Emery–Dreifuss muscular dystrophy, Barth syndrome, myofibrillar myopathy, and Duchenne muscular dystrophy [62, 63]. Recently, familial co-occurrence of peripartum cardiomyopathy (PPCM) and DCM have been observed, which led to the suggestion that PPCM is part of the phenotypic spectrum of familial DCM [64, 65].

Phenotypic overlap exists between DCM and end stage HCM as well as ARVC, which was initially believed to be restricted to a right ventricular defect but is now increasingly recognized to have a left ventricular contribution.

Molecular Basis of Disease

DCM is, by far, the most heterogeneous of the diseases discussed in this chapter. Mutations in *MYH7*, *LMNA*, *SCN5A*, *TNNI3*, and *TNNT2* make up roughly 20 % of familial DCM cases [3, 23]. Additional genes (Table 17.1) typically contribute a small fraction of the remaining DCM-causing mutations. The recent discovery that loss of function mutations in the *TTN* gene are responsible for as much as 25 % of genetic DCM is a notable exception and a radical improvement for genetic testing for DCM [12]. Missense mutations in the *LMNA* and *SCN5A* genes are responsible for inherited DCM with conduction system disease [66–68]. Autosomal recessive DCM is less frequent and is characterized by a significantly younger age of onset and a worse prognosis compared to the dominant form. This form is typically associated with skeletal myopathy and caused by mutations in the *SGCD* and *TCAP* genes. Additionally, autosomal dominant forms of DCM can present with skeletal myopathy and include mutations in the

CSRP3, *DES*, *DMD*, *EMD*, *LMNA*, *MYH7*, and *TTN* genes [3, 20] (Table 17.1). The *TAZ* gene is associated with Barth syndrome but DCM can be the first presenting feature [69–72]. In addition, recent studies have provided evidence that mutations in the *LAMP2* gene, which typically cause Danon disease in young boys, can cause DCM in the fourth decade of life in women [37]. Finally, there is emerging evidence of genetic overlap with ARVC as mutations in traditional ARVC genes have been detected in individuals with DCM [25, 26].

Clinical Utility of Testing

Molecular testing for DCM is most useful when there is a confirmed family history and/or conduction system disease in the proband or other affected family members. The profound genetic heterogeneity has long precluded a prominent role for molecular testing in isolated DCM, though this is rapidly changing. Multiple modes of inheritance have been described in DCM, and knowing the cause of an individual's disease allows for more accurate genetic counseling regarding the risk to other family members. Distinguishing the different genetic causes of heart muscle weakness is extremely important, as the clinical management for primary DCM can differ from DCM associated with other conditions. The prognostic utility of genetic testing is limited to a higher risk for SCD in *SCN5A* and *LMNA* mutation carriers, and screening for mitochondrial disease and skeletal myopathy in the genes associated with those features. For those individuals who are at risk for SCD due to arrhythmias caused by *SCN5A* and *LMNA* mutations, an implantable cardioverter defibrillator (ICD) can be implanted as a preventative measure.

Available Assays

Molecular testing for the DCM genes listed in Table 17.1 is currently available through clinical laboratories (www.genetests.org). Both Sanger sequencing and NGS methods are used.

Interpretation of Test Results

The detection rate of mutations in individuals with DCM is rapidly evolving. Until 2012, approximately 20 % of individuals with idiopathic DCM and more than 30 % of those with familial DCM were expected to have a mutation in one of the genes listed in Table 17.1 [3, 73]. With the discovery that *TTN* mutations may account for another 25 %, the detection rate for DCM is now approaching that of HCM. A negative test result reduces but does not eliminate the likelihood that an individual carries a causative mutation. The variability in phenotypic expression of mutations could be due to environmental influences or acquired traits (differences in lifestyle, risk factors, and exercise). Variants of unknown significance are difficult to interpret and should not be used for predictive testing for at-risk family members.

Arrhythmogenic Right Ventricular Cardiomyopathy

Initially termed arrhythmogenic right ventricular dysplasia (ARVD), this disease is now more commonly referred to as arrhythmogenic right ventricular cardiomyopathy (ARVC). ARVC is characterized by progressive degeneration and fibro-fatty replacement of the right ventricular myocardium, arrhythmias with a left bundle branch block profile, and increased risk of SCD in juveniles [74–76]. Although initially thought to affect predominantly the right ventricle, left ventricular involvement is now increasingly recognized, generating phenotypic overlap with other inherited cardiac disease of left ventricular origin [17]. Recent studies have revealed that the cellular defect underlying fibroadiposis is impaired WNT signaling, which leads to a redirection of myocyte fate to adipocyte fate [77, 78].

Molecular Basis of Disease

Two modes of inheritance, autosomal dominant and autosomal recessive, are observed with ARVC. This disease is often described as a disease of the desmosome because mutations are predominantly found in genes encoding this multiprotein complex. Desmosomes form cell–cell junctions and are prevalent in tissues that are subjected to mechanical stress (such as the heart and skin). To date, six genes (*PKP2*, *DSP*, *DSC2*, *DSG2*, *JUP*, and *TMEM43*) have been implicated in autosomal dominant ARVC and two of these genes (*DSP* and *JUP*) have been associated with rare autosomal recessive forms that have cutaneous involvement (wooly/kinky hair and palmoplantar hyperkeratosis) [79–82]. These variants are referred to as Naxos syndrome (OMIM: #601214) and Carvajal syndrome (OMIM: #605676). Autosomal dominant ARVC has incomplete penetrance and variable phenotypic expression [83]. Catecholaminergic polymorphic ventricular tachycardia (CPVT) is characterized by SCD during physical or emotional stress [84, 85]. Although considered clinically distinct, CPVT shares some features with ARVC and given that ARVC can be difficult to diagnose clinically, genetic testing sometimes includes the *RYR2* gene, which is the main gene associated with CPVT. A recent study provided convincing evidence for a role of the *TTN* gene, which is strongly associated with DCM, in ARVC [30].

Clinical Utility of Testing

The variability of phenotype, disease progression, and underlying genetic cause contribute to the difficulties of diagnosis and risk stratification in ARVC. Given these complexities, genetic testing can be helpful in providing a definitive diagnosis when a pathogenic mutation is found. Although a few patterns have emerged in relation to genotype–phenotype

correlations, the evidence is limited and the prognostic and therapeutic implications of genetic testing are still being debated. Because the age of onset, symptoms, and penetrance vary so widely in ARVC, genetic testing may be more accurate at identifying at-risk relatives than clinical screening alone.

Available Assays

Molecular testing for the ARVC genes listed in Table 17.1 is currently available through clinical laboratories (www.genetests.org). Both Sanger sequencing and NGS methods are used.

Interpretation of Test Results

Approximately 50 % of individuals who meet task force criteria for ARVC have a pathogenic mutation in one of the six genes listed in Table 17.1 [86, 87]. *PKP2* mutations make up the majority of cases. Therefore, a negative test result reduces but does not eliminate the likelihood that the individual carries a causative mutation. The variability in phenotypic expression of the mutations could be due to environmental influences or acquired traits (differences in lifestyle, risk factors, and exercise). VUS are difficult to interpret and should not be used for predictive testing for at risk family members.

Restrictive Cardiomyopathy

RCM is a rare myocardial disorder characterized by increased stiffness, impaired diastolic filling of the left ventricle, and reduced diastolic volume in the presence of normal systolic function and normal myocardial thickness [33]. Although most frequently caused by diseases causing infiltration or fibrosis of the myocardium, RCM may be found in the absence of a precipitating condition in many patients and is then referred to as idiopathic RCM [88].

Molecular Basis of Disease

Idiopathic RCM is most commonly sporadic, but familial disease has been reported with autosomal dominant inheritance [89, 90]. Missense mutations in the *DES* (desmin) gene have been found in several families with desmin-related myopathy with and without RCM [91, 92]. Additionally, mutations in *ACTC*, *MYH7*, *TNNI3*, and *TNNT2* have been associated with RCM, confirming that RCM is part of the spectrum of hereditary sarcomeric contractile protein disease (reviewed in refs. 3, 20).

Clinical Utility of Testing

Given the low detection rate for RCM genetic testing, the diagnostic utility of genetic testing is limited to predictive testing for family members. No genotype–phenotype correlations have been established and genetic testing has limited prognostic value.

Available Assays

Tests for most genes which have been associated with RCM are available as single gene tests using Sanger sequencing. Most clinical laboratories do not offer panels of genes specifically tailored to RCM but all genes associated with RCM to date are part of panels offered for HCM testing.

Interpretation of Test Results

The clinical detection rate of the genes listed in Table 17.1 is estimated to be roughly 10–15 %; however, due to the unclear etiology of the disease and limited numbers, a true detection rate is unknown [3]. Therefore, a negative test result reduces but does not eliminate the likelihood that the individual carries a causative mutation. VUS are difficult to interpret and should not be used for predictive testing for at-risk family members.

Isolated Left Ventricular Noncompaction

Isolated LVNC is characterized by a hypertrophic left ventricle with deep trabeculations and poor systolic function with or without associated left ventricular dilation. LVNC is thought to be due to an arrest of myocardial morphogenesis during embryonic development leading to a failure to complete the normal compaction process [93, 94]. Others have proposed that LVNC may be an acquired process based on some individuals who developed LVNC after initially negative echocardiographic findings [95]. There is ongoing controversy whether LVNC is a distinct clinical entity. The World Health Organization as well as a position statement of the European Society of Cardiology lists LVNC as an unclassified cardiomyopathy (reviewed in ref. 95). In contrast, the American Heart Association classified LVNC as a primary genetic cardiomyopathy in 2006 [96].

Molecular Basis of Disease

Familial recurrence in LVNC is high and found in approximately 40 % of patients [94]. Gene mutations have been detected in sarcomere/Z-disk genes including *MYH7*, *MYBPC3*, *TNNT2*, *ACTC1*, and *LDB3* [97]. In addition, LVNC can be the presenting feature of Barth syndrome caused by mutations in the *TAZ* gene [98, 99].

Clinical Utility of Testing

The ability to identify asymptomatic family members who may be at risk of developing LVNC is the main utility of genetic testing for this disease. As multiple modes of inheritance (autosomal dominant and X-linked) have been described in LVNC families, knowing the cause of an individual's disease allows for more accurate genetic counseling regarding the risk to other family members. No genotype–phenotype correlations have been established and as such genetic testing has limited prognostic value.

Available Assays

Molecular testing for the LVNC genes listed in Table 17.1 is currently available through clinical laboratories (www.genetests.org). Both Sanger sequencing and NGS methods are used.

Interpretation of Test Results

Between 17 and 41 % of individuals who meet criteria for LVNC will have a pathogenic mutation in one of the genes listed in Table 17.1 [20, 100]. Therefore, a negative test results reduces but does not eliminate the likelihood that an individual carries a causative mutation. The variability in phenotypic expression of the mutations could be due to environmental influences or acquired traits (differences in lifestyle, risk factors, and exercise). VUS are difficult to interpret and should not be used for predictive testing for at-risk family members.

Cardiac Channelopathies and Primary Arrhythmia Syndromes

The molecular understanding of cardiac channelopathies and primary arrhythmias has exploded over the last decade. At the turn of the century genetic testing was only available through research laboratories. As of 2013 there are over 30 channelopathy and arrhythmia genes for which genetic testing is available through clinical laboratories (Genetic Testing Registry; http://www.ncbi.nlm.nih.gov/gtr/).

Congenital Long QT Syndrome

Molecular Basis of Disease

Congenital LQTS is an inherited cardiac channelopathy characterized by prolongation of the QT interval of the cardiac cycle and increased susceptibility for syncope, seizures, and sudden cardiac death secondary to polymorphic ventricular tachyarrhythmias (torsades de pointes). Congenital LQTS occurs in two main heritable forms: autosomal dominant LQTS, originally described as Romano–Ward syndrome, and autosomal recessive LQTS, originally described as the Jervell and Lange-Nielsen syndrome. LQTS is the first type of arrhythmia to be understood at the molecular level as a primary cardiac channelopathy [101–103].

Over thirteen LQTS genes have been identified. Mutations in *KCNQ1* (*KVLQT1*, LQT1) [104], and *KCNH2* (*HERG*, LQT2) [105] cause the majority (about half) of LQTS. In approximately 25 % of families with LQTS, a genetic defect cannot be identified in the currently known LQTS-causing genes (www.genereviews.com). *KCNQ1*, the gene responsible for LQTS type 1 (LQTS1), encodes the α-subunit of the slowly activating delayed rectifier potassium ion channel (I_{Ks}). LQTS mutations in this gene cause a loss-of-function; the loss of I_{Ks} channel function decreases the I_{Ks} current, resulting in prolongation of the action potential duration and ventricular repolarization. LQTS type 2 (LQTS2) is due to mutations in *KCNH2*, which codes for the α-subunit of the rapidly activating delayed rectifier potassium ion channel (I_{Kr}). Mutations in *KCNH2* reduce the I_{Kr} current, resulting in prolongation of the action potential duration and repolarization. LQTS type 3 (LQTS3) results from mutations in *SCN5A*, which encodes the α-subunit of the cardiac sodium channel [106]. In contrast to the other forms of LQTS, in which a reduction of repolarization causes the prolongation of the action potential, *SCN5A* mutations that cause LQTS3 cause a "gain-of-function" in the cardiac sodium channel with an increase in late sodium current [107]. Ankyrin-B (*ANK2*) is a member of a family of versatile membrane adapters [108]. This gene was the first non-cardiac channel gene implicated in LQTS. Since this discovery, other non-cardiac cannel genes (*CAV3*, *AKAP9*, and *SNT1*) have been associated with LQTS [109–111]. The remaining LQTS-causing genes and their associated mutations are shown in Table 17.2.

Interestingly, correlations have been identified between the type of mutation and phenotypic outcome. For example, loss-of-function and dominant negative mutations in *KCNJ2* are thought to cause 50 % of Andersen syndrome (AS), while gain-of-function mutations in the same gene are associated with short QT syndrome (SQTS). AS is a rare inherited disorder (approximately 200 cases reported) characterized by periodic paralysis, prolongation of the QT interval with ventricular arrhythmias, and characteristic dysmorphic features including low-set ears, micrognathia, short stature, scoliosis, hypertelorism, broad forehead, and clinodactyly [112, 113]. AS is inherited in an autosomal dominant manner [114], although many cases are sporadic. Gain-of-function mutations in *KCNH2*, *KCNQ1*, and *KCNJ2* result in short QT syndrome (SQTS), a cardiac arrhythmia characterized by shortening of the QT interval on electrocardiogram and

paroxysmal atrial and ventricular tachyarrhythmias (episodes of rapid heartbeats originating from the heart chambers). SQTS is associated with an increased risk of atrial fibrillation and sudden cardiac death, resulting from an accelerated cardiac atrial and ventricular repolarization [115–117]. Fewer than 30 cases of SQTS have been published since the condition was first described in 2000 [118]. Autosomal recessive LQTS (Jervell and Lange-Nielsen syndrome) is secondary to homozygous or compound heterozygous mutations in either *KCNQ1* (~90 %) or *KCNE1* [119]. By definition, both parents are heterozygous for a pathogenic mutation; however, they are typically asymptomatic with negligible QT interval prolongation [120]. In contrast, their affected offspring not only have a severe cardiac phenotype but also are deaf. The I_{Ks} channel plays a critical role in potassium homeostasis in the endolymph of the inner ear [121, 122].

Clinical Utility of Testing

In addition to the utility of known mutation testing in family members, knowing the molecular cause of an individual's LQTS also has prognostic implications. First, cardiac events occur more frequently at rest or during sleep in LQTS3, whereas cardiac events are typically related to emotion or exercise (particularly swimming) in LQTS1 [123, 124] and auditory stimuli in LQTS2 [124]. Second, the recurrence rate of cardiac events while on β-blocker therapy was significantly lower in patients with LQTS1 (19 %) compared to LQTS2 (41 %) and LQTS3 (50 %) [125]. These insights further justify the utility of molecular testing for patients with LQTS. Given the high risk of sudden death in individuals with LQTS, an ICD can be placed in individuals who are confirmed to have a pathogenic mutation. However, these associations are limited and clinical care should not be driven by genotype alone.

Available Assays

Molecular testing for the LQTS genes listed in Table 17.2 is currently available through clinical molecular laboratories (www.genetests.org). Mutational analyses of the known LQTS genes are performed by Sanger sequencing and NGS, as well as MLPA for deletions or duplications, which are known to be a considerable part of the mutation spectrum for LQTS.

Interpretation of Test Results

Molecular genetic testing for LQTS plays a critical complementary role in the diagnostic evaluation and risk stratification for LQTS. However, the present sensitivity of genetic testing is approximately 75 % [3]. As such, a negative LQTS gene screen will not provide sufficient objective evidence to exclude the diagnosis of LQTS. The variability in phenotypic expression of the mutations could be due to environmental influences or acquired traits (differences in lifestyle, risk factors, and exercise). VUS are difficult to interpret and should not be used for predictive testing for at-risk family members.

Brugada Syndrome

BrS is characterized clinically by syncope and increased risk of SCD, particularly in young men at night, electrocardiographically by a right bundle branch block pattern and ST segment elevation in the precordial leads V1–V3, and echocardiographically by a structurally normal heart [126, 127]. BrS has been considered a distinct subgroup of idiopathic ventricular fibrillation (IVF) and may account for at least 20 % of all patients with IVF [128]. IVF is classified as ventricular fibrillation without demonstrable cardiac or noncardiac causes [129] and accounts for approximately 5–12 % of

all sudden deaths. IVF is associated with a high mortality rate and high recurrence rates of up to 30 % during the 5 years after an initial episode of survived cardiac arrest. For both BrS and IVF, the treatment of choice is principally ICD placement.

Molecular Basis of Disease

In 1998, Chen and colleagues reported the first gene linked to BrS [130]. Mutations in the cardiac sodium channel encoded by *SCN5A* were subsequently identified in three families. BrS-causing *SCN5A* mutations result in a loss-of-function and have been identified in approximately 20 % of patients with familial BrS [131, 132]. Mutations in *SCN5A* also have been associated with progressive conduction system disease (PCCD) as well as LQT3. In contrast to BrS and PCCD, mutations causing LQT3 result in a gain-of-function. Mutations in seven additional genes have now been identified, including *GPDL*, *CACNA1C*, *CACNB2*, *SCN1B*, *KCNE3*, *SCN3B*, and *HCN4*, each one contributing a small fraction of mutations found in patients with BrS [133].

Clinical Utility of Testing

In 2010 the HRS and EHRA released guidelines stating that comprehensive or *SCN5A* targeted BrS genetic testing can be useful for any patient with suspected BrS based on examination of the patient's clinical history, family history, and expressed electrocardiographic phenotype [3]. If a pathogenic mutation is identified, an ICD can be placed to prevent sudden cardiac death. Additionally, known mutation testing can be performed on asymptomatic family members to determine their risk for developing BrS.

Available Assays

Clinical testing for the eight genes associated with BrS is available from clinical molecular laboratories. Various sequencing technologies as well as deletion/duplication analysis (MLPA) are used to detect mutations that cause BrS.

Interpretation of Test Results

The clinical sensitivity of current BrS molecular genetic testing is approximately 25–40 %. As such, a negative Brugada gene screen cannot exclude the presence of BrS. VUS are difficult to interpret and should not be used for predictive testing for at-risk family members.

Catecholaminergic Polymorphic Ventricular Tachycardia

CPVT is a distinct arrhythmogenic entity in children and adolescents with structurally normal hearts characterized by episodes of ventricular arrhythmias (predominantly bidirectional ventricular tachycardias) resulting in syncope, seizures, or sudden death in response to physical activity or emotional stress [134].

Molecular Basis of Disease

CPVT can be transmitted in either an autosomal dominant or an autosomal recessive inheritance pattern [84, 135]. Ryanodine receptor (*RYR2*) gene mutations are the primary cause of autosomal dominant CPVT, though recent studies have suggested that *KCNJ2* could play a role as well [136]. Autosomal recessive CPVT is caused by missense mutations in the calsequestrin 2 (*CASQ2*) gene [137, 138]. It is currently estimated that approximately 50 % of autosomal dominant cases occur de novo, which is a direct consequence of the high mortality rate associated with CPVT. The identification of a variant that occurred de novo in an individual without a family history of the tested disease is commonly regarded as strong support for a pathogenic role.

Clinical Utility of Testing

Although only 55 % of CPVT has been elucidated genetically, some important genotype–phenotype relationships have emerged that support a role for molecular genetic testing in addition to the preclinical identification of asymptomatic carriers. Families with mutations in *RYR2* are more prone to stress-induced ventricular tachycardia at an earlier age than genotype-negative CPVT. In addition, males with *RYR2* mutations may be at greater risk for syncope than males lacking *RYR2* mutations [85]. However, there are no prognostic or therapeutic changes which would be made based on these results and the clinical utility is limited.

Available Assays

Sequence analysis of the *RYR2*, *CASQ2*, and *KCNJ2* genes is available clinically by Sanger sequencing and NGS methods (www.genetests.org).

Interpretation of Test Results

The sensitivity of molecular testing for the three CPVT-causing genes is greater than 55 %. A negative CPVT gene screen cannot rule out a diagnosis of CPVT. VUS are difficult to interpret and should not be used for predictive testing for at-risk family members.

Coronary Artery Disease

Atherosclerosis, or CAD, is the leading cause of death worldwide. It is a prime example of a common, complex disease caused by the interaction of many genetic, lifestyle, and environmental factors. A genetic component is evident by familial clustering and the heritability (the fraction of phenotypic variability that can be attributed to genetic variation) is

estimated to be 63 % for premature myocardial infarction (reviewed in ref. 139). Affected physiologic processes include lipoprotein metabolism, coagulation, and inflammation. Among those, LDL cholesterol and blood pressure have an established strong association with and elevated risk for CAD (reviewed in ref. 5). As is typical for complex diseases, rarer Mendelian forms such as familial hypercholesterolemia (FH) have led to the identification of candidate genes for the more common forms. Today, many genome-wide association studies (GWAS) have successfully mapped a number of common susceptibility variants for CAD [140]. However, each one of those loci contributes only a small fraction of the overall genetic risk and translating these population risks to a personal risk for an individual carrying several of these risk alleles has proven challenging. Clinical testing for risk prediction is therefore not yet within reach. The following section discusses rare, Mendelian diseases predisposing to CAD.

Hyperlipidemias (Lipoprotein Metabolism)

Molecular Basis of Disease

Goldstein and Brown first reported one of the most important molecular mechanisms leading to atherosclerosis: defects of the low-density lipoprotein (LDL) receptor [141, 142].

Autosomal dominant FH is one of the most frequent hereditary disorders of lipid metabolism with a prevalence of approximately 1 in 500 in the general population (reviewed in ref. 5). FH is characterized by an isolated elevation of LDL particles leading to premature death from atherosclerosis. FH is caused mainly by defects in the genes encoding the LDL receptor (*LDLR*) [143, 144], apolipoprotein B (*APOB*) [145, 146], proprotein convertase subtilisin/kexin type 9 (*PCSK9*) [147–149], and other unidentified gene(s) at chromosome 16q22.1 [150]. More than 1,000 different *LDLR* mutations have been identified to date [151, 152] (HGMD.org).

Autosomal recessive hypercholesterolemia (ARH) is a very rare recessive disorder caused by mutations in a putative adaptor protein called ARH, and is characterized by severe hypercholesterolemia (elevation of LDL level), xanthomatosis, and premature CAD [153]. Additional genes shown in Table 17.3 have been associated with other rare CAD diseases. Examples are the *ABCG5* and *ABCG8* genes where mutations have been associated with sitosterolemia [154, 155].

Several CAD modifying genes have been identified. Apolipoprotein E (APOE) is a constituent of several plasma lipoproteins including chylomicrons (VLDL, IDL, and HDL-E), and may be a risk-stratifying biomarker for CAD. The *APOE* alleles (ε2, ε3, and ε4) have a strong and consistent influence on plasma lipids and CAD. Both, ε2 and ε4 are associated with higher plasma triglyceride concentrations and more than 90 % of patients with hyperlipoproteinemia type III (HLPIII) are homozygous for the ε2 allele. However, homozygosity for ε2 occurs with a frequency of 0.5–1 in 100 Caucasian individuals and only a fraction of those develop overt HLPIII. Therefore, ε2 is believed to contribute to but not be the sole cause of this disease [156]. Interleukin-6 (IL6) is an inflammatory cytokine associated with the development and severity of CAD [157]. The -174C allele of the *IL6* gene is associated with risk of CAD and high systolic blood pressure in men [158]. Endothelial nitric oxide synthase (NOS) is an enzyme catalyzing the synthesis of nitric oxide (NO) in vascular endothelium and effects vascular relaxation. Alterations in the NOS pathway leading to decreased generation or action of NO are potential mechanisms in the development of premature atherosclerosis [159].

Clinical Utility of Testing

Clinical genetic testing for FH has been implemented in several countries. For example, the National Institute for Health and Clinical Excellence in the UK recommends that all patients are offered a referral for DNA testing to enable identification of affected (presymptomatic) relatives [160].

Available Assays

Gene sequencing tests (*LDLR APOB*, *PCSK9*) as well as deletion/duplication analysis (*LDLR*) are available clinically. The three common *APOE* alleles (ε2, ε3, and ε4) can be assessed using various genotyping methods (www.genetests.org).

Interpretation of Test Results

Multi-mutation test panels covering between 20 and 200 mutations have been used and identify mutations in 50–70 % of patients with FH [5]. Gene sequencing can be performed when targeted mutation panels are negative. In the future, testing is expected to be carried out by NGS of gene panels or ultimately by ES/GS. For patients with a lipid profile characteristic of hyperlipoproteinemia type III, APOE analysis will detect the homozygous ε2 allele.

Isolated Congenital Heart Defects

Molecular Basis of Disease

Congenital heart defects (CHD) are the most common type of birth defects and can be caused by chromosome abnormalities, single gene mutations, teratogenic exposures, and other unknown etiological mechanisms. While some CHD occur as part of Mendelian syndromes or with other birth defects, the majority occur in isolation. The estimated incidence of moderate and severe CHD is approximately

Table 17.3 Primary hyperlipoproteinemias caused by known single-gene mutations

Disease	Clinical findings	Elevated lipoprotein	Gene	OMIM#	MOI	Estimated prevalence	Key reference (Author_year_PMID)
Autosomal dominant familial hypercholesterolemia	Tendon xanthomas, CAD	LDL	*LDLR*	606945	AD	1/500	Varret_2007_18028451

6 per 1,000 live births, approximately half of which are cardiac septal defects (CSD) [161, 162]. Although much of CHD is thought to have a complex genetic and/or environmental etiology, an increasing number of families with monogenic CHD have been reported and disease genes are being identified [6].

CSD include atrial septal defects (ASD), ventricular septal defects (VSD), and atrioventricular septal defects (AVSD). CSD are characterized by openings in the septal wall between the left and right sides of the heart that allow oxygen-rich (red) blood to recirculate through the lungs instead of traveling to the rest of the body, resulting in increased pressure and stress in the lungs. Several genes have been identified as having a causative role, including *GATA4* and *NKX2-5*. A range of *GATA4* and *NKX2-5* mutations have been observed in both familial and isolated cases of CSD, and can be associated with additional CHD including tricuspid valve abnormalities (including Ebstein's anomaly), conotruncal anomalies (tetralogy of Fallot, double outlet right ventricle, interrupted aortic arch, and transposition of the great arteries), left sided lesions (hypoplastic left heart syndrome, coarctation, left ventricular hypertrophy), and pulmonary valve stenosis [163–169].

Cyanotic heart disease is a defect causing mixing of pure oxygen-rich blood with venous blood, resulting in a low blood oxygen concentration. The most common form is tetralogy of Fallot (TOF), which is characterized by a combination of four abnormalities: (1) VSD, (2) pulmonary stenosis (PS) or atresia (PA), (3) overriding aorta (the aorta lies directly over the VSD), and (4) right ventricular hypertrophy (RVH). TOF accounts for 6.8 % of all CHD [170], of which approximately 70 % occurs sporadically without another anomaly [171]. Mutations in *NKX2-5* are thought to account for up to 4–5 % of individuals with TOF [167, 168, 170]. Mutations in the Jagged 1 (*JAG1*) gene are the main cause of Alagille syndrome (AGS) but can also present as isolated CHD. The most common malformation in carriers of *JAG1* mutations is peripheral pulmonic stenosis (PPS), but other malformations such as isolated TOF, PS, or VSD with aortic dextroposition have been observed [172–174]. Of the cases of AGS caused by mutations in *JAG1*, the vast majority (88 %) are small sequence variants [174].

Clinical Utility of Testing

Genetic testing of clinically affected individuals with CHD and their relatives can help to confirm a clinical diagnosis and identify the cause of CHD in a particular family. Genetic testing also is useful to rule out a syndromic cause of CHD and to identify at-risk family members.

Available Assays

Sequencing assays for several CHD genes are offered clinically (genetests.org). A recent meta-analysis of published literature on CNVs in children with structural birth defects including CHD revealed that pathogenic CNVs appear to occur at increased frequency in this patient population [175]. Microarray based testing is widely available and can detect gross CNVs.

Interpretation of Test Results

Sensitivity and specificity are not known for most of the tests.

Laboratory Issues

The majority of molecular genetic testing for inherited cardiac diseases is done by sequencing one or several disease genes, usually the entire coding sequence, because allelic heterogeneity is the norm for all diseases covered in this chapter. Similarly, the assays that are commonly used to detect small deletions or duplications (e.g., MLPA or aCGH) are not unique to any given gene or disease. Hence, laboratory issues the physician (and patient) should be aware of do not differ by disease and are reviewed here instead of in the individual disease sections.

The majority of currently available tests are laboratory developed tests (LDTs), which (at the time of writing this chapter) are not subject to US FDA clearance, but are developed in laboratories accredited under the Clinical Laboratory Improvement Amendments (CLIA) regulations by the Centers for Medicare and Medicaid Services (CMS). Analytical performance (such as false-positive and false-negative rates) is established by the testing laboratory. The analytical sensitivity (the ability of the test to identify a mutation that is known to be present) is often not 100 % though typically very close [176]. Technical performance parameters have to be disclosed in the methods section of clinical reports issued by clinical molecular laboratories.

In addition to technical limitations that can lead to false negatives, the design of gene sequencing tests can impact mutation detection. For example, testing is typically limited to coding sequence (exons) as well as the splice consensus sequence. Therefore, mutations in noncoding regions that can affect gene regulation (e.g., promoter, enhancer, and the 3′ untranslated region) will not be detected. In addition, Sanger sequencing does not detect large copy number changes (such as partial or whole gene deletions/duplications) or structural mutations such as translocations. NGS technologies have the ability to detect these types of mutations but detection of these types of variants depends on the bioinformatics tools used by the laboratory for analysis of the sequencing data [177]. At the time of writing this chapter, gross structural changes are typically not part of the analysis offered by clinical molecular laboratories using NGS test methods, though this is expected to change rapidly.

Genetic testing laboratories commonly confirm any mutation that is detected using a second testing method. This is

done because most technologies used are not immune to technical artifacts (false-positive mutations). A second use of confirmatory testing is to rule out a sample switch although this does not include a switch prior to the sample's arrival at the testing laboratory. It is therefore essential to reconcile the result with the phenotype of the tested individual and to contact the laboratory when a discrepancy (such as the absence of a familial pathogenic mutation in an affected family member) exists. While there are alternate explanations such as environmental phenocopies of a disease or the presence of more than one disease causing mutation in a family, genotype–phenotype discrepancies should trigger a thorough investigation of possible sample switch.

Conclusions

Since the completion of the Human Genome Project in 2003, the number of identified disease genes has increased dramatically. Testing for genetically heterogeneous cardiac disorders, which has long been challenging due to high test cost, is now increasingly used in clinical practice and medical management of patients. Recent technological breakthroughs have increased the size of genetic test panels by an order of magnitude and the $1,000 genome, which was unthinkable just 10 years ago is now within reach and is anticipated to radically change the landscape of genetic testing as we know it today. It is likely that with rapidly dropping test cost and increasing accuracy and coverage, genome sequencing will soon replace most if not all genetic tests we know today. It is possible (even likely) that clinical genome sequencing will be performed at birth. Once obtained, an individual's genome can be used in a predictive fashion. Alternatively, data can be stored and subsets can be analyzed as needed, for example initiated by the presence of a specific family history or the onset of a disease that is known to have a genetic etiology. These indications can trigger the analysis of disease specific gene sets or, if the diagnosis is not clear, the exome or genome.

Current challenges include the timely and accurate interpretation of the approximately three million variants that are present per genome. We are only beginning to be able to understand the complete spectrum of benign variation, which is critical to narrow the number of variants detected. Although tools and processes to analyze human genomes are still in their infancy, success stories where ES/GS successfully identified the cause of diagnostically challenging cases are inspiring and give an outlook to what will be common in the relatively near future. As we are beginning to sequence many genomes, we will undoubtedly identify so far elusive genetic etiologies for inherited cardiovascular disorders such that the clinical utility of genetic testing will dramatically improve.

Neurodegenerative Disorders

18

Maria Martinez-Lage

Abstract

Neurodegenerative disorders are characterized by progressive neuronal deterioration resulting in cognitive or mental degeneration, dementias, muscle weakness, and/or movement disorders. Some disorders, such as Alzheimer disease or Parkinson disease exhibit sporadic as well as familial forms, with familial forms generally developing at an earlier age. Others, such as Huntington disease, are always inherited. Molecular genetics has elucidated the basis for a number of neurodegenerative disorders, and molecular testing may identify familial mutations, allowing presymptomatic or prenatal testing for family members.

Keywords

Alzheimer's disease • Parkinson's disease • Frontotemporal degeneration • Amyotrophic lateral sclerosis • Hereditary dystonia • Spinocerebellar ataxia • Autosomal dominant cerebellar ataxias • Friedrich ataxia • Huntington disease

Introduction

Neurodegenerative disorders are characterized by progressive neuronal deterioration resulting in cognitive or mental degeneration, dementias, muscle weakness, and/or movement disorders. Some disorders, such as Alzheimer disease or Parkinson disease, exhibit sporadic as well as familial forms, with familial forms generally developing at an earlier age. Others, such as Huntington disease, are always inherited. Molecular genetics has elucidated the basis for a number of neurodegenerative disorders, and molecular testing may identify familial mutations, allowing presymptomatic or prenatal testing for family members.

Alzheimer Disease

Molecular Basis of Disease

Alzheimer disease (AD) is an adult-onset, slowly progressive, and complex neurodegenerative disease that initially affects memory and later involves other cognitive and basic neurologic functions. AD is the most common form of dementia, particularly in the elderly. An estimated 5.2 million Americans had Alzheimer's disease in 2014, including approximately 200,000 individuals younger than age 65 [1]. The pathological hallmarks of AD are extracellular amyloid plaques composed of beta-amyloid (Aβ), and intracellular neurofibrillary tangles composed of phosphorylated tau protein, which can also be seen in the form of neuropil threads. AD can be clinically categorized as either late onset, presenting after 65 years of age, (LOAD) or early-onset disease (EOAD), which accounts for 1–5 % of all cases. Approximately 25 % of all AD is familial (i.e., ≥2 persons in a family have AD) of which approximately 95 % is LOAD [2].

Pathologic mutations in at least three genes have been associated with the development of early-onset familial Alzheimer disease (EOFAD) (Table 18.1). Approximately 10–15 % of EOFAD is associated with mutations in the

Table 18.1 Molecular genetic classification of Alzheimer disease (AD)

Gene symbol	Gene product	Chromosomal location	Key information
Definitive disease-causing genes (causative mutations of early onset Alzheimer disease)			
APP (AD1)	Amyloid precursor protein	21q21.3	Autosomal dominant, 25 pathogenic mutations, 16 % of early onset AD
PSEN1 (AD3)	Presenilin-1	14q24	Autosomal dominant, 185 pathogenic mutations, 66 % of early onset AD
PSEN2 (AD4)	Presenilin-2	1q31	Autosomal dominant, 12 pathogenic mutations
Genes with increased susceptibility (risk variants for late-onset Alzheimer disease)			
APOE (AD2)	Apolipoprotein E	19q13.32	
SORL1	Sortilin-related receptor	11q24.1	
ABCA7	ATP-binding cassette, subfamily A, member 7	19p13.3	
BIN1	Bridging integrator 1	2q14.3	
CD33 (*SIGLEC6*)	CD33 antigen/Sialic-acid binding immunoglobulin-like lectin 6	19q13.41	
CD2AP	CD2-associated protein	6p12.3	
CLU	Clusterin	8p21.1	
CR1	Complement component receptor 1	1q32.2	
EPHA1	Ephrin receptor EphA1	7q34-q35	
MS4A4E/*MS4A6A*	Membrane-spanning 4-domains, ubfamily A, members 6E, 4A	11q12.2	
PICALM	Phosphatidylinositol-binding clathrin assembly protein	11q14.2

gene encoding the amyloid precursor protein (APP), a 110–130 kDa ubiquitously expressed protein [2]. A small proteolytic fragment of APP, $A\beta_{1-42}$, is found as a major component of amyloid plaques, one of the neuropathological hallmarks of AD. Up to 25 pathogenic mutations have been identified to date, all of which are clustered in a 54 amino acid segment of APP that lies within or adjacent to the sequence encoding Aβ peptides [3]. The London mutation (V717I) is the most common APP mutation and results in increased levels of $A\beta_{1-42}$. The Swedish mutation involves two different codons (K670M and N671K) and increases total levels of Aβ production. The excess of Aβ is considered sufficient to cause AD, and this has been largely supported by the observation of a high prevalence of AD neuropathological changes and increased incidence of dementia in patients with trisomy 21 (Down syndrome), who carry an extra copy of the *APP* gene [2].

Mutations in presenilin-1 (*PSEN1*), located at chromosomal position 14q24.3, are responsible for the highest percentage of autosomal dominant EOFAD. Approximately 185 pathogenic mutations have been identified to date [3], all with complete penetrance by age 60–65 years. Presenilin-1 is the catalytic component of γ-secretase, a protein complex responsible for the cleavage of membrane proteins, including APP. Normal γ-secretase activity yields mainly $A\beta_{1-40}$ with smaller amounts of $A\beta_{1-42}$. *PSEN1* mutations alter the secretase activity [4], which likely increases the ratio of $A\beta_{1-42}$ to $A\beta_{1-40}$, facilitating the deposition of amyloidogenic species. Presenilin-2 (*PSEN2*), located at chromosomal position 1q31-q42, is highly homologous to *PSEN1* and participates in the γ-secretase complex as the catalytic domain in the absence of Presenilin-1. *PSEN2* mutations are less common than *PSEN1* variants, with only 13 pathogenic mutations identified to date [3]. Compared to *PSEN1*, patients with *PSEN2* mutations tend to have an older age of onset (accounting for the very small number of LOAD caused by an inherited mutation), longer course of disease, and more variable penetrance.

The association of the apolipoprotein E (*APOE*) ε4 allele with LOAD in non-Hispanic whites of European ancestry has been well known for more than a decade. ApoE is a plasma protein involved in the transport of cholesterol that exists as three isoforms determined by three alleles (ε2, ε3, and ε4). The ApoE ε2 and ε3 alleles are the most common in the general population. A single ApoE ε4 allele conveys a two-fold to three-fold increased risk of developing AD, whereas having two copies is associated with a five-fold increased risk, demonstrating an additive risk association. The ε2 allele is considered protective, also in an additive manner, so that a

homozygous ε2/ε2 genotype confers a lower risk than just one ε2 allele. The ε4 allele s associated with not only a higher risk of developing the disease, but also an earlier age of onset; however, the presence of ε4 is neither sufficient nor necessary to develop AD, since approximately 45 % of AD patients do not have an ε4 allele [1]. Other susceptibility genes associated with increased risk for AD are shown in Table 18.1.

Clinical Utility of Testing

The use of *APOE* genotyping in the clinical setting remains controversial. As a diagnostic adjunct in the clinical evaluation of a patient with late-onset dementia, the test may have some clinical utility; however, there is general agreement that this test should not be used for predictive purposes and should never be considered for prenatal testing. In contrast, within the context of a high degree of clinical suspicion and the documentation of a family history of AD, clinical molecular testing for *APP*, *PSEN1*, and *PSEN2* has demonstrable utility. Confirmation of a pathologic mutation in a proband will establish a diagnosis and clarify the EOFAD subtype such that both presymptomatic testing for appropriate family members and prenatal testing for at-risk pregnancies could be offered to family members.

Available Assays

APOE genotyping can be performed by traditional polymerase chain reaction-restriction fragment length polymorphism (PCR-RFLP) analysis, Sanger sequencing, or TaqMan® SNP assay (Life Technologies, Grand Island, NY). Detection of pathologic mutations in *APP*, *PSEN1*, and *PSEN2* requires DNA sequencing, either Sanger sequencing or next-generation sequencing.

Interpretation of Test Results

Interpretation of an *APOE* genotype requires the concurrent evaluation of clinical information available at the time of testing and should never be interpreted in the absence of this information. As such, testing is limited to situations where the index of clinical suspicion for AD is quite high. In contrast, the identification of a pathologic *PSEN1* or *PSEN2* mutation in a symptomatic individual is diagnostic. While both presymptomatic as well as prenatal testing are theoretically possible in mutation-positive kindred, the possible existence of incomplete or reduced penetrance must be discussed during genetic counseling.

Laboratory Issues

APOE genotyping is commercially available in several reference laboratories. The College of American Pathologists (CAP) offers *APOE* genotyping proficiency testing challenges twice a year as part of the CAP/ACMG Biochemical and Molecular Genetics Survey. Methods-based sequencing challenges (Sanger or next-generation sequencing) are also available through CAP.

Parkinson Disease

Molecular Basis of Disease

Parkinson disease (PD) is a chronic, progressive, idiopathic neurodegenerative disorder of late onset, clinically characterized by the development of parkinsonism, which consists of rigidity, bradykinesia, resting tremor, and postural instability. Additional frequent non-motor symptoms include insomnia, depression, anxiety, rapid eye movement, behavior disorder, fatigue, constipation, dysautonomia, and anosmia. With progression of the disease, 15 % of affected individuals develop psychosis (visual hallucinations and delusions) and dementia. PD is the second most common neurodegenerative disorder, after AD [5]. The neuropathologic hallmark is the presence of α-synuclein positive intracytoplasmic inclusions called Lewy bodies, with selective degeneration of dopaminergic neurons in the pars compacta of the substantia nigra in the midbrain. Although most patients present with a late-onset sporadic form of the disease, the identification of familial forms of PD has clearly established the role of genetic factors in disease etiology and pathogenesis. Of note, the neuropathology of some forms of genetically based parkinsonism may differ significantly from the classic findings documented in classical PD, including nigral pathology in the absence of Lewy bodies [6].

Genes for ten familial forms of PD (PARK1, PARK2, PARK4, PARK6, PARK7, PARK8, PARK9, PARK12, PARK15, and PARK17) have been identified (Table 18.2). The inheritance patterns for PD include autosomal dominant (PARK1, PARK4, PARK8, and PARK17), autosomal recessive (PARK2, PARK6, PARK7, PARK9, and PARK15), and X-linked (PARK12). Three different but interconnected cellular processes appear to be involved in these forms: synaptic transmission, mitochondrial quality control, and lysosome-mediated autophagy [7].

PARK1 is associated with early-onset autosomal dominant PD. Despite an earlier age of onset, PARK1 patients have typical dopa-responsive parkinsonism symptoms with classic neuropathologic findings at autopsy. Three pathogenic missense mutations in the α-synuclein (*SNCA*) gene at 4q21 have been identified. The first, A53T, was found in 13 families of Italian–Greek descent [8] and the second, A30P, identified in a single German kindred [9]. A third point mutation, E46K, was described in a Spanish kindred with clinical manifestations of both parkinsonism and dementia, clinically similar to Lewy body dementia [10]. All three point mutations appear to be highly penetrant. Other pathogenic variants include gene duplications and triplications [3], some of which are responsible for the PARK4 phenotype with late-onset parkinsonism and extensive cortical Lewy bodies. α-Synuclein is a 140 amino acid protein predominantly expressed in neuronal tissues. Although the function of α-synuclein is not well characterized, this protein is one of the major protein

Table 18.2 Molecular genetic classification of Parkinson disease (PD)

Locus name	Gene	Gene product	Chromosomal location	Inheritance pattern
PARK1, PARK4	*SNCA*	Alpha-synuclein	4q21	Autosomal dominant
PARK2	*PARK2*	Parkin	6q25	Autosomal recessive
PARK6	*PINK1*	Serine/threonine protein kinase PINK1	1p35	Autosomal recessive
PARK7	*PARK7*	Protein DJ-1	1p36	Autosomal recessive
PARK8	*LRRK2*	Leucine-rich repeat serine/threonine protein kinase 2	12p11	Autosomal dominant
PARK9	*ATP13A2*	Probable cation-transporting ATPase 13A2	1p36	Autosomal recessive
PARK12	*TAF1*	Transcription initiation factor TFIID subunit 1	Xq21-q25	X-linked
PARK15	*FBX07*	F-box only protein 7	22q12.3	Autosomal recessive
PARK17	*VPS35*	Vacuolar protein sorting-associated protein 35	16q11.2	Autosomal dominant

Source: http://www.ncbi.nlm.nih.gov/books/NBK1223/

constituents of the Lewy body. One attractive hypothesis proposes that the mutant forms of the protein have a propensity to oligomerize and form toxic neuronal aggregates that contribute to the formation of insoluble fibrils through the disruption of the cellular ubiquitin–proteasome pathway and ultimately neuronal cell death via an apoptotic mechanism.

PARK2, or juvenile-onset autosomal recessive PD, is associated with mutations in the *PARK2* gene that maps to chromosome 6q25. The gene consists of 12 exons and encodes a 465 amino acid protein, parkin. Functionally, parkin contains an ubiquitin-like domain in the N-terminus and two RING finger domains in the C-terminus. Similar to other proteins containing RING finger domains, parkin has been shown to have an E3 ubiquitin ligase activity. The association of parkin mutations with an autosomal recessive form of PD suggests that it is the loss of E3 ubiquitin ligase activity that directly contributes to the pattern of neurodegeneration seen in PD. Like PARK1, this mechanism is thought to involve disruption of the ubiquitin–proteasome system, resulting in the abnormal accumulation of substrate proteins. To date, more than 127 pathologic loss-of-function *PARK2* mutations have been identified [7]. Mutations are generally exon rearrangements leading to deletions, duplications, triplications, or point mutations.

PARK6 is associated with mutations in the serine/threonine protein kinase gene (*PINK1*), with an autosomal recessive pattern of inheritance [5]. PARK7, another autosomal recessive form of PD, is caused by mutations (deletion and point mutations) in the *PARK7* gene. PARK9 defines a particular autosomal recessive phenotype with parkinsonism and iron accumulation in basal ganglia and is due to mutations in the cation-transporting ATPase 13A2 protein encoded by *ATP13A2*. PARK15, also known as pallidopyramidal syndrome, is characterized by the presence of pyramidal tract signs in addition to parkinsonism, and is associated with mutations in *FBX07* [11].

PARK8 is a dominantly inherited late-onset form of PD associated with mutations in the leucine rich repeat kinase 2 gene (*LRRK2*). Nearly a dozen different pathogenic variants have been reported in LRRK2; the most common, p.Gly2019Ser, has been found in approximately 5–7 % of autosomal dominant PD. Of note, the frequency of this variant is substantially higher among individuals of Ashkenazi Jewish ancestry or Northern African ancestry [5].

Mutations of *TAF1* are the only known cause of PD with X-linked inheritance (PARK12), a rare event only found among individuals of Panayan (Philippines) origin [5].

Clinical Utility of Testing

Testing for *SNCA*, *PARK2*, *PINK1*, *PARK7*, and *LRRK2* mutations is available clinically. With a high degree of clinical suspicion and the documentation of a family history of PD, molecular testing has demonstrable utility. Confirmation of a pathologic mutation in a proband will establish a diagnosis and clarify the mode of inheritance such that both presymptomatic testing for appropriate family members and prenatal testing for at-risk pregnancies could be offered.

Available Assays

Testing for most of the PD genes can be performed by conventional Sanger sequencing of the mutation-containing exons. Testing for *PARK2* mutations generally necessitates the use of a semiquantitative PCR methodology to detect heterozygous exonic rearrangements (deletions, duplications, and triplications), which would not be detected by conventional non-quantitative PCR or Sanger sequencing [12]. Next-generation sequencing panels of multiple Parkinson-associated genes are available in international laboratories.

Interpretation of Results

The identification of a pathologic mutation in a symptomatic proband is diagnostic.

Laboratory Issues

No commercial in vitro diagnostic test kits or formal proficiency testing are currently available.

Amyotrophic Lateral Sclerosis and Frontotemporal Degeneration

Molecular Basis of Disease

Amyotrophic lateral sclerosis (ALS) is a progressive neurodegenerative condition affecting upper and lower motor neurons characterized by rapidly progressive weakness, hyperreflexia, spasticity, muscle wasting, and fasciculations, usually leading to death in a few years. The peak incidence of ALS is in the sixth decade for sporadic cases (SALS, 90 %), and 10 years earlier for the 5–10 % of familial cases (FALS) [13].

Frontotemporal degeneration (FTD) is a neurodegenerative disorder characterized clinically by progressive changes in social, behavioral, and/or language function and pathologically by degeneration of the frontal and/or anterior temporal lobes. Clinical and pathologic phenotypes of FTD are heterogeneous, with several subtypes recognized depending on the most prominent clinical manifestation. In contrast to AD, memory is relatively preserved in FTD until late stages of disease. FTD accounts for 5–15 % of all dementia and is the second most common cause in the presenile age group. A subset of patients with FTD have associated motor neuron disease or parkinsonism. Onset is usually between 35–75 years of age and a family history of a similar disease is present in approximately 40 % of patients.

About 5 % of patients with ALS also have clinically documented FTD, and up to 30–50 % have milder evidence of executive dysfunction, supporting the hypothesis that at least in a majority of cases, FTD and ALS are part of a disease continuum. The presence of pathological deposits of TDP-43 in most cases of ALS, in most cases with overlap between FTD and ALS (FTD-ALS), and in most cases of FTD provides a potential unifying mechanistic link [14]. Mutations in the gene coding for TDP-43 (*TARDBP*) cause FALS in a 1–4 % of families.

The first gene to be identified in ALS is associated with the ALS1 locus. The *SOD1* gene encodes copper-zinc superoxide dismutase, a metalloenzyme consisting of 153 amino acids with both copper and zinc binding sites. SOD1 catalyzes the conversion of superoxide anions to hydrogen peroxide and molecular oxygen and, as such, is thought to have a protective function in the cell by preventing oxidative damage caused by the accumulation of free radicals. More than 100 mutations have been reported in the *SOD1* gene, with one, A5V (previously known as A4V), accounting for approximately 50 % of all mutations found in North American families. Approximately 20 % of patients with FALS and 3 % of patients with SALS have *SOD1* mutations [13]. Incomplete penetrance has been documented in some families. Table 18.3 includes the gene products, chromosomal location, and clinical features of other ALS-related genes.

Several different genes and chromosomal loci have been associated with FTD, primarily with an autosomal dominant inheritance. Mutations in the microtubule (MT)-associated protein tau (*MAPT*) are responsible for 10–20 % of familial cases, and all these have tau-based neuropathology. The main function of these proteins is to stabilize the MTs and to promote MT assembly by binding to tubulin. More than 40 mutations in *MAPT* have been associated with FTD [3]. These cause disease by either altering the MT-binding properties of tau or by altering the splicing of exon 10 of *MAPT*, which alters the ratio of isoforms with 3 or 4 microtubule binding repeats.

A number of other FTD families with linkage to the same region on chromosome 17 as *MAPT* (17q21) but with no identifiable *MAPT* mutation and no significant tau pathology demonstrate mutations in the progranulin (*GRN*) gene, including frameshift, nonsense, and splice-site mutations. Progranulin (PGRN) is a 593 amino acid-secreted growth factor known to play a role in central nervous system development. The underlying disease mechanism is likely due to loss-of-function leading to protein haploinsufficiency, and the end point is TDP-43 neuropathology. *GRN* mutations account for approximately 20 % of familial FTD.

In 2011, GGGGCC hexanucleotide repeat expansions in the first intron of the *C9orf72* gene were identified as the most common genetic cause of both FTD and ALS [15, 16]. Normal individuals have between 2 and 32 GGGGCC repeats, whereas affected individuals with expansions usually have more than several hundred repeats [17]. The average mutation frequencies in North Americans and Europeans are 37 % for FALS, 6–7 % for SALS, 21–25 % for familial FTD, and 6 % for sporadic FTD (http://www.omim.org/entry/614260). Penetrance of the mutation is high, with 90 % of people with an expansion having onset of symptoms by age 70 years. No clear relationship between phenotype and expansion size has been determined. ALS patients with a *C9orf72* expansion have earlier age of onset and reduced survival compared to ALS patients without an expansion.

Clinical Utility of Testing

Within the context of a high degree of clinical suspicion and the documentation of a positive family history, clinical molecular testing for most of the above ALS and FTD related genes has demonstrable utility. Confirmation of a pathologic mutation in a proband will establish a diagnosis and clarify the

Table 18.3 Molecular genetic classification of amyotrophic lateral sclerosis (ALS) and frontotemporal lobar degeneration (FTD)

Locus name	Gene	Gene product	Chromosomal location	Inheritance pattern	Clinical presentation
ALS1	*SOD1*	Superoxide dismutase (Cu-Zn)	21q22.1	Autosomal dominant	20 % of FALS
ALS2	*ALS2*	Alsin	2q33	Autosomal recessive	
ALS3	*ALS3*	Unknown	18q21	Autosomal dominant	FALS

FTD-GRN	*GRN*	Progranulin	17q21	Autosomal dominant	FTD

Sources: http://www.ncbi.nlm.nih.gov/books/NBK1450/, http://omim.org/entry/600274 *AD* Autosomal dominant, *AR* Autosomal recessive, *ALS* amyotrophic lateral sclerosis, *CMT* Charcot-Marie-Tooth syndrome, *FALS* familial amyotrophic lateral sclerosis, *FTD* frontotemporal dementia, *IBMPFD* inclusion body myopathy with early onset Paget disease and frontotemporal dementia, *SCA2* spinocerebellar ataxia type 2, *SMA* spinal muscular atrophy

mode of inheritance such that both presymptomatic testing for appropriate family members and prenatal testing for at-risk pregnancies could be offered. Clinical testing for a *C9orf72* hexanucleotide repeat expansion can help to confirm the diagnosis of ALS or FTD and be used for screening and genetic counseling of patients and family members after an affected family member has been found to carry an expansion.

Available Assays

Direct DNA sequencing analysis is most commonly used for ALS related genes (*SOD1*, *ALS2*, etc.), as well as for *GRN* and *MAPT*. When the mutation is known in the proband, directed sequencing is preferred in the screening of family members. Next-generation sequencing as well as Sanger sequencing panels that include many of these genes are currently

available. The hexanucleotide expansion in *C9orf72* uses a combination of PCR-based amplification for normal alleles with expansion analysis, usually by Southern blot analysis, for homozygous PCR results, and is available at most reference laboratories.

Interpretation of Test Results

The identification of a pathogenic mutation in any of the above genes in a symptomatic proband is considered diagnostic. However, negative results must be interpreted with caution, because not all genetic causes of ALS and FTD have been identified. Once a mutation has been identified in the proband, directed gene mutation testing can be performed in affected family members as well as in unaffected adult family members who wish to know their mutation status, after presymptomatic genetic counseling with a certified genetic counselor. Prenatal testing may be considered; however, it is important to note that onset of disease is in the adult years and is variable. In addition, penetrance may not be 100 % with all mutations.

Normal, nonpathogenic alleles of *C9orf72* contain between 2 and 32 hexanucleotide repeats at this locus, while pathogenic expansions contain from 32 to >1,000 repeats. The clinical significance of alleles with 20–32 repeats is currently unclear and should be interpreted with caution.

Laboratory Issues

Formal proficiency testing is not available for any of these ALS/FTD associated genes.

Huntington Disease

Molecular Basis of Disease

Huntington disease (HD) is an autosomal dominant neurodegenerative disorder clinically characterized by the presence of choreiform movements, psychiatric symptoms, and cognitive decline. While >90 % of HD patients become symptomatic in adulthood, 5–10 % present before the age of 20 years (juvenile-onset) which is frequently associated with inheritance of the mutant allele from a symptomatic father. Unlike the adult-onset form, juvenile-onset HD is generally characterized by the presence of rapidly progressive rigidity, seizures, ataxia, dystonia, and intellectual decline [18].

The Huntington gene (*HTT*, formerly *IT15*) is at chromosomal location 4p16.3. The gene spans more than 200 kilobases (kb) and contains 67 exons. *HTT* encodes a 3,142 amino acid protein with an approximate molecular weight of 350 kilodaltons (kDa) that shares no known homologies with other characterized proteins. HD is caused by a toxic gain-of-function mechanism associated with the expansion of a polyglutamine tract within the protein that is translated from a CAG repeat region within exon 1 of the gene. The CAG repeat length is highly polymorphic in the general population, with the largest normal allele currently defined as carrying ≤26 CAG repeats. Alleles carrying ≥40 CAG repeats are considered diagnostic, since they have never been identified in the absence of HD pathology. Alleles with 27–35 CAG repeats are defined as "mutable normal or intermediate alleles." While alleles in this size range have yet to be convincingly associated with an HD phenotype, they can be meiotically unstable in sperm and result in the expansion of paternally derived alleles. Alleles of 36–39 CAG repeats are defined as "HD alleles with reduced penetrance," as they have been found in both clinically as well as neuropathologically confirmed HD patients and in elderly asymptomatic individuals [19].

Clinical Utility of Testing

As HD is largely a genetically homogeneous disease, molecular testing has been routinely utilized for confirmatory, predictive, and prenatal purposes. Professional standards strongly encourage that predictive test should be offered only to individuals 18 years of age or older. The recommended multidisciplinary presymptomatic protocol includes pretest counseling and evaluation by a clinical geneticist, genetic counselor, psychologist or psychiatrist, and neurologist over several visits, with the option to not receive test results even after testing has been completed. With few exceptions, interpretation of laboratory results is unambiguous and the resulting genetic counseling consultations follow those for other autosomal dominant adult-onset disorders. Prenatal testing can be performed using amniotic fluid cells or chorionic villus samples after a molecular diagnosis of HD in the family. Maternal cell contamination studies should be performed on every prenatal sample to confirm the fetal origin of the tested sample [19].

Available Assays

The presence of CAG repeat expansions can be determined by both PCR and Southern blot methods. For PCR, several sets of primers, assay conditions, amplicon separation, and detection techniques have been published. Regardless of the particular PCR test method employed, optimization of the assay conditions and post-PCR analyses is essential to ensure accurate and unambiguous quantitation of the HD CAG repeat length (Fig. 18.1), given that sizing anomalies have been observed in analyses utilizing agarose, capillary, and denaturing polyacrylamide gel electrophoretic (PAGE) methods [19]. As such, accurate quantitation of patient amplicon sizes should be empirically determined by comparison to appropriate external or internal standards [19].

As the length of the polymorphic CAG repeat alone is associated with HD, testing must be designed to amplify only the CAG repeat and not an adjacent CCG repeat [19]. The CCG repeat, which lies 12 base pairs (bp) 3′ of the HD

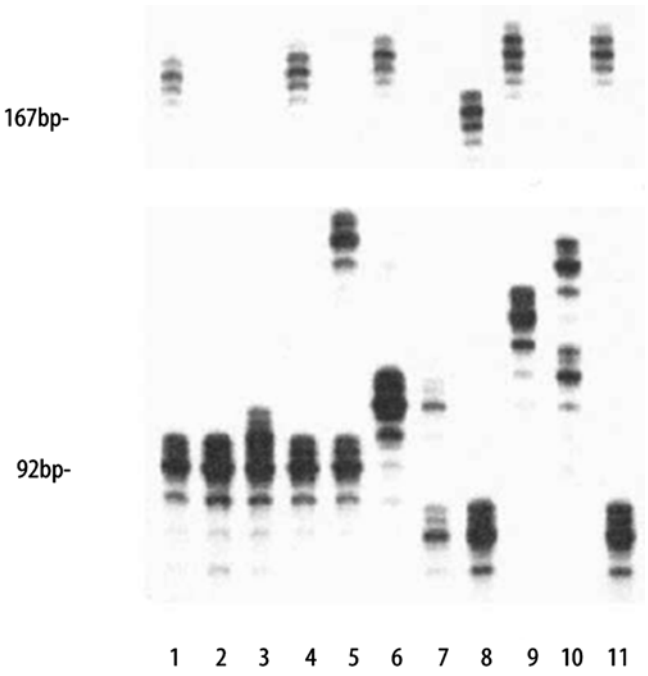

Figure 18.1 PCR genotyping of the Huntington disease polymorphic CAG repeat utilizing ^{32}P-dCTP incorporation and the Al/C2 primer pair [20, 21]. Separation and sizing of alleles was performed on a 35 cm × 43 cm 6 % denaturing polyacrylamide gel followed by autoradiography. The numbers of CAG repeats in each of the two alleles for patients in *lanes 1–11* are 17 and 44, 17 and 17, 17 and 18, 17 and 44, 17 and 25, 19 and 45, 15 and 19, 15 and 40, 22 and 45, 20 and 24, and 15 and 45, respectively

CAG repeat, is also polymorphic and as a result may lead to diagnostic inaccuracies for both normal and HD allele sizing. Furthermore, polymorphisms surrounding or within the CAG tract have been identified with a collective frequency of approximately 1 %. These nucleotide substitutions can be categorized into two groups: (1) those that modify primer-annealing sites and (2) those that result in the loss of sequence interruption between the CAG and CCG repeat tracts. With the first category, nucleotide changes may result in the misinterpretation of genotyping data due to an allele-specific amplification failure associated with improper primer annealing. In the second category, rare A to G substitutions within the intervening 12 bp segment between the CAG and CCG tracts can result in increased meiotic instability of the tract as well as miscalculation of uninterrupted CAG repeat length based on conventional calculation formulas [19].

Triplet-repeat primed PCR (TP PCR) allows for the rapid identification of large pathogenic repeats refractory to conventional PCR amplification by using a chimeric PCR approach that generates different sized amplicons due to multiple annealing sites on the template [22]. The forward primer is fluorescently labeled and the design of the chimeric reverse primer introduces nonspecific DNA amplification by hybridization to multiple sites within the expanded region originating PCR products of varying sizes. Capillary electrophoresis is used to separate the products and the true alleles are easily distinguished as the highest peaks, with a stutter peak of decreasing amplitude seen when an expanded allele is too large to be amplified by the assay (usually >101 repeats).

Southern blot methods, although not generally used for routine diagnostic testing, often are essential for the identification or confirmation of very large expansions typically associated with juvenile-onset HD. Furthermore, Southern blot or TP PCR may be used for confirmation testing of patients (generally children) who appear to be homozygous for two normal-sized alleles [19].

Interpretation of Test Results

PCR testing for the HD CAG repeat has a reported sensitivity of 99 % [23]. The remaining 1 % of patients represent HD phenocopies, and to date at least two distinct genetic loci, *HDL1* which corresponds to the prion protein gene *PRNP* (http://www.omim.org/entry/176640#0001) and *HDL2* which is discussed below in the section on dystonia, have been identified. Testing specificity is nearly 100 % [24]. In summary, the interpretative challenges in HD testing are primarily related to the need to recognize that CAG ranges and descriptors may be modified over time. For reporting of HD results, the American College of Medical Genetics and Genomics (ACMG) has recently established updated guidelines regarding the definitions of CAG repeat range descriptors and interpretative guidelines for test reporting and genetic counseling purposes [19].

Laboratory Issues

CAP offers HD proficiency challenges twice per year as part of the CAP/ACMG Molecular Genetics Laboratory (MGL2) Survey. Genotyped HD patient DNA for use as controls can be obtained from the Coriell Cell Repositories (Camden, NJ; http://ccr.coriell.org/).

Autosomal Dominant Cerebellar Ataxias and Friedreich Ataxia

Molecular Basis of Disease

The autosomal dominant cerebellar ataxias (ADCAs) or spinocerebellar ataxias (SCAs) represent a clinically and genetically heterogeneous group of neurological disorders with an autosomal dominant mode of inheritance. To date, at least 35 distinct loci have been identified, and clinical testing is presently available for most in which a causative gene has been identified. Because the collective incidence of these disorders is high in both unselected and selected ataxia cohorts [25, 26] and the degree of clinical overlap among the various ADCAs is extensive, molecular genetic testing is a valuable

diagnostic tool. Most of the molecularly characterized ADCAs (dentatorubro pallidoluysian atrophy or DRPLA and SCA1, 2, 3, 6, 7, 8, 10, 12, 17, 31, and 36) are associated with reiterated repeat expansion mutations and neuropathologically share the presence of inclusions or aggregates. DRPLA and SCA1, 2, 3, 6, 7, 12, and 17 are associated with CAG trinucleotide repeat expansion, and SCA8 with a CTG trinucleotide repeat expansion. SCA10 is associated with an ATTCT pentanucleotide repeat expansion, SCA31 with a TGGAA pentanucleotide repeat expansion, and SCA36 with a GGCCTG hexanucleotide repeat expansion (Table 18.4). In general, larger repeat expansions correlate with earlier onset of disease and greater severity of disease symptoms. Also, expanded repeats are less stable and can change, and usually to a larger size of the repeat, when passed on to the next generation. This repeat expansion with passage to the next generation results in the clinical phenomenon of anticipation, which is the observation of an earlier age of onset and more severe disease when an expansion is passed on to the next generation.

In the majority of the ADCAs, the location of the repeat region is exonic (DRPLA and SCA1, 2, 3, 6, 7, and 17), and the mechanism of disease pathogenesis (with the exception of SCA6) is thought to involve a toxic gain of function in the protein. Genes associated with polyglutamine expansion ADCAs are involved in RNA metabolism, chromatin structure, transcription regulation, glutamate transmission, mitochondrial function, and their dysfunction can lead to the toxic accumulation of aggregates and intranuclear inclusions. The non-polyglutamine expansion ADCAs (SCA8, 10, 12, and 31) demonstrate expansions in noncoding regions which also can trigger a gain of function mechanism. These genes are associated with chromatin structure, RNA metabolism, mitochondrial function, and toxic accumulation of protein and RNA aggregates. The rest of the ADCAs, not associated with repeat expansion, are linked to conventional mutations, such as missense point mutations, insertions, and deletions. The genes involved in the ADCAs without repeat expansions are responsible for calcium homeostasis, glutamate transmission, mitochondrial function, axonal transport, tau metabolism, and potassium transmission [27].

Friedreich ataxia (FRDA) is the most common form of hereditary ataxia, with a prevalence of approximately 2–4 per 100,000 and a carrier frequency of approximately 1 in 90. The disease has an autosomal recessive mode of inheritance. FRDA is clinically characterized by the onset of gait and limb ataxia before the age of 25 years, decreased deep tendon reflexes, dysarthria, pyramidal signs, Babinski responses, and decreased position or vibration sense (or both) in the lower limbs. Approximately 65 % of patients also develop a cardiomyopathy, while approximately 10 % of patients develop diabetes. Atypical clinical presentations have been reported in approximately 25 % of patients and generally have included later ages of onset (after 25 years of age), retained reflexes, and slower disease progression. In addition, genetically confirmed patients with more complex phenotypes have recently been reported and include individuals with idiopathic spastic paraparesis, motor and sensory neuropathy, limb and axial dystonia, and chorea with myoclonus [28]. FRDA is caused by mutations in the *FXN* gene that encodes the 210 amino acid protein frataxin that localizes to the mitochondrial inner membrane, where it is required for mitochondrial iron homeostasis. Approximately 90–94 % of patients are homozygous for GAA expansion mutations within intron 1 of *FXN*, whereas 6–10 % of patients are compound heterozygotes for a GAA expansion on one allele and an inactivating point mutation or deletion on the other. As opposed to what occurs in most ADCA with trinucleotide repeat expansion, FRDA is not associated with the phenomenon of genetic anticipation [29].

Ataxia-telangiectasia (AT) is an autosomal recessive, early onset, progressive cerebellar ataxia with characteristic oculomotor apraxia, choreoathetosis, conjunctival telangiectasias, immunodeficiency, and increased risk for leukemia, lymphoma, and other malignancies. AT is caused by homozygous or compound heterozygous mutations in the *ATM* gene, encoding the ATM serine/threonine kinase protein. Mutations include missense, nonsense, and splice site mutations, small intragenic deletions/insertions, and, in 1–2 % of cases, large genomic deletions. Of note, in AT, DNA sequence analysis of *ATM* in search of mutations may have lower sensitivity than immunoblotting for intracellular ATM protein depletion [30].

Clinical Utility of Testing

The utility of offering testing for the molecularly characterized hereditary ataxias is very high. For the ADCAs with well-characterized genetic loci, diagnostic, predictive, as well as prenatal testing is available. Although allelic heterogeneity has been reported in FRDA (i.e., point mutations in compound heterozygotes), the vast majority of FRDA patients have homozygous expansions of the GAA repeat; hence, diagnostic, predictive, and prenatal testing also is available. As is the case with HD, predictive testing for the ADCAs should be offered only to individuals who have reached the statutory age of majority (generally 18 years). Before testing is performed for an asymptomatic family member at risk, a formal multidisciplinary predictive testing protocol, similar to the one utilized for HD predictive testing, should be offered to those desiring determination of their carrier status. Again, with few exceptions, interpretation of the laboratory result is unambiguous, and the resulting genetic counseling consultations follow those for other autosomal dominant adult-onset disorders. For FRDA and AT families, appropriate counseling consistent with an autosomal recessive pattern of inheritance is required. AT patients

Table 18.4 Molecular genetic classification of the autosomal dominant cerebellar ataxias (ADCA) and selected autosomal recessive ataxias

Locus name	Gene	Gene product	Chromosomal location	Key information
SCA1	*ATXN1*	Ataxin-1	6p22.3	Peripheral neuropathy, (CAG)*n* trinucleotide repeat
SCA2	*ATXN2*	Ataxin-2	12q24.12	Peripheral neuropathy, dementia, (CAG)*n* trinucleotide repeat
SCA3	*ATXN3*	Ataxin-3	14q32.12	Machado–Joseph disease, most common ADCA worldwide, (CAG)*n* trinucleotide repeat
SCA4	–	Unknown	16q22.1	SCA with sensory axonal neuropathy; same region but not allelic with SCA31
SCA5	*SPTBN2*	Spectrin, beta, non-erythrocytic 2	11q13.2	Early onset and slow progression, point mutations and deletions
SCA6	*CACNA1A*	P/Q-type voltage-gated calcium channel, transmembrane pore-forming alpha 1A subunit	19p13.2	Very slow progression, sometimes episodic ataxia, (CAG)*n* trinucleotide repeat
SCA7	*ATXN7*	Ataxin-7	3p14.1	SCA with pigmentary macular dystrophy, (CAG)*n* trinucleotide repeat
SCA8	*ATXN8*, *ATXN8OS*	Ataxin-8, Ataxin-8 opposite strand	13q21	'CTG*CAG' complementary repeat expansion of both genes
SCA10	*ATXN-10*	Ataxin-10	22q13.31	(ATTCT)*n* repeat
SCA11	*TTBK2*	Tau tubulin kinase-2	15q15.2	Relatively pure SCA, insertions/deletions
SCA12	*PPP2R2B*	Protein phosphatase PP2A, regulatory subunit beta	5q32	SCA with early tremor, (CAG)*n* trinucleotide repeat
SCA13	*KCNC3*	Potassium channel, voltage-gated, Shaw-related member 3	19q13.33	Point mutations
SCA14	*PRKCG*	Protein kinase C, gamma	19q13.42	Missense mutations, deletions
SCA15	*ITPR1*	Inositol 1,4,5-triphosphate (IP3) receptor type 1	3p26.1	Very slow progression, point mutations, and deletions
SCA17	*TBP*	TATA box-binding protein	6q27	SCA with seizures, psychiatric and cognitive symptoms; trinucleotide repeat encoding glutamine (CAG or CAA)
SCA18	*SCA18*	Unknown	7q22-q32	SCA with early sensory/motor neuropathy
SCA19/22	*KCND3*	Potassium channel, voltage-gated, Shal-related member 3	1p13.2	Point mutations, deletions
SCA20	–	–	11q12	SCA with early dysarthria and dysphonia, 260 kb contiguous gene duplication
SCA21	*TMEM240*	Transmembrane protein 240	1p36.33	SCA with cognitive impairment, point mutations
SCA23	*PDYN*	Prodynorphin	20p13	Point mutations
SCA25	*SCA25*	Unknown	2p21-p13	
SCA27	*FGF14*	Fibroblast growth factor-14	13q33.1	Point mutations, deletion
SCA28	*AFG3L2*	ATPase family gene 3-like 2	18p11.21	Point mutations, autosomal dominant; allelic with AR spastic ataxia 5
SCA29	*ITPR1*	Inositol 1,4,5-triphosphate (IP3) receptor type 1	3p26.1	Congenital nonprogressive cerebellar ataxia, missense mutations

(continued)

Table 18.4 (continued)

Locus name	Gene	Gene product	Chromosomal location	Key information
SCA31	*BEAN1*	Brain-expressed associated with NEDD4	16q21	Common in Japan, (TGGAA)*n* pentanucleotide repeats, same region but not allelic with SCA4
SCA35	*TGM6*	Transglutaminase-6	20p13	Point mutations
SCA36	*NOP56*	Homolog of S. Cerevisiae NOP56	20p13	SCA and fasciculations, (GGCCTG)*n* hexanucleotide repeat
DRPLA	*ATN1*	Atrophin-1	12p13.31	Dentatorubral-pallidoluysian atrophy, ataxia, dementia, myoclonic epilepsy, and choreoathetosis), (CAG)*n* trinucleotide repeat
ATM	*ATM*	ATM serine/threonine kinase (Ataxia-telangiectasia mutated gene)	11q22.3	Ataxia telangiectasia, AR, cerebellar ataxia, telangiectasias, immune defects, and cancer predisposition
FRDA	*FXN*	Frataxin	9q21.11	Friedreich ataxia, AR, slowly progressive ataxia with limb weakness, areflexia, sensory loss, and cardiomyopathy, biallelic (GAA)*n* trinucleotide repeat

AR autosomal recessive, *SCA* spinocerebellar ataxia

and their families require genetic counseling and additional screening due to the increased risk of developing cancer, which also is a risk for unaffected carriers.

Available Assays

Detection and quantitation of the repeat expansions associated with the ADCAs can be determined by both PCR and Southern blot methods, and the choice of methodology is dependent on the characteristic size range for the disease-specific expansion mutation. For example, very large expansions, such as those routinely seen in SCA10, require Southern blot analysis, whereas those seen in other ADCAs (SCA6, for example) are amenable to detection by routine PCR analysis. Some notable exceptions, however, are described below. As noted above for HD, regardless of the particular PCR method used, assay conditions and post-PCR analyses should be optimized to ensure accurate and unambiguous quantitation of repeat length. Furthermore, CAG sizing anomalies for ADCA testing also have been observed in comparative studies of capillary and denaturing PAGE methods. As such, accurate quantitation of patient amplicon sizes should be empirically determined by comparison to appropriate external or internal standards.

One of the important methodological considerations for quantitation of expansion mutations in general is the recognition of the existence of "extreme expansions" associated with several of the SCAs. For example, both the infantile and juvenile-onset forms of SCA2 and SCA7 have been associated with large, or "extreme," expansions generally greater than 200 CAG repeats [31]. In a situation that is analogous to the large expansions of juvenile-onset HD, these alleles can be refractory to PCR amplification or difficult to separate using conventional PAGE. Test results that are apparently "homozygous normal" genotypes in infants or children with a high index of clinical suspicion of SCA2 or SCA7 should be confirmed using a Southern blot test that can detect large expansions (Fig. 18.2) [32]. As discussed above in reference to HD, TP-PCR is a novel, rapid and robust technique that can be used to detect large trinucleotide repeats in FRDA and ADCAs (SCA1, 2, 3, 6, 7, 8, and 17).

Analysis of the FRDA GAA expansion mutation is generally performed by long-template PCR (Fig. 18.3) or by Southern blot analysis. Although the fidelity of this assay is high, PCR artifacts resembling expansions can be seen, particularly in samples with two normal-sized alleles (Fig. 18.3a, lane 4). The expansion artifacts are thought to be heteroduplexes, as they do not appear when amplicons are analyzed under denaturing conditions. These artifacts should not result in significant diagnostic errors for patients who are clearly heterozygous for two normal-sized alleles, as the intensity of the true alleles is usually much greater than that of the heteroduplexes. Ambiguities may remain,

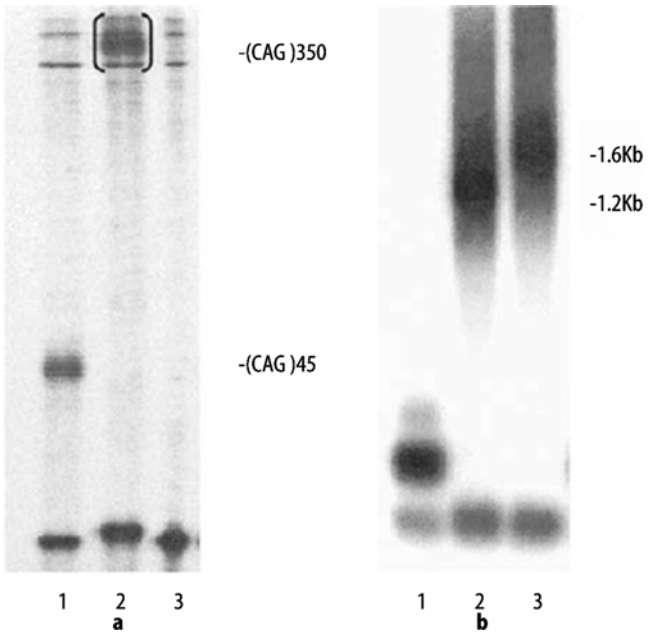

Figure 18.2 Molecular testing for the SCA2 CAG repeat. (**a**) PCR genotyping of the SCA2 polymorphic CAG repeat utilizing the UH13/UH10 primer pair [33] is shown for two related patients (*lane 1*: mother; *lane 2*: son) with adult-onset and juvenile-onset SCA2, respectively [31]. Separation and sizing of alleles was performed on a 35 cm × 43 cm 6 % denaturing polyacrylamide gel followed by autoradiography. The numbers of CAG repeats in each of the two alleles are 22 and 45 for the affected mother (*lane 1*), 23 and approximately 350 for the affected son (*lane 2*), and 22 and 22 for a normal unaffected control (*lane 3*). (**b**) PCR-Southern blot analysis [32] of the same mother-son samples shown in (**a**), confirming the presence of the extreme expansion in the affected son. Allele sizes are 22 and 45 for the affected mother (*lane 1*), 23 and approximately 350 for the affected son (*lane 2*), and 23 and approximately 400 for a positive extreme expansion control (*lane 3*). ((**b**) Courtesy of Dr. Karen Snow-Bailey, Auckland District Health Board, Auckland, New Zealand)

however, because the resolution of 1 % agarose gels for amplicons in the 500 bp range is limited. These can be clarified, if necessary, by either Southern blot or denaturing PAGE.

For screening purposes in a proband with no documented mutation, given the significant overlap between phenotypes in ADCAs, next-generation sequencing panels that include multiple genes in a single test have demonstrated significant value [35] allowing for a final diagnosis in patients that had been negative for multiple single gene tests over time. The caveat with this approach however is the possibility of novel variants that may need to be proven as pathogenic before clinical testing is offered to other family members.

Interpretation of Test Results

PCR tests for the ADCAs have a sensitivity of >99 %, and complete testing including Southern blot or TP PCR has a sensitivity of close to 100 %. For the reporting of results, interpretation of the findings requires the integration of available clinical information, repeat size, and its clinical descriptor (i.e., normal, intermediate, or abnormal). PCR tests for FRDA have a sensitivity of approximately 96 %, but the presence of a *FXN* point mutation must be considered in patients with a high degree of clinical suspicion and only one expanded GAA allele (Fig. 18.3b, lane 3; Fig. 18.4). In such situations, referral to a laboratory that offers point mutation analysis is strongly recommended.

Laboratory Issues

No commercial test kits are available for the ADCAs, FRDA, or AT. The CAP offers proficiency testing twice a year as part of the CAP/ACMG MGL Survey (MGL2) that includes challenges for several SCAs (1, 2, 3, 6, and 7) as well as FRDA.

Dystonia

Molecular Basis of Disease

While the dystonias are not strictly considered a neurodegenerative disease but rather a movement disorder, clinical and molecular descriptions of the dystonias have historically been found in texts describing neurodegenerative disorders. Neuropathological descriptions have traditionally been scant due to the scarcity of postmortem material, so the underlying histopathology of dystonia is still poorly understood [37]. The dystonias represent a clinically heterogeneous group of disorders characterized by sustained involuntary muscle contractions leading to repetitive twisting movements and abnormal postures. Many forms of dystonia (Table 18.5) can be distinguished on a genetic basis and several causative genes have been identified [38].

Dystonias are classified clinically into isolated and combined dystonias, where the latter demonstrate additional clinical features other than pure dystonia. The presence of other neurological symptoms such as parkinsonism, myoclonus, and dyskinesia define some of these combined dystonias. In addition, dystonia can be a prominent characteristic in other complex neurodegenerative disorders that can present both in childhood and in the adult, some of which are documented in Table 18.5 [38]. The isolated dystonias encompass three forms: DYT1, DYT6, and DYT25, all of which have an autosomal dominant pattern of inheritance. DYT1, also known as early-onset primary dystonia, is usually associated with reduced penetrance, since only 30 % of heterozygotes for a pathogenic variant of the gene will develop the disease. Essentially all patients with DYT1 (>99.9 %) have a 3 bp deletion (GAG) in the *TOR1A* gene, at chromosomal location 9q34 and encoding a 332 amino acid protein called torsin-1A. Torsin-1A is a member of the AAA super-family of ATPases prominently expressed in the

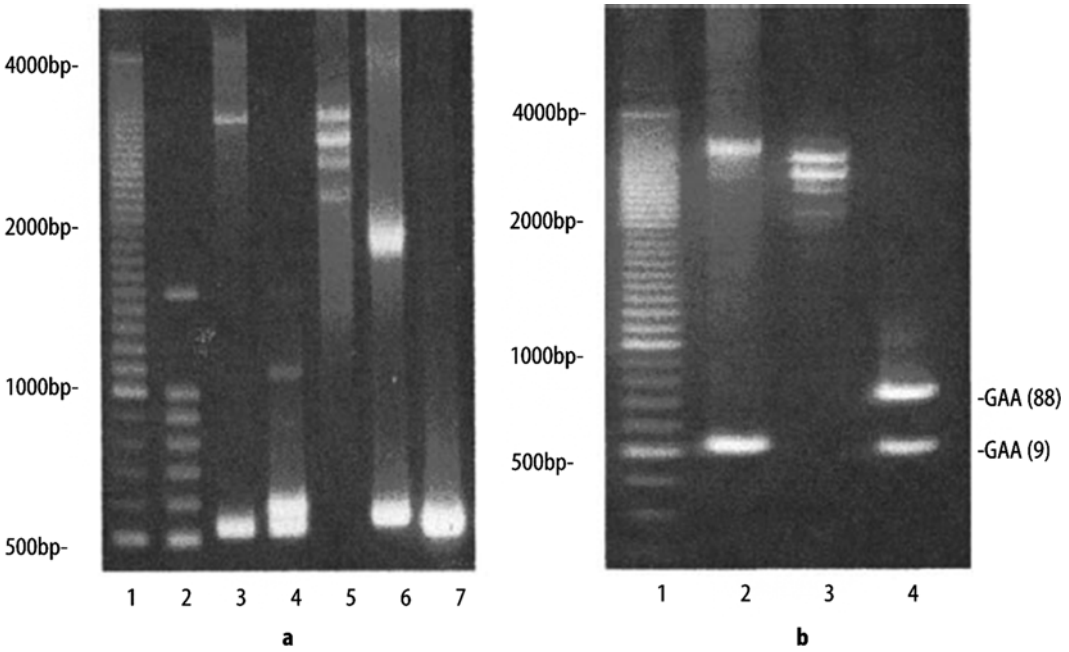

Figure 18.3 PCR analysis of the Friedreich ataxia (FRDA) polymorphic 4,000 bp GAA expansion mutation utilizing the 104F/629R primer pair [34] and the Expand Long Template PCR System (Roche Diagnostics, Mannheim, Germany). (**a**) *Lane 1*: 100 bp step ladder G6951 (Promega, Madison, WI); *lane 2*: 100 bp ladder G2101 (Promega); *lane 3*: 2,000 bp FRDA carrier with approximately 850 GAA repeats; *lane 4*: normal individual with allele sizes of 9 and 26 GAA repeats; *lane 5*: FRDA patient with allele sizes of approximately 800 and 900 GAA repeats; *lane 6*: FRDA carrier with approximately 450 GAA repeats; *lane 7*: normal control. (**b**) *Lane 1*: 100 bp step ladder G6951 (Promega); *lane 2*: FRDA compound heterozygote (see Fig. 18.4) with approximately 1,000 GAA repeats; *lane 3*: FRDA patient with allele sizes of approximately 800 and 900 GAA repeats; *lane 4*: FRDA carrier with allele sizes of 9 and 88 GAA repeats (confirmed by DNA sequencing). PCR products were separated through 1 % agarose on a 10.5 cm × 14 cm horizontal gel and the alleles visualized after ethidium bromide staining

Table 18.5 Molecular genetic classification of the inherited (monogenic) dystonias

Locus name	Gene	Gene product	Chromosomal location	Inheritance pattern	Key information
Isolated dystonias					
DYT1	*TOR1A*	Torsin-1A (part of the AAA family of ATPases)	9q34.11	Autosomal dominant	Primary torsion dystonia with early-onset generalized dystonia, 3 bp deletion, GAG (delE302/303) most common change
DYT6	*THAP1*	THAP domain containing protein 1	8p11.21	Autosomal dominant	Adolescent-onset dystonia
DYT25	*GNAL*	Guanine nucleotide-binding protein, alpha-activating activity polypeptide, olfactory type	18q11.21	Autosomal dominant	Adult onset cranial-cervical dystonia
Dystonia plus parkinsonism					
DYT3	*TAF1*	TATA-binding protein (TBP)-associated factor-1 gene	Xq13.1	X-linked	Filippino founder effect, caused by a retrotransposon insertion
DYT5a/14	*GCH1*	GTP cyclohydrolase-1	14q22.1-q22.2	Autosomal dominant	Childhood-onset dopa-responsive dystonia
DYT5b	*TH*	Tyrosine hydroxylase	11p15.5	Autosomal recessive	Infantile-onset dopa-responsive dystonia (Segawa syndrome)
Not assigned	*SPR*	Sepiapterin reductase	2p13.2	Autosomal recessive	Infantile-onset dopa-responsive dystonia
DYT12	*ATP1A3*	Na+/K+ ATPase transporting alpha-3 polypeptide	19q13.2	Autosomal dominant	Rapid-onset dystonia-parkinsonism
Dystonia plus myoclonus					
DYT11	*SGCE*	Sarcoglycan, epsilon	7q21.3	Autosomal dominant	Myoclonic dystonia
Paroxysmal dystonia plus other dyskinesia					
DYT8	*PKND*	Probable hydrolase PNKD (formerly MR-1, myofibrillogenesis regulator-1)	2q35	Autosomal dominant	Paroxysmal nonkinesigenic dyskinesia
DYT10	*PRRT2*	Proline-rich transmembrane protein 2	16p11.2	Autosomal dominant	Paroxysmal kinesigenic dyskinesia
DYT9/18	*SLC2A1*	Solute carrier family 2 (facilitated glucose transporter) member 1 (formerly GLUT1)	1p34.2	Autosomal dominant	Paroxysmal exertion-induced dyskinesia
Complex dystonias: inherited neurodegenerative/metabolic disorders (selected)					
PKAN	*PANK2*	Pantothenate kinase 2	20p13	Autosomal recessive	Neurodegeneration with brain iron accumulation 1 or pantothenate kinase-associated neurodegeneration
WD	*ATP7B*	ATPase, Cu2+-transporting, beta polypeptide	13q14.3	Autosomal recessive	Wilson disease, accumulation of intracellular hepatic copper with hepatic dysfunction and neurologic symptoms
HDL2	*JPH3*	Junctophilin-3	16q24.3	Autosomal dominant	Huntington disease-like 2, juvenile onset, CTG repeat expansion

substantia nigra pars compacta, and is present in cytoplasmic inclusion bodies in the brainstem of patients with confirmed DYT1 [39].

DYT5, or dopamine-responsive dystonia (DRD), is clinically characterized by dystonia plus parkinsonism with a dramatic response to treatment with levodopa, and is associated with mutations in three different genes. Homozygous as well as compound heterozygous mutations in the tyrosine hydroxylase (TH) gene at 11p15.5 are associated with the rare autosomal recessive form of DRD known as Segawa syndrome. A second form of autosomal recessive DRD is not assigned a DYT number, and is associated with mutations in the *SPR* gene, located at 2p13.2 and encoding the sepiapterin reductase protein. The more common autosomal dominant form of DRD is associated with mutations in the GTP cyclohydrolase I (*GCH1*) gene, at chromosomal location 14q22.1. DYT3 (X-linked dystonia-parkinsonism, also known as "lubag" from the Filipino word for "twisted") is associated with mutations in *TAF1* and is endemic to the Philippines. DYT11, or myoclonus-dystonia, is associated with loss-of-function mutations in the ε-sarcoglycan (*SGCE*) gene at 7q21 in a large number of families and represents a major locus for myoclonus-dystonia.

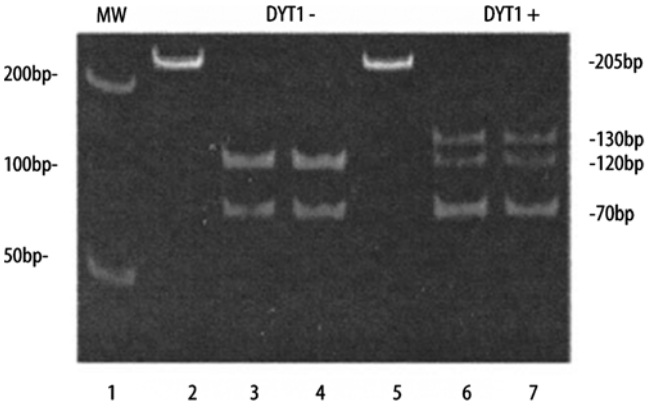

Figure 18.5 PCR-RFLP analysis of the *TOR1A* GAG deletion mutation associated with dominant early-onset torsion dystonia (DYT1). DNA was amplified with the 6419/H48 primer pair [36] and the resulting 25 bp amplicons digested with *Bse* RI. The presence of the GAG deletion mutations results in the loss of a *Bse* RI site on the mutant allele and the generation of a novel 130 bp DNA fragment in addition to the 120 bp and 70 bp DNA fragments generated from the normal allele. *Lane 1*: 100 bp ladder G2101 (Promega, Madison, WI); *lane 2*: undigested amplicons; *lanes 3* and *4*: *Bse* RI digests from two patients without DYT1; *lane 5*: undigested amplicons; *lanes 6* and *7*: *Bse* RI digests from two patients with DYT1 (note the presence of the novel 130 bp DNA fragment)

Clinical Utility of Testing

Clinical molecular testing is presently available for several of the dystonia genes (see http://www.ncbi.nlm.nih.gov/gtr/).

Available Assays

Molecular testing can be performed by PCR-RFLP analysis of the GAG-containing *DYT1* exon (Fig. 18.5). Determination of pathologic mutations in *GCH1* requires direct DNA sequencing of the gene.

Interpretation of Test Results

Essentially all patients with typical DYT1 carry the GAG deletion on one allele, and thus, the test sensitivity approaches 100 %. In contrast, the specificity of the assay is 60–70 %, because DYT1 is inherited as an autosomal dominant trait with reduced penetrance (30–40 %). Counseling of the parents of the proband should include an evaluation of their clinical status and consideration of molecular testing to determine parental origin of the mutation. The risk of inheriting a *TOR1A* mutation allele from a proband is 50 %; however, the probability that the mutation carrier will become symptomatic is estimated to be 30–40 %. Prenatal testing is clinically available for fetuses at 50 % risk of inheriting a *TOR1A* mutation allele, once the presence of the mutation has been confirmed in the family. New mutations, although rare, have been reported, but the de novo mutation rate is unknown.

Unlike in DYT1, other dystonia genes show a high frequency of diverse mutations, so clinical testing requires complete gene sequencing and is usually limited to diagnostic testing in a proband with the knowledge that testing sensitivity may reach only 60 %. If a mutation is detected, carrier testing or prenatal testing or both can be considered for family members.

Laboratory Issues

No commercial test kits are available for dystonia testing. Control DNA can be obtained from the Coriell Cell Repositories (Camden, NJ; http://ccr.coriell.org/). No formal proficiency testing is available.

Polycystic Kidney Disease

19

Adrian Y. Tan, Jon Blumenfeld, and Hanna Rennert

Abstract

Polycystic kidney disease (PKD) is a group of monogenic disorders that result in renal cyst development, progressive chronic kidney disease, and are associated with extrarenal manifestations. The most common form, autosomal dominant PKD (ADPKD), is a multisystem disease most often diagnosed in adults and caused by mutations in *PKD1* and *PKD2*. The *PKD1* gene product, polycystin-1 (PC1), is a large receptor like protein. The *PKD2* gene product, polycystin-2 (PC2)' is a member of the transient receptor potential family (i.e., TRPP2) and is a nonselective cation channel that is permeable to calcium. Both PC1 and PC2 are located on non-motile cilia located on virtually all epithelia and other cell types.

Autosomal recessive PKD (ARPKD) usually presents during infancy with enlarged kidneys and hepatic fibrosis, but patients are increasingly being identified during childhood and early adulthood. ARPKD is caused by mutations in *PKHD1*. The protein encoded by this gene, polyductin, is localized to the basal body of non-motile cilia and can form a complex with PC2.

Molecular genetic testing plays an increasingly important role in the management of PKD. In ADPKD, testing enables early diagnosis of patients with inconclusive results by kidney imaging; this can clarify the disease status of a prospective related kidney donor. In both ADPKD and ARPKD, testing can inform pre-implantation genetic diagnosis (PGD). The purpose of this chapter is to review the clinical and laboratory characteristics of these disorders and to describe the application of emerging molecular technologies.

Keywords

ADPKD • Polycystic kidney disease • PKD genes • Gene variation • Mutation • Variants of uncertain significance

Introduction

Polycystic kidney disease (PKD) is a group of monogenic disorders that result in renal cyst development. Autosomal dominant PKD (ADPKD) (OMIM#173900; 173910) is the most common inherited renal disease and the fourth most common cause of end stage renal disease (ESRD) in adults. The prevalence of ADPKD is approximately 1 in 400-1,000 live births in all races [1], and affects approximately 12.5 million individuals worldwide, with 5,000–6,000 new cases diagnosed in the USA each year. The age of presentation of ADPKD varies largely, ranging from onset in utero with enlarged, cystic kidneys to incidental diagnosis in the elderly with adequate renal function [2]. The principal renal manifestation of ADPKD is the formation of cysts as a result of abnormal proliferation of renal tubular epithelial cells. Cysts increase gradually in both size and number, resulting in marked kidney enlargement and a progressive decline in renal function (Fig. 19.1).

Other common renal manifestations include hypertension, kidney stones, urinary tract infections, and hematuria. Extrarenal manifestations are highly prevalent, including cysts in the liver, pancreas, seminal vesicles, and arachnoid membranes, cardiac valve abnormalities, and aneurysms. These renal and extrarenal abnormalities are a significant cause of morbidity and mortality. The mean age of onset of hypertension is 20–30 years, usually occurring while renal function is still within the normal range; this is approximately one decade earlier than in the general population with essential hypertension [3]. The prevalence of intracranial aneurysm is about five times higher than in the general population [4]. Approximately 50 % of the ADPKD patients progress to ESRD by the seventh decade [5], and account for approximately 5 % of all patients requiring hemodialysis or kidney transplant [6].

Autosomal recessive PKD (ARPKD) (OMIM#263200) is characterized by non-obstructive dilation of the cortical collecting tubule in utero or during the neonatal period, resulting in massive renal enlargement. However, a subset is increasingly being identified in childhood, adolescence, or even adulthood. These cases with later onset diagnosis usually have milder kidney disease, but more significant complications of liver disease [7]. This is accompanied by a ductal plate malformation of the liver, resulting in congenital hepatic fibrosis. Approximately 2–5 % of ADPKD patients also present during the neonatal period with significant morbidity and mortality [8], and may only be differentiated from ARPKD at that time by histological or genetic analysis.

Many other pediatric disorders are associated with renal cysts or cystic dysplasia as a component of their phenotypes. However, they generally can be distinguished from ARPKD and ADPKD by a detailed physical examination, basic laboratory and imaging studies, and by their extrarenal clinical characteristics [9]. The prevalence of ARPKD has been estimated to be 1 in 20,000-40,000 live births, with a carrier frequency of 1 in 70 [7].

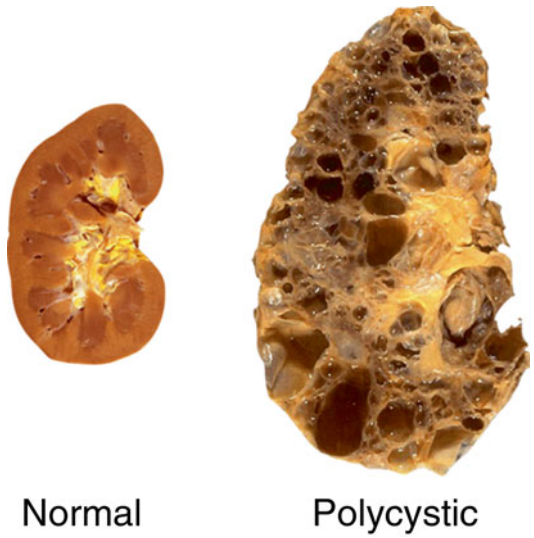

Figure 19.1 Normal and polycystic kidneys. A normal kidney is shown on the *left* and a kidney with a high number of variable-sized cysts that characterize polycystic kidney disease is shown on the *right*

Autosomal Dominant Polycystic Kidney Disease

Molecular Basis of Disease

ADPKD is genetically heterogeneous, caused mainly by mutations in two genes: *PKD1* and *PKD2*, located on chromosome 16p13.3 [10] and 4q21 [11], respectively.

PKD1 is a large gene, with 46 exons, occupying 50 kb of genomic sequence on chromosome 16, and encoding a large transcript with an open reading frame of 12,909 bp. The first 33 exons of *PKD1* are located in a region that is duplicated six times on chromosome 16 [12]. These homologous genes, also termed pseudogenes, have 97–99 % homology to *PKD1*, which complicates genetic testing [13]. *PKD2* consists of 15 exons, spanning 68 kb of genomic sequence, and encoding a transcript 2,904 bp [11]. De novo *PKD1* and *PKD2* mutations are reported to occur in approximately 10 % of affected individuals [14]. The reported prevalence of *PKD2* mutations among ADPKD patients is variable. In community-based studies, *PKD2* mutations accounted for approximately 29–36 % of cases [15], while in hospital-based studies, *PKD2* mutations comprised only 15 % of cases; the remainder had *PKD1* mutations. This discrepancy is likely due to a detection bias toward cases with more severe manifestation that characterize patients with *PKD1* gene mutations [15].

The *PKD1* gene encodes a large integral membrane protein, polycystin-1 (PC1), which has 11 transmembrane domains and an extracellular segment consisting of a variety of domains that occupy approximately 75 % of the entire protein. Overall, PC1 has the structure that is suggestive of a receptor or adhesion molecule and is thought to be a mechanical sensor of fluid flow [16]. The *PKD2* gene product, polycystin-2 (PC2), is a member of the transient receptor potential family (i.e., TRPP2) that functions as a nonselective cation channel that transports calcium [17]. PC1 and PC2 localize to the immotile cilia on renal tubule epithelium [18], where PC1 and PC2 interact with each other [19]. A current hypothesis is that the polycystin complex functions as a mechanoreceptor that senses fluid flow in the tubular lumen, triggering Ca^{2+} influx through TRPP2, consequently affecting the intracellular calcium and cyclic AMP (cAMP) levels [20]. Mutations in either *PKD1* or *PKD2* result in malfunction of the polycystin complex, leading to abnormal cross talk between the adenylate cyclase and receptor tyrosine kinase pathways. These abnormalities, together with reduced intracellular calcium concentration, promote renal tubular epithelial cell proliferation and fluid secretion, which are key phenotypic features of ADPKD [21].

The renal cysts of ADPKD have two distinctive characteristics: significant size variation and focal development. These features can be explained by a two hit model in which two separate inactivation events in either one of the PKD genes is required for cyst formation [22]. The first hit is a germline mutation, usually inherited from the affected parent, which is necessary but not sufficient for cyst formation. The second hit, a somatic mutation only occurring in an individual renal tubular cell, inactivates either the normal *PKD1* or *PKD2* allele, thus initiating abnormal, monoclonal proliferation of tubular epithelial cells and cyst formation [23, 24]. The somatic mutation can occur at any given point during the patient's lifetime, resulting in formation of cysts of different size. The size of the cyst typically correlates with the time the second mutation occurred. Although ADPKD is a dominant disease, the requirement of both a germline and a somatic mutation for cyst formation supports a recessive disease model at the cellular level. In a small number of families, germline mutations can be found in trans in *PKD1* and *PKD2*. This bilineal inheritance demonstrates that co-inheritance of a mutation in both genes is not necessarily lethal during embryogenesis, but is associated with a more severe disease phenotype [25]. Interestingly, somatic *PKD2* mutations can be detected in cysts of patients with *PKD1* germline mutations and vice versa, further supporting the two-hit model and the dosage effect hypothesis for cyst formation [26, 27].

Various cellular mechanisms have been implicated in the pathogenesis of ADPKD as a consequence of impaired interactions of PC1 and PC2. These can be summarized as negative growth regulation, G protein activation, and Wnt pathway modulation [28]. Increased proliferation of renal tubular epithelial cells has been attributed to loss of inhibition by the mammalian target of rapamycin complex (mTOR) and cyclin-dependent kinases, among others. These pathways have been the targets of treatment strategies [29].

At the population level, ADPKD presents great phenotypic variability, including interfamilial and intrafamilial variability. This phenomenon is best explained by three genetic levels of attributions: genic (gene), allelic, and gene modifier effects. Interfamilial heterogeneity is mainly explained by genic effects; *PKD1* gene mutations are associated with more severe disease and earlier age of ESRD onset [30]. The mean age of onset of ESRD is approximately 20 years earlier in patients with *PKD1* mutations compared to patients with *PKD2* mutations (54.3 years vs 74.0 years) [30]. The more severe phenotype, accounting for the younger age of diagnosis of ADPKD and earlier age of onset of ESRD in the *PKD1* population, is likely due to the development of renal cysts at an earlier age, rather than a faster rate of cyst growth [31]. *PKD1* patients also have a higher incidence of hypertension and hematuria.

Allelic effects in ADPKD are relatively small compared with genic effects. Patients with mutations in the 5′ region of *PKD1* have been reported to reach ESRD slightly earlier than patients with mutations in the 3′ region (53 years vs 56 years) [32]. They also have a higher prevalence of intracranial aneurysms as well as aneurysm rupture [33]. However, in a more recent study, the phenotype was found to be affected by the type of *PKD1* mutation, but not the position of the mutation in the gene [34]. No clear correlation has been reported between severity of disease phenotype and the position of the mutation in *PKD2*. Recently, hypomorphic alleles have been reported in both *PKD1* and *PKD2*, which usually are missense mutations and reduce the levels of gene activity, but do not totally inactivate gene function [35]. Patients with one hypomorphic allele have mild cystic disease, while patients who are homozygous or compound heterozygous for two hypomorphic alleles present with moderate to severe disease, with cyst formation similar to that observed in patients with pathogenic PKD mutations. A hypomorphic allele coexisting with a pathogenic mutation can cause early onset disease [35].

The significant intrafamilial phenotypic variability, both in the rate of progression of chronic kidney disease and in the array of extrarenal manifestations, has been attributed, at least in part, to gene modifier effects [36]. Analysis of the phenotypic variability in renal function between monozygotic twins and siblings supports the involvement of genetic modifiers [37, 38]. Heritable modifying factors were estimated to account for 18–50 % of the variability in disease severity [39]. Recently, a candidate gene approach has identified Dickkopf 3 (*DKK3*) as marginally associated with ADPKD disease severity; however, replication studies are needed to

verify the association reported [40, 41]. The development of high-resolution single nucleotide polymorphism (SNP) arrays enables properly powered genome-wide association studies (GWAS) for mapping modifier genes in an unbiased way; however, the success of such studies is strongly dependent on the availability of clinically well-characterized, large ADPKD cohorts.

Clinical Utility of Testing

Genetic testing for ADPKD has two main clinical applications: (1) clarifying whether ADPKD is present in a young family member without kidney cysts who is considering kidney donation, and (2) identifying the PKD gene mutation in an affected individual for reproductive decision-making (e.g., preimplantation genetic diagnosis). The gold standard method for diagnosis of ADPKD is an age-specific renal phenotype, based on the number of cysts identified by renal ultrasonogram in an individual with a 50 % risk of inheritance, determined by a positive history of ADPKD in a first-degree relative [42]. However, these criteria were suboptimal for patients with *PKD2* mutations. A recent revision of the Ravine criteria has improved diagnostic performance for renal ultrasonography in patients with either PKD1 or PKD2 mutations [43]. Accordingly, in families of unknown genotype with an affected first-degree relative, the presence of three or more (unilateral or bilateral) renal cysts is sufficient for establishing the diagnosis of ADPKD in individuals aged 15–39 years; two or more cysts in each kidney is sufficient for individuals aged 40–59 years; and four or more cysts in each kidney is required for individuals 60 years of age or older. Conversely, fewer than two renal cysts in at-risk individuals aged 40 years or older is sufficient to exclude the disease [43]. Diagnostic imaging is sufficient for most patients; however, it is often ambiguous in young patients whose renal sonogram may not be conclusive or when the family history is unknown. A recent, single-center study found that magnetic resonance imaging has high sensitivity and specificity in patients at risk for ADPKD. Specifically, among subjects aged 16–40 years old, the presence of a total of more than 10 renal cysts was found to be sufficient for diagnosis [44].

Recently, Huang et al. proposed an algorithm that incorporates the use of DNA testing and imaging for donors with a family history of ADPKD [45]. They concluded that genetic testing, especially DNA sequencing, is cost effective because it shortens the waiting time for a living related transplant if at least one living donor per year results from every ten linkage or every five DNA sequencing tests performed, given that many individuals are on a transplant list for many years. Although genetic testing of *PKD1* and *PKD2* can be useful for clarifying the disease status in these individuals, the low sensitivity by the reference commercial laboratory (40–60 %) and high cost (approximately $6,000 per test) limits the use of widespread genotyping at this time [46].

Available Assays

Two methods are available for genetic testing of ADPKD: gene-based mutation screening and DNA linkage analysis. Molecular testing by gene-based mutation screening currently is the predominant method of ADPKD genetic testing. However, the marked allelic heterogeneity of the disease-associated mutations, the vast majority of which are private, and the duplicated structure of *PKD1* together with its large size, makes mutation screening a significant technical challenge. Although mutation analysis of the *PKD2* gene and the *PKD1* single copy region (exons 34–46) is straightforward, analysis of the duplicated 5′ region of *PKD1* is more complex because of its 98 % identity to the six *PKD1* pseudogenes on chromosome 16.

Several strategies are available for ADPKD genetic testing (Fig. 19.2). Prior to 2001, genetic analysis of ADPKD could be only performed for *PKD2* and the 3′ single copy region of *PKD1*. The first assay for analyzing the entire *PKD1*, developed in 2001, uses long-range PCR (LR-PCR) to specifically amplify the duplicated exon 1 to exon 33 regions, followed by nested PCR of the individual exons [47]. This method was later commercialized by Athena Diagnostics, Inc., which until recently had the exclusive license for analyzing *PKD1* and *PKD2* and was the sole provider of clinical ADPKD genotyping in the USA. Garcia-Gonzalez et al. evaluated the clinical utility of this commercially available test by analyzing a cohort of 82 ADPKD patients [48]. Definite pathogenic mutations were detected in 42 % of the patients and the maximal mutation detection rate was 78 %, after including missense, in-frame insertion/deletion, and atypical splice mutations that were likely to be pathogenic [48].

Although complete gene sequencing remains the gold standard for ADPKD genetic testing, it is expensive and time-consuming. Thus, several screening-based methods were developed to lower testing costs and minimize turnaround time. Denaturing gradient gel electrophoresis, a traditional

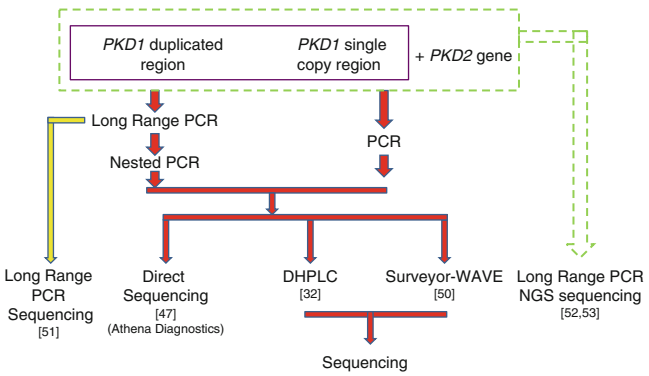

Figure 19.2 Strategies for ADPKD genotyping. *NGS* next-generation sequencing

gel-based heteroduplex analysis method, as well as single strand conformation polymorphism (SSCP) have been successfully used to screen both the single copy and the duplicated regions of the *PKD1* gene [49]. However, these methods suffer from a low mutation detection rate (30–40 %). Rossetti et al. [32] developed a denaturing high-performance liquid chromatography (DHPLC) screening method that was more sensitive than previous assays, with a detection rate of 64 % for definite pathogenic mutations. Further improvement in the utility of DHPLC for PKD genetic testing is the use of *Cel*I endonuclease (SURVEYOR® nuclease, Transgenomic Inc.) and the Transgenomic WAVE® Nucleic Acid High Sensitivity Fragment Analysis System [50]. This method is 100 % sensitive when compared to the complete DNA sequencing method of the entire genes used by a commercial reference laboratory, with a detection rate of 64 % for definite pathogenic mutations, comparable to the rate reported in the literature [32].

An improved method for genetic analysis of ADPKD was developed by Tan et al. [51] using direct sequencing of the *PKD1* LR-PCR products. In this strategy, the entire *PKD1* coding region is amplified in nine LR-PCR reactions, generating products ranging in length from 2 to 6 kb, followed by column purification and direct sequencing with several pairs of walking primers. When compared with the direct sequencing result of the reference laboratory, this method was highly sensitive (100 %) and specific (98.5 %), circumventing the need for nested PCR of the *PKD1* duplicated region, and reducing the risk of PCR amplification carryover contamination that can lead to false-positive results. In addition, this method has decreased the number of required PCR reactions by 80 %, substantially lowering test cost by approximately 20 % and improving turn-around time compared with both the direct sequencing and the SURVEYOR-WAVE screening methods. Another advantage of the LR-PCR sequencing method is that it covers intronic regions extending 200–300 bp beyond the exon-intron junctions, enabling better detection of deep intronic mutations.

Next-generation sequencing (NGS) technology is revolutionizing the field of human genetics and has been recently applied to PKD genetic testing. Rossetti et al. [52] reported a mutation screening strategy for analyzing *PKD1* and *PKD2* genes using NGS by pooling LR-PCR amplicons and multiplexing barcoded libraries. To increase the throughput, amplicons from four patients and libraries of up to 12 patients were pooled together and analyzed in a single reaction using indexed DNA barcodes. Using this strategy, these authors detected definite and likely pathogenic variants in 115 (63 %) of 183 patients with typical ADPKD. When compared with Sanger sequencing, this approach had a sensitivity of 78 % and a specificity of 100 % for mutation detection. This method also enabled the identification of atypical mutations, including a gene conversion event, and the characterization of deep intronic variations.

A second NGS approach amplifies *PKD1* and *PKD2* genes in a total of ten LR-PCR reactions, using locus-specific primers [51]. Indexed libraries from up to 25 patients are pooled together and analyzed in a single flow-cell using the MiSeq system (Illumina Inc., San Diego, CA). Sequencing results are sorted according to the barcodes with the FASTX toolkit and aligned against the reference sequence using the BWA program (http://bio-bwa.sourceforge.net/). Sequence variants are called using the GATK software package (The Genome Analysis Toolkit, The Broad Institute), carefully following The Best Practice Guidelines recommended by GATK (Fig. 19.3). With addition of an improved bioinformatics analysis pipeline, this approach has a sensitivity of 100 % in mutation detection when compared with Sanger sequencing, while retaining high specificity [51]. Several typical genetic variations detected by this approach are shown in Fig. 19.4. NGS approaches have the potential to dramatically improve genetic testing for ADPKD by allowing simultaneous detection of point mutations and copy number variations in a single test. Accordingly, these methods can increase the mutation detection rate, particularly of deep intronic mutations, and significantly reduce testing costs and turnaround time.

Large DNA rearrangements also play a role in ADPKD causation, but their detection is complicated by the presence of the *PKD1* pseudogenes [53]. Field inversion gel electrophoresis followed by Southern blot analysis traditionally has been used to identify large deletions in *PKD1*. Recently, a multiplex ligation dependent probe assay (MLPA) was developed for detecting large genomic rearrangements in the PKD genes [54]. In this assay, a set of probes were designed to target *PKD1*, *PKD2*, and *PKD1–TSC2*, covering a total of 320 kb genomic region including flanking regions. The amplified products are analyzed using the Luminex FlexMAP technology in a single assay. Using this method, Consugar et al. identified large deletions in 31 % of the previously mutation-negative cases, accounting for approximately 4 % of all patients in a prospectively studied cohort of patients with ADPKD [54]. This method has been recently commercialized by MRC-Holland (MRC-Holland, Amsterdam, The Netherlands) and is available as a clinical test. An example of MLPA analysis results is shown in Fig. 19.5.

Family linkage analysis provides another approach to genetic testing for ADPKD. This strategy employs highly informative microsatellite markers flanking *PKD1* and *PKD2*. Once linkage analysis has been performed, haplotype reconstruction can be used to predict the disease status of other family members. However, this method is suitable in fewer than 50 % of families because of constraints such as an insufficient number of affected family members [55]. Although it is now seldom used for genetic testing in ADPKD, linkage analysis may be considered in situations

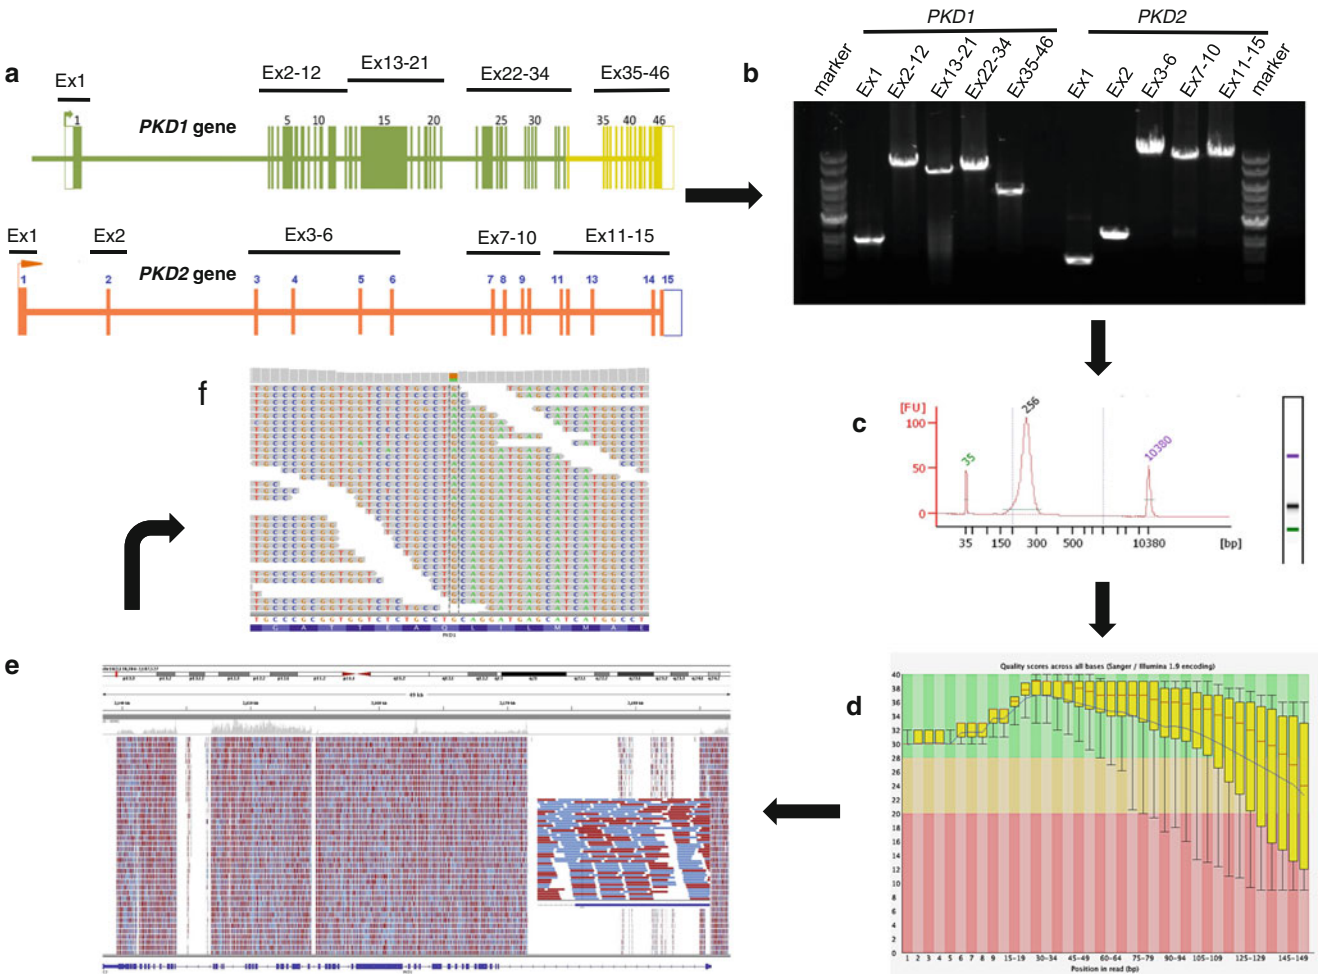

Figure 19.3 Schematic visualization of the NGS testing workflow for ADPKD. The workflow indicated by the *arrows* is as follows: (**a**) *PKD1* and *PKD2* sequences are individually amplified as ten locus-specific long-range PCR products (1.4–10.9 kb in size), covering all coding regions and most intronic regions for a total of ~80 kb. (**b**) Amplification quality verified using agarose gel electrophoresis with ethidium-bromide staining. (**c**) Amplicons from each individual sample are batched in equimolar ratios, fragmented, and subjected to library preparation using sample-specific barcodes. The indexed libraries are pooled and analyzed for quality using an Agilent Bioanalyzer. (**d**) Samples are sequenced on an Illumina MiSeq instrument, and the reads exported as FASTQ files, deconvoluted by bar code, and subjected to quality control analysis before proceeding with the mutation analysis bioinformatics pipeline. The quality score (Phred-like score) is shown at each specific bp location in *PKD1*. The *red line* in each box-and-whiskers plot shows the median value of the quality score at each bp position. The *yellow box* represents the inter-quartile range (25–75 %) of the quality score at each base. The *upper* and *lower* whiskers represent the 10 %th and 90 %th percentiles points, respectively. The *blue line* represents the mean quality score. Very good quality calls (Phred-like score within the green region at >28; chance of error 1:10,000), reasonable quality (Phred-like score within the orange region; chance of error 1:1,000), and calls of poor quality (Phred-like score within the red region; chance of error 1:100). (**e**) Reads were then mapped back to the genome with the BWA program. In this example, *PKD1* sequencing coverage and read depth for a single patient are shown. The *x*-axis represents *PKD1* genomic interval and the *y*-axis represents the number of reads. *Red lines*, reads from the plus DNA strands; *blue lines*, reads from the minus strands. The overall mean coverage of *PKD1* sequences was 668-fold. (**f**) Variant calls made by the GATK software

such as preimplantation genetic diagnosis (PGD), where low amounts of genomic DNA limit the utility of other genotyping approaches. Typing of several markers also is recommended to ensure against confounders such as allele dropout (see below), which can occur when amplifying very low amounts of DNA and/or when evaluating highly polymorphic genes such as *PKD1* [56].

Interpretation of Results

Mutations in *PKD1* and *PKD2* are usually private, highly variable and are distributed throughout the entire gene, with no mutation hot spot. This high level of allelic heterogeneity makes the interpretation of genotyping results challenging. The ADPKD Mutation Database at Mayo Clinic (http://pkdb.mayo.edu/) [57] is the most complete mutation data-

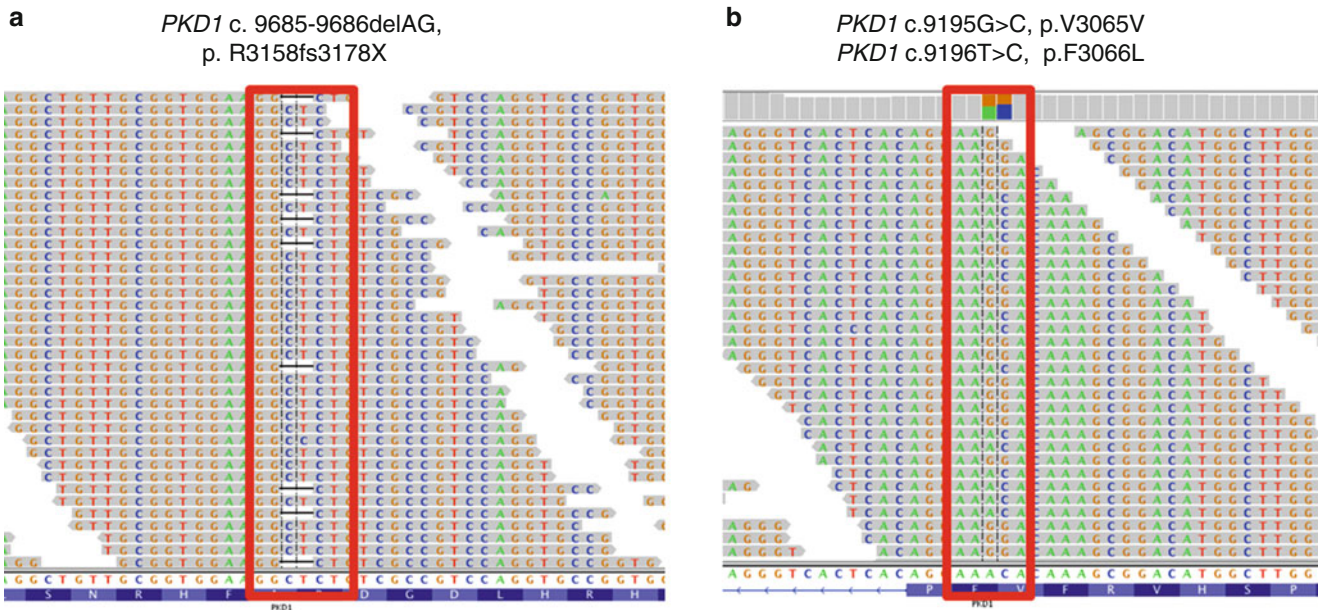

Figure 19.4 Typical alignment of *PKD1* NGS data and gene variation calls. (**a**) A two-base deletion (c.9685-9686delAG) resulting in a downstream truncation in the protein. (**b**) A synonymous (c.9195G>C; p.V3065V) variant. Minus strand is called. *Colored boxes* above each variant indicate the ratios of the two bases at the variant position. Sequence shown in Integrative Genomics Viewer (IGV), Broad Institute, Cambridge, MA

base for ADPKD. Mutation information has been reported for a total of 1,794 families: 1,420 (79 %) have *PKD1* mutations and the remaining 21 % have mutations in *PKD2* (as of November, 2013).

Genetic variations in the ADPKD Mutation Database are classified into 12 categories according to their characteristics at the DNA or protein level, including frameshift mutations, nonsense mutations, splice-site substitutions, intervening sequence (IVS), variations, silent changes, silent 5′ and 3′ untranslated region changes, synonymous changes, and rearrangements (deletions and duplications). Based on their predicted pathogenicity, those variations have been further classified into six categories: definitely pathogenic, highly likely pathogenic, likely pathogenic, hypomorphic, indeterminate, and likely neutral. A total of 1,923 changes for *PKD1* are reported in the ADPKD Mutation Database (Table 19.1), including 48.3 % pathogenic (with 32.2 % definitely pathogenic, 7.5 % highly likely pathogenic, and 8.6 % likely pathogenic), 0.5 % hypomorphic, 9.0 % indeterminate, and 42.2 % neutral. Large rearrangements account for 3 % of the pathogenic mutations reported for *PKD1*. A total of 241 *PKD2* changes are documented in the same database, consisting of 69.2 % pathogenic (with 53.5 % definitely pathogenic, 6.6 % highly likely pathogenic, and 9.1 % likely pathogenic), 0.4 % likely hypomorphic, 6.6 % indeterminate, and 23.7 % neutral (Table 19.1). Figure 19.6 shows the distributions of all known genomic changes in the *PKD1* (Fig. 19.6a) and *PKD2* (Fig. 19.6b) genes.

Determining the pathogenicity of gene variants that truncate the protein, such as frame-shift, nonsense, atypical splicing, or large rearrangements, can often be accomplished with a high level of certainty. However, interpretation of missense changes and other genetic variations that are not predicted to truncate the protein can be challenging. These groups of genetic changes, which are usually referred to as variants of uncertain significance (VUS), include synonymous and non-synonymous variants and small exonic in-frame deletions. Due to the high level of genetic variation found in *PKD1*, with an average of 10.1 variants per patient, ranging from 0 to 55 total variants, analyzing the pathogenic potential of VUS plays an important role in molecular testing for ADPKD [50].

Computational analysis of VUS includes evaluation of interspecies conservation and chemical differences of resulting amino acid substitutions. Rossetti et al. developed a method based on the Grantham Matrix Score (GMS) to predict the pathogenic effect of non-synonymous changes for ADPKD [58]. The GMS can be calculated online using Align-GVGD (http://agvgd.iarc.fr/) [59]. In addition to Align-GVGD, two other analysis programs can be used to predict pathogenicity of variants: SIFT (http://sift.jcvi.org/) [60] and PolyPhen (http://genetics.bwh.harvard.edu/pph/) [61]. SIFT and PolyPhen are based on principles similar to those used for GMS, but employ different analysis criteria. Both applications can search online databases and generate multiple sequence alignments [49].

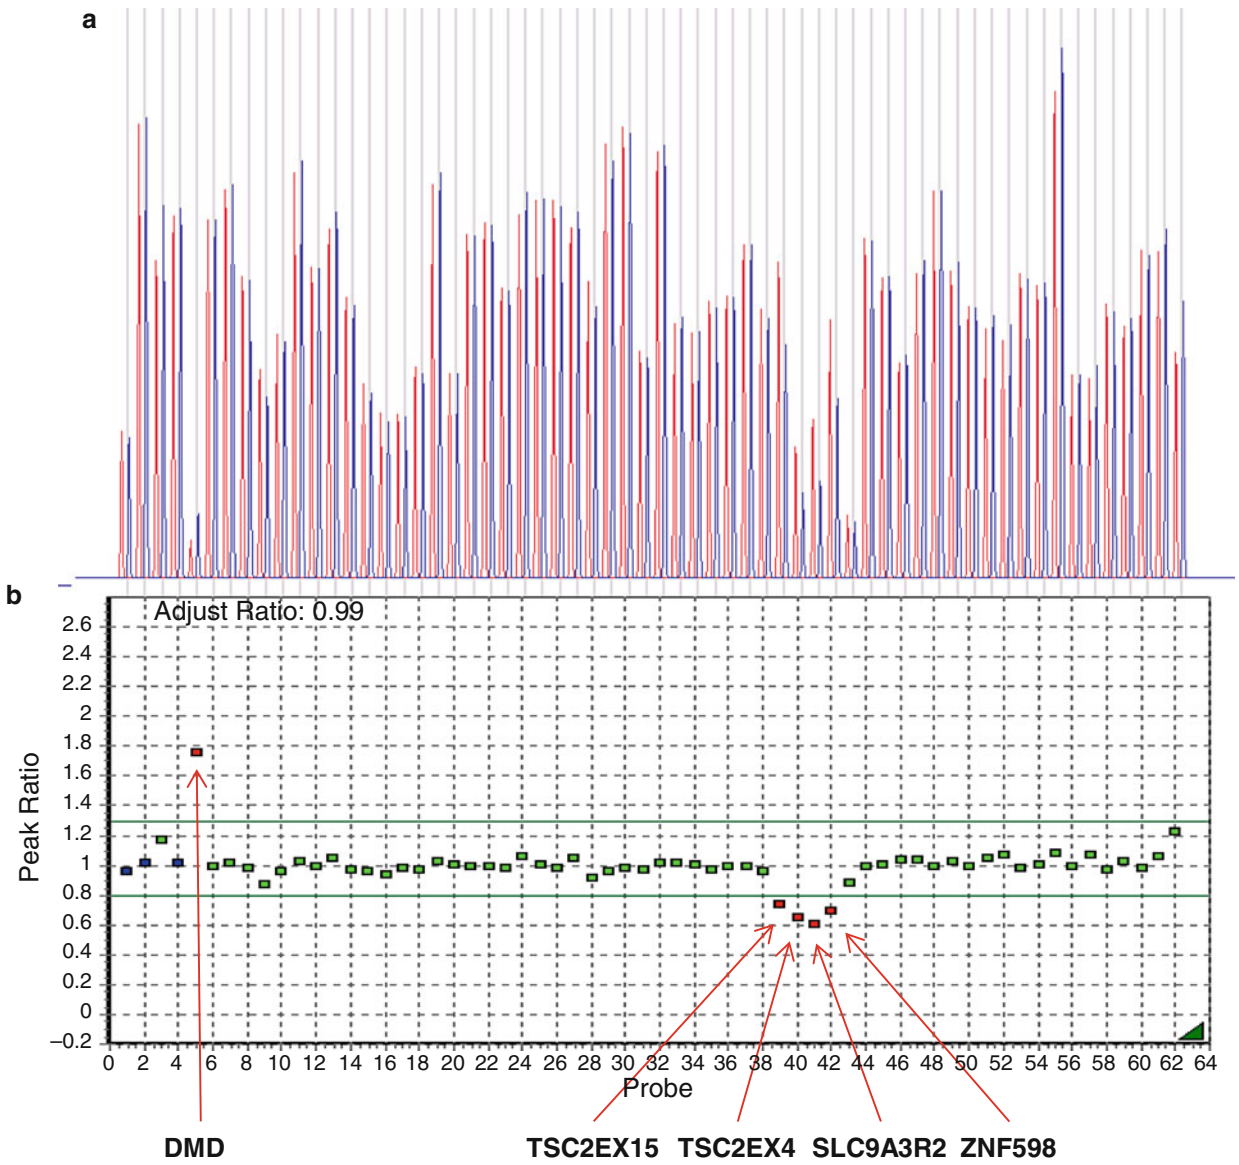

Figure 19.5 Multiplex ligation-dependent probe amplification (MLPA) analysis of a positive control DNA sample (Coriell, Camden, NJ), using probes covering the *PKD2* gene on chromosome 4 as well as numerous continuous genes (*PKD1*, *TSC2*, *SLC9A3*, *ZNF598*, and *TBL3*) on chromosome 16. Data were deconvoluted according to relative copy number compared to both the internal control genes as well as a normal control male sample using the GeneMarker software (Softgenetics, LLC; State College, PA, USA). (**a**) The *Dosage Histogram* displays the ratio of normalized peak intensities between the reference and the sample trace. Sample probes are represented by *blue bars* and control probes by *red bars*. (**b**) The *Ratio Plot* displays, in graphical form, the ratio of normalized peak intensities between the reference and the sample trace. Each *square* represents a specific probe. Analysis results show the expected deletions corresponding to one copy of *TSC2EX15*, *TSC2EX4*, *SLC9A3R2*, and *ZNF598* genes (*red squares* and *arrows*), and two copies of all *PKD1* and *PKD2* gene probes (*green squares*) and the two-copy internal controls (*blue squares*). The X-linked *DMD* control (*upper left side*) is indicated in *red*, demonstrating a patient-control peak ratio of approximately 1.8, consistent with a two-copy female DNA and a single-copy male reference control

In order to predict the potential splicing site mutation, several other programs based on different prediction principles have been developed to predict the impact of splice site variants. These include Splice Site Prediction by Neural Network (http://www.fruitfly.org/seq_tools/splice.html) [62], ESEfinder (http://rulai.cshl.edu/cgi-bin/tools/ESE3/esefinder.cgi) [63], and Human Splicing Finder (http://www.umd.be/HSF/) [64]. The prediction results of atypical splicing could be further confirmed by reverse transcription (RT)-PCR analysis, if the patient's RNA is available.

Assessing the functional impact of missense mutations is more difficult, especially for *PKD1*, particularly because of the large size and uncertain functions of the polycystins. For the CRISP cohort, 38 of 99 (38 %) missense changes were

Definitely pathogenic including nonsense, frameshift, typical splicing, and in-fame changes of five or more amino acids. The pathogenicity of other changes were assessed by a scoring system integrating Grantham Matrix Score, the likelihood for aberrant splicing, segregation analysis results (if available), and contextual information. A score ≥11 were classed as highly likely pathogenic; a score 5–10 as likely pathogenic; −4 to 4 as indeterminate; and ≤−5 as likely neutral [57]. Hypomorphic mean incompletely penetrant

Data derived from the ADPKD Mutation Database (http://pkdb.mayo.edu/), November 2013

predicted to be pathogenic, with 35 in *PKD1* and 3 in *PKD2* [58]. By including the probably pathogenic mutations, the mutation detection rate can be increased to over 85 % [50, 58]. In 10–15 % of individuals with clinical ADPKD, no mutation in either *PKD1* or *PKD2* could be detected. This could be due to other atypical genetic events such as deep intronic changes that affect splicing, gene conversion events not readily detected by current exon-based screening methods, or mutations in other yet undiscovered cyst related genes [65, 66]. Low-level mosaicism caused by de novo mutations can also account for these apparent mutation-negative cases [67].

Laboratory Issues

Most of the currently used genotyping methods for ADPKD employ nested PCR to amplify each individual exon of the duplicated sequences of *PKD1*. This approach requires ultra-high (10^5-fold) dilutions of the primary *PKD1* LR-PCR products, which then serve as template for the second round of nested PCR. This process is especially vulnerable to carryover of PCR amplification products, potentially leading to PCR contamination and false-positive results. Consequently, special precautions, such a second PCR set-up chamber, are needed.

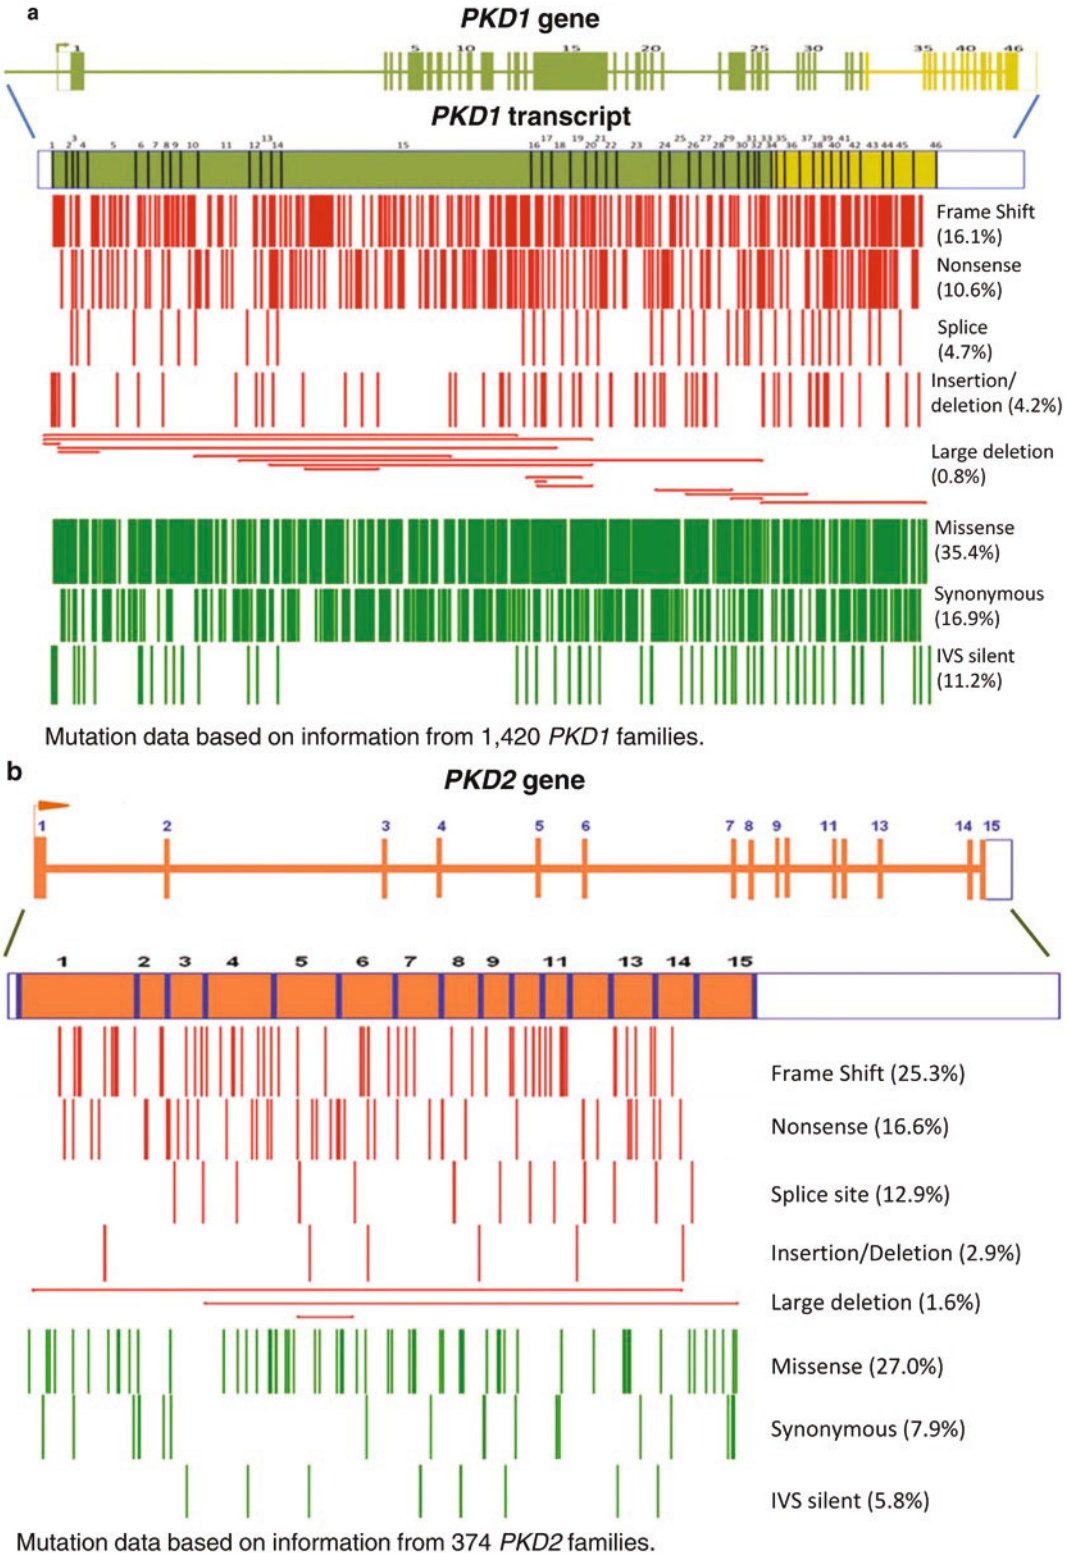

Figure 19.6 *PKD1* and *PKD2* gene structures and distribution of genetic variants. *Upper panels* show the gene and mRNA structure of *PKD1* (**a**) and *PKD2* (**b**), respectively. *Lower panels* show the spectrum and distribution of genetic variants for *PKD1* (**a**) and *PKD2* (**b**), grouped by mutation type, according to their relative position on the mRNA. Definite pathogenic mutations are colored *red*; other changes are colored *green*

PKD1 is highly polymorphic, increasing the chance that a SNP is located in the primer-binding region of an allele, resulting in lower or complete lack of amplification of one of the two alleles during the PCR reaction. This phenomenon, termed allele dropout or pseudo-homozygosity, has been well documented in ADPKD testing [50]. A homozygous mutation result in either *PKD1* or *PKD2* is most likely due to allele dropout, since homozygous mutations are thought to be embryonically lethal [68]. Therefore, the finding of a homozygous PKD gene mutation would warrant confirmation before reporting.

Another issue is the existence of the six highly identical *PKD1* pseudogenes. The primers used for amplifying these regions must complement the rare mismatch sites that distinguish the genuine *PKD1* gene from the pseudogenes to avoid amplification of the pseudogenes. Fortunately, it is relatively easy to distinguish whether these *PKD1* pseudogenes are co-amplified because they are enriched in polymorphisms and pathogenic variations that are not present in *PKD1*.

Autosomal Recessive Polycystic Kidney Disease

Molecular Basis of Disease

Despite the highly variable phenotype, genetic linkage studies indicate that mutations at a single locus are responsible for all ARPKD phenotypes [69]. The ARPKD gene, polycystic kidney and hepatic disease 1 (*PKHD1*), maps to locus 6p21 and is a large gene with 67 exons and a 470 kb genomic sequence [70]. *PKHD1* has a variety of alternatively spliced transcripts, and the longest open reading frame has 12,222 bp with 66 exons. *PKHD1* encodes a protein called polyductin or fibrocystin, which is a multidomain integral membrane protein with 4,074 amino acids [6]. The function of polyductin has not been defined. Based on the predicted structure with a highly glycosylated N-terminal extracellular domain, a single transmembrane domain, and a short cytoplasmic C-terminal tail, polyductin is thought to be an integral membrane receptor. Furthermore, polyductin complexes with PC2, and together with other proteins, localizes to primary cilia, thus it may execute its function through PC2 [71].

PKDH1 exhibits a high level of allelic heterogeneity, with 303 different mutations described in approximately 650 alleles; 40 % are truncation mutations and the remaining are in-frame changes, mainly missense mutations. About one-third of these mutations are unique private mutations with some mutations enriched in specific geographic areas. One missense mutation T36M, likely of European origin, accounts for approximately 17 % of all mutant alleles [72].

Clinical Utility

Similar to ADPKD, the diagnosis of ARPKD usually relies on imaging studies by renal ultrasonography. Clinical molecular testing can establish a diagnosis in 85 % of patients, but is not recommended for those in whom a diagnosis can be obtained by imaging techniques because of the high cost of genotyping. The clinical utility of molecular diagnosis in ARPKD is to confirm the diagnosis, especially in cases with a less severe phenotype, or when imaging results are not diagnostic. Due to the significant morbidity and mortality associated with ARPKD, many families with ARPKD seek prenatal and PGD testing. A robust molecular testing approach is critical for these indications.

Available Assays

DNA-based diagnostic testing for ARPKD is complicated by the large size of the *PKDH1* gene, its complex pattern of RNA splicing, and the unknown function of the encoded protein. There are two major approaches used for clinical molecular testing for ARPKD: sequencing-based mutation screening and family linkage analysis. Sequencing-based mutation screening can be achieved by directly sequencing all the exons of *PKDH1*, or by a mutation screening step before sequencing to lower the cost. Over the years, two approaches have been established for mutation screening of *PKHD1*: SSCP and DHPLC. SSCP has a mutation detection rate of 61 % while DHPLC achieves a detection rate of 85 %, for detection of both causative mutations in a family [73]. Direct sequencing was reported to have a slightly higher detection rate of 87 % [74], with at least one mutation detected in more than 95 % of ARPKD families [73]. Because of the existence of mutation hot spots, mutation screening approaches can be further simplified by analyzing only a subset of exons, accelerating the testing process [75].

If mutations are identified, prenatal and PGD testing for at-risk pregnancies can be performed by Sanger sequencing of the corresponding exons. Without prior knowledge of the causative mutation, PGD can only be performed by linkage analysis, requiring at least one affected individual in the family. A novel protocol method for PGD testing for ARPKD is genome amplification of single blastomeres and haplotype analysis with 20 novel STR loci. This approach can significantly reduce allele dropout. Large genomic rearrangements seen in ARPKD can be analyzed using MLPA, with *PKHD1-specific* probes.

Interpretation of Results

A locus-specific ARPKD mutation database is available at http://www.humgen.rwth-aachen.de/. All reported cases with two truncating mutations have the most severe disease, dying with respiratory distress by the end of the neonatal period. Patients surviving the neonatal period have at least

one missense mutation, indicating that many missense variations have incomplete penetrance and some residual protein function. Missense mutations are significantly more prevalent than truncating mutations among patients with less severe disease manifestations, although some missense mutations are as deleterious as truncating mutation. No significant phenotype differences could be found between cases with two missense mutations and cases with a truncating and a missense mutation in trans [76].

Despite the fact that 60 % of mutations found in ARPKD are missense, an approach that can definitively assess the potential pathogenicity of these changes is still lacking. As discussed for ADPKD, computational algorithms can be used to predict the likelihood of whether or not a missense change is pathogenic, or an intronic change can affect splicing, and are crucial in characterization of newly identified VUS.

Laboratory Issues

The same issues discussed for ADPKD molecular diagnosis also apply for ARPKD, including PCR contamination and allele dropout that require special attention, especially when considering prenatal and PGD testing, where extremely low amounts of genomic DNA are available.

Conclusions and Future Directions

This chapter reviews the molecular mechanisms underlying PKD and the strategies used for clinical molecular testing for both ADPKD and ARPKD. Completion of the Human Genome Project, the rapid development of new molecular testing tools, improved bioinformatics applications, and the establishment of strong PKD mutation databases have greatly aided with mutation identification and characterization. Genetic testing for ADPKD and ARPKD is now available, in some instances becoming the method of choice for diagnosis. Better understanding of genotype–phenotype correlation will further enhance the development of novel diagnostic and prognostic biomarkers, as well as facilitate personalized patient management. This process will likely accelerate as more effective and personalized therapies for PKD become available. Among the biggest challenges in this field include the evaluation of new testing technologies for diagnosis of PKD, incorporation of new approaches for data analysis and management, and changing regulatory standards for clinical laboratories.

Host Factor Pharmacogenetics for Treatment of Infectious Diseases

20

Patricia R. Slev and David R. Hillyard

Abstract

Progress in therapeutics and testing for infectious diseases over the past 100 years has resulted in dramatic reductions in morbidity and mortality. However, with developments of effective drugs has come the recognition that not all individuals respond the same to a given therapy, and this marked the beginning of initiatives to study human genetic variations as a factor in response to drug therapy. The pharmacogenetics of infectious diseases is in its infancy; however, the goal of maximizing drug efficacy while minimizing toxicity has important implications for clinical care and better understanding of the biology of the host-pathogen interface. This chapter provides an overview of the progress that has been made in pharmacogenetics and summarizes the challenges that remain for bridging the gap between research and clinical use. The few illustrative examples of genetic testing currently utilized as tools for patient management are discussed.

Keywords

Genetic factors for drug response • Pharmacogenetics • Genetic testing • Infectious diseases • Drug toxicity • Host-pathogen interactions

Introduction

Progress in therapeutics and testing for infectious diseases over the past 100 years has resulted in dramatic reductions in morbidity and mortality. However, with developments of effective drugs has come the recognition that not all individuals respond the same to a given therapy, marking the beginning of initiatives to study human genetic variations as a factor in response to drug therapy. The pharmacogenetics of infectious diseases is in its infancy; however, the goal of maximizing drug efficacy while minimizing toxicity has important implications for clinical care and better understanding of the biology of the host-pathogen interface.

Type A adverse drug reactions (ADRs) are dose dependent and therefore a large component of pharmacogenetics is genotyping for functionally important polymorphisms in genes that affect pharmacokinetics. These include genes that code for drug-metabolizing enzymes and transporter proteins, for example, phase I oxidative isozymes of the cytochrome P450 (CYP) superfamily, phase II conjugative

enzymes such as uridine diphosphate glucuronosyltransferase 1 (UGT1A1) and *N*-acetyltransferase 2 (NAT 2), P-glycoprotein (P-gp), and multidrug resistance proteins. CYP2C9, CYP2D6, and CYP2B19 as a group metabolize approximately 40 % of drugs currently on the market, including drugs used to treat various microbial infections. Many CYP, NAT, MDR, and other gene polymorphisms that affect pharmacokinetics of drugs used to treat infectious diseases have been identified, but there is little consensus regarding utilization of these associations for prospective screening.

There are several reasons that may explain why clinical use of pharmacogenetic variants affecting antimicrobial therapy is limited. First, pharmacogenetic testing is best suited for drugs that have a narrow therapeutic index. Second, genotype-phenotype correlation often is difficult, especially if multiple genes are involved in the metabolism of a single drug, or when drug-drug interactions and other non-genetic factors influence the phenotype. Third, there must be a clear relationship between drug concentration and effective drug response. Today, the most notable examples of applied pharmacogenetics as related to Type A ADRs are in the areas of oncology, psychiatry, and cardiology.

Type B ADRs are not dose dependent and are largely caused by immunoallergic reactions. As such, these ADRs are a consequence of pharmacodynamics, rather than pharmacokinetics resulting in drug toxicity. Growing evidence suggests that a significant proportion of these immunoallergic reactions have a strong HLA association [1]. HLA associations with hypersensitivity reactions to drugs, due to inappropriate HLA presentation and ensuing immune response, have become the more common reason for clinical determination of HLA genotype (excluding transplantation). HLA pharmacogenetic testing for prevention of this type of ADR is one of the most rapidly evolving fields with direct clinical application.

Until recently, the candidate gene approach based on known metabolic pathways or suspected etiology was the only option available for detecting relevant gene polymorphisms. With the advent of high-throughput platforms that can genotype thousands of single-nucleotide polymorphisms (SNPs) simultaneously, interrogation of the entire human genome is possible and can detect polymorphisms associated with a disease, treatment response, or an ADR. This strategy holds the promise of identifying functionally important polymorphisms in genes that have an unexpected role in drug metabolism or drug toxicity. Studies conducted utilizing this methodology known as genome-wide association studies (GWAS) have had little clinical impact as far as providing novel targets that would predict disease, treatment outcome, or toxicity. Although many variants associated with complex diseases have been identified, the variants themselves explain only a small fraction of the heritable contribution to disease risk or response to treatment [2, 3]. Advances in technology have increased discovery of host genetic markers that have provided critical insight into disease pathogenesis, pharmacokinetics, pharmacodynamics, and drug toxicity, but these have not altered clinical practice significantly.

An enormous amount of work has been dedicated to identifying functionally important human polymorphisms with the ultimate goal of improving patient care. Significant progress has been made in detecting such polymorphisms in drug-metabolizing genes, HLA and non-HLA immunity genes, and other host genetic markers that impact either susceptibility to infectious disease, therapy selection, or therapy response. One of the primary barriers to translating most of these genetic associations into the clinical setting is the weakness of the predictive value of any given association with an unfavorable outcome, be it disease risk, poor treatment response, or ADRs. Even in the rare cases where positive and negative predictive values approach 100 %, suggesting clinical utility, the lack of prospective studies addressing cost-effectiveness and demonstrating clear benefits with broad applicability across different ethnic populations precludes testing as part of routine medical practice. This chapter provides an overview of the progress that has been made in host pharmacogenetics and summarizes the challenges that remain for bridging the gap between research and clinical use. The few illustrative examples of genetic testing currently utilized as tools for patient management are discussed in detail.

HLA-B*5701 and Abacavir

HLA-B*5701 screening prior to administering abacavir to treat human immunodeficiency virus (HIV) infection is the best described and extensively studied example of a pharmacogenetic marker for infectious diseases. It also represents one of the few and arguably the most successful example of a pharmacogenetic marker that has been adopted into medical practice. Abacavir is a nucleoside reverse transcriptase inhibitor antiretroviral drug used to treat HIV infection. Abacavir hypersensitivity reaction syndrome (ABC-HSR) is a multi-organ reaction characterized by rash, fever, fatigue, and respiratory and gastrointestinal symptoms. These nonspecific symptoms can be easily confused with other etiologies such as unrelated viral disease or adverse reactions to concomitant medications. Distinguishing between ABC-HSR and other causes of the symptoms is important because continuing therapy with abacavir in those who develop this hypersensitivity reaction can result in serious illness and even death. ABC-HSR usually develops within the first six weeks of treatment and has been estimated to affect 5–8 % of patients treated with abacavir [4]. Although discontinuation of therapy reverses the symptoms, re-initiation of therapy can be life threatening [5].

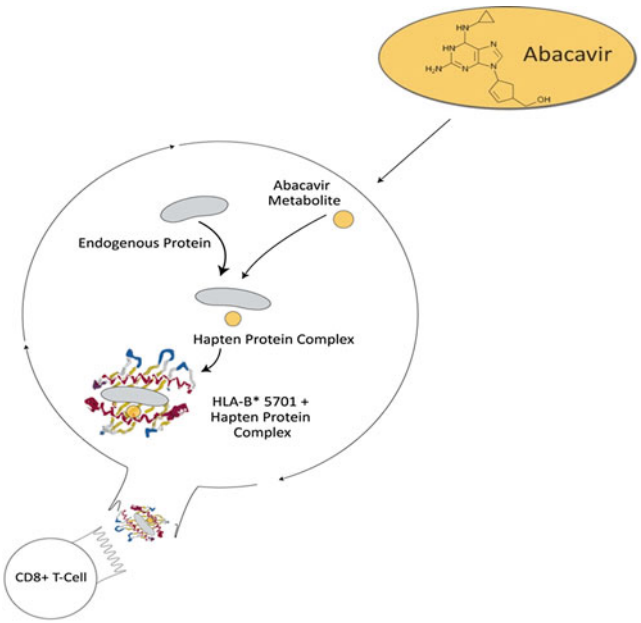

Figure 20.1 Proposed mechanism for HLA-B*5701 abacavir hypersensitivity

In 2002, initial reports of abacavir hypersensitivity reactions occurring in one family suggested a genetic component [6]. Further investigation demonstrated that prevalence of ABC-HSR varied among different ethnic populations, which reinforced the hypothesis of a genetic etiology [7]. Today, the genetics are no longer disputed as it is clear that ABC-HSR is indeed restricted to HLA-B*5701 carriers [4, 8]. Early clues that suggested an immunogenetic mechanism included the symptoms of abacavir hypersensitivity syndrome that had the hallmark features of a cellular delayed-type hypersensitivity reaction. Subsequent observational and experimental data confirmed this suspicion and provided insight into the immunopathogenesis of ABC-HSR [9, 10].

HLA-B*5701 is a class I HLA allele at the B locus, and successful binding of a pathogen-derived peptide by HLA-B*5701 results in presentation to CD8+ T cells and initiation of the adaptive cellular immune response. In this case, a hapten-carrier complex, composed of an abacavir metabolite and an endogenous protein, bind the HLA-B*5701 molecule possibly in the presence of HSP70, resulting in presentation to and activation of CD8+ T cells (Fig. 20.1) [11]. Each HLA-encoded molecule has exquisite specificity and as few as one or two amino acid differences in the peptide-binding cleft of an HLA molecule can change the subset of pathogen-derived peptides each HLA molecule can bind and present. Abacavir presentation is clearly HLA-B*5701 restricted which explains why ABC-HSR is not observed in those who carry closely related alleles such as HLA-B*5702 and HLA-B*5703 that only differ by a few amino acids in the HLA-binding groove.

Australia was one of the earliest countries to introduce routine HLA-B*5701 screening and results from the prospective study that was conducted between 2002 and 2005 demonstrated a significant reduction of ABC-HSR from 8 to 2 % [11, 12]. Additional studies with similar results prompted one of the largest pharmacogenetics clinical trials ever conducted, the Prospective Randomized Evaluation of DNA Screening in a Clinical Trial (PREDICT-1) [13]. This double-blind, randomized trial was also the first study to address the clinical utility of a pharmacogenetic marker to reduce toxicity of a drug. PREDICT-1 enrolled 1,956 patients, who were predominantly Caucasian, from 19 different countries. Patients were randomized into two groups. The control group received standard of care, meaning no screening and administration of abacavir without restriction. The second group received prospective HLA typing and abacavir was withheld from patients who tested positive for HLA-B*5701. One aspect that made this study unique was that all suspected cases of clinical ABC-HSR were confirmed by patch testing. The results obtained were important because prescreening eliminated all cases of patch-confirmed, immunologically mediated, HLA-related abacavir hypersensitivity and yielded 100 % negative predictive value.

Prior to PREDICT-1, reliance on clinical diagnosis had led to inaccurate estimates of the negative predictive value of HLA-B*5701 testing, casting doubts on the utility of prospective screening. This study provided robust evidence for preventive screening in Caucasians, but the lack of ethnic diversity in study participants limited generalization to other ethnic populations. The frequency of the HLA-B*5701 allele varies globally, with a high frequency of 8 % in Caucasians and only 2.5 % in African Americans [14]. The Study for Hypersensitivity to Abacavir and Pharmacogenetic Evaluation (SHAPE) confirmed the reduced prevalence of ABC-HSR in African Americans, but presented clear evidence that screening had applicability across races [15].

Further studies evaluated the cost-effectiveness of pretreatment screening and considered variables such as the frequency of HLA-B*5701 carriers, and the sensitivity and specificity of assays for detection of the HLA-B*5701 allele, as well as the cost of preventive screening, alternative therapies, and treatment of ABC-HSR. The conclusion was that pretreatment screening was a cost-effective approach and the evidence supported adoption of widespread implementation of prescreen testing [16, 17].

Clinical Utility

Clinical utility of prospective screening for HLA-B*5701 to prevent abacavir hypersensitivity reaction is well established. Genetic screening has now been widely adopted in most Western countries, particularly Australia, Ireland, the United Kingdom, and the USA. In 2007, guidelines from the US Department of Health and Human Services that address

antiretroviral treatment recommended screening for HLA-B*5701 prior to initiation of abacavir therapy [18]. In 2008, the US Food and Drug Administration also revised the product label and added a black box warning for all abacavir-containing formulations to reflect the new guidelines for HLA-B*5701 screening.

Available Assays

One hurdle for widespread implementation of screening was the availability of a simple, reliable, and inexpensive assay to detect HLA-B*5701 carriers. Because of the level of resolution needed to discriminate between the many closely related alleles present at each locus, sequencing is the gold standard for HLA haplotyping. Generally, HLA-B*5701 haplotyping by sequencing is available only in highly specialized laboratories that perform tissue matching in the setting of organ transplantation. The expense, labor, and expertise required for the sequencing method are barriers to widespread availability of testing. In an effort to overcome these challenges, simplified molecular assays have been developed and some groups have even explored alternative, surrogate markers for HLA-B*5701. Rs2395029(G) allele in the HCP5 region of the HLA complex is in linkage disequilibrium with HLA-B*5701 and has been proposed as a substitute for HLA-B*5701 testing [19, 20]. Genotyping for the rs2395029 T/G SNP is technically less challenging than genotyping for HLA-B*5701, as this necessitates reliable discrimination between closely related alleles, and it is less expensive than sequencing methods; however, as discussed below, this marker does not always correlate with the presence of an HLA-B*5701 allele.

For direct detection of HLA-B*5701, allele-specific PCR methods with gel electrophoresis or melting curve analysis are available commercially [21, 22]. Flow cytometry-based typing is cost effective and also utilized by diagnostic laboratories. A Taqman allelic discrimination assay for the HCP5 rs2395029 T/G SNP has also been described [19]. Sequencing for HLA-B*5701 remains an alternative.

Interpretation of Results

The presence of one HLA-B*5701 allele is sufficient to predispose to ABC-HSR, because HLA expression is codominant. As reviewed above, HLA is extremely polymorphic; therefore, most individuals will be heterozygous at this locus and carry only one copy of the HLA-B*5701 allele. Laboratories may offer HLA-B*5701 allele detection but not all assays directly detect HLA-B*5701. Assays that rely on the detection of the HCP5 rs2395029(G) allele that is in linkage disequilibrium with HLA-B*5701 and is an indirect test for HLA-B*5701 are available in the USA. In the initial study using this approach, 100 % sensitivity and 99.4 % specificity were observed [19]. However, there are now multiple reports that HLA-B*5701 and the HCP5 rs2395029(G) allele are not in complete linkage disequilibrium and patients can be positive for HLA-B*5701 but negative for HCP5 rs2395029 [23, 24].

Although HLA-B*5701 allotype has a negative predictive value approaching 100 %, a negative HLA-B*5701 result does not absolutely preclude the development of ABC-HSR. Therefore, careful clinical observation for signs and symptoms associated with a hypersensitivity reaction remain a vital component of patient care. Abacavir therapy should be withdrawn in individuals with symptoms of a hypersensitivity reaction regardless of the HLA-B*5701 genotype result. Skin patch testing can be used to immunologically confirm ABC-HSR, but has no usefulness in prospective screening. As is typical for most HLA associations with disease or ADRs, the positive predictive value is often low and has been estimated to be only 47 % in this case [13]. In other words, only about half of patients that carry an HLA-B*5701 allele would be expected to develop ABC-HSR when placed on abacavir therapy. Clearly, other genetic or environmental factors contribute to the risk of developing ABC-HSR in patients who are HLA-B*5701 positive.

Hepatitis C and *IL28B* Genotyping

Chronic hepatitis C (HCV) infection affects millions of individuals worldwide with a substantial risk for liver cirrhosis and hepatocellular carcinoma decades after infection. Although the incidence of HCV infection has decreased, the number of patients that will be diagnosed and must be treated is expected to increase for years to come. Current therapeutic regimens can produce a sustained viral response (SVR) and slow or prevent these long-term complications [25]. Current therapy is based on the combined use of interferon and ribavirin (RBV) for infections with HCV genotypes 2 through 6, and beginning in 2011, the combined use of interferon, RBV, and a protease inhibitor for HCV genotype 1 infections [26].

The first important biomarker for guidance of therapy was pre-therapeutic viral genotyping. Genotype 1 infections require longer treatment and have substantially lower rates of SVR. Identification of HCV genotypes 2 or 3 infection allows for a reduction in the length of interferon RBV treatment to 24 weeks compared to 48 weeks for other genotypes. More recently, measurement of the kinetics of viral clearance during therapy has been implemented as standard of care to predict the likelihood of SVR for all HCV genotypes. A rapid viral response (RVR) defined as a fall in HCV viral load to undetectable levels after 4 weeks of therapy strongly predicts SVR. Although RVR is less likely to be achieved with an HCV genotype 1 infection, achieving an RVR is the best predictor of SVR compared to HCV genotype or host physiologic markers. This observation suggests the existence of host factors which affect the likelihood of achieving an

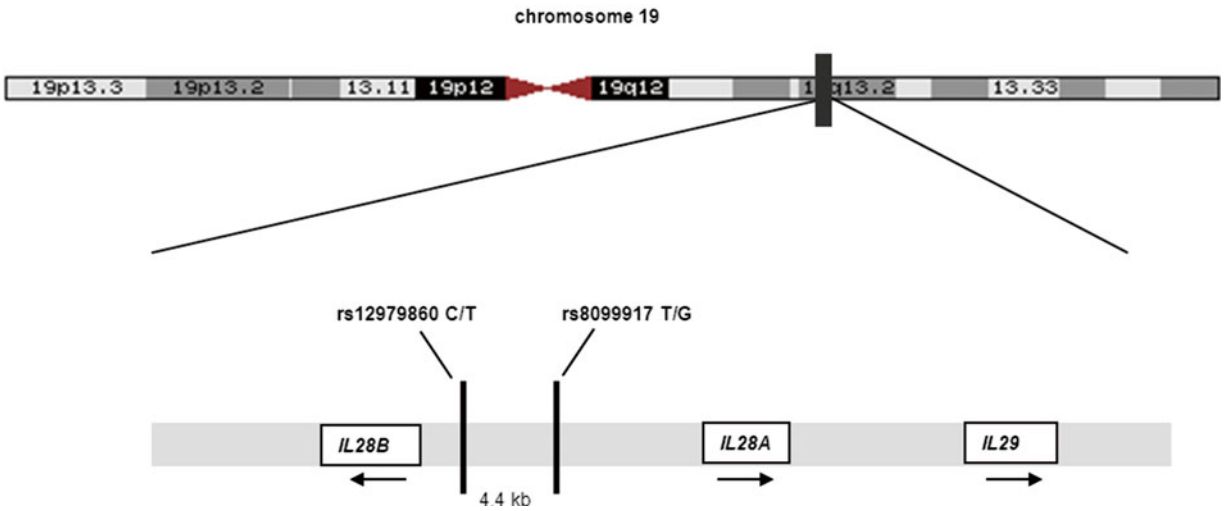

Figure 20.2 Location of SNPs in the *IL28* region

SVR. Until recently, no host genetic markers have been available to predict the likelihood of response or drug toxicity prior to therapy.

In late 2009, a series of papers was published by several groups that performed GWAS seeking biomarkers associated with HCV treatment outcome. Several SNPs were identified on chromosome 19 near the *IL28B* gene that were associated with both spontaneous and treatment-induced HCV clearance (Fig. 20.2) [27–31]. Two SNPs, rs12979860 and rs8099917, have been identified by multiple investigators as having the strongest predictive values for achieving an SVR in patient cohorts of varied ethnic background and have emerged as candidates for *IL28B*-associated genotyping assays. For the rs12979860 C/T SNP those with the CC genotype are two-fold more likely to achieve an SVR and 2.5 times more likely to clear HCV spontaneously, compared to CT heterozygotes or TT homozygotes [28, 29]. For rs8099917, the TT genotype predicts likelihood of an SVR, while TG heterozygotes and GG homozygotes have an increased risk of treatment failure [27].

These associations more powerfully predict spontaneous clearance and therapeutically driven SRV than all previously described host markers including gender, age, liver steatosis, and insulin resistance [32, 33]. In addition, they account for a significant component of the long-appreciated poor treatment outcomes for individuals of African descent. African-American populations have a much higher prevalence of the rs12979860 TT genotype compared to Caucasian or Hispanic populations. African Americans who carry the CC genotype fare better than those carrying CT or TT genotypes but still worse than Caucasian or Hispanic population with the same genotype, suggesting that IL28 explains much but not all of the long-observed differences in HCV spontaneous clearance and treatment response [29].

The mechanism by which *IL28B* genotype exerts its effects remains elusive. The two SNPs, rs 12979860 and rs 8099917, are in linkage disequilibrium, approximately 4 kb apart, and both are located upstream of *IL28B*. The *IL28* gene encodes a type III lambda interferon. Lambda interferons, like alpha interferons, stimulate antiviral effects through the JAK-STAT signaling pathway, but use a different cell surface receptor that is preferentially expressed in hepatocytes. Lambda interferons can inhibit HCV growth in vitro, but the precise mechanism for clearance of HCV in vivo remains uncertain [34, 35]. Further complicating interpretation is that both SNPs associated with HCV response are located upstream of the *IL28B* gene and not in the gene itself. This finding suggests that these SNPs affect transcription of the gene. However, initial messenger RNA expression studies have yielded conflicting results. Although the underlying mechanism has not been clarified, the predictive power of these *IL28B*-associated SNPs for HCV clearance has been unequivocally substantiated.

Clinical Utility

The significance of the *IL28B* genotype was originally discovered in patients infected with HCV genotype 1 who were undergoing standard-of-care (SOC) treatment with interferon and RBV. Subsequent studies have investigated *IL28B* genotype in patients infected with HCV genotypes 1, 2, and 4. Although the results from these investigations support the overall conclusion that favorable *IL28B* genotype is predictive of likelihood of response to treatment, *IL28B* genotype has lower predictive value in patients infected with HCV genotypes other than 1. Clinical trials and one study have investigated the utility of *IL28B* genotyping in the era of direct-acting antiviral therapies. Data demonstrate that those with a favorable *IL28B* genotype are more likely to have

abbreviated therapy under this new treatment regimen [36–38]. Individuals with the favorable *IL28B* genotype have higher SVR rates with triple therapy as compared to SOC; therefore, no recommendation can be made for one therapy over another based on *IL28B* genotype.

In summary, *IL28B* genotyping is a strong pretreatment predictor of treatment response to interferon and RBV therapy, as well as protease inhibitor triple therapy, in patients infected with HCV genotype 1. Predictive value is lower in patients infected with HCV genotypes 2 and 3 [26, 33]. Currently, insufficient evidence exists to recommend one therapy over another for HCV genotype 1 or to recommend a specific duration of therapy based on *IL28B* genotype alone. *IL28B* genotype should be considered, if information regarding the likelihood of response and probable duration of response is needed [26].

Available Assays

Both TaqMan allelic discrimination and dual-color fluorescence resonance energy (FRET) probe assays for *IL28B* genotyping have been published and are commercially available [39].

Interpretation of Results

Caution must be taken in interpreting *IL28B* genotype results. First, *IL28B* genotype is primarily a predictive marker for likelihood of response and duration of treatment, but cannot be used to recommend a particular therapy and does not directly dictate duration of treatment. Second, not all individuals with a favorable genotype will achieve a positive treatment outcome, and conversely not all individuals with a risk genotype are destined to fail therapy. Third, *IL28B* genotype assays are now commercially available that genotype for the rs12979860 or the rs8099917 SNP or both, and it is clinically important to know which SNP is the target. These two SNPs are in linkage disequilibrium with *IL28B*, but the degree (strength) of linkage disequilibrium between these two SNPs varies with ethnic background [29, 31, 39, 40]. The two SNPs provide interchangeable information in Caucasians, but not in African Americans. Because both SNPs are tag SNPs and neither is the causal variant, it is not well established which of the two SNPs is more reflective of observed response in patients who are discordant for these two SNPs.

Future Directions

HCV and *ITPA*

GWAS for HCV infection and therapy markers discovered that polymorphisms in the inosine triphosphatase (*ITPA*) gene were associated with hemoglobin concentrations in patients treated with RBV. Follow-up studies identified two variants, rs1127354 and rs7270101, that cause inosine triphosphatase (ITPAse) deficiency and protect patients from RBV-induced hemolytic anemia [41–45]. The rs1127354 C-to-A polymorphism is a missense mutation and the rs7270101 is an A-to-C splice mutation, both of which are significantly and independently associated with enzyme deficiency and protective effects. The biological mechanism is not well defined, but the protective effects have been confirmed. Genotyping assays for *ITPA* polymorphisms are available clinically on a limited basis.

Antiretroviral Therapy

One of the most promising areas of pharmacogenetics is antiretroviral therapy. The introduction of highly active antiretroviral therapy (HAART) in the mid-1990s for treatment of HIV infection has proven to be extremely effective and has virtually transformed HIV infection into a manageable, chronic disease. Because HIV is never cleared, long-term antiretroviral therapy (ART) is necessary for suppressing viral replication and is often complicated not only by emergence of viral resistance, but also by the development of severe toxic syndromes and unexpected health consequences. For example, extended use of ART correlates with an increased risk of developing accelerated atherogenesis and cardiovascular complications (events). Consequently, the link between genetic variations in lipid metabolism or transport genes and dyslipidemia has been examined by many investigators. Polymorphisms in *APOC3*, *APOE*, and *APOA5* genes are believed to significantly contribute to increased triglyceride concentrations in patients on long-term ART, particularly those treated with ritonavir [46–49].

Other host-treatment associations of note include (1) HLA-DRB*0101 class II allele and nevirapine-associated hypersensitivity; (2) atazanavir- and indinavir-induced hyperbilirubinemia associated with *UGT1A1* primarily but also P-gp (formerly *MDR1*) SNPs; (3) tenofovir renal proximal tubulopathy associated with multidrug-resistance protein (MRP2) transporter variation; and (4) efavirenz-associated neurotoxicity attributed to *CYP2B6* differences [46, 47]. Genetic screening has been proposed for both *UGT1A1* and *CYP2B6* prior to atazanavir and efavirenz treatment, respectively. However, even for these well-established associations clinical utility of genetic testing remains controversial, because it is becoming increasingly clear that variation in more than one drug-metabolizing gene and multiple mechanisms may affect the pharmacokinetics of any one drug. The relative contribution of variation in all genes that impact metabolism of a drug has to be determined before utility of genotyping

for one or multiple markers can be demonstrated. Currently, the majority of these associations are of research interest only due to the many limitations of pharmacogenetics, as discussed above. Perhaps the foremost limitations are the lack of widespread applicability and well-designed cost-effectiveness studies. Nevertheless, HLA-B*5701 is a great example that genetic associations can be successfully translated into clinical practice if the appropriate studies are conducted. There is considerable anticipation that personalized HAART pharmacogenetics will be possible in the near future.

Tuberculosis

Tuberculosis (TB) is an infectious disease with a long history. There is resurgence in the global morbidity and mortality caused by TB, primarily due to the emergence of antibiotic-resistant Mycobacterium strains and HIV coinfection. Globally, the prevalence of TB has been estimated at 30 %, with the highest burden in developing nations. SOC treatment for TB is a combination of multiple drugs: rifampicin, streptomycin/ethambutol, and pyrazinamide combined with isoniazid. Serious dose-dependent side effects associated with isoniazid therapy, mainly hepatotoxicity, were apparent as early as the 1970s. It is now well accepted that polymorphisms in *NAT2* are responsible for the differential extent of N-acetylation of isoniazid and observed phenotypes. Genetic testing for this marker could reduce dose-dependent ADRs in slow metabolizers while increasing efficacy in fast metabolizers or acetylators. Appropriate patient dosing based on genetic testing likely would increase patient compliance with the added benefit of minimizing drug resistance. Drug resistance is a growing problem and has led to combination therapy as the mainstay for TB treatment. Although *NAT2* testing is not recommended prior to prescribing isoniazid, pharmacogenetic information regarding the role of NAT2 in isoniazid metabolism is included in US drug labels. *NAT2* genotyping or phenotyping is not widely available.

Malaria

Malaria is one of the deadliest infectious diseases known to man, with an enormous human and financial toll. Ironically, one of the earliest examples of an ADR associated with host genetics was the recognition that those who have glucose-6-phosphate dehydrogenase (G6PD) deficiency develop severe hemolytic anemia when administered primaquine, an antimalarial drug introduced in 1950 [50]. Importantly, G6PD deficiency is still relevant to developing efficacious antimalarial drugs, and as recently as 2008, complications due to G6PD deficiency caused withdrawal of chlorproguanil/dapsone therapy [51–53]. Antimalarial drugs have been available for decades and were initially effective and relatively inexpensive. However, monotherapy approaches to treatment led to widespread resistance. Hope was restored around 2000 with the development of artemisinin combination therapies (ACT). ACT is predicated on different classes of drugs with different modes of action for parasite elimination, impeding the emergence of drug-resistant parasites. At the moment, the three ACT options widely utilized for TB management are amodiaquine and artesunate, artemether-lumefantrine, and artesunate-mefloquine [54].

The availability of ample data for both components of the amodiaquine-artesunate ACT therapy provides a good illustration of the potential for pharmacogenetic testing in the setting of malaria. Amodiaquine has a well-established association with severe toxicity. Concerns over high rates of lethal agranulocytosis and hepatoxicity observed in Caucasians prompted removal of this drug from the WHO Essential Medicines List, but it had to be reintroduced due to growing resistance to remaining therapeutic options [55–57]. The adverse reaction has been attributed to the *CYP2C8*2* polymorphism. Impaired amodiaquine metabolism by *CYP2C8*2* results in accumulation of a toxic metabolite and the severe adverse reactions. Despite the fact that other *CYP2C8* low activity-alleles, such as **3* and **4*, have been identified in Zanzibar, the first line of therapy in this country is amodiaquine-artesunate, placing this population at increased risk of adverse events [58]. Overall, the percentage of individuals at risk for developing an ADR is small, but this translates into large absolute numbers due to the vast number of people who need to be treated. In contrast, therapy regimens including amodiaquine would be well suited to West Africa, where low-activity alleles are rarely found [51, 54].

Conversion of artesunate to the active metabolite dihydroartemisinin (DHA) is dependent on CYP2A6 [59]. *CYP2A6* is highly polymorphic with approximately 40 gene variants [60]. Many of these have decreased metabolizing function and some alleles have no activity in vivo. Clearly, prescribing therapy containing artesunate to individuals that do not have the ability to convert the drug to an active metabolite is futile. Furthermore, for those who have reduced metabolizing capacity, the concentration of active metabolite formed is insufficient, severely impairing parasite elimination and increasing the potential for development of drug resistance. Reports suggest that resistance to artesunate-based therapy is already as high as 10 % in some parts of the globe, such as Thailand [61]. Interestingly, Thailand has a high prevalence of low-activity alleles [62] and this may have contributed to the emergence of drug-resistant strains in this location [51].

For malaria and to some extent TB, it is not likely that personalized medicine would be possible, given the cost of genetic testing compared to treatment and the great number of patients that would require testing. For both, however,

population-level application of pharmacogenetics could have important implications for global disease control. Simply knowing the frequencies of relevant genetic polymorphisms at the population level may shape a global strategy and drug policy for the developing world that would increase therapeutic efficacy, minimize adverse reactions, and diminish the potential for drug resistance. Drug resistance is an increasingly difficult problem that is even more acute in the context of a pathogen that infects 100 million people annually and for which only a limited number of effective drugs exist.

Summary

In summary, advances in technology coupled with intensive studies have improved our understanding of the underlying basis of the genetics associated with disease and drug response. Despite significant progress made from the biological perspective, translation to routine medical practice for most discoveries is lagging. Demonstration of the clinical utility of genetic association using large, well-designed prospective clinical trials is just the first step in translating a pharmacogenetic test into routine healthcare. Test endorsements in consensus statements and practice guidelines are pivotal for acceptance. Furthermore, the speed of adoption is often influenced by logistical considerations such as widespread access to a reliable and cost-effective test and reasonable reimbursement for the test. Nevertheless, good examples now exist of successful implementation of pharmacogenetic testing in medical practice and there is ample hope that future applications of pharmacogenomics are likely to become important in infectious disease treatment.

Pharmacogenetics

21

Stuart A. Scott and Elaine Lyon

Abstract

Pharmacogenetics is the study of the genetic determinants of drug response variability. Some pharmacogenetic tests can be used to explain or predict adverse events and/or non-responsiveness to therapy. The goal and promise of clinical pharmacogenetic testing is to deliver the right drug to the right person at the right dose. As such, when a genetic variant directly involved in drug response variability is identified in a patient prior to initiating therapy, adverse reactions, excessive use of ineffective drugs, or ineffective dosing can hopefully be prevented. Despite challenges to demonstrate clinical utility, clinical tests are currently available for selected genes where clinical validity has largely been established. This chapter describes pharmacogenetic applications for which clinical tests are currently available, including *CYP2D6*, *CYP2C19*, *CYP2C9* and *VKORC1*, *TPMT*, and *UGT1A1*.

Keywords

Pharmacogenetics • Drug metabolism • Cytochrome P450 • Thiopurine *S*-methyltransferase • Toxicity • Warfarin • Irinotecan

Introduction

Pharmacogenetics is the study of the genetic determinants of drug response variability. Accordingly, pharmacogenetic variant alleles often occur in genes that encode drug metabolism enzymes and alter their enzymatic activity. These enzymes can activate a prodrug to its active form or catalyze the inactivation and elimination of a drug or metabolite. Prominent among these enzymes are the cytochrome P450 (CYP450) superfamily, which directly influence the pharmacokinetics of many drugs. In addition, genetic variants in cell receptors can influence drug transport, which often plays a role in pharmacodynamics. Consequently, pharmacogenetic tests are now available that can be used to explain or predict adverse events or non-responsiveness to therapy. The goal and promise of clinical pharmacogenetic testing is to deliver the right drug to the right person at the right dose. As such, when a genetic variant directly involved in drug response variability is identified in a patient prior to initiating therapy, adverse reactions, excessive use of ineffective drugs, or ineffective dosing can potentially be prevented.

Despite many robust associations between specific variant alleles and drug response variability, the clinical utility of pharmacogenetic genotyping has been difficult to establish for some clinical applications. Important pharmacogenetic variants are often rare in the general population, which makes identifying enough individuals with a particular genotype in the research setting challenging. To achieve an adequate sample size, some studies group heterozygotes (one variant) and homozygotes or compound heterozygotes (two

variants) together, yet many enzymes exhibit an autosomal recessive inheritance. By combining the two genotypes, the effect of two variants, and therefore the true "poor metabolizers," may not be evident.

Since genotyping may not detect all variants that affect drug metabolism, it does not necessarily replace the need for drug monitoring when indicated. Other factors such as concomitant medications, comorbidities, and diet often affect drug metabolism and drug levels. Despite these challenges, clinical genetic tests are currently available for selected genes where clinical validity has largely been established. This chapter describes clinical pharmacogenetic applications for which tests currently are available, including genotyping tests for variants in *CYP2D6*, *CYP2C19*, *CYP2C9* and *VKORC1*, *TPMT*, and *UGT1A1*.

CYP2D6

Cytochrome P450-2D6 (CYP2D6) is an important isoenzyme of the P450 superfamily that is involved in the metabolism of approximately 25 % of commonly prescribed drugs, including tamoxifen [1], alpha-blockers, analgesics [2], antidepressants [3], antihypertensives [4], antipsychotics [5], β-receptor blockers [6], norepinephrine reuptake inhibitors [7], and others. More than 100 *CYP2D6* alleles have been described (http://www.cypalleles.ki.se/cyp2d6.htm); however, many are rare in the general population. Although the effect of all of these variant alleles on enzyme activity has not been established, many of the commonly interrogated *CYP2D6* variants include nonfunctional, reduced-, and increased-function alleles. The combination of these alleles in a given genotype results in four predicted phenotype categories: ultrafast (ultrarapid), extensive (normal), intermediate, and poor metabolizers [8]. Depending on the drug, CYP2D6 may be involved in the activation of a prodrug or inactivation of an active drug. Consequently, reduced CYP2D6 activity due to loss-of-function alleles can result in ineffective treatment when activating a prodrug or adverse reactions by allowing toxic compounds to accumulate due to impaired drug inactivation.

Clinical Utility

Although the clinical utility of testing for *CYP2D6* variants has been difficult to establish for many medications, it has been shown for a few drugs. Tamoxifen is metabolized by CYP2D6 to its active metabolite endoxifen [9], although other cytochrome P450 enzymes also are involved (e.g., CYP2C19, CYP2C9, CYP3A4/5). As such, *CYP2D6* genotyping can be used to identify individuals in which tamoxifen is potentially less effective. Identification of a poor metabolizer may help in drug or dose adjustment. Less is understood for intermediate metabolizers, although a potential dose modification may be considered. However, routine testing for women being placed on tamoxifen is not currently recommended due to conflicting data in the literature [10].

The Clinical Pharmacogenetics Implementation Consortium (CPIC) has published practice guidelines for the use of *CYP2D6* genotyping to guide codeine therapy [11, 12] (Table 21.1). Evidence also exists for a role of *CYP2D6* genotyping for individualized treatment with tricyclic antidepressants, which also has prompted a recent CPIC guideline [13]. For example, CYP2D6 poor metabolizers treated with amitriptyline and nortriptyline have impaired drug metabolism and increased risks of side effects, whereas ultrafast metabolizers have elevated risks of reduced drug efficacy due to rapid drug elimination (Table 21.2). Evidence supporting a role for *CYP2D6* in selective serotonin reuptake inhibitor response variability also exists and a CPIC guideline is currently in development (http://www.pharmgkb.org/page/cpic).

Table 21.1 CPIC recommendations for *CYP2D6*-directed dosing of codeine[a]

Predicted CYP2D6 metabolism phenotype	Implications for codeine metabolism	Therapeutic recommendations
Ultrarapid metabolizer (UM)	Increased formation of morphine following codeine administration, leading to higher risk of toxicity	Avoid codeine use due to potential for toxicity
Extensive metabolizer (EM)	Normal morphine formation	Use label-recommended age- or weight-specific dosing
Intermediate metabolizer (IM)	Reduced morphine formation	Use label-recommended age- or weight-specific dosing. If no response, consider alternative analgesics such as morphine or a non-opioid
Poor metabolizer (PM)	Greatly reduced morphine formation following codeine administration, leading to insufficient pain relief	Avoid codeine use due to lack of efficacy

CPIC Clinical Pharmacogenetics Implementation Consortium
[a]Adapted from Crews et al. [12]

Table 21.2 CPIC recommendations for *CYP2D6*-directed dosing of tricyclic antidepressants[a,b]

Predicted CYP2D6 metabolism phenotype	Implications for tricyclic antidepressant metabolism	Therapeutic recommendations
Ultrarapid metabolizer (UM)	Increased metabolism of tricyclics to less active compounds when compared to extensive metabolizers. Lower plasma concentrations will increase the probability of pharmacotherapy failure	Avoid tricyclic use due to potential lack of efficacy. Consider alternative drug not metabolized by CYP2D6 If a tricyclic is warranted, consider increasing the starting dose. Utilize therapeutic drug monitoring to guide dose adjustments
Extensive metabolizer (EM)	Normal metabolism of tricyclics	Initiate therapy with recommended starting dose
Intermediate metabolizer (IM)	Reduced metabolism of tricyclics to less active compounds when compared to extensive metabolizers. Higher plasma concentrations will increase the probability of side effects	Consider 25 % reduction of recommended starting dose. Utilize therapeutic drug monitoring to guide dose adjustments
Poor metabolizer (PM)	Greatly reduced metabolism of tricyclics to less active compounds when compared to extensive metabolizers. Higher plasma concentrations will increase the probability of side effects	Avoid tricyclic use due to potential for side effects. Consider alternative drug not metabolized by CYP2D6 If a tricyclic is warranted, consider 50 % reduction of recommended starting dose. Utilize therapeutic drug monitoring to guide dose adjustments

CPIC Clinical Pharmacogenetics Implementation Consortium

[a]Adapted from Hicks et al. [13]

[b]Note that dosing guidelines for tricyclic antidepressants and *CYP2C19* genotype-directed therapy were also reported [13]. Optional dosing recommendations based on both *CYP2D6* and *CYP2C19* can be found in the supplemental material of Hicks et al. [13].

Available Assays

CYP2D6 genotyping typically is performed by platforms that simultaneously detect multiple variants across the gene (Fig. 21.1). Several commercial assays are currently available, including the AmpliChip® (Affymetrix/Roche [14]), Luminex [15], and AutoGenomics [16] assays, as well as other laboratory-developed tests (e.g., single-nucleotide extension assay) [17]. The AmpliChip® CYP450 Test (Roche Diagnostics, Indianapolis, IN) is an oligonucleotide microarray hybridization method that tests variants in both *CYP2D6* and *CYP2C19*. The Tag-It™ Luminex (Luminex Molecular Diagnostics, Toronto, Canada) platform is a bead array with oligonucleotides bound to microspheres and genotyping by allele-specific primer extension. The AutoGenomics (Carlsbad, CA) platform is a film-based microarray tested on the INFINITI® PLUS Analyzer. These assays typically interrogate 15–20 important *CYP2D6* variants including the deletion and duplication alleles.

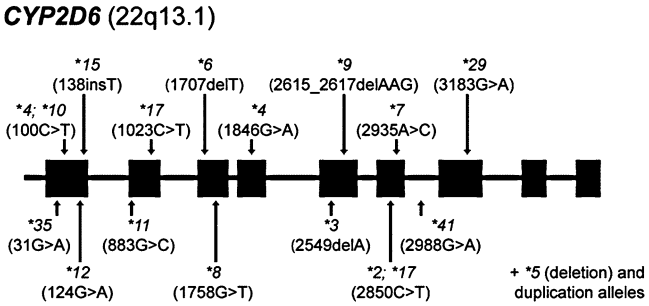

Figure 21.1 Gene diagram of *CYP2D6* (and chromosome location) indicating common alleles and their molecular alteration (in *parentheses*), including the deletion (**5*) and duplication alleles. Note that variants are referred to by their common names (GenBank Accession Number M33388)

Interpretation

CYP2D6 alleles are designated by the common star (*) allele nomenclature system, which often include multiple variants on the same haplotype. The *CYP2D6*1* allele is the wild-type haplotype encoding normal enzyme activity; however, this is typically assigned in the absence of other detected variants. Consequently, when **1* is reported by targeted genotyping, a rare *CYP2D6* star (*) allele not included in the genotyping panel would not be detected, which can only be identified by gene sequencing. Commonly interrogated *CYP2D6* alleles are summarized in Table 21.3.

Two functional *CYP2D6* alleles or one functional and one reduced-function *CYP2D6* allele predict normal or extensive metabolizers. Two reduced-function alleles or one reduced-function and one nonfunctional allele predict intermediate metabolizers. Two nonfunctional alleles predict a poor metabolizer phenotype. Duplicated functional *CYP2D6* alleles predict an ultrarapid metabolizer phenotype [8]. In addition to duplicated functional alleles, duplicated nonfunctional or reduced-function alleles also have been described. As such, determining which *CYP2D6* allele is duplicated is important for proper interpretation when a

Table 21.3 Examples of commonly tested pharmacogenetic alleles and their effect on enzyme activity

Gene	Loss-of-function alleles	Reduced-function alleles	Increased-function alleles
CYP2D6	**3*, **4*, **5*, **6*, **7*, **8*, **12*, **14*	**9*, **10*, **17*, **29*, **41*	Functional allele duplication
CYP2C19	**2*, **3*, **4*, **5*, **6*, **7*, **8*	**9*, **10*	**17*
CYP2C9	**3*, **6*	**2*, **5*, **8*, **11*	–
TPMT	**2*, **3A*, **3B*, **3C*, **4*	–	–

gene duplication is identified in addition to a heterozygous genotype [18].

CYP2D6 genotyping is complicated by the fact that several variants occur on a number of important star (*) alleles and commercial assays cannot determine the phase of identified genotypes [19]. For example, the nonfunctional **4* allele is defined by several variants, including 100C>T and 1846G>A. The 1846G>A variant is the defining functional mutation for **4*, which disrupts exon splicing and results in a frameshift and loss of enzyme activity. However, the **10* reduced-function allele also has the 100C>T variant but without 1846G>A. Of note, 1846G>A can also exist on a haplotype without 100C>T (**4M*), and this allele is very rare. When one copy of each variant is detected, the most probable genotype is heterozygous **4* (one copy of a nonfunctional allele), since 100C>T and 1846G>A are presumed to be on the same haplotype. As genotyping platforms generally do not predict *CYP2D6* haplotypes, individual laboratories are responsible for interpreting results and reporting *CYP2D6* genotypes. Without haplotyping by more involved molecular assays, it is possible that one copy of both 100C>T and 1846G>A could be misinterpreted as a **4M/*10* compound heterozygote (one nonfunctional allele and one decreased-function allele). Although this scenario would be rare in the general population, the **4/*10* genotype is more appropriately defined by two copies of 100C>T and one copy of 1846G>A.

Further interpretation challenges exist when a duplication is detected with a reduced-function or nonfunctional allele, as most platforms are not capable of identifying which allele is duplicated. Furthermore, the number of duplicated *CYP2D6* copies on an allele is not typically determined. When in combination with a reduced-function allele, the number of copies may become clinically relevant in predicting the phenotype. Family studies (such as parental testing) may help determine the phase of identified variants in these scenarios, if warranted.

Laboratory Issues

The *CYP2D6* gene is highly homologous to a related pseudogene (*CYP2D7P1*), which complicates the design of PCR primers used for genotyping. As such, primers are designed to avoid co-amplification of pseudogenes by employing a specific long-range PCR of the entire *CYP2D6* gene. Given the technical challenges with long-range PCR, suboptimal or degraded DNA may not perform well for many commercial *CYP2D6* assays.

When a *CYP2D6* platform is unable to identify if a duplication is a functional or nonfunctional allele in a heterozygous sample, laboratories may report an "indeterminant" result. As noted above, family studies can facilitate identifying which allele is duplicated in these cases. Although laboratory guidelines for *CYP2D6* genotyping in relation to tamoxifen therapy have recently been reported [19], no current professional guidelines detail which alleles should be included in clinical *CYP2D6* assays. Therefore, different laboratories may include different *CYP2D6* alleles in their testing panels, which can result in conflicting *CYP2D6* genotypes and predicted phenotypes between laboratories.

CYP2C19

Cytochrome P450-2C19 (CYP2C19) is another important member of the cytochrome P450 superfamily that metabolizes commonly prescribed medications including anticonvulsants, antidepressants, antifungals, proton-pump inhibitors, antithrombotics, and chemotherapy, antimalarial, and antiulcer drugs [20]. Another drug metabolized by CYP2C19 is the antiplatelet agent clopidogrel, commonly prescribed for patients with acute coronary syndromes and those undergoing percutaneous coronary intervention (PCI). CYP2C19 converts clopidogrel in a two-step enzymatic reaction to an active metabolite, which binds irreversibly to platelet receptors and inhibits aggregation for the duration of the platelet life span. About 25 % of ACS/PCI patients have reduced platelet inhibition due in part to *CYP2C19* loss-of-function alleles [21], which reduces the effectiveness of clopidogrel treatment.

Although over 30 *CYP2C19* variant alleles have been identified, the effect of some rare alleles on enzyme function has not been established. Notable among the *CYP2C19* alleles are **2* to **8*, which impart loss of function, and **17*, which has been reported as an increased-function allele (http://www.cypalleles.ki.se/cyp2c19.htm). In contrast to the role of the *CYP2C19*2* to **8* alleles in reduced clopidogrel effectiveness, **17* may be associated with an enhanced response to clopidogrel and some antidepressants [22]. Variant *CYP2C19* allele frequencies vary between racial and ethnic groups, with **2* being present in approximately 30 %

Table 21.4 CPIC recommendations for *CYP2C19*-directed dosing of tricyclic antidepressants[a,b]

Predicted *CYP2C19* metabolism phenotype	Implications for tricyclic antidepressant metabolism	Therapeutic recommendations
Ultrarapid metabolizer (UM)	Increased metabolism of amitriptyline when compared to extensive metabolizers	Consider alternative drug not metabolized by *CYP2C19*. If a tricyclic is warranted, utilize therapeutic drug monitoring to guide dose adjustments
Extensive metabolizer (EM)	Normal metabolism of amitriptyline	Initiate therapy with recommended starting dose
Intermediate metabolizer (IM)	Reduced metabolism of amitriptyline when compared to extensive metabolizers	Initiate therapy with recommended starting dose
Poor metabolizer (PM)	Greatly reduced metabolism of amitriptyline when compared to extensive metabolizers. Higher plasma concentrations of amitriptyline will increase the probability of side effects	Consider 50 % reduction of recommended starting dose. Utilize therapeutic drug monitoring to guide dose adjustments

CPIC Clinical Pharmacogenetics Implementation Consortium
[a]Adapted from Hicks et al. [13]
[b]Note that dosing guidelines for tricyclic antidepressants and *CYP2D6* genotype-directed therapy were also reported [13]. Optional dosing recommendations based on both *CYP2D6* and *CYP2C19* can be found in the supplemental material of Hicks et al. [13]

Table 21.5 CPIC recommendations for *CYP2C19*-directed antiplatelet therapy when considering clopidogrel for ACS patients undergoing PCI[a]

Predicted *CYP2D6* metabolism phenotype	Implications for clopidogrel	Therapeutic recommendations
Ultrarapid metabolizer (UM)	Increased platelet inhibition; decreased residual platelet aggregation[b]	Clopidogrel label-recommended dosage and administration
Extensive metabolizer (EM)	Normal platelet inhibition; normal residual platelet aggregation	Clopidogrel label-recommended dosage and administration
Intermediate metabolizer (IM)	Reduced platelet inhibition; increased residual platelet aggregation; increased risk for adverse cardiovascular events	Alternative antiplatelet therapy (if no contraindication); e.g., prasugrel, ticagrelor
Poor metabolizer (PM)	Significantly reduced platelet inhibition; increased residual platelet aggregation; increased risk for adverse cardiovascular events	Alternative antiplatelet therapy (if no contraindication); e.g., prasugrel, ticagrelor

ACS acute coronary syndrome; *CPIC* Clinical Pharmacogenetics Implementation Consortium; *PCI* percutaneous coronary intervention
[a]Adapted from Scott et al. [23]
[b]The *CYP2C19*17* allele may be associated with increased bleeding risks [27]

of Asians and 15 % of Caucasians and African Americans, while **3* has a frequency of approximately 8 % in the Asian population, but is rare in other populations.

Clinical Utility

CYP2C19 genotyping can identify individuals who should avoid medications or may require modified doses of medications metabolized by CYP2C19. For ACS/PCI patients being treated with clopidogrel, *CYP2C19*2* and **3* carriers have reduced platelet inhibition compared to extensive metabolizers due to reduced metabolic activation of the prodrug. Consequently, an alternative antiplatelet agent has been recommended for ACS/PCI patients who are *CYP2C19* intermediate and poor metabolizers [23]. For tamoxifen, *CYP2C19*17* carriers have been shown to produce higher concentrations of the active endoxifen metabolite and may have a more favorable outcome than **1*, **2*, and **3* carriers [24]. CPIC guidelines are available for the use of *CYP2C19* genotyping results for patients treated with tricyclic antidepressants [13, 25] (Table 21.4) and clopidogrel [23, 25] (Table 21.5).

Available Assays

A number of multiplexed molecular assays are available to identify selected variant *CYP2C19* alleles. For example, *CYP2C19* is combined with *CYP2D6* in the AmpliChip® assay (Roche) described above. Additional *CYP2C19* assays are commercially available from Luminex Molecular Diagnostics (xTAG® CYP2C19 Kit), AutoGenomics (Infiniti® CYP2C19 Assay), Nanosphere (Verigene® CYP2C19 Test), GenMark Diagnostics (eSensor® 2C19 Test), Sequenom (iPLEX® ADME CYP2C19 Panel), and Spartan Bioscience (Spartan RX CYP2C19 Test). All these assays include the common nonfunctional alleles (**2* and **3*, with or without **4* to **8*), and some also include **17* and other variants (Fig. 21.2; Table 21.3).

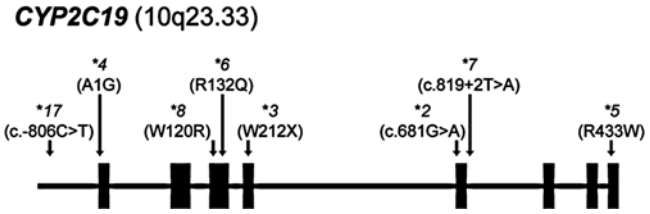

Figure 21.2 Gene diagram of *CYP2C19* (and chromosome location) indicating common alleles and their molecular alteration (in *parentheses*)

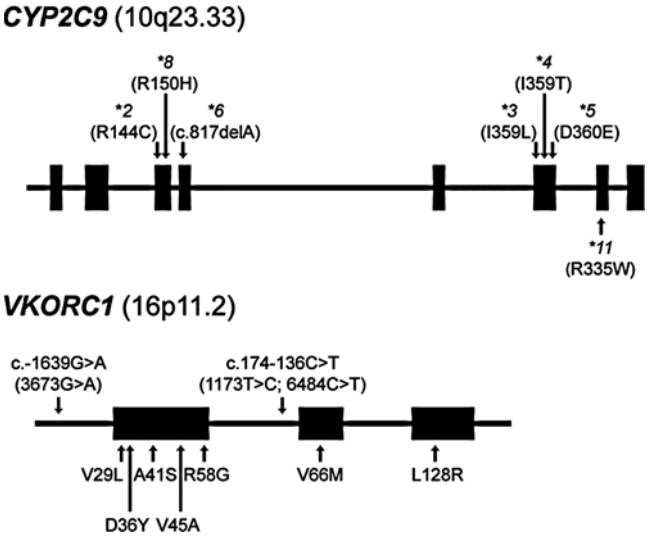

Figure 21.3 Gene diagrams of *CYP2C9* and *VKORC1* (and chromosome locations) indicating common alleles and their molecular alteration (in *parentheses*). Note the rare "warfarin-resistant" *VKORC1* mutations listed below the *VKORC1* gene, which are not commonly included in clinical *CYP2C9* and *VKORC1* genetic tests

Interpretation

Based on identified *CYP2C19* genotype, individuals typically are categorized as extensive (**1/*1*), intermediate (e.g., **1/*2*, **1/*3*), or poor (e.g., **2/*2*, **2/*3*) metabolizers [20]. The frequencies of *CYP2C19* poor metabolizers are 2–5 % of Caucasians and African Americans and approximately 15 % of Asians [23, 26]. Additionally, individuals who have at least one copy of the *CYP2C19*17* allele often are categorized as ultrarapid metabolizers (e.g., **17/*17*). However, given that **17* is unable to completely compensate for the **2* loss-of-function allele [27], **2/*17* compound heterozygotes can be classified as intermediate metabolizers, although some laboratories may report the predicted phenotype for this genotype as "unknown" or "indeterminate."

Laboratory Issues

Although most commercial assays include the common *CYP2C19*2* and **3* loss-of-function alleles, some assays also include the **4* to **8* alleles. Moreover, some assays include the **17* increased-function allele. Like other *CYP450* genotyping assays, the wild-type **1* allele is assigned in the absence of other detected alleles. Consequently, different laboratories may test different allele panels which can result in conflicting *CYP2C19* genotypes and predicted phenotypes depending on which alleles were interrogated.

CYP2C9 and VKORC1 (Warfarin Sensitivity)

Warfarin is a commonly prescribed vitamin K antagonist for the prevention of thromboembolism among patients with atrial fibrillation, deep vein thrombosis, and other indications. However, the drug has a very narrow therapeutic index and a large interindividual variability in response, in part due to inherited genetic variability within genes involved in warfarin pharmacokinetics and pharmacodynamics. For example, cytochrome P450-2C9 (CYP2C9) is the principal enzyme involved in S-warfarin inactivation and elimination. Like other cytochrome P450 genes, *CYP2C9* is highly polymorphic with several known variant alleles encoding reduced enzyme activity (http://www.cypalleles.ki.se/cyp2c9.htm). Importantly, in vitro studies have shown that the common **2* and **3* alleles are functionally defective, exhibiting only approximately 70 % and 5 % of wild-type activity toward S-warfarin, respectively [28]. Consequently, these *CYP2C9* alleles result in reduced warfarin inactivation, higher warfarin blood levels with standard warfarin doses, and increased bleeding risks [29, 30]. The frequencies of **2* and **3* are approximately 15 % and 6 %, respectively, among Caucasians and 2–4 % among Asians and African Americans [31]. Of note, other variant alleles are more prevalent in individuals of African descent (e.g., **5*, **6*, and **8*) [31], which may provide additional utility for genetically guided warfarin dosing in these populations.

Warfarin acts as a vitamin K antagonist by inhibiting the regeneration of reduced vitamin K, an essential cofactor for the clotting cascade. The target enzyme for warfarin is VKORC1, which catalyzes the rate-limiting step in the vitamin K cycle [32]. Importantly, common *VKORC1* haplotypes that result in reduced gene expression have been reproducibly implicated as the major genetic determinant of warfarin dose variability [33–38]. The most commonly interrogated *VKORC1* allele associated with warfarin sensitivity is the c.-1639G>A promoter polymorphism (Fig. 21.3) [38]. Like *CYP2C9*, the frequencies of *VKORC1* alleles vary between racial and ethnic groups, with c.-1639G>A allele frequencies of approximately 10 %, 45 %, and 70–90 %, among African-American, Caucasian, and Asian individuals, respectively [31]. Of note, rare *VKORC1* coding region mutations also have been identified that are strongly correlated with warfarin resistance.

Taken together, common *CYP2C9* and *VKORC1* variant alleles account for approximately 35 % of interindividual

dose variability [36, 37], which can be used in conjunction with known clinical variables (e.g., age, race, body weight, gender) to predict individual therapeutic warfarin doses. These data prompted the US Food and Drug Administration (FDA) to modify the warfarin label noting the importance of pharmacogenetic testing with dosing recommendations based on *CYP2C9* and *VKORC1* genotypes (Table 21.6).

Clinical Utility

Using genotype information to guide initial warfarin dose has the potential to improve initial dosing accuracy, reduce the time to attain a stable dose, and lead to improved outcomes in warfarin-treated patients, such as decreased hemorrhagic or thrombotic events associated with supra- or subtherapeutic anticoagulation, respectively. Several dosing algorithms have been developed that incorporate demographic, clinical, and genetic variables (including variant *CYP2C9* and *VKORC1* alleles) [39], and some are freely available online (http://www.warfarindosing.org/) [36, 37]. As noted above, to facilitate physician interpretation of clinical *CYP2C9* and *VKORC1* genotyping, the FDA updated the "Dosage and Administration" section of the warfarin label in 2010 to include a table containing stable maintenance doses (Table 21.6). Although these label dosing recommendations are likely to be more accurate than empiric dosing (i.e., 5 mg/day), a retrospective study has shown that pharmacogenetic-guided dose prediction is more accurate than both empiric dosing and the dosing guideline table listed on the warfarin label [40]. However, recently reported randomized clinical trials indicate that although pharmacogenetic-guided dosing is more accurate than routine fixed dosing [41], a dosing algorithm with only three *CYP2C9* and *VKORC1* variants common among Caucasians is not superior to a clinical variable dosing algorithm, particularly among individuals of African ancestry [42]. As such, a major issue behind pharmacogenetic-guided warfarin dosing continues to be the appropriate selection of *CYP2C9* and *VKORC1* variants for a given ethnicity and the ongoing debate over clinical utility [43, 44].

Available Assays

Most commercial assays for warfarin genotyping include the *CYP2C9*2* and **3* alleles and *VKORC1* c.-1639G>A (or the linked c.174-136C>T [1173C>T] allele) together in a multiplexed assay. FDA-approved or FDA-cleared *CYP2C9–VKORC1* genotyping platforms include the INFINITI® Warfarin Assay (AutoGenomics, Inc., Vista, CA), eSensor® Warfarin Sensitivity Test (GenMark Diagnostics, Inc., Carlsbad, CA), Verigene® Warfarin Metabolism Nucleic Acid Test (Nanosphere, Northbrook, IL), and the eQ-PCR™ LC Warfarin Genotyping Kit (TrimGen, Sparks, MD). Other assays, many with additional variant alleles, not currently FDA-approved, are available from AutoGenomics, Inc., GenMark Diagnostics, Inc., and Luminex Molecular Diagnostics. Importantly, analytical performance for these platforms is very good, with high concordance being reported for the AutoGenomics, Luminex, Invader, and pyrosequencing assays [45].

Interpretation

The American College of Medical Genetics and Genomics has published guidelines on *CYP2C9* and *VKORC1* genotyping for warfarin sensitivity [46]. *CYP2C9* results are reported with a predicted metabolizer status (e.g., extensive, intermediate, poor) and *VKORC1* c.-1639G>A results with a predicted degree of sensitivity (e.g., G/G, low; G/A, intermediate; A/A, high). Since most currently available *CYP2C9* and *VKORC1* genotyping tests do not include the rare *VKORC1* coding region mutations, they will not be able to assess warfarin resistance.

Laboratory Issues

Some assays will interrogate the *VKORC1* c.1173C>T allele that is in linkage disequilibrium (LD) with c.-1639G>A [46]. Although this allele will provide results consistent with c.-1639G>A for most populations, the LD is reduced in individuals of African descent [38], which may result in c.1173C>T being less predictive for warfarin dosing. As mentioned above, other variables influence warfarin dose variability such as gender, body mass, other medications, and age. If laboratories do not provide a predicted therapeutic dose in their reports, they should include where physicians can incorporate genotype results with other clinical variables into pharmacogenetic dosing algorithms. Two commonly used algorithms are available online (http://www.warfarindosing.org/ and http://www.pharmgkb.org/guideline/PA166104949) and are recommended by CPIC practice guidelines when genotype results are available [47].

Table 21.6 Range of expected therapeutic warfarin doses based on *CYP2C9* and *VKORC1* genotypes[a]

	CYP2C9					
***VKORC1* (c.-1639G>A)**	****1/*1***	****1/*2***	****1/*3***	****2/*2***	****2/*3***	****3/*3***
G/G	5–7 mg	5–7 mg	3–4 mg	3–4 mg	3–4 mg	0.5–2 mg
G/A	5–7 mg	3–4 mg	3–4 mg	3–4 mg	0.5–2 mg	0.5–2 mg
A/A	3–4 mg	3–4 mg	0.5–2 mg	0.5–2 mg	0.5–2 mg	0.5–2 mg

TPMT

Thiopurine *S*-methyltransferase (TPMT) inactivates azathioprine, 6-mercaptopurine (6-MP), and 6-thioguanine. These drugs are used to treat acute lymphoblastic leukemia [48], autoimmune diseases [49, 50], and inflammatory bowel disease [51, 52], as well as to prevent rejection of solid organ transplants [53]. They are metabolized to 6-thioguanine nucleotides (6-TGN) by hypoxanthine-guanine phosphoribosyltransferase (HGPRT). The TGNs are incorporated into the DNA of dividing cells and inhibit several metabolic pathways; the exact mechanism of action is not known but likely is a combination of inducing apoptosis and inhibiting cell metabolism.

About 10 % of the population have intermediate levels of TPMT activity and 0.3 % have low or undetectable enzyme activity and are considered TPMT deficient. Individuals with low TPMT activity are at risk for 6-thioguanine-mediated toxicity, but may be treated successfully with decreased doses. When TPMT enzyme activity is reduced, proportionately more 6-MP may be converted into the active and cytotoxic TGNs. Since TPMT catalyzes the metabolism of TGNs, low TPMT activity results in the accumulation of the active/cytotoxic metabolites. Excess 6-thioguanine in the bone marrow inhibits purine synthesis, thus inhibiting cell proliferation, and contributes to excess myelosuppression. Accordingly, individuals at risk for 6-thioguanine-mediated toxicity can be treated with decreased doses of thiopurine drugs. Identifying at-risk individuals prior to treatment can be accomplished by genotyping the most common *TPMT* variant alleles (Fig. 21.4; Table 21.3); however, genotyping alone does not replace the need for clinical monitoring of patients treated with thiopurine drugs.

Clinical Utility

TPMT genotyping is used to identify patients prior to initiating therapy who may be at risk for severe myelosuppression with standard dosing. One copy of a nonfunctional *TPMT* allele is associated with intermediate enzyme activity and an increased risk for bone marrow toxicity. Two copies of nonfunctional alleles result in lack of TPMT activity and a high risk for severe myelosuppression. Carriers of one copy may need a dose reduction, while individuals who have two nonfunctional alleles require significant dose reduction. A CPIC guideline with dosing recommendations for azathioprine, mercaptopurine, and thioguanine based on *TPMT* genotype is available [54] (Table 21.7).

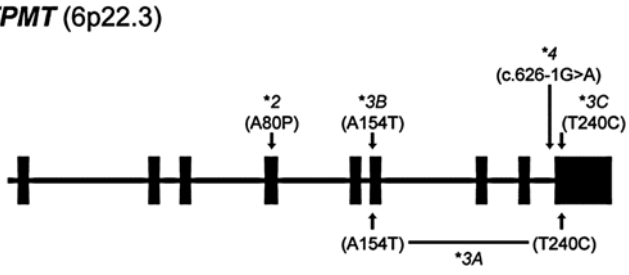

Figure 21.4 Gene diagram of *TPMT* (and chromosome location) indicating common alleles and their molecular alteration (in *parentheses*)

Available Assays

Among the over 20 variants described in *TPMT*, three common alleles (**2*, **3A*, and **3C*) are often included in testing panels [55, 56]; however, panels with additional variants also are available [57]. PCR-based assays that interrogate the three common variants detect 80–95 % of low and intermediate enzyme activity individuals in the Caucasian, African-American, and Asian populations [58]. The analytical performance of *TPMT* genotyping is generally high for most testing platforms. Of note, *TPMT* genotyping tests have high specificity and positive predictive values, but lower sensitivity and negative predictive values [59].

Interpretation

Patients with reduced-function or nonfunctional alleles are at high risk of bone marrow toxicity and require significant dose reduction (ten-fold lower than the standard dose) [54]. One copy of a nonfunctional or reduced-function allele may be associated with an increased risk of toxicity, with possible dose reductions of 30–50 % [54]. Therapeutic drug monitoring may help optimize dosing for individuals with one or two *TPMT* mutations; however, myelosuppression may be due to other factors, such as drug-drug interactions. When none of the targeted *TPMT* mutations are detected, patients are presumed to have normal TPMT activity, be at low risk of bone marrow toxicity, and treated with the standard dose. However, unless the gene is sequenced, the patient still may have an undetected and/or rare *TPMT* variant that affects enzyme activity.

Laboratory Issues

In addition to genotyping assays, TPMT phenotyping for enzyme activity and metabolite tests also are available. However, enzyme phenotype testing should be done prior to treatment because the drug or metabolites may directly interfere with assay performance. Given that other polymorphic enzymes are involved in mercaptopurine metabolism (e.g., inosine triphosphatase [ITPA]) and that not all *TPMT* variants are detected by genotyping, *TPMT* genotype results may not always correlate with phenotype test results. For example, selected studies on azathioprine-treated rheumatic patients suggest that *TPMT* genotyping alone may not be sufficient to personalize azathioprine dosage and that TPMT enzyme and azathioprine metabolite

Table 21.7 CPIC recommendations for *TPMT*-directed dosing of azathioprine[a]

Predicted TPMT phenotype	Implications for azathioprine metabolism	Therapeutic recommendations
Homozygous wild-type or normal, high activity (two functional **1* alleles)	Lower concentrations of TGN metabolites, higher methyl-TIMP; normal	Start with normal starting dose (e.g., 2–3 mg/kg/day) and adjust doses of azathioprine based on disease-specific guidelines. Allow 2 weeks to reach steady state after each dose adjustment
Heterozygote or intermediate activity (one functional allele—**1*, plus one nonfunctional allele—**2*, **3A*, **3B*, **3C*, or **4*)	Moderate to high concentrations of TGN metabolites; low concentrations of methyl-TIMP	If disease treatment normally starts at the "full dose," consider starting at 30–70 % of target dose (e.g., 1–1.5 mg/kg/day) and titrate based on tolerance. Allow 2–4 weeks to reach steady state after each dose adjustment
Homozygous variant, mutant, low, or deficient activity (two nonfunctional alleles—**2*, **3A*, **3B*, **3C*, or **4*)	Extremely high concentrations of TGN metabolites; fatal toxicity possible without dose decrease; no methyl-TIMP metabolites	Consider alternative agents. If using azathioprine start with drastically reduced doses (reduce daily dose by ten-fold and dose thrice weekly instead of daily) and adjust doses of azathioprine based on the degree of myelosuppression and disease-specific guidelines. Allow 4–6 weeks to reach steady state after each dose adjustment. Azathioprine is the likely cause of myelosuppression

CPIC Clinical Pharmacogenetics Implementation Consortium; *TGN* 6-thioguanine nucleotide; *TIMP* 6-thioinosine monophosphate; *TPMT* thiopurine S-methyltransferase

[a]Adapted from Relling et al. [54]. Note that this CPIC guideline also has *TPMT*-directed guidelines for mercaptopurine and thioguanine

assays may be warranted in this context [49]. However, given the reliability of *TPMT* genotyping and that performing both genotyping and phenotyping is not typically feasible, genotyping may be considered the primary choice for pretreatment evaluation of TPMT function before initiation of thiopurine therapy [60].

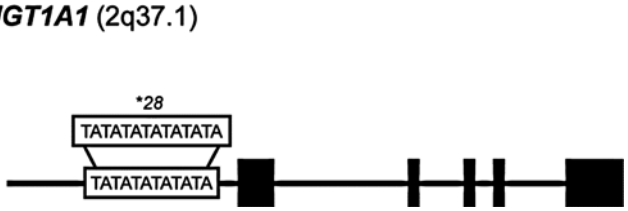

Figure 21.5 Gene diagram of *UGT1A1* (and chromosome location) indicating the **28* allele associated with irinotecan sensitivity

UGT1A1

The UDP-glucuronosyltransferases (UGT) are a superfamily of enzymes that aid in drug excretion by conjugating glucuronic acid, which renders drugs and endogenous compounds more hydrophilic and amenable to biliary or renal elimination. A number of UGT family members have been identified and one of the most commonly studied is encoded by the *UGT1A1* gene [61]. The most important variant *UGT1A1* alleles is **28*, which is a promoter polymorphism comprised of seven thymine-adenine (TA) dinucleotide repeats [$(TA)_7TAA$] [62], compared to the normal *UGT1A1*1* allele with six TA repeats [$(TA)_6TAA$] (Fig. 21.5). Importantly, the length of the TA repeat sequence is inversely correlated with UGT1A1 activity [63]. Consequently, *UGT1A1*28* heterozygotes and homozygotes have an approximately 25 % and 70 % reduction in enzyme activity, respectively [63]. Five [$(TA)_5TAA$] and eight [$(TA)_8TAA$] repeats also have been reported, but due to their rarity, they are not well studied. In addition, **28* has been associated with Gilbert's syndrome, an inherited unconjugated hyperbilirubinemia that does not indicate liver damage but affects the metabolism of several substances [64].

Irinotecan commonly is used to treat advanced stage colorectal cancer and may be used for the treatment of lung, brain, and breast cancers. Irinotecan is a prodrug that is activated to SN-38, which is then conjugated by UGT1A1 to excretory glucuronides (SN-38G). Patients with the *UGT1A1*28* allele are at higher risk for irinotecan toxicity (e.g., neutropenia), particularly when administered at higher doses, since they express lower levels of UGT1A1-mediated glucuronidation activity [65–67]. These data prompted the FDA, in 2005, to modify the irinotecan drug label with information on toxicity risk due to *UGT1A1*28* and the availability of clinical genetic testing. Like other variant pharmacogenetic alleles, the frequencies of *UGT1A1*28* vary between populations with the **28/*28* genotype ranging from 1 to 2 % in Asians to approximately 10 % and 20 % in Caucasians and individuals of African descent, respectively [61].

Clinical Utility

The most commonly tested *UGT1A1* alleles are the promoter TA dinucleotide repeats that influence gene transcription and UGT1A1 activity. The wild-type **1* allele (six TA repeats) is associated with normal enzyme activity and the **28* allele (seven TA repeats) is associated with reduced activity. This test can be used prior to irinotecan administration to predict toxicity or after exposure to explain adverse effects such as severe diarrhea and neutropenia. However, no study has prospectively documented the potential benefits (reduced adverse drug events) or harms (reduced proportion of responsive tumors) from changes in irinotecan dosing based on *UGT1A1*28* genotyping.

Available Assays

Several assays are available that detect the *UGT1A1* TA repeat polymorphism. The most straightforward assay is a laboratory-developed test involving fluorescent PCR amplification and size separation by capillary electrophoresis. This assay also detects the less common five and eight TA repeat alleles. One *UGT1A1*28* genotyping test has been FDA-approved, the Invader® UGT1A1 Molecular Assay from Hologic, Inc. (Madison, WI). The analytic validity of current *UGT1A1* genetic testing methods is adequate, and available data indicate that both analytic sensitivity and specificity for the **1* and **28* alleles are high [68].

Interpretation

One or two copies of the *UGT1A1*28* allele predict irinotecan sensitivity. The rare five repeat allele is assumed to maintain efficient transcription, while the rare eight repeat allele indicates irinotecan sensitivity similar to the seven repeat allele (**28*). Although the Evaluation of Genomic Applications in Practice and Prevention (EGAPP) Working Group found that the evidence was insufficient to recommend for or against the routine use of *UGT1A1* genotyping in patients with metastatic colorectal cancer who are treated with irinotecan [68], the Royal Dutch Pharmacists Association – Pharmacogenetics Working Group has evaluated therapeutic dose recommendations for irinotecan based on *UGT1A1* genotype and recommended dose reduction for **28* homozygous patients receiving more than 250 mg/m^2 [25].

Laboratory Issues

Genotyping assays that interrogate *UGT1A1* need to be robust, since often the patient is being treated with chemotherapy and may have low white cell counts, yielding minimal DNA from a peripheral blood specimen. Some research gaps reported by the EGAPP include the need for prospective studies of *UGT1A1* genotyping and clinical decision-making with clinical outcomes, which are needed to answer the overarching question of clinical utility.

Future Perspectives

The continued progression of translational genomics research will undoubtedly identify more DNA variants associated with drug response variability. In addition, future studies are warranted to assess the clinical utility of pharmacogenetic-guided therapy, including cost-effectiveness studies. Although the FDA continues to modify labels by adding pharmacogenetic information and genetic testing recommendations, a number of obstacles remain for effective clinical use of pharmacogenetic test results, including physician education, regulatory issues, rapid turnaround time testing [69], and reimbursement [70]. To address some of these issues, some large academic medical centers are deploying progressive preemptive pharmacogenetic testing for specific patient populations [71–74]. In addition, ongoing whole-exome and genome sequencing programs will undoubtedly change the future landscape of clinical pharmacogenomics by enabling the rapid identification of additional genetic variants implicated in drug response. Of great importance is the continued study of the clinical utility of pharmacogenetics and the incorporation of both genetic and nongenetic variables for the most effective use of personalized medicine.

Inherited Breast Cancer

22

Rachel Michaelson-Cohen, Rachel Beeri, Eliahu Golomb, and Ephrat Levy-Lahad

Abstract

Inherited mutations in high-risk breast cancer-predisposing genes explain approximately 10 % of all breast cancer cases. Most of these mutations are in the *BRCA1* and *BRCA2* genes, as part of hereditary breast and ovarian cancer (HBOC). Others are in genes associated with syndromes which include a wider spectrum of malignancies and/or distinct clinical features. Molecular analysis, guided by clinical criteria and application of risk assessment models, currently reveal the underlying cause in roughly half of hereditary breast cancer families. Women who have inherited mutations in the *HBOC* genes have a high lifetime risk for both breast cancer and ovarian cancer. In *BRCA1* and *BRCA2* carriers, effective surveillance and prevention measures (such as risk-reduction salpingo-oophorectomy) reduce morbidity and mortality, and mutation status can enable targeted therapy (such as PARP inhibitors).

Clinical genetic analysis for suspected inherited predisposition to breast cancer, previously mostly limited to Sanger sequencing of *BRCA1* and *BRCA2*, has been transformed by next-generation sequencing (NGS) technology, which enables rapid and simultaneous analysis of multiple genes. The ability of NGS assays to accurately and cost-effectively detect all classes of mutations, including large rearrangements, offers an important advantage over previous testing strategies. However, clinical interpretation of variants remains a significant challenge even in the well-studied *BRCA1* and *BRCA2* genes, let alone other breast cancer-associated genes. Testing numerous individuals is revealing an ever greater number of rare variations, whose effect on gene and protein function remains unclear. Reporting such variants of unknown significance is not driven by their clinical utility, and there is an urgent need for improved strategies to assess their functional and clinical effects. Testing genes beyond *BRCA1* and *BRCA2* is further complicated by the current lack of evidence-based guidelines for surveillance and prevention measures, even for carriers of mutations in genes considered to be clear moderate-risk predisposition genes.

Nevertheless, identifying cancer-predisposing mutations is increasingly feasible, will lead to optimized, personalized care for mutation carriers, and is likely to provide insights of broader relevance to cancer.

Introduction

Breast cancer is the most common invasive cancer in women and in Western countries is the leading cause of cancer deaths in women after lung cancer. Breast cancer risk is affected by both environmental/behavioral and genetic factors, reflecting complex disease etiology. Established risk factors include age, family history of breast cancer, reproductive behavior, hormonal exposures, lifestyle habits, and personal breast-specific history (e.g., mammographic density, previous breast cancer, breast biopsy features of benign lesions) [1]. Family history of breast cancer is the most significant risk factor after female gender and older age. In the Swedish Family-Cancer Database, the attributable risk of a positive family history was estimated at about 11 % [2]. The risk to relatives of a person with breast cancer increases with closer degree of relationship and with younger age at cancer diagnosis [3]. Presence of an affected first-degree relative confers a relative risk of 1.76–2.96, depending on the age at diagnosis and the tumor's receptor status [4]. Male breast cancer is rare in general and has a higher genetic component than female breast cancer [5].

The Molecular Basis of Inherited Breast Cancer

Inherited mutations in high-risk breast cancer-predisposing genes explain 8–10 % of all breast cancer cases [6]. Most of these mutations are in the *BRCA1* and *BRCA2* genes, which were identified in 1994 and 1995, respectively, as the bases of hereditary breast-ovarian cancer syndrome (HBOC). More rarely, breast cancer predisposition is caused by mutations in genes associated with other syndromes which include a wider spectrum of malignancies and/or distinct clinical features. Examples include *TP53* (Li-Fraumeni syndrome), *PTEN* (Cowden syndrome), and *STK11* (Peutz-Jeghers syndrome). Molecular analysis guided by clinical criteria [7, 8] and application of risk assessment models (see below) currently reveal the underlying cause in roughly half of hereditary breast cancer families [9].

The remaining cases have been the subject of intense investigation in the past 15 years, but this has not led to the discovery of additional major breast cancer genes. Although some familial aggregates may be explained by mutations conferring moderate (two- to three-fold) risks, e.g., *CHEK2* or *ATM* mutations, or by combinations of low-risk alleles [10], a plausible explanation is that non-*BRCA1–BRCA2* hereditary breast cancer is caused by high-risk mutations in a large number of genes, with each gene mutated in only a small proportion of families [11]. This hypothesis is being tested, with the advent of genome sequencing in clinical practice. Indeed, *RAD51C* [12] and *RAD51D* [13] mutations have been identified as rare causes of HBOC (approximately 1 % of non-*BRCA1–BRCA2* families), and a significant number of new genes can be expected to be identified in the near future.

BRCA1 and *BRCA2* Structure and Function

BRCA1 (NG_005905.2) and *BRCA2* (NG_012772.1) were identified as genes mutated in HBOC, by genetic analysis in families with multiple cases of these malignancies [14, 15]. The *BRCA1* gene on chromosome 17 encodes a 7.8 kb transcript composed of 24 coding exons that is translated to a 1,863 amino acid (220 kD) protein [16]. BRCA1 is a chromatin-interacting protein with an amino-terminal RING domain that has E3 ubiquitin ligase activity, a nuclear localization signal, and the BRCA1 C-terminal (BRCT) phosphopeptide-binding domain, which is conserved in multiple proteins involved in the DNA damage response (DDR). The *BRCA2* gene on chromosome 13 encodes a 10.4 kb transcript composed of 27 exons that is translated to a 3,418 amino acid (380 kD) protein. BRCA2 contains a DNA-binding domain (DBD) that binds both single-stranded DNA (ssDNA) and double-stranded DNA (dsDNA), eight BRC repeats that bind RAD51, a key protein in homologous recombination (HR), and a C-terminal NLS [17].

Both BRCA1 and BRCA2 play important roles in the DDR, the cellular defense mechanism against genotoxic stress. The DDR is a multistage process that includes sensing ssDNA and dsDNA breaks (DSBs), mediating between

sensors and repair effectors, and repairing DNA damage. Impairment of the DDR can lead to genomic/chromosomal instability, a hallmark of many malignancies, and indeed, cells lacking either BRCA1 or BRCA2 have multiple chromosomal aberrations, suggesting that both proteins function as "caretakers" of genomic integrity (reviewed in Ref. 17). Additional BRCA1 roles include estrogen receptor (ER) signaling [18], TP53 stabilization, and transcription modulation including heterochromatin-mediated silencing [19]. BRCA2 has more limited functions and, by recruiting RAD51, is primarily a co-effector of DNA repair by HR, in which the undamaged sister chromatid is used as an accurate template for DSB repair. The BRCA1-PALB2 complex is required for BRCA2 recruitment [17], and RAD51 binding to the BRCA2-BRC repeats facilitates recruitment of RAD51 to DSBs [20].

BRCA1 and *BRCA2* Mutations

Mutational analysis is complicated by the large size of the *BRCA1* and *BRCA2* genes and the wide variety and distribution of mutations. Interpretation of test results is complicated by occurrence of variants of unknown significance (VUS, see below). Both public and commercial databases curate *BRCA1* and *BRCA2* mutations. The National Human Genome Research Institute hosts the Breast Cancer Information Core (BIC) (see URL list), which at the time of this writing includes 15,311 entries for *BRCA1*, with 1,787 distinct mutations, polymorphisms, and variants, 981 of which had been reported only once. For *BRCA2*, BIC contains 14,914 entries, including 2,000 distinct mutations, polymorphisms, and variants, 1,065 of which have been reported only once. Additional online databases include the Human Gene Mutation Database (HGMD, see URL list), the Leiden Open Variation Database (LOVD), and ClinVar (see URL list).

Founder Mutations

The frequency and spectrum of *BRCA1* and *BRCA2* mutations are highly dependent on ethnicity [21, 22]. While the majority of mutations are rare, "private" mutations observed in single cases or families, some mutations recur in particular ethnic groups and are called founder mutations. These founder mutations are thought to have occurred once in the history of an ethnic group and predominate because of population isolation and expansion. *BRCA1* and *BRCA2* testing is obviously simplified when founder mutations account for a high proportion of mutations in a specific ethnic group.

Founder *BRCA1* and *BRCA2* mutations have been described worldwide including in Norway [23], Sweden [24], Poland [25], and numerous other countries, as well as in many ethnic groups [21], including people of African ancestry [26]. Perhaps the most prominent examples are the founder mutations in Ashkenazi Jews (Jews of European origin) and in Iceland. Among Ashkenazi Jews, two *BRCA1* mutations (185delAG and 5382insC) and one *BRCA2* mutation (6174delT) are found in approximately 2.5 % of healthy individuals and account for approximately 10 % of all breast cancer cases, approximately one quarter of breast cancers diagnosed before age 40, and approximately 40 % of ovarian cancer at any age [27, 28]. Other *BRCA1* and *BRCA2* mutations are rare [29].

In Iceland, the frequency of the common *BRCA2* mutation (999del5) is 0.4 % and accounts for 8.5 % and 7.9 % of breast cancer and ovarian cancer patients, respectively [30]. In addition, a rare *BRCA1* founder mutation (G5193A) is present in 1 % of cases of breast cancer and ovarian cancer [21]. In males, these Icelandic founder mutations are responsible for about half of male breast cancer cases and a large percentage of prostate cancer in breast cancer families. Founder mutations also include deletions and duplications. The 6 kbp *BRCA1* exon 13 duplication is an ancestral British mutation found in 10 of 1,831 (0.5 %) of affected families [31]. Three *BRCA1* genomic deletions in exons 22, 13, and 13–16 account for as much as 36 % of *BRCA1* mutations in families of Dutch ancestry [32].

Clinical Utility of *BRCA1* and *BRCA2* Testing

Cancer Risks in *BRCA1* and *BRCA2* Mutation Carriers

Women who have inherited mutations in the *BRCA1* and *BRCA2* genes have a high lifetime risk of breast cancer (56–84 %) [27, 33–35], an increased risk of contralateral breast cancer [27, 36–39], and a substantial lifetime risk of ovarian cancer (11–62 %, depending on the gene involved and the population studied) [27, 36, 37, 40, 41]. The average age at diagnosis of both breast and ovarian cancer is generally younger for *BRCA1* carriers than for *BRCA2* carriers, but each can manifest as breast cancer in the 20s. In addition to breast and ovarian cancer, an excess of male breast cancer occurs in *BRCA2* families and to a lesser extent in *BRCA1* families [29]. Lifetime risk of breast cancer is about 6 % for male *BRCA2* carriers and is probably lower for male *BRCA1* carriers. *BRCA2* mutations also are associated with an excess risk for prostate cancer in males and for pancreatic cancer and melanoma in both sexes.

In fact, *BRCA2* has been considered an important pancreatic cancer predisposition gene for many years [42], and more recent reports have estimated that it accounts for 6–12 % of pancreatic cancer families [43, 44]. *BRCA1* and *BRCA2* mutation carriers have a 2.5-fold and 3.5- to 10-fold

increased risk of pancreatic cancer, respectively [45, 46], although absolute risks are low (<2 %) [47].

Risk Management in *BRCA1* and *BRCA2* Mutation Carriers

Effective cancer risk management strategies are available for *BRCA1* and *BRCA2* carriers as well as for families with a high clinical suspicion of genetic predisposition. HBOC management includes both surveillance and preventive measures, e.g., early breast cancer surveillance (from age 25 to 30 years) by annual mammography and breast MRI, chemoprevention for breast (e.g., tamoxifen) and ovarian (e.g., oral contraceptives) cancers, and risk-reducing (RR) surgery by mastectomy (RRM) and salpingo-oophorectomy (RRSO). Two large prospective studies [48, 49] showed that in *BRCA1* and *BRCA2* carriers, RRSO reduces overall mortality by 60–77 %. Breast cancer-specific mortality was reduced by 56 % and ovarian cancer-specific mortality by 79 % [48].

Testing Family Members

In the setting of a known familial mutation, identifying a relative as a noncarrier obviates the need for aggressive surveillance and prevention measures and provides reassurance to the individuals tested as well as to their offspring. Identifying that a person is a *BRCA1* or *BRCA2* carrier provides an opportunity for effective interventions.

Therapeutic Implications

Testing may have clinical implications for individuals newly or previously diagnosed with breast or ovarian cancer. Some evidence indicates that tumors in *BRCA1* and *BRCA2* mutation carriers are particularly sensitive to platinum-based chemotherapy (reviewed in Ref. 50), and a new class of compounds, poly-ADP-ribose-polymerase (PARP) inhibitors, were designed specifically to target BRCA-associated tumors. PARP inhibitors target the ssDNA repair pathway. Unrepaired ssDNA breaks convert to DSBs, which cannot be repaired by BRCA-deficient cells, resulting in selective synthetic lethality of these tumor cells [51]. A PARP inhibitor has already been approved by the FDA for advanced ovarian cancer in *BRCA* mutation carriers [52, 53], heralding the therapeutic utility of *BRCA1* and *BRCA2* testing in treatment selection. Responses have also been observed in BRCA carriers with pancreatic cancer, and clinical trials are underway with various PARP inhibitors in a variety of BRCA and BRCA-pathway-associated tumors [52, 54, 55].

BRCA1 and *BRCA2* Testing

Breast Cancer Pathology in *BRCA1* and *BRCA2* Mutation Carriers

Gene expression analysis studies indicate five major breast cancer types: luminal A, luminal B, "normal breast-like," HER2 amplified, and basal [56, 57]. Luminal A tumors tend to be of lower grade, showing tubule formation, lower proliferative activity, cellular pleomorphism, and estrogen (ER) and progesterone receptors (PR) expression, and lack of HER2 amplification. Luminal B tumors tend to be high grade (show high proliferative activity and pleomorphism, with little or no tubule formation), express ER and PR, and show variable HER2 expression and amplification. Basal-type carcinomas tend to be high grade, not to express ER, PR, or HER2 (i.e., are triple negative), and express the high molecular weight cytokeratins: 5/6 and 14 and/or EGFR1. This basal group includes medullary and atypical medullary breast carcinomas. The *HER2* oncogene amplification subtype tends to be high grade and not to express ER or PR.

BRCA1-associated breast cancers tend to be basal-type, high grade, and show a syncytial growth pattern with metaplastic features more than sporadic and other familial breast cancers. Basal-type carcinomas are 27 times more likely to be associated with a *BRCA1* mutation compared to other breast cancer subtypes [58]. In contrast, *BRCA2*-associated breast cancers have less distinct morphological characteristics. *BRCA2*-associated breast cancers tend to have luminal B-type features, i.e., tubule formation, "pushing" borders, high mitotic counts and proliferative activity (by Ki-67 immunostaining), and ER and PR expression. A differentiating point between *BRCA2*-associated tumors and characteristic sporadic tumors may lie in the discrepancy between their high proliferative activity relative to the "quiescent" features of hormone receptor expression and tubule formation [58] and in the tendency to have "pushing" borders [59]. However, pathological and expression profile differences are neither sufficiently sensitive nor specific to preclude *BRCA1* or *BRCA2* testing in cases lacking these features.

Immunohistochemistry for BRCA1 and BRCA2

Lack of BRCA1 or BRCA2 protein expression occurs in BRCA1- and BRCA2-associated tumors of almost all carriers (except those with missense mutations). This is a result of loss of the normal (nonmutant) allele. In affected persons, tumor BRCA1 and BRCA2 immunohistochemistry (IHC) is a plausible screening test to identify potential carriers, similar to IHC for mismatch repair protein expression to screen for hereditary nonpolyposis colon cancer (HNPCC). IHC for

BRCA1 was originally confounded by conflicting evidence regarding its subcellular localization and lack of robust antibodies, and evidence suggested that it did not reliably identify *BRCA1* carriers [60]. More recent studies demonstrated a 52 % positive predictive value (PPV) in ovarian cancer cases (86 % sensitivity and 78 % specificity for germline mutations) [61] and 80 % sensitivity and 100 % specificity in breast cancers [62]. These studies all used a nuclear staining monoclonal antibody (Ab-1/MS110) against the N-terminus. A reliable BRCA1 C-terminal antibody is not commercially available, precluding distinction between wild-type and truncated BRCA1 proteins. For BRCA2, IHC combining both N-terminal and C-terminal antibodies has been shown to be highly sensitive (95 %) and specific (98 %) in identifying potential carriers of *BRCA2* truncating mutations [63]. However, BRCA1 and BRCA2 IHC is not widely used, probably due to lack of robust BRCA1 IHC, the lack of identification of missense mutations in either gene, and the existence of other mechanisms, e.g., promoter methylation, leading to loss of BRCA1 protein (Meisel et al. 2014).

Refining the morphological and IHC characteristics of carcinomas associated with specific mutations, and quantitative assessment of these associations, may still play a role in prioritizing genetic analysis. Even if new sequencing methods render prioritization superfluous, these correlates remain important for assessment of VUS, both in *BRCA1* and *BRCA2*, and in other susceptibility genes.

BRCA1 and *BRCA2* Genetic Testing Methods

Clinical and Pathological Correlates of *BRCA1* and *BRCA2* Mutations

The complexity of full molecular analysis of *BRCA1* and *BRCA2* has led to attempts to identify clinical, pathological, and gene expression correlates of mutations in these genes, to aid in selecting cases to test and prioritize the genes to be analyzed. Despite the excess of male breast and other cancers in *BRCA2* vs *BRCA1* families, breast and ovarian cancer are the predominant malignancies in both cases, so generally the types of cancers in a family cannot reliably distinguish *BRCA1* from *BRCA2*. More importantly, approximately half of the affected female carriers do not have a significant family history that would have led to testing before their cancer diagnosis [27, 64].

Probability Models

Probability models were developed to estimate the likelihood that an individual or family has a *BRCA1* or *BRCA2* mutation. Testing costs were a major impetus for developing these models, and testing is commonly considered as indicated if the probability of mutation detection is at least 10 % (common in the USA and for privately funded testing) or 20 % (for public health services, e.g., the UK NHS NICE guidelines; see URL list). Although decreasing testing costs and increasing therapeutic implications lessen the relevance of such thresholds, estimating the likelihood of a HBOC mutation remains important because of the complexity of interpreting test results. In particular, the significance of a VUS is in part determined by the PPV calculated a priori by a prediction model.

Two broadly used models are BRCAPRO and Myriad II. BRCAPRO ([65], also see Cancer Pro in URL list) is a computer-based Bayesian probability model that uses breast and/or ovarian cancer family history to determine the probability that a *BRCA1* or *BRCA2* mutation accounts for cancer in the index case. The main parameters integrated in the risk assessment are the population prevalence of mutations, age-specific risks for carriers, and Ashkenazi Jewish heritage. The model is frequently updated, and the recent addition of breast tumor markers (hormone receptor and HER2 status) has improved prediction accuracy [66]). Myriad II (see URL list) is an online set of frequently updated prevalence tables categorized by ethnic ancestry (Ashkenazi Jewish or other), age of breast cancer diagnosis (<50 years or >50 years), and personal or family history of ovarian cancer. Myriad II is based on test results from the Myriad Genetic Laboratories commercial testing service [29]. Both models predict mutation presence more accurately than family cancer history alone and are part of the publicly available, convenient CancerGene software package (Cancer Pro, see URL list), which simultaneously calculates results for both models. In a direct comparison, BRCAPRO had higher sensitivity and similar specificity to Myriad II [67].

Other probability models include the Breast and Ovarian Analysis of Disease Incidence and Carrier Estimation Algorithm (BOADICEA) [68, 69], which performs as well as BRCAPRO [70], Tyrer-Cuzick [34, 71], and the Manchester Scoring System [72]. Notably, most prediction models were developed using data from non-Hispanic Caucasian women and may be less accurate in other populations. Both BOADICEA and BRCAPRO have poorer performance in African Americans and Hispanics [73], and BRCAPRO and Myriad II underpredicted Asian carriers [74].

Standard Genetic Testing Methods

Targeted Mutation Analysis

In relevant populations, targeted founder mutation testing remains the first step in *BRCA1* and *BRCA2* analysis. Because targeted analysis is simple, inexpensive, and detects only clearly pathological mutations, it can be offered to all women affected with breast/ovarian cancer in populations with founder mutations, even without prior risk assessment

as detailed above [64]. Targeted mutation analysis techniques include PCR-RFLP which requires postamplification restriction enzyme digestion and TaqMan real-time allelic discrimination which is more rapid and scalable to high-throughput genotyping. If no founder mutation is detected, full analysis is considered based on the residual likelihood that a *BRCA1* or *BRCA2* germline mutation is present in the particular individual.

Mutation Scanning and Sanger Sequencing

Because Sanger sequencing large genes is both time- and cost-intensive, historically, various scanning techniques were used to detect *BRCA1* and *BRCA2* mutations, e.g., single-strand conformation polymorphism (SSCP) and high-performance liquid chromatography (HPLC). However, sensitivity of scanning is low, with nearly one-third of *BRCA1* and *BRCA2* mutations detectable by sequencing are missed by scanning methods [75]. Therefore, despite higher costs, Sanger sequencing of *BRCA1* and *BRCA2* coding exons and flanking intronic sequences has been the gold standard for non-rearrangement mutation analysis. An important concern with any sequencing technique is identification of VUS which are found in 5–10 % of all fully sequenced individuals ([76] and discussed below).

BRCA1 and *BRCA2* Genomic Rearrangement Testing

Large deletions or insertions are estimated to account for 12–18 % of *BRCA1* mutations but are less frequent in *BRCA2* and in Ashkenazi Jews [77–79]. Such rearrangements are not detectable by Sanger sequencing. In the USA, until many claims of the Myriad patent for *BRCA1* and *BRCA2* testing was invalidated by the US Supreme Court, standard testing included both Sanger sequencing and screening for four large deletions and duplications in *BRCA1*, specifically large deletions in exons 13, 14–20, and 22, and duplication of exon 13. In a study of 20,000 patients, 66 of 2,634 (2.5 %) deleterious mutations were rearrangements [80]. The exon 13 duplication represented 80 % of rearrangement mutations and 2 % of total mutations, making this the most prevalent non-Ashkenazi mutation [80]. Outside the USA, testing for large rearrangements has been comprehensive, revealing that approximately 10 % of *BRCA1* and *BRCA2* mutations are genomic rearrangements ([79], [81]). Genomic rearrangement testing has usually been performed using PCR-based quantitative methods such as multiplex ligation-dependent probe amplification (MLPA) [82]. Even with the advent of next-generation sequencing (NGS) technologies, detection of large genomic rearrangements remains challenging, requiring very high coverage, so complementing NGS with specific rearrangement testing has been advocated [83, 84].

Next-Generation Sequencing of *BRCA1* and *BRCA2*

BRCA1 and *BRCA2* testing has become integral to the clinical management of women with a personal or family history of breast or ovarian cancer [77] and has significantly increased the number of tests performed. In parallel, NGS testing methods allow higher throughput and lower cost per sequenced base. NGS can generate gigabases of nucleotides of sequence data in a single instrument run [85, 86], enabling sequencing of human exomes and genomes (NGS as a method is described in Chap. 59). NGS testing for *BRCA1* and *BRCA2* analysis [83, 87–91] has become routine in many clinical laboratories in the last five years.

NGS for point/small mutation analysis was originally reported using the GAIIx-Illumina MPS platform on templates produced by long-range PCR of the *BRCA1*, *BRCA2*, and *TP53* genes [87] or by in-solution capture using custom-designed complementary RNA oligonucleotide baits for 21 breast/ovarian cancer predisposition genes including *BRCA1* and *BRCA2* [82]. A multiplex bar-coded amplicon pyrosequencing method for *BRCA1* and *BRCA2* analysis was also reported (Roche/GS-FLX) [88, 89], with 98 % sensitivity. Only 3 of 133 (2 %) variants were not detected, which were all deletions or duplications in homopolymers of ≥7 nucleotides, a known limitation of pyrosequencing [88, 89]. All other studies ([82, 87], Hernan et al. 2012, [91]) reported 100 % sensitivity for point mutations and small insertions/deletions (indels). Specificity ranged from 84 % [87] to 100 % [82, 88, 89]. Bar coding strategies that enable pooling samples in one run are available and further reduce sequencing costs without compromising accuracy.

Next-Generation Sequencing for *BRCA1* and *BRCA2* Genomic Rearrangements

Detecting genomic rearrangements is possible with some but not all NGS strategies. De Leeneer et al. reported a lack of detection of large rearrangements, which is typical of NGS using short reads from short-fragment libraries [88, 89]. In contrast, Walsh identified all six large rearrangements tested (160 bp to 101 kbp in size) by comparing the number of reads at each base pair in each sample to the number of reads at the same base pair for all other samples [82]. This read depth analysis was possible because of significantly higher read depth (>1,200 vs 38 in Ref. 88, 89) and use of a mate-paired library template. In mate-paired libraries, template DNA fragments of known size (typically 2–5 kbp) are circularized and re-sheared, so that both ends of the original fragment are adjacent to each other ("mates") in a new fragment which is sequenced. The original distance between the sequenced "mates" is known and can be compared to the expected distance in the reference sequence. This approach is now commonly used in genome-wide detection of structural rearrangements [92, 93].

The ability of NGS assays to accurately and cost-effectively detect all classes of mutations, including large rearrangements, offers an important advantage compared to previous testing strategies, which required multiple techniques to achieve comprehensive *BRCA1* and *BRCA2* analysis.

NGS Testing for Breast Cancer Predisposition Genes Beyond *BRCA1* and *BRCA2*: Advantages and Challenges

In recent years, testing has expanded to cancer predisposition genes other than *BRCA1* and *BRCA2*. These genes can be defined as genes in which rare mutations confer a greater than two-fold relative breast cancer risk [94]. Advances in technology have allowed development of multiplex gene panels in which many genes can be assessed simultaneously by NGS. NGS has made large-scale, high-throughput testing available and affordable. The advantage of this approach is an efficient evaluation that may be only slightly more expensive than standard-of-care genetic testing (or in the case of serial testing even less expensive) [95]. For familial cancer conditions, exome sequencing is gradually becoming more successful and is identifying new breast cancer risk genes [96, 97]. Identification of non-syndromic genes will remain challenging until it is possible to interpret data from testing of thousands of individuals. Analytical prioritization strategies will thus have high utility over the next few years [98].

Identifying a cancer-predisposing mutation will lead to optimized, personalized care for mutation carriers and will probably provide insights of broader relevance to cancer.

Currently, over 20 breast cancer predisposition genes are associated with at least a moderately increased risk for breast cancer, including *BRCA1, BRCA2, TP53, PTEN, STK11, CHEK2, ATM, BRIP1, PALB2, CDH1, RAD51C, RAD51D*, and more genes are likely to be identified in the future [99]. Although approximately 5 % of high-risk patients with negative *BRCA* results can be expected to carry a mutation in *CHEK2* or *TP53* [77], these and other genes were often tested only selectively [100] because of the low expected yield per gene, compounded by high sequencing costs. NGS testing has revolutionized the possibility of multiple gene testing. NGS testing of over 20 genes has been reported at less than half the cost of commercial testing of only *BRCA1* and *BRCA2* [82], and NGS-based panels of multiple cancer-related genes are available in clinical laboratories. Multiple gene testing is also being performed for other familial cancers, such as in Lynch (HNPCC) syndrome and pancreatic cancer [101]. In 278 young onset (<40 years) breast cancer patients in which previous *BRCA1* and *BRCA2* testing was negative, a 20-gene NGS panel revealed a deleterious or likely deleterious mutation in 11 % [102]. A similar yield of 11.4 %, after excluding *BRCA1* and *BRCA2* mutations, was observed in a study of 198 persons including a mix of affected and unaffected high-risk individuals [103].

NGS panels also present a number of challenges. Multiple genes present in current clinical testing panels were chosen based on their participation in cancer pathways (particularly the Fanconi anemia pathway) or on other hypothetical grounds, without previous epidemiological or clinical evidence that they are indeed hereditary cancer predisposition genes [94]. Overestimation of a likely causal link between the presence of a gene variant and cancer in an individual is not rare, since rare coding variations, including putative deleterious mutations, are collectively common [98, 104]. For example, heterozygosity for *MUTYH* mutations was found in 2.2 % of young-onset breast cancer cases, yet *MUTYH* has not been previously shown to be a breast cancer predisposition gene [102]. Furthermore, VUS are more commonly observed as new genes are added to panels, particularly genes for which the full extent of benign variation is not yet described. Currently, the VUS rate is approximately 20 % for a 22-gene panel, with VUS being more common in non-Whites [102]. The extent of VUS will reflect a balance between increasing knowledge of existing variation and the number of genes added to panels. Finally, with respect to clinical utility, it must be recognized that even for genes considered to be clear moderate-risk predisposition genes, evidence-based guidelines for surveillance or prevention measures in mutation carriers are not available [95, 102].

Interpretation of *BRCA1* and *BRCA2* Test Results

Sequencing of *BRCA1* and *BRCA2* generates 36,000 nucleotides of sequence per person, posing problems of data management and leading to detection of multiple variants, often novel. Nonsense mutations, frameshift mutations, and large rearrangements are clearly deleterious, i.e., associated with loss of gene function and highly increased cancer risks. However, in the absence of simple assays for either BRCA1 or BRCA2 function in the presence of identified variants, the clinical significance of missense variants, leading to amino acid substitutions, is more difficult to determine. This is also true of splice site mutations with no clear biological implications, intronic variants, small in-frame indels (inserting or deleting only a single or few amino acids), and silent mutations (nucleotide substitutions that do not change the amino acid). Although over time a large number of such variants have been classified as either pathogenic or benign, many remain unclassified, and full *BRCA1* and *BRCA2* sequencing detects VUS in 5–10 % of individuals tested [76, 105]. VUS pose difficult challenges in genetic counseling and clinical management and are currently assessed using a number of tools, described below.

Literature and Database Searches and Analysis of Control Noncancer Groups

Online databases, e.g., the Breast Cancer Information Core (BIC) database, the BReast CAncer genes IARC database, and ClinVar (see URL list) include information on the possible clinical significance of reported variants. Comparing the frequency of a variant between cancer cases and controls also can indicate if a VUS is pathogenic, if found in the cases with a significantly higher frequency than the controls.

In Silico Assessment of Missense Mutations

Missense variants can be assessed for location within a functional domain of the protein (e.g., the BRCA1-RING finger), evolutionary conservation, and severity of modification of the biophysical characteristics due to the amino acid change. Examples of public, in silico tools for all proteins include SIFT (Sorting Intolerant From Tolerant) and PolyPhen (Polymorphism Phenotyping, see URL list) which predict the possible impact of an amino acid substitution on the structure and function of a specific protein based on sequence homology and comparative physical methods [106, 107]. An in silico analysis using a combination of evolutionary conservation and the Grantham score (a measure of the chemical difference between the normal and mutant amino acids) enabled tentative classification of 50 % of missense VUS observed during clinical testing of *BRCA1* with 50 of 314 missense variants and 2 of 8 in-frame deletions classified as probably deleterious and 92 of 314 missense variants as probably neutral [108, 109].

Assessment of Effects on Splicing

Variants can affect splicing, even if they are located outside exon-intron junctions, e.g., by affecting exonic splicing elements. Therefore, VUS should be analyzed in silico using splicing prediction models and experimentally using RNA-based assays. The BReast CAncer genes IARC database (see URL list) has a *BRCA1*- and *BRCA2*-specific tool which assesses effect of variants on splicing. In a study of VUS using five splicing prediction programs and experimental assays, 10 of 53 VUS were predicted to affect splicing by two or more programs, and four of these predictions were confirmed by splicing assays. Experimental assays showed that another five intra-exonal VUS, though not predicted to alter splicing in silico, caused variable levels of exon skipping [110].

Co-segregation with Cancer in the Family

In families with multiple cases of cancer, a pathogenic mutation is expected to segregate with the disease, i.e., be present in affected relatives and absent in healthy older relatives. Lack of segregation decreases the likelihood that a VUS is pathogenic. However, segregation studies are often not possible, because of small family size, or limited availability of family data and DNA samples, especially for deceased relatives.

Co-occurrence with a Pathologic Mutation

Based on the lethality of both *BRCA1* and *BRCA2* knockout mice, biallelic deleterious mutations in *BRCA1* or *BRCA2* are expected to be lethal or associated with a severe developmental phenotype. Indeed, biallelic *BRCA2* mutations cause Fanconi anemia-type D1 which can include various congenital anomalies [111], and rare biallelic *BRCA1* mutations are associated with severe developmental abnormalities [112, 113]. Therefore, determining that a VUS is in trans with a known deleterious mutation supports its classification as neutral. In general, proving that variants are in trans is complicated by the need to test additional family members to determine the phasing of the mutations based on inheritance patterns in the family [109].

Loss of Heterozygosity in the Tumor

Based on Knudson's two-hit hypothesis, *BRCA*-associated tumors are expected to show loss of heterozygosity (LOH) at the *BRCA* locus more frequently than sporadic tumors [114], mainly through loss of the normal allele. If a VUS is identified in an affected person whose tumor is available, LOH information can be incorporated into integrated models to assess the pathogenicity of the VUS [76].

Tumor Pathological Characteristics

As detailed above, *BRCA1*-associated tumors have characteristic features, which can be helpful in determining VUS pathogenicity [115]. In particular, *BRCA1*-associated breast cancer is more often "triple negative" (lack of ER, PR, and HER2 expression) with a basal-like expression profile and medullary morphology.

Functional Assays

A few studies have utilized functional assay results to refine the likelihood of pathogenicity of missense changes in *BRCA1* or *BRCA2* [116, 117]. A functional assay measuring the effect of missense mutations on BRCA2 activity in HR DNA repair and centriole amplification demonstrated a strong correlation between the functional assay and the likelihood model [116]. Functional assays also have been developed for BRCA1 (reviewed in Ref. 118) and BRCA2 [119].

Classification and Reclassification of *BRCA1* and *BRCA2* Variants

BRCA1 and *BRCA2* are among the largest genes frequently sequenced in the clinical setting, which led to early realization of the issue of VUS, which has become a general issue since NGS testing has moved into clinical care. The *BRCA*-testing community established a research-based consortium, ENIGMA (evidence-based network for the interpretation of germline mutant alleles; see URL list), which aims to facilitate classification of variants through collaborative large-scale projects by sharing data and improving classification methods [120]. This consortium also intends to analyze variants in other cancer predisposition genes and develop generally applicable strategies.

Clinically, *BRCA1* and *BRCA2* VUS pose a significant dilemma for carriers, who must make difficult decisions regarding risk-reduction surgeries based on inconclusive test results. Although a VUS may be reclassified to natural or pathologic over time, clinical decisions must be made in the present, leading some patients to undergo irreversible procedures before VUS reclassification is achieved. Of 107 women who received a *BRCA* VUS result between 1998 and 2009, 11 (10.3 %) pursued RRM and 22 (20.6 %) pursued RRSO [105]. These uptake rates overlap rates for women both with and without clearly pathogenic mutations. Reclassification of VUS occurred up to 9 years after testing, but five of 22 (22.7 %) women, followed up for 8 years or longer, continued to have a VUS result.

Laboratory Issues

Implementing a molecular genetic test for clinical use is a complex process involving many levels of assessment and validation. This is particularly true for implementation of a completely novel technology and is the major laboratory issue confronting cancer predisposition testing. Principles of validation and verification in the area of human molecular genetic testing have been delineated by the EuroGentest Validation Group [121] and by the College of American Pathologists' Molecular Pathology Resource Committee [122]. Use of NGS has only recently transitioned from the research to the clinical setting, and criteria for clinical NGS testing, as well as better delineation of the types of NGS errors, are still evolving [88, 89, 123]. NGS involves multiple steps, including sample preparation, enrichment and capture strategies, library preparation, sequence generation, and sequence analysis including result interpretation and reporting. Furthermore, the volume of data generated by NGS requires new protocols for data transfer, storage, secondary processing, and security [124].

Quality management practices are obviously essential at all stages of the testing process to ensure accuracy and utility. Although proficiency testing/external quality assessment (PT/EQA) schemes for Sanger sequencing of *BRCA1* and *BRCA2* exist, the list of genes for which PT is not available is rapidly growing and potentially encompasses all human genes [125]. Furthermore, a single gene/mutation PT/EQA process is inadequate to assess multigene NGS tests [126]. One alternative is methods-based proficiency testing (MBPT), an EQA scheme that is based on method rather than on each individual gene or specific mutation analyzed. MBPT approaches, such as PT for NGS, would allow assessment of many tests for which formal PT is not available and are likely to be the most efficient, practical, and cost-effective method to measure laboratory proficiency in genome-based sequencing analyses [126]. *BRCA* mutation analysis tests are complex processes, and validation and quality control will be necessary both for sequencing and data-analysis platforms and for the specific tests performed.

Conclusions

Assessment of genetic risk for individuals and families with suspected hereditary predisposition to breast cancer has important clinical implications. Such risk assessment should be performed in the context of genetic counseling and culminate in genetic analysis of relevant genes. Currently, the genetic basis for cancer predisposition can be determined in approximately half of high-risk families, and mutation testing can distinguish between carriers who are at risk and noncarriers who are at background risk. The most commonly mutated genes in HBOC are *BRCA1* and *BRCA2*, and effective surveillance and prevention measures, in addition to targeted therapy, reduce morbidity and mortality in *BRCA1* and *BRCA2* carriers.

Mutation detection and interpretation for the *BRCA1* and *BRCA2* genes is still technically challenging. The large variety and extensive distribution of mutation types mandates the use of multiple mutation detection methods to achieve complete sensitivity, and clinical interpretation is beleaguered by the high prevalence of VUS. Although Sanger sequencing has been the gold standard for clinical *BRCA1* and *BRCA2* testing, new sequencing technologies are producing a sea change in this field, leading to identification of novel breast cancer predisposition genes and enabling large-scale, multiple gene testing.

Familial Adenomatous Polyposis and Turcot and Peutz–Jeghers Syndromes

23

Kandelaria M. Rumilla

Abstract

To date the majority of colorectal cancers are thought to be sporadic. However, familial predisposition has been well recognized for years. Familial adenomatous polyposis coli, Turcot syndrome, Gardner syndrome, and Peutz–Jeghers syndrome are examples of hereditary syndromes that predispose individuals to colorectal adenocarcinoma as well as a host of other malignant, hamartomatous, and benign growths. While not comprehensive of all familial colorectal predisposition syndromes, a summary of these syndromes is provided in this chapter.

Keywords

Familial Adenomatous Polyposis Coli

Familial adenomatous polyposis coli (FAP) is estimated to account for approximately 1 % of colorectal adenocarcinoma in the general population. The reported incidence ranges from 1 in 7,500 [1] to 1 in 30,000 [2] and the penetrance is approximately 100 % by age 40 [3]. Early references to this autosomal dominant disorder date back to the 1880s. By 1960, the association with epidermoid cysts, osteomas [4], and central nervous system tumors had been described [5]. The disease is caused by constitutional mutations in the adenomatous polyposis coli (*APC*) gene identified in 1991 [6]. Variants of FAP also are described and include attenuated FAP (AFAP), Gardner syndrome, and Turcot syndrome.

Clinical Features

Familial Adenomatous Polyposis Coli

While the diagnostic criteria for FAP rests primarily in the number of adenomatous polyps that are identified in the distal colorectum at an early age (>100 colorectal adenomatous polyps), the true impact of this syndrome is seen in the risk for colorectal cancer and other neoplasms. If untreated, virtually 100 % of affected individuals will develop colorectal adenocarcinoma. The average age of diagnosis is 39 years in the classic presentation. The risk for malignant neoplasm is not limited to the colorectum. Individuals with this syndrome are also at increased risk of other malignancies compared to the general population. Adenocarcinomas from other gastrointestinal primary sites (small intestine, including duodenum and periampullary) occur in 4–12 % of patients, while pancreatic adenocarcinoma and papillary thyroid carcinoma (PTC) occur in approximately 2 % of FAP patients. Although this is a small percent of FAP patients, both pancreatic adenocarcinoma and PTC are much less common in the general population; there is 0.2 % incidence of PTC in the general population [7]. FAP is associated with a specific histologic subtype of PTC, the cribriform-morular variant [8], but is not pathognomonic [9]. Gastric adenocarcinoma and medulloblastoma [10] occur in less than 1 % of FAP patients, while hepatoblastoma occurs in approximately 1 of 150 FAP patients under the age of 5. Other malignant tumors arising from the bile duct or adrenal gland are associated with FAP, but are infrequent.

The clinical diagnosis rests on the identification of numerous pre-cancerous adenomatous polyps. Colonic adenomatous polyps can be identified in affected patients at young ages; polyps are present in 50 % of affected individuals by age 16 years, and in 95 % by age 35. Adenomatous polyps can be seen in the stomach of approximately 10 % of patients. Adenomatous polyps of the duodenum and ampulla of Vater can present as intussusception and obstructive pancreatitis, respectively.

Desmoid tumors (proliferation of myofibroblasts) occur in 3.5–32 % of FAP patients. Although most common after surgery, desmoid tumors may occur in the absence of prior surgery and are the presenting symptom in approximately 16 % of FAP patients. Characteristic features, such as abdominal location, may help distinguish FAP-associated and non-FAP-associated desmoid tumors. Gender does not correlate between FAP and non-FAP cases as women have more desmoids than men in both the FAP and non-FAP groups [11].

Hamartomatous and benign lesions seen in FAP include gastric fundic gland polyps (50 % of FAP cases), lipomas, fibromas, sebaceous, and epidermoid cysts [12], osteomas usually affecting the long bones, mandible, or skull, nasal angiofibromas, dental abnormalities ranging from unerupted teeth to absent or supernumerary teeth (17 % of FAP cases). Congenital hypertrophy of the retinal pigment epithelium (CHRPE) is a benign finding which does not affect visual acuity but can be the presenting finding.

Attenuated Familial Adenomatous Polyposis Coli

AFAP is an important clinical phenotypic variant of FAP. AFAP has fewer polyps (from 30 to 100 polyps) which are located more proximal in the colon, and has a later age of onset [13]. The AFAP phenotype can overlap with other syndromes, including MYH-associated polyposis and Lynch syndrome (Hereditary Non-polyposis Colon Cancer, HNPCC). Several criteria have been proposed for clinical diagnosis of AFAP, with most including a lower number of polyps present at slightly older ages with family history, polyposis, or cancer. One example is less than 100 polys by 25 years and an autosomal dominant family history [14]. Most of these proposals do not include mutation status of the *APC* gene, exclusion of other predisposing syndromes, or consideration of other noncolonic manifestations, which likely limits the sensitivity of such diagnostic criteria in clinical practice.

Gardner Syndrome

Gardner syndrome is a clinical diagnosis that includes colorectal adenocarcinoma and colorectal polyposis as seen with FAP plus osteomas, fibromas, or epidermoid cysts within the individual or family.

Turcot Syndrome

Widely recognized as a subset of FAP and Lynch syndrome, Turcot syndrome is defined by the combination of primary colonic neoplasms with synchronous or metachronous malignant central nervous system tumors. As originally described, Turcot syndrome overlaps both FAP and DNA mismatch repair (MMR) defective tumor syndromes with *APC* gene mutations identified in approximately two-thirds of affected individuals. The type of cancer to which patients are predisposed depends in part on the affected gene. For example, the risk of medulloblastoma with an *APC* gene mutation is 92 times greater than for the general population, but the lifetime risk remains low (less than 1 %). *APC* mutations also are associated with astrocytomas and ependymomas. Individuals with mutations in a MMR gene (e.g., *MLH1*, *MSH2*, *PMS2*) are predisposed to glioblastoma.

Prevention and Surveillance

Familial Adenomatous Polyposis Coli

Prevention and surveillance target the detection of malignant and premalignant lesions characteristic of FAP. Evaluation

of patients 18 years or younger identified that 68 % were already symptomatic, which led to the recommendation that colonoscopy screening begin at age 10 years [15]. Controversy remains regarding the use and frequency of some screening tests, such as for hepatoblastoma (alpha-fetoprotein and hepatic ultrasound). The mainstay of screening remains colonoscopy every 1–2 years prior to colectomy. Screening methods also continue to evolve; for example, more recent work done in screening for PTC suggests that ultrasound is more effective than palpation [7]. Other gastrointestinal manifestations also require screening, including esophagogastroduodenoscopy (EGD) for small bowel disease starting at about age 25 years, although the age to start and frequency of screening is not clear. Flexible sigmoidoscopy may be sufficient for initial diagnosis, but insufficient for surveillance in carriers who have not undergone colectomy. For prophylactic colectomy, the extent of resection also is debated [16]. For those who have not had molecular testing or do not have an identified mutation such that the diagnosis is based on clinical diagnosis alone, and first-degree relatives, the recommendation is to have regular colon/sigmoidoscopy from 10 years of age until multiple polyps are found or the patient reaches age 50 years, and then to follow routine population-based colon cancer screening recommendations [17].

As surveillance and prophylactic methods result in longer survival for affected individuals, such that other lesions (including nonmalignant lesions) are becoming more significant as their impact on morbidity and mortality grows. Most notably, 5–20 % of FAP patients who develop desmoid tumors, which can cause compression or obstruction, have significant morbidity or mortality [18]. Fortunately, nonsurgical options are available for treating desmoid tumors, including hormonal therapy, embolization, and chemotherapy, since surgery can trigger the growth of desmoids [19].

Attenuated Familial Adenomatous Polyposis Coli

Surveillance recommendations are similar to FAP with modifications for the lesser severity and later onset of the disease. AFAP surveillance includes colonoscopy every 2–3 years starting at age 18–20 years of age, and EGD by 25 years of age and every 1–3 years depending on extent of small bowel disease observed.

Gardner Syndrome

Appropriate surveillance is similar to FAP for gastrointestinal disease. Recommendations to address other manifestations of Gardner syndrome are less specific, but include physical examinations. Some patients come to clinical attention for cosmetic reasons related to superficial fibromas, or epidermoid cysts.

Turcot Syndrome

Appropriate surveillance is similar to FAP or HNPCC with additional screening and awareness of the increased risk for CNS tumors.

Genetics

Familial Adenomatous Polyposis Coli

Mutations located in the *APC* gene located at 5q21 cause FAP [6]. *APC* encodes a 2,843-amino acid protein, 75 % of which is encoded by the last exon historically numbered exon 15. Approximately 20 % of families with a clinical diagnosis do not have an identifiable mutation using current testing methods. Several possible explanations for this include mutations in regions of the gene not typically tested (introns for example); mutation in a different gene; and de novo mutations that are not represented in the bone marrow. One-third of affected individuals are thought to have a de novo mutation, and may have a more variable phenotype, lack a significant family history, and testing from peripheral blood may be negative or mosaic depending on the sensitivity of the method used for analysis. Genetic counseling is important due to the limitations of testing, and the medical implications of genetic testing. In general, genetic testing is considered standard of care [20]. Additionally, the fact that FAP includes childhood onset of tumors with recommendations for surveillance procedures to begin at 10–12 years of age, genetic screening prior to the age of 18 is medically and ethically supported.

Attenuated Familial Adenomatous Polyposis Coli

Less than 30 % of individuals with AFAP have a germline mutation identified in *APC* [21]. One likely reason for this lower detection rate is the greater degree of overlap in the phenotypic spectrum with other predisposing syndromes, including *MUTYH*-associated adenomatous polyposis syndrome.

Gardner Syndrome

Gardner syndrome is caused by mutations in the *APC* gene, as described above for FAP.

Turcot Syndrome

Turcot syndrome can be caused by *APC* mutations, but also may be caused by mutations in MMR genes. In addition, several different inheritance patterns have been reported, including autosomal dominant, autosomal recessive, and compound heterozygous changes involving *APC* and the MMR genes. Of Turcot syndrome families, 66–80 % have an identifiable mutation in *APC* and 20–33 % have a mutation in one of the MMR genes.

Molecular Mechanism

Familial Adenomatous Polyposis Coli/Attenuated Familial Adenomatous Polyposis Coli

APC functions as a classic tumor suppressor with a role in signal transduction and modulation of transcription factors, which in turn regulate a number of cellular processes including cell division and cell adhesion. The normal APC protein product interacts with a number of components of the Wnt signaling pathway. APC regulates cytoplasmic beta-catenin levels by ubiquitination and degradation, thereby reducing the beta-catenin available to localize to the nucleus and resulting in reduced activation of genes involved in promoting cell proliferation, including *MYC* and cyclin D1 (*CCND1*). Therefore, loss of APC function results in increased levels of beta-catenin by reducing its degradation rate and increased cell proliferation. The increased beta-catenin expression can be seen in the cytoplasm and nucleus by immunohistochemistry. This APC loss of function mechanism for FAP is consistent with the finding that the majority of germline mutations are truncating mutations or result in decreased expression of APC [24].

Genotype–Phenotype Correlation

Familial Adenomatous Polyposis Coli

Although genotype–phenotype correlations involving the locations of mutations in *APC* can be made, variation of the phenotype can be seen between and within families. While some correlations are useful clinically to focus screening procedures, the associations are not definitive. In classic FAP cases, the FAP phenotype is usually clear, but by young adulthood a spectrum that ranges from florid polyposis to a few adenomatous polyps can be seen [22, 23].

Nomenclature of the *APC* gene located on 5q21 can be confusing as there are multiple transcripts with varying numbers of exons. The more common transcript has 15 translated exons that produce a 2,843 amino acid protein [22]. The protein has a number of functional domains including binding sites for beta-catenin, DNA, axin, and microtubules, as well as a nuclear export motif. Two "hot spot" germline mutations occur at codons 1061 and 1309 which together represent approximately 28 % of FAP [17, 24]. Two other important variants in the *APC* gene are p.I1307K and p.E1317Q. Testing for p.I1307K in the Ashkenazi Jewish population has been controversial. The *APC* p.I1307K mutation increases the lifetime risk of colorectal carcinoma to 10–20 %, with an odds ratio of 1.85. The p.I1307K mutation is found in approximately 6 % of the Ashkenazi Jewish population but has been reported in up to 28 % of patients with a family history of colorectal cancer. It is important to note that this mutation is not sufficient to cause a polyposis phenotype and does not alter clinical management of carriers, as many carriers would already be undergoing increased screening due to their family history. Since p.I1307K does not result in a nonfunctional protein, the theorized mechanism by which this mutation results in increased cancer risk is different than typical FAP. The p.I1307K change is thought to create a hypermutable site in *APC* which leads to loss of protein function mutations [25]. Whether or not the p.E1317Q variant confers an increased risk of colorectal carcinoma is not as well established, and the clinical significance remains debatable.

The classic FAP phenotype is associated with mutations involving codons 168–1600, while severe expression of the disease based on number of polyps is associated with mutations in codons 1350–1464. Other associated lesions have also been correlated with the location of the mutation in the *APC* gene, including extra colonic manifestations such as CHRPE which has been associated with mutations in codons 1403–1578 and codons 463 and 1387. Osteomas and desmoids appear to have the highest association with mutations in codons 1395 and 1560. In general, mutations at either end of the *APC* gene, before codon 400 and after codon 1500, and whole gene deletions, have been associated with the attenuated phenotype and have more variable expressivity [24, 26]. Somatic mutations also are common in *APC* but the location of these mutations is more restricted, with about 80 % occurring between codons 1284 and 1580, a region designated as the mutation cluster region [24].

Attenuated Familial Adenomatous Polyposis Coli

AFAP is associated with mutations in different regions of the gene, including: (1) 5′ to codon 157 in exon 4; (2) alternative splice in exon 9; (3) 3′ to codon 1595 in exon 15; and (4) some in-frame deletions [27].

Gardner Syndrome

Desmoid tumors are more strongly associated with *APC* mutations between codons 1444 and 1580 than with mutations either 5′ or 3′ of this region [28].

Turcot Syndrome

Although *APC* mutations between codons 457–1309 have been associated with brain tumors [23], specific genotype–phenotype correlations within the *APC* gene are not widely used. Importantly, medulloblastomas are associated with *APC* mutations and glioblastomas are associated with MMR gene mutations (Lynch syndrome).

Clinical Testing and Laboratory Issues

The methods used for clinical testing of the *APC* gene have changed over the years with direct germline sequencing of the entire coding region becoming more common than targeted testing for specific mutations. Unlike screening assays, sequencing can detect changes in the coding region, flanking sequences and intron/exon boundaries, and can identify novel mutations. Depending on the sequencing method and platform used, there are various pitfalls including inability to detect large deletions and duplications and the interpretation of novel nontruncating alterations that are likely to be classified as variants of unknown significance (VUS). While Sanger sequencing is still commonly used for testing this is being quickly replaced by next-generation sequencing (NGS) and will likely continue to gain momentum as bioinformatics improves and larger insertions/deletions (indels) and copy number variants can be detected by NGS. Large deletion/duplication analysis is routinely performed using multiplex ligation dependent probe amplification assays (MLPA) or array comparative genomic hybridization (aCGH) technologies.

The protein truncation test (PTT) is a screening method that is still used in some clinical laboratories for several reasons. PTT allows for higher throughput mutation screening for the large last exon of *APC* where many mutations are located. Since PTT detects truncated protein products, the underlying mutations are almost certainly deleterious. PTT does have drawbacks, however. For example, missense alterations that have an effect on protein function will likely not be detected, and several gene regions will not be well covered in terms of mutation detection, including alterations outside of the coding regions and mutations that are located at the 5′ or 3′ ends of the segments. Additionally, follow-up sequencing is required to identify the exact sequence change detected by PTT.

Although once common, linkage analysis is rarely performed, but may be useful in cases where sequencing or MLPA fail to detect a specific mutation. This process requires informative markers and participation of affected and unaffected family members, although not all families are large enough or have informative markers to allow for successful linkage analysis. Since a third of cases are de novo, linkage analysis will not be useful for these families.

Other largely historical screening methods include denaturing high-performance liquid chromatography, single strand conformation polymorphism, and denaturing gradient gel electrophoresis. Much like PTT, these methods also require follow-up sequencing for positive results. Other methods, such as allele-specific oligonucleotide hybridization, are useful in specific populations with founder or limited numbers of common mutations (such as p.I1307K), but will not detect other changes.

Testing for AFAP, Gardner syndrome, and Turcot syndrome is similar to testing for FAP. Given the lower detection rate, additional genes should also be considered and can be tested in tandem or parallel to *APC*. Due to the overlap with Lynch syndrome, testing of both *APC* and MMR genes should be considered for patients with a diagnosis of Turcot syndrome.

In general genetic counseling is recommended for a patient undergoing germline testing for a tumor predisposition syndrome. As one of the syndromes in which children can be affected, testing individuals under the age of 18 is acceptable and recommended when the familial mutation is known or the child has symptoms.

Other laboratory issues, such as proficiency testing (PT), have evolved in recent years. Where once a laboratory would have been running PT for each gene/assay, the Collage of American Pathologists (CAP) and the International Program RIQAS are moving towards more platform-based PT, in particular for well-established technologies such as Sanger sequencing. Interlaboratory exchanges also are used to meet PT requirements. Similarly the number and kind of controls that are run with clinical patients has also evolved. As it is impossible to have controls for all possible alterations, representative alterations are often chosen for each platform being used.

Genetic Testing Interpretation and Utility

The clinical sensitivity of *APC* sequencing is approximately 70 % in cases with a clinical diagnosis and family history. Copy number assays for large deletions and insertions add about 5–10 % to the detection rate. Linkage analysis can accurately detect 95–99 % of carriers. In families in which a mutation is identified, genetic testing for the identified mutation in at-risk family members can be useful for determining recommendation and need for surveillance for individuals. Testing and early screening improves the life expectancy of individuals with FAP. There are limitations to testing, as discussed above since mutations are not detected in 20 % of clinically diagnosed cases. There are several possible explanations for this, including that the disease tracking in the family may be a phenocopy of FAP or the mutation in the *APC* gene may be located in an untested region.

Peutz-Jeghers Syndrome

Patients with Peutz-Jeghers syndrome (PJS) have characteristic polyps of the gastrointestinal tract which have low malignant potential, hyperpigmented mucocutaneous lesions, and a family history. PJS occurs in approximately 1 in 8,300–200,000 live births and has an autosomal dominant inheritance pattern. PJS was first reported in 1921 by Johannes Laurentius Augustinus Peutz, with a follow up study of the same family by Westerman [29], and by Harold Joseph Jeghers in 1949 [30].

Depending on the criteria used to classify individuals, up to 25 % are defined as sporadic cases. The clinical diagnostic criteria as established by the World Health Organization are as follows: a positive family history plus either histology-confirmed PJS type hamartomatous polyps or characteristic hyperpigmented mucocutaneous lesions. In the absence of a family history, the clinical criteria for diagnosis of PJS is three Peutz-Jeghers-type polyps or any number of other types of polyps, plus the characteristic pigmentation pattern [31].

Clinical Features

The age of clinical presentation due to symptoms varies widely, with an average age of presentation of 29 years. Variation may be partly due to ascertainment and severity bias, and the availability of genetic testing for clinically asymptomatic individuals. Despite this variation between individuals, the most common presentation due to the gastrointestinal lesions is small bowel intussusception. Other presentations include colon obstruction, GI bleeding, intermittent abdominal pain, and/or rectal prolapse.

Individuals with PJS are predisposed to a number of neoplasms: colon (39 %); small intestine (13 %); stomach (29 %); pancreas (7–36 %); lung (15 %); breast (54 %); benign ovarian sex-cord stromal tumors with annular tubules (21 %); uterus (9 %); adenoma malignum of the cervix (10 %); and estrogen producing sertoli-cell tumors that can lead to precocious puberty and gynecomastia in the testis (9 %) [32–34]. The sites of the pre-cancerous lesions in individuals with PJS reflect the organs that are commonly associated with related malignant neoplasms. One of the two most characteristically associated lesions is the PJS polyp with its pathognomonic smooth muscle extending to the lamina propria with a branching tree-trunk like pattern [35]. Approximately 90 % of these polyps occur in the small intestine and colorectum, and although once thought to be hamartomatous, 33 % can be mixed with an adenomatous component. The other characteristic feature is the hyperpigmented mucocutaneous lesions that often develop prior to the age of 5 years. This feature is not pathognomonic as these lesions are present in approximately 15 % of the general population, as well as with other syndromes/complexes such as Carney's complex [36]. Typically, these dark blue to brown pigmented macules are clustered at mucocutaneous junctions such as the buccal mucosa, perioral areas, nostrils, eyes, and perianal areas, as well as the axillae, hands, and feet. This feature is not consistent within families or within individuals as they tend to fade with increasing age.

In a recent Dutch cohort, the median age of death was 45 years and the median age of living patients was 34 years. The most common cause of death was cancer (67 %), giving a lifetime cumulative cancer risk of 76 %. Overall, this is ten times the risk of the general Dutch population. The authors note that the second-most-common cause of death was intussusception and that deaths from this cause had occurred prior to 1970 and that the ages of these individuals ranged from 3 to 20 years [37].

Prevention and Surveillance

Clinical management of individuals with PJS has primarily centered on surveillance programs that allow for early detection of cancer and management of the cancers that do occur. The debate regarding which organs to monitor, when to start screening, at what time intervals, and by which modalities continues. Several recommendations have recently been proposed. Colonoscopy starting at age 8–10 years with the frequency dependent on the colonoscopy findings, similar time frame for video capsule endoscopy or magnetic resonance enterography and barium follow-through for the small bowel. For women, monthly breast self-examinations beginning at age 18 years, annual breast MRI starting at age 25 years, and standard cervical screening protocols are recommended. For men, the recommendations include yearly testicular exams with ultrasound if abnormalities are detected [33, 38]. Management for these individuals is also likely to undergo changes in the coming years based on the development of new therapeutic options. Potential inhibitor therapy is being assessed in clinical trials using mTOR inhibition with rapamycin or everolimus [39], and inhibitors targeting PI3CA, AKT, and PDK1 are on the horizon.

Genetics

STK11 (previously called *LKB1*) located on chromosome 19p13.3, has been identified as the causative gene for PJS [40, 41]. Over time, the percent of individuals who meet clinical criteria in whom mutations are found has varied widely, ranging from 10–96 % [37, 42, 43]. While it has been

suggested that locus heterogeneity may be present [44], a second locus has yet to be positively identified.

Molecular Mechanism

The *STK11* gene, a tumor suppressor, encodes a 433-amino acid protein that is expressed in both the cytoplasm and nucleus. The STK11 kinase domain (codons 50–337) shares homology with other serine-threonine and tyrosine kinase family members. STK11 is involved in a number of cellular functions, including regulation of cell cycle arrest via CDKN1A (also known as WAF1 and p21) signaling [45]; TP53 mediated apoptosis [46]; cell polarity [47]; metabolism and energy homeostasis [48]; regulation of the WNT signaling pathway [49]; the TSC pathway; and the MTOR pathway [38, 50]. Multiple types of mutations have been identified, including truncating mutations, missense mutations, and deletions.

Genotype–Phenotype Correlation

Mutations have been identified throughout the *STK11* gene and genotype–phenotype correlations have yet to be definitively identified [34, 51].

Clinical Testing and Laboratory Issues

Clinical testing is available and methods most commonly include Sanger sequencing and MLPA, but NGS is rapidly replacing these methods, allowing for larger gene panel testing. Estimated detection rates are associated with the presence or absence of family history, approaching 100 % with a positive family history. Reasons for decreased detection rates in sporadic cases and cases with atypical phenotypes include the disease tracking in the family may be a phenocopy of PJS or the mutation in *STK11* may be located in an untested region, as was discussed above for FAP.

In general, genetic counseling is recommended for a patient undergoing germline testing for a tumor predisposition syndrome. As one of the syndromes in which children can be affected, testing individuals under the age of 18 is acceptable and recommended when the familial mutation is known or the child has symptoms.

Other laboratory issues, such as PT, have evolved in recent years. Where once a laboratory would have been running PT for each gene/assay, the CAP and EQA have been moving towards more platform-based PT, in particular for well-established technologies such as Sanger sequencing. Interlaboratory exchanges also are used to meet PT requirements. Similarly the number and kind of controls that are run with clinical patients has also evolved. As it is impossible to have controls for all possible alterations, representative alterations are often chosen for each platform being used.

Genetic Testing Interpretation and Utility

Regardless of methodology used, careful consideration must be given to the clinical significance and pathogenicity of identified variants. Identification of the germline mutation in individuals with PJS not only can confirm the diagnosis (particularly in individuals who do not have a family history), but once identified can be used to screen at-risk family members who would then be offered appropriate cancer screening. Genetic counseling is an integral part of the process for both the proband and family members at risk. While a number of pathogenic mutations have been identified and are well established, novel alterations continue to be identified and interpretation of the pathogenicity of these alterations may not be clear. The distinction between mutation, VUS, and polymorphism is crucial for the appropriate diagnosis of the affected individual and screening of asymptomatic at risk family members.

Hereditary Nonpolyposis Colorectal Cancer and Lynch Syndrome

24

James P. Grenert

Abstract

Hereditary nonpolyposis colorectal cancer (HNPCC) is an autosomal dominant cancer disorder associated with a greatly increased risk of colorectal, uterine, and other cancers. Most cases of HNPCC are due to inherited mutations in DNA mismatch repair (MMR) genes and their encoded proteins which correct errors made during DNA replication. HNPCC associated with inherited MMR defects is also called Lynch syndrome. Additionally, sporadic cancers occurring in individuals without HNPCC may have diminished expression of MMR protein(s) due to epigenetic silencing. Defective MMR function leads to reduced fidelity of DNA synthesis and microsatellite instability (MSI), the accumulation of mutations in repetitive sequences of DNA called microsatellites. Testing for defective MMR can be done directly by immunohistochemical staining for MMR proteins or indirectly by PCR fragment analysis of microsatellites.

Keywords

Lynch syndrome • Hereditary nonpolyposis colorectal cancer • HNPCC • Microsatellite instability • MSI • Mismatch repair • BRAF V600E • MLH1 methylation • MSH2 • MSH6 • PMS2

Hereditary nonpolyposis colorectal cancer (HNPCC) is an autosomal dominant cancer disorder. Initially defined clinically, a distinct subset of HNPCC can be identified through molecular testing and is responsible for approximately 3 % of all colorectal carcinomas.

Clinical Characteristics

The use of the term HNPCC has a long and problematic history. It was first coined by Dr. Harry T. Lynch and colleagues in 1984 to differentiate what were known as the cancer family syndrome (CFS), characterized by early-onset, predominantly proximal colorectal cancer as well as other cancers, and hereditary site-specific colon cancer (HSSCC), which differed from CFS in that non-colorectal cancers were not increased, from familial adenomatous polyposis (FAP) [1]. HNPCC has significant descriptive shortcomings. While these families do not exhibit the numerous colonic polyps characteristic of FAP, their colorectal cancers (CRC) nevertheless arise from adenomatous polyps. Additionally, despite its name, HNPCC is associated with not only a greatly increased risk of CRC but also of several other cancers, most commonly endometrial cancer of the uterus. These limitations led many researchers to adopt the alternative designation of Lynch syndrome, in place of HNPCC, and in both the literature and common usage, the terms are often used interchangeably.

Since the discovery of the underlying molecular basis for most cases of HNPCC, specifically, a heritable defect in DNA mismatch repair (MMR, discussed below), some authors have advocated for the use of Lynch syndrome to specifically refer to those that fit the clinical picture of HNPCC and

Table 24.1 Clinical criteria for identification of Lynch syndrome carriers

Amsterdam Criteria II
There should be at least three relatives with an HNPCC-associated cancer (CRC, cancer of the endometrium, small bowel, ureter, or renal pelvis)
One should be a first-degree relative of the other two
At least two successive generations should be affected
At least one should be diagnosed before age 50 years
Familial adenomatous polyposis should be excluded in the CRC case(s), if any
Tumors should be verified by pathological examination
Revised Bethesda Guidelines
CRC in a patient who is less than 50 years of age
Presence of synchronous, metachronous colorectal, or other HNPCC-associated tumors,[a] regardless of age
CRC with the MSI-H histology[b] diagnosed in a patient who is less than 60 years of age
CRC diagnosed in one or more first-degree relatives with an HNPCC-related tumor, with one of the cancers being diagnosed under age 50 years
CRC diagnosed in two or more first- or second-degree relatives with HNPCC-related tumors, regardless of age

[a]Hereditary nonpolyposis colorectal cancer (HNPCC)-related tumors include colorectal, endometrial, stomach, ovarian, pancreas, ureter and renal pelvis, biliary tract, and brain (usually glioblastoma as seen in Turcot syndrome) tumors, sebaceous gland adenomas and keratoacanthomas in Muir–Torre syndrome, and carcinoma of the small bowel

[b]Presence of tumor infiltrating lymphocytes, Crohn's-like lymphocytic reaction, mucinous/signet ring differentiation, or medullary growth pattern

CRC colorectal cancer, *HNPCC* hereditary nonpolyposis coli, *MSI-H* microsatellite instability-high

demonstrate MMR deficiency, while reserving HNPCC for cases where no MMR abnormality is identified [2–4]. HNPCC, then, encompasses two groups: Lynch syndrome and a second, possibly heterogeneous group that has been called "familial colorectal cancer type X." A number of explanations have been proposed to account for type X, including familial environmental causes, undiscovered genetic syndromes, and even aggregation of cancers occurring by chance [5, 6]. In the absence of a well-defined, testable etiology for type X, the focus of this chapter will be HNPCC-associated cancers that fit the current definition of Lynch syndrome and other tumors caused by defective MMR.

HNPCC is characterized by a greatly increased risk of malignancies, particularly CRC and endometrial carcinomas, which occur at a younger age than is typical for these tumors. These often striking clinical features have led to the development of clinical criteria for the diagnosis of HNPCC. The earliest system in widespread use was that created by the International Collaborative Group on Hereditary Non-Polyposis Colorectal Cancer (ICG-HNPCC) at a 1990 meeting in Amsterdam, subsequently referred to as the "Amsterdam Criteria." These criteria emphasized multigenerational disease, early age of onset (<50 years), and the lack of a polyposis syndrome [7]. Recognizing some deficiencies in the system, most notably the lack of extracolonic cancers in the criteria, the ICG-HNPCC updated these criteria in 1998 (Amsterdam Criteria II) [8]. A second group at an HNPCC workshop at the National Cancer Institute in Bethesda, MD, which included some of the members of the ICG-HNPCC, developed guidelines for identification of tumors that should undergo microsatellite instability (MSI) testing for evidence of defective MMR and published their conclusions in 1997 (the "Bethesda Guidelines"). These guidelines focused on not only the clinical features and family history of the patient but also on pathological features of the tumor including site and histologic appearance/subtype [9]. The Bethesda Guidelines were revised in 2004 to include less-restrictive age criteria and eliminate testing of adenomas in young people [10]. The updated Amsterdam and Bethesda systems are shown in Table 24.1. The reported clinical performance of these criteria varies widely. While some authors report nearly 100 % sensitivity and specificity for the Bethesda Guidelines, it is unlikely that such performance can be achieved in all settings [11, 12]. A large study of 500 patients from the Ohio State University found only 39 and 72 % sensitivity for the Amsterdam and Bethesda criteria, respectively [13]. In particular, the age limits have the potential to exclude Lynch carriers who present at more advanced age.

CRC arising in the setting of defective MMR has a tendency toward a number of pathologic features, including location in the proximal colon, mucinous or signet ring differentiation, poor differentiation, and prominent lymphocytic inflammation in and around the tumor. Examples of histologic features of MMR-deficient tumors are shown in Fig. 24.1. Recognition of histologic patterns has been shown to be highly sensitive for tumors with defective MMR, with reported sensitivity in some studies greater than 90 %. The specificity of histology, however, is only 55–67 %, making additional testing a necessary component of tumor evaluation [14–16].

Lynch syndrome is associated with several other cancers (listed among the Bethesda Guidelines). The association of some of these cancers with CRC has been noted by medical researchers over the years, and these have been given eponymous syndromes such as Turcot (glioblastoma) and Muir–Torre (keratoacanthoma and sebaceous tumors) syndromes. The importance of gynecologic cancers in the disease burden

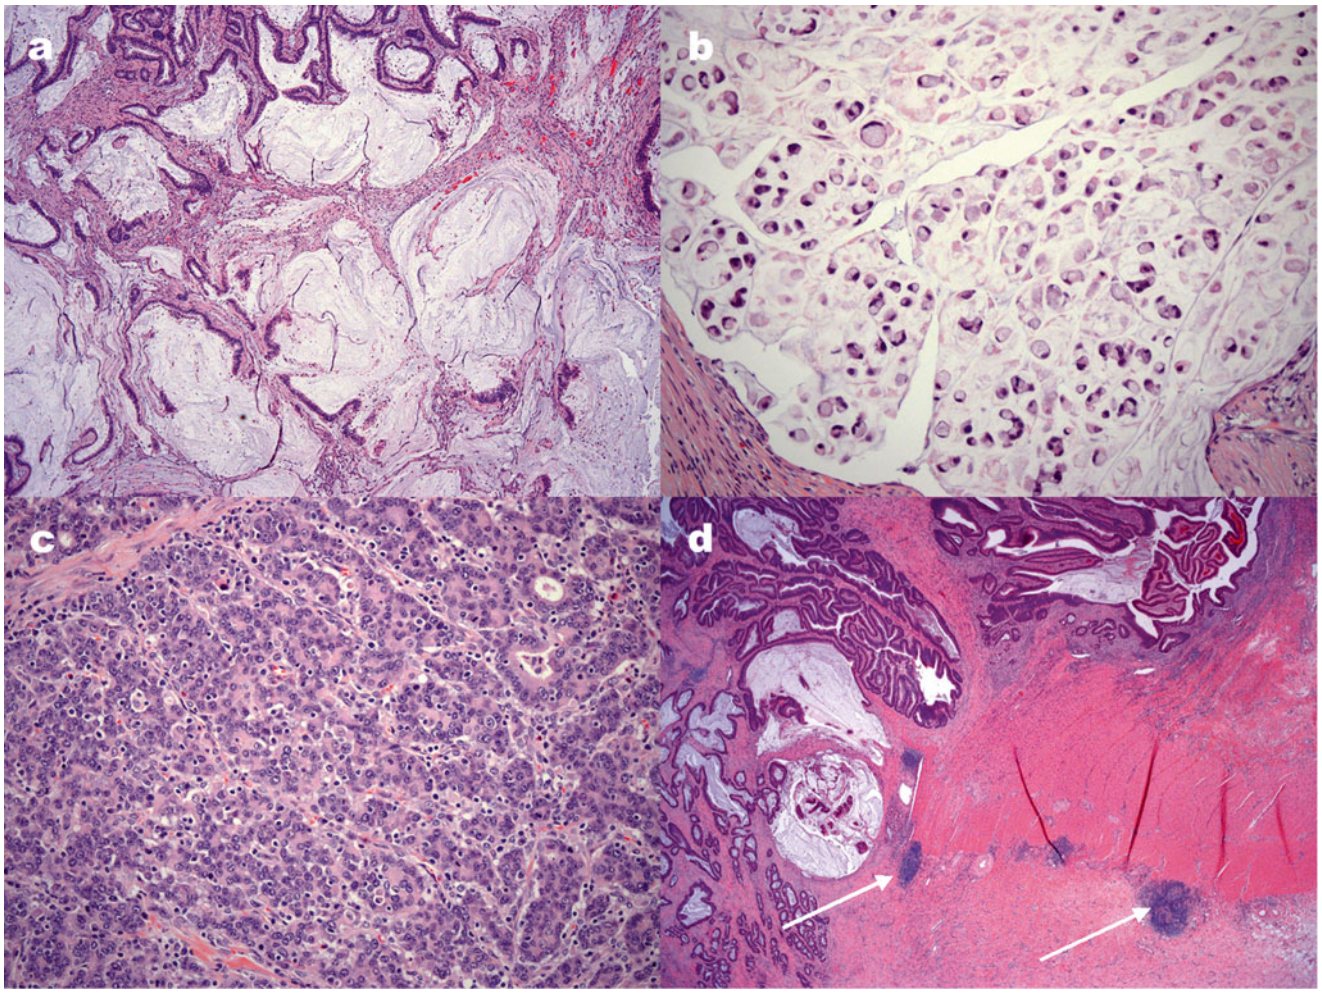

Figure 24.1 Examples of histological features of colorectal carcinomas with defective DNA mismatch repair. (**a**) Extracellular mucin pools in a mucinous adenocarcinoma. (**b**) Signet ring cell adenocarcinoma with tumor cells containing a single, large mucin vacuole. (**c**) Tumor-infiltrating lymphocytes are seen as small, round cells, often with a surrounding clear "halo," infiltrating among tumor cell glands or aggregates. (**d**) Crohn's-like lymphocytic response is illustrated by discrete lymphocytic aggregates (*arrows*) away from the tumor, resembling the transmural inflammation of Crohn's disease

cannot be stressed enough, with uterine and ovarian cancer comprising half of the presenting cancers in women with Lynch syndrome [17]. The overall risk of CRC by age 70 in Lynch carriers has been reported as high as 82 %, although some studies have shown a lower risk of 30–74 %, with men at significantly higher risk than women [18–20]. The risk of uterine cancer in women with Lynch syndrome is 34–60 % [18, 20, 21]. For some less common tumors such as gastric, small bowel, and urinary tract cancers, the lifetime risk of cancer is approximately 5–15 % [22].

Molecular Basis of Disease

In 1993, through the work of multiple groups working independently, the molecular basis for Lynch syndrome began to be uncovered. This was first recognized in HNPCC tumors as changes in the size of microsatellites, tandem repetitive sequences of DNA which make up about 3 % of the human genome. The repeating sequence in these microsatellites ranges in size from 1 to 13 bases, although microsatellites longer than 5 bases are not typically used in testing. In HNPCC tumors, the number of repeats in microsatellites expanded or contracted, resulting in a shift in the size of the microsatellites. These changes were called replication errors or microsatellite instability (originally abbreviated MIN but now usually shown as MSI). MSI was found to be much more common in tumors of families with HNPCC than in sporadic CRC [23–25].

Soon after the discovery of MSI in HNPCC, the phenomenon was linked to defective function of proteins involved in the repair of errors introduced during DNA replication. These proteins have homologs, MutS and MutL, originally described in *E. coli*, whose function is to recognize and

correct DNA heteroduplexes of mismatched base pairs [26]. Microsatellites, due to the repetitive nature of their sequences, appear to represent a "slippery" template along which DNA polymerase is prone to skip forward or backward during replication, creating small loops of unpaired bases in the process [27]. Depending on the direction of the slippage, the newly synthesized strand will contain a greater or lesser number of repeats than the template. Single base–base mismatches can occur when an incorrect nucleotide is incorporated into the new strand. An intact MMR system recognizes these alterations and directs a multistep process of strand breakage, excision of the error, and resynthesis of the strand, thereby resulting in a corrected sequence. The connection between the MSI and the MMR system was first shown by the identification of germline mutations in *MSH2*, the human homolog of *mutS*, in families with Lynch syndrome, and later in the MutL homolog *MLH1* [28, 29]. Most of these mutations result in a premature stop codon and a truncated protein. Less commonly, missense mutations affect protein-protein interactions that are essential for MMR function.

CRC arising in Lynch syndrome are believed to follow a typical adenoma–carcinoma sequence in common with non-Lynch tumors. This has been shown through the presence of adenomas adjacent to early carcinomas identified in prophylactic colectomies performed in Lynch syndrome carriers [30]. Furthermore, adenomas arising in Lynch syndrome, particularly those that show high histologic grade, often have evidence of MSI prior to the development of invasive carcinoma [31]. While there have been reports of MSI in histologically normal cells and tissues of patients with Lynch syndrome, in most cases, testing of normal tissue in Lynch syndrome carriers does not demonstrate MSI, and the presence of MMR proteins can be demonstrated with immunohistochemical staining [32–35]. Thus, despite the loss of one functional copy of a MMR gene, DNA MMR largely remains intact until a second genetic hit results in deletion or mutation of the functioning allele.

At least seven MMR proteins involved in DNA repair during mitosis have been identified in humans [36]. Four of these, MLH1, PMS2, MSH2, and MSH6, appear to be largely responsible for Lynch syndrome, with mutations in MLH1 and MSH2 causing approximately 90 % of cases [37]. The MMR proteins function as heterodimers, and MLH1 and MSH2 serve as the obligate components of dimers homologous to the bacterial *mutL* and *mutS*, respectively. MLH1 primarily pairs with PMS2 but can also be paired with PMS1 or MSH3. MSH2 pairs primarily with MSH6, and MSH3 is a secondary partner [36]. The specific combinations formed determine the types of DNA mismatches that are corrected. For example, MSH2 and MSH6 can repair single base pair mismatches as well as longer insertions and deletions, while MSH2 and MSH3 mainly correct larger mismatches [26]. The different pairings and their functions seem to have clinical relevance, as shown by the fact that different Lynch mutations do not appear to be equal with respect to the clinical manifestations of the syndrome and the associated cancer risk. Carriers with mutations in the obligate components MLH1 and MSH2, without which MMR dimers cannot function, have an approximately four-fold higher risk of CRC than do those with an MSH6 mutation [21]. This may be explained by substitution of MSH6 by MSH3 in the MutS-type dimer, partially compensating for MSH6 loss. The effect of this substitution is restoration of repair of longer mutations, while single base errors may go uncorrected [38].

In addition to HNPCC-associated cancers, sporadic CRC (i.e., those not associated with a strong family history of CRC) also can have MSI [39]. These microsatellite-unstable tumors make up approximately 15–25 % of sporadic CRC, a much greater number of tumors than those attributable to Lynch syndrome [40]. Like Lynch-associated CRC, sporadic tumors with MSI have a tendency toward a right-sided proximal location in the colon, but the age of onset of these tumors does not differ significantly from MMR-proficient tumors [41, 42]. The precursor lesion of these cancers, sessile serrated adenoma, lacks the cellular atypia of tubular adenomas that precede Lynch-associated tumors and has the saw-toothed microscopic appearance of a common hyperplastic polyp. However, the sessile serrated adenoma differs from hyperplastic polyps by increased architectural complexity, which is due to altered distribution of proliferating cells in colonic glands [43]. Analysis of MMR genes showed that most of the sporadic tumors lack either germline or somatic mutations in MMR genes, yet immunohistochemical staining for MMR proteins shows that these tumors commonly lack expression of MLH1 [44]. This apparent discrepancy was explained by the recognition that the *MLH1* promoter was epigenetically silenced via hypermethylation in sporadic CRC with MSI [45]. Further, *MLH1* hypermethylation is closely linked to the activating V600E mutation in the BRAF kinase, with *BRAF* mutation seen in 31–87 % of CRC with silenced MLH1. Significantly for diagnostic purposes, BRAF mutation is virtually never seen in Lynch syndrome-associated CRC [46–48]. A causal relationship between *BRAF* mutation and *MLH1* silencing has yet to be discovered. *MLH1* hypermethylation also has been demonstrated in sporadic endometrial cancers with MSI. However, in stark contrast with what is seen in the colon, these tumors consistently lack *BRAF* mutation, suggesting that *MLH1* hypermethylation can occur independently of *BRAF* mutation [49]. Thus, *BRAF* mutation may indicate an *MLH1*-methylated CRC but may not be the underlying etiology. Rarely, constitutional MLH1 methylation may be inherited, resulting in Lynch syndrome without protein-coding mutations in MMR genes. While this constitutes <1% of all Lynch syndrome patients, it is an important Lynch etiology in individuals who are MLH1-deficient but negative for MLH1 mutation [50].

While DNA replication errors in microsatellites can be used as an indicator of defective mismatch repair function, it is not clear what role MSI may play in vivo in cancer pathogenesis. The Human Genome Project has revealed that many microsatellites are located in the coding regions of hundreds of genes. These include genes encoding proteins with important roles in signal transduction (TGFBII and IGFIIR, receptors for TGFB and insulin-like growth factor, respectively), tumor suppression (PTEN), and apoptosis (BAX). Ironically, the genes for two of the MMR proteins, MSH3 and MSH6, also contain microsatellites. Supporting the idea that instability in these and other microsatellite-containing genes can affect colon carcinogenesis is the observation that frameshift mutations in these genes have been identified in tumors from HNPCC families, and this instability can occur as early as the adenoma stage [51, 52].

Clinical Utility of Testing

The primary goal of most testing for defective mismatch repair is to screen for Lynch syndrome carriers. The high risk of malignancy in this population makes their identification, increased surveillance, and consideration of medical and surgical prophylaxis of critical importance in preventing morbidity and mortality. Carriers of MMR protein mutations do not have an increased rate of development of precancerous adenomas, but progression from adenoma to carcinoma appears to be accelerated [53]. For this reason, the recommended interval for colonoscopy in this population is every 1–2 years, shorter than the 5-year interval for non-carriers. Increased frequency of colonoscopy in surveillance appears to result in fewer invasive cancers due to removal at the adenoma stage [54, 55].

In addition to increased surveillance, another strategy under investigation to protect against cancer is chemoprevention. Aspirin has been used in a long-term trial (CAPP2) with Lynch carriers to see if it lowers the incidence of CRC. After nearly 5-year average follow-up, participants taking aspirin had a nearly 40 % reduction in CRC risk compared to those taking placebo [56]. The most definitive preventive measure is surgical resection of organs at high risk of malignancy, including subtotal or greater colectomy for Lynch carriers undergoing CRC resection. This is a complex issue that is beyond the scope of this chapter, but it has been addressed by a number of authors and been shown to be both medically effective and cost effective [55, 57, 58].

Once one Lynch carrier has been identified, the specific germline MMR gene mutation detected can be assayed in the patient's blood relatives, greatly expanding the importance of the initial detection. The first-degree relatives of a Lynch carrier each have a 50 % risk of being a carrier. Given the potential interventions for Lynch syndrome carriers, some have advocated for universal screening of all CRC for evidence of defective MMR [59, 60]. While the specific recommendations for screening method differ, universal screening may be cost effective [13, 61, 62].

Determination of MMR status has prognostic and predictive significance. Clinical studies of patients with MMR-deficient CRC have shown that these tumors present with more advanced local disease (have deeper invasion into the colonic wall), yet paradoxically, patients with these tumors have a longer survival than those with MMR-proficient cancer [63–65]. A very thorough review of survival studies by Popat et al. estimated the survival advantage of patients with MMR-deficient CRC to be 15 % or more [66]. Although both sporadic and Lynch-associated MMR-deficient tumors have a better prognosis, this effect is most pronounced in patients with Lynch syndrome [63]. It is unlikely that the younger age of presentation of patients with Lynch syndrome completely explains the improved survival. When early-onset CRC patients were compared with respect to MMR function, there remained a trend toward improved survival in those with defective MMR [67]. For reasons that are not clear, MMR-deficient tumors show less aggressive behavior in terms of lymphatic and distant metastasis and prolonged time to recurrence [63, 68, 69].

The improved survival in patients with MMR-deficient tumors means there is less opportunity for benefit from chemotherapy. Patients and their physicians may feel that the adverse effects of chemotherapy outweigh the modest improvement in survival (5 % at 5 years in stage II patients) that has been associated with adjuvant treatment [70]. Additionally, in patients with stage II and III disease, studies have shown that while fluorouracil treatment of tumors with intact MMR improves survival, patients with MMR-deficient tumors may not benefit [71, 72].

Available Assays

The majority of testing is directed toward identifying tumors with defective MMR, both as a means of screening for potential Lynch carriers and for its prognostic and therapeutic implications. Once potential carriers have been identified, additional testing can identify the presence of a germline mutation in an MMR protein to confirm a Lynch syndrome diagnosis and to allow counseling and targeted testing of family members for carrier status. However, since most MMR-deficient tumors arise sporadically, the number of patients who require germline mutation testing is relatively small, and the focus of this section is on screening assays. Protocols for germline testing have been published and involve both direct sequencing for small mutations and denaturing high-pressure liquid chromatography for large rearrangements [73]. Hundreds of Lynch syndrome mutations have been identified and are catalogued online by the

International Society for Gastrointestinal Hereditary Tumours (InSiGHT; http://www.insight-group.org) [74]. Different Lynch syndrome mutations have different cancer risks, with *MLH1* and *MSH2* mutations associated with approximately four-fold greater risk of cancer than *MSH6* mutation [21]. Thus, identification of the specific mutation can provide useful information for counseling carriers and their family members.

Immunohistochemistry

The most readily available assay for detecting MMR deficiency is immunohistochemical (IHC) staining of tissue sections for MMR proteins. This can be performed by most histology laboratories using standard protocols with commercial antibodies against MLH1, PMS2, MSH2, and MSH6. This technique directly detects the presence or absence of these MMR proteins in the tumor but does not assay for the activity of the MMR proteins. MMR mutations result in a truncated or otherwise nonfunctional protein that is then degraded by the cell [75, 76]. IHC, then, identifies the loss of one or more mismatch repair proteins in a tumor.

Related to their function to ensure the fidelity of DNA replication, MMR proteins are normally found in the nucleus. In a tumor with a functioning MMR system, staining for each MMR protein will reveal positive staining in the nuclei of tumor cells. This system is also at work in non-tumor cells, which also should have positive nuclear staining. Evaluation of non-tumor cells can serve as an internal positive control for each stain [77]. Although every cell in a MMR-proficient tumor is expected to be positive if the MMR proteins are intact, in practice, this is usually not the case. As is seen with many IHC stains, staining often is variable throughout the tumor. Indeed, non-tumor cells may show the same inconsistency in staining [78]. It is unclear if this represents variable fixation/antigen retrieval issues which abound with IHC, biologic variability at the cell level, or a combination of these factors. In general, MMR proteins that are nonfunctional will fail to dimerize and will be degraded. Using IHC, this typically corresponds to widespread loss of nuclear staining in the tumor cells [77]. Similarly, epigenetic silencing of MLH1 expression also results in a loss of staining [44]. An example of loss of MMR staining by IHC is shown in Fig. 24.2.

MMR protein heterodimer composition allows prediction of the underlying molecular defect based on the pattern of protein loss. Usually, when the obligatory partner of a MMR component is lost, that protein will be lost as well. On the other hand, MMR proteins that may dimerize with multiple partners can still be present if one of the partners is deficient. For example, PMS2 can only pair with MLH1, and therefore, loss of MLH1 most often results in lack of staining for both MLH1 and PMS2. MLH1, on the other hand, can pair with proteins other than PMS2, and loss of PMS2 may occur without MLH1 loss. Table 24.2 demonstrates the common protein loss patterns and the causative genetic defects. Although definitive diagnosis of Lynch syndrome requires identification of a germline mutation in one of the MMR genes, this information from IHC testing can direct the germline testing to a specific MMR gene.

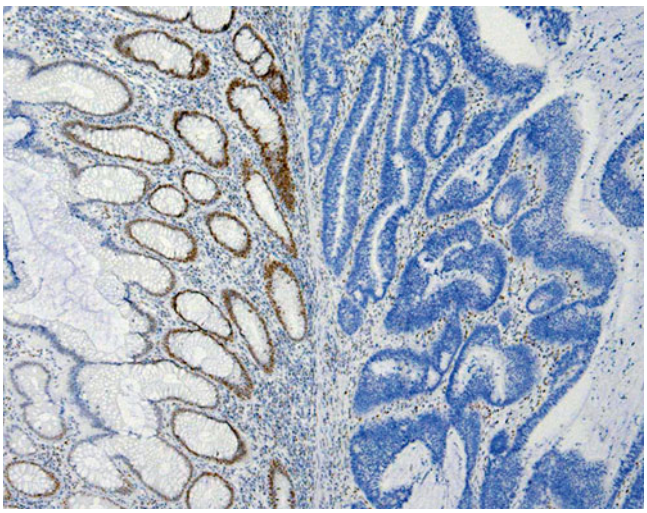

Figure 24.2 Example of loss of immunohistochemical staining for the mismatch repair protein PMS2 in a colon carcinoma. The normal glands on the *left* show positive, brown staining for PMS2 in cell nuclei, while the cancerous glands on the *right* lack the brown staining. The blue staining present in the nucleus is a counterstain to show the tissues. Note that even in the normal tissue on the left, not every cell will stain positively

Table 24.2 Interpretation of protein loss patterns in MMR immunohistochemistry

Protein(s) lost	Possible gene defecta
MLH1 and PMS2	The most common pattern of loss. Both sporadic and hereditary tumors may show this pattern, but most are sporadic. *MLH1* hypermethylation in sporadic tumors. *MLH1* mutation in hereditary tumors.
MSH2 and MSH6	The most common exclusively hereditary pattern. *MSH2* mutation.
MSH6 only	Uncommon. *MSH6* mutation.
PMS2 only	Rare. *PMS2* mutation or, less likely, *MLH1* mutation.

[a]MMR immunohistochemistry is not diagnostic for Lynch syndrome, and suspected gene mutation must be confirmed.
MMR mismatch repair

Although IHC should ideally clearly show that a MMR protein is either present or absent in a tumor, IHC results can be ambiguous. Tumor cells often show variable staining, making interpretation difficult, and even tumors that harbor MMR gene mutations may still demonstrate detectable protein staining [78–80]. One MLH1 truncation mutation has been reported to avoid degradation and stains positively by IHC, while its partner PMS2 is destabilized and shows protein loss, a pattern which would normally indicate PMS2 mutation [81]. It has been suggested that IHC staining for only two MMR proteins, MSH6 and PMS2, may be as effective as staining for all four MMR proteins as a screening test, since one of these should be lost in any of the most common Lynch syndrome scenarios [82]. This has a cost advantage, but many laboratories may choose to use all four stains to help clarify difficult cases and to provide immediate guidance for gene testing.

Sometimes, a tumor that is otherwise completely negative for a protein may show scattered positive nuclei. These may actually represent staining of benign lymphocytes admixed with tumor, the intratumoral lymphocytes (ITL) that are one of the histologic features of MMR-deficient tumors. One feature that can distinguish this artifact from true tumor staining is if the staining is limited to uniform, small, round nuclei characteristic of lymphocytes. Occasionally, apoptotic cells may aberrantly stain for a MMR protein that is absent in the tumor. It is often helpful to review the histologic appearance of the tumor for the presence of ITL and apoptotic cells. Another potential source of misinterpretation is diminished MSH6 staining in rectal carcinomas that have been treated with chemoradiation. Although the staining may be completely absent in these tumors, some may not have an MSH6 mutation or evidence of MSI. If a pretreatment specimen is available, staining is likely to be more representative of the true MSH6 status [83]. Finally, the interpretation of IHC testing should be reported as having MMR proteins "present" or "absent," rather than positive or negative, to avoid possible misinterpretation by the recipient of the test results; "positive" may be incorrectly read as "positive for MMR deficiency."

Microsatellite Instability PCR

PCR testing of DNA microsatellites represents an indirect functional assay for MMR proteins. After DNA is extracted from tumor tissue and from a non-tumor control tissue from the same patient, a panel of microsatellites is amplified by PCR using primers adjacent to but not including the repetitive sequence. The size of the PCR products is then analyzed by capillary electrophoresis, or less commonly by gel electrophoresis. Because defective MMR causes frameshift mutations in microsatellites, instability is shown by a change in the size of the PCR products from the microsatellite. Commonly used panels of microsatellites for MSI testing in the USA are the NCI panel (three dinucleotide [*D2S123*, *D5S346*, and *D17S250*] and two mononucleotide [Big Adenine Tract, *BAT-25*and *BAT-26*] microsatellites) and the panel supplied in a commercial kit available from Promega (Madison, WI) with five mononucleotide repeats (*BAT-25*, *BAT-26*, *NR-21*, *NR-24*, and *MONO-27*) [84]. Different microsatellites vary in their ability to identify tumors with defective MMR, with mononucleotide repeat loci generally superior to dinucleotide loci in both sensitivity and specificity [85]. This may be particularly true with MSH6 deficiency, which preferentially causes errors in mononucleotide repeats, as described earlier. The Promega panel includes two additional pentanucleotide repeats which are not evaluated to identify MSI but are used to ensure correct pairing of a patient's tumor and normal DNA. These repeats are highly polymorphic in the population, and different patterns seen between a patient's samples raise the possibility of specimen contamination or a labeling error.

As established by criteria from the National Cancer Institute, tumors exhibiting stability in all of the microsatellites tested are called microsatellite stable (MSS). Those with instability in ≥30–40 % of tested microsatellites are designated microsatellite instability-high (MSI-H). The third category, microsatellite instability-low (MSI-L), encompasses tumors that have at least one unstable microsatellite, but not enough to meet MSI-H criteria [86]. In common practice with the 5-microsatellite Promega or NCI panels, MSS, MSI-L, and MSI-H correspond to zero, one, or two or more unstable microsatellites, respectively. MSS tumors usually have intact MMR function, while MSI-H tumors correlate with MMR deficiency. MSI-L tumors have not been shown to be associated with defective MMR and are usually regarded as equivalent to MSS in the absence of solid evidence for Lynch syndrome. Instability is defined by a change in the length of a microsatellite in tumor DNA when compared to non-tumor ("normal") DNA from the same patient. When compared with the normal control, an unstable allele will appear as a novel allele or a shift in the length of the allele.

The types of patterns seen in MSI testing depend upon whether dinucleotide or mononucleotide repeats are being evaluated. Dinucleotide repeats are polymorphic in the population, and a patient will often have alleles of different sizes on the maternal and paternal chromosomes. Thus, the normal sample will show two peaks, each representing one allele. One or both of these may change in length in the tumor as a result of defective MMR. The presence of two peaks in the normal DNA may mask a shift if the novel allele is obscured by an overlapping normal allele. Mononucleotide repeats, on the other hand, are generally very homogeneous ("quasi-monomorphic"), with same-sized alleles inherited from each parent. Thus, the normal sample will typically

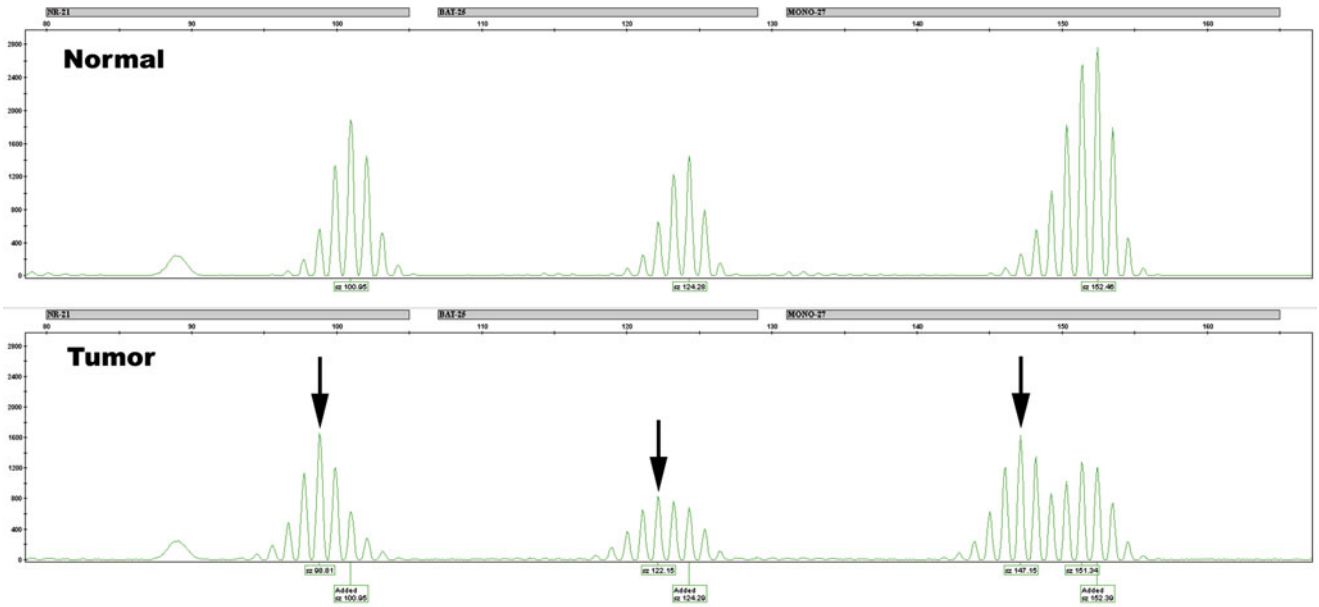

Figure 24.3 Three microsatellites with instability. Capillary electrophoresis data for three microsatellites, *NR-21*, *BAT-26*, and *MONO-27*, is shown for a patient's normal (*above*) and tumor (*below*) DNA. *Arrows* point to changes in the size of microsatellites in the tumor, indicative of stability. Note that the subtle 2-bp size change in *NR-21* and *BAT-26* may be difficult to appreciate unless a comparison with the normal sample is made

show only a single peak for each microsatellite. Tumor instability will be demonstrated as a shift in length for that peak or the presence of a second peak that was not seen in the normal tissue. Examples of unstable mononucleotide microsatellite alleles are shown in Fig. 24.3.

The effectiveness of MSI testing is closely related to the panel of microsatellites used in the assay. Poor performance of some markers may result in MSI-L designation, and when many microsatellites are tested, the percentage of MSI-L tumors increases [87]. The percentage of MSI-L tumors in older reports, before the use of only mononucleotide panels, is as high as 35 % [88]. In contrast, when mononucleotide repeats are used exclusively, MSI-L tumors become very uncommon [89]. The significance of MSI-L when testing with a mononucleotide panel is unclear, and these patients should be offered genetic counseling. Fortunately, the percentage of unstable microsatellites in MSI-H tumors is usually 80–100 % when mononucleotide repeats are used [90]. Note that the pentanucleotide repeats in the Promega panel may show instability themselves in MSI-H tumors, and this can cause confusion if used to match a patient's tumor and normal samples [89].

Recognition of some general patterns of instability in mononucleotide microsatellites can be helpful in MSI interpretation. First, mononucleotide markers nearly always shift to a smaller size when unstable. While larger sizes can be seen, their presence may indicate another genetic event such as an insertion, rather than instability. Second, the magnitude of a shift is usually no greater than approximately 10–12 bases, and large shifts often have some intermediate-sized alleles present as well. These intervening peaks are due to heterogeneous instability in the tumor. Shifts greater than approximately 12 bases may be the result of a deletion, and a deletion would not be expected to show the intermediate-sized alleles. A third pattern to be aware of is heterozygosity for a mononucleotide microsatellite. While most individuals have inherited alleles of the same size for a mononucleotide microsatellite, occasionally, patients have two different-sized alleles. This will be evident in both tumor and normal samples. Because heterozygosity is uncommon (only occurring in up to 5 % of cases), it is unlikely to be present in more than one or two microsatellites, and cases with more than this should be carefully evaluated for the possibility of specimen mislabeling or contamination of the normal DNA sample with tumor DNA. Finally, the minimum size of a shift is one base, the length of the repeating unit. Since identification of such a small shift is difficult, some clinical laboratories require a minimum of a two-base shift to score a microsatellite unstable. Fortunately, if a mononucleotide panel is being used, most MSI-H tumors will show 3–5 clearly unstable microsatellites.

Some authors have suggested that the nearly monomorphic character of certain mononucleotide repeats (i.e., nearly all alleles in the population are approximately the same length) precludes the need for a non-tumor sample for testing. Because the expected allele size is very limited, any deviation indicates instability [90]. Although rational, some circumstances can only be resolved if a non-tumor sample is

tested in parallel with the tumor sample. Every tumor sample, unless obtained with laser capture microdissection, contains non-tumor cells such as fibroblasts, blood vessels, and inflammatory cells. These cells will dilute the tumor DNA and make shifted alleles more difficult to detect. Adding further difficulty is the presence of "stutter" peaks, a distribution of secondary peaks around the true size of the microsatellite. Stutter peaks occur because *Taq* polymerase used in the PCR reaction also slips on the microsatellite template, and in the absence of an in vitro MMR system, the errors are retained. When the change in microsatellite size is small, only a subtle shift may be evident on the electropherogram, largely masked by normal DNA and stutter peaks. Without a normal sample for comparison, such a shift may not be evident.

BRAF V600E and *MLH1* Methylation

Testing for the BRAF V600E mutation and hypermethylation of the *MLH1* promoter are important adjuncts to IHC and MSI testing. Because *BRAF* mutation in an MSI-H colorectal tumor is a very strong indication of a sporadic tumor, it can help rule out Lynch syndrome. The specific mutation seen in these tumors is a T-to-A transversion at position 1799, which produces an amino acid change from valine to glutamate at codon 600 (V600E). The uniformity of this mutation allows for many methods of detection, including Sanger sequencing, pyrosequencing, allele-specific PCR, and hybridization probe melting analysis. The high degree of specificity with which the BRAF V600E mutation can identify a sporadic MSI-H tumor has led the Association for Molecular Pathology to recommend testing for this mutation in all CRC [91].

Detection of *MLH1* hypermethylation, the underlying defect causing sporadic loss of MLH1, nearly always points to a sporadic tumor. Nevertheless, it is important to correlate MLH1 results with clinical and family history, since rare cases of MLH1 methylation may represent an inherited epimutation that is the underlying cause in up to 13% of MLH1-deficient but mutation-negative Lynch families [92]. Sequencing, restriction digestion, or methylation-specific PCR following bisulfite treatment of tumor DNA can be used to identify this epigenetic modification of the promoter region of the *MLH1* gene. However, this assay is more difficult to perform and interpret compared to *BRAF* testing, so is less commonly available in clinical laboratories. *MLH1* hypermethylation testing has one advantage over *BRAF* testing in that it is suitable for use in testing MSI-H endometrial tumors of the uterus, which have not been shown to have *BRAF* mutations [93–95].

Laboratory Issues

Biopsies from the colon, endometrium, or elsewhere are typically small, perhaps no more than a few millimeters in size. While in theory these small tumors may be suitable for IHC and MSI testing, this specimen type has limitations. For IHC testing, irregular staining in a tumor may result in the appearance of MMR loss in a small specimen, especially when the amount of tumor is scant. Testing of a larger resection specimen is more likely to include areas where the protein can be demonstrated with IHC. MSI testing requires a relatively pure sample of tumor for testing (usually >20 % tumor cells) and a normal sample not contaminated by tumor cells. Biopsies often have intimately intermixed tumor and non-tumor tissue in a very small physical space. Unless laser capture microdissection is used, separation of tumor and normal cells for DNA extraction may not be possible. If the tumor tissue is adequate, the limitation on the normal tissue may be overcome with the use of the patient's peripheral blood or a previous non-tumor specimen. Biopsies of precancerous colorectal adenomas often do not demonstrate MSI or MMR protein loss unless they are advanced stage (high-grade dysplasia/intramucosal carcinoma), so while adenomas of Lynch carriers may test positive, a negative result does not rule out Lynch syndrome [31, 35]. Testing of unselected young patients with adenoma does not appear to be an effective means of screening for Lynch syndrome [96].

An important decision for the clinical laboratory is the selection of testing method(s) to screen for defective MMR, as well as which cases to screen. This is likely to be driven in no small part by the technology available locally. While most pathology practices have ready access to IHC, molecular testing may be difficult to obtain. Other nonanalytical considerations include cost and turnaround time. When test performance is compared, both IHC and PCR are highly effective. MMR IHC is estimated to be 76–88 % sensitive in detection of an inherited mutation in a MMR protein, while MSI PCR is 76–90 % sensitive. The best performance is with MMR gene sequencing, which is over 99 % sensitive and specific; it is the primary test used to confirm a diagnosis of Lynch syndrome [91]. Arguments in favor of IHC and PCR have been put forth [97, 98]. Analytically, an advantage of IHC is the ability to detect MSH6 mutations that could be missed by MSI, while a disadvantage is variable/patchy staining, especially for MSH6, which may also have decreased staining following chemoradiation [83, 97, 99]. In favor of MSI is "indifference" to the underlying defect, which includes MMR proteins that cannot be tested by IHC, and a high rate of interlaboratory concordance (98 %) [98]. Decreased sensitivity of MSI to MSH6 defects has already been discussed, but this disadvantage may be of lesser importance with the current use of mononucleotide repeat panels.

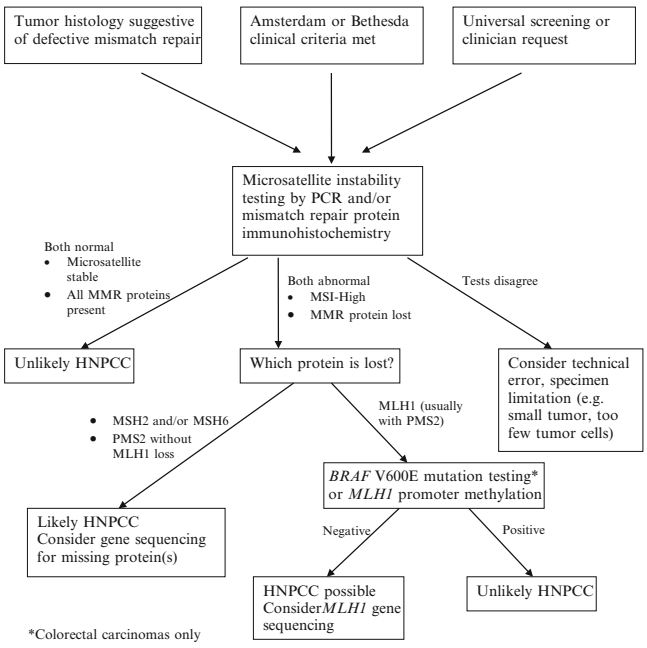

Figure 24.4 HNPCC testing algorithm

While IHC and PCR results have greater than 90 % concordance, neither test is superior in all cases [100].

Independent of analytical performance, each assay has distinct advantages. IHC results can guide MMR gene mutation testing; MSI testing can immediately be followed with *BRAF* or *MLH1* methylation testing on the same sample (if the tumor is MSI-H). The combination of IHC and PCR was shown to have 100 % sensitivity in a review of four large case series [91]. Thus, many laboratories elect to use both tests in some or all cases. A suggested testing protocol is shown in Fig. 24.4. Recent guidelines from the Association for Molecular Pathology have recommended simultaneous testing with MMR IHC, MSI PCR, and *BRAF* mutation testing [91]. Tumors which are MSS and stain positively for all four MMR proteins, which will make up the great majority of cases (approximately 75–85 %), are unlikely to represent Lynch syndrome and do not require MMR gene sequencing. MSI-H and MLH1-deficient tumors occurring in conjunction with the BRAF V600E mutation also do not require gene sequencing, unless there is other clinical, family, or historical information raising concern for Lynch syndrome. Thus, only those MSI-H tumors lacking *BRAF* mutation, or those tumors with loss of only MSH2, MSH6, or PMS2, should be considered for MMR gene sequencing, with a referral of the patient for genetic counseling prior to sequencing.

Finally, development of systems for Lynch syndrome testing requires a team approach, including pathologists, oncologists, surgeons, medical geneticists, genetic counselors, and other healthcare providers. This begins with selection of which tumors to screen. Some institutions or regulatory bodies may conclude that testing for defective MMR is similar enough to genetic testing that patient consent is required, while others may decide that only gene mutation testing requires consent. If all tumors are not screened, who should initiate testing? Pathologists may want to test tumors that show histology suggestive of MMR deficiency, and a decision should be made whether this can be ordered by the pathologist or requires discussion with the healthcare provider for the patient. Adequate genetic counseling resources are required for follow-up on patient results. Some testing algorithms may recommend genetic counseling for all patients with abnormal test results (i.e., MSI-H, MSI-L, or MMR loss). If all CRC are screened, up to 20–25 % of patients with these tumors will require the opportunity for a genetic consultation. Once these plans are in place, a reliable reporting system must be established to ensure that all testing results will be communicated to clinicians and/or genetic counselors to arrange proper patient follow-up.

Multiple Endocrine Neoplasia Syndromes

25

Barbara A. Zehnbauer

Abstract

Multiple endocrine neoplasias (MEN) are familial cancer syndromes which feature autosomal dominant inheritance of genetic risks for a variety of endocrine gland tumors. Patients with multiple endocrine neoplasia type 1 (MEN1) have a high frequency of peptic ulcer disease and abnormalities involving the parathyroids, pancreatic islets, and anterior pituitary. Patients with MEN2 (MEN2A, MEN2B, or familial medullary thyroid carcinoma [FMTC]) exhibit a high frequency of medullary thyroid carcinoma, pheochromocytoma, parathyroid hyperplasia plus mucosal neuromas (lips and tongue), ganglioneuromas of the gastrointestinal tract, and marfanoid habitus (in MEN2B only). These tumors are typically diagnosed at an earlier age and with bilateral or multiple sites of tumor compared to the general population risk for the same tumors. Germline mutations in the *MEN1* gene and the *RET* gene are identified in nearly all families affected with these syndromes. Presymptomatic genetic testing provides early diagnosis of disease risk and facilitates clinical intervention at earlier stages of tumor development with increased likelihood of improved patient outcomes.

Keywords

Familial cancer syndrome • Autosomal dominant • MEN1 • Menin • Tumor suppressor • MEN2 • RET • Receptor tyrosine kinase • Genetic risk • Presymptomatic screening • Genotype–phenotype

Introduction

Multiple endocrine neoplasia (MEN) syndromes include several types of inherited autosomal dominant familial cancer syndromes, each characterized by a different pattern of endocrine gland tumors in affected individuals. The two major types are MEN type 1 or MEN1 (Wermer syndrome) and MEN type 2 or MEN2 (Sipple syndrome). MEN1 is characterized by a high frequency of peptic ulcer disease and primary endocrine abnormalities involving the parathyroids (90–97 % of patients), pancreatic islets (30–80 % of patients; including adenoma, prolactinoma, insulinoma, glucagonoma, gastrinoma, etc.), and anterior pituitary (15–50 % of patients) [1]. MEN2 includes subtypes MEN2A, MEN2B, and familial medullary thyroid carcinoma (FMTC, non-MEN), with the primary clinical features of medullary thyroid carcinoma (MTC; 95 % of patients), pheochromocytoma (50 % of patients with MEN2A and MEN2B but not in FMTC), parathyroid hyperplasia (15–30 % of patients with MEN2A and rarely MEN2B) plus mucosal neuromas of the lips and tongue, ganglioneuromas of the gastrointestinal tract, and marfanoid habitus (only in patients with MEN2B) [1]. The MEN2A diagnostic category characterizes approximately 60–90 % of patients with MEN2, FMTC accounts for 5–35 %, and MEN2B for about 5 % [2]. In MEN2, MTC usually presents as bilateral or multifocal neoplasia rather than the unilateral tumors in sporadic occurrences.

An earlier age of onset of these tumors is also observed in these familial cancer syndromes with children as young as 5 years of age diagnosed with MTC in MEN2A rather than 50–60 years of age in the sporadic incidence of MTC. MEN2B is the most aggressive form with children less than 3 years of age diagnosed with MTC with metastases in cervical lymph nodes. FMTC is least aggressive with MTC presenting between 20 and 40 years of age.

Penetrance of both MEN1 and MEN2 is nearly complete by 60 years of age [1, 3]. While these syndromes are uncommon (1 in 10,000–100,000 for MEN1 and 1 in 25,000–30,000 for MEN2), diagnosis of these autosomal dominant disorders has important implications for other family members because first-degree relatives have a 50 % risk of inheriting the causative mutation and developing the disease. Early detection is critical for the most effective intervention with the goal of treatment prior to tumor metastasis. However, these two syndromes and their underlying molecular pathology present very different challenges for the clinical molecular laboratory as a study in contrast to allelic heterogeneity and detection sensitivity.

MEN1

Molecular Basis of Disease

The *MEN1* gene maps to human chromosome 11q13 and was cloned in 1997 [4]. *MEN1* is a tumor suppressor gene [5] that contains 10 exons (the first one is untranslated) and encodes a ubiquitously expressed 2.8 kilobase (kb) transcript. The predicted 610-amino-acid (67 kDa) protein product, termed menin, exhibits no apparent similarities to any previously known proteins or consensus protein motifs but acts as a tumor suppressor to prevent MEN1 neoplasias [6]. Menin is a nuclear protein that interacts with proteins involved in transcription and cell growth regulation, control of the cell cycle, and genomic stability. More than 1,000 different *MEN1* loss-of-function mutations (nonsense, frameshift, insertion, deletion, missense, and splicing defects) have been described and are distributed throughout the 9.8 kb of genomic DNA comprising the *MEN1* gene (Fig. 25.1) [3, 7]. At least 75 % of all reported *MEN1* mutations will produce an inactivating, truncated menin protein primarily by nonsense and frameshift mutations.

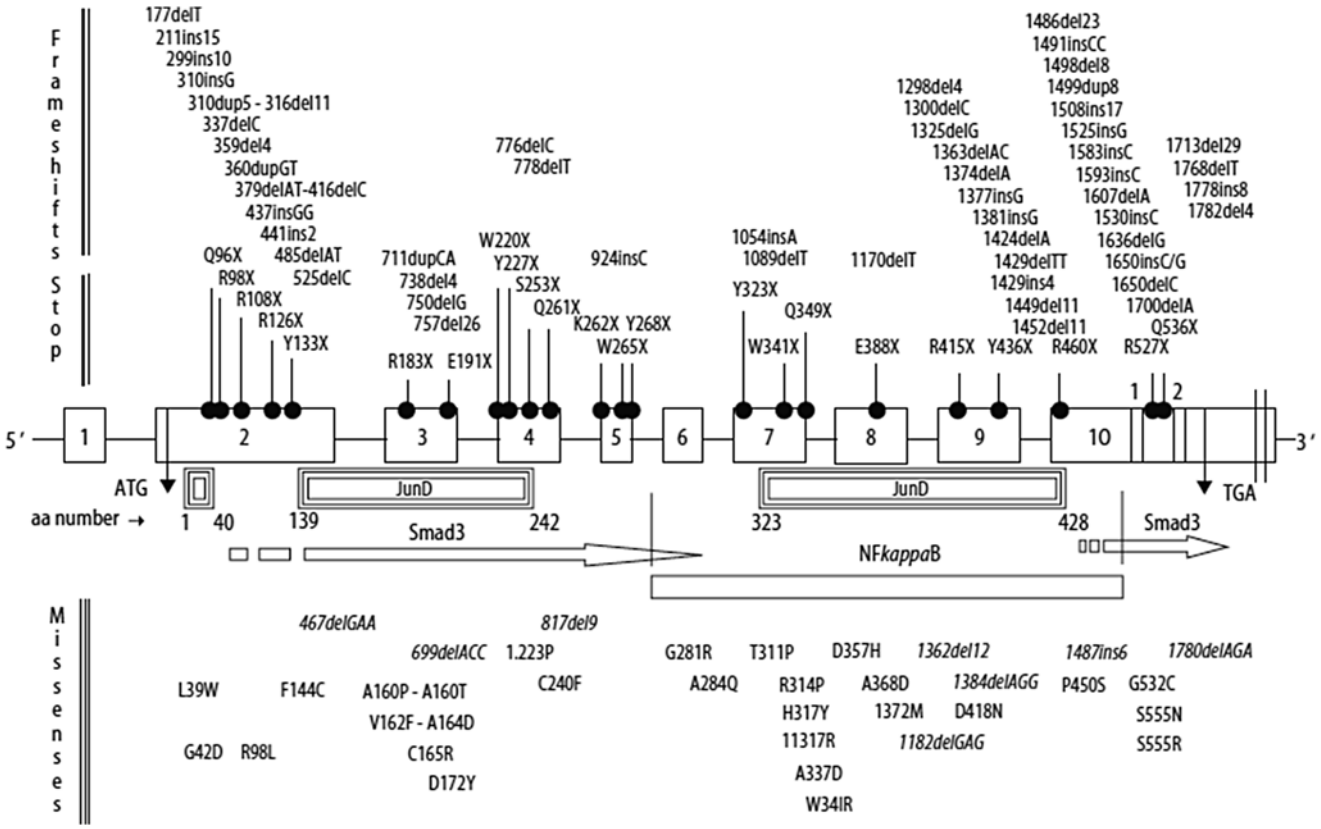

Figure 25.1 Schematic representation of the *MEN1* gene indicating the intron–exon organization, as well as the relative location, type, and distribution of germline mutations characterized in patients with MEN1. Functional domains of menin that interact with JUND, SMAD3, and NFKB are indicated below the gene map. Regions 1 and 2 within exon 10 note the locations of the nuclear localization signals 1 and 2 of the menin protein. From Wautot V, Vercherat C, Lespinasse J, et al. Germline mutation profile of MEN1 in multiple endocrine neoplasias type 1: search for correlations between phenotype and the functional domains of the MEN1 protein. Hum Mutat 2002;20:35–47, copyright © 2002 [3]. Reprinted with permission from John Wiley and Sons

Missense and in-frame genomic alterations have been described in the domains of menin that interact with *JUND*, *SMAD3*, and *NFKB1*, three major effectors in transcription and cell growth regulation pathways [8]. These and other alterations that predict a loss of menin function are consistent with a role of *MEN1* as a tumor suppressor gene [3]. In mouse models of MEN1, loss of both *MEN1* alleles in the mouse germline is lethal in the embryo but does not result in tumor formation [9]. Conditional gene knockouts targeted to pancreatic islet β-cells or parathyroid cells result in growth of insulinomas or parathyroid adenomas, respectively [10, 11]. No correlation has been observed between *MEN1* genotype and MEN1 phenotype [1, 3, 7, 12]. In approximately 20 % of MEN1 families, no mutation in the *MEN1* gene has been identified [13]. While this cancer syndrome displays an autosomal dominant pattern of inheritance of a single germline mutation, at the cellular level, *MEN1*-associated tumors are caused by inactivation of both copies of this tumor suppressor gene [13]. Extensive listing and descriptions of *MEN1* mutations are available online from the Human Gene Mutation Database Cardiff (http://www.hgmd.cf.ac.uk/ac/index.php, accessed 10/2/2014) and the Weizmann Institute of Science GeneCards (http://www.genecards.org/cgi-bin/carddisp.pl?%20gene=MEN1, accessed 10/2/2014).

Clinical Utility of Testing

Genetic testing for *MEN1* gene mutations is performed for three main reasons: (1) confirmation of a clinical diagnosis of MEN1, (2) identification of a presymptomatic at-risk relative, and (3) cessation of clinical screening in relatives who do not carry a mutation previously identified in affected family members. Approximately 50 % of patients with MEN1 will die as a result of their disease; thus, genetic screening to identify family members with germline *MEN1* mutations may lead to closer monitoring, earlier identification and treatment of tumors, improved outcomes, and longer survival. Confirmation of the diagnosis relies on identification of an *MEN1* germline mutation. Primary hyperparathyroidism is present in 100 % of patients with MEN1 by the age of 50 years [14], but parathyroid carcinomas are rarely seen. In addition, pancreatic islet cell adenomas may be observed in about 60 % of patients with MEN1 and are most commonly classified as gastrinomas or insulinomas. Pituitary adenomas also occur in approximately 30 % of MEN1 patients, but pituitary carcinomas are not usually detected. Variable expressivity and reduced penetrance also have been reported in many MEN1 families, making distinction of a familial condition difficult to discern from sporadic tumor occurrence. Absence of a detectable germline *MEN1* mutation does not exclude the diagnosis of MEN1. Genetic variability in other genes with which the menin protein interacts also may contribute to variable phenotypes of family members with the same *MEN1* allele.

Identification of carriers of *MEN1* gene mutations has not been very successful in either predicting or preventing the course of MEN1. The utility of *MEN1* mutation detection in directing individual patient care is limited by the absence of very sensitive imaging methods for early detection and treatment of MEN1-associated tumors, coupled with the lack of adequate treatment options for the types of tumors observed in MEN1 [12]. Knowledge of the carrier status is not an indicator for prophylactic surgery as in MEN2; thus, mutation screening in MEN1 patients does not avoid or cure the malignancy but may assist in clinical monitoring and lifestyle decisions. Predictive testing of at-risk relatives or prenatal screening requires that a disease-causing *MEN1* mutation has been previously detected in the family. When a family-specific mutation can be identified, the clinical significance of a subsequent negative genetic analysis in an at-risk relative can aid the genetic counselor in reassuring that family member and reducing screening to that of the general population. Targeting therapy to the menin protein has not been attempted because its function and the protein domains required for tumorigenesis have not been identified [13]. However, some small-molecule drug therapies are in development (see Conclusions and Future Directions below).

Available Assays

The mutations in the 9.8 kb genomic DNA of the *MEN1* gene that are associated with the MEN1 syndrome are diverse in both type and distribution. The initial molecular pathology screening of affected members of MEN1 families should include analysis of the entire gene. Up to 95 % of patients will have a *MEN1* mutation identified [15] when a combination of complete gene sequencing and deletion/duplication analyses is employed. Most approaches incorporate polymerase chain reaction (PCR) amplification of each exon with a survey for sequence variants by dideoxy fingerprinting [4], heteroduplex analysis (HA), single-strand conformation polymorphism (SSCP), or direct DNA sequencing [3, 12, 16]. PCR products from exons showing sequence variants by conformational changes usually are sequenced to identify the specific mutation. These strategies will identify mutations in 80–90 % of MEN1 families [17]. As in most PCR-based screening procedures, some types of mutations can be missed, including large deletions or insertions, point mutations in the 5′ regulatory or untranslated regions, nucleotide changes in the introns, or at the sites of PCR primer annealing, which may adversely affect PCR amplification efficiency. The majority of mutations are nonsense or frameshift mutations that predict expression of a truncated menin protein with loss of function [15]. Missense mutations in *MEN1* are primarily clustered in the domains that interact with the transcription factors, JUND (*MEN1* codons 1–40, 139–242, 323–428), SMAD3 (distal to *MEN1* codon 478), and NFKB (*MEN1* codons 276–479), of key cell growth pathways

(Fig. 25.1) [18]. Additional analysis using Southern hybridization [19, 20], long-range PCR, quantitative PCR, multiplex ligation-dependent probe amplification, or targeted genomic hybridization arrays will detect larger deletion and duplication mutations in MEN1 families following negative findings of direct DNA sequencing approaches. Clinical laboratories also may use next-generation sequencing methods to detect a broader range of mutations in a single test, including single-nucleotide variants, as well as small and large insertions and deletions. Thirty-seven Clinical Laboratory Improvement Amendments (CLIA)-certified clinical laboratories are listed in the Genetic Testing Registry database (www.ncbi.nlm.nih.gov/gtr/ accessed 6/25/15) as offering clinical testing for MEN1 [21]; while all of these laboratories indicate that DNA sequencing is performed, 25 also indicate that deletion and duplication analysis is included. Linkage analysis methods may be used to define familial haplotypes that confer genetic predisposition to MEN1.

Interpretation of Results

For any clinical molecular genetic test, the ability to identify a specific gene mutation to correlate with the disease status of an affected individual depends on the sensitivity of the assay. A well-defined clinical phenotype is essential for accurate interpretation and reporting of molecular test results to the healthcare professional. Genotype–phenotype correlations are either imperfect or nonexistent for MEN1.

Approximately 95 % of patients with MEN1 will have a germline mutation identified in the *MEN1* gene coding for the menin protein [15, 17]. *MEN1* germline mutations also have been identified in nearly two-thirds of patients with sporadic MEN1 [12]. There is presently no specific genotype–phenotype association of *MEN1* mutations to predict the clinical course or onset of this disease [15, 17]. More than 1,000 different mutations have been described [7], and some have been reported in multiple, independent kindreds. Characterization of these same genetic variations in newly diagnosed individuals supports the role of the mutant allele in the disease etiology and is very helpful for interpretation of the identified variant. As in many genetic syndromes, molecular identification of a pathogenic *MEN1* mutation in a family member with clinical features of MEN1 is most significant in the risk assessment of other first-degree relatives. Approximately 20 % of patients with familial isolated hyperparathyroidism, characterized by parathyroid adenoma or hyperplasia in the absence of other endocrine neoplasias, carry germline *MEN1* gene mutations [17, 22].

As reviewed by Guo and Sawicki [12], *MEN1* mutations are not limited to patients with MEN1. A significant number of sporadic endocrine tumors also may harbor *MEN1* mutations but not with the same prevalence as the same types of tumors in the syndromic cases. *MEN1* mutations do not provide clinically useful information for sporadic tumor staging [13]. While one third of MEN1 patients will develop pituitary tumors and have germline *MEN1* mutations, only about 1 % of sporadic pituitary tumors have *MEN1* mutations. The frequency of *MEN1* mutations also differs between different types of pancreatic endocrine tumors. In sporadic gastrinomas, the rate of *MEN1* mutations is 37 % in contrast to 15 % of sporadic nongastrinoma pancreatic tumors. Insulinomas, another pancreatic endocrine tumor of MEN1, develop in MEN1 knockout mice [23], but *MEN1* mutations have not been found in sporadic insulinomas [24]. Clearly the role of menin in familial and sporadic tumors is not the same. Sporadic parathyroid and pituitary adenomas with no detectable *MEN1* mutation may be characterized as phenocopies of MEN1, particularly when there is no family history of MEN1 [12].

Information about the penetrance and expressivity of the mutations in *MEN1* described to date suggests that carriers of a familial *MEN1* mutation have a 100 % risk of developing MEN1 by the age of 60 years [3]. Mutations leading to expression of a truncated menin protein create a loss of functional menin protein. Missense mutations may disrupt menin interaction with cell growth regulatory molecules or its cellular localization. These mutations also may decrease the stability of menin protein and lead to its degradation.

Laboratory Issues

Complete analysis of the *MEN1* gene sequence by PCR amplification of each exon and untranslated regions followed by direct DNA sequencing fails to identify mutations in 10–20 % of patients with MEN1. Some *MEN1* mutations have been identified repeatedly in apparently unrelated families, suggesting some tendency for mutational hot spots within *MEN1*, with mutation clusters at codons 83–84, 516, and 210–211 accounting for approximately 12 % of all mutations [7]. Caution must be used in the interpretation of the pathogenic functional consequences of DNA sequence variants. Predicting abnormal protein function from a DNA sequence change is imperfect. Approximately 24 polymorphisms of *MEN1* have been reported. For example, Arg171Gln and Ala541Thr produce amino acid substitutions featuring different polar side chains but are not associated with a disease phenotype [12]. Missense mutations in amino acids surrounding these same codons are consistent with MEN1 incidence in affected families [3]. Classification of polymorphisms as benign may change with long-term follow-up or ascertainment of additional MEN1 kindreds. Some frameshift or nonsense mutations do not completely abolish normal protein function. The existence of phenocopies (clinical presentations that may mimic familial disorders) also should be a consideration due to the relatively high frequency of sporadic parathyroid and pituitary adenomas [12], particularly in the absence of a family history of MEN1.

Genotype–phenotype prediction may be further complicated by variable expression among family members or different families with the same sequence change or by slow growth of an MEN1 tumor even after a gene mutation has been characterized. Once a sequence change has been documented as present in individuals with clinical features of MEN1 and absent in unaffected individuals, one can be reasonably certain of the significance of the finding as a true disease-associated mutation.

Approximately 70 % of reported mutations are nonsense, frameshift, or splice-site mutations that predict the expression of a truncated menin protein product. An in vitro protein truncation test (PTT) for diagnostic MEN1 screening proved to be too problematic for routine clinical laboratory implementation, given the problems inherent in (1) the instability of abnormal mRNA in peripheral blood lymphocytes of patients with MEN1 and (2) the scarcity of methionine residues for ^{35}S-methionine substitution in labeling the amino terminus polypeptides of the menin protein. Newer approaches with nonisotopic PTT [25, 26] may be more successful in applying this strategy to MEN1 mutation detection. Identification of large deletions by Southern blot or fluorescence in situ hybridization analysis may be useful for mutation screening because deletion of an entire exon or exons will result in amplification and sequencing of the remaining, normal allele and a false-negative test result, although next-generation sequencing can detect large deletions. Genetic variants in the regulatory regions of *MEN1*, including promoter mutations or methylation defects, may indicate abnormal gene expression but have not yet been documented.

For the MEN1 patients with no demonstration of germline MEN1 gene mutation, biochemical screening is an alternative course for monitoring disease. Careful biochemical screening may reveal evidence of neoplasia, including hyperparathyroidism, 10 years prior to the expression of overt clinical symptoms [20].

Formal proficiency testing programs are not available for MEN1 molecular testing. Clinical laboratories must meet the proficiency testing requirements by alternative proficiency assessment methods.

Conclusions and Future Directions

Currently, no preventive measures are available for prophylaxis or cure of MEN1-associated tumors. Radiologic imaging for identification of MEN1-associated tumors generally has low sensitivity in asymptomatic individuals. Biochemical screening for the tumor-secreted hormones may help detect early disease in asymptomatic mutation carriers [27]. Treatment usually involves surgery to remove the tumors, sparing unaffected tissue to preserve normal hormone production. Several clinical trials of drug therapies for patients with MEN1 have been launched. Various approaches focus on the modulation of the hypercalcemia and hypercalciuria of primary hyperparathyroidism by administration of the calcium-sensing receptor agonist, cinacalcet [28], or high-dose somatostatin with octreotide-LAR [29]. More extensive studies are needed to establish the efficacy of these molecules for clinical use.

MEN2

Molecular Basis of Disease

In 1993, the *RET* proto-oncogene ("*re*arranged during *t*ransfection"), located on chromosome 10q11, was cloned and characterized as encoding a transmembrane tyrosine kinase with a cysteine-rich extracellular receptor domain (Fig. 25.2) present on neuroendocrine cells of neural crest origin [30, 31]. *RET* spans 60 kb with 21 exons encoding a protein of approximately 1,100 amino acids [1]. Glial cell-derived neurotrophic factor and neurturin are two ligands for the *RET* receptor domain [32]. The ligands initiate homodimerization of *RET* protein molecules resulting in phosphorylation and activation of the tyrosine kinase domain, leading to downstream signal transduction [32]. *RET* is the only gene known to be associated with MEN2. Missense mutations in the *RET* gene were characterized in individuals with the MEN2 syndromes [30, 31, 33, 34] with a very restricted pattern of vari-

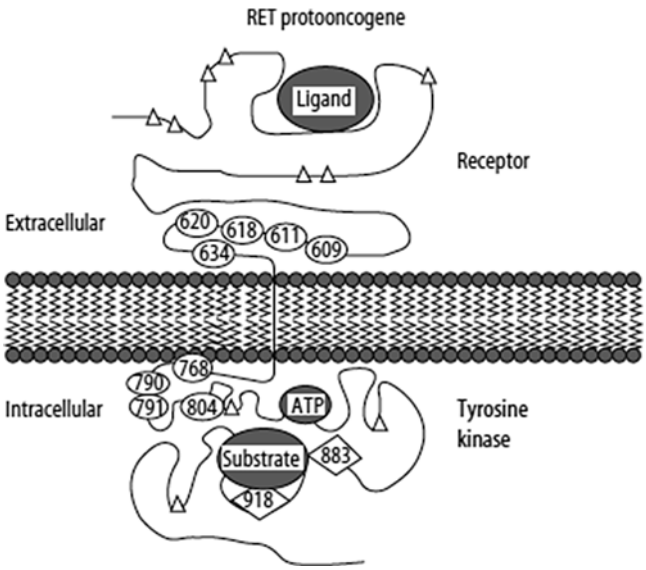

Figure 25.2 Diagram of *RET* gene product indicating the relative location of germline mutations characterized in patients with MEN2. *Ovals* are numbered to represent the codons that commonly contain germline missense mutations associated with MEN2A and FMTC. *Diamonds* are numbered to represent the codon location of germline mutations in MEN2B. *Triangles* indicate the positions of mutations in hereditary Hirschsprung disease. ations (Fig. 25.2). In patients with MEN2A or FMTC, nearly all the mutations in this gene are activating, gain-of-function missense mutations localized to exons 10, 11, and 13–15. Most commonly, heterozygous missense mutations are found in a cysteine-rich, extracellular domain adjacent to the transmembrane domain of the RET protein including six conserved cysteine residues in *RET* exon 10 (codons 609, 611, 618, and 620) and exon 11 (codons 630 and 634) (Table 25.1 and Fig. 25.2) [30, 31, 33]. Most of these mutations replace a cysteine with another amino acid that cannot form intramolecular disulfide bonds. The unpaired cysteine is then able to form a disulfide bond with another RET protein molecule producing constitutive dimerization and increased kinase activation of the aberrant RET protein [35, 36]. Missense mutations in codons 768 and 804, located in exons 13 and 14, respectively (Table 25.1), affect the intracellular portions of the RET protein next to the transmembrane domain (Fig. 25.2) [37, 38]. Nearly 95 % of all patients diagnosed with MEN2B have been characterized with a single missense mutation in codon 918 of *RET* exon 16, M918T, replacing a methionine residue with a threonine [33, 34]. Another 2–3 % of patients have an Ala833Phe mutation in exon 15. Both variants affect the intracellular tyrosine kinase catalytic domain (Fig. 25.2), altering substrate recognition, which leads to cellular transformation [35]. In each case, these common *RET* mutations produce a gain-of-function change for the aberrant RET protein. Online information about many other *RET* mutations is available from the Human Gene Mutation Database Cardiff (http://www.hgmd.cf.ac.uk/ac/index.php, accessed 10/2/2014), the Weizmann Institute of Science GeneCards (http://www.genecards.org/cgi-bin/carddisp.pl?gene=RET&search=RET, accessed 10/2/2014), and the ARUP Institute for Clinical and Experimental Pathology (http://www.arup.utah.edu/database/MEN2/MEN2_welcome.php, accessed 10/2/2014).

Hirschsprung disease (HSCR), an absence of enteric ganglia in the colon, also is associated with somatic or germline *RET* mutations, either in codons 609, 618, or 620, or distributed throughout other regions of the *RET* gene [40, 41]. Some families have been described in which HSCR cosegregates with either MEN2A or FMTC [42]. *RET* mutations in patients with HSCR may produce either loss or gain of RET protein function and include frameshift and nonsense mutations. Papillary thyroid carcinoma is associated with somatic gene rearrangements of the *RET* gene [43].

Clinical Utility of Testing

In an autosomal dominant inherited disorder, an individual with a single *RET* allele mutation has (1) a high likelihood of developing MTC (approximately 95 % of carriers) and (2) a 50 % risk of transmitting this risk allele and the high likelihood of developing MTC to each offspring. Genetic testing for *RET* mutations is the accepted best practice for confirmation of the diagnosis of MEN2, predictive risk-assessment testing for family members, and prenatal diagnosis of MEN2. Approximately 25 % of all MTC occurs as part of MEN2. Early detection of a pathogenic *RET* mutation improves the prognosis for presymptomatic individuals by offering an opportunity for therapeutic intervention prior to advanced disease, metastasis, or both [44–46]. Reduced morbidity and mortality is achieved by increased clinical monitoring, prophylactic thyroidectomy (followed by thyroid hormone replacement therapy plus autotransplantation of the parathyroids), or both [1, 47]. This can be a very effective treatment to prevent disease metastasis. Resected thyroid tissue from

children and adults with positive genetic findings demonstrates C cell hyperplasia or microscopic foci of malignancy in the absence of biochemical screening abnormalities or clinical symptoms [46]. Thus, genetic testing for *RET* mutations is a more sensitive and specific screening tool than either physiological testing or histopathologic examination of the thyroid for assessing familial cancer risk for MEN2 in these families [44–46].

The clinical significance of identifying a *RET* mutation is considerable, given that there is virtually 100 % penetrance of these mutations for MTC. But genetic findings alone cannot predict the age of disease onset; thus, continued surveillance for residual or recurrent MTC plus adrenal tumors is included in the follow-up care of MEN2 patients and asymptomatic carriers. About 50 % of MEN2 patients (both subtypes A and B) will develop pheochromocytoma, while 20–30 % of MEN2A patients develop parathyroid hyperplasia [1]. Patients with FMTC typically develop only MTC and none of the other clinical manifestations of MEN2A or MEN2B. Each subtype appears to be consistent within a family. Any RET mutation in codon 634 in exon 11 results in a higher incidence of pheochromocytomas and hyperparathyroidism. In particular, the C634R (Cys to Arg) mutation has been associated with a higher incidence of metastases at diagnosis; the allele is virtually absent in patients with FMTC [48]. Families with both MEN2A or FMTC and HRSC most frequently have germline *RET* mutations in codons 609, 618, or 620 in exon 10 [49]. Individuals within the same family who carry the same RET mutation may still display a variable phenotype indicating that additional modifier gene functions or environmental or epigenetic factors affect the expression of altered RET protein function and tumorigenesis. Concomitant mutations in genes coding for RET ligands or coreceptors are the most likely modifier molecules.

Genetic screening and mutation identification are currently recommended by 5 years of age for children who are at risk in MEN2A families. Children should be screened at birth if MEN2B has been diagnosed in close relatives, due to the earlier age of onset and aggressive clinical course of the MEN2B type [44, 45]. Patients with MEN2B should be treated as soon as the diagnosis is made. Some of the other advantages of DNA testing in MEN2 are that the test is relatively noninvasive and low risk, it is usually better tolerated by the patient than biochemical screening by metabolic challenge [47], genotype results are not subject to physiologic status, and serial genotype testing is not necessary. Individuals in MEN2 families who are not carriers of the familial *RET* mutation have the lower, general population risk for sporadic incidence of these endocrine neoplasias and do not require the same frequent monitoring for abnormal thyroid or adrenal function in the absence of clinical symptoms.

Several tyrosine kinase inhibitors that inhibit the activated (mutant) RET are being tested in clinical trials for treatment of MEN2 neoplasms (see Conclusions and Future Directions).

Available Assays

Screening for *RET* proto-oncogene mutations to confirm MEN2 diagnosis or to determine predisposition for MEN2 in asymptomatic relatives may be accomplished with a focused survey of a few exons of the *RET* gene. The majority of pathogenic mutations have been characterized in exons 10, 11, 13, 14, 15, and 16, including codons 609, 611, 618, 620, 634, 768, 804, 883, and 918, with few exceptions [48, 49]. In addition, all mutations of these *RET* codons associated with MEN2 are missense substitutions [30, 31, 33, 34, 37, 38]. Direct DNA sequencing of these exons or the entire *RET* coding sequence is the most commonly used strategy for detecting mutations in patients with MTC with no prior family history of MEN2. A targeted sequencing approach limited to exon 16 or specific codons also is used to screen or confirm a diagnosis of MEN2B or 2A in an at-risk family member when a familial mutation has been previously identified in an affected family member. These methods usually confer a 95–98 % frequency of *RET* mutation detection in patients with MEN2. Currently, the Genetic Testing Registry database (www.ncbi.nlm.nih.gov/gtr/, accessed 6/25/2015) lists 76 CLIA-certified clinical laboratories which offer genetic testing for MEN2. Fifty-six of these laboratories indicate that sequencing of all *RET* coding regions is available, while 21 offer this assay for selected exons or targeted variants (some laboratories offer both types of testing).

The *RET* cysteine codons are not mutated with equal frequency, with the majority of patients with MEN2A having alterations of codon C634 (Fig. 25.3). Nearly every base position of these TGC cysteine codons has been a point of allelic variation, generating more than 20 distinct alleles; thus, mutation detection methods must be designed with the capability to interrogate each nucleotide position of the cysteine codons. In clinical molecular laboratory practice, the preferred approach is to first characterize the causative (pathogenic) mutation in an affected individual using a comprehensive PCR plus direct DNA sequencing or next-generation sequencing approach either of the commonly

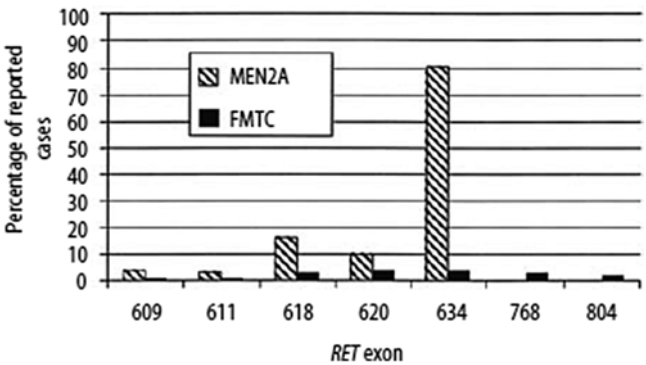

Figure 25.3 Distribution of *RET* mutations in MEN2A and FMTC. Summarized from the literature. Codon 634 in exon 11 represents a mutation hot spot for MEN2A

altered exons (Table 25.1) or of the entire *RET* gene. With decreasing costs and analytical improvements in DNA sequencing chemistry and data analysis, this has become the preferred method for comprehensive and direct *RET* mutation identification [50]. Nonsense and frameshift mutations in *RET* have not been observed in MEN2, and small, in-frame deletions or insertions are rarely identified [51].

Other physical detection methods for rapid discovery of DNA sequence variations such as denaturing gradient gel electrophoresis (DGGE) [52], SSCP [51, 53, 54], HA [55], and denaturing high-performance liquid chromatography (DHPLC) [55] have been used extensively in research studies but are less specific than direct DNA sequencing in the clinical laboratory. The utility of these indirect approaches for initial localization of a single-nucleotide sequence variation remains as a valuable diagnostic screening tool with some well-recognized analytical limitations. The high GC content of some *RET* sequences can confound physical detection methods by reducing the sensitivity of resolution between homoduplex and heteroduplex DNA molecules. Confirmation by direct DNA sequencing identifies both the exact position and nature of the base change localized by conformational screening methods. One major advantage of many of these conformational techniques is that they are frequently performed with automated instrumentation. Most of these methods identify a single-nucleotide sequence change by the altered mobility caused by the DNA conformational change using electrophoretic or melting profile shift analysis in comparison to the wild-type nucleotide sequence for the same DNA fragment. Sensitivity in the detection of the mobility shift is optimal in fragments of 200–400 base pairs (bp) for these approaches and may include 50–600 bp targets or up to 1.5 kb with DHPLC. Determination of the exact position of the base change within these fragments (e.g., TGC to TAC or TGC to GGC) can sometimes be deduced by comparison with an extensive panel of controls of defined mutant alleles previously confirmed by DNA sequencing [52, 55].

Increasingly, mutation scanning approaches have been replaced by high-resolution melting (HRM) analysis as a rapid, cost-effective method to analyze PCR amplicons and avoid contamination during post-amplification analyses [56]. In addition to PCR amplification primers, HRM requires oligonucleotide hybridization probes with sequences specific for each variant nucleotide. HRM analysis detects the mutant allele nucleotide substitution by using specific oligonucleotide probe sequences to distinguish normal and mutant sequences by virtue of their different melting temperatures conferred by the nucleotide substitution. The probes may be fluorescently labeled or unlabeled with fluorescent dye detection of the hybridization duplexes. *RET* missense mutations are more challenging to distinguish with these probes because several positions in the same codon may be variable and unique mutations may have similar or identical melting temperatures. Margraf and colleagues addressed this complexity by designing a two-stage *RET* genotyping assay in which mutation-specific probes for unambiguous genotyping of more than 50 *RET* sequence variations were simplified by the use of a masking technique [57].

Following the identification of the specific pathogenic mutation in an affected relative, other family members may be tested for just this allele with a more targeted, follow-up test of a single codon within one exon of *RET*. The molecular methodology may not be limited to direct DNA sequencing [47]. For example, many missense mutations identified in the comprehensive screening also may be directly detected by PCR–restriction fragment length polymorphism (RFLP) using a variety of enzymes [47], DGGE, DHPLC, SSCP, HA, or single-nucleotide polymorphism (SNP) testing methods [58]. Site-specific, single-base extension assays, such as those used for single-nucleotide polymorphism detection, have been described [58] for detection of many of the *RET* mutations. Linkage analysis is feasible [59] when direct mutation analysis fails to identify one of the common mutations in a family with a clear pattern of heritable disease.

Interpretation of Results

At least 95 % of patients with MEN2 will have one of a limited number of well-characterized mutations in the *RET* gene leading to a gain of function and activation of RET tyrosine kinase activity. Some genotype–phenotype specificity has been determined for the separate MEN2 subtypes, as summarized in Table 25.1 and Refs. 60 and 61. Significant overlap of clinical symptoms and missense variations occurs for any of six conserved cysteine codons (609, 611, 618, 620, 630, 634) which may be diagnostic for either MEN2A (95 %) or FMTC (80 %) (Fig. 25.3). Mutations at codon 634 account for about 85 % of kindreds with MEN2A and are the most common *RET* mutations associated with expression of hyperparathyroidism and pheochromocytomas. Mutations at codons 768, 804, and 891 in exons 13, 14, and 15, respectively, were initially described as consistent with the diagnosis of FMTC [37]; however, these variants also occur in rare families with MEN2A [60, 61]. In addition, some double heterozygous combinations of point mutations in addition to V804M are diagnostic for rare cases of MEN2B. The substitution of methionine at codon 918 with threonine, M918T, is diagnostic for MEN2B and is observed in 95–98 % of MEN2B patients. The substitution of alanine by phenylalanine at codon 883 of exon 15 (A883F) also is diagnostic for MEN2B. About half of the patients with MEN2B have de novo *RET* mutations and thus lack a family history for this syndrome. Somatic mutations at codon 918 have been frequently observed in patients who do not have a family history of MTC. The sensitivity of *RET* mutation screening requires concise clinical description of the patient's phenotype. The specificity of *RET* mutation detection for these disorders, MEN2A, FMTC, and MEN2B, is nearly 100 % [62].

The American Thyroid Association (ATA) Guidelines Task Force has completed evidence-based recommendations for clinical management of patients with MTC to establish current, rational, and optimal medical practice [39] (Table 25.1). Several of the recommendations specifically address the role of *RET* mutation testing in MEN2 syndromes. A key feature of the guidelines is the assignment of levels of risk (D through A) for development of aggressive MTC [39]. The highest risk, level D, is defined for *RET* mutations associated with MEN2B, i.e., M918T and A883F; a high risk, C, is assigned to C634R and other codon 634 missense mutations; a less high risk, B, applies to all exon 10 substitutions in the commonly mutated cysteine codons (609, 611, 618, 620); and the least high risk applies to all other point mutations and rare insertions and duplications in exons 5, 8, 10, 11, 13, 14, 15, and 16. Two variant alleles that had been thought to be pathogenic, S649L and Y791F, have now been reclassified as polymorphisms rather than disease-associated alleles. The ATA Guidelines further recommend that the ages for *RET* testing should be at diagnosis or <1 year of age for level D risk and <3–5 years of age for risk levels C through A. Patients as young as 5 years of age with M918T germline mutations have been diagnosed with MTC and distant metastases, conferring a greatly diminished likelihood of a surgical cure [63], and thus, the need for the earliest possible diagnosis with *RET* screening.

Interpretation should be conducted within the context of family history and the clinical presentation of the types of endocrine tumors in an affected family member, when available. Specific classification of a patient's MEN2 subtype is essential for the most accurate prognosis and effective clinical management. Distinguishing FMTC or MEN2A may be difficult in small kindreds, with limited or relatively young affected family members, or when scant family medical history is documented, because pheochromocytomas or parathyroid hyperplasia may primarily manifest in older relatives.

FMTC is considered as a reduced penetrance, phenotypic variant of MEN2A rather than a distinctly separate syndrome in the ATA recommendations [39]. Identical point mutations have been observed in families with only FMTC and in those with MEN2A as well as in kindreds that have MEN2A plus HSCR. Thus, the genotype–phenotype associations of MEN2 demonstrate variable expressivity and are not solely defined by *RET* mutations alone. Within particular kindreds, the clinical presentation is fairly consistent, considering the variable expression of tumor types in MEN2A. As a membrane tyrosine kinase molecule, the RET protein interacts with several coreceptor molecules and ligands including GDNF, neurturin, persephin, and artemin [64]. Base substitutions at the key conserved cysteine codons create amino acid substitutions which affect intermolecular associations, disrupt normal signaling, and change the activity or specificity of the kinase, or both [35]. It is hoped that clearer elucidation of concomitant variations in these other "modifier" genes will aid in the definition of more precise genotype–phenotype effects.

MEN2 syndromes account for approximately 25–30 % of MTC cases, based on epidemiological studies of new index cases. The remainder of MTC cases are sporadic, unilateral, or manifest in older adults with negative genetic findings of germline *RET* mutations. A significant proportion of the sporadic tumors (30–67 %) have somatic M918T mutations of *RET* in the absence of a constitutive germline mutation in leukocyte DNA of the same patient [65, 66]. Sporadic MTC also may feature a much more diverse type and distribution of *RET* mutations than MEN2A and FMTC. Disease-causing germline *RET* mutations also have been reported in 1–24 % of individuals with apparent sporadic MTC in the absence of previous family history of MEN2 but may be attributed to incomplete penetrance of some genetic variations [67]. Somatic *RET* mutations have not been detected in sporadic pheochromocytoma [66], but this tumor may also occur in von Hippel–Lindau (VHL) disease and neurofibromatosis type 1 (NF1). Neumann and colleagues showed the utility of additional mutation screening of the *VHL* gene associated with VHL disease in individuals with pheochromocytoma, but no other MEN2 symptoms and no identifiable *RET* gene mutation [68]. Screening for mutations in *VHL* and *NF1* genes should be considered in familial cases of pheochromocytoma with no detectable germline mutation in *RET*. HSCR is generally characterized by a broader spectrum of mutations distributed throughout the *RET* gene than those typical of MEN2, in both the familial and sporadic HSCR presentations [41, 42]. The rare occurrence of MEN2 family with no identifiable *RET* mutation may be tested by linkage analysis to identify the disease-associated haplotype if the disease is truly associated with an unidentified *RET* mutation, or perhaps a clinical misdiagnosis if the disease is caused by mutation of another gene. Many polymorphic markers are tightly linked to the *RET* gene, assuring high accuracy for linkage analysis.

Laboratory Issues

Overall, germline DNA sequencing for *RET* mutations is favored in clinical molecular laboratories because the mutations are localized, with limited regions to sequence and a low false-negative rate (approximately 5 %). Some of the limitations of *RET* genetic testing approaches can be attributed to the inherent technical aspects of PCR, DNA sequencing, restriction endonuclease digestion, fragment comigration, and nonpathogenic sequence changes. PCR primer and target fragment design are critical for sensitive detection of mutations by DNA conformation methods. DNA fragment size and base composition directly influence the melting profile of the PCR product and alter the optimal analytic conditions for heteroduplex and homoduplex separation (temperature, buffer

concentrations, resolution). Conformational changes or mobility shifts in mutation screening methods should be confirmed with targeted direct DNA sequencing of the same fragment. DNA sequence polymorphisms within the PCR product at positions other than the ones being scored for pathogenic changes can alter the fragment mobility, prompting false-positive results. For example, a frequent silent polymorphism at *RET* codon 769 of exon 13 changes one leucine codon, CTT, to another leucine codon, CTG. This may produce altered mobility of the fragment, which could be attributed to a change at the adjacent codon 768, consistent with FMTC. Careful comparison with both wild-type and previously characterized mutant alleles as positive controls may assist with the appropriate interpretation of these variations, as it will direct DNA sequence confirmation of the same template.

When reviewing DNA sequence electropherograms from automated instruments, both the base sequence indicated by the software and the nucleotide-specific peaks or signals in the trace must be critically examined, because true heterozygous base positions, such as the common cysteine codon substitutions in exons 10 and 11 of *RET*, may be difficult to discern. The peaks should overlap with signals of nearly equal intensity, a condition that may be adversely affected by flanking sequence composition. For example, short repeats of G or C nucleotides may display decreasing peak heights for the more distal residues, thereby quenching adjacent signal intensity. Sequencing of both strands of the amplified DNA fragment should confirm the heterozygous base detection and is the standard approach in many clinical laboratories using sequencing technology for clinical molecular testing. The DNA oligonucleotide primers used for direct cycle sequencing reactions may be the same or nested within the PCR fragment but should be positioned 20–40 bases from the codons being scored in the mutation screening to optimize clear sequence interpretation. Some fluorescent dye chemistries used in automated DNA sequence techniques yield high background signals (particularly of thymidine nucleotides) resulting from incomplete removal of unincorporated dye terminator reagents prior to electrophoresis.

A few pitfalls specific to *RET* mutation screening have been encountered. We observed preferential (or biased) PCR amplification resulting from specific DNA sequence polymorphisms in primer binding regions. The polymorphisms caused poor primer annealing and failed amplification of the allele sequences adjacent to the polymorphism. We observed this variable performance with some *RET* PCR primer sequences for exon 11 in clinical genetic testing for direct detection of mutations in codon 634. Both affected and at-risk family members were screened by PCR–RFLP for the C634Y mutation (TGC>TAC) in codon 634 in *RET* exon 11 using the *Rsa*I enzyme. One individual had a DNA fragment pattern consistent with two copies of the mutant allele and no wild-type allele, which was unlikely in this autosomal dominant disorder. The patient's disease presentation and course were not dissimilar (neither more severe, nor more extensive, nor at an earlier age) from other affected relatives who were heterozygous for the same allele. Direct DNA sequencing of the PCR product did not resolve the problem. We next selected PCR primers that flanked the same region of exon 11 but did not overlap the original primer binding sites. These primers amplified both the mutant and wild-type alleles to demonstrate that the individual was heterozygous, and both PCR–RFLP and DNA sequencing detected both alleles with the new PCR primers. A downstream DNA polymorphism (codon 691) was identified in a cis configuration with the wild-type allele at codon 634. The original primer that overlapped this polymorphic region annealed poorly and did not amplify the adjacent wild-type C634 allele, resulting in efficient amplification of only the C634Y allele and a false homozygous mutant pattern (Fig. 25.4). Another solution to restore the amplification of both alleles was to lower the annealing temperature slightly for the first primer pair, thus allowing the mismatch and facilitating the efficient PCR amplification of both alleles. Consequently, our standard procedure for *RET*

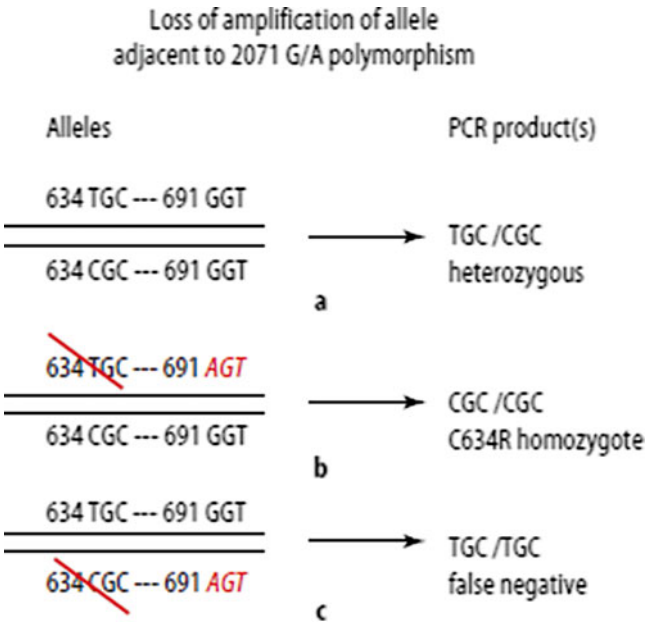

Figure 25.4 Schematic representation of the basis of unequal amplification of codon 634 in *RET*. When the GGT sequence is present at codon 691, complete homology with the PCR primer results in efficient amplification of the upstream, adjacent 634 codon on both alleles (**a**). When AGT is present at codon 691 on one *RET* allele, the match with the PCR primer is imperfect resulting in poor or absent amplification of the codon 634 region. The heterozygous condition, produces preferential amplification of only the 634 allele adjacent to the GGT 691 codon, producing either a false-positive (**b**; homozygous mutant, e.g., C634R) or a false-negative (**c**; wild type) genotype depending on whether the AGT variant is positioned in *trans* (**b**) or *cis* (**c**) configuration relative to the mutant C634 allele. Only the 634 alleles (mutant or wild type) linked to GGT at codon 691 are amplified efficiently

screening employs two independent sets of PCR primers to amplify each exon, followed by enzymatic digestion of each product or DNA sequencing of both strands of the PCR products. Findings from both PCR products must be concordant before a test interpretation is reported. In our standard quality control practice, positive (same mutant allele) and negative (no mutation) DNA controls are analyzed in parallel every time the assay is performed. A PCR with no added nucleic acid is also included in each test run and must be free of amplified DNA fragments, indicative of contamination, in all reported assays. In some reactions, small primer-dimer products (<30 bp) may appear, but are distinct from diagnostic DNA patterns.

The clustering of these common mutations in a limited region of the *RET* proto-oncogene allows the use of pyrosequencing technology as an alternative DNA-based diagnostic method of screening [69]. Reports of novel *RET* DNA alterations affecting noncysteine codons within exons 10 and 11 [50] require extended family studies to determine the clinical significance and the *RET* activation status of these variants.

Conclusions and Future Directions

Genetic testing for *RET* mutations can direct clinical care decisions to prevent and cure MEN2-associated cancers. Mortality from MTC and pheochromocytoma has been significantly reduced with earlier identification, prophylactic surgical thyroidectomy, or improved pharmacological therapy. Many clinical trials are currently testing small-molecule tyrosine kinase inhibitors (TKIs) for ability to target the RET protein or disrupt the RET signaling pathways as therapy for MTC, both sporadic cases and those associated with MEN2. The TKIs are not specific for RET, because most were developed to target other oncogenic proteins (such as EGFR, PDGFR, KIT, BRAF, and cMET), but several have activity against the RET kinase and tumor growth [36]. Trials of imatinib, vandetanib, motesanib, sorafenib, sunitinib, and XL-184 have overall produced modest or minimal partial responses (2–33 % of patients enrolled) for hereditary and sporadic MTC. Responses did not correlate with codon 618, 620, 634, or 918 mutations in *RET*. Somatic *RET* mutations were present in 70–80 % of the sporadic MTC tumors, primarily at codon 918 [36]. Comparisons across these trials are imperfect due to many differences in the activity of each TKI against RET, the extent of MTC tumor progression and aggressiveness, and the tolerated dose profiles for each TKI within various clinical disease groups. Development of RET-specific targeted therapies is an area for future work perhaps coupled with many approaches for the components of the RAS/RAF/MTE/MAPK or PI3K/AKT/mTOR intracellular pathways of signal transduction regulating proliferation and angiogenesis. Drug resistance to TKIs will probably challenge the efficacy of anti-RET therapies as has been observed with the treatment of other cancers with TKIs.

Von Hippel-Lindau Disease

26

Catherine A. Stolle

Abstract

Von Hippel-Lindau disease (VHLD) is an autosomal dominant cancer predisposition syndrome characterized by tumors of the brain and spine, retina, kidney, adrenal glands, and several other organs. Point mutations and deletions in the *VHL* tumor suppressor gene have been identified in virtually 100 % of patients who meet strict clinical criteria. Molecular diagnostic testing consists of DNA sequence analysis of the coding region (~72 % of mutations) as well as deletion analysis (~28 % of mutations). Most cases are inherited; however about 20 % of cases are the result of de novo mutations; individuals mosaic for a VHL gene mutation have been reported. Molecular testing may be used to confirm a clinical diagnosis in an affected patient or rule out the disease in individuals with a single typical tumor. In families with a known mutation, molecular testing may be used for predictive testing of at-risk members or for prenatal testing.

Keywords

Von Hippel-Lindau disease • *VHL* gene • Tumor suppressor • De novo mutations • Molecular testing • Diagnostic testing • Predictive testing • Prenatal testing

Introduction

Von Hippel-Lindau disease (VHLD; OMIM#19330) is an autosomal dominant cancer predisposition syndrome that gives rise to hemangioblastomas of the brain and spine, retinal angiomas, clear cell renal cell carcinoma, pheochromocytoma, endolymphatic sac tumors, tumors of the epididymis or broad ligament, and pancreatic tumors or cysts [1]. The incidence of VHLD is approximately 1 in 36,000 live births [2]. Onset is typically between the second and fourth decades of life, with penetrance for the disease nearly complete by the age of 65 years. In most cases, a family history of the disorder is apparent. In about 20 % of cases, however, the proband appears to have acquired a new mutation [3].

Molecular Basis of Disease

The *VHL* tumor suppressor gene was isolated by positional cloning in 1993 [4]. The gene, which consists of three exons spanning about 10 kilobases (kb) of genomic DNA on the short arm of chromosome 3 (3p25.3), is highly conserved among worms, flies, frogs, fish, chickens, humans, and other mammals (reviewed in Refs. 5 and 6). Two transcripts, 6.0 and 6.5 kb in size, are almost ubiquitously expressed and encode proteins of 213 and 160 amino acid residues, respectively. The latter isoform is the major product in most tissues and results from initiation of translation from an internal methionine codon at position 54. Both protein isoforms appear to be functional.

The VHL protein has been implicated in a variety of functions including transcriptional regulation, posttranscriptional gene expression, apoptosis, extracellular matrix formation, and ubiquitylation (reviewed in Refs. 5 and 6). The role of VHL in the regulation of hypoxia-inducible genes through the targeted ubiquitylation and degradation of hypoxia-inducible factor 1 alpha subunit (HIF1A) has been elucidated, leading

D.G.B. Leonard (ed.), *Molecular Pathology in Clinical Practice*, DOI 10.1007/978-3-319-19674-9_26

to a model of how disruption of the *VHL* gene results in the production of highly vascularized tumors.

Normal VHL binds to the protein elongin C, which forms a complex with elongin B, cullin-2 (CUL2), and Rbx1. This complex resembles the SKP1-CUL1-F-box protein (SCF) ubiquitin ligase or E3 complex in yeast that catalyzes the polyubiquitylation of specific proteins and targets them for degradation by proteosomes. Under normoxic conditions, HIF1A is hydroxylated at a specific asparagine residue by a member of the egg-laying deficiency protein nine-like (EGLN) protein family of prolyl hydroxylase enzymes. VHL binds to hydroxylated HIF1A and targets it for degradation. Under hypoxic conditions, HIF1A is not hydroxylated, VHL does not bind, and HIF1A subunits accumulate. HIF1A forms heterodimers with HIF1B and activates transcription of a variety of hypoxia-inducible messenger RNAs (i.e., *VEGF*, *EPO*, *TGFA*, *PDGFB*). Likewise, when VHL is absent or mutated, HIF1A subunits accumulate, resulting in cell proliferation and the neovascularization of tumors characteristic of VHLD [5].

Predisposition to VHLD is inherited in an autosomal dominant manner. However, tumor formation requires inactivation of the second allele (i.e., through loss of heterozygosity, methylation, or point mutation), and so the disease is recessive at the level of the cell. Mutations known to result in predisposition to VHLD include partial or complete deletions of the gene and point mutations (missense, nonsense, frameshift, and splice site). Point mutations are predicted either to truncate the protein, alter protein folding, or interfere with the binding of VHL to elongin C, HIF1A, or other target proteins [5, 7]. Although a handful of mutations and one mutation "hotspot" in exon 3 are common, point mutations are distributed over all three exons of the gene from codon 54 (internal initiator methionine) to the stop codon.

Four VHLD phenotypes have been described based on the likelihood of pheochromocytoma or renal cell carcinoma [8]. Type 1 is characterized by a low risk for pheochromocytoma. Truncating mutations or missense mutations that are predicted to grossly disrupt the folding of the VHL protein [7] are associated with VHLD type 1. VHLD type 2 is characterized by a high risk for pheochromocytoma. Most patients with VHLD type 2 have missense mutations of *VHL*. VHLD type 2 is further subdivided into those with a low risk (type 2A) and those with a high risk (type 2B) of renal cell carcinoma, as well as individuals at risk for pheochromocytoma only (type 2C). Some missense mutations correlate with a specific type 2 VHLD phenotype [6, 8].

A novel genotype-phenotype correlation has been reported, but is not yet considered to be a separate VHL type [9]. Individuals with a complete deletion of the *VHL* gene are more likely to present with multiple hemangioblastomas of the brain or spine or both as the first or only symptom of disease. Pheochromocytoma and renal cell carcinoma are less likely or may present at a later stage in life. At present, it is not clear why a complete deletion of the *VHL* gene would result in a phenotype distinctly different from that caused by a partial deletion or truncating mutation (i.e., VHL type 1). However, deletion of a neighboring gene(s) at the same locus may contribute to this phenotype [6].

Clinical Utility

Clinical molecular testing for VHLD has proven to be virtually 100 % effective at detecting germline mutations in patients with pathology-proven disease [10]. For this reason, molecular testing may be used to confirm a clinical diagnosis in an affected patient, screen for a mutation in an unaffected individual with a family history of VHLD, or rule out the disease in individuals with one VHLD-like tumor but no family history. When the mutation in the family is known, molecular testing may be used for diagnostic or presymptomatic testing of at-risk family members or for prenatal testing.

A clinical diagnosis of VHLD may be made in an individual with at least two typical VHLD tumors with or without a family history of VHLD or in an individual with at least one typical tumor and a significant family history [1]. In such cases, a *VHL* gene mutation is almost invariably found. Identification of a *VHL* mutation confirms the clinical diagnosis, establishes the need for periodic clinical screening, and facilitates presymptomatic testing of at-risk relatives.

Presymptomatic testing of at-risk family members for a known *VHL* gene mutation permits identification of presymptomatic mutation carriers and leads to early detection of tumors, timely intervention, and improved outcome. Identification of mutation-negative individuals eliminates the need for costly annual clinical screening. Genetic testing for a known *VHL* gene mutation is definitive.

Since the detection rate for germline mutations is high, and since approximately 20 % of patients have VHLD due to a de novo mutation, testing is indicated in individuals with a single VHLD-type tumor and no family history of the disease. A negative-mutation screen greatly reduces the risk of VHLD in this circumstance. Since tumors have been reported in children as young as 4 years of age, and since the mutation status of at-risk individuals affects clinical care, presymptomatic testing of asymptomatic children is appropriate. Prenatal testing for a *VHL* gene mutation is possible when the disease-causing mutation in an affected parent is known. However, prior to testing, consultation with a genetic counselor knowledgeable about the natural history of the disease and available treatment options is strongly recommended.

Available Assays

A 100 % mutation detection rate has been reported in individuals with a germline mutation in the *VHL* gene using a combination of deletion analysis and DNA sequence analysis [10]. A variety of methods, including quantitative Southern blot analysis [10], fluorescence in situ hybridization [11], real-time quantitative PCR [12], multiplex ligation-dependent probe amplification (MLPA; [13]), and array comparative genomic hybridization [14], have been used for the analysis of deletions in the *VHL* gene. MLPA is commonly used in clinical molecular laboratories for deletion analysis of the *VHL* gene since it is a relatively simple and rapid technique. Partial and complete gene deletions account for approximately 28 % of all cases of VHLD, with complete deletions occurring in 3–5 % of patients. Duplications have not as yet been reported to cause VHL disease.

PCR amplification and DNA sequence analysis of exons 1–3 of the *VHL* gene (including the adjacent splice donor and acceptor sequences) will detect all disease-causing point mutations. The *VHL* gene has few benign polymorphisms. DNA sequence analysis is typically performed by Sanger sequencing using fluorescently labeled dideoxy terminator nucleotides. Analysis for known point mutations in the *VHL* gene using next-generation sequencing technologies is available from several clinical molecular laboratories as part of a panel of cancer-related genes.

Interpretation of Results

Using a combination of deletion analysis and DNA sequence analysis, germline mutations in the *VHL* gene have been identified in over 300 consecutive patients with well-documented (pathology-proven) VHL disease seen at the National Cancer Institute since 1995. The sensitivity and specificity of the assays used to detect *VHL* gene mutations, therefore, are very high.

If a disease-causing mutation is identified in an affected or at-risk individual, that individual will be predisposed to developing tumors characteristic of VHLD. Periodic screening of target organ systems is recommended for early detection and treatment of tumors. Molecular testing of offspring would be appropriate, as they are at 50 % risk of inheriting the disease-causing mutation. The parents of the proband should be offered molecular testing, as they may have unappreciated disease. The risk to siblings depends on the mutation status of the parents, since the mutations in approximately 20 % of patients are de novo.

The interpretation of a negative-mutation screen depends on the circumstances surrounding the testing and the strength of the clinical diagnosis in the affected family member. A negative test in an individual at risk for a known *VHL* gene mutation is definitive, and the individual is not at risk for developing VHLD and need not undergo clinical screening for VHLD-associated tumors.

In screening of an unaffected at-risk individual for an unknown mutation in the *VHL* gene (i.e., first-degree relative of a patient with a clinical diagnosis of VHLD but no identified *VHL* mutation), a negative-mutation screen indicates only that the individual does not have a germline *VHL* gene mutation. This may be because (1) the individual did not inherit the mutant allele in the affected relative (i.e., a parent), (2) the affected relative does not have VHLD (i.e., as a result of an incorrect or inconclusive diagnosis), or (3) if the unaffected individual is the parent, he or she may be mosaic for a mutation that was transmitted to the affected offspring. Whenever possible, careful clinical evaluation or molecular analysis of an affected family member is suggested to improve the accuracy of the test interpretation for at-risk family members.

For an individual with a clinical diagnosis of VHLD but no family history, a negative-mutation screen indicates that either the patient is a phenocopy (coincidental occurrence of tumors typical of VHLD but without a gene mutation) or a mosaic (with a mutation in some, but not all, cells of the body). Mosaicism has been documented in the affected but mutation-negative parents of patients with a germline *VHL* gene mutation [3]. The frequency of mosaicism is not known but is believed to be low (i.e., <5 %). If the diagnosis of VHLD is supported by pathologic findings, i.e., magnetic resonance imaging of brain or spine, eye examination, abdominal ultrasound or computed tomography scan, urinary catecholamines, etc., then the patient is more likely to be mosaic and should be periodically screened for additional tumors characteristic of VHLD. Offspring (if any) should be considered at risk and should be considered for periodic clinical screening for tumors or molecular testing. The degree of risk (0–50 %) depends on the extent of mosaicism and the potential for transmitting the mutant allele, neither of which can be determined by clinical molecular testing at this time.

For patients who do not fulfill the clinical criteria for VHLD diagnosis because they have a single type of tumor and no family history, a negative-mutation screen would indicate that they are very unlikely to have VHLD; however, mosaicism cannot be entirely ruled out. Although routine clinical surveillance for characteristic VHLD tumors would not appear warranted, regular follow-up visits to a physician regarding the initial tumor would be expected. Likewise, routine screening of offspring would not be indicated unless the proband develops additional tumors (especially of another typical organ system) or if the offspring begin to develop symptoms of VHLD.

Occasionally, a base change in the *VHL* gene will be detected that is neither a known disease-causing mutation nor a known polymorphism. These "variants of unknown significance" with regard to VHLD are generally missense mutations or mutations in introns outside the consensus splice sequences. Novel mutations may be evaluated as disease-causing mutations or polymorphisms using criteria described by Cotton and Scriver [15] and in silico programs such as SIFT and PolyPhen. In such cases, it is helpful to test other affected or unaffected family members or both to determine whether the mutation segregates with the disease in the family.

Laboratory Issues

Point mutation analysis of the *VHL* gene is performed as a laboratory-developed test. PCR primers and conditions have been published [10]. A kit for deletion analysis of the *VHL* gene by MLPA is available from MRC Holland (Amsterdam, the Netherlands). No organized proficiency testing program is available for VHLD; therefore, proficiency testing may be performed either by interlaboratory exchange or by repeat testing of previously analyzed samples.

Various sources of DNA are suitable for use in DNA sequencing and MLPA assays. Ethylenediaminetetraacetic acid anticoagulated peripheral blood is the most commonly submitted specimen; however, DNA, frozen tissue, cultured cells, saliva, paraffin-embedded tissue, cheek epithelial cells (buccal swab), unspun amniocytes, or direct chorionic villus sampling specimens may be used as well. Mutation screening by MLPA and DNA sequence analysis can be completed in approximately 1 week. Interpretation of the assays is fairly straightforward (described above). Point mutations may be compared to an online database of human gene mutations, either at the Human Gene Mutation Database at http://www.hgmd.org/hosted by the Institute of Medical Genetics in Cardiff or a list of *VHL* gene mutations in the Universal VHL-Mutation Database (http://www.umd.be/) [16].

The mutation detection rate quoted by laboratories in the USA varies from 95 % to greater than 99 %. Since all laboratories are using the same basic methodologies, this variability is likely due to uncertainty regarding the patient's diagnosis or inadequate clinical information rather than the inability to detect germline mutations in the *VHL* gene.

Hereditary Skin Cancer

27

Dani Bercovich and Inbal Kedar

Abstract

Skin cancer can be divided into three categories: basal cell carcinoma, squamous cell carcinoma, and melanoma. Because of the heterogeneity of the skin cancer phenotypes as well as the unknown exact correlation to genotypes, genetic testing is not offered on routine bases for all types of skin cancers. Several approaches are being used by clinicians, to determine the possible genetic components, which may be involved after complete skin examination by a dermatologist as a screening tool for skin cancer and family history determination. Molecular genetics of melanoma can be both diagnostically and therapeutically useful. When candidate's genes are known, according to the skin cancer phenotypes or the syndrome, Sanger sequencing and gene copy number variations (MLPA or RT-PCR) are applied. More recently, the use of comparative genomic hybridization (CGH), analysis of copy number in known miRNA genes, and exome sequencing, followed by screening of targeted genes in melanoma, helps to elucidate the genetic background of several skin cancers and the appropriate therapeutic approach. Referral of individuals affected or at risk for skin cancers to a genetic counselor or hereditary cancer center that routinely tests skin cancers patients is recommended.

Keywords

Hereditary • Skin • Cancer • Melanoma • Clinical testing • NGS

Skin cancer can be divided into three categories: basal cell carcinoma, squamous cell carcinoma, and melanoma. Basal cell carcinoma (BCC) is the most common and the least aggressive, although it can be very destructive to local tissue. BCC can be treated with surgery or topical chemotherapy and has a hereditary factor. Squamous cell carcinoma (SCC) is the second most common type of skin cancer and accounts for approximately 20 % of cutaneous malignancies. Although most cancer registries do not include information on the incidence of nonmelanoma skin cancer, annual incidence estimates range from 1 million to 3.5 million cases in the USA [1]. Mortality is rare from SCC; however, the morbidity and costs associated with treatment of SCC are considerably high. Sun exposure is the major known environmental factor associated with the development of skin cancer of all types; however, different patterns of sun exposure are associated with each major type of skin cancer [2]. In addition to environmental radiation, exposure to therapeutic radiation is another risk factor for SCC. Individuals with skin disorders treated with psoralen plus ultraviolet-A radiation (PUVA) have a three-fold to six-fold increase in SCC [3]. Current or previous cigarette smoking has been associated with a 1.5- to 2-fold increase in SCC risk [4]. Available evidence suggests that the effect of smoking on cancer risk seems to be greater for SCC than for BCC. Malignant melanoma is a neoplasm of pigment-producing cells called melanocytes that occurs most often in the skin but may also occur in the eyes, ears, gastrointestinal tract, leptomeninges, and oral and genital mucous membranes [5].

	Werner syndrome
Cutaneous malignant melanoma (CMM)	–

Molecular Basis of Disease

Cutaneous BCC is the most common cancer among people of European ancestry [6]. The primary environmental risk factor for BCC is sun exposure, but genetic risk factors also have a substantial role. Susceptibility to BCC is a genetically heterogeneous trait. Some of the sequence variants that confer susceptibility seem to operate through their association with fair-pigmentation traits common among Europeans, resulting in reduced protection from the damaging effects of ultraviolet (UV) radiation. Genes which are known to be associated with fair skin or sensitivity to sun in BCC are *ASIP*, *TYR*, and *SHEP5* [7]. Other sequence variants have no obvious role in pigmentation or UV susceptibility but, instead, function in the contexts of growth and differentiation of the basal layers of the skin. BCC occurs as a feature of multiple syndromes, including basal cell nevus syndrome (BCNS), Bazex syndrome, Rombo syndrome, Brooke-Spiegler syndrome, Muir-Torre syndrome, and xeroderma pigmentosum (XP) (Table 27.1). Somatic mutations within the catalytic domain of the *RASA1* gene and four mutations within its C-terminal SH2 region occur in BCC syndromes. The region in which these mutations are clustered is A/T rich, raising the possibility that UV radiation is a contributing factor [8, 37]. For sporadic BCCs, mutations occur in the *PTCH1* and *PTCH2* genes [9, 10].

XP is a rare autosomal recessive hereditary disorder affecting approximately one in one million individuals in the USA and Europe but is more common in Japan, North Africa, and the Middle East. XP is caused by dysfunction of nucleotide excision repair that results in cutaneous malignancies in the first decade of life. Affected individuals have an increased sensitivity to sunlight, resulting in a markedly increased risk of SCC, BCC, and melanoma. One report found that non-melanoma skin cancer was increased 150-fold in individuals with XP; for those younger than 20 years, the prevalence was almost 5,000 times the general population incidence [11]. Seven complementation groups plus one variant form of XP are based on the underlying genetic cause of the disease. Complementation group A, due to mutations in *XPA*, accounts for approximately 10 % of cases [12]. Approximately 40 % of the XP cases in complementation group C are due to mutations in the *XPC* gene. *ERCC2* (*XPD*) mutations are present in about 20 % of the affected individuals and constitute complementation group D. Other mutated genes in this disorder include *ERCC3* (XP group B), *DDB2* (XP group E), *ERCC4* (XP group F), and *ERCC5* (XP group G). Carriers of a mutation in one XP gene are generally asymptomatic. Founder mutations in *XPA* (R228A) and *XPC* (V548A fs X572) have been identified in North African populations, and direct screening for these mutations has been proposed for this group of patients [13]. The variant form of XP, or type V XP, is caused by mutations in the *POLH* gene, which encodes a polymerase required in S-phase of the cell cycle.

Ferguson-Smith syndrome is an autosomal dominant disorder characterized by invasive skin tumors that are histologically identical to sporadic cutaneous SCC, which resolve spontaneously without intervention. Linkage analysis of affected families has shown loss of the long arm of chromosome 9, and haplotype analysis has localized this gene to 9q22.3 between D9S197 and D9S1809. *PTCH* (mutated in BCNS) and *XPA* are among the candidate genes located in this chromosomal region; however, neither one of these genes has been found to be mutated in the families affected with Ferguson-Smith syndrome. Two fructose bisphosphatase genes (*FBP1* and *FBP2*), a possible membrane alanine aminopeptidase (*C9orf3*), and three other genes of unknown function (*AL133071*, *FLJ14753*, and *CDC14B*) are additional candidates [14, 15].

Two types of oculocutaneous albinism are associated with increased risk of SCC of the skin. Oculocutaneous albinism type 1, or tyrosinase-related albinism, is caused by mutations in the tyrosinase gene, *TYR*, located on the long arm of chromosome 11. The *OCA2* gene, also known as the P gene, is mutated in oculocutaneous albinism type 2, or tyrosinase-positive albinism. Both disorders have an autosomal recessive inheritance pattern, with frequent compound heterozygosity [16]. Mutations in the genes *MATP* (*OCA4*) and *TYRP1* (tyrosinase-related protein) are associated with less common types of oculocutaneous

albinism. Several other albinism syndromes such as Hermansky-Pudlak syndrome also are inherited in an autosomal recessive manner but may have a pseudodominant inheritance pattern in Puerto Rican families, due to its high prevalence in this population. The underlying cause is believed to be a defect in melanosome and lysosome transport in skin cells. A number of mutations at disparate loci have been associated with this syndrome, including *HPS1*, *HPS3*, *HPS4*, *HPS5*, *HPS6*, *HPS7* (*DTNBP1*), and *HPS8* (*BLOC1S3*) [17].

Two autosomal recessive syndromes, Chediak-Higashi syndrome and Griscelli syndrome, are caused by mutations in the *LYST* and *MYO5A* genes, respectively [18]. Approximately 95 % of individuals with the heritable disorder dystrophic epidermolysis bullosa have a detectable germline mutation in the gene *COL7A1*, located at 3p21.3, which is expressed in the basal keratinocytes of the epidermis and encodes for type VII collagen [19].

Junctional epidermolysis bullosa (JEB) is an autosomal recessive type of epidermolysis bullosa. JEB results in considerable mortality with approximately 50 % of cases dying within the first year of life. Mutations in any of the genes encoding the three basic subunits of laminin 332, previously known as laminin 5 or *COL17A1*, can result in this syndrome [19].

Fanconi anemia is a complex disorder that is characterized by increased incidence of hematologic and solid tumors, including SCC of the skin. Thirteen complementation groups defined by the underlying causative genetic factors have been identified for Fanconi anemia, of which Fanconi anemia complementation group A (FANCA) is the most common [20]. Individuals with dyskeratosis congenita have an incidence of SCC of approximately 1.5 %, and the median age at diagnosis is 21 years. These SCCs are generally managed as any other SCC of the skin. Several genes associated with telomere function (including *DKC1*, *TERC*, *TINF2*, *NHP2*, *NOP10*, and *TERT*) have been implicated in dyskeratosis congenita [21].

Rothmund-Thomson syndrome, also known as poikiloderma congenitale, is a heritable disorder characterized by chromosomal instability. The precise increased risk of skin cancer is not well characterized, but the point prevalence of nonmelanoma skin cancer, including both BCC and SCC, is 2–5 % in young individuals affected by this syndrome. A mutation in the *RECQL4* gene, located at 8q24.3, is present in 66 % of clinically affected individuals and has an autosomal recessive inheritance pattern. *RECQL4* encodes the ATP-dependent DNA helicase Q4, which promotes DNA unwinding to allow for cellular processes such as replication, transcription, and repair [22]. Loss of genomic stability is also the major cause of Bloom syndrome (*BLM* gene) and Werner syndrome (*WRN* gene). Approximately 20 % of the cancers reported in these syndromes are cutaneous, with melanoma and SCC of the skin accounting for 14 % and 5 %, respectively [23].

Susceptibility loci for several forms of familial cutaneous malignant melanoma (CMM) have been mapped, including *CMM1* on chromosome 1p36. Other familial CMM susceptibility loci include CMM2 which has been found to be affected by mutations in the *CDKN2A* gene on chromosome 9p21 and CMM3 by mutations in the *CDK4* gene on chromosome 12q14. *CMM4* has been mapped to chromosome 1p22. Susceptibility to melanoma has been associated with polymorphisms in the *MC1R* (*CMM5*) and *XRCC3* (*CMM6*) genes. The melanocortin 1 receptor (MC1R or alpha melanocyte-stimulating hormone receptor) is a key protein regulating skin and hair pigmentation. *CMM7* has been mapped to chromosome 20q11.22. The *CDKN2A* gene encodes proteins that regulate two critical cell cycle regulatory pathways, the TP53 pathway and the RB1 pathway. Through the use of shared coding regions and alternative reading frames, the *CDKN2A* gene produces two major proteins: p16 (INK4), which is a cyclin-dependent kinase inhibitor, and p14 (ARF), which binds the p53-stabilizing protein MDM2 [24]. Sporadic somatic mutations causing malignant melanoma have also been identified in several genes, including *BRAF*, *STK11*, *PTEN*, *TRRAP*, *DCC*, *GRIN2A*, *ZNF831*, and *BAP1*. A large percentage of melanomas (40–60 %) carry an activating somatic mutation in the *BRAF* gene, most often the missense mutation V600E [25] (Table 27.2).

Melanoma Risk Assessment

Family history of melanoma increases risk of melanoma by about two-fold. A family cancer registry study assessed over 20,000 individuals with melanoma and found a standardized incidence ratio of 2.62 for offspring of individuals with melanoma and 2.94 for siblings [38]. A study looking at the contribution of family history to melanoma risk showed a population-attributable fraction ranging from <1 % in northern Europe to 6.4 % in Australia [39], suggesting that only a small percentage of melanoma cases are caused by familial factors. Rarely in some families, many generations and multiple individuals develop melanoma and are at much higher risk. For individuals from these families, the incidence of melanoma is higher for sun-protected rather than sun-exposed skin [40]. The major hereditary melanoma susceptibility gene, *CDKN2A*, is mutated in approximately 35–40 % of families with three or more melanoma cases. To date, more than half of the families with multiple cases of melanoma have no identified mutation [41].

Patients with a personal history of melanoma or dysplastic nevi should be asked to provide information regarding a family history of melanoma and other cancers to detect the presence of familial melanoma. Age at diagnosis in family members and pathologic confirmation should also be sought. The presence of multiple primary melanomas in the same individual may also provide a clue to an underlying genetic

susceptibility. Approximately 30 % of affected individuals in hereditary melanoma kindreds have more than one primary melanoma, compared to 4 % of sporadic melanoma patients [42]. Family histories should be updated regularly.

For individuals without a personal history of melanoma, several models have been suggested for prediction of melanoma risk. Data including gender, age, family history of melanoma, number of severe sunburns, number of moles larger than 3 mm on the limbs, and hair color were used to create a model for prediction of melanoma risk [43].

Clinical Utility of Testing

Because of the heterogeneity of the skin cancer phenotypes as well as the unknown exact correlation to genotypes, genetic testing is not routinely offered for all types of skin cancers. Several approaches are used clinically for monitoring for the presence of skin cancer, including a complete skin examination by a dermatologist and a family history assessment. A physical examination in conjunction with ancillary diagnostic techniques such as epiluminescence microscopy, more commonly known as dermoscopy (dermatoscopy), may incline the physician to biopsy a suspicious skin lesion early in its evolution. An appropriate biopsy that is representative of the entire lesion is mandatory for an accurate histologic diagnosis of skin cancer; this is especially true for the diagnosis and staging of melanoma. Currently, the definitive diagnosis of melanoma and non-melanoma skin cancers is by histopathologic evaluation of skin lesion resection specimens.

With a family history consistent of a hereditary form of skin cancer, appropriate genetic counseling and targeted genetic testing appropriate to the family history are used. Identification of the familial mutation can be used to screen of other family members to identify those with the mutation who will require close monitoring and avoidance of sun exposure and those without the mutation who are at the population risk for skin cancer. For severe forms of inherited skin cancer syndromes, prenatal testing or preimplantation genetic diagnosis may be offered to family members of childbearing age.

Molecular genetics of melanoma can be both diagnostically and therapeutically useful [26]. When candidates' genes are known, according to the skin cancer phenotypes or the syndrome, Sanger sequencing and gene copy number variation testing such as multiple ligation probe amplification (MLPA) or reverse-transcription PCR (RT-PCR) can be used. More recently, array-based comparative genomic hybridization (aCGH), analysis of copy number in known miRNA genes, and exome sequencing (by next-generation sequencing, NGS) followed by screening of targeted genes in melanoma are being used to elucidate the genetic background of several skin cancer syndromes and the appropriate therapeutic approach. Distinct patterns of genetic alterations, both chromosomal aberrations and the frequency of specific gene mutations, suggest that the subtypes of melanoma arise from separate mechanistic routes in response to different selective influences. For example, melanoma patients without chronic sun-induced damage have frequent losses of chromosome 10 and frequent mutations in the *BRAF* gene, while melanomas on skin with chronic sun-induced damage had frequent increases in the number of copies of the *CCND1* gene and infrequent mutations in *BRAF* [27]. The oncogene *KIT* has been identified as a potential therapeutic target in melanomas of mucosal membranes, acral skin, and skin with chronic sun-induced damage. This is of value, as this subset of melanomas infrequently has mutations in *BRAF*. The observation of such chromosomal aberrations in melanoma, and a virtual deficiency of abnormalities in benign nevi, leads to the possibility that chromosomal analysis could be used diagnostically in melanocytic lesions that are ambiguous based on our current methods of assessment [28]. Identifying such causative genetic alterations also offers targets for therapy. For example, a major response has been noted using imatinib mesylate in *KIT*-mutated melanoma and in a phase II trial of patients with metastatic melanoma having at least one protein tyrosine kinase mutation [29].

Available Assays

Both the general population and members of families with a history of skin cancer should have a complete skin examination by a dermatologist as a screening tool for skin cancer. The American Cancer Society recommends using the ABCDE mnemonic (asymmetry, border irregularity, color abnormalities, diameter greater than 5 mm, and evolving) to identify lesions that may require further evaluation by biopsy for histopathologic examination. The diagnostic utility of the dermatologist's visual examination technique has been confirmed and studies have shown that its sensitivity in the diagnosis of skin cancer ranges from 65 to 97 %, with a positive predictive value of 35–75 % [30]. Dermatoscopy is a noninvasive visualization technique that uses optical lenses and fluid immersion to closely examine suspicious cutaneous lesions, allowing the detailed inspection of skin pigment, vascular structures, and subtle skin color changes.

For molecular genetic testing, denaturing high-performance liquid chromatography, single-strand conformation polymorphism, and denaturing gradient gel electrophoresis are mutation screening methods that may be used in conjunction with Sanger or NGS sequencing for the analysis of the entire coding region or sequence analysis of select exons in the *CDKN2A* and *CDK4* genes. Deletions and duplications are most commonly detected by MLPA or quantitative real-time PCR (qPCR). For somatic mutation analysis of skin cancer specimens, Sanger or NGS sequencing of the full coding regions or selective single-nucleotide polymorphisms of candidates genes, such as *MC1R*, *BRAF*, *TP53*, *PTEN*, *KIT*, and *CCND1*, are available in some clinical molecular laboratories [44]. Melanomas can be characterized by somatic changes such as copy number variants and structural variants using aCGH [32].

Interpretation of Test Results

The sensitivity or accuracy of genetic tests varies by the method used and the phenotypic characterization (which depends on the examination by a dermatologist as a screening tool for skin cancer and/or genetic consultants). In the *CDKN2A* gene, germline mutations can be detected in 15–20 % of patients with melanoma [33, 34]. Mutations in the *CDKN2A* gene are melanoma predisposition alleles with high penetrance, although they have low population frequencies. In contrast, variants of *MC1R* confer much lower melanoma risk but are common in European populations. Three MC1R variants (R151C, R160W, and D294H) increase risk of melanoma with a hazard ratio of 3.72 and are associated with red hair, fair skin, and skin sensitivity to ultraviolet light [35]. *BRAF* somatic missense mutations are found in up to 66 % of malignant melanomas [36]. All mutations are within the BRAF kinase domain, with a single substitution, V600E, originally reported as V599E, accounting for 80 % of the mutations. Mutated BRAF proteins have elevated kinase activity and are transforming in NIH 3 T3 cells. BRAF is a serine/threonine kinase that is commonly activated by somatic point mutation in many human cancer types, which provides new therapeutic opportunities for treatment of melanoma.

Laboratory Issues

Genetic counseling is recommended before genetic testing is ordered. Referral of individuals affected or at risk for skin cancers to a genetic counselor or hereditary cancer center that routinely tests skin cancers patients is recommended.

Future Directions

MicroRNA (miRNA) expression signatures are not only found in cancer tissue but also in the blood of cancer patients. Specifically, miRNA detection in blood offers the prospect of a noninvasive analysis tool. Blood samples of melanoma patients and healthy individuals can be well differentiated from each other based on miRNA expression analysis [31]. In miRNA expression analysis using a subset of 16 significantly deregulated miRNAs, a pathogenicity classification accuracy of 97.4 % was achieved, with a specificity of 95 % and a sensitivity of 98.9 % by supervised analysis [31].

NGS technologies have enabled genome-wide identification of germline and somatic mutations in large-scale cancer sample sets [45]. Population screening of high-risk families will be the gold standard in the coming years to identify individuals who may be at high risk of skin cancer and should take proper preventive actions.

Li-Fraumeni Syndrome

28

Arupa Ganguly and Zhao Chen

Abstract

Li-Fraumeni syndrome (LFS) is a rare familial cancer-predisposing syndrome, which is inherited in an autosomal dominant pattern. LFS patients often present with multiple primary tumors and an early age of onset. The lifetime risk of cancer is estimated to be 73 % for males and nearly 100 % for females. Germline mutations in the tumor suppressor gene, *TP53*, are associated with LFS and can be detected in more than 60 % of classic LFS families. Clinical genetic testing for *TP53* is available for individuals with a suspected or known clinical diagnosis of LFS or a molecular diagnosis based on a history of an identified *TP53* mutation in a family member. Although preventive and surveillance options for LFS are currently limited, presymptomatic genetic testing can provide early diagnosis of individuals at risk of cancer, closer surveillance, earlier detection, and treatment for cancers and an increased likelihood of improved outcomes.

Keywords

Li-Fraumeni syndrome • Familial cancer • Brain tumor • Osteosarcoma • Breast cancer • *TP53* gene • Genetic testing and counseling

Introduction

Li-Fraumeni syndrome (LFS) (OMIM #151623) is a rare familial cancer syndrome, which is inherited in an autosomal dominant pattern. Li and Fraumeni first reported this cancer predisposition syndrome in 1969 [1]. Individuals with LFS often present with a specific set of primary cancers in early childhood that include osteosarcoma, soft-tissue sarcoma, brain tumor, and adrenocortical carcinoma. Adult onset cancers in LFS include colorectal cancer, breast cancer, and other cancers (Fig. 28.1). Among the various cancers, osteosarcoma, breast cancer, soft-tissue sarcoma, colorectal cancer, brain tumor, and adrenocortical carcinomas are referred to as the "core" cancers of LFS and account for the majority of cancers observed. LFS is also referred to as *s*arcoma, *b*reast, *l*eukemia, and *a*drenal gland (SBLA) syndrome or sarcoma family syndrome of Li and Fraumeni. The lifetime risk of cancer in LFS is estimated to be 73 % for males and nearly 100 % for females, which is higher due to the increased risk for breast cancer [2].

LFS is an autosomal dominant disease. This means inheritance of a single copy of the mutated gene predisposes an individual to the disease. Based on clinical presentation, two forms of LFS are recognized: classic Li-Fraumeni syndrome (LFS) and Li-Fraumeni-like syndrome (LFL). Classic LFS is defined by the following criteria: a proband with a sarcoma diagnosed before 45 years of age, a first-degree relative with any cancer under 45 years of age, and a first- or second-degree relative with any cancer under 45 years of age or a sarcoma at any age [1]. LFL is characterized by a proband with any childhood cancer or sarcoma, brain tumor, or adrenal cortical tumor diagnosed before 45 years of age, a first- or

second-degree relative with a typical LFS cancer (sarcoma, breast cancer, brain tumor, adrenal cortical tumor, or leukemia) at any age, and a first- or second-degree relative with any cancer under the age of 60 years [3]. A second definition of LFL is that the affected person can have two first- or second-degree relatives with LFS-related malignancies at any age [4]. The classic LFS criteria were refined and broadened to facilitate identification of individuals without immediate family history.

Breast cancer, brain tumor, and soft-tissue sarcoma account for more than 50 % of the tumors reported in patients with LFS or LFL features (Fig. 28.1) [5, 6]. Meanwhile, individuals with LFS are more likely to develop cancer at younger ages. Age-specific penetrance for cancer in LFS is about 50 % by age 30 years and 90 % by age 60 years. For individuals with LFS carrying germline mutations in the *TP53* gene, the median age of cancer onset can be even earlier [7–9]. In contrast, only 2 % of cancers occur under the age of 30 years in the general population [10]. Genetic testing is recommended for patients with multiple tumors, two of which represent characteristic LFS tumors diagnosed at age 36 or younger, or patients with adrenocortical carcinoma diagnosed at any age, regardless of family history [11].

Molecular Basis of Disease

Germline mutations in the tumor suppressor gene, *TP53*, are associated with LFS and LFL. The human *TP53* gene is located on chromosome 17p13.1. This gene spans approximately 20 kb on chromosome 17p13 with 11 exons of which exon 1 is not translated. The gene has multiple promoters and can give rise to multiple isoforms by alternate splicing. The *TP53* gene encodes the tumor protein p53 (TP53) that plays an important role in cell cycle control and apoptosis. As a DNA-binding protein, TP53 is composed of several functional domains: N-terminal transcription activation domains (TAD, consists of AD1 and AD2), the central DNA-binding domain (DBD), and the C-terminal tetramerization domain. Other important structural elements include the proline-rich domain, the C-terminal regulatory domain, and several nuclear localization or export signals. The central DNA-binding domain is crucial to the TP53 protein-DNA interaction and is the most frequent site for mutations, especially at codons 248, 273, and 213 (Fig. 28.2). Most of the posttranslational modification sites are localized in the C-terminal or N-terminal domains, which regulate the stability and activity of TP53 [12].

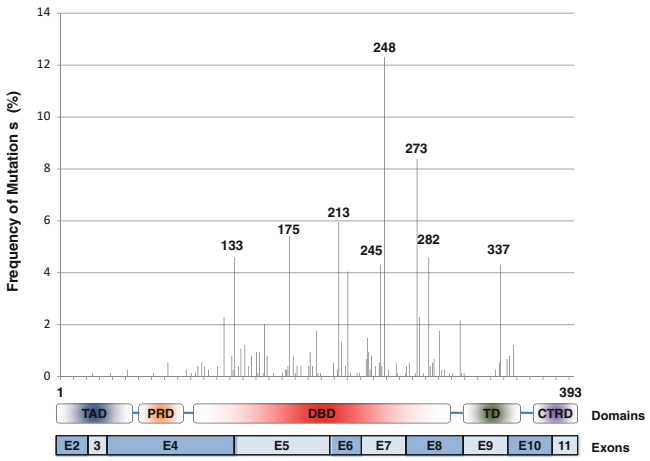

Figure 28.2 Structural organization of the coding exons of the *TP53* gene and functional domains of TP53 are illustrated at the *bottom* of the figure. Relative frequencies and codon positions of germline *TP53* mutations found in LFS and LFL families are *plotted*. Only single base substitutions and insertions/deletions in the codons are listed. Adapted from the International Association for Research on Cancer (IARC) database (R17, November 2013, http://p53.iarc.fr/)

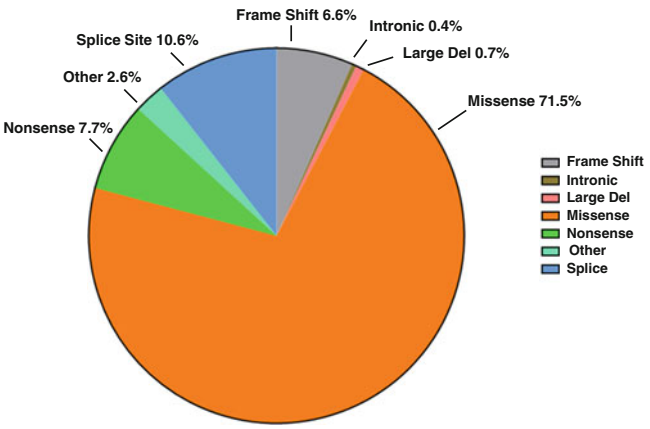

Figure 28.3 Types of germline mutations in the *TP53* gene found in LFS and LFL cases. *Pie chart* shows the percentage of the different types of observed mutations. Adapted from the International Association for Research on Cancer (IARC) database (R17, November 2013, http://p53.iarc.fr/)

The *TP53* gene is regarded as the guardian of the genome and is the most extensively studied tumor suppressor gene. In response to diverse cellular stresses, TP53 regulates a wide variety of genes involved in various cellular processes, including apoptosis, cell cycle, DNA damage repair, senescence, and cellular metabolism. In response to DNA damage caused by ionizing radiation or ultraviolet (UV) light, TP53 protein is stabilized by dissociation from its negative regulator, murine double minute 2 (MDM2). TP53 then translocates to the nucleus and activates the expression of relevant downstream genes, especially CDKN1A (*CIP1–WAF1*) [13]. CDKN1A protein can function as a cyclin-dependent kinase inhibitor and mediate the TP53-dependent G1-S cell cycle arrest through targeting cyclin-dependent kinases, such as CDK2 and CDK4. The activation of the cell cycle checkpoint facilitates the repair of damaged DNA [14].

Somatic *TP53* mutations occur in almost every type of cancer at varying frequencies, and they are more frequent in advanced stage or in more aggressive tumor types [15]. The International Agency for Research on Cancer (IARC) maintains a regularly updated database of all known *TP53* gene variations and mutations (germline and somatic) identified in human tumor samples (http://TP53.iarc.fr/). As of November 2013, the R17 release of IARC TP53 database contains 750 germline mutations, 28,000 somatic mutations, and TP53 mutation status of 2,700 cell lines. The database also includes functional data of 2,314 mutant TP53 proteins. The codon distribution and relative frequencies of germline mutations in *TP53* as observed in LFS or LFL families are summarized in Fig. 28.2. The spectrum of different types of *TP53* mutations observed in LFS and LFL is summarized in Fig. 28.3 (R17, November 2013) [5, 6, 16].

The majority of the germline mutations (83.7 %) reside within the central DBD, which can interfere with the ability of TP53 to bind to its target DNA sequences. Common mutations found in LFS and LFL families occur in codons 175, 213, 245, 248, 273, and 337 and account for 39 % of all the single base substitutions. Many tumor suppressor genes like *RB1* and *APC* are mainly altered by nonsense or truncating mutations. In contrast, the majority of germline *TP53* mutations found in LFS and LFL families are missense substitutions (71.5 %). Other alterations include splice site mutations (10.6 %), nonsense mutations (7.7 %), frameshift mutations (6.6 %), and other infrequent alterations such as large deletion (<1 %) and deep intronic mutations (<1 %) (Fig. 28.3) [5, 6]. Heterozygous deletion of the entire *TP53* gene has been observed in one of 79 LFS families without any coding sequence mutation in *TP53* [17]. Attwooll and colleagues detected a single nucleotide deletion within the *TP53* promoter region in two of 18 LFS/LFL families without an identifiable *TP53* coding sequence mutation. Later, their data indicated that this mutation does not have any functional consequence and is a rare polymorphism [18].

The results of sequence analysis of the entire coding region of *TP53* indicate that 60–80 % classic LFS families carry germline *TP53* mutations, while only 8–22 % of individuals with LFL have detectable mutations [19]. The frequency of de novo mutations in LFS is approximately 7–20 % [8, 9]. The reasons for a lower detection rate of *TP53* mutations in LFS families include undetected intronic or cytogenetic lesions of the *TP53* gene, other genes predisposing to LFS, or the presence of mutations in modifier genes.

The variability of the cancer spectrum and age of onset within LFS families suggests the presence of modifier genes. One of the plausible candidate genes is *MDM2*, which is a negative regulator of TP53 through its E3 ubiquitin ligase

activity [20]. A single nucleotide polymorphism (SNP) within the promoter region of *MDM2*, SNP309 T>G (dbSNP ID, rs2279744), has been associated with earlier onset of tumors among germline *TP53* mutation carriers [21, 22]. It has also been suggested that there is a cumulative effect in cases where both *MDM2*-SNP309 polymorphism and *TP53* codon 72Arg variant (R72P, dbSNP ID, rs1042522) are present in LFS patients [21, 22]. A different line of evidence from Tabori and colleagues suggested the presence of accelerated telomere attrition in LFS families and postulated that the shorter telomere length in *TP53* mutant carriers can predict genetic anticipation observed in LFS patients and serves as a rational biological marker [23].

The relatively low frequency of detectable germline mutations in *TP53* in many LFS and LFL probands suggests the possible involvement of other genes, which may or may not directly involve in the TP53 pathway. The candidates include but are not limited to *p63*, *p73*, *BCL10*, *BAX*, *CDKN2A*, *PTEN*, *BRCA1*, *BRCA2*, *CHEK1*, and *CHEK2* genes. However, despite numerous efforts to screen these genes for mutations, studies have not detected any high-penetrance mutations [19, 24, 25]. For example, 1100delC and I157T mutations in the *CHEK2* gene have been recurrently found in LFS families and possibly represent low-penetrance mutations, which confer increased risk for breast, prostate, and thyroid cancer [19].

It has been generally accepted that mutation in all tumor suppressor genes will act in a recessive manner, which means both alleles should be inactivated to cause tumor initiation and progression [26]. Although the majority of *TP53* mutations are missense mutations that reside within the central DNA-binding domain, loss of heterozygosity is only identified in approximately 60 % of tumors [27, 28]. Approximately two-thirds of the tumors arising in LFS patients carry missense mutations on one allele of *TP53* while the other *TP53* allele remains as wild type. One explanation is that the mutant form of TP53 can exert a dominant negative effect and functionally inactivate the wild-type TP53. Various lines of evidence further indicate that certain *TP53* mutations may result in new TP53 functions that contribute to tumor initiation and progression and are referred to as gain-of-function mutations [29].

Clinical Utility of Testing

According to the practice guidelines in oncology (v.1.2010, of National Comprehensive Cancer Network (NCCN) http://www.nccn.org/professionals/physician_gls/f_guidelines.asp), *TP53* gene testing is considered necessary for individuals with a known family history of a *TP53* mutation, or with a suspected or known clinical diagnosis of LFS or LFL, or with a diagnosis of early-onset breast cancer before 30 years with a negative *BRCA1* and *BRCA2* test. Testing also is recommended if there is a family history of sarcoma, brain tumor, or adrenocortical carcinoma. Several general recommendations and guidelines are available regarding diagnostic testing for germline *TP53* mutations among cancer-prone individuals [30]. Individuals chosen for genetic testing on the basis of their family histories should be given current, relevant information on the test to make an informed voluntary decision.

Since cancers occur with high frequency among children in LFS families, testing these children (rather than delaying testing until young adulthood) is recommended. However, as children mature, obtaining of their assent or dissent to testing is appropriate, as well as the consent of their parents. Annual surveillance strategies are recommended for at-risk children and include complete physical examination, urinalysis, blood count, and abdominal ultrasound examination. Additional organ-targeted surveillance based on family history (e.g., imaging studies of the head if a relative had a childhood brain tumor) also is recommended.

For women with early-onset breast cancer with a negative *BRCA1* and *BRCA2* gene mutation, *TP53* gene testing is only meaningful in the context of a family history characteristic of classic LFS or LFL criteria. Several studies have shown that the likelihood of a germline *TP53* mutation in this population can range from 0–7 %, even if no family history of cancer is present [8, 9, 31, 32]. Females with a germline *TP53* mutation have the option of prophylactic mastectomy to reduce the risk of breast cancer [33]. Routine mammograms and clinical breast examinations are effective in women over age 40 years, but have not been proven to be beneficial for younger women with LFS or LFL. However, controversy exists regarding the use of routine mammograms in women with LFS, because of possible radiation sensitivity associated with *TP53* mutations [10, 34]. In addition, based on family history of specific cancers, colonoscopies or full-body MRI examination or PET scan has been suggested

Available Assays

Several approaches to clinical testing for *TP53* are used, but most use sequence analysis due to the distribution of mutations throughout the gene. A comprehensive list of available clinical tests is available through the Genetic Testing Registry database (http://www.ncbi.nlm.nih.gov/gtr/).

For sequence analysis, PCR amplification of the entire coding region of TP53 (exons 2–11) and the immediate flanking intronic sequences is performed on genomic DNA isolated from blood or saliva of the proband(s). Direct sequencing is performed using traditional automated

fluorescent dideoxynucleotide sequencing. Approximately 75 % of disease-causing mutations can be identified in exons 5–8 of the *TP53* gene by sequence analysis [27]. Identified sequence variations can be classified as pathogenic mutations, benign variants, or variations of unknown clinical significance. Splice site mutations are common (12 %) in LFS and LFL probands [5, 6]. Further interpretation of the results of molecular analysis is usually based on the clinical presentation and family history of the patient.

Traditional direct sequencing strategies described above cannot identify mutations within the promoter region or deep intronic regions and will also miss genomic rearrangements involving partial or entire *TP53* gene. In cases where no coding sequence mutations are detected, deletion/duplication analysis should be used to determine the relative copy numbers of the coding exons of *TP53*. Several methods including quantitative PCR (copy number analysis), multiplex ligation-dependent probe amplification (MLPA), long-range PCR, or array-based comparative genomic hybridization (aCGH) are available. For detection of deep intronic splice site mutations, reverse-transcription polymerase chain reaction (RT-PCR) of RNA followed by sequencing can be used. IHC staining for TP53 is extensively utilized in clinical histopathology laboratories. The rationale of this method is based on the observation that mutant TP53 usually has a much longer half-life than wild-type protein and gives rise to a diffuse nuclear staining. However, the correlation between an abnormal TP53 staining pattern and the presence of sequence mutations can be imperfect [35].

Presymptomatic screening has been effective and beneficial to high-risk family members of some common hereditary cancer syndromes (Lynch syndrome, hereditary breast and ovarian cancers, etc.). But whether genetic screening for LFS can affect prognosis positively is still under debate because no preventive treatment options are currently available to high-risk individuals [19]. Also, presymptomatic testing raises concerns about the potential adverse psychological impact of positive results, risks to relationships with family members, and insurability or even employability [36].

Prenatal testing and preimplantation genetic diagnosis (PGD) are available for families with LFS in which the disease-causing mutation has been or can be identified. For prenatal diagnosis, fetal DNA can be obtained by chorionic villus sampling (CVS) which is performed at 10–12 weeks of gestation or by amniocentesis performed at 15–18 weeks of gestation. PGD has recently been offered for couples with an inherited predisposition for genetic diseases including LFS. Using a standard in vitro fertilization procedure, single cells from 8- to 16-cell-stage embryos are tested for different mutations predisposing to disease, and embryos without a mutation are selected and transferred back to the uterus of the mother for implantation. Despite existing controversy on the use of PGD, existing data demonstrate the usefulness of this approach as the only acceptable option for at-risk couples to avoid the birth of children with an inherited predisposition to cancer and to have a healthy child [37].

Interpretation of Results

Currently, the classification of LFS and LFL is based on clinical criteria, which means the family history or pedigree must meet the diagnostic guidelines of the diseases. In order to confirm the suspected diagnosis of LFS or LFL in a proband, or identify at-risk individuals among LFS/LFL families, sequencing of the *TP53* gene is recommended following the clinical diagnosis. Approximately 60–80 % of families with LFS have an identifiable germline *TP53* mutation, and the detection rate is even lower in LFL families [19, 38]. The percent of families with LFL syndrome who have an identifiable *TP53* mutation varies from 8 % using Eele's definition to 22 % using Birch's definition [10]. Classic LFS criteria have been estimated to have a high positive predictive value and a high specificity, but the sensitivity is reported to be relatively low (approximately 40 %). The sensitivity of the LFL criteria has been estimated to be higher, although the estimated specificity is relatively low [8, 9]. Special attention should be paid to the cases of de novo germline *TP53* mutations, because these families, which are infrequent, may not be classified as LFS or LFL by classic clinical criteria due to the absence of a family history [2].

Irrespective of the *TP53* mutation status, LFS is a highly penetrant cancer syndrome. Individuals with LFS are also at increased risk for developing multiple primary tumors. A retrospective study of 200 affected members of families with LFS found that 15 % had developed a second cancer, 4 % a third cancer, and 2 % a total of four cancers. In this cohort, survivors of childhood cancers were found to have the highest risks for developing additional malignancies [39].

Due to variable expression and differential penetrance of different *TP53* mutations, genotype-phenotype correlation for LFS is complicated. Even for the same codon, multiple mutations can occur at different frequencies and confer different phenotypes. For example, three different mutations have been documented at codon 337, which is located in the homo-oligomerization domain of TP53: R337H (CGC>CAC, 80 %), R337C (CGC>TGC, 13.9 %), and R337P (CGC>CAC, 6.1 %). The R337H mutation is presumed to be preferentially associated with cancer development in the adrenal cortex and may have a pH-dependent defect in oligomerization. Due to the fact that the R337H mutant may still largely maintain wild-type TP53 activity in vivo, it may be less penetrant with respect to tumor predisposition when compared to other variants, like R337S [40–42]. However, another study indicates that the spectrum of cancers seen in families

with R337H mutation is similar to that of LFL families carrying other types of *TP53* mutations [5, 6].

The mean ages of tumor onset are reported to vary significantly between patients with missense mutations compared to other types of mutations (splicing, nonsense, and deletions) in *TP53*. Various lines of evidence further indicate that the *TP53* missense mutations are gain-of-function mutations that can contribute to tumor initiation and progression [29, 31]. At the same time, certain kinds of mutations in *TP53*, such as missense mutations that involve codons 152 and 158, are known to confer a lower cancer risk [43]. Large heterozygous deletions that encompass the entire *TP53* gene as well as up to 2 Mb of upstream and downstream sequences do not seem to confer increased cancer risk when the remaining allele is intact [44]. Therefore, not all *TP53* mutations are functionally equivalent, and different amino acid substitutions can lead to different consequences for TP53 structure and function that, in turn, may significantly influence clinical outcome.

Laboratory Issues

DNA sequencing is the most commonly used method for *TP53* genetic testing due to the wide distribution of mutations throughout the *TP53* gene. General practice guidelines for both the sequencing procedure and the interpretation of data all apply in the clinical testing for *TP53* mutation. First of all, the samples for genetic testing should be collected, identified, shipped, stored, and processed under quality-controlled conditions that maintain the DNA integrity and proper identification of the specimen. Genomic DNA from peripheral blood lymphocytes is typically used for testing. Alternative sources such as saliva, tumor tissue, formalin-fixed paraffin-embedded (FFPE) tissue, cultured amniocytes, or CVS can be used but require special quality control measures during sample processing, sequencing reactions, data analysis, and interpretation. For example, DNA from FFPE tissue generally yields poorer sequence reads because of degradation and/or chemical cross-linking. Special caution should be exercised to recover as much usable DNA as possible from FFPE tissue. Decreasing the amplicon size (<300 bp) also may improve the efficiency of PCR and sequencing.

The standard quality control measures for DNA sequencing, such as inclusion of both negative and positive controls, should be routinely performed. To eliminate the possibility of sample mix-up, all identified mutations in *TP53* can be confirmed by an independent sequencing assay on a DNA sample isolated at a different time from the first isolation. Bidirectional sequencing is also recommended for confirmation of heterozygous or homozygous mutations. The presence of a de novo or mosaic mutation requires careful analysis of bidirectional sequence reads.

False-negative results can occur for several reasons. Allele dropout due to presence of SNPs or indels (INsertion/DELetion) at the binding sites of sequencing primers can lead to allele dropout (amplification failure of one allele). Primers should be designed outside of the known polymorphic regions. Low-level tissue mosaicism, the preferential amplification of the smaller allele caused by a large indel, and exon or gene deletion also can produce false-negative results. Also of note, traditional sequencing panels that include only the coding exons and limited flanking intronic regions cannot detect deep intronic mutations, translocations, inversions, or copy number variations involving large chromosome regions. Other technologies, such as long-range PCR, MLPA, SNP array hybridization assays, aCGH, and next-generation sequencing technology, can address these issues.

Conclusions

LFS and LFL are autosomal dominantly inherited cancer predisposition syndromes. Mutations in the *TP53* gene are associated with 60–80 % of LFS and 8–22 % of LFL families. Irrespective of the *TP53* mutation status, the risk of specific LFS-associated cancers in first-degree relatives of a proband with LFS is significantly higher compared to the general population. Genetic testing for *TP53* mutations can identify presymptomatic individuals at risk of cancer and have important implications for clinical diagnosis, counseling, monitoring, and clinical management of LFS and LFL individuals. The benefits of surveillance and genetic testing in changing disease-related morbidity and mortality are still evolving.

Retinoblastoma

29

Arupa Ganguly and Zhao Chen

Abstract

Retinoblastoma (RB) is the most common primary intraocular malignancy of childhood associated with blindness and mortality. Mortality from RB has been significantly reduced with earlier diagnosis and improved methods of treatment. Biallelic inactivation of the tumor suppressor gene, *RB1*, is the cause of retinoblastoma. Multistep genetic analyses, including DNA sequencing, Southern blot, transcript promoter methylation analysis, and real-time PCR, have been used to characterize potential genetic abnormalities of *RB1*. Predisposing germline *RB1* mutations can be detected in 90–95 % of probands with heritable RB, while the detection rate is about 13 % for individuals with unilateral RB. Due to the presence of low-level mosaicism, chromosome rearrangements, or deep intronic splice site changes, detection of mutations can be challenging. The absence of detectable *RB1* mutations in a subset of unilateral RB tumors or in bilateral cases suggests the presence of alternate genetic mechanisms. A subset of unilateral RB tumors is associated with amplification of the *MYCN* oncogene.

Keywords

Retinoblastoma • Childhood onset cancer • Ocular malignancy • *RB1* gene • Genetic test • Genetic counseling

Introduction

Retinoblastoma (RB) is the most common intraocular cancer in children and occurs at a frequency of approximately 1 in 20,000 live births with about 300 new cases diagnosed each year in the USA and about 5,000 cases worldwide [1, 2]. Clinically, RB can present as bilateral (both eyes) or unilateral (one eye) disease, with or without a family history. The individuals with a family history of RB have the hereditary form. Individuals with hereditary RB most often present with bilateral disease at an early age of onset and infrequently as unilateral disease with multiple foci (Table 29.1) [3, 4]. From 5–15 % of patients with hereditary RB develop "trilateral" RB, defined as an additional pineoblastoma, a primitive neuroectodermal tumor located in the pineal region of the brain. The chance of pineoblastoma is only 0.5 % among unilateral cases [5]. Individuals with heritable RB also have higher risk for second primary tumors, such as osteosarcomas, soft tissue sarcomas, or melanomas. These non-ocular tumors usually occur in adolescence or adulthood. For patients who have been exposed to external beam radiation, the incidence of second non-ocular tumors can increase up to 50 % [6, 7]. Individuals with unilateral disease usually have the nonhereditary form of RB. In the past 25 years, the genetic basis of RB has been unraveled and new insights into the molecular pathogenesis of RB have evolved. This understanding has allowed for more effective approaches to clinical management and resulted in greater than 85–90 % cure rate for RB in developed countries. A subset of unilateral RB tumors without detectable mutation in the *RB1* gene is associated with amplification of the *MYCN* oncogene [8].

Table 29.1 Features that distinguish heritable from nonheritable retinoblastoma

Tumor type	Heritable retinoblastoma	Nonheritable retinoblastoma
Eyes affected	Bilateral in 90–95 % of cases	Unilateral in 100 % of cases
	Unilateral in remaining cases	
Age of onset	Usually < 1 year	Variable — < 1–5 years
Presence of family history	10–20 % of newly diagnosed cases	Negative
Risk of second malignancy	5–15 %	0.5 %
Recurrence risk	50 % risk of passing on an *RB1* mutation to an offspring	Almost zero. Very low risk of passing on an *RB1* mutation due to presence of germline mosaicism

Molecular Basis of Disease

RB is caused by biallelic inactivation of the *RB1* gene. Friend and colleagues identified the *RB1* gene in 1986, the first tumor suppressor gene to be cloned [9]. The gene consists of 27 exons that span 183 kilobases of genomic DNA on chromosome 13q14 (Fig. 29.1). *RB1* encodes a 928 amino acid protein known as RB1, which is a nuclear phosphoprotein that plays a critical role in regulating cell cycle progression at the G1 to S phase transition. The regulatory activity of RB1 results from its ability to bind to and inhibit the function of the E2F families of transcription factors, which regulate multiple genes involved in S-phase entry. Unphosphorylated RB1 binds to the E2F/DP (dimerization partners of E2F) complex through a critical functional region containing RB1 A/B pocket domains. The pocket domains are encoded by exons 12 through 17 and 20 through 22 of the *RB1* gene and are hotspots for inactivating mutations in RB and other cancers. The C-terminal region of RB1 contains the nuclear localization signal and the interaction motif that is the target site of cyclin-CDK (cyclin-dependent kinase) complexes. The C-terminal region can also bind to the nuclear c-Abl tyrosine kinase and MDM2 (Mdm2, TP53 E3 ubiquitin protein ligase homolog [mouse]), which have oncogenic properties (Fig. 29.1). In the presence of mitogenic or oncogenic stimuli, RB1 is phosphorylated by CDKs (CDK4 and CDK6) and dissociates from E2F/DP complexes, which leads to the release of inhibition of E2F target genes and progression through the cell cycle (Fig. 29.2) [10, 11].

Inactivation of the RB1 pathway through direct perturbation of the *RB1* gene (deletion, mutation, or epigenetic mechanisms) leads to deregulated cell proliferation and ultimately tumorigenesis. Recent evidence suggests that *RB1* also plays important roles in multiple cellular processes beyond cell cycle regulation, such as mitochondria biogenesis, cell senescence, and others [12]. Inactivation of the RB1 pathway also can cause a mitotic defect, and genomic instability and aneuploidy [12, 13].

RB has served as the paradigm for the "two-hit" model of tumorigenesis [14]. The Knudson hypothesis is that inactivation of both alleles of *RB1* (two "hits") is necessary to develop RB. In children with hereditary RB, the first hit is the germline mutation on one allele of *RB1*. The second hit is a somatic inactivation event on the remaining allele which

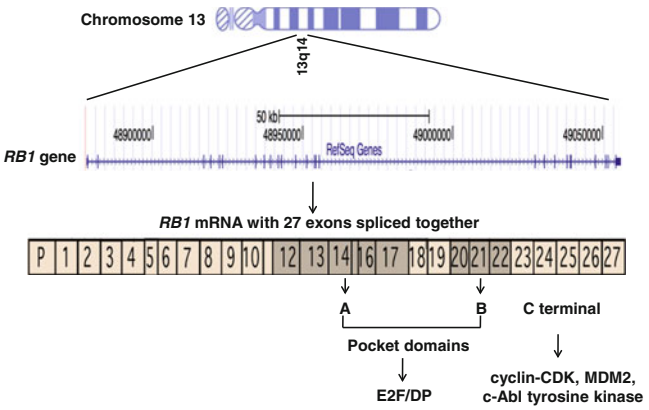

Figure 29.1 Genomic location and structure of the *RB1* gene on chromosome 13q14 and spanning 183,000 bases. The 27 exons encode the 928 amino acid RB1 protein. The *shaded exons* encode the pocket domains A and B of RB1, which mediate interactions with the E2F and DP families of transcription factors

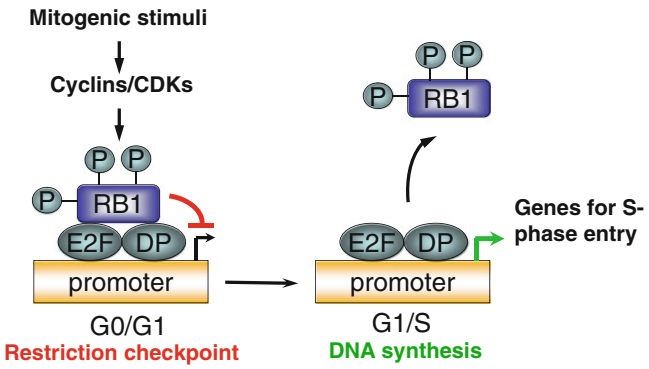

Figure 29.2 A simplified model for RB1 function. RB1 is hypophosphorylated during the G0/G1 phase of the cell cycle and interacts with E2F/DP family of transcription factors that inhibit transcription of downstream genes. In the presence of mitogenic stimuli, the cyclin-dependent kinase 4 (CDK4) protein phosphorylates RB1, which releases the E2F/DP factors and induces gene expression leading to the G1/S transition and progression through the cell cycle

includes point mutations, intragenic rearrangements, or hypermethylation of the promoter region and causes inactivation of RB1 protein and initiation of RB. In about 65 % of the RB cases, the second hit to the *RB1* gene is accomplished by the mechanism of loss of heterozygosity (LOH), which can result from deletions or chromosomal rearrangements affecting *RB1* [15]. In children with nonhereditary RB, the tumors develop as the result of two somatic *RB1* inactivation events in a retinal progenitor or precursor cell during embryonic development.

The presentation of RB can be classified in three categories: familial hereditary (5–10 %), de novo hereditary (20–30 %), or sporadic (60–70 %) [16]. Familial hereditary cases are characterized by a positive family history and germline mutations in *RB1* in individuals that present with bilateral disease in most cases and unilateral disease in 10–15 % of cases. However, only 20 % of bilateral cases and 15 % of unilateral cases have a positive family history and inherit the mutation from one of the parents. For individuals carrying a germline mutation in *RB1*, the risk of transmission of the mutation to an offspring is 50 %. In 80 % of newly diagnosed bilateral cases, the family history is negative and RB is caused by a de novo germline mutation on one of the parental germ cells. These represent the 20–30 % of sporadic hereditary cases with de novo mutations. In 90 % of these sporadic bilateral cases, the de novo mutation occurs on the paternal allele [17]. Approximately 60 % of RB cases are sporadic and nonheritable, with a unilateral presentation. Germline mutations are not present in the sporadic unilateral cases, and the risk of passing on the mutant allele to offspring is very low. There are reports of gonadal mosaicism in the parents of children with RB. In this setting, instead of being a single de novo event in one germ cell, a subset of the parental gametes carries the mutant *RB1* allele. The degree of mosaicism determines the risk of transmitting the mutant allele to future offspring. Thus, the risk of RB in the siblings of a sporadic heritable RB case should not be underestimated.

Almost all types of mutations have been identified in the *RB1* gene, including point mutations, deletions, translocations, insertions, and epigenetic changes. Conventional cytogenetic analysis of peripheral blood lymphocytes can identify deletions or rearrangements involving 13q14 in approximately 8 % of bilateral cases and 1–5 % of sporadic unilateral cases [15]. Smaller deletions in the *RB1* region are identified in approximately 10 % of bilateral RB cases by Southern blot analysis [15]. Approximately half of all defined *RB1* mutations are caused by single-base substitutions in coding exons, one third by small frameshift mutations, and another 10 % by rearrangements, such as intragenic or intergenic deletions or duplications involving chromosome 13q. These rearrangements may be limited to the *RB1* gene or include genes flanking the *RB1* locus [15, 18–21]. Nichols et al. carried out an investigation of a total of 180 RB cases, and the frequencies of germline mutations detected in bilateral, familial unilateral, and sporadic unilateral cases were 91 %, 70 %, and 7 %, respectively. Of the identified mutations, 76 % were coding sequence mutations, and 14 % were deletions of individual or multiple exons or the whole *RB1* gene [22].

The majority (70 %) of mutations identified in *RB1* are nonsense mutations or frameshift mutations, which lead to premature termination codons. Approximately 76 % of these nonsense mutations are recurrent CGA>TGA transitions affecting one of the 12 CGA codons within the open reading frame of *RB1*. Approximately 10 % of identified single-base substitutions are missense mutations, most of which localize to the pocket domains of RB1. Very few mutations have been identified in the promoter region of *RB1* or exons 25–27, although this region contains two CGA codons [15]. A recent study reported the presence of a germline frameshift mutation in exon 27 in an unaffected father of a child with unilateral RB. Interestingly, the mutant transcript showed reduced expression, which might explain the milder unilateral disease manifestation [23]. Thus, unlike similar mutations located elsewhere in the gene, truncating mutations in the last exon of *RB1* may be unique in their clinical presentations.

In addition to coding sequence variations, mutations affecting the conserved nucleotides in 5′ and 3′ splice sites within *RB1* introns are observed in approximately 18 % of RB cases [15]. *RB1* has 26 introns and the sizes of the introns range from small (intron 15 with 80 base pairs [bp]) to very large (intron 17 with 71,500 bp). While splice site mutations at the exon–intron junctions can be detected by routine sequence analysis, mutations located deep within the introns can be missed without analysis of the *RB1* mRNA. A few cases harboring deep intronic mutations have been documented by cDNA analysis. These deep intronic mutations usually generate cryptic splice sites and cause retention of intronic sequences, which lead to subsequent frameshift and premature termination of translation [22, 24, 25]. Furthermore, missense or nonsense mutations that flank the consensus sequences of splice sites also may give rise to aberrant splicing [22]. Hypermethylation of CpG dinucleotides within the promoter region of *RB1* can lead to gene silencing and is a somatic event in approximately 10 % of RB tumors and is almost never observed in constitutional cells [26, 27].

As described earlier, RB has a high rate of de novo mutations, which can originate at the preconception or postconception stage leading to germline or somatic mosaicism, respectively. Preconception mutation events occur mainly during spermatogenesis [17, 28]. Postzygotic events can occur at earlier stages of embryo development, and the mosaicism may extend to various organs and tissues, including retina or even gonads. Postzygotic germline mosaicism can

occur on either paternal or maternal alleles, and the mosaic mutations can be detected in lymphocyte DNA in some cases [28, 29]. Mosaicism for *RB1* mutation should always be taken into account in genetic diagnosis, counseling, and disease management. In 1998, Sippel and colleagues reported that germline mosaicism occurs in up to 10 % of families with newly diagnosed RB using combined technologies of single-strand conformational polymorphism and pedigree analysis [30].

Approximately 10 % of RB cases are caused by heterozygous deletions of chromosome 13q that include the *RB1* gene. The sizes of the deletions vary from small (4,000 bases) to large (34 million bases) and the breakpoints are usually nonrecurrent [31]. Because larger deletions may involve many other genes besides *RB1*, individuals with deletions of 13q14 can exhibit other clinical manifestations in addition to RB. As might be expected, the length of the deletion seems to define the spectrum of clinical manifestations, with smaller deletions (those confined to 13q14) associated with macrocephaly, tall stature, obesity, and motor and/or speech delays, and larger deletions manifesting with characteristic craniofacial features, microcephaly, psychomotor delays, and other findings such as constipation and feeding problems [3, 31–33]. Interestingly, deletions larger than 1 Mb and encompassing the *MED4* gene, which encodes a mediator of RNA polymerase type II, are associated with a milder phenotype (i.e., unilateral eye involvement and less penetrant disease) [31]. The mechanism by which deletion of *MED4* lessens the severity of RB disease is unclear; however, reduced expression and nonpenetrance in carriers of large deletions might result from the loss of one or more genes contiguous with *RB1* that are important for basic cellular functions. In a susceptible retinal cell, loss of the second copy of these critical genes may lead to cell death as opposed to tumor formation.

Finally, interfamilial or intrafamilial variations of phenotypic expression of identical *RB1* mutations have been observed among RB families. This indicates that additional genetic factors modify genotype–phenotype correlations in RB [3, 34, 35]. For example, Klutz et al. reported the parent-of-origin effect in two unrelated families that segregate an identical base substitution within intron 6 of *RB1* gene. The substitution leads to exon skipping and a frameshift mutation that creates a premature termination codon. In addition to the fact that both families show incomplete penetrance, carriers who inherited the mutant allele from the maternal germline are unaffected, while carriers who inherited the mutant allele from the paternal germline are affected [3, 34, 35].

The identification and characterization of the *RB1* gene has provided critical insights into the biology of RB, and also many other tumor types, including lung, brain, breast, and bladder cancers. In the latter cases, somatic inactivation of the RB1 pathway is essential for tumorigenesis [36]. Since tumor development is associated with the sequential acquisition of multiple mutations that drive unregulated proliferation and/or reduced cell death [37, 38], it is apparent that alterations in other critical signaling pathways underlie RB tumorigenesis. For example, in addition to deletions flanking the *RB1* gene, karyotype analysis has identified various recurrent chromosome imbalances in RB, which include isochromosome 6p, trisomy 1q, monosomy 16, add(1p), double-minute chromosomes, and homogeneously staining regions involving the *MYCN* and *INT1* oncogenes [39].

The tumor suppressor protein, TP53, is a master regulator of cell cycle, apoptosis, and DNA damage and is the most frequently mutated gene in human cancer. But many studies have shown that the *TP53* gene is not mutated in RB [40, 41]. In 2006, Laurie and colleagues shed light on this issue by demonstrating that the TP53 pathway is also inactivated by the MDM (murine double minute) family of proteins following loss of *RB1* during retina development [42]. The MDM family of proteins, such as MDM2 and MDM4 (MDMX), are known inhibitors of TP53 and both are expressed in RB cells [43]. Additionally, a single-nucleotide polymorphism (SNP) located in the promoter region of *MDM2* (rs2279744, SNP309, 309 T>G) is correlated with enhanced MDM2 expression and attenuation of the TP53 pathway [44]. It has been postulated that the *MDM2* 309 T>G SNP behaves as a modifier gene in RB [45]. Another similar study pointed out that the *TP53* p.Arg72Pro SNP (rs1042522), which correlates with increased expression of *MDM2* and compromised TP53 pro-apoptotic activity, is significantly associated with onset of RB [46]. Collectively, these data strongly support that inactivation of the TP53 pathway is an important cooperating event in the development of RB.

In addition to TP53, genetic lesions in other signaling pathways might contribute to RB malignancy. A recent report implicated the involvement of oncogenic microRNA cluster miR-17~92 in RB tumorigenesis in a mouse model and possibly also in humans [47]. In another study, Zhang and his colleagues performed whole-genome sequencing of RB tumor samples and matched normal DNA utilizing next-generation sequencing technology. Surprisingly, they observed very few recurrent genetic lesions, except in *RB1* and *MYCN*. But gene expression and epigenetic analyses identified changes in other cancer-related genes, such as the protooncogene *SYK* [48].

Clinical Utility of Testing

The diagnosis of RB is essentially based on clinical examination of the fundus of the eye, which is confirmed by imaging technologies including B scan ultrasonography and computerized tomography or magnetic resonance

imaging scans. Once diagnosis is established, *RB1* genetic testing is indicated. For individuals with bilateral or familial RB, the goal of genetic testing is to identify the predisposing germline *RB1* mutation, which can be detected in approximately 94 % of cases [22]. The identification of the germline *RB1* mutation enables appropriate primary tumor treatment and surveillance for additional ocular tumors and/or non-ocular malignancies. Furthermore, the identification of a germline mutation allows risk estimation for siblings and offspring. One of the main benefits of genetic testing is to rule out germline mutations in other young at-risk relatives of the proband to avoid unnecessary screening of children under anesthesia for early detection of RB. For individuals with sporadic unilateral RB, genetic testing focuses on identification of somatic mutations in the tumor (when available), followed by germline testing. Once mutations are identified in the tumor, peripheral blood DNA should be tested to determine whether one of the mutations is actually a predisposing germline mutation, which is estimated to exist in 13 % of sporadic unilateral cases [49].

Prenatal diagnosis and preimplantation genetic diagnosis (PGD) are available for at-risk pregnancies, which require the prior identification of predisposing germline mutations within the families. Prenatal genetic testing options include the molecular analysis of DNA isolated from the cells of the developing fetus through chorionic villus sampling or amniocentesis. More recently, PGD is available at a limited number of institutions [50–52]. PGD is performed in combination with in vitro fertilization and offers a way to test an individual's embryos for genetic disorders before transfer of unaffected embryos into the uterus. A recent report demonstrated the feasibility of PGD based on the inheritance of SNPs that are tightly associated with a wild-type or mutant *RB1* allele [52]. This approach is used when genetic screening for mutation detection is not readily available or the disease-causing mutation has not been identified. However, this approach can lead to erroneous conclusions in the presence of gonadal mosaicism and should be used with caution [53].

Available Assays

A broad spectrum of mutations ranging from point mutations, deletions/insertions, chromosomal rearrangements, and epigenetic silencing has been documented in the *RB1* gene. Accordingly, various types of molecular testing are used by clinical molecular laboratories for *RB1* mutation analysis. The genetic tests to identify mutations involve multiple testing approaches, which should be adjusted according to the diagnosis, family history, and availability of genetic materials.

For individuals with bilateral or multifocal unilateral RB, or unilateral tumor with a positive family history, clinical genetic testing for germline mutations starts with sequence analysis of the *RB1* coding exons, flanking introns, and the promoter region using DNA isolated from peripheral blood lymphocytes. Given the fact that larger deletions and insertion involving the whole *RB1* gene or certain exons are not readily detectable by sequence analysis, alternative methods can be applied, including fluorescence in situ hybridization (FISH), multiplex ligation-dependent probe amplification, quantitative real-time PCR, targeted array-based comparative genomic hybridization, and heterozygosity testing based on informative polymorphic markers. Cytogenetically visible deletions or rearrangements involving *RB1* can be detected by karyotype and FISH analyses, respectively, and are estimated to occur in 5 % of unilateral cases and 7.5 % of bilateral cases [49]. To detect deeper intronic mutations, reverse transcription-polymerase chain reaction methods can be used to test RNA isolated from RB tumor tissues or peripheral blood lymphocytes, followed by evaluation for abnormalities in the size and sequence of *RB1* transcripts [25]. Through the use of multiple sequential testing methods, the sensitivity of mutation detection has reached 90–95 % for probands with heritable RB [22, 49].

Mutation screening for nonhereditary unilateral RB cases is more complicated because only approximately 13 % of patients have germline mutations [49]; so genetic testing is more effective when tumor tissue is available. In the ideal scenario, if two inactivating *RB1* mutations are identified in the tumor, then it is straightforward to test lymphocyte DNA for the presence of the tumor-associated alterations.

In addition to the methods mentioned above, methylation analysis of the *RB1* promoter region or LOH analysis by comparing polymorphic markers flanking and inside the *RB1* gene between tumor and peripheral blood DNA can be performed. To evaluate hypermethylation of the *RB1* promoter, genomic DNA isolated from tumors is digested with two restriction endonucleases whose activities depend on the presence or absence of methylated cytosines in CpG dinucleotides [35]. The products of these digestions are quantified and compared, using sequence-specific primers and PCR. The results can demonstrate the degree of methylation in CpG dinucleotides within the promoter region of the *RB1* gene that can lead to gene silencing. Individuals with unilateral RB and no detectable germline mutation in *RB1* are generally classified as sporadic, nonheritable cases; however, there is a small possibility that the affected individuals carry low-level germline mosaic mutation which is beyond the detection limits of the testing method.

Currently, Sanger sequencing is the major method used to screen the *RB1* gene for mutations. However, the detection of mosaic mutations by Sanger sequencing is technically challenging and the threshold of detection of the mutant allele is only 10–20 %. Allele-specific PCR strategies can detect 11 recurrent nonsense mutations (CGA>TGA) within the *RB1*

gene and can increase the sensitivity of the detection of mosaic mutations. Using this technology, the frequency of germline mosaicism is estimated to be 5.5 % in bilateral and 3.8 % in unilateral RB patients [54]. Next-generation sequencing has been used for genetic analysis for *RB1* mutations and has significantly increased sensitivity of detection of mosaic mutations [55].

A systematic approach to mutation detection that is designed to detect most *RB1* germline alterations facilitates the clinical management and genetic counseling of RB patients. The Genetic Diagnostic Laboratory at the University of Pennsylvania uses a sequence of test methods, beginning with PCR amplification and DNA sequencing of the 27 *RB1* coding exons and flanking intronic sequences, as well as 1,000 bp of the *RB1* promoter region. The DNA for this testing is isolated from peripheral blood lymphocytes, saliva, or frozen/formalin-fixed paraffin-embedded (FFPE) tumor sections following standard procedures. The results are compared with data reference *RB1* gene sequence to identify mutations, including nucleotide substitutions and small insertions or deletions. If no mutations are identified, samples are analyzed using quantitative dosage-sensitive PCR to identify rearrangements encompassing 1 or more of the 27 *RB1* coding exons. Whole-genome SNP arrays are used to identify the boundaries of larger genomic deletions or duplications when present. If no mutations are identified, testing for the methylation status of the *RB1* promoter or alterations in the *RB1* transcript by RNA analysis is performed.

Since 2001, the Genetic Diagnostic Laboratory has performed testing for a total of 545 individuals with bilateral RB, 37 cases with hereditary unilateral RB, and 561 probands with sporadic unilateral RB. For the bilateral and hereditary unilateral RB cases, the sensitivity of mutation detection approaches 96 % with a coding sequence mutation in approximately 80 % of patients and a partial- or whole-gene deletion/duplication involving the *RB1* locus in approximately 16 % of patients. Mosaic mutations account for at least an additional 4 % of these RB cases. For the 561 sporadic unilateral RB cases, germline *RB1* mutations were identified in about 13 %, among which 53 mutations (10 %) lead to silent, missense, nonsense, or frameshift changes, and 16 mutations (3 %) lead to intragenic deletions or duplications involving the *RB1* gene.

Interpretations of Results

The sensitivity of mutation detection using peripheral blood DNA is 90–95 % for probands with familial or bilateral RB and approximately 13 % for individuals with nonhereditary unilateral RB [49]. The reason the sensitivity of mutation detection is less than 100 % could be due to undetectable intronic mutations or intragenic rearrangements of *RB1* or very low-level mosaicism. It is also possible that additional genes are associated with RB.

For individuals with bilateral or familial RB, the chance of detecting a disease-causing *RB1* mutation in the DNA of the peripheral white blood cells is very high (more than 90 %). The identification of a mutation usually indicates the presence of a germline mutation. For unilateral cases without a family history, tumor tissue becomes the primary resource to detect the two somatic mutations. When the mutations detected in the tumor are not present in constitutional DNA, the probability of carrying a germline mutation is very low. Additionally, approximately 80 % of RB cases are due to a de novo mutation, which implies that the mutations identified in affected children are usually not present in the germline of the parents. It should be noted that germline mosaic mutations may not be uncommon in the unaffected parents and the risk of RB in their offspring should not be underestimated [30].

RB1 mutation carriers show variable phenotypic expression and penetrance, which is determined to a certain extent by the nature of the predisposing *RB1* mutations. Generally, carriers of an *RB1* mutant allele with nonsense or frameshift mutations have a very high risk of developing bilateral RB. But when these mutations exist in a mosaic form, the phenotypic expression can be milder [3]. Additionally, splice site mutations, small in-frame deletions, or missense mutations are usually associated with a milder phenotype, which exhibits incomplete penetrance and reduced expressivity. The effects of these mutations on RB1 protein function are considered to be less pronounced compared to nonsense mutations. For example, only a few missense mutations outside the RB1 pocket domains have been reported with putative oncogenic effect, and most of the cases show incomplete penetrance [20]. With splice site mutations, a fraction of the total transcripts usually are still processed as normal mRNA. In contrast, cryptic splice site mutations that result in change of the reading frame are usually associated with more severe phenotypes. Additionally, for mutations occurring in the promoter region of *RB1* gene, the expression of RB1 is less likely to be completely compromised and usually leads to milder phenotypes.

Laboratory Issues

DNA sequencing is the most commonly used method for *RB1* genetic testing. Adherence to best clinical laboratory practices for both the sequencing and data interpretation are important to ensure the quality of test performance. First, the samples for genetic testing should be collected, identified, shipped, stored, and processed under quality-controlled conditions. Genomic DNA from peripheral white blood cells is

the typical starting material. Alternative sources such as saliva, tumor tissue, FFPE tissue, cultured amniocytes, or chorionic villi require special quality controls during sample processing, sequencing, and data interpretation. For example, DNA from FFPE tissue generally does not result in good sequence data and has a high failure rate because of degradation or chemical cross-linking. DNA isolation procedures should be optimized to recover as much usable DNA as possible. More importantly, to ensure the success of PCR and sequencing, special attention should be paid to the primer design, making sure all the amplicons are less than 300 bp in length when using FFPE tissue as a specimen type.

The standard quality control measures for DNA sequencing, such as inclusion of known negative control and positive controls should be routinely performed. Bi-directional sequencing is recommended for confirmatory mutation testing. Also, laboratories may confirm any mutation identified in an affected individual by repeat testing of an independent DNA sample to ensure no sample carry-over or specimen misidentification during testing.

False-negative results can occur for several reasons. Allele dropout can be caused by SNPs or insertion/deletions at the binding sites of PCR or sequencing primers. If allele dropout is suspected, alternate sequencing primers outside of the polymorphic regions can be used. Lower-level mosaicism, deep intronic cryptic splice mutations, preferential amplification of the smaller allele in a large insertion, or regional deletion/insertion can also introduce false-negative results. These limitations apply to most PCR-based sequencing methods currently used for any gene including *RB1* and are not limited to any specific gene test.

Accurate and unambiguous mutation nomenclature is important for the communication between clinical molecular laboratories, physicians, genetic consultants, and other healthcare providers. The mutation type, nucleotide base, or amino acid changes should be specified following the recommended nomenclature developed by Human Genome Variation Society (HGVS) [56]. *RB1* mutations are commonly annotated with reference to a specific genomic reference sequence (GenBank accession number L11910) [15]. Additionally, several databases are useful for interpretation of test results, including the RB1 Mutation Database (http://rb1-lovd.d-lohmann.de/home.php), the Human Gene Mutation Database (HGMD, http://www.hgmd.cf.ac.uk/ac/index.php), and dbSNP (http://www.ncbi.nlm.nih.gov/projects/SNP/).

Conclusions and Future Directions

Although RB remains the most common primary intraocular malignancy of infancy and childhood, mortality from RB has been significantly reduced with earlier diagnosis and improved methods of treatment. However, in cases with low-level mosaicism or deep intronic splice mutations, the mutations may not be easily detected. More exhaustive techniques such as next-generation sequencing technology may overcome these barriers. Also the absence of detectable *RB1* mutations in some patients suggests the presence of alternative underlying genetic mechanisms which requires better understanding of molecular pathology of RB.

Hereditary Paraganglioma and Pheochromocytoma

30

Fang-Yuan Li and Lee-Jun C. Wong

Abstract

Paragangliomas (PGLs) and pheochromocytomas (PCCs) are rare neuroendocrine tumors, which predominantly occur in the head and neck. They can be part of a syndrome, such as multiple endocrine neoplasia (MEN), neurofibromatosis (NF) type 1, and von Hippel-Lindau syndrome (VHL). Hereditary PGLs/PCCs are caused by molecular defects in the mitochondrial respiratory chain complex II, also known as the succinate dehydrogenase (SDH) complex, which contains protein subunits and assembly factors encoded by the nuclear genes, *SDHA*, *SDHB*, *SDHC*, *SDHD*, and *SDHAF2*. This chapter focuses on molecular mechanisms, available clinical molecular tests, interpretation of test results, and the clinical utility of molecular testing for hereditary PGL/PCC caused by mutations in the *SDH* genes. In general, diagnosis can be achieved by immunohistochemical studies of tumors, sequence analysis of *SDH* genes in germline cells and tumor tissues, and detection of large heterozygous deletions or duplications by microarray-based technology. Detailed clinical evaluation and family history are vital to appropriate prioritization of the diagnostic testing and for interpretation of test results.

Keywords

Paragangliomas • Pheochromocytomas • Hereditary paragangliomas • Mitochondrial respiratory chain complex II • Succinate dehydrogenase (SDH) • *SDHA* • *SDHB* • *SDHC* • *SDHD* • *SDHAF2*

Introduction

Paragangliomas (PGLs) and pheochromocytomas (PCCs) are rare neuroendocrine tumors, which predominantly occur in the head and neck. PGLs are vascularized neuroendocrine tumors that arise from paraganglia of neural crest origin. PGL can be categorized into two groups. The sympathetic PGLs are confined to the adrenal medulla, called pheochromocytoma (PCC), and usually secrete catecholamines. The nonsecretory extra-adrenal parasympathetic PGLs occur predominantly in the head and neck, for example, in the carotid body, the chemoreceptive organ responsible for sensing of and adaptation to hypoxia in the blood. PGLs/PCCs have a prevalence of one in 2,500–6,500 with an annual incidence of 500–1,600 in the USA [1].

Most PGLs/PCCs are benign and occur predominantly at age 40–60 years. Familial cases develop tumors earlier and are more likely to have bilateral tumors [2]. The predisposition for PGL/PCC tumors is inherited in an autosomal dominant mode, with loss of heterozygosity (LOH) in tumors. PGL/PCC can be part of a syndrome, such as multiple endocrine neoplasia syndrome types 2A and 2B (MEN types 2A and 2B), von Hippel-Lindau (VHL) disease, and neurofibromatosis (NF) type 1. Hereditary PGL/PCC syndrome may also result from defects in mitochondrial complex II function.

Table 30.1 Number of germline mutations identified in the *SDHB*, *SDHC*, and *SDHD* genes in PGL/PCC

Gene	Study 1 (%)	Study 2 (%)	Study 3[a] (%)
SDHB	16 (8.4)	24 (4.8)	38 (24.7)
SDHC	2 (1.1)	4 (0.8)	2 (1.3)
SDHD	3 (1.6)	47 (9.4)	31 (20.1)
Total cases	190 (11.1)	501 (15)	154 (46.1)

Study 1: [10]
Study 2: [14]
Study 3: Cases tested during July 2007 to January 2012 in the Medical Genetics Laboratories (MGL), Baylor College of Medicine (BCM)
[a]The higher mutation rate in Study 3 is likely due to the selection bias of specimens tested because samples were sent to MGL specifically for mutation analysis of *SDH* genes

Currently, ten genes are associated with PGL/PCC: *RET*, *VHL*, *NF1*, *MAX*, *TMEM127*, *SDHA*, *SDHB*, *SDHC*, *SDHD*, and *SDHAF2 (SDH5)*. This chapter will focus on PGL/PCC due to defects in the mitochondrial respiratory chain complex II also called the succinate dehydrogenase (SDH) complex. Five different PGL phenotypes have been identified, with each related to mutations in a different gene: *SDHA* (PGL5), *SDHB* (PGL4), *SDHC* (PGL3), *SDHD* (PGL1), and *SDHAF2* (PGL2).

The SDH complex is at the crossroad of the tricarboxylic acid cycle and the respiratory chain for adenosine triphosphate generation, which oxidizes succinate to fumarate and transfers electrons from $FADH_2$ to coenzyme Q (CoQ). Of the five mitochondrial respiratory chain complexes, SDH is the only one for which all of the subunits are encoded by the nuclear genome. The SDH complex has two functional domains: the catalytic domain consisting of SDHA and SDHB and the mitochondrial inner membrane anchor domain composed of SDHC and SDHD. Assembly of complex II requires at least two proteins, SDHAF1 [3] and SDHAF2 [4].

The association of PGL/PCC with mitochondrial complex II defects was first established by the identification of mutations in the *SDHD* gene [5]. Mutations in *SDHB*, *SDHC*, *SDHA*, and *SDHAF2* (*SDH5*) also cause PGL/PCC [4, 6–8]. Germline mutations in the *SDH* genes occur in 25–45 % of familial PGL/PCC cases, depending on clinical findings and classification, and in approximately 12 % of sporadic cases [9–11]. The mutation detection rate in patients with a family history is very high (>90 %). Large germline deletions also occur but are less frequent (<5 %) [12–14]. Mutations are identified more often in *SDHD* and *SDHB* than in *SDHC* [13] (Table 30.1). The only gene that is part of mitochondrial complex II subunits and assembly that has not been associated with PGL/PCC is *SDHAF1*. Autosomal recessive mutations in the *SDHAF1* gene, however, have been identified in patients with mitochondrial complex II deficiency [3].

Molecular Basis of Disease

The molecular mechanism underlying *SDH* mutations in PGL/PCC has yet to be identified. A proposed mechanism is that mutations in the *SDH* genes may cause a cascade of molecular events, leading to the abnormal stabilization of hypoxia-inducible factor (HIF) under normoxic conditions known as pseudo-hypoxia. The pseudo-hypoxia may lead to increased angiogenesis in the PGL/PCC tumor tissue [7]. Defects in the SDH complex cause an accumulation of succinate that inhibits prolyl-4-hydroxylases (PHDs) and subsequently impairs prolyl-hydroxylation of HIF [15, 16], leading to tumorigenesis, possibly via a glycolytic shift (Warburg effect). Glycolytic shift is observed in solid tumors, in which tumor cells generate energy from glycolysis followed by lactic acid fermentation [16–20]. Stabilized HIF activates transcription of genes downstream of the HIF pathway, resulting in cell proliferation and angiogenesis, and ultimately tumorigenesis [21].

The HIF pathway, which has been proposed to be defective in tumorigenesis caused by *SDH* mutations, normally functions to control cells' responses to low O_2 in vivo. Mammalian cells have complicated machineries to respond to O_2 deprivation. A key modulator is HIF. HIF is a heterodimer consisting of one O_2-labile α subunit and one O_2-stable β subunit. The α subunit has three forms: HIF1α, HIF2α (EPAS1), and HIF3α (IPAS). HIF1α exists ubiquitously. In the normoxic state, approximately 20 % of the HIFα subunits are hydroxylated at conserved proline residues and then degraded via the E3 ubiquitin pathway after forming a complex with the VHL protein [18, 22]. However, in hypoxic conditions, HIFα is stabilized and activates transcription of genes adaptive to hypoxic conditions. Accumulation of succinate due to mutations in *SDH* genes can inhibit the degradation of HIF1α protein, resulting in increased transcription of genes important for response to hypoxic conditions. In moderate hypoxic conditions (1.5 % O_2), mitochondria stimulate the production of cellular reactive oxygen species that may inhibit HIFα degradation. These oxygen radicals are specifically formed from complex III of the mitochondrial respiratory chain [23, 24].

The molecular mechanism underlining PGL/PCC caused by mutations in *SDH* genes may differ from those associated with mutations in *VHL*, *RET*, *NF1*, and *TMEM127*. A study of the expression profile of PGL/PCC tumors using microarray technology demonstrated a different expression pattern in tumors with mutations in the *SDH* genes compared to tumors with mutations in *VHL*, *RET*, *NF1*, or *TMEM172*. A somatic point mutation may function similarly to LOH in causing PGL/PCC tumors [10].

The study of *SDHD* knockout mice showed that $SDHD^{-/-}$ mice died in early embryonic stage (<7.5 days post conception)

and *SDHD*$^{+/-}$ mice had a deficiency of SDH activity. However, tumorigenesis in these *SDHD*$^{+/-}$ mice was not increased, indicating differences of the pathophysiology between human and mouse [25].

SDHA

The *SDHA* gene is located at human chromosome 5p15.33 [26] and codes for the largest subunit of the SDH complex. The gene consists of 15 exons and produces a 2,286 nucleotide transcript, which encodes a 644 amino acid polypeptide of 70 kDa. SDHA is a flavoprotein, which forms the SDH catalytic domain in complex with SDHB, an iron-sulfur protein. Disease-related mutations in the *SDHA* gene were first identified in Leigh syndrome patients with mitochondrial respiratory chain complex II deficiency [27], which is inherited in an autosomal recessive fashion. In 2010, the first case of an *SDHA* mutation associated PGL/PCC syndrome was reported in a patient with an extra-adrenal PGL [7], which is also categorized as paraganglioma syndrome type 5 (PGL5, OMIM #600857). The mutation was a germline heterozygous missense mutation, c.1765C>T (p.R589W), identified in the patient's blood sample. However, in the patient's tumor tissue, the mutant molecules were found to be predominant (much greater than 50 %), suggesting LOH, which was confirmed by array comparative genomic hybridization (aCGH) analysis. The predisposition to PGL/PCC tumors due to an *SDHA* germline mutation is inherited as an autosomal dominant trait at the pedigree level, but recessive at the cellular level, requiring a second mutation to lead to tumorigenesis.

Twenty-eight (28) point mutations in the *SDHA* gene have been reported in Human Genome Mutation Database (HGMD) (as of November 2014). Five mutations are associated with PGL/PCC. The remaining mutations are associated with Leigh syndrome, optic atrophy, ataxia, and myopathy [27–32]. The germline mutations were found in sporadic cases of PGL/PCC with negative SDHA immunostaining and LOH in their tumor tissues. The penetrance of *SDHA* mutations may be low. For example, the p.R31* and p.R585W mutations were found at a frequency of 0.3 % and 0.1 %, respectively, in the general population who are not affected with PGL/PCC, suggesting a low penetrance [33].

SDHB

The *SDHB* gene is located at chromosome 1p36.13 and consists of eight exons encoding a 30 kDa protein of 280 amino acids. The SDHB protein is an iron-sulfur protein forming part of the SDH complex catalytic domain with the SDHA subunit. *SDHB* is the most commonly mutated gene in PGL/PCC (PGL4, OMIM #185470). Currently, 195 *SDHB* mutations associated with PGL/PCC have been recorded in the HGMD, in contrast to the number of mutations in the other *SDH* genes (5 in *SDHA*, 44 in *SDHC*, 144 in *SDHD*, and 2 in *SDHAF2*) (Table 30.2). *SDHB* mutations are more frequently found in secreting PGL and malignant tumors [8, 34]. However, the penetrance of *SDHB* mutations is low (approximately 18 % at age 60) [35], which may explain why *SDHB* mutations are more common in sporadic PGLs/PCCs. Since the survival rate for patients with SDHB-immunonegative tumors is lower than for patients with SDHB-immunopositive tumors, *SDHB* germline mutation may serve as a prognostic marker for patients with PGL/PCC [36].

Table 30.2 Types of mutations in *SDH* genes associated with paragangliomas and pheochromocytomas based on data from the Human Genome Mutation Database (HGMD; November 2014)

	Missense	Nonsense	Splicing	Small indels	Gross indels	Total
SDHA	4	1	0	0	0	5
SDHB	78	16	26	53	22	195
SDHC	19	7	6	5	7	44
SDHD	39	20	12	57	16	144
SDHAF2	1	0	0	1	0	2

SDHC

The *SDHC* gene is located at chromosome 1q23.3 and has at least four alternatively spliced isoforms, although the functional significance of the isoforms is not well understood. The longest isoform (NM_003001.3) consists of six exons. The SDHC protein is located in the mitochondrial inner membrane and together with SDHD forms an anchor domain for the mitochondria respiratory chain complex II. *SDHC* was the second SDH gene associated with PCC/PGL [8]. Mutations in *SDHC* have been found in paraganglioma syndrome type 3 (PGL3, OMIM #602413) but are much less frequent than those in *SDHB* or *SDHD* (Table 30.1). *SDHC* mutations are mostly found in head and neck PGL, although PGLs/PCCs in other loci caused by *SDHC* mutations have been reported [37, 38]. Germline deletion of exon 3 of the *SDHC* gene has been identified in a patient in a study of 190 patients affected with PGL/PCC. The patient had germline deletion of *SDHC* exon 3, but LOH was not found in the tumor. Instead, there was a gain of the entire 1q harboring the mutated *SDHC* gene with exon 3 deletion in the tumor tissue, suggesting that the mutant allele was duplicated [10].

SDHD

SDHD is the smallest subunit in the SDH complex and was the first protein subunit in the SDH complex identified to cause paraganglioma syndrome type 1 (PGL1, OMIM #168000) [5]. The *SDHD* gene is located at chromosome 11q23.1 and has four exons encoding a 159-amino-acid polypeptide. *SDHD* mutations are predominantly found in head and neck PGL [34, 39]. Although PGL/PCC with an *SDHD* mutation is transmitted in an autosomal dominant mode, inheritance is almost exclusively through paternal transmission, which suggests maternal imprinting (inactivation) even though the *SDHD* gene itself is not imprinted [5]. Hensen and colleagues studied 23 SDHD-linked tumors and found all had lost the entire maternal chromosome 11. Thus, they hypothesized that PGL/PCC caused by *SDHD* mutations might require three hits: an *SDHD* germline mutation, the loss of or a somatic mutation in the wild-type *SDHD* gene in the tumor, and defects in another paternally imprinted tumor suppressor gene on chromosome 11, most likely 11p15 where the only imprinted gene cluster on chromosome 11 is located [40]. However, one definitive adrenal PCC case had maternal transmission of the *SDHD* mutation. Molecular studies on tumor and blood demonstrated a germline mutation, a loss of the wild-type paternal *SDHD*, and a loss of the maternal 11p region. Although lacking the typical paternal transmission, this case also supports a 3-hit hypothesis [41].

SDHAF2 (SDH5)

SDHAF2 (SDH5) is the latest SDH complex gene found to be involved in the tumorigenesis of PGL/PCC. *SDHAF2 (SDH5)* is located at chromosome 11q12.2, about 50 Mb away from the *SDHD* gene, and consists of four exons encoding a 166-amino-acid polypeptide. SDHAF2 interacts with SDHA and is required for the flavination of SDHA. Thus, mutations in *SDHAF2* destroy SDH activity, reduce the stability of the SDH complex, and result in paraganglioma syndrome type 2 (PGL2, OMIM #601650) [4]. Inheritance of the risk for PGL/PCC due to an *SDHAF2* mutation is also via an autosomal dominant mechanism but shows parent-of-origin effects. Similar to *SDHD* mutations, *SDHAF2* mutations are paternally inherited for tumor susceptibility, and maternally transmitted mutations do not result in tumors [4]. By studying a large family with an *SDHAF2* mutation, Kunst et al. found that 12 of 16 carriers who inherited the mutation from their fathers were affected. Twenty-four tumors were found in 11 affected family members (one patient's clinical information was unavailable) and 10 of the 11 patients had at least two tumors. All tumors were found in the head and neck with the majority in the carotid body (17/24 or 71 %) [42]. Currently, two mutations have been reported. One mutation, c.232G>A (p.G78R), was identified in a large Dutch family and a Spanish family [4, 42, 43]. A study of 443 sporadic PGL/PCC patients who had no mutations identified in the *SDHB*, *SDHC*, or *SDHD* genes did not identify any germline mutations or gross deletions in the *SDHAF2* gene, suggesting a very low incidence [43]. The other mutation, c.358dupT, was reported in a sporadic patient with head and neck paraganglioma in the right carotid body [44].

Available Assays

In general, immunostaining of tumor tissues is a straightforward assay for the prediction of mutated genes and can be used as a first step in screening. SDHB immunostaining can be diagnostic based on a study of 200 PGL/PCC tumors in which all 102 PGLs/PCCs with an *SDHB*, *SDHC*, or *SDHD* mutation lacked SDHB protein staining, while all 65 PGLs/PCCs associated with MEN2, VHL, and NF1, and 47 of the 53 PGLs/PCCs without identifiable germline mutations had SDHB immunostaining [45]. This study supports that hypothesis that the major effect of an *SDH* mutation is to alter assembly or stability of the SDH complex, as opposed to disruption of catalytic dysfunction [45]. Later, SDHB-immunonegative staining was found in all eight PGLs/PCCs with a heterozygous *SDHA* germline mutation [7, 33]. Based on clinical findings such as family history, malignancy and location of tumors, and clinical symptoms, the appropriate candidate gene(s) may be sequenced. For example, a patient with a sporadic malignant, SDHB-immunonegative, extra-adrenal tumors is highly suggestive of an *SDHB* germline mutation. Lack of SDHA immunostaining may be quite specific for an *SDHA* germline mutation. Based on a study of 316 PGL/PCC tumors using SDHA immunostaining, six of seven SDHA-negative staining tumors were found to have a heterozygous *SDHA* germline mutation. The remaining one did not have enough DNA for *SDHA* sequence analysis [33].

Sequence analysis of the *SDH* genes is the gold standard for mutation detection of point mutations and small deletions and insertions. Currently, the most widely used method is Sanger sequencing. Each coding exon and approximately 50 base pairs of flanking intronic sequences are amplified using polymerase chain reaction (PCR), followed by sequencing of the PCR products using dideoxy chain termination Sanger sequencing, and analysis on an automated DNA sequencer. The sequencing results are compared to reference sequences to determine nucleotide changes. This testing approach is widely used in clinical molecular laboratories.

For detection of large deletions and duplications involving the *SDH* genes, aCGH technology can be performed. The aCGH technology compares the genomic DNA isolated from

a patient and a control. The optimal microarray for *SDH* gene assessment contains oligonucleotide probes across the entire human genome with dense probes targeted to exons of genes involved in mitochondrial and metabolic disorders [46]. A custom-designed oligonucleotide microarray (MitoMet oligonucleotide microarray, developed by Medical Genetics Laboratories at the Baylor College of Medicine, http://www.bcm.edu/geneticlabs/) has been successfully used to detect a deletion involving exon 2 of the *SDHC* gene.

Interpretation of Results

Negative immunostaining of SDHB (i.e., lack of SDHB staining) is diagnostic of a germline mutation in one of the *SDH* genes [45]. Thus, sequence analysis of the *SDHB*, *SDHC*, and *SDHD* genes should be performed. SDHA-negative immunostaining of a tumor tissue is specific for an *SDHA* germline mutation. Thus, sequence analysis of the *SDHA* gene is highly recommended.

Sanger sequencing of the *SDH* genes has 98 % sensitivity; however, interpretation of the pathogenicity of an identified variant, especially a novel change, may be challenging. Information regarding clinical findings, detailed family history, testing of other affected and unaffected family members, molecular analyses of tumor tissues, the effect of the variant on protein structure, and the conservation of the base and/or codon across species may help with the correct interpretation of a novel variant. Databases such as Human Gene Mutation Database (HGMD; http://www.hgmd.org/) and dbSNP (http://www.ncbi.nlm.nih.gov/snp/) are excellent resources to help with the evaluation of a novel variant. Currently, approximately 390 *SDH* gene mutations have been reported in HGMD. It is worth noting that even though recessive mutations in the *SDHC* and *SDHD* genes have not been reported in the literature, the possibility that severe mitochondrial respiratory chain complex II deficiency caused by two recessive mutations in these genes cannot be ruled out.

The penetrance of mutations in the *SDH* genes is variable. The available data for penetrance studies focused on the two most commonly mutated *SDHB* and *SDHD* genes. The penetrance of *SDHB* mutations is 40–55 % at age 40 years and 70–95 % at age 60 years [34, 47, 48]. The differences among studies may be due to the limited number of family members studied, especially the members who do not have clinical presentations, the particular mutations involved in a family, and family-specific modifiers. Another study used a modified algorithm to recalculate the penetrance based on the same datasets and found that the penetrance is 8 % (4–11 %) at 40 years old and 18 % (10–26 %) at 60 years old [35]. The penetrance of an *SDHD* mutation is approximately 80 % at age of 50 years [34, 47].

Recessive *SDHA* mutations cause severe mitochondrial respiratory chain complex II deficiency and Leigh syndrome in early childhood [27, 29, 31]. However, a dominant *SDHA* germline mutation may result in PGL5 with LOH in the tumors, late-onset optic atrophy, ataxia, and myopathy, or gastrointestinal stromal tumors [7, 28, 30, 33]. As described by Korpershoek and colleagues, some *SDHA* mutations in PGL/PCC may occur in sporadic cases and may exhibit low penetrance. Therefore, an accurate clinical evaluation, family history, immunohistochemical and enzymatic analyses on tumor tissues, LOH study, and an estimated allelic frequency of a particular variant in the population must be considered for the proper interpretation of a variant.

An accurate detailed family history is especially important for the interpretation of mutations in the *SDHD* and *SDHAF2* genes due to their parent-of-origin effects. The tumors are exclusively from paternally inherited alleles [4, 5]. Thus, a paternal transmission pattern in a family pedigree is highly suggestive of an *SDHD* or *SDHAF2* germline mutation.

Clinical Utility of Testing

Although the majority of PGLs are benign, about 10 % may develop malignant features. Up to 65 % of PGLs in children/adolescents (<20 years old) are malignant [48]. Malignancy of PGL/PCC is defined by the presence of metastases, not by local invasion. Malignancy is not easy to determine by imaging or histochemistry. The prognosis for malignant PCC is about 50 % 5-year survival [1, 2]. Approximately 29 % of head and neck PGL produce significant amounts of catecholamines [50]. Excessive catecholamines may cause a variety of clinical symptoms including hypertension, palpitations, headache, sweating, and pallor.

Early detection of a PGL/PCC tumor with confirmed molecular testing is useful for disease prognosis and patient care. The primary goals for molecular testing of the *SDH* genes in patients affected with PGL/PCC are to confirm a clinical diagnosis, to improve medical management for the patients, and to facilitate carrier testing and genetic counseling for family members. Confirmation of the clinical diagnosis by the identification of a causative mutation may help clinicians to focus on the proper treatment and patient management rather than further expensive screening for differential diagnosis. Since *SDH* genes are tumor suppressor genes with an autosomal dominant mode of inheritance, identification of a mutation warrants testing of at-risk family members, including parents, children, and siblings of the proband. First-degree relatives have a 50 % carrier risk. If the mutation is not found in the parents, the mutation may be considered de novo, although gonadal mosaicism, which has

not been documented, cannot be ruled out. Familial testing may find the mutation in young, presymptomatic relatives. Those presymptomatic mutation carriers could be closely monitored, for example, by regular computed tomography (CT) scanning or magnetic resonance imaging (MRI). Thus, a tumor may be identified at an early stage, which may allow early removal of the tumor to cure the disease. Surgery is still the primary treatment of PGL/PCC. Laparoscopic surgery is the first choice for resection of adrenal and extra-adrenal tumors. Other treatments include chemotherapy, radiotherapy, and/or [^{131}I] meta-iodobenzylguanidine [1]. Those relatives who have tested negative for the familial mutation may be spared the monitoring procedures.

Quality Control and Laboratory Issues

Although lack of SDHB immunostaining of tumor tissues is highly suggestive of a mutation in the *SDH* genes, the specific gene is not identified by this test. Other information including family history, location and malignancy of the tumor, and the number of tumors may help to prioritize candidate genes. Sequence analysis of *SDHB* should be the top priority if a sporadic patient is affected with malignant PGL/PCC. *SDHD* sequencing is highly recommended for a patient with a family history, especially if all the affected family members show inheritance from their fathers. While Sanger sequencing has high sensitivity for detection of point mutations in the coding regions, some mutations may be missed. For example, single nucleotide polymorphisms at PCR primer sites may result in allele dropout due to lack of or reduced PCR amplification of that allele and mutations in the promoter and deep intronic regions, and large heterozygous deletions/duplications may not be detected by sequencing. These drawbacks can be overcome by careful test design. For instance, two pairs of primers amplifying the same exon may be designed to avoid reduced amplification due to SNPs at the primer sites, and PCR primers may be used to amplify promoter and deep intronic regions for mutation testing. Large heterozygous germline deletion mutations have been reported [14]. If clinical findings strongly suggest an *SDH* mutation and sequence analysis is negative, aCGH testing or MLPA should be considered [46].

Special attention is required for the test design for *SDHA* sequence analysis due to the existence of a highly homologous pseudogene, which is located on chromosome 3q29. The homologous region involves exons 3–14. When clinical manifestation and other laboratory results strongly suggest an *SDHA* germline mutation but a mutation cannot be found by routine *SDHA* sequence analysis, the other factors mentioned above need to be considered. For example, long-range PCR (LR-PCR) may be used to avoid amplification of the pseudogene. Additional pairs of PCR primers may be used to avoid SNPs in PCR primer sites. In our laboratory (Medical Genetics Laboratories at the Baylor College of Medicine), we design LR-PCR primers that are located in nonhomologous regions to specifically amplify the *SDHA* gene and not the pseudogene. The LR-PCR products are then used as templates for PCR amplification of each exon that has homologous sequence in the genome. This strategy can avoid interference from homologous sequences. Even though the *SDHD* gene has a processed pseudogene on chromosome 1, sequence analysis may not be an issue because PCR primers are usually designed to include partial introns where sequences are locus specific. Due to existence of homologous sequences for the *SDHA* and *SDHD* genes, aCGH may not be useful to detect exonic deletions/duplications. In these cases, MLPA analysis is an option.

Proficiency testing programs are not available for the *SDH* genes, so laboratories must meet the proficiency testing requirements through interlaboratory sample exchange.

Abstract

Molecular testing of colorectal cancer (CRC) has become the standard practice in the management of patients who are candidates for chemotherapy and gene- or pathway-targeted therapies, providing critical information for precision therapy. Current and emerging testing approaches and guidelines used to select *EGFR* pathway-targeted therapies for CRC are reviewed, as well as the use of DNA mismatch repair deficiency testing in CRC for identification of patients who might not benefit from conventional therapies containing 5-fluorouracil (5FU). Recent recommendations for extended *RAS* mutation testing encompassing exons 2, 3, and 4 of *KRAS* and *NRAS* in CRC are highlighted. An overview of laboratory considerations includes the critical role of tumor tissue evaluation by pathologists, in order to select the best areas of tumor for testing. In addition to a number of conventional testing platforms, given the increasing number of gene mutations that may be critical to achieve targeted therapy efficacy in CRC, advances in the use of gene panels for mutation analysis with platforms that permit detection of hundreds of mutations in a single sample, such as next-generation sequencing (NGS) gene panels, are described.

Molecular Basis of Colorectal Cancer

Colorectal cancer (CRC) is the third most common cause of cancer in men and women in the USA with approximately 140,000 new cases annually [1, 2]. The majority of CRCs arise from precursor adenomas or from serrated polyps [3, 4]. The classifications of CRC based on molecular alterations have been centered on genomic and epigenomic alterations, leading to CRC molecular subtypes with chromosomal instability (CIN), CpG island methylator phenotype (CIMP), and microsatellite instability (MSI) [5–7]. Based on these genomic and epigenomic changes, five CRC types with prognostic significance have been defined: CIN only (58.2 %), MSI associated (12.6 %), CIMP only (5.3 %), CIMP+/CIN+ (13.4 %), and triple negative (10.6 %) [7].

D.G.B. Leonard (ed.), *Molecular Pathology in Clinical Practice*, DOI 10.1007/978-3-319-19674-9_31

The CIN pathway CRCs arise through the conventional adenoma-to-carcinoma progression and are characterized by widespread imbalances in chromosome numbers and alterations of multiple tumor suppressor genes and oncogenes, including adenomatous polyposis coli (*APC*), deleted in colorectal cancer (*DCC*), and deleted in pancreatic cancer 4 (*DPC4, SMAD4*), *TP53*, *KRAS*, and *CTNNB1* [3]. The CIMP pathway CRCs are characterized by methylation of CpG islands in genes associated with CRC carcinogenesis such as the *CDKN2A* tumor suppressor gene, *THBS1*, *MLH1*, and other cancer-related genes [8, 9].

MSI occurs in both sporadic and hereditary CRCs, however, by different mechanisms. The MSI pathway utilized by sporadic CRCs is characteristic of tumors with loss of expression of *MLH1* resulting from CIMP-associated CpG promoter methylation of the promoter region of this DNA mismatch repair (MMR) gene [9, 10]. In contrast, in hereditary nonpolyposis colorectal cancer (HNPCC), also known as Lynch syndrome, which represents 3–6 % of all CRC cases, MSI is due to germline mutations in one of the MMR genes. In both cases, deficient MMR function results in ineffective repair of DNA polymerase slippage errors in microsatellites and repetitive nucleotide sequences during DNA synthesis, resulting in changes in the number of nucleotides in these repeats, which is called MSI [11, 12]. Notably, CIMP is not a feature of HNPCC CRCs [13]. HNPCC patients inherit germline mutations of *MLH1*, *MSH2*, *MSH6*, or *PMS2*, in approximately 40 %, 40 %, 10 %, and 5 % of HNPCC cases, respectively [14].

Recently, The Cancer Genome Atlas (TCGA) project reported the results of a comprehensive analysis of 276 CRCs that included exome and DNA copy number analysis, CpG methylation assessment, and messenger RNA and microRNA expression [5]. The TCGA exome sequence analysis revealed two CRC groups: hypermutated and non-hypermutated tumors, consistent with previous studies [5]. Most hypermutated tumors (70 %) had high levels of MSI (MSI-H), with the majority showing *MLH1* promoter methylation, and most but not all cases showed overlapping CIMP. The remainder of the hypermutated tumors (30 %) lacked MSI-H, CIMP, or *MLH1* promoter methylation, but had somatic mutations in MMR genes or the *POLE* gene [5]. The most frequently mutated genes in the hypermutated tumors were *ACVR2A*, *APC*, *TGFBR2*, *MSH3*, *MSH6*, *SLC9A9*, *TCF7L2*, and *BRAF* (specifically the V600E mutation). The most frequent mutations in non-hypermutated tumors were detected in the following genes: *APC*, *TP53*, *KRAS*, *PIK3CA*, *FBXW7*, *SMAD4*, *TCF7L2*, and *NRAS* [5]. The TCGA report provided a detailed analysis of altered pathways in CRC, summarized below [5].

WNT Signaling Pathway

Alteration of the WNT signaling pathway occurs in 93 % of all CRCs, and inactivation of *APC* or activating mutations of *CTNNB1* occur in approximately 80 % of tumors. The WNT receptor frizzled (*FZD10*) was overexpressed in approximately 17 % of cases [5].

PI3K, RAS, and MAPK Signaling Pathways

Among non-hypermutated CRCs, 55 % have alterations in *KRAS*, *NRAS*, or *BRAF*, with significant mutual exclusivity. *IGF2* and *IRS2* overexpression was seen in some tumors. Mutually exclusive mutations in *PIK3R1* and *PIK3CA* and deletions in *PTEN* occur in 2 %, 15 %, and 4 % of non-hypermutated tumors, respectively. Co-occurrence of alterations involving the RAS and PI3K pathways occur in one-third of tumors, suggesting that simultaneous inhibition of the RAS and PI3K pathways may be required to achieve therapeutic benefit when treating these CRCs [5].

TGF-β Signaling Pathway

Genomic alterations in *TGFBR1*, *TGFBR2*, *ACVR2A*, *ACVR1B*, *SMAD2*, *SMAD3*, and *SMAD4* occur in 27 % of non-hypermutated and in 87 % of hypermutated CRCs [5].

TP53 Pathway

Alterations in *TP53* occur in 59 % of non-hypermutated CRCs. Alterations in ATM, a kinase that phosphorylates and activates TP53 after DNA damage, are seen in 7 % of non-hypermutated tumors. Alterations in these two genes trend toward mutual exclusivity [5].

Role of MYC in CRC

Integrated analysis of copy number, gene expression, methylation, and pathway data show that most CRCs have changes in the genes that are transcriptionally regulated by MYC. Activation of the WNT signaling pathway and inactivation of the TGF-β signaling pathway, resulting in increased activity of MYC, were nearly always present in CRC [5].

Molecular Testing of Colorectal Cancer for Targeted and Conventional Therapies

In clinical practice, molecular testing of CRCs is used to identify gene mutations that help oncologists select the therapeutic regimen for individual patients and to evaluate MMR deficiency to identify patients with HNPCC or sporadic MSI CRCs. Testing for DNA MMR in CRC is discussed in Chap. 24. This chapter reviews current and emerging testing approaches used to (1) select EGFR pathway-targeted therapies for CRC treatment and (2) identify patients who might not benefit from conventional therapies containing 5-fluorouracil (5-FU).

Table 31.1 Frequencies of mutations in EGFR pathway genes in colorectal cancer

Pathway	Genes	Frequency (%)
MAPK pathway	*KRAS*	40–45
	NRAS	2.5
	BRAF	5–10
PI3K pathway	*PIK3CA*	15
	PTEN	10–20
	AKT	5

Targeting EGFR Signaling Pathways in CRC

Aberrant activation of EGFR signaling pathways is frequent in CRC and is primarily associated with activating mutations of genes in the MAPK and PI3K pathways [1, 15]. In contrast to lung cancers, activating mutations in the *EGFR* gene itself have not been identified in CRC [1, 15]. The frequencies of mutations in EGFR pathway genes in CRC are shown in Table 31.1 [16]. Combined mutations of *KRAS* or *NRAS* and *PIK3CA* (5–10 %) also occur. Together, *BRAF* and *KRAS* are mutated in about half of all CRC cases, and *KRAS* and *BRAF* mutations are mutually exclusive [17, 18]). Activating mutations in the *KRAS* gene are associated with lack of responsiveness to monoclonal antibody-based therapy for CRC that targets EGFR. *KRAS* mutations occur mostly at exon 2 (codon 12 [70–80 %] or 13 [20–30 %]), followed by mutations in exon 3 at codon 61 and in exon 4 at codon 146 [19]. Mutations at codons 59 and 117 have also been recently reported (Table 31.2). A similar spectrum of *NRAS* mutations is seen in CRC (Table 31.2).

The most frequent *BRAF* mutations in CRC occur in exon 15 with a T-to-A transversion at nucleotide position 1,796, which leads to the substitution of valine for glutamate (V600E) [16]. The *BRAF* V600E mutation occurs in 4–12 % of MMR-proficient (microsatellite stable) CRCs and in 40–74 % of MLH1-deficient/MSI-H sporadic CRCs, but is not found in MLH1-deficient MSI-H CRC in HNPCC CRCs [17, 22, 23]. Therefore, determination of *BRAF* V600E mutation status may differentiate sporadic from hereditary MSI-H CRC, since hereditary CRC will not have a *BRAF* V600E mutation.

Mutations in the PI3K pathway have been reported in approximately 20 % of all CRCs [16, 17]. Interestingly, mutations involving genes in the two EGFR signaling pathways are not mutually exclusive, and about 5–10 % of CRCs carry mutations in genes from both the MAPK and PIK3 signaling pathways [16, 17].

Cetuximab and panitumumab are antibodies that bind to the extracellular domain of EGFR, block EGF and binding of other endogenous ligands to the EGFR, and thereby block EGFR signaling. Targeted EGFR therapies improve progression-free and overall survival in metastatic CRC [24].

Table 31.2 Overall *RAS* mutations in CRCs without mutations in *KRAS* codons 12 and 13

	OPUS trial (% of total CRCs)	CRYSTAL trial (% of total CRCs)
CRCs with other *RAS* mutations (WT *KRAS* C12 and C13)	27.9	17.0
Other *KRAS* mutations	15.2	8.9
Exon 3: C59 and C61	5.9	3.3
Exon 4: C117 and C146	9.3	5.6
***NRAS* mutations**	12.7	8.1
Exon 2: C12 and C13	6.8	3.5
Exon 3: C59 and C61	5.1	2.8
Exon 4: C117 and C146	0.8	0.9

The cutoff used for scoring mutation positivity was 5 % in both OPUS and CRYSTAL trials [20, 21]
C codon, *WT* wild type

For patients with metastatic CRC with wild-type *KRAS*, treatment with cetuximab significantly improved overall survival (median 9.5 vs 4.8 months) as compared to supportive care alone (Karapetis et al. [25]). In contrast, patients with mutated *KRAS* CRCs showed no significant difference between those who were treated with cetuximab and those who were not, leading to the conclusion that patients with CRC carrying a mutated *KRAS* do not benefit from cetuximab, whereas patients with wild-type *KRAS* CRC benefit from cetuximab therapy because the antibody effectively blocks the activating EGFR signaling at the cell surface [25]. The mutations tested for in the first trials were limited to *KRAS* exons 12 and 13 [24]. Further evidence from phase II and III clinical trials using monoclonal antibodies as monotherapy or in combination with chemotherapy for metastatic CRC (stage IV: any T, any N, M1) demonstrated that CRC with a *KRAS* mutation in codons 12, 13, or 61 did not benefit from treatment with cetuximab or panitumumab [26]. Based on the available clinical trial data in 2009, the American Society of Clinical Oncology recommended that patients with metastatic CRC who are candidates for anti-EGFR antibody therapy should have their tumor tested for *KRAS* mutations in a CLIA-accredited laboratory [26].

Up to 40 % of patients with a CRC without a *KRAS* mutation respond to anti-EGFR antibody therapy, while the remaining 60 % of patients with *KRAS* wild-type tumors did not respond [26]. The lack of response may be due to (1) mutations in genes downstream of KRAS, (2) the presence of *KRAS* mutations in exons not tested in the assay used for *KRAS* mutation testing, (3) mutations in *NRAS*, or (4) changes in other oncogenic pathways in individual cancers. For CRC with mutant *KRAS*, a number of drugs targeted to inhibit downstream signaling molecules, such as inhibitors of mTOR, RAF, and MEK, are under evaluation [27].

The role of *BRAF* mutation for prediction of response to anti-EGFR therapy in CRC is still pending results from larger studies [28, 29]. One study reported that colon cancer cells were unresponsive to the BRAF inhibitor vemurafenib due to rapid feedback activation of EGFR, blunting the benefit of vemurafenib [30]. However, the low proportion of CRC cases with *BRAF* mutations and the poor prognosis associated with *BRAF* mutations make determination of a definitive impact on outcomes difficult [28, 29].

Conflicting roles of *PIK3CA* mutations in tumor response to anti-EGFR antibody therapy have been reported in a number of small studies [31, 32]. However, a large study found that the presence of a *PIK3CA* mutation is associated with a poor response to cetuximab [17]. In this study, *BRAF*, *NRAS*, and *PIK3CA* exon 20 mutations were significantly associated with a poor response to cetuximab, and objective response rates were improved by stratifying patients by genotype of *BRAF*, *NRAS*, and *PIK3CA* exon 20 mutations in the *KRAS* wild-type population and excluding patients with any mutation from the treatment arm [17, 33]. However, guidelines for testing CRC of patients who are candidates for anti-EGFR antibody therapy for *BRAF* and *PIK3CA* mutations have not yet been reported.

Tissue Sample and Gene Testing Considerations for CRC-Targeted Therapies

The standard of practice for selection of patients with metastatic CRC who are candidates for targeted therapies with anti-EGFR antibodies has been primarily based on the mutation status of *KRAS* [26]. However, as discussed above, the mutation status of *BRAF*, *NRAS*, *PI3KCA*, and other genes downstream of EGFR may affect the tumor response to anti-EGFR therapy [33]. Therefore, testing for mutations in other genes may be indicated in candidate patients, particularly in the setting of clinical trials, at the present time. *EGFR* mutation testing is not indicated for CRC since activating *EGFR* mutations in CRC are rare and were not demonstrated to confer sensitivity to tyrosine kinase inhibitors or to cetuximab therapy [34].

In addition to *KRAS* mutations in codons 12 and 13 of exon 2, *KRAS* mutations in codons 59 and 61 of exon 3 and codons 117 and 146 of exon 4 and similar mutation hot spots in *NRAS* need to be considered when selecting true *RAS* wild-type patients who will benefit from cetuximab therapy for metastatic CRC (Tables 31.2 and 31.3) [20, 21, 35]. Further, the addition of cetuximab therapy for patients with any *RAS* mutation is of no benefit [20, 21, 35]. Therefore, patients with metastatic CRC should undergo expanded testing for all known activating *RAS* mutations, to avoid use of cetuximab in patients whose CRCs will not respond [20, 21, 35]. Interestingly, in contrast to other activating mutations in *KRAS*, use of cetuximab for patients with chemotherapy-refractory CRC with the *KRAS* G13D mutation may be associated with longer overall and progression-free survival than with other *KRAS* activating mutations [18], although this has not been supported by some studies.

Table 31.3 Effect of cetuximab in true *RAS* wild-type CRC: results from the CRYSTAL and OPUS clinical trials [20, 21]

Clinical trial	ORR (%)	PFS (months)	OS (months)
OPUS	57.9 % vs 28.6 %	12 vs 5.8	19.8 vs 17.8
	$p=0.008$	$p=0.062$	$p=$NS
CRYSTAL	66.3 % vs 38.6 %	11.4 vs 8.4	28.4 vs 20.2
	$p<0.0001$	$p=0.0002$	$p=0.0024$

ORR overall response rate, *OS* overall survival, *PFS* progression-free survival

Regarding the choice of tissue for DNA mutation analysis, since *KRAS* mutations occur early in colorectal carcinogenesis, most clinical trials have tested the primary tumor. Published studies show a good correlation between *KRAS* mutation status in primary and metastatic CRC lesions with an average concordance of 93 % (76–100 %) [36, 37]. Therefore, testing tumor tissue from either the primary site or from a metastatic lesion is appropriate, and a metastatic lesion when available is preferred. Pathologists should select a block of formalin-fixed, paraffin-embedded (FFPE) tissue with the highest proportion of viable tumor and highest percentage of tumor cells as possible, understanding that all cells present in the tissue contribute DNA, so this percentage is of all cells, namely, those that normally compose the colonic wall and variable amounts of inflammatory cells. For small samples, adequate DNA amount can be obtained by pooling macro- or microdissected tumor tissue from multiple tissue levels. This procedure may also provide a larger sampling of the tumor, including areas of mutational heterogeneity, thereby improving mutation detection. Importantly, a pretreatment biopsy sample may be preferable for testing rather than a resection specimen removed after neoadjuvant therapy, as is the case in rectal cancers, where minimal numbers of residual viable tumor cells may persist, making these tissues inadequate for molecular testing. Cytology specimens, particularly from metastatic lesions, also provide an adequate source of tumor for DNA extraction and mutation analysis.

In summary, *RAS* mutation analysis of CRC tumor tissues is recommended as the standard of care in patients who are candidates for anti-EGFR antibody therapy [20, 21, 35]. Additional mutation testing of other EGFR signaling pathway genes may be helpful to better select patients for targeted therapies with improved outcomes, but a general consensus about which genes should be tested is not yet

established. In large practice centers, the trend is to test all CRCs for *RAS* and *BRAF* V600E mutations and for MMR deficiency (with the use of immunohistochemical and/or MSI testing), thus allowing for selection of patients for conventional therapy as well as targeted therapy [38]. The use of gene panels for mutation analysis with platforms that permit detection of hundreds of mutations in a single sample, such as next-generation sequencing (NGS) gene panels, may provide further insight into the issue of which genes should be tested. However, determination of which mutations should be considered for CRC treatment selection or exclusion still needs to be better defined based on data from clinical trials. The practice of Genomic Tumor Boards to address the use of gene mutation results and other molecular test results is evolving and is being used in some centers to evaluate treatment options other than established treatment protocols by providing clinical trial options for individual patients.

DNA Mismatch Repair Defects and Microsatellite Instability

Approximately 15 % of all CRCs have a deficient MMR system and are characterized by MSI. In 3–5 % of MMR-deficient/MSI-positive CRCs, patients have germline mutations in MMR genes diagnostic of HNPCC or Lynch syndrome, while the remaining are sporadic-type CRCs [39, 40]. In cells with deficient MMR, errors in DNA replication accumulate and are detectable in short tandem repeats of microsatellite regions but also in functional gene coding regions, which results in changes in the length of repeats at any one location (known as MSI) [41–43]. MSI, specifically when a tumor is identified to have a high level of MSI (MSI-H), is a genomic marker of deficient DNA MMR [43]. Six different genes (*MSH2*, *MLH1*, *PMS1*, *PMS2*, *MSH6*, and *MLH3*) encode the MMR system [44]. In HNPCC, as in other hereditary cancer syndromes, recessive mutation of one allele followed by somatic inactivation of the other is the main mechanism of gene silencing [45]. In contrast, in sporadic CRCs, the most frequent mechanism of DNA MMR gene downregulation is biallelic inactivation by CpG methylation and transcriptional silencing of the *MLH1* promoter region [46, 47].

MSI status of CRC can be tested by immunohistochemistry (IHC) of CRC tissue sections to assess expression of the MMR proteins or by PCR-based DNA testing for MSI to detect instability at microsatellite sequences [43, 48]. One advantage of IHC is that the protein identified as showing lost or reduced expression in tumor cell nuclei can be an indicator of which MMR gene has a mutation, which is particularly useful in the workup of HNPCC patients, helping to focus the germline mutation analysis on the most likely affected MMR gene. In addition, combining testing for the *BRAF* V600E activating mutation and CpG island methylation status of the promoter region of *MLH1* can be done to help determine whether a MSI-positive CRC with loss of *MLH1* expression is likely to be an inherited HNPCC CRC (*BRAF* mutation negative and *MLH1* promoter methylation negative) or sporadic-type CRC (*BRAF* mutation positive in up to 70 % of cases and *MLH1* promoter methylation positive) [49].

MSI positivity in CRCs is a prognostic marker for improved survival [42]. MSI was detected in 17 % of CRCs of patients < 50 years of age and was associated with (1) a lower likelihood of tumor metastasis to regional lymph nodes as well as distant organs, contributing to improved survival through tumor downstaging, and (2) an overall survival advantage independent of stage of disease [50]. In addition, no significant difference in survival was found between patients with MSI due to hereditary (HNPCC) CRC compared to sporadic CRC [50, 51]. A reported survival benefit for patients with HNPCC CRC is mainly determined by a diagnosis at younger age and less advanced tumor stage as compared with sporadic MSI-H CRC patients [51].

Deficient DNA MMR and MSI status are predictive of response to therapy in some subsets of deficient MMR CRCs [52]. Both the tumor stage and whether the CRC is sporadic or hereditary (HNPCC) are important factors for selection of adjuvant therapy for CRC patients. Patients with stage II CRCs with MMR-deficient/MSI-positive status receiving 5-FU have no improvement in disease-free survival, and treatment is associated with reduced overall survival [53]. The effect of deficient MMR/MSI in stage III CRC on response to therapy has been more difficult to establish, which may be related to heterogeneity of the studied populations in terms of the proportions of sporadic and HNPCC cases. Some studies showed improved outcomes with chemotherapy for advanced stage III CRCs that were MSI-H [54], but other studies did not [55]. In patients with stages II and III CRC, MMR-deficient CRC patients receiving 5-FU had no improvement in disease-free survival [53]. Sinicrope et al. reported that distant recurrences were reduced by 5-FU-based adjuvant treatment in MMR-deficient stage III CRCs, and a subset analysis suggested that any treatment benefit was restricted to suspected inherited CRCs as compared to sporadic tumors [56]. In summary, larger trials are needed to determine with certainty the utility of MMR and MSI status for treatment selection in routine patient care [56, 57]. Current data support the concept that MMR-deficient/MSI-H stage II and III CRC patients do not benefit from 5-FU-based adjuvant therapy, although one study of stage III MMR-deficient CRC patients showed a treatment benefit restricted to patients with suspected hereditary (HNPCC) CRC.

Assays for CRC Mutation Testing for Selection of Therapy

Many technical approaches and assays are used for mutation testing by clinical molecular laboratories. Laboratory-developed tests (LDTs) are frequently used and follow requirements for validation and interpretation as dictated by CLIA and state regulations, while some commercial in vitro diagnostic (IVD) test kits also are used. Assay methods for mutation detection include Sanger sequencing, pyrosequencing, multiplex PCR with primer extension, fluorescent bead detection assays, MassARRAY matrix-assisted laser desorption/ionization time-of-flight (MALDI-TOF) mass spectrometry, allele-specific PCR such as amplification refractory mutation system/scorpions (ARMS/S), melt curve analysis (as performed in Taq-Man assays using real-time quantitative PCR (qPCR)), and, most recently, NGS [58–62]. Table 31.4 compares three technologies commonly used for mutation detection in cancer-related genes in CRC. Until a few years ago, Sanger sequencing of PCR products was a commonly used method for mutation detection. Recent studies comparing Sanger sequencing with other approaches have highlighted its limited analytical sensitivity for clinical testing of DNA from solid tumor samples, requiring 20–50 % mutant alleles in the amplified products [62, 63].

A number of commercial IVD and LDT assays are available to detect the most common mutations in *KRAS* and *BRAF*. Many of the early assays only tested for a small number of mutations, limiting the correlation between mutation status and drug response in early clinical trials. Of note, early assays for *KRAS* mutation analysis performed both in clinical laboratories and as part of clinical trials were limited to codons 12 and 13 in exon 2, excluding other mutation hot spots. Clinical trials have demonstrated the importance of mutations in previously excluded codons of *KRAS*, in exons 2, 3, and 4, as well as the corresponding codons in *NRAS*. Additionally, mutations in other genes downstream of EGFR in the EGFR signaling pathway also are clinically significant for patient management decisions, as discussed above.

For mutation testing, genomic DNA can be extracted from fresh, frozen, or FFPE tissue using standard molecular laboratory methods. For solid tumor testing, histologic slides should be reviewed by an anatomic pathologist to assess the percent of tumor cells relative to total cells on the slide and to prioritize areas for macro- or microdissection, if necessary, to increase the percentage of tumor cells in the sample used for testing.

Pyrosequencing Assays

Pyrosequencing is a DNA sequencing technique based on the sequencing-by-synthesis principle [64], which is used for analysis of gene regions that are frequently mutated. A pyrosequencing result (pyrogram) for *BRAF* exon 15 is shown in Fig. 31.1. Non-mutated samples show the wild-type sequence

Table 31.4 Comparison of three technologies commonly used for mutation testing for colorectal cancer

Platform	Sanger sequencing	Pyrosequencing	Next-generation sequencing[a]
Principle of technology	Synthesis by addition of labeled nucleotide	Synthesis by nucleotide followed by release of pyrophosphate	Semiconductor: synthesis by nucleotide followed by release of proton
Detection method	Single sequence of varying length by high-resolution (capillary) electrophoresis	Single sequence of limited length using pyrosequencer	Multiple sequences of varying length using chip-based technology
Amplification	Incorporation of labeled nucleotides for strand elongation	Incorporation of unlabeled nucleotides followed by light emission	Incorporation of unlabeled nucleotides followed by pH change
Enzymes	DNA polymerase	DNA polymerase, ATP sulfurylase, luciferase, and apyrase	DNA polymerase
Advantages	Successfully call repeats. Good visual discrimination for interpretation	Fast. Accurate for short sequence reads. Good visual discrimination for easy interpretation	Emulsion PCR and indexing/bar coding allows for high-throughput multiplexing
Disadvantages	Low throughput	Relatively low throughput. Need to input sequence. Difficult to read repeats and homopolymers	Labor-intensive. Difficult to read repeats and homopolymers
Cost	+++ Reagents are expensive	++ Slightly less expensive than Sanger sequencing	+ Comparatively less expensive than both
Turnaround time	8 h/gene sequence	6 h for up to 4 gene sequences	24–36 h for up to 16 gene sequences
Technical issues	++	+	+++
Sensitivity	+	++	++

[a]Next-generation sequencing using the Ion Torrent PGM instrument (Life Technologies, Grand Island, NY)

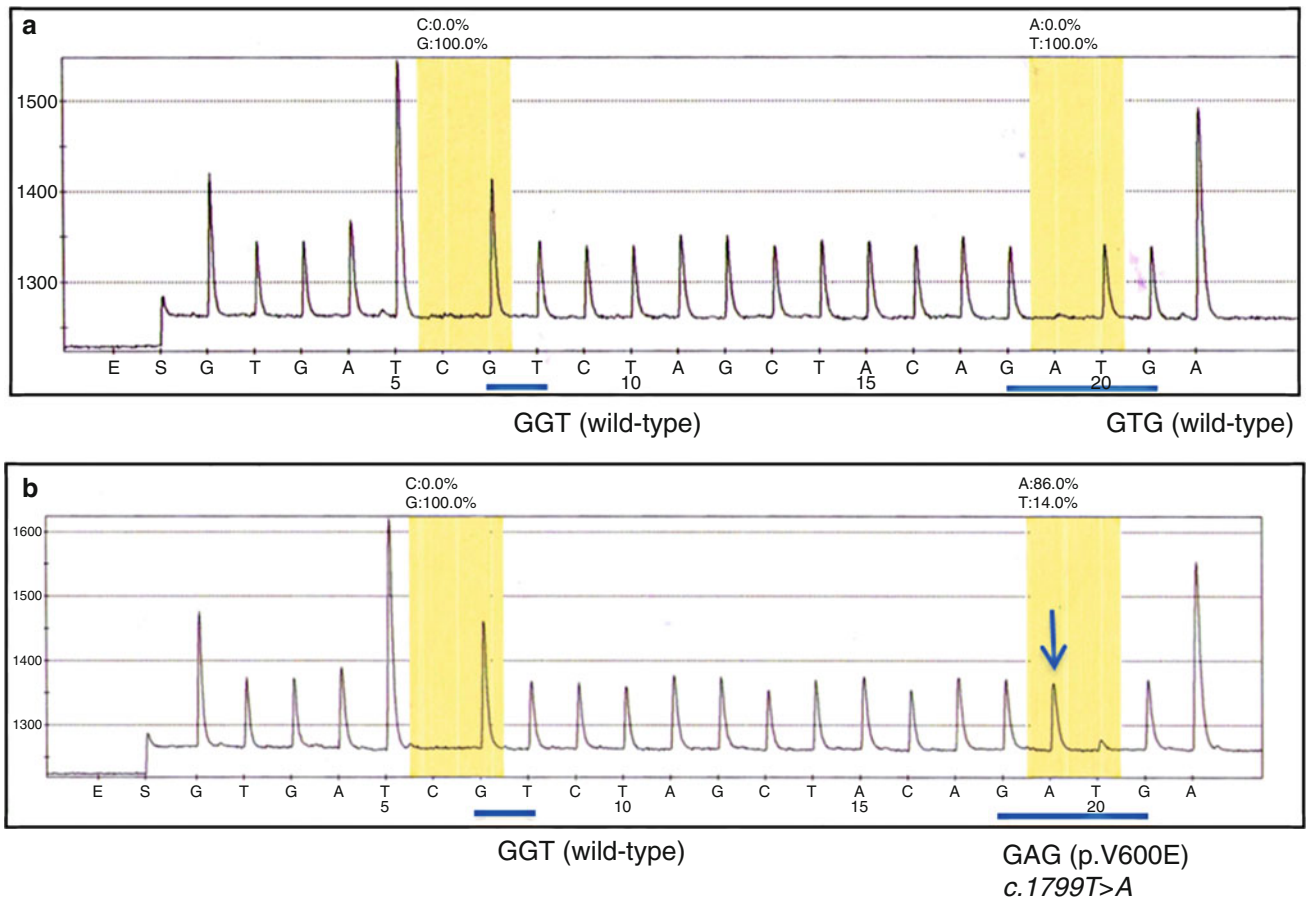

Figure 31.1 Pyrosequencing analysis of *BRAF* exon 15. (**a**) Wild-type *BRAF* sequence. (**b**) An "A" peak (*downward blue arrow*) is present instead of the "T" peak in the wild-type *BRAF* sequence, due to a T>A mutation (c.1799T>A), which results in an amino acid change from valine to glutamic acid in the BRAF protein (p.V600E)

with appropriate peaks and peak heights. Mutations are indicated as different peaks compared to the wild-type sequence or alterations in the height of wild-type peaks relative to a neighboring peak or compared to the reference peak. A reference peak is usually the first peak on each pyrogram. If the background is too high or the peaks are too low, pyrosequencing should be repeated. Indeterminate cases can be verified by Sanger sequencing or other available assays. Examples of *BRAF* mutation testing by pyrosequencing from CRCs of two different patients are shown in Fig. 31.2.

Compared to Sanger sequencing, which has an analytic sensitivity of 20 % mutant alleles, pyrosequencing has a higher sensitivity of approximately 5 % using FFPE tissue [65–69]. With its short read length (approximately 50 base pairs), pyrosequencing is optimal for scanning for mutations in hot spot gene regions and has been used to detect mutations in *KRAS* codons 12, 13, 61, and 146 and the *BRAF* V600E mutation [70–72]. Pyrosequencing is suitable for single-nucleotide polymorphism (SNP) genotyping [73] and DNA methylation analysis [74, 75], such as *MLH1* methylation in CRC [76, 77]. The assay can be performed in 96- or 384-well plates and scaled for sequencing hundreds of megabases of DNA using a large-scale parallel pyrosequencing system.

The limitations of pyrosequencing include the short read length of DNA sequences and sequencing errors in homopolymer regions, since the light intensity in such regions is not proportional to the number of nucleotides incorporated.

Multiplexed Primer Extension Assays

The primer extension method is a template-directed dye termination assay designed to detect the base immediately 3′ to the sequencing primer [78]. After the sequence of interest is amplified by PCR and the unincorporated nucleotides are removed, primer extension can be performed in a single reaction tube using, for example, the SNaPshot Multiplex kit (Applied Biosystems, Foster City, CA). The four major

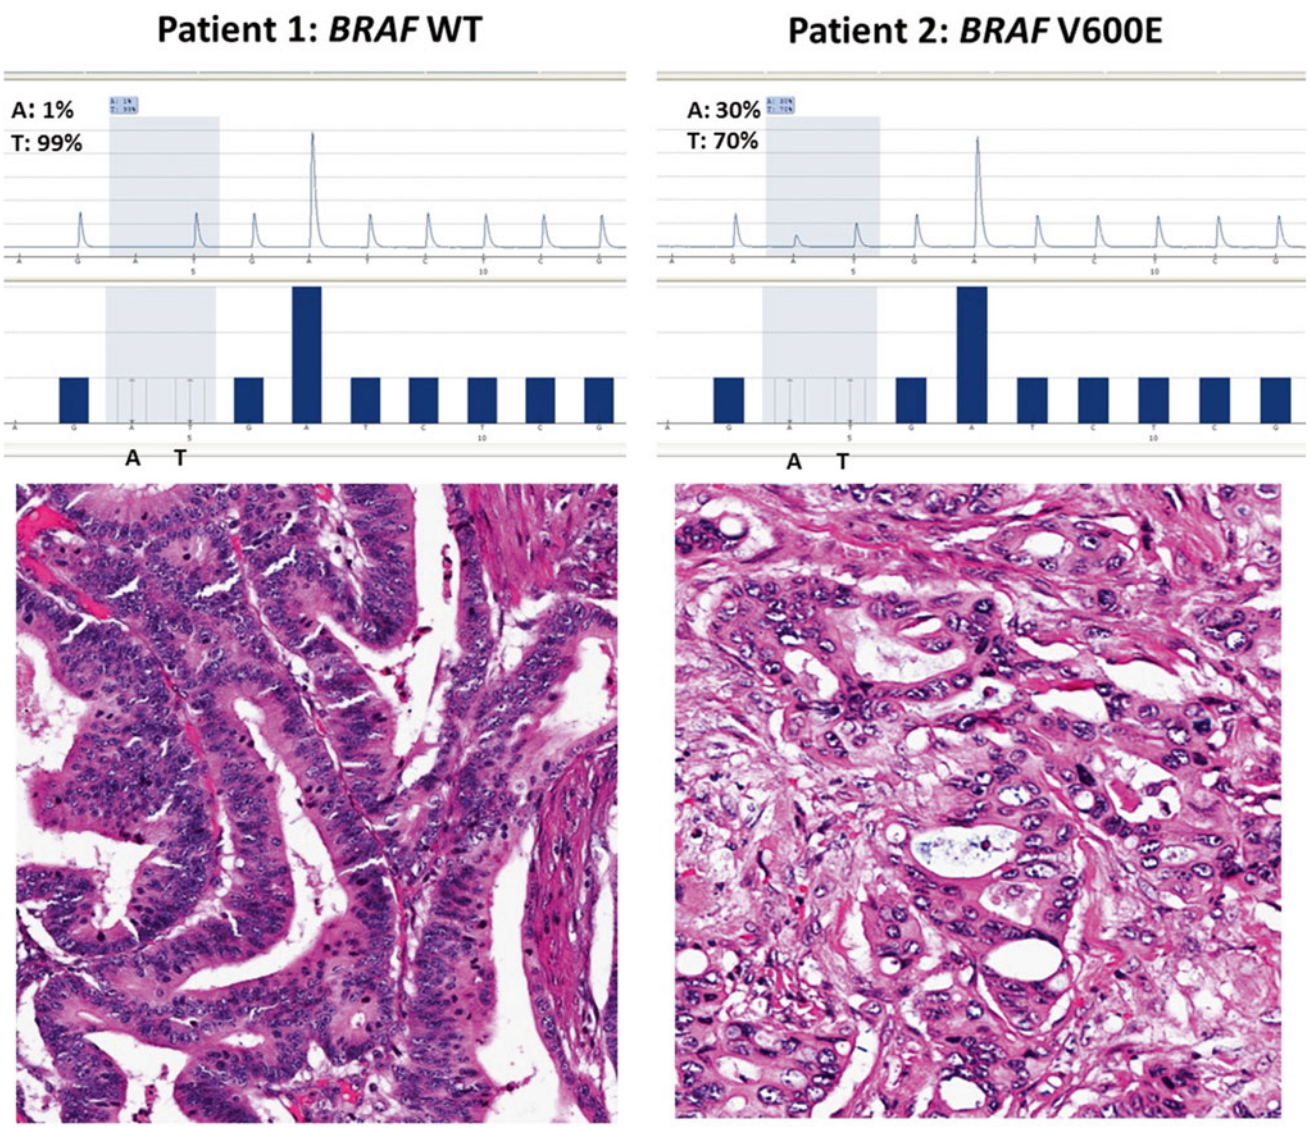

Figure 31.2 Colorectal cancers from two patients tested for *BRAF* V600E mutation by pyrosequencing. Patient 1 (*left*) has a wild-type (WT) gene (99 % T allele at position 1,799) and patient 2 (*right*) is positive for the *BRAF* V600E mutation (30 % A allele at position 1,799). Note that the "A" allele is only present at 30 % of total alleles due to DNA from non-tumor cells in the tissue section that have only the wild-type T allele

steps in a primer extension assay are (1) PCR amplification and column purification of the PCR product; (2) primer extension; (3) alkaline phosphatase digestion and heat inactivation; and (4) capillary electrophoresis of the fluorescently labeled products. Concurrent detection of mutations at multiple sites is possible by multiplexing at the PCR step [79]. When multiplex reactions are run, the primer extension probes are designed with varying lengths of deoxythymidine monophosphate homopolymers at their 5′ end to allow for discrimination of the probe for each site of interrogation by size.

An example of a multiplex primer extension assay for concurrent detection of *BRAF* V600 and K601 and *KRAS* exons 2 and 3 mutations in CRC is shown in Fig. 31.3. Genomic DNA from FFPE CRC tissue is isolated, and the coding sequences for *BRAF* exon 15 and *KRAS* codons 12, 13, and 61 are amplified using specific primers in a multiplex PCR reaction. The probes for primer extension are either in the sense or antisense direction and end one base 5′ of the following positions: nucleotides 1,799 and 1,801 of the *BRAF* gene and nucleotides 34, 35, 37, 38, 181, 182, and 183 of the *KRAS* gene. The probes allow for detection of common variants present in codons V600 and K601 of the *BRAF* gene and codons 12, 13, and 61 of the *KRAS* gene. After amplification, the PCR products are incubated with the unlabeled oligonucleotide primer extension probes, four dideoxynucleotide triphosphates (ddNTPs) labeled with different fluorescent colors, and DNA polymerase. During this primer

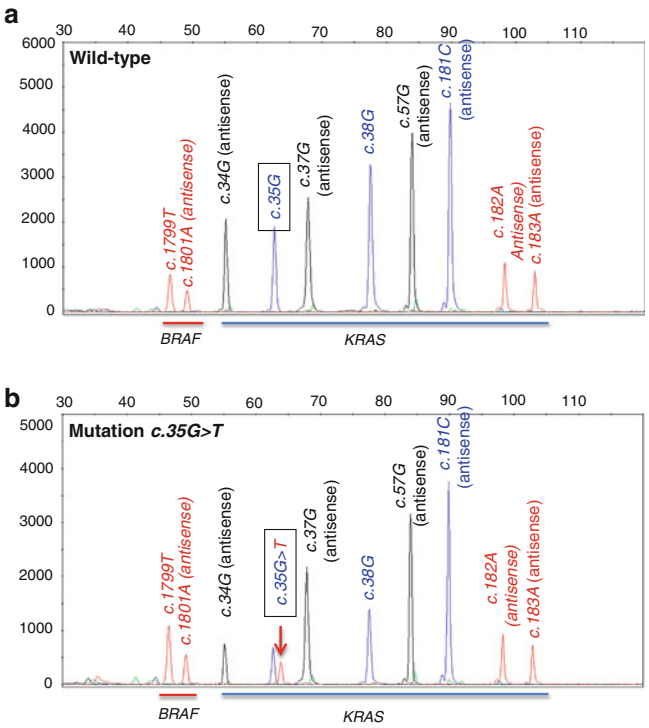

Figure 31.3 Multiplex primer extension assay for detection of *KRAS* codons 12, 13, and 61 mutations and *BRAF* V600E mutations. FFPE tissue section of CRC was manually macro-dissected and used for genomic DNA extraction. *KRAS* codons 12, 13, and 61 and *BRAF* codon 600 sequences were PCR amplified in a multiplex reaction and primer extension was performed. (**a**) No mutation is detected (wild type). (**b**) An extra peak is detected at nucleotide position 2 of the 3-nucleotide codon 12 of *KRAS*, which corresponds to a G>T mutation (c.35G>T) which results in an amino acid change of glycine to valine (p.G12V) in KRAS.

extension step, only the next complementary 5′ nucleotide is added to each probe. The primer extension products are analyzed by capillary electrophoresis. The base at the mutation site is determined by detection of the fluorescent color of the ddNTP that is incorporated.

Controls for primer extension assays included with each run are a wild-type or negative patient sample and a positive sensitivity control (cell line DNA or plasmid). The negative control should show amplification of the valid sizes and colors for all of the normal- or wild-type peaks for the primer extension products. Each patient's PCR and primer extension product serves as its own internal control for extraction and amplification. If no mutation is present, amplification of the valid size and color for the wild-type sequence is seen. If a mutation is present, the mutant peak(s) will be present admixed with the wild-type product. Failure to amplify a product may be due to poor quality or insufficient quantity of DNA or nucleotide polymorphism(s) or mutation(s) that prevents proper annealing of the primer to the DNA template. In the latter situation, an alternate method such as pyrosequencing or Sanger sequencing can be used to confirm the findings.

Primer extension assays combine the specificity of template-directed incorporation of nucleotide by DNA polymerase and the sensitivity of fluorescence polarization in SNP genotyping [79]. Since both wild-type and mutant DNAs are amplified, the limit of detection is determined to some extent by the degree of resolution of the ratio of wild-type to mutant signal. The analytical sensitivity is approximately 2–5 % [80, 81] and the reaction only requires 5–10 ng of genomic DNA [81].

MassARRAY technology (Sequenom, San Diego, CA) is another primer extension method which uses MALDI-TOF for analysis. After PCR amplification and primer extension reactions, nanoliter volumes of the primer extension products are spotted onto a matrix-array chip. The chip is analyzed using MALDI-TOF, and raw data is analyzed using manufacturer's analysis software [82, 83]. The number of assays that can be multiplexed into a single well for MALDI-TOF analysis is dependent on the mutation type and sequencing chemistry, with multiplexing limited to 40 assays for constitutional genetics and eight to ten assays for somatic mutations using iPLEX chemistry [84]. The analytical sensitivity for the MassARRAY platform is approximately 2.5–10 % for somatic mutations [83]. This platform has been used to develop assay panels that include mutations important for predictive and prognostic testing for CRC treatment, including mutations in *KRAS*, *BRAF*, *PI3KCA*, and *PTEN* [83].

Liquid Bead Array Assays

Liquid bead array assays are easy to perform and interpret using predetermined, laboratory-validated cutoffs for positive and negative results. Tumor DNA is used for PCR amplification of the multiple gene region(s) to be analyzed plus an additional conserved genetic sequence, which serves as an amplification control. Biotin-labeled primers are used and are incorporated into the PCR products. The labeled PCR products are hybridized to capture probes, which are covalently bound to fluorescently labeled beads with the color of each bead corresponding to a specific capture probe. The fluorescently labeled beads are incubated with streptavidin-phycoerythrin, a reporter for the presence of the biotin-labeled PCR product, and are analyzed by flow cytometry, to simultaneously detect the presence or absence of hybridized biotin-labeled PCR products and the fluorescent identity of the corresponding bead. Typically, a minimum of 50 beads are assessed for each analyte, and based on the collective fluorescence, the mean fluorescence intensity (MFI) is calculated. The MFI cutoffs for reporting of positive and negative results are validated by the clinical molecular laboratory. The assay result is considered positive when the MFI for an analyte exceeds the predetermined cutoff. When none of the analyte MFI

b

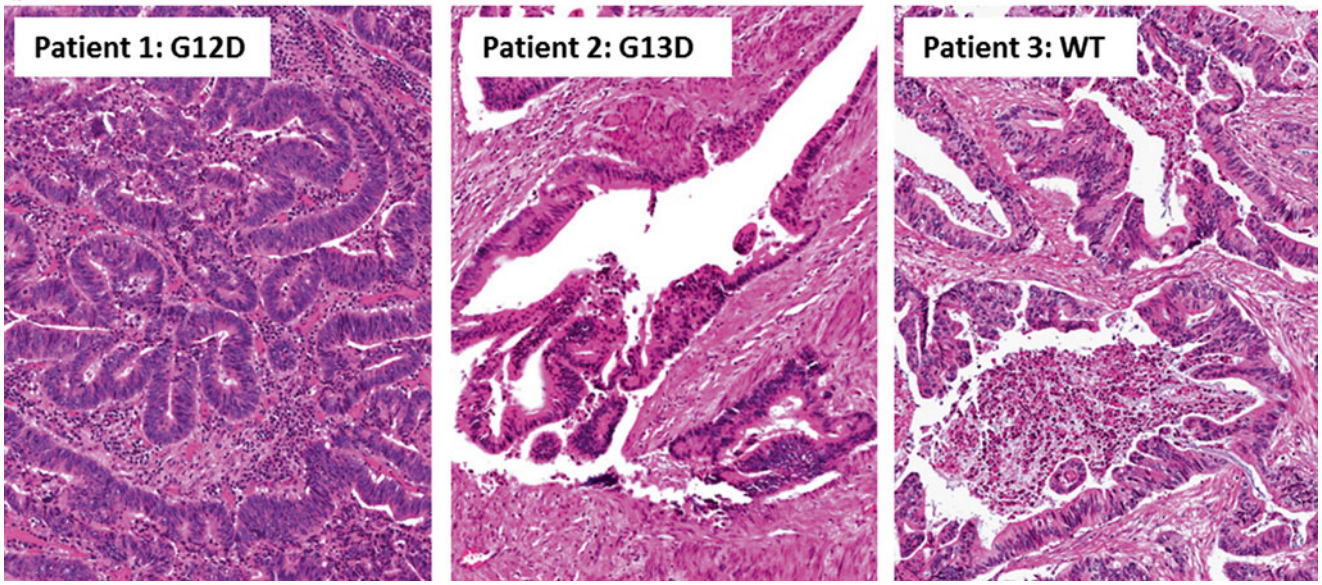

Figure 31.4 Results from a single run of *KRAS* mutation testing using a bead array assay. Results for three patients are shown, as well as results of the controls, including negative, positive, and no-template (NTC) controls. *EC* external positive control, *AMP* amplification

values exceed their cutoffs, but the amplification control is positive, the assay result is reported as negative. Specimen results are reported as inconclusive when MFI values for all analytes and the endogenous control fail to exceed their cutoff values [85].

A liquid bead array assay for the seven most common mutations in the *KRAS* gene is commercially available for the Luminex (Austin, TX) flow cytometer. The assay is relatively easy to perform with a total assay time of approximately 4 h, excluding DNA extraction. This assay has a clinical sensitivity of approximately 98 % and an analytical sensitivity of approximately 1 % mutant DNA in a background of wild-type DNA [86]. Pre-analytical variables, such as DNA amount and extraction method, can affect the analytical sensitivity of this assay, especially in samples with low tumor percentages [87]. Appropriate positive and negative controls are analyzed on all runs with clinical specimens. Cell line or plasmid DNA with one of the seven *KRAS* mutations detected by the assay can be used as a positive control while DNA from a cell line without a *KRAS* mutation can be used as a negative control. A water (no template) control is used as a control for reagent contamination with DNA or amplification products [85]. Figure 31.4 shows the results of *KRAS* mutation detection in three

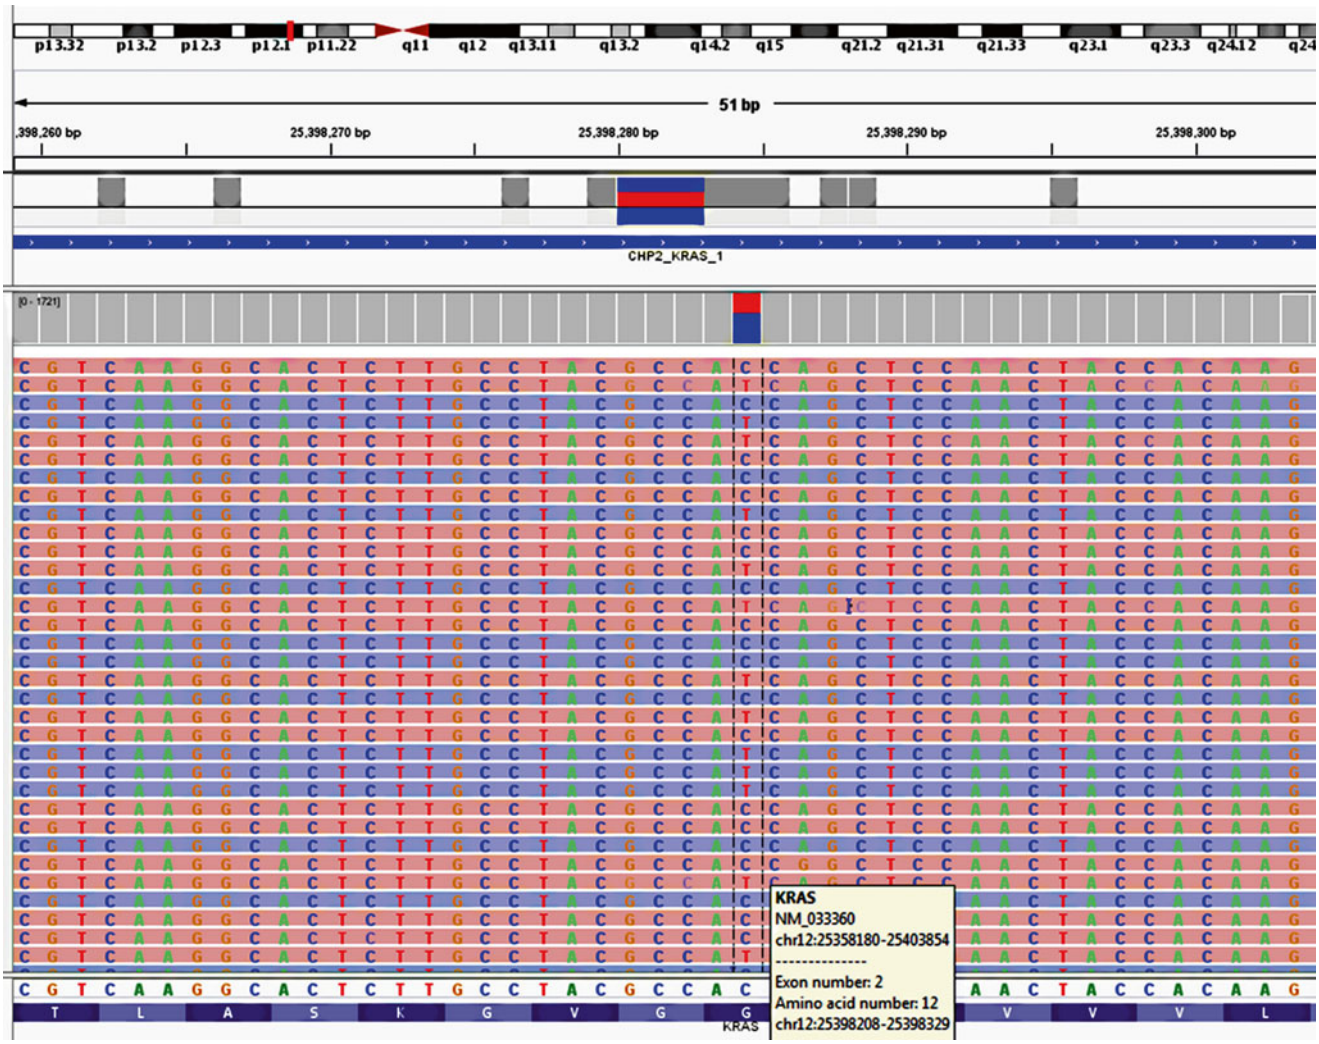

Figure 31.5 Next-generation sequencing results for a 41 bp region of *KRAS* showing a c.35G>A mutation at codon 12, resulting in a G12D mutation in the protein. The location of this region in the context of the human chromosome hg19 is shown above. The different colors of each row (*blue* or *red*) represent the sequences of the forward and the reverse strand, respectively. The heterozygous configuration of the variant is clearly identifiable in the demarcated column (*vertical dashed lines*) with both C and T nucleotides present

CRCs. Patient 1 CRC has a G12D mutation, patient 2 a G13D mutation, and patient 3 a wild-type sequence at codons 12 and 13 of *KRAS*.

Next-Generation Sequencing Assays

Assessment of multiple clinically actionable mutations using targeted NGS testing has greatly advanced cancer testing in the clinical molecular laboratory (see Chap. 59 for a description of the NGS method and Chap. 60 for cancer NGS). Information obtained from targeted NGS cancer panels is useful for concurrent assessment of a panel of hot spots directly related to cancer, for classification and diagnosis of tumor type, prognosis, and for the determination of response to EGFR-targeted therapy.

Sanger sequencing has been the gold standard for identification of mutations and variants in the clinical molecular laboratory. Modifications such as pyrosequencing were subsequently developed to enhance the sensitivity and detect 1–5 % mutant alleles in a background of wild-type DNA. NGS testing offers more information than other assays, combining sequence information and high analytical sensitivity for detection of actionable mutations in cancer tissues. NGS platforms work with minimal FFPE tissue and simultaneously detect many known and novel genetic variants in genes important for CRC. However, NGS testing validation, standardization, quality assurance, and quality control must be performed by the individual clinical molecular laboratory under CLIA and other regulatory standards, such as those of the College of American Pathologists and the New York State Department of Health. Figure 31.5 shows an example of a

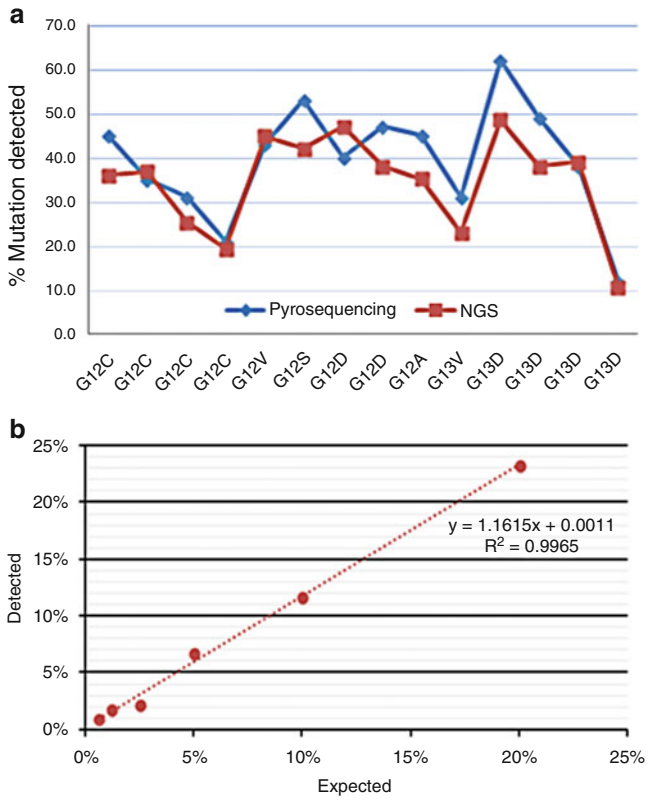

Figure 31.6 Comparison of pyrosequencing and next-generation sequencing (NGS) testing for detection of *KRAS* mutations commonly identified in CRC. (**a**) Quantifications of mutant allele percentages by both test methods show good concordance. Variant percentages from 10 % and above were accurately identified by NGS. (**b**) Analytical sensitivity of *KRAS* mutation detected by NGS showed linearity from 1 % to 20 % mutant allele in a wild-type background

KRAS C>T heterozygous mutation detected by NGS. In addition to *KRAS*, *BRAF*, and *EGFR*, CRCs have detectable mutations in additional genes, such as *PDGFRA*, *APC*, *FGFR3*, *MET*, and *TP53,* using an NGS gene panel test.

Comparison of Technologies

Table 31.4 provides an overview of the features of three technologies (Sanger sequencing, pyrosequencing, and NGS) commonly used to detect mutations in genes related to CRC. A comparison of pyrosequencing and NGS (Ion Torrent PGM, Life Technologies) assays for detection of representative CRC gene mutations is shown in Fig. 31.6a and shows excellent correlation of testing results by the two technologies. The graph (Fig. 31.6b) shows linearity from 1 % to 20 % for the NGS assay, indicating that the assay is able to detect 1 % of (homozygous) mutant DNA in a background of wild-type DNA.

Laboratory Issues

Molecular testing for gene mutations in CRCs requires attention to specific laboratory issues.

Tissue Block Review and Selection

A pathologist with expertise in anatomic or surgical pathology should select a tissue block containing non-necrotic, and if possible non-mucinous, regions of the CRC, with the most cancer cells. Necrotic and mucinous regions do not provide high-quality or significant amounts of DNA. Consideration must be given to the percentage of tumor cells compared to the total cells in the section, since all cells contribute DNA and will dilute the cancer DNA, including inflammatory cells, fibroblasts, noncancer epithelial cells, and other normal cells. Agreed criteria and training for the estimation of the percent of cancer cells relative to the total cells in a tissue section for molecular testing should be developed, for reproducible reporting of the percent of tumor cells. For most cancer gene mutation detection tests, a minimum of 10–25 % tumor cells is required. The pathologist may circle the highest density of cancer cells in a tissue section to allow for appropriate micro- or macro-dissection.

DNA Quality and Quantity

The quality of the DNA can be affected by necrosis or prolonged fixation times, as well as suboptimal storage conditions for FFPE tissue blocks. High-quality DNA is needed for most molecular testing. Accurate DNA quantification may not be significant for some molecular tests, but is essential for NGS testing. Quantification of DNA using qPCR or measurement of double-stranded DNA (dsDNA) using fluorometry provides accurate quantification of the amount of dsDNA prior to library amplification.

Conclusions and Future Directions

Currently, *RAS* mutation analysis of CRC tissues is recommended as the standard of care in patients who are candidates for targeted anti-EGFR antibody therapy. Additional mutation testing of other EGFR signaling pathway genes may be helpful to better select patients for targeted therapies with improved outcomes, but a general consensus regarding which genes should be tested is not yet established for CRC patient management. In academic medical centers, the trend is to test all CRCs for *RAS* and *BRAF* V600E mutations and for microsatellite instability, thus

allowing for selection of patients for conventional therapy as well as targeted therapy [38]. The use of gene panels for mutation analysis, tested with platforms that permit detection of hundreds of mutations in a single sample, such as NGS gene panels, is a powerful and promising approach that provides the mutation status for multiple critical genes of cancer driver pathways. Genomic Tumor Boards which address the integrated use of gene mutation and other molecular test results for the clinical management of cancer patients are becoming more common to evaluate treatment options as well as enrollment in ongoing clinical trials of targeted therapies for individual patients.

Abstract

Molecular classification of lung cancer, specifically non-small cell lung cancer (NSCLC), is increasingly utilized to determine optimal treatment. Recent advances have demonstrated the utility of testing for specific alterations such as *EGFR* mutations and *ALK* rearrangements, as these determinations guide utilization of targeted therapies. Assays to detect mutations must balance comprehensiveness of detection of mutations and the need to achieve analytic sensitivity which can reliably detect mutations in mixed cell populations. Assays to detect rearrangements must balance comprehensiveness of identification of alterations and ease of use. As the number of targets for testing increases, greater emphasis will be placed on technologies which simultaneously detect multiple molecular variants from small tissue samplings.

Keywords

NSCLC • ALK • EGFR • KRAS • Fluorescence in situ hybridization (FISH) • Tyrosine kinase inhibitor (TKI) • Gene fusions • Sequencing

Introduction

Lung cancer is the leading cause of cancer-related mortality in males and the second most common cause of cancer-related death in females worldwide [1]. For much of the twentieth century, lung cancer was not only the leading cause of cancer-related death in the USA but also the fastest growing cause of cancer-related mortality. A sharp decline in this growth was noted beginning in the 1990s and has been attributed mostly to successful efforts to curb smoking [2].

The majority of lung cancer patients have advanced disease at the time of diagnosis which is unfortunately associated with a 5-year relative survival rate below 5 %. Even for those with early-stage disease, the 5-year relative survival is only approximately 50 %, which reflects the high lung cancer recurrence rate [2, 3].

Traditionally, the classification of lung cancer is based on a morphologic distinction between small-cell lung carcinoma (SCLC) and non-small cell lung carcinoma (NSCLC). With advances in molecular pathology, distinct entities with unique molecular underpinnings are increasingly recognized. Although many of the molecular alterations in SCLC are known, few have been translated into clinically actionable findings. In contrast, in NSCLC, the identification of molecular markers for targeted therapies has advanced rapidly in the last decade. Within NSCLC, the majority of findings that have become adopted in routine practice are most applicable to adenocarcinoma; thus, the focus of this chapter will be on molecular testing of NSCLC, with examples drawn from testing in pulmonary adenocarcinoma.

Molecular Basis of Disease

The molecular profile of lung cancer is complex and vastly heterogeneous, which, until recently, has slowed the progress of clinical molecular applications. As specific molecular alterations have been identified, the focus has been on the evaluation of specific oncogenic pathways for targeted therapy development. Chief among these have been the epidermal growth factor receptor (EGFR) and other receptor tyrosine kinase (TK) signaling pathways.

The identification of *EGFR* mutation status as a predictor of response to tyrosine kinase inhibitors (TKIs) emerged from the convergence of clinical advances and laboratory science. Underpinning this work were the original isolation of EGF from mouse salivary gland in 1962 [4], demonstration of its binding to a cell membrane receptor [5], and sequencing of the receptor [6]. In the 1990s, EGFR was found to be highly expressed in squamous cell carcinoma. When monoclonal antibodies against EGFR that could be used to evaluate formalin-fixed, paraffin-embedded (FFPE) tissues became available, EGFR was found to be strongly expressed in lung adenocarcinomas [7]. EGFR overexpression in NSCLC is closely linked to *EGFR* gene amplification [8].

In 2004, two laboratories reported that mutation of the EGFR TK domain was largely responsible for the sensitivity of some pulmonary adenocarcinomas to TKIs [9, 10]. Mutations cluster in the ATP-binding pocket of the intracellular domain of *EGFR* and most commonly consist of either a single base substitution in exon 21 (c.2573G>C, p.L858R) or an in-frame deletion within exon 19 ranging from 9 to 18 base pairs. These and other less commonly identified mutations in *EGFR* have been associated with sensitivity to TKI therapy. Although the common mutations are understood to result in strong auto-activation of EGFR, the degree to which this is true for the less commonly identified mutations is not well understood.

Resistance to TKI therapy inevitably develops in treated patients. The two best studied mechanism of resistance to EGFR TKI therapy are *MET* amplification and a single point mutation in exon 20 of *EGFR* (c.2369C>T, p.T790M) [11–15]. In the latter, a bulky methionine side chain is thought to alter affinity of EGFR for the inhibitor [11, 16]. Tumor cells with the p.T790M mutation may exist in low numbers in untreated tumors and emerge through selective pressure exerted by targeted therapy [17]. The p.T790M mutation is found as a germline change in rare individuals [18]. In addition, some other mutations, such as insertions in exon 20 of *EGFR*, which can be found in untreated tumors, are predominantly associated with primary resistance to TKI therapy, although the mechanism of this resistance is unclear [19].

Mutations in *KRAS* are more common in lung cancer than *EGFR* mutations and, unlike *EGFR* mutations, occur predominantly in smokers [20, 21]. Coexistence of *KRAS* and *EGFR* mutation is uncommon but has been reported [22]. KRAS is a member of a superfamily of guanosine-5-triphosphatase (GTPase) proteins that also includes NRAS and HRAS [23]. The role of these proteins is to transduce stimuli from surface growth factor receptors along a pathway leading to transcriptional changes. As multiple simultaneous sources of signals from different receptors and ligands have been identified, the RAS proteins are increasingly recognized as integrators and processors of signals from the cell surface and not just transducers. RAS proteins activate an intracellular signaling cascade that involves numerous effector molecules including PI3K and MAPK. Because of its position "downstream" of EGFR signaling, the hypothesis that an activating mutation in *KRAS* would render a tumor unresponsive to TKI therapy has been extensively investigated with conflicting results [24].

Mutations are not the only molecular driver mechanisms in lung cancer. Overexpression of oncogenes also is driven by gene activation through chromosomal rearrangements. Rearrangements that fuse constitutively activated gene promoters to the TK domain of growth factors, growth factor receptors, or transcription factors can result in inappropriate signaling from the fusion product. Examples of activation by gene fusion in lung cancer involve *ALK*, *ROS1*, and *RET*. In 2007, Soda et al. discovered a transcript derived from a patient with NSCLC that could transform 3T3 cell line fibroblasts [25]. Further investigation demonstrated the transcript to be derived from the fusion of a gene called echinoderm microtubule-associated protein-like 4 (*EML4*) with the anaplastic lymphoma kinase (*ALK*) gene, which is also rearranged in large cell lymphomas. The rearrangement has been detected in 4–7 % of pulmonary adenocarcinomas, with increasing proportion seen when cohorts are selected based on clinicopathologic features such as never-smoker or light-smoker history, signet-ring subtype [26–30]. The driver of tumorigenesis with this rearrangement is thought to be inappropriately expressed ALK, which is not typically expressed in adult lung tissue. Fusions involving ALK lead to inappropriate constitutive activation of its kinase domain through dysregulation driven by a 5′ fusion partner, such as EML4, which is expressed in adult lung tissue [25, 31].

In less than 5 years from the initial discovery of the *EML4-ALK* rearrangement, over 10,000 lung cancers have been tested for the presence of this rearrangement, with more than 13 molecular variants of *EML4-ALK* fusion identified [27, 32], including two other gene partners for *ALK* [33, 34]. A novel targeted therapeutic agent, crizotinib, is effective against tumors driven by ALK overexpression [35] and received approval for treatment of NSCLC with *ALK*

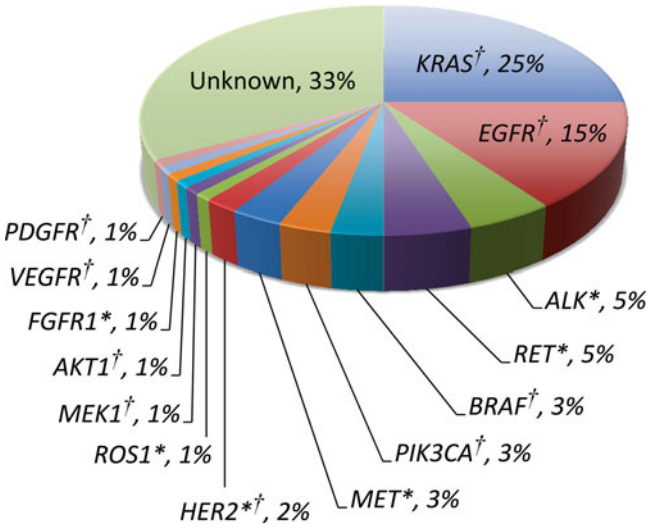

Figure 32.1 Approximate prevalence of identified "driver mutations" in unselected pulmonary adenocarcinoma. While many of these alterations are typically seen in isolation, others, such as *PIK3CA*, are often seen concurrently with other gene mutations. The spectrum of changes is different from that seen in squamous cell carcinoma of lung and varies by smoking status. *Asterisk* indicates a rearrangement or amplification; *dagger* indicates mutation [41] Ding L et al. 2008

rearrangement by the US Food and Drug Administration (FDA) [36].

These three examples, *EGFR* and *KRAS* mutations and *ALK* rearrangements, underscore the diversity of molecular alterations in NSCLC. "Driver mutations" are present in a significant proportion of lung cancers (Fig. 32.1). Efforts to exploit these alterations are underway with a wide array of targeted therapies.

Clinical Utility of Testing

Molecular testing significantly drives clinical therapeutic decision making for patients with NSCLC. Three commonly performed molecular tests, *EGFR* mutation testing, *KRAS* mutation testing, and *ALK* rearrangement testing usually by fluorescence in situ hybridization (FISH), illustrate three different scenarios for the clinical utility of molecular testing in NSCLC.

EGFR TKIs, including erlotinib and gefitinib, gained regulatory approval in unselected populations of NSCLC patients in the USA and Europe. The response rate in early studies of unselected lung cancer patients was only 10–15 % but was of marked degree in those patients who did respond. Later, activating *EGFR* mutations were identified to confer sensitivity to EGFR TKIs and accounted for the subset of tumors with response to therapy in early studies [9, 37] and that such therapy results in significantly higher overall response rates and progression free survival compared to standard chemotherapy. For patients without "sensitizing" *EGFR* mutations, chemotherapy without TKIs was clearly superior [37–39]. Thus, despite the broad indication for these drugs, the use of EGFR TKIs has dramatically shifted to their preferential early use in patients with proven "sensitizing" *EGFR* mutations. Patients without a "sensitizing" *EGFR* mutation also can benefit from the use of EGFR TKI in maintenance or later lines of therapy, but the benefit is modest [40, 41].

The oral kinase inhibitor, crizotinib, first entered clinical trials as a MET inhibitor for patients with *MET* gene amplification or activating mutations. After the discovery of *ALK* gene fusions in approximately 5 % of NSCLC patients, the trial was amended to include patients who demonstrated evidence of an *ALK* gene rearrangement by FISH. Following phase I and II data with overall response rates of 55–63 %, crizotinib gained provisional FDA approval for this highly selected group of patients [34, 42]. Unlike EGFR TKIs, which are approved for all patients with pulmonary adenocarcinoma, crizotinib is only approved for the treatment of patients with lung cancer carrying an *ALK* rearrangement, although its utility in other molecular subtypes, such as *ROS1* rearrangement-positive tumors, is under investigation [44, 45].

KRAS activating mutations occur in approximately 25 % of patients with NSCLC. Unfortunately, no KRAS-targeted therapies are currently FDA approved. The presence of a *KRAS* mutation, however, is still informative. The overlap of *KRAS* mutations with either sensitizing *EGFR* mutations, *ALK* gene rearrangements, or other oncogenic abnormalities is infrequent [46]. The presence of a *KRAS* mutation thus augments the negative predictive value of a negative *EGFR* mutation test or a negative *ALK* FISH test. Likewise, the presence of a *KRAS* mutation predicts a lack of tumor response from an EGFR TKI, although it does not necessarily predict a complete lack of benefit from an EGFR TKI [40, 41]. The detection of *KRAS* mutations can identify patients for participation in clinical trials. Currently, inhibition of MEK and PI3K pathways, both of which are downstream of KRAS, is under investigation in lung and other cancers. Thus, directing patients with a *KRAS* mutation-positive lung cancer to these clinical trials may enrich for patients who are likely to benefit from these strategies. Conversely, the presence of a *KRAS* mutation may provide a useful negative selection criterion for clinical trials that are targeting pathways upstream of KRAS [47].

In summary, molecular testing can provide guidance for prioritizing therapies to those patients most likely to receive the greatest benefit (*EGFR* mutations). Alternatively, molecular testing can identify patients with proven benefit from a targeted therapy (*ALK* gene rearrangements). Finally, molecular testing can provide clinicians with a rationale to guide certain patients toward clinical trials of targeted therapeutics

(*KRAS* mutations). These selected examples of targets are by no means the only ones of interest in NSCLC, in which a growing number of molecularly targeted agents are under investigation in association with specific molecular alterations. This includes mutations in *BRAF*, *HER2*, *PIK3CA*, and rearrangements in *RET*, among others [47].

Available Assays

Specimen Type, Quality, and Tumor Content

A discussion of the practical elements of molecular testing in NSCLC necessitates an understanding of the variability of specimen types likely to be encountered. As the majority of NSCLC patients present with advanced disease, they are not surgical candidates, and the diagnostic tumor sample is often the only tissue available for testing. This has driven the need to undertake evaluation of small specimens obtained from diagnostic biopsies, fine needle aspirations (FNA), and body cavity fluids. Cytopathology specimens are suitable for molecular testing, including cell block preparations as well as smeared and imprinted slides [49–55]. For small specimens, the quality of the specimen is often more important than the quantity [52, 56]. Individual laboratories are responsible for validation of the adequacy of all specimen types for each test.

Of paramount importance for any specimen type is the evaluation of the specimen by a pathologist with experience in the assessment of pathology specimens for molecular analysis. The tumor content of the specimen should be assessed for the presence of adequate non-necrotic tumor cells, as well as an estimation of the percent of tumor cells relative to all nucleated cells, which meets the criteria for acceptability for testing set by the clinical molecular laboratory [53]. Features suggesting that the specimen may not be of optimal quality include extensive necrosis, paucity of tumor cells, low abundance of tumor cells compared to other non-tumor cells in the specimen, and exposure to reagents which negatively impact molecular testing (e.g. decalcification) [52, 57, 58].

Some specimens are not sufficiently tumor rich to be utilized without tumor enrichment methods. Tumor enrichment methods include manual macrodissection, manual microdissection, and laser capture microdissection (LCM) [59]. Manual macrodissection is when a region of interest is scraped from a slide or carved from a paraffin block without microscope assistance. Manual microdissection is performed with a dissecting or light microscope, often using a scalpel, needle tip, or hollow bore pipette to preferentially isolate tumor cells and using a microscopically marked guide slide. LCM utilizes computer-aided imaging to select specific cells for capture from specially coated slides. However, the cost of equipment and specialized consumables, combined with a labor intensive process, makes LCM the costliest approach to tumor enrichment, and assays typically do not require this degree of precision. However, in some circumstances, the use of LCM may increase the ability to utilize low-sensitivity assays for some specimen types [60–62].

Common Driver Mutations Assays

Evaluation of mutation status in genes such as *EGFR* and *KRAS* can be accomplished using a variety of platforms. Historically, Sanger sequencing has been the "gold standard" for *EGFR* and *KRAS* mutation detection. Because of the comparatively low analytic sensitivity of Sanger sequencing, numerous other platforms have been developed with higher analytic sensitivity but typically assess only specific known mutations (Fig. 32.2) [56, 63]. The compromise for these mutational assays is the loss of detection of rare alterations. However, the clinical relevance of rare mutations is often not well established, and thus, many clinical laboratories find that the ease of use of a targeted assay, combined with improved analytic sensitivity (thus reducing the degree to which tumor enrichment must be achieved), is an acceptable trade-off. Owing to the rapid evolution of the recommendations for which specific genes and alleles should be tested, specific recommendations are not elaborated herein, and recent guidelines should be consulted [64]. The more common methods for cancer gene mutation testing are described here.

Sanger Sequencing

The primary advantage of Sanger sequencing for somatic mutation detection in NSCLC is the comprehensive assessment of the sequenced gene regions. The importance of comprehensive gene mutation assessment differs for different genes. Some of these assessments are influenced by the degree to which a specific target gene has been evaluated. For example, extensive evaluation of mutations in *EGFR* in NSCLC has demonstrated that a small number of mutations comprise the majority of changes. Thus, comprehensive assessment may only seldom identify a rare mutation not detected using targeted assays. In contrast, evaluation of mutations in *DDR2* in squamous cell carcinoma has been undertaken to a lesser degree in recent years, and the data to date suggest a wide distribution of mutations, indicating that the advantages of Sanger sequencing are indeed relevant.

Modifications to Sanger Sequencing

A number of modifications to Sanger sequencing, including *c*o-amplification at *l*ower *d*enaturation *t*emperature-PCR (COLD-PCR) [65, 66] and *i*mprove and *c*omplete *e*nrichment COLD-PCR (ICE-COLD-PCR) [67], leverage the advantages of Sanger sequencing, i.e., comprehensive

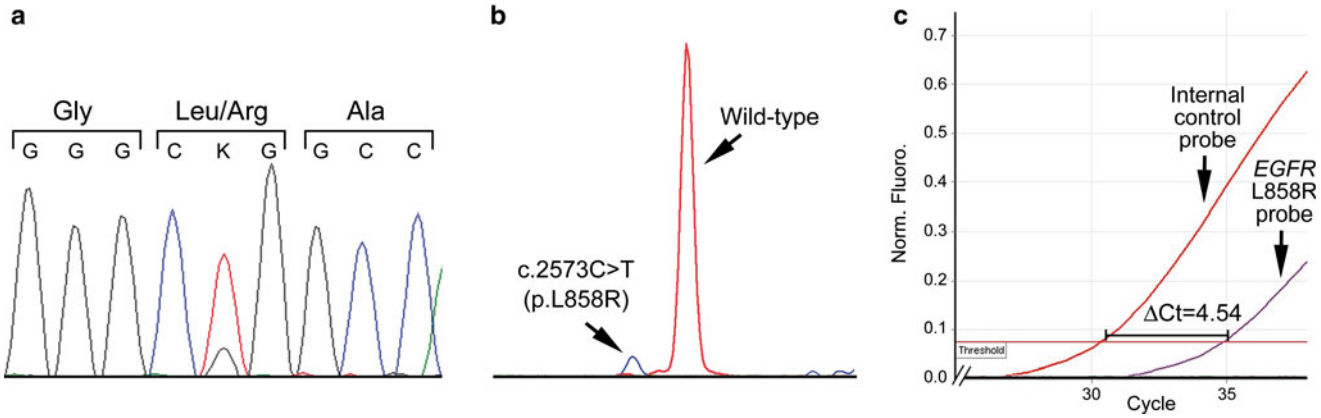

Figure 32.2 Different analytic sensitivities of mutation detection methods. (**a**) Sanger sequencing showing an *EGFR* c.2573T>G (p.L858R) mutation at 12.5 % allelic burden. (**b**) Single nucleotide base extension assay (SNaPshot®) showing the same mutation detectable at 6 % allelic burden. (**c**) Real-time PCR assay demonstrating the same mutation detectable at 1 % allelic burden

assessment, while achieving improved analytic sensitivity. These methods typically utilize alterations in cycling parameters to achieve imbalanced amplification favoring mutated alleles, thus increasing analytic sensitivity, followed by Sanger sequencing.

Restriction Fragment Length Polymorphism and PCR Fragment Sizing

A common method for *EGFR* mutation detection is combined PCR fragment sizing and restriction fragment length polymorphism (RFLP) for exon 19 deletions and L858R (c.2573C>T), respectively [68]. This approach is straightforward and has an analytic sensitivity of approximately 5 % mutant allele detection and excellent ease of use. The major disadvantage to this approach is the limitation in mutations detected, specifically that a number of mutations in *EGFR* which are not common, but similarly are not exceptionally rare, are not detected by this approach. Recent guidelines suggest that all mutations which are seen with a frequency of at least 1 % of *EGFR*-mutated lung adenocarcinomas, should be included in routine screening, which would not be accomplished by this approach [64].

Real-Time PCR

Multiple (non-FDA approved) commercial real-time PCR test kits are available for the detection of specific mutations in some genes, including *EGFR*, *KRAS*, and *BRAF*. Many of these kits indicate an analytic sensitivity of approximately 1 % mutant allele detection. A major advantage of real-time PCR is the high analytic sensitivity, which therefore reduces the likelihood of a false-negative result based on insufficient tumor content in the specimen [63]. In mid-2013, two real-time PCR-based assays (therascreen EGFR RGQ PCR Kit [Qiagen, Manchester, the United Kingdom] and cobas® EGFR Mutation Test [Roche, Pleasanton, CA]) were approved by the FDA for the evaluation of common *EGFR* mutations.

PCR Screening Methods

High-resolution melting curve analysis and denaturing high-performance liquid chromatography allow for rapid assessment of whether an alteration is present in a targeted region but do not identify the specific gene variation [69, 70]. The major advantage of mutation screening approaches is a rapid initial assessment of the status of a target region. However, precisely defining the alteration requires a follow-up test method to confirm and delineate the finding.

Pyrosequencing

Pyrosequencing has greater analytic sensitivity compared to Sanger sequencing and, rather than a purely targeted approach, does allow for the evaluation of short stretches of sequence. Pyrosequencing can be used for the detection of most single base substitutions and, although more challenging to interpret, can also be utilized for deletions and insertions (such as are commonly seen in *EGFR*) [71, 72]. The major advantages of pyrosequencing include better analytic sensitivity, ability to design custom nucleotide dispensations to query specific changes, and comprehensive evaluation over short stretches of sequence.

Ultrahigh Sensitivity Methods

Specific alterations may indicate the need for ultrasensitive methods for detection. One example of this is *EGFR* T790M (c.2369C>T), which is known to exist at varying percentages within the tumor cell population, due to both variable degrees of *EGFR* amplification and subclonality of the alteration. Multiple methods to achieve analytic sensitivities

below 1 % allelic burden include locked nucleic acid assays and PCR assays utilizing restriction endonucleases to cleave wild-type sequences and beads, emulsion, amplification, and magnetics (BEAMing) [73–77]. The implementation of these approaches is dependent upon the clinical need for enhanced sensitivity in mutant allele detection, for example, in approaches which evaluate circulating tumor DNA, which are under evaluation [76].

Multiplex Methods

Increasingly, test methods which allow for the simultaneous detection of many mutations in a number of genes are used by clinical molecular laboratories. These include multiplexed single nucleotide base extension assays and mass spectrometry-based assays [78–80]. These assays rely on the development of multiplex PCR amplification followed by interrogation by multiple probes with spacer sequences and base extension reactions to allow for discrimination based on size or molecular weight. In addition, next generation sequencing (NGS) can query numerous entire genes, and the implementation of this approach into the clinical molecular laboratory is undergoing rapid adoption with the evaluation of appropriate metrics for quality assurance [81, 82]. Importantly, depending on methodology utilized for NGS, an assay may be able to identify selected gene rearrangements and copy number alterations.

Gene Rearrangements Assays

FISH Assays

The *EML4-ALK* fusion is generated by a paracentric chromosomal inversion in the short arm of chromosome 2, between bands p21 and p23.2. These two genes originally are separated by approximately 12.8 MB. The other described *ALK* fusions in lung cancer, *KIF5B-ALK* [34] and *TFG-ALK* [33], are caused by chromosomal translocations t(2;10)(p23.2;p11.22) and t(2;3)(p23.2;q12.1), respectively.

Numerous technical platforms are available for molecular diagnosis of *ALK* rearrangements in lung cancer, but the most commonly used for clinical testing is FISH. The standard FISH assay uses a dual-color break-apart probe set encompassing the 3′ and the 5′ sequences immediately adjacent to the breakpoint area in *ALK* (intron 19), labeled in orange and in green fluorophores, respectively (Fig. 32.3) [83].

The *ALK* BA FISH probe was used in the initial clinical trials for crizotinib [35, 84] and is approved by the FDA as a companion diagnostic test. The *ALK* BA FISH assay is DNA based and is thus robust and resistant to technical artifacts. Other advantages include being highly suitable for detection in FFPE tissue sections, detecting all variants of EML4-*ALK*, and detection of translocations with and of the reported or uncharacterized partner genes. On the other hand, the FISH platform requires specialized resources (fluorescence microscope, light-protected laboratory space) and highly trained personnel.

Two other receptor kinase genes were identified as activated in lung cancers by fusions, *ROS1* [33] and *RET* [85]. Integrated molecular and histopathologic screening systems have been successful in detecting a large number of fusion partners in lung cancer for these two genes, and preclinical studies have confirmed their tumorigenic potential [34]. Additionally, targeted therapy may have a role for these molecular subsets, which are predominantly identified using FISH assays [44, 45, 86].

Reverse-Transcription PCR

Reverse-transcription PCR (RT-PCR) can be used to detect and identify gene rearrangements. Messenger RNA (mRNA) is isolated from tumor tissue and reverse transcribed to complementary DNA (cDNA). Amplification with polymerase is performed using primers that bind sequences within the 5′ gene fusion partner (e.g., *EML4*) and the 3′ end of the fusion gene encoding the kinase domain of the oncogene (e.g., *ALK*). The presence of a gene fusion can thus be detected and identified by size discrimination assays and sequencing of the amplification product. To date, over ten *EML4-ALK* variants have been reported, involving eight different *EML4* exons and exon 20 of *ALK* [31]. Although methods exist to identify unknown gene fusion partners, such as inverse PCR and 5′ rapid amplification of cDNA ends (RACE), high-throughput targeted assays will typically only allow known fusion partners and variants to be detected [32]. Specific primers are designed for each *EML4* variant, which can be multiplexed for PCR amplification, as long as the amplicons are of different sizes and/or labeled with different fluorophores. Amplicon size must be kept relatively small (up to 150–200 base pairs) to allow the use of FFPE tissue, since frozen tissue is not routinely available. The implementation of these assays in the clinical molecular laboratory requires either follow up on testing for negative findings (i.e., extensive analysis of RNA quality), separate amplifications for each variant, or design of assays to minimize amplicon size [32].

Other Methods

Immunohistochemistry (IHC) using antibodies specific for the C-terminal region of the ALK protein is a surrogate method to detect the presence of an *ALK* gene rearrangement in NSCLC [87, 88]. The most commonly used antibodies are ALK1 (DAKO, Carpinteria, CA), 5A4 (Novocastra, Newcastle, the United Kingdom, and Abcam, Cambridge, MA), and D5F3 (Cell Signaling Technology, Danvers, MA). IHC is a favored test method due to rapid turnaround time and low cost. However, for ALK IHC, the methods are not standardized, and method variations include antibody dilu-

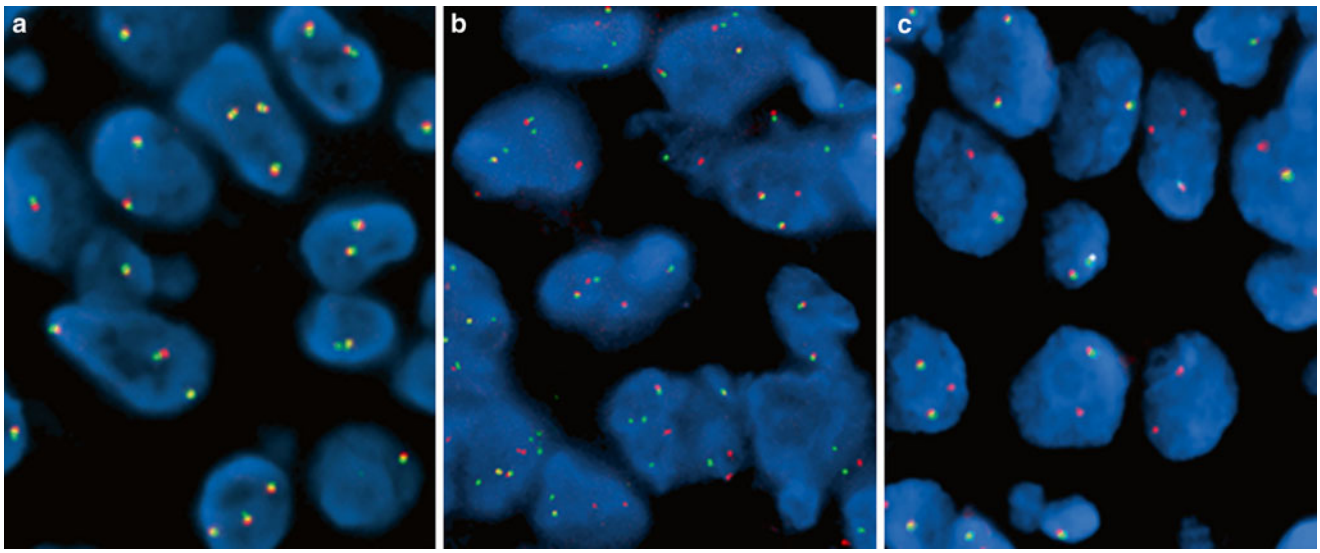

Figure 32.3 Lung adenocarcinoma specimens hybridized with the Vysis *ALK* Break Apart FISH Probe (Abbott Laboratories, Abbot Park, IL). (**a**) *ALK*-negative pattern (only native *orange*/*green* fused fluorescent signals), (**b**) *ALK*-positive pattern (split *orange*-*green* signals), and (**c**) *ALK*-positive pattern (single *orange* signals)

tions, detection systems with or without signal amplification, scoring criteria (qualitative, semiquantitative, and image-based), and cutoffs for classifying positive specimens, limiting the utility of IHC in the clinical molecular laboratory. However, extensive study is underway to define the concordance and reproducibility of this methodology with the expectation that following large-scale evaluations, IHC may become a dominant approach [89, 90, 91].

Quantitative real-time PCR (qPCR) techniques, using primers that amplify a portion of the 3′ end of the *ALK* gene (encoding the kinase domain), detect higher *ALK* mRNA expression in comparison with a housekeeping gene [92]. Both IHC and qPCR rely on the observation that ALK is not typically expressed in normal lung tissue or in NSCLC without an *ALK* gene rearrangement. Both techniques thus infer the presence of an *ALK* gene rearrangement but could also detect aberrant expression of native, full-length ALK.

Gene Amplification Assays

Oncogene activation is also achieved through amplification of gene copies. Mechanisms for gene amplification include the extrachromosomal double minutes and the intrachromosomal homogenously staining regions, both of which are easily detected by FISH assays.

In NSCLC, numerous genes can be amplified and typically confers a poor prognosis. Amplification of the *EGFR* gene is associated with response to EGFR inhibitors [93], although, at least in patients of Asian ethnicity, this association may largely reflect the amplification of activated mutant alleles [94] and the degree of this association is relatively weak compared to the evaluation of *EGFR* mutation status. Amplification of the *MET* gene has been associated with poor overall survival [95] and with acquired resistance to EGFR TK inhibitors [96], which is thought to arise from positive selection of low-level clones carrying the alteration [97]. *MET* amplification evaluation may also have relevance for the selection of targeted therapy as studies evaluating this analyte with respect to inhibitors of hepatocyte growth factor receptor (HGFR, the protein product of the *MET* gene) are ongoing [48]. A number of other genes encoding growth factors, growth factor receptors, and transcription factors can be amplified in lung cancer, such as *HER2*, *FGFR1–FGFR2*, *SOX2*, and *PIK3CA*. The availability of novel therapeutic agents that specifically inhibit these proteins has created an increased interest in testing for these molecular markers in order to select patients who are more likely to be sensitive (or resistant) to the targeted therapies [48].

Interpretation of Results

Driver Mutation Detection Assays

One of the key issues in the interpretation of somatic mutation testing is correlation between the preanalytic specimen features, preanalytic processing (especially tumor enrichment), testing method, and test results. This is especially relevant for negative results, which should be interpreted in the

context of the above-listed features. Given that assessments of tumor cellularity are highly subjective and only a single specimen may be available for testing, a laboratory may elect to test a borderline specimen with a low percentage of tumor cells, because a positive result would be informative, even though a negative result may be inconclusive.

With gene sequencing assays, the interpretation of rare mutations can be challenging. For many gene targets, mutational hotspots have been identified, and a finding of a mutation outside of one of these known regions must be carefully interpreted for clinical significance. Since FFPE tissue is frequently used for somatic mutation testing, the possibility that a rare mutation represents a procedural artifact must be considered. Furthermore, as especially relevant to testing in NSCLC, using extremely limited tissue and DNA quantities, as may be seen with some small specimens, can also lead to sequencing artifacts [98]. Thus, rare mutations must be interpreted with these procedural artifacts in mind, especially for genes which have been extensively characterized. Rare mutation findings should be repeated from the earliest feasible stage of testing and potentially with an alternate testing method. If a rare mutation is confirmed, the report should reflect that the clinical implications are not well understood, unless the scientific medical literature supports an interpretation of clinical significance. Public databases for interpretation of cancer gene mutations include the Catalogue of Somatic Mutations in Cancer (COSMIC) [99] and dbSNP through NCBI. These resources are especially valuable in identifying literature relevant for the interpretation of a specific mutation.

For gene mutations which are previously reported with a known clinical significance, the molecular pathology report should include an interpretive statement as to the clinical relevance of the finding. The implications of a particular result with respect to prognosis or responsiveness to a targeted therapy can change rapidly with new clinical studies, and efforts should be undertaken to ensure the most up-to-date clinically validated implications are noted.

Gene Rearrangement Assays

FISH

Usually, interpretation of FISH results using the *ALK* BA probe is straightforward. However, the fact that the *EML4* and *ALK* genes are separated by a small distance (12.8 MB) makes the identification of split signals subtle and challenging in a fraction of tumor cells. In the native copy of *ALK*, the orange and green probes recognize homologous sequences that are physically close to each other and show up as a fused orange (red)/green fluorescent signal (Fig. 32.3a). Therefore, fusion fluorescent signals in this setting indicate a normal copy of the *ALK* gene. When the break occurs around the *ALK* intron 19, the orange (red) signals from the 3′ probe sequences separate from the green signals of the 5′ probe sequences (Fig. 32.3b). When *EML4-ALK* fusion occurs, the sequences recognized by the green probe are positioned approximately 12.8 MB more centromeric to their original locus. Because of the relatively small genomic distance between these signals, scoring criteria require that the split seen be at least two signal diameters wide. In approximately 30 % of the rearrangements involving *ALK*, chromosomal deletions also occur in association with the inversion causing loss of the genomic sequences recognized by the green-labeled 5′ end sequences (Fig. 32.3c). Thus, the split between orange (red) and green signals and the presence of single orange (red) signals are interpreted as a rearrangement of the *ALK* gene. A minimum of 50 cells should be counted for assay scoring, and when greater than 15 % of cells are scored as positive (either split pattern or single orange (red) pattern), the result is interpreted as positive for an *ALK* rearrangement. Additional scoring criteria for the FDA-approved companion diagnostic include an equivocal range of percent positive cells with requirement for a second reader in such cases, although a routine two-reader practice is recommended.

Reverse-Transcription PCR

Interpretation of RT-PCR assays for the detection of ALK rearrangements has particular benefits in that it provides the most direct evidence of a gene rearrangement. Furthermore, this technique can provide the details not only of the 5′ gene fusion partner identity in each case but also the specific exon fusion (Fig. 32.4). In *ALK* gene-rearranged NSCLC, there are at least three different 5′ gene fusion partners (*EML4*, *KIF5B*, and *TFG*) and multiple different fusion variants in which different exons of *EML4* (and occasionally *ALK*) have been detected for *EML4-ALK* gene fusions [32–34, 100, 101]. Distinction of which specific fusion partner is involved in the rearrangement can be accomplished through size analysis for some assays, wherein specific fusions produce products of predictable size or may require sequencing of the fusion gene product. For assays which identify fusion events based on the presence of an amplicon of specific size, sequencing should be routinely performed on the amplification product to ensure that the amplicon detected is actually a gene fusion transcript and not the results of false priming. If the assay is designed in a directed fashion (i.e., uses bidirectional primers for the detection of specific fusion variants), negative results must always be interpreted in the context of known fusion partners not detected by the assay and also consider false-negatives attributable to novel fusion partners not yet described. Additionally, as these assays are based on RNA which is typically derived from FFPE tissue, consideration of false negatives attributable to low RNA quality is imperative, and appropriate quality control metrics (such as independent measures of RNA quality) should be

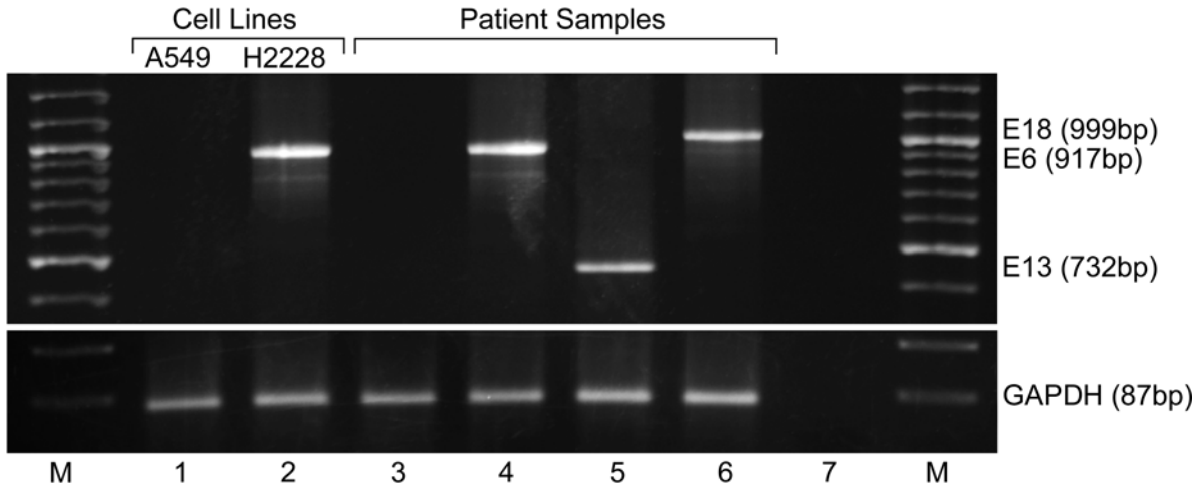

Figure 32.4 Reverse-transcription PCR (RT-PCR) for the detection of known *ALK* fusions from frozen non-small cell lung cancer (NSCLC) tissue. Multiplex RT-PCR including forward primers to exons 2 and 13 of *EML4* and one reverse primer to exon 20 of *ALK* are utilized in a single reaction. *Lanes 1* and *2* are results for negative (A549) and positive (H2228) cell lines, respectively. *Lane 3* is a patient sample negative for *ALK* rearrangement. *Lanes 4–6* are patient samples with *ALK* rearrangements with different *EML4* breakpoints. *Lane 7* is a no template control. *GAPDH* mRNA control reactions are shown in the *lower panel*. Negative results from an assay with amplicons >200–250 bp should be interpreted with caution, and multiplex primers can be designed with amplicon size aimed for detection in FFPE [31, 97]. *M* molecular weight markers

included and evaluated for assays of this nature. If such quality metrics are suboptimal, reporting should include caveats about potential false negatives. Finally, this technique has the potential to be extremely sensitive because of the combined effects of PCR amplification and the lack of background signal as only the fusion gene transcript is detected by this assay.

Gene Amplification Assays

Interpretation of results in FISH assays for copy number analysis is relatively simple. The number of copies per cell of a probe for the target gene sequence is compared with the number of copies of a reference probe, commonly represented by the centromere of the chromosome containing the target gene. Other gene sequences mapped in the same chromosome arm or in the opposite arm of the target gene are acceptable as reference sequences and sometimes even preferable, for instance, when complex rearrangements involve loss of centromeric sequences. Gene amplification is determined when the copy number ratio between the target and reference probe signals is greater than a prespecified value, commonly 2.0.

When a target gene is located close to the chromosomal centromere, both the target gene and the centromeric region may be amplified, making interpretation using a ratio greater than 2.0 inappropriate. *EGFR* maps at 7p12 near the centromere and is amplified in approximately 10 % of NSCLC [102]. With *EGFR* gene amplification, the chromosome 7 centromeric sequences also can be amplified, in which case the ratio between the mean *EGFR* probe signals per cell and the mean centromere 7 probe signals per cell will be approximately 1. Customized scoring systems have been developed to account for such phenomenon, when more than two probe signals for both the *EGFR* gene and the centromere 7 are identified [103].

Laboratory Issues
