Handbook of Odor

Buettner

Editor

Springer

Springer Handbook of Odor

Springer Handbooks provide a concise compilation of approved key information on methods of research, general principles, and functional relationships in physical and applied sciences. The world's leading experts in the fields of physics and engineering will be assigned by one or several renowned editors to write the chapters comprising each volume. The content is selected by these experts from Springer sources (books, journals, online content) and other systematic and approved recent publications of scientific and technical information.

The volumes are designed to be useful as readable desk reference book to give a fast and comprehensive overview and easy retrieval of essential reliable key information, including tables, graphs, and bibliographies. References to extensive sources are provided.

Foreword

More knowledge is needed!
(*Wir können wissen, wir müssen wissen*)

Around odors there is a wealth of very different jobs, but all are wonderful when they are done with passion. Passion is the common denominator for all three of us, even if we have different activities. What activities, by the way? Some analysis is needed first in order to see more clearly, so that we can identify more precisely what has to be done for the *odor realm*.

The three of us agree: Rembrandt was an artist and he was not a house painter; on the other hand, when doing his job, a house painter does not look for emotion, and he or she has to be a technician, even if there is some artistic component involved. The most ineffable Rembrandt painting is appealing.

We don't say that technique is better than art, or that art is better than technique, because the evaluation criteria are not the same in the two fields. Should we personally prefer art to technique, as is frequently proposed? Probably not, because sometimes we need to paint walls, and Rembrandt is useless in this regard, and sometimes we need something different, and Rembrandt becomes interesting.

All this shows that our choices have to be carefully analyzed, and this discussion is particularly important in the realm of odors, because it is a place where preferences are ubiquitous. Of course, it is easy to understand that *It smells good* indeed means *Personally, I like this odor*, so that we can ask the question of the legitimacy of a personal preference, even if this comes from a master perfumer. How is his preference more important than that of a non-specialist? This is a first question ..., which we propose not to answer. Our goal here will be this one: ask questions, because we would love you to think about them and propose your own answers.

Coming back to jobs, the vision proposed here consists in considering that there are different jobs, in the areas of art, technique, technology, science. In order to avoid hierarchy, let's consider them in alphabetical order: art, science, technique, and technology.

Some people, such as Maurice Roucel, with odors, or the French chef Pierre Gagnaire, with cooking, are reluctant to call themselves artists, because they fear pretentiousness, but facts are always the most important. As we said before, Rembrandt was not a house painter, and his project was emotion, even if it included, of course, mastering the technique, and a commercial component.

In art, there is probably a passion for *beauty*, as Pierre Kurzenne says, and much apprenticeship work is needed, because work never ends in the quest for perfection in art. We slog and we work. Passion frequently means being able to see the intimate interest of the work. But with respect to beauty, the issue is huge.

In the kitchen, the issue is not to look at dishes, but to eat them. Here *good* means *beautiful to eat*; with music, it means beautiful to hear (we don't care if the pianist is well dressed or not). And one can easily understand that with odors, the issue is to make *beautiful odors* as well, which means odors that we admire.

Beauty is, then, the main question in art, and it is interesting to observe that it has had thousands of definitions in the past centuries, but it always had something do to with emotion and culture. This holds for odors; the project of the *odor artist* can be to please, to make happy, to anger, to seduce ..., but never to leave you indifferent.

For Plato, art was bad, because representing (reproducing the odor of mango, of olive oil, ..., etc.) meant a double detachment from the truth, but at the same time, the philosopher could not escape discussing art and he had to tackle difficult questions, such as the fascination for perfect representation, like the painting of grapes that appeared so *true* that birds were confused!

Anyway, Plato was refuted by Aristotle! *The* odor of *the* raspberry does not exist: any particular raspberry has a particular odor, and this means that the production of *the* raspberry odor is a lost battle. We can only produce one chosen odor among an infinity thereof. This is the old debate of realism against idealism.

Which particular odor of raspberry does the perfumer or the fla-

vorist want to interpret and why? This is a question of individuals, but also of space, time, and … Moreover, concerning reproduction, we have to admit that the copy is never the original, which is why one of us (Hervé This) proposes that the new *note by note* way of cooking (see below) should not reproduce, but instead invent. It is the same with synthesizers in music: it is sure that one can reproduce the sound of a violin, but why? If one loves music, why not discover unknown sounds, timbers, and music?

Let's move to technique now. Here, the project is very different, because the goal is to make, to build. *Techne*, in Greek, means *to do*. For this kind of activity, the criteria are precise reproduction, regularity, and care. After decades of studying culinary productions, it appeared to one of us that care is the most important parameter of technicians, because it means giving pleasure, creating a kind of social osmosis through the product.

Here, two possibilities exist. One is to reproduce what was done in the past, by ancestors who lacked our modern information on chemistry, physics, and biology; the other is to use all modern information in order to get new skills and, often, to reach new products.

With odors, these skills can be used in various cases, such as perfumes, flavors, consumer care products, technical preparations, etc. But in all cases, the issue is to deal with mixtures of odorant compounds (i. e., compounds which can link – in one way or another – to olfactory receptors) interacting with a *matrix*, from which components of the mixture are released, at different velocities. For perfumes, this definition is clear, but for flavors? Indeed, if we eat a raspberry, we perceive the flavor of this raspberry. By definition, flavor is the synthetic sensation based on many different perceptions such as consistency, color, taste, odor, trigeminal perception, and others, because we discover more and more every year, such as the specific perception of long unsaturated fatty acids on taste buds, or of calcium ions, …; and we're probably not finished.

Odor is one component only, but the status of odorant compounds in food is more than odor, because many foods have an odor as well as a taste and a trigeminal effect! It was frequently published in the past that odor was the most important component of flavor. This is not true, as is easily demonstrated by eating after burning one's mouth with a hot potato, for example: all the flavor is lost, even if the odor remains. Let's keep in mind that it is not necessary to diminish some (other perceptions) to make others (odors) appear more important. If we recognize this, we will be able to better include odor in flavor!

Here, let's conclude by coming back to the idea that new information makes new techniques. It is the goal of this *Handbook of Odors* to give as fresh information as possible, and this is why this book is important: new information equals modernized techniques.

However, the issue of improving technique is, indeed, the goal of *technology*, from *techne* and *logos*. One of us published a whole book in order to propose that there are two kinds of technology, one called *local* (the technician, or someone near him, proposes new, more rational ways of doing) and one *global*, for which the engineer looks for results of science, selecting the useful ones and transferring them to the technical field. Here again, this *Handbook* is important because by including chapters from specialists among the best, it gives the basis for innovation. Innovation, the keyword for the industry!

And finally we look at science. Here we need to give an explanation, because there is much confusion about it. Indeed, the word *science* means knowledge, and this is why it is legitimate to speak of the *science of the shoemaker*, or the *science of the cook*, or the *science of the perfumer* … However, the science that we need to discuss here is very different: now, we restrict the general meaning to the *sciences of nature* or *natural philosophy*.

For sciences of nature, the goal is to discover the mechanisms of phenomena, using the scientific method based on:

1. Observing a phenomenon
2. Measuring it, which produces a lot of numerical data
3. Grouping these data into *laws* (i. e., equations)
4. Producing *theories*, i. e., explanations quantitatively compatible with the data
5. Making theoretical predictions which are experimentally tested, and so on, forever.

One could ask if there is a link between science and art, and one of us (Hervé This, certainly a scientist), after decades of close friendship and work with Pierre Gagnaire (certainly an artist), answers with a very strong *no*, even if there has been an intense relationship between artists and scientists, and common characteristics such as intuition, liberty, curiosity, enthusiasm … Indeed, the goals of science and art are different (mechanisms on the one hand, emotion on the other), as well as the *ways* (*methodon*, in Greek, method) in which they are achieved.

The method of science was described above; with art it is based on intuition, experience, personal emotion, the desire to communicate, … If a scientist wants to move toward art, he or she has to get away from science to technology, whereas the artist who would like to move toward science has to go through technique. No relationship between art and science, but rather re-

lationships between the applications of sciences (very different from the sciences) and the technical component of art (very different from art, even if it is needed).

All this being said, all of us three agree that one very important component of our activities is to think correctly and use good vocabulary, taking the utmost care with semantics. Very frequently, in building odors, young artists don't find the precise *words*, and this has technical consequences because they cannot select the right raw materials. For sciences of nature, also, words are very important, and the great Antoine Laurent de Lavoisier, the creator of modern chemistry, quoted Condillac in order to show why nomenclature was the basis for advances: sciences explore phenomena, but we have to think of the phenomena in order to study them; in order to think we need words, and this is why, Lavoisier said, you cannot improve science without improving words and vice versa.

By the way, all of us three also agree that with respect to odors or flavors, we would love to have more scientific knowledge.

Imagine that you make an odor without taking into account some trigeminal effect. Imagine that you make food without pepper: the dish would not be what it could be. Imagine that you don't know about some particular interaction effects of odorants on olfactory receptors: again, the result would not be what it should be. In music, it is as if the piano had only a limited number of notes. We need more information on the relationship between the molecular structure of odorant compounds and the odors of such compounds. We need more information about *odor release*, which means the physical and chemical description of the diffusion of odorants inside and outside matrices, including supramolecular associations. We need more information on the perception of odorants and the various interactions, before smelling them, and on the hedonistic interpretation of the olfactory perceptions. Of course, all this holds for food!

Perfumers succeed empirically with their current methods, for example making more vanilla note with bergamot, instead of increasing the quantity of vanillin! This is what two of us (Pierre Kurzenne and Maurice Roucel) name *contrast*. Perfumers also use metaphoric words such as *hot* or *sparkling*, and in the future it could be interesting to better understand what this is.

Concerning all this research, the past makes promises for the future. For odors, Nobel prizes have already been awarded to advances in the field (terpenes, olfactory receptors), but so much remains to be done! At this point, in particular, the prediction of the odor of a particular chemical structure is out of reach, and the effect of mixtures of odorants remains elusive. Of course, the exploration of God's shop is important, but we have to recognize that *nature*, in spite of our ideas, is far from perfect! Isn't plague natural, as are as volcanoes, tsunamis, and so on? If we use clothes, buildings, and perfumes, it is because – in a way – we are fighting against nature … because human beings belong to culture.

It is strange, in this regard, to classify odors into poisonous and non-poisonous ones. It is also strange that some odorant compounds are not as *they should be*. Why are lead salts sweet, yet toxic? Why are some bitternesses accepted (think of beer), yet often associated with toxic alkaloids? The same holds for some odorants!

Let's finish with the issue of regulation. It is clear that the public should be protected –but from what? Let's first recognize that there is a big difference between danger (a knife is dangerous) and risk (the knife can be used to kill, but if it is in a closed drawer, there is no risk). Danger is everywhere, but we have to reduce risks. In this regard, it is certainly good to know the dangers and the exposures in order to make regulations – but such rules should focus only on risk, not on hazard.

Now, coming back to the issue of nature/culture, we should say that no product of the perfume or flavor industries is natural, because it was produced! Let's remember that something is natural when it was not transformed by human beings. If you extract an essence from a flower, for example, the flower had to be cultivated, and the essence had to be extracted. It's no longer natural. But who cares: some products of culture are much better than natural products. Remember Rembrandt, Matthias Grünewald, Zao Wo-Ki, Bach, Mozart, Debussy, etc.

Moreover, in this regard, the issue of *note by note cooking* is probably important for the development of the odor industry. This new way of cooking was proposed for the first time in 1994 by one of us (Hervé This) and it is the culinary equivalent of synthetic music. Instead of using flutes and violins, one uses pure waves, in order to make sounds, after which music is composed. For cooking, the elementary units are not sound waves, but rather compounds, and note by note cooking does not use traditional ingredients (animal and plant tissues), but rather pure compounds, from which dishes are made.

This proposal is important for regulation because it kills the need to make particular categories for additives and flavorings: compounds used for making food would simply be *food ingredients*. Where will we find the needed compounds? Of course they can be extracted or synthesized, and we have to tell this to the public! Extracted or synthesized, vanillin is always vanillin, and water is always water. Of course, today a part of

the public *fears* chemistry, but, indeed, it is because it does not understand it. One way to circumvent fear is to make it desirable, trendy, fashionable, even forbidden. This is how Augustin Parmentier succeeded in making the French public eat potatoes, before the French Revolution: he invited the king to eat them! This strategy has been used to implement note by note cooking.

Let's imagine that we succeed in developing this new culinary trend. How shall we cook? A good way being explored today is to design the shapes and consistencies, then to design color, taste, odor and trigeminal perception, as we add spices to traditional dishes. However flavorists know too well that knowledge is needed in order to get the desired sensation, because of the chemical and physical interactions with the various compartments of the matrix. Chefs will have to learn, which means that flavorists' collaboration will be needed. Of course, one could imagine using flavorings as we use aromatic herbs and spices, but wouldn't it be much more interesting to use pure solutions of particular odorants (for example, a very small concentration of 1-*cis*-hexen-3-ol in ordinary oil), or *kits* of odors, in order to make entirely new flavors (*edible perfumes*)? By experience, chefs are not ready to have flavorists take the lead on their productions, which means that the first, traditional solution of using flavorings is probably not the future. If kits or pure solutions are the future, the odor industry has to be ready to make entirely new products.

Finally, after this long tour, we have to recognize that life is wonderful, in particular because the world of odors is fascinating. About art, for technique, for technology, for science, there are so many open questions! Questions are promises of answers – if we work with passion! Passion for odors, passion for imagination, passion for emotions, passion for knowledge ...

In mathematics, the great David Hilbert said *Wir müssen wissen, wir werden wissen* (*we must know, we will know*)!

Hervé This

Preface

Olfaction in humans is a sensory dimension that is often underestimated or overlooked entirely. The sense of smell is commonly believed to play only a minor role in human perceptual experiences, which is an understandable misconception when considering the everyday dominance of vision and hearing for communication, augmented by touch for interaction with the immediate surroundings. Moreover, these more prominent sensory modalities are known to exert both physiological and psychological influences on humans (e.g., sound/noise, light/vision, and temperature/climate) that can have an impact on our general wellbeing. In addition, our sense of smell is typically considered to be inferior to olfaction found elsewhere in the animal kingdom; for example, numerous species are able to trace the path of an odor source over great distances, or habitually undergo behavioral responses that are strongly modulated by volatile chemicals, e.g., pheromone-type compounds, that may play a role in aggression, mating, or rearing offspring. An absence of scientific proof does not preclude such remarkable capabilities in humans, yet there is widespread disregard for the importance and impact of the human sense of smell. Seemingly, this most likely relates to its association with *primitive*, animal-like behavior and potentially uncontrollable effects and responses that are elicited by smells, which are considered to be less rational and, therefore, more appropriate for the animal kingdom; surely the higher intellect of homo sapiens is not prone to behavioral responses from such primitive influences!

Yet, there is more to the human sense of smell than meets the nose, so to speak. There is an ever increasing body of evidence from ground-breaking research discoveries that demonstrates the crucial role that smells play in shaping our lives. From birth onwards we learn to interact with our environment using our sense of smell. Evolutionary processes have engendered a multifaceted communication that is supported – even dominated – by olfaction. This might be in the form of the smells that nurture the relationship between mother and child or influence partner selection, aromas that form our food preferences, or odors that warn us of dangers.

In the modern world we are increasingly exposed to smells that were not encountered by our ancestors. These are ubiquitous in our present-day environments and are met in all aspects of daily life, with sources ranging from manmade materials, industry, transport, household products, etc.; the list is practically endless. The outcome of this constant evolutionary process in material, product and application development is that we have generated a tolerance or even unawareness to numerous *modern* smells despite their often pervasive and abundant nature. By contrast, smells that relate to our appreciation of products such as foods have attracted intense scientific interest spanning decades, with the earliest discoveries dating back to when chemistry was still in its infancy. Specifically, pleasantly-smelling raw materials and compounds considered to be attractive to humans (e.g., as body scents or room fragrances) were at the focus of early research, sometimes with enormous efforts made to recover and enrich substances to a sufficient extent to enable a chemo-analytical elucidation of the underlying odorous molecules; such efforts were especially laborious and time-consuming at a time when the analytics and respective instrumentation were still rudimentary. Nowadays, an array of methods are at our disposal to resolve even the most complex of odor mixtures and decode the structures of individual molecules at extremely low concentrations; thus, rather than the insufficient sensitivities and resolutions limiting early research in this field, present odorant analytics might be considered as searching for a needle in a haystack, with individual odorants present amongst a forest of competing signals.

With emerging progress in the biochemical, biomedical, and neurosciences, research in olfaction has subsequently expanded to include a strong focus on the impact of smells on humans. This new direction has revealed important insights into how smells are perceived, processed and memorized, and how odor impressions influence our everyday lives. Nevertheless, the nature of numerous odorants remains unknown, as does their influence on perception, physiology and wellbeing. This is especially true for the modern smells that are encountered on a daily basis at home, at work, or when out and about.

A comprehensive treatment of smells – from ancient to modern and rare to common – in relation to the impact they have on our lives currently does not exist. This handbook aims to bridge this gap by aligning the senso-chemo-analytical characterization of smells encountered by mankind, tracing the diverse routes of po-

tential formation and release pathways, and elucidating the perceptual hedonic, behavioral, and physiological responses of humans to such odors at different stages of life. This book is intended to build a foundation for a hitherto widely overlooked area of research that has wider ramifications for human life, and to instigate intensified interdisciplinary discussions as a catalyst for gaining further insights and discoveries.

Andrea Buettner
Munich, Germany
October 2016

About the Editor

Andrea Buettner read for an undergraduate degree in food chemistry at Ludwig Maximilian University of Munich, Germany, and then completed her postgraduate and postdoctoral research at both the German Research Center for Food Chemistry (DFA) and the Technical University of Munich from 1995 to 2002. Following her habilitation to qualify for full professorship in 2007 she was appointed and still holds two concurrent positions, both as Founder and Head of the Department of Sensory Analytics at the Fraunhofer Institute for Process Engineering and Packaging IVV in Freising, Germany, and of the Odor and Aroma Research Group at Friedrich-Alexander-Universität (FAU) Erlangen-Nürnberg, Germany. Andrea has received several accolades for her research, including the Kurt-Täufel Prize for young scientists from the Food Chemistry Division of the German Chemistry Society (2010), the Young Investigator Award from the Food and Agricultural Division of the American Chemical Society (2011), the Danone Innovation Prize (together with Caroline Siefarth, 2012), and the Nutricia Science Award (2013). Since 2012, Andrea has held a position as Full Professor of Aroma Research at FAU in Erlangen.

Andrea's expertise encompasses the characterization of the main odor triggers in aromas, flavors, and common odors. Specifically, Andrea is renowned for identifying and characterizing the primary odor triggers in typical aromas, flavors, fragrances, and smells that are associated with everyday life. Amongst other things, her work involves disentangling and subsequently reconstructing characteristic smells, from food aromas to modern man-made materials, based on combined chemo-analytical and human-sensory characterization of the molecular odor constituents. Her specialized field extends to characterizing odorant release via on-line monitoring of distribution and delivery processes. This particular aspect of her work, for example, has provided insights into the importance of the combined effects of the food matrix, saliva, mucosa, mastication, and swallowing on flavor release and perception. In view of physiological processes related to odorant exposure and uptake, recent investigations have targeted pharmacokinetic aspects of odorant inhalation, absorption, biotransformation, and elimination via breath, urine, sweat, and human milk. Accordingly, Andrea's research aims to raise awareness of smell and odor dimensions in human life, especially in common, everyday situations. Her goal is to cross-link technological, chemical, or physiological aspects and to provide novel solutions in odor research. Novel or modified techniques, methodologies, processing technologies, analytical tools, and approaches related to smell are further outcomes of her research strategy, with the ultimate aim to nourish interdisciplinary cross-talk on a topic that links chemical, analytical, material, and process engineering sciences with the fields of sociology and socio-ecology, psychology, and physiology.

Part B Food and Flavors

Part E Psycho-Physical and Cognitive Aspects of Odor Perception

Part F Human Body Odor, Chemo-Communication and Behavioral Implications

List of Abbreviations

1-D	one-dimensional
2-D	two-dimensional
2-DG	2-deoxy-D-glucose
3-D	three-dimensional
3M2H	3-methyl-2-hexenoic acid
4-D	four-dimensional

A

AAT	alcohol acyl transferase
ABC	ATP-binding cassette
ACC	anterior cingulate cortex
ACD	allergic contact dermatitis
ACP	acyl carrier protein
ADH	alcohol dehydrogenase
ADI	acceptable daily intake
AEDA	aroma extract dilution analysis
AHI	apnea-hypopnea index
ALA	alpha-lipoic acid
ALDH	aldehyde dehydrogenase
AM	autobiographical memory
AMP	adenosine monophosphate
AMP	adenosine 5′-monophosphate
AMRE	axillary malodor releasing enzyme
ANOVA	analysis of variance
AO	anterior olfactory nucleus
AOB	accessory olfactory bulb
AOP	adverse outcome pathway
APC	anterior piriform cortex
APCI	atmospheric pressure chemical ionization
APET	added portions exposure technique
API-MS	atmospheric pressure ionization mass spectrometry
APLI	atmospheric pressure laser ionization
ARP	Amadori Rearrangement Product
ARS	acetone reference standard
ATP	adenosine triphosphate

B

BDI	Beck depression inventory
BDNF	brain-derived neurotrophic factor
BLA	basolateral amygdala
BMI	body mass index
BOLD	blood-oxygen-level-dependent
BOTT	basic odor term test
BSA	bovine serum albumin
BTTT	basic taste term test

C

CA	Cornu Ammonis
cAMP	cyclic adenosine monophosphate
CANN	cortical-based artificial neural network
CCCRC	Connecticut Chemosensory Clinical Research Center test
CD	cyclodextrin
CE	carboxyl esterase
CI	chemical ionization
CNG	cyclic nucleotide gated
CNS	central nervous system
COA	conditioned odor aversion
CREB	cAMP responsive element binding
CSERP	chemosensory event-related potential
CSIA	compound-specific isotope analysis
CWA	chemical warfare agent

D

DAG	diacylglycerol
DES	diethyl sulfide
DESI	desorption electrospray ionization
DG	dentate gyrus
DHE	dynamic headspace extraction
DMAPP	dimethylallyl diphosphate
DMDS	dimethyl disulfide
DMS	dimethyl sulfide
DMSO	dimethyl sulfoxide
DNA	deoxyribonucleic acid
DNPH	dinitrophenylhydrazine

E

e-nose	electronic nose
EBC	exhaled breath condensate
EC	entorhinal cortex
ee	enantiomeric excess
EEG	electroencephalography
EESI	extractive electrospray ionization
egr-1	early growth response protein 1
EH	epoxide hydrolase
EI	electron ionization
ELDI	electrospray-assisted laser desorption
EMEM	Eagle's modified essential medium
EMG	electromyography
EOG	electroolfactogram
EOS	emotion and odor scales
er	enantiomeric ratio
EROM	European reference mass odor
ERP	event-related potential
Es-GC	enantioselective gas chromatography
ESP	epithio-specifier proteins
EST	expressed sequence tag
EtSH	ethanethiol

F

FAD	flavin adenine dinucleotide
FD	flavor dilution

FDSS	functional drug screening system
FDT	flow drift tube
FFI	food freshness indicator
FGE	flavoring group evaluation
FID	flame ionization detection
FLEC	field and laboratory emission cell
fMRI	functional magnetic resonance imaging
FPD	flame photometric detection
FT	Fourier transform
FTIR	Fourier transform infrared
FWHM	full-width at half maximum

G

GABA	γ-amino butyric acid
GC	gas chromatography
GC-FID	gas chromatography with flame-ionization detection
GC-IRMS	gas chromatography isotope ratio mass spectrometry
GC-O	gas chromatography-olfactometry
GC-PO	GC-pedestal olfactometer
GC-RO	GC-recomposition-olfactometry
GC-SNIF	GC-surface of nasal impact frequency
GEOS	Geneva emotion and odor scale
GFP	green fluorescent protein
GG	Grüneberg ganglion
GPCR	G protein coupled receptor
GPMT	guinea pig maximization test

H

HCC-HS	high concentration capacity headspace
HD	homeodomain
HEK	human embryonic kidney cell
HLA	human leukocyte antigen
HLB	hydrophilic-lipophilic balance
HPLC	high performance liquid chromatography
HRIPT	human repeat insult patch test
HS	headspace
HS-LPME	headspace liquid-phase microextraction
HS-SPME	headspace solid-phase microextraction
HS-STE	headspace sorptive tape extraction
HSSE	headspace sorptive extraction
HTS	high-throughput screening
HVP	hydolysed vegetable protein

I

IAMS	ion attachment mass spectrometry
IAT	implicit association test
IBMX	isobutyl methyl xanthine
IC50	half-minimal inhibitory concentration
IGF	insulin-like growth factor
IL	interleukin
IMR	ion-molecule reaction
IMS	ion mobility spectrometry
IPP	isopentenyl diphosphate
IR	infrared
IRMS	isotope ratio mass spectrometry
IT	ion trap
IT-MS	ion trap mass spectrometry
ITE	individual threshold estimate

J

JND	just noticeable difference

K

KC	K-complex
Kegg	Kyoto Encyclopedia of Genes and Genomes
KSOM	Kohonen self-organizing map

L

LAB	lactic acid bacteria
LAESI	laser-assisted electrospray ionization
LBP	LPS-binding protein
LC	liquid chromatography
LDL	low density lipoprotein
LLE	liquid-liquid extraction
LLNA	local lymph node assay
LOD	limit of detection
LOQ	limit of quantitation
LOT	lateral olfactory tract
LOX	lipoxygenase
LPP	late positive event-related potential
LPS	lipopolysaccharide

M

MALDI-ESI	matrix-assisted laser desorption electrospray ionization
MAP	modified atmosphere packaging
MCC	multicapillary column
MCS	multiple chemical sensitivity
MDGC	multidimensional GC
MDR	multidrug resistence
MDT	mediodorsal thalamic nucleus
MEG	magneto-encephalogram
MeSH	methanethiol
MEST	mouse ear swelling test
MHC	major histocompatibility complex
MICA	metabolism of ingestion correlated amount
MLF	malolactic fermentation
MOB	main olfactory bulb
MoE	margin of exposure
MOE	main olfactory epithelium
mOR-EG	mouse olfactory receptor protein
MOSFET	metal oxide semiconductor field effect transistors
MRI	magnetic resonance imaging
mRNA	messenger ribonucleic acid
MS	mass spectrometry
MSDI	maximized survey-derived daily intake

MSG	monosodium glutamate
mTAMDI	modified theoretical added maximum daily intake
MUFA	monounsaturated fatty acid
MUP	major urinary protein

N

NIF	nasal impact factor
NMR	nuclear magnetic resonance
NOAEL	no observed adverse effect level
NOEL	no observed effect level

O

O	olfactometry
OAV	odor activity value
OB	olfactory bulb
OBP	odor binding protein
OCAM	olfactory cell adhesion molecule
ODR	odorant response
ODT	odor detection threshold
OE	olfactory epithelium
OERP	olfactory event-related potential
OET	open epicutaneous test
OFC	orbitofrontal cortex
OIRS	odor intensity referencing scale
OMP	olfactory marker protein
OR	olfactory receptor
ORN	olfactory receptor neuron
ORP	olfactory receptor protein
ORT	odor recognition threshold
OSN	olfactory sensory neuron
OTH	odor detection threshold
OU	odor unit

P

PA	proton affinity
PAD	pleasure, arousal, and dominance
PAH	polycyclic aromatic hydrocarbons
PAMP	pathogen-associated molecular pattern
PBMC	peripheral blood mononuclear cell
PC	piriform cortex
PCA	principal components analysis
PCC	posterior cingulate cortex
PCR	polymerase chain reaction
PDMS	polydimethylsiloxane
PDO	protected designation of origin
PE	polyethylene
PEA	phenylethylalcohol
PEEK	polyether ether ketone
PET	positron emission tomography
PFC	prefrontal cortex
PFPD	pulsed flame photometric detector
PFS	passive flux sampler
PI	perceived intensity
PIB	polyisobutylene
PID	photoionization detector
PLC	phospholipase C
PMMA	polymethylmethacrylate
PP	polypropylene
PPC	posterior piriform cortex
premox	prematurely aged
PS	polystyrene
PTFE	polytetrafluoroethylene
PTR	proton transfer reaction
PU	polyurethane
PUFA	polyunsaturated fatty acid
PUT	provocative use test

Q

QC	quality control
QOD	questionnaire olfactory disorder
QoL	quality of life
QRA	quantitative risk assessment

R

RAS	retronasal aroma simulator
REM	rapid eye movement
RIA	retention index allowance
RNA	ribonucleic acid
ROAT	repeated open application test
ROS	reactive oxygen species
RTL	retention time locking

S

S-HS	static headspace
SAFE	solvent assisted flavor evaporation
SAR	structure–activity relationship
SCFA	short-chain fatty acid
SDE	simultaneous distillation extraction
SEC	size exclusion chromatography
SESI	secondary electrospray ionization
SID	selected ion detection
SIDA	stable isotope dilution analysis
SIFDT	selected ion flow drift tube
SIFT	selected ion flow tube
SIM	selected ion monitoring
SIRA	stable isotope ratio analysis
SND	sinunasal disease
SNP	single nucleotide polymorphism
SOA	secondary organic aerosol
SPE	solid phase extraction
SPME	solid phase micro extraction
Src	sarcoma
SVHC	substance of very high concern
SVOC	semivolatile organic compound

T

TA	titratable acidity
TAAR	trace amine associated receptor
TAGA	trace atmospheric gas analyzer
TD	thermal desorption

TDS	temporal dominance of sensation
tERP	trigeminal event-related potential
TIC	toxic industrial compound
TIR	Toll/interleukin-1 receptor
TLR	Toll-like receptor
TM	transmembrane
TMR	targeted memory activation
TNF	tumor necrosis factor
TOF	time-of-flight
TPOA	taste potentiated odor aversion
TPS	terpene synthase
TRP	transient receptor potential
TRPC	transient receptor potential channel
TSS	total soluble solids
Tu	olfactory tubercle
TVOC	total amount of volatile organic compounds

U

UPSIT	University of Pennsylvania smell identification test
URTI	upper respiratory tract infection
UTA	untypical aging off-flavor
UV	ultraviolet
UV–Vis	ultraviolet-visible

V

V-SMOW	Vienna Standard Mean Ocean Water
VMR	volume mixing ratio
VNO	vomeronasal organ
VOC	volatile organic compound
vPvB	very persistent and very bioaccumulative
VR	vomeronasal receptor
VSC	volatile sulfur compound
VSN	vomeronasal sensory neuron
VUV-SPI	vacuum ultraviolet single-photon ionization

W

WOF	warmed-over-flavor

1. History of Odor and Odorants

Wilhelm Pickenhagen

Smell is the oldest sense of living species on our planet and has allowed communication between species from the beginning of life on earth. Odor has always fascinated mankind even in prehistorical times and the use of scented materials is documented since early history. Materials used were extracts from odorous natural products until the advent of organic chemistry. Progress in analytical methods allowed the isolation and structure identification of odor impact compounds from natural extracts and subsequent syntheses made it possible to produce these compounds on an industrial scale for use in many applications of modern perfumery.

1.1 Defining Odor and Odorants

Chemical communication, namely a signal initiated by a chemical compound emitted by a donor, received by a receptor and recognized as such, is one of the foundations of the development of life on earth.

While the two chemical senses, namely the senses of taste and smell, are directly elicited by a chemical entity perceived by a receptor, all other senses (sight, hearing, and touch) recognize the very first signal by physical forces such as light, sound, temperature, or pressure, respectively. A cascade of biochemical reactions then amplify and transmit these signals to the brain where they can be analyzed as such.

In this context, it might be useful to define what an odor is, namely the impression in the brain elicited by the recognition of a (mostly) volatile chemical by an odorant receptor. It follows that a chemical (or molecule) can be considered as an odorant if it fulfills the following conditions:

1. It has to bind to an odorant receptor.
2. It has to result in the odorant receptor transmitting the recognition to the brain.
3. The brain has to recognize it as a signal that can be interpreted.

1.2 The Chemical Senses

While the origin of biological life on Earth is not exactly known, some hypotheses do exist [1.1]. What is certain however is that primitive forms of life began in an aqueous environment where sound and optical impressions were very limited. The so-called chemical senses were of essential importance for survival long before species with some form of brain and capabilities of reflection developed. The chemical senses are thus the oldest senses in the development of life on earth, and allowed primitive species to find food, sexual partners, and warned them for potential predators by recognizing certain low molecular chemicals in their surroundings [1.2].

As life on earth became more complex, when single cells developed into multicell organisms, a primitive brain form developed capable of recognizing and an-

alyzing different odor impressions. During evolution, these increasingly complex species eventually left the aqueous environment, and in order to survive, developed new senses of hearing and vision. Because treatment of such new stimuli could no longer be handled by the primitive brain, the neocortex developed which allowed for the compilation of these new sensory signals as well as endowed the more complex species with other capabilities still found today in the *modern brain*. Nevertheless, the perception of odors is still, even in humans, relayed directly in the limbic lobe, which has also be shown to be the neural substrate of emotional behavior [1.3]. Because of this, olfaction is the only sense capable of suddenly retrieving long forgotten memories by a single sniff of a specific scent. This phenomenon led the famous French mathematician Blaise Pascal to the desperate, but true statement *The nose knows things that the mind does not understand* [1.4].

1.3 History of Use of Odorants

1.3.1 Prehistory

If the use of fire to transform food material is considered the first direct production of odorous material, then the use of odorants by hominids by far precedes the period which we call *human history*, and in fact the existence of *Homo sapiens sapiens* themselves.

The oldest described traces of fire not ignited by lightning have been found at a site called Gesher *Benot Ya'aqov* in Israel and are dated back to about 790 000 years. The authors of this discovery discuss the probability that these fires were created by hominids belonging either to *Homo erectus*, *Homo ergaster, or even to an archaic Homo sapiens* [1.5].

During the evolution to *Homo sapiens* some of the pure instincts for survival changed slowly into reflective habits and needs, that is, into cultural rites of different kinds. The ability of recognition and interpretation of olfactory stimulation is one of the most important differences between humans and other living creatures. Use of odors as cultural acts is much older than written history. Indeed, odorous signals initiated by sacrificial burning of different objects were ways to address Gods and ancestors to ask for clemency or to thank for their kindness. *Pro fumum*, odors that were created by smoke is often considered the oldest form of perfumery.

One of the oldest known prehistorical rites is dated back to about 60 000 years. During the excavation of the *Shanidar* cave in northern Iraq, the remains of nine *Homo sapiens neanderthalensis* were discovered in a depth of about 7 m. The surrounding soil contained seeds of a total of eight different kinds of flowers. These flowers of local origin are quite odorous. It was shown that these flowers had neither grown in the cave nor had they been transported there by animals; it has thus been concluded that they were added at the burial of these bodies, indication that already at that time odorous plants were used to honor the dead [1.6].

1.3.2 Early History

The oldest sources of history stem from Mesopotamia, the land between Euphrates and Tigris, the area considered by many as the cradle of humanity. It is believed that it is the place where earthly paradise was located; Genesis 2.7 describing that creation of human life occurred through a sniff [1.7]:

> *the Lord God formed the man from the dust of the ground and breathed into his nostril the breath of life and man became a living being.*

The oldest known epic in human history, the *Gilgamesh Epic*, was found in this region of Mesopotamia. This is written on 12 clay tables and is dated somewhere between 2750 and 2500 BC Indeed in the 11th table, the first father Utnapishtim thanks for being rescued from the deluge [1.8, 9]:

> *I offered incense in front of the mountain-ziggurat,*
> *Seven and seven cult vessels I put in place*
> *And into the bowls I poured reeds, cedar, and myrtle. The gods smelled the sweet savor,*
> *And collected like flies over a sacrifice.*

Mesopotamian cuneiform tablets contain some of the oldest written documents describing the use of odorants. For example, in order to honor the sun God Baal in the Assyrian capital Nineveh, frankincense was burned at about 3000 BC. During the time of Hammurabi around 1700 BC about 2000 talents of frankincense were burned every year in the temple of Bel in Babylon [1.10]. Moreover, the use of odorants was known to exist in the Persian Empire. For example, virgins that were selected to be presented to king Xerxes had to complete twelve month of beauty treatment, six months with oil of myrrh, and six months with perfumes and cosmetics [1.11]. Even Esther had to undergo the same treatment before she was presented to the king and became his preferred wife and queen [1.12].

Odorants were not only used for religious rites but also for private purposes. Priests, royalties and other dignitaries generously used perfumes. The king honored special subjects by putting an odorous wreath on his head, the same way people of today are honored with a medal. The Babylonian king Nebuchadnezzar II built the Hanging Gardens of Semiramis, considered as one of the seven wonders of the antic world, for his wife Amyris. Mainly cypress, mimosas, roses, and lilies were planted there because their perfumes were preferred by the queen [1.13].

At around the same time as in *Mesopotamia*, that is, about 5000 years ago, odors and odorants played an important part in the cultural life of historical Egypt. The Gods by definition emitted an attractive odor whereas common people needed odorants to smell nicely. It is said that in the legend of God Amun, who appears as pharaoh in order to marry his queen, the latter used his odor as the most important attribute to conquer her. It is documented in a text on papyrus that [1.13]:

> *the queen is awakened by the fragrant breath of the God and she smiled in his presence. He came directly to her and fell in love. He gave her his heart and stepped in front of her to show her his divine nature. When she realized his beauty she rejoiced and feelings of love went through her body. The whole palace was filled with the odor of the God; all his scents were those of Punt.*

Punt was considered as the place of origin of the scent of Gods.

Incense burning of different materials was practiced three times a day in Heliopolis, residence of the sun God Ra: frankincense at sunrise, myrrh at noon and kyphi at sunset. Kyphi, a mixture of 16 ingredients was considered as the most agreeable scent belonging to the Gods [1.14].

Gods played an important part of daily life in ancient Greece. The sensory impression of odors was as inexplicable as the nature of the Gods... and there were many. At one time there was an estimate of about 30 000 of them. It followed that the origin of odors was considered as divine. Many myths connect the odor of different plants and flowers with different Gods. For example, Aphrodite kept vigil over Hector's corps night and day and anointed him with ambrosial oil of roses [1.14], and Circe traps Odysseus with the aid of seductive perfume [1.8, p. 107]. Despite the belief in the divine origin of odors the Greeks already knew about the attraction of human odor to the opposite sex. The sweat of wrestlers after the fight was collected with creams and oils, and these mixtures were commercialized [1.13, p. 205] as were other fragrances. Perfumery shops were popular meeting points for all kinds of gossip, and even the cynic Diogenes consented from time to time to place his home, the famous barrel, close to these shops. He used fragrant oils only for his feet, arguing that if only the head is anointed with perfume it would escape into the air and only the birds would benefit from it. However, the use of perfumes was not without harsh critics. The famous philosopher Socrates said that [1.8, p. 112]:

> *if a slave and a free man are oiled with scent they both smell the same but the mark of a free man should be his smell after work and exercise.*

After the Romans had conquered the territories of the Near East, they began to learn about and to adopt the luxuries of Greek lifestyles, including use of odorants, and in some cases excessively. Roman women who belonged to a class that would today be considered as socialites had their special slaves who were instructed to carry out cosmetic and hair care, as well as perfumery tasks. Hygienic care was indeed well developed: the citizens of Rome had public baths at their disposal where they would, after their bath, be anointed with scented oils. Emperor Nero and his wife Poppea Sabina used excessive amounts of scented materials, especially at their receptions and banquets. Nevertheless, there were also critics of the extensive overuse of odorous products including the consuls Licinius Crassus and Julius Caesar who eventually forbade the sales of these products [1.8, p. 116].

The Bible is a rich source of information about historical trade and use of odorous materials. Genesis 37, 25 describes the sale of Joseph by his brothers to midianite merchants who transported spices, balsam, and myrrh from Gilead on their way down to Egypt, where the use of scents for sacrifices and personal care was highly developed. After the exodus of the Jewish population from Egypt, *Moses* received many commandments, one of them ordering the construction of an altar as described in detail in Exodus 30, 1–6. The use of this altar is regulated in Exodus 30, 7–10, where Aaron is ordered to:

> *burn fragrant incense on the altar every morning when he tends the lamps at twilight so incense will burn regularly before the Lord for the generations to come.*

Exodus 30, 23–25 is a recipe for making *the sacred anointing oil* consisting of:

> *500 shekels of liquid myrrh, half as much of fragrant cinnamon, 250 shekels of fragrant cane, 500 shekels of cassia and a hint of olive oil.*

This formula could be considered as one of the oldest *captive* products, that is, products protected by law and

which can only be used by unique people for special purposes because in Exodus 30, 33 it is stated:

> *whoever makes perfume like it and whoever puts it on anyone other than a priest must be cut off from his people.*

Exodus 30, 34 describes another recipe consisting of gum resin, onycha, galbanum, and pure frankincense, also for one special purpose: *consider it holy to the Lord*. Use of myrrh and frankincense are mentioned 22 times in bible texts [1.15] and *Wolfgang Pilz* lists in his collection *Frühe Weltmacht: Parfumerie und Kosmetik* [1.16] about 50 citations from the bible that describe botanical origins of odorous plants and use of them as perfumes.

With the slow fall of the Western Roman Empire around 480 A.C. the cultural development of the Occident came to a sort of a stillstand which lasted until the middle Ages. At the same time the Byzantine Empire grew out of the East Roman Empire till 1453, the fall of Constantinople. During these about 10 centuries, the influences of the surrounding Islamic world became an important factor for the cultural development of this area. Already about 800 BC the inhabitants of the Arabian Peninsula countries cultivated myrrh, frankincense, and other aromatic materials which they also exported to the developed countries around the Mediterranean. The culture of making and using sophisticated odorous materials was highly developed and described in many tales. Based on the knowledge of the discoveries and philosophical interpretation of these by the Greeks and the Egyptians, the Arabs began to discover and develop new techniques through experimentation, just to mention distillation, sublimation, filtration, and – very important – the production and concentration of ethanol (*Arab. al koh'l*) from wine. The application of these tools and techniques gave rise to the isolation of a multitude of odorous materials from different scented raw materials. The technique of steam distillation, an Arab invention, is still a very important method to isolate volatile materials from their matrix.

1.3.3 The Middle Ages till Beginning of Industrialization

It took a while until the culture of using scented materials reached Western Europe. It is dated to the Merovingian period. The first products, mainly spices, were shipped up the Rhone river from the Mediterranean before a more active trade, especially with Venice, developed. At the end of the eighth century, the Benedictine monk *Ansegis* compiled methods for the cultivation of aromatic plants for medicinal and flavoring uses which were published as instructions in Charlemagne's *Kapitular* [1.17]. The well-equipped monasteries of that time used these instructions to cultivate mainly dill, marjoram, mint, parsley, rosemary, and sage. The Abbes *Hildegard von Bingen* (1098−1179) is one of the first scientists to describe the use of these products and their extracts for therapeutic use.

The European participants of different Crusades starting in 1095 discovered the use of the highly developed scented materials of the Near East of which they brought back samples as gifts for their ladies. One of the first ones is probably *Eau de Chypre*, a composition of extracts of two plants indigenous to Cyprus, rose and styrax. This Mediterranean island had been conquered by *Richard Lionhart* during a crusade.

Cultivation and extraction of plants for use as therapeutics that had started at the end of the 8th century [1.17] in the developed gardens of different European monasteries became more and more sophisticated and at around the beginning of the 14th century, these mixtures, the recipes of which were kept highly secretive, became items of trade. *Eau d' Ange*, a composition of aqueous extracts of rose, orange, styrax, and rue was sold by the mobile traders of that time. Another product, *Aqua Regina Hungarica*, is probably the first bestseller in the history of perfumery. It is said that this product, an aqueous extract of mainly rosemary, was given by a monk or even an angel!! [1.18] to the than 70-year-old highly arthritic Queen Elizabeth of Hungary, who, thanks to the regular use of this product recovered health and youth to the extent that the Polish king asked her for marriage.

Probably the most famous and still existing of all waters is *Eau de Cologne*. Its origin most probably dates back to an Italian immigrant to the German city of Cologne. *Giovanni Paolo de Feminis*, originally from the province of Novara brought with him a recipe based on a mixture created by the Abbes of the Monastery of Santa Maria Novella of Florence which he called *Eau admirabilis de Cologne* [1.18]. To underline the uniqueness of this product, he searched and obtained a document from the medicinal faculty of the University of Cologne, dated 13th of January 1727, certifying that it had the property of renewing, refreshing, and reviving the human life spirit [1.18]. *Eau admirabilis de Cologne* became a commercial success and *Feminis* engaged his nephews *Johann- Maria* and *Johann-Antonius Farina* as his partners who developed the commerce under their name. During the 7-year war, French officers that got acquainted with this product brought it to Paris where it became popular around 1760. The commercial success encouraged different manufacturers to engage in its production and sale, one of which was *Ferdinand Mülhens* who manufactured *Eau de Cologne* in his house in the Glockengasse in Cologne. Following

a decree of 1794 by the French occupants of Cologne all of the 7440 houses of the city were numbered and the house of *Mülhens* was given number 4711, which is the origin of the still used commercial name *Eau de Cologne 4711* [1.19]. It is said that *Napoleon* was very lavish with *Eau de Cologne*, using about two bottles a day, so he took large quantities with him in his campaigns.

The preparation of extracts of natural products, especially strong smelling flowers, expanded from the monasteries to regions of abundant starting materials, especially in the town of Grasse in Southern France where it developed from laboratory quantities to industrial dimensions. In 1768, *Antoine Chiris* founded the first of these factories in Grasse making extracts from natural products that were used for the composition of perfumes. Paris became the center of creation and a number of specialized boutiques opened their commerce. One of the first were *Jean Francois Houbigant* in 1775 as well as *Michael Adams* whose establishment *La Reine de Fleur* later became the famous *House of Piver*. *Pierre-Francois Lubin* created the famous *Eau de Lubin* around 1790. *Napoleon*, in addition to his campaigns to conquer Europe also changed the judicial system in his native France. The Code Napoleon, introduced in 1804, is still the base of law in France. One of his decrees of 1810 defines the term *Perfume* in which a perfume had to be distinguished from products for pharmaceutical use and no longer be used for internal applications. Composition of products for medicinal applications had to be declared whereas the formula for perfumes remained a company secret, encouraging the foundation of several perfumery companies, one of which was created by *Pierre-Francois Guerlain*, a Frenchman who had studied chemistry and pharmacy in England. He opened his store as *parfumeur-vinaigreur* in 1828 in the Rue Rivoli in Paris [1.20], creating products that were much in fashion at the Parisian societies. Trends of the time were mainly reconstitutions of flower scents and compositions thereof [1.21] *Guerlains* first successes such as *Senteur de Champs* and *Esprit de Fleurs* were compositions of light floral themes, heavy flower, and animalic notes were not in fashion [1.21]. The so-called soliflores [1.22], reconstitutions of single flower scents appeared and dominated the market for a while, just to mention *Rose* and *Jasmin* by *Molinard* (1860), *Rose Jaqueminot* and *Jasmin de Corse* by *Coty* (1906), *Violette Pourpre* by *Houbigant* (1907), *Narcisse Noir* by *Caron* (1912), *Gardenia* by *Chanel* (1925), and *Le Muguet de Bois* by *Coty* (1942) [1.23]. All these creations were compositions of different extracts of natural products already made by industrial procedures.

1.3.4 The Advent of Organic Chemistry and Its Contribution to Perfumery

The beginning of organic chemistry is generally considered *Friedrich Wöhler's* publication of the conversion of ammonium cyanate into urea, a synthesis of an organic molecule found in living organisms from an inorganic salt [1.24], even if he had, already 4 years earlier, synthesized oxalic acid by hydrolysis of dicyane [1.25]. These discoveries initiated the abandon of the *vitalism*, a philosophy believing that organic molecules could only be synthesized – or better created – by living organisms, even if it still took a while to be recognized as not valid.

What are the connections between these discoveries and modern perfumery? As described earlier, creation of perfumes consisted of the skillful composition of different extracts of odorous natural extracts. The nascent organic chemistry enabled scientists to analyze the composition of natural products, identify the molecules of odor impact, and subsequently synthesize those for the use in perfume compositions. This statement is of course an extreme abbreviation of these developments which took a long time and is still going on today as one of the main branches of research in perfumery science.

Even before *Wöhler's* discoveries systematic analyses were executed on natural products. *Jaques-Julien Houton de Labadière* showed that turpentile oil consisted only of carbon and hydrogen and that the atomic proportions of these were 5 to 8 [1.26]. Later, compounds of natural origin having these elementary proportions were called *terpenes*. The French scientist and later agricultural minister *Dumas* developed methods that helped to separate natural extracts into simple hydrocarbons and into their derivatives containing sulfur, nitrogen, and/or oxygen. However, analytical methods only allowed isolating and identifying compounds that occurred in larger quantities in the natural extracts. As an example, *Buignet* described in an extensive publication a series of analyses to distinguish between different species of strawberries [1.27]; the volatile part that imparts the odor of these fruits is mentioned in only some sentences concluding that the odor is due to volatile materials that occur in very small quantities and that it would need a *very large quantity of starting material to determine the exact chemical nature of these extracts*. This statement is to be considered as very optimistic, even with today's sophisticated methods for the analysis of volatile materials not all trace odorous materials have been identified.

One of the first impact odorants isolated and identified was cinnamaldehyde **1** out of cinnamon oil by *Dumas* and *Peligot* in 1833 [1.28]. Benzaldehyde **2**, the

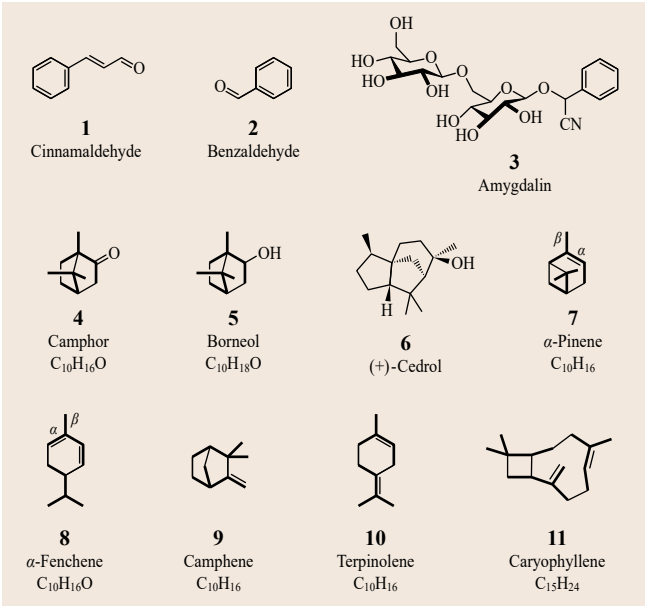

Fig. 1.1 Odorants isolated from natural sources and identified in the early times of organic chemistry

odorous principle of bitter almond oil and cherry flavor is to be considered the first synthetic odorous material after *Wöhler* and *Liebig* could show that it results from the enzymatic cleavage of amygdaline **3** that occurs in the stones of fruits like plums, cherries, peaches, and almonds. Analytical techniques improved over time so that odor impact compounds could be isolated from odorous natural products and their chemical structures could be elucidated. The first compounds thus isolated were those that are solid at room temperature and could be separated from their matrix by crystallization such as camphor **4**, borneol **5**, and cedrol **6**. Further improvement of distillation techniques like vacuum and column distillation as well as specific derivatization allowed the isolation and structure elucidation of liquid compounds. Pioneer in these techniques was Otto Wallach who, in the years 1884–1920 published from his laboratory at the University of Göttingen more than 100 papers describing the isolation and identification of many important monoterpene compounds, inter alia, α-pinene **7**, α-fenchene **8**, camphene **9**, terpinolene **10**, as well as some sesquiterpenes like caryophyllene **11** (Fig. 1.1).

1.3.5 Beginning of Modern Perfumery

Modern perfumery however began when these natural products to be used in compositions could be made by other methods than by extracting them from their natural sources. This area began with the synthesis of coumarine **12** by *Perkin* [1.29] in 1868. This product, smelling of freshly cut grass had been isolated earlier from tonka beans by *Wöhler* [1.30]. Improvement of the procedure by *Tiemann* and *Herzfeld* [1.31] made it possible to produce this product on an industrial scale to be used in perfumery. One of the first successful uses of coumarine resulted in a perfume called *Fougère Royal* by *Houbigant*, marking a family of scents called fougère which are still alive in modern perfumery; well-known examples are *Drakkar Noir* in 1982 and *Cool Water* in 1988. Coumarine is still used in about two thirds of all new perfumes. Vanillin **13** is the aromatic principle of vanilla pods in which it occurs at about 2%. Because of the costs of isolation from an already expensive starting material it could not be used in perfumery. The structure of **13** had been elucidated by *Tiemann* and *Haarmann* after they had obtained a crystalline alcohol by treating coniferine with emulsine, a hydrolytic enzyme, followed by oxidation with potassium bicromate in sulfuric acid [1.32]. This method not only allowed to obtain the pure product to determine its chemical structure but could be also considered

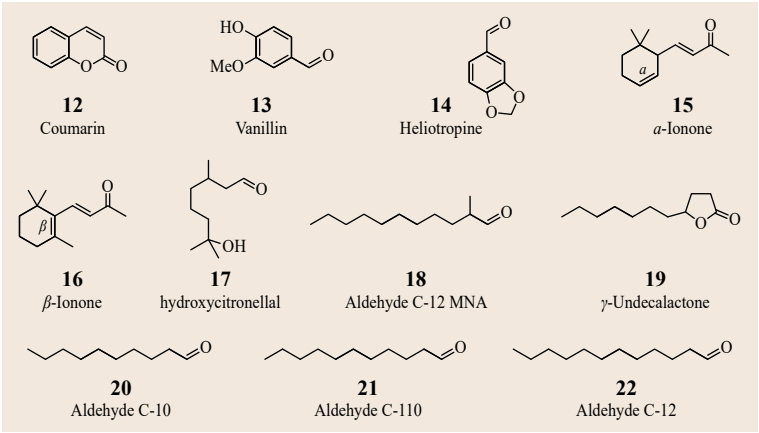

Fig. 1.2 Naturally occuring odorants available through chemical syntheses

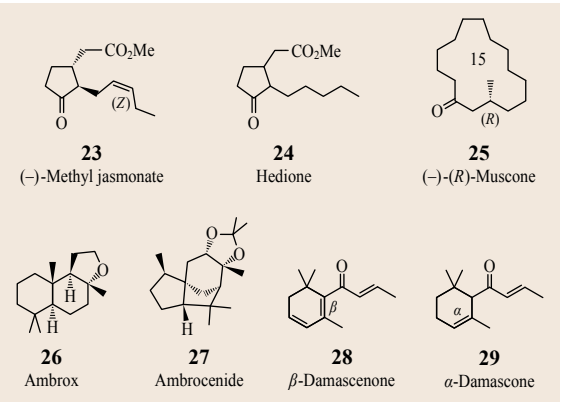

Fig. 1.3 Important natural and non-natural odorants obtained by chemical syntheses

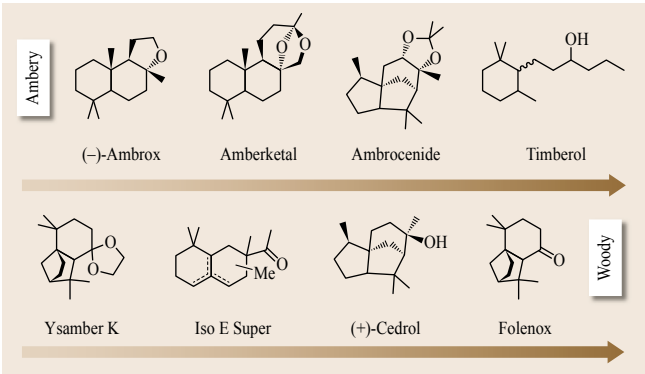

Fig. 1.4 Conversion from ambery to woody notes on the example of eight commercial odorants

as an industrial method. *Haarmann*, who originally came from Holzminden close to the Solling mountain in Germany where pine wood, the starting material for coniferine, is in great abundance, took on this task and founded *Haarmann's Vanillinfabrik* to produce **13**. A completely new synthesis of this product was developed again by *Tiemann* using a reaction discoverd by *Reimer*; this reaction known as the Reimer–Tiemann *Reaction*. Later on *Reimer* joined *Haarmann* to found *the Haarmann & Reimer Corporation* in Holzminden, one of the oldest industrial Flavor & Fragrance Companies. It acts now under the name of *Symrise* after the merger with *Dragoco* also from Holzminden in 2002.

In 1889, the French perfumer *Aimé Guerlin* created the perfume *Jicky* in which he used synthetically produced vanillin **13**, heliotropine **14**, and coumarine **12**. This creation is to be considered as a turning point in perfumery because it was the first time a perfume was not the recreation of a natural product, the so-called soliflores, but it allowed new interpretations of harmonized odor accords not necessarily occurring in nature [1.33]. Extracts of the violet flower were very much appreciated for perfume creation but because of its limited availability too expensive for general use. To identify the smelling principle of this flower, *Tiemann* and *Krüger* extracted the similar smelling but much cheaper orris root oil to discover the ionones **15** and **16** as the odorous principle [1.34]. Their synthesis was straightforward so the material became generally available and is still a basic material for the creation of flowery perfumes.

The scent of the popular lily-of-the-valley flower was very desirable to be obtained but its extraction from the natural source was not possible. In the beginning of the 20th century, three different groups nearly simultaneously succeeded in the synthesis of hydroxycitronellal **17**. *Knoll* in Germany in 1905, *Givaudan* and *Firmenich*, both in Switzerland in 1906 and 1908 respectively marketed this product under different names and qualities because of different byproducts due to their different synthetic procedures that alter the smell. The first significant use was by Houbigant in the famous perfume *Quelques Fleurs* in 1912. *Cylosia*, the product from *Firmenich* is still in popular use for flowery perfumes. Another flowery product not found in nature, aldehyde MNA, methyl nonyl acetaldehyde **18**, was discovered around the same time and is still very much in use. Around 1920, fruity notes became popular after the success of the perfume *Mitsouko* by *Guerlain* who used the so-called aldehyde C-14 which actually is γ-undecalactone **19** and has a very pronounced odor of ripe peach.

A historial trend setting event in modern perfumery was the creation of *Chanel No 5* by *Beaux*. He added to a mixture of flowery notes like ylang ylang, vanilline and musks high amounts of the straight chain aldehydes decanal **20**, undecanal **21**, and dodecanal **22**, which by themselves have a pronounced unpleasant fatty odor of candlewax. This combination became a great success and *Chanel No 5* is still today one of the most appreciated and sold perfumes.

Jasmine flower notes are very important in modern perfumery. Until around 1960, extracts from jasmine flowers were used which were very expensive and could thus be used only in very small quantities in limited applications. The turnaround came after the isolation and identification of methyljasmonate **23** by *Demole* et al. [1.35]. Its synthesis proved to be quite expensive but *Demole* could show that the dihydro derivative **24** had very close odor properties to the natural product, that is its boosting effect to floral notes. The product, called *Hedione* was first introduced by *Roudnitska* in *Eau Sauvage* in 1962. Due to its success and the steady improvement of its synthesis *Hedione* is now available

at a price that allows its use even in applied perfumery for soaps and detergents. It is not exaggerated to say that today *Hedione* is used in every perfume.

Musk odorants are in wide use in perfumery (Fig. 1.2). Analysis of the extracts from the musk deer glands secretion, that was initially used in compositions, allowed *Walbaum* in 1906 to identify a ketone $C_{16}H_{30}O$ which he called muscone as the smelling principle [1.36]. It was *Ruzicka* who 20 years later identified this compound as (−) 3-methylcyclopentanone **25** [1.37]. With this discovery, he overturned *Bayer's* theory of too much strain in carbocyclic rings greater than 12 carbon atoms [1.38] and for which he was awarded the Nobel Price in Chemistry in 1939. A carbocyclic ring ketone smelling of musk was isolated by *Sack* from the glands of the civet cat and identified by *Ruzicka* as cycloheptadecanone [1.39]. Another musk-smelling compound was isolated by *Kerschbaum* from ambrette seed oil and identified as 7-*cis*-hexadecen-16-olide [1.40]. Numerous macrocyclic and noncyclic compounds exhibiting a musk odor have since been discovered and are in use in modern perfumery [1.41].

Ambra notes are appreciated in perfumery. The first product to be used was ambergris, a mixture extracted from a pathological metabolite from the sperm whale which floats on the surface of the oceans after excretion. This extract contains a number of terpenoic structures that are degradation products from the triterpene ambreine, discovered by *Lederer* [1.42]. The high interest in amber notes initiated research into the discovery of amber-smelling compounds from other sources. Among the several synthetic compounds available today for perfume creation are Ambrox **26**, Cetalox, which is racemic **26** and the extremely powerful Ambrocenide **27** [1.43].

Woody notes are much used in perfumery. A stepwise conversion from strong amber, slightly woody to slightly amber-strong woody has been established by *Pickenhagen* using a series of different chemicals used in perfumery [1.44] (Fig. 1.4).

The invention of gas chromatography by *James* and *Martin* in 1952 [1.45] and its systematic application allowed the isolation and structure elucidation of strong smelling compounds that occur only in traces in nature. An example with wide ramifications for perfumery is the discovery of an important odorant in Bulgarian rose oil (*rosa damascena* Mill) by *Demole* et al. when they isolated a compound by preparative gas chromatography and determined its structure as 1-(2,6,6-trimethylcyclohexa-1,3-dienyl) but-2-en-1one **28**, which was named β-damascenone [1.46]. Synthetic work around this structure showed that the isomer α-damascone **29** is from a perfumistic standpoint the most interesting of different isomers tested. It is interesting to note that this product had been synthesized in another context before by *Ohloff* and *Uhde* [1.47] but its perfumistic value had not been recognized. The use of **29** led to a series of new types of perfumes of which *Poison* by *Dior* with an extremely high amount of 0.04% was the most successful trendsetter (Fig. 1.3).

Further improvement of gas chromatography and its hyphenation with analytical methods like mass-spectrometry and nuclear magnetic resonance spectroscopy allowed the isolation and identification of a plethora of new natural substances, many of them are now used as synthetic materials in perfumery. Today, the perfumer has for the creation of new and original perfumes an arsenal of about 3000 commercially available compounds at his disposal, most of them of synthetic origin. In the future, many more will be discovered and used, confirming the prediction of *Ernest Beaux*, the creator of the famous Channel No. 5 who stated [1.48]:

> *the future of perfumery is in the hands of chemists. We will rely on them to find new odorants to make original new accords.*

Part A

Molecular

Part A Molecular Aspects and Formation Pathways

Odorous compounds are typically volatile or semi-volatile in nature and have low molecular weight, the majority being below 300 u. Despite this apparently limited range, odorous stimuli belong to a broad variety of substance classes that comprise diverse structural moieties such as ester, carbonyl, alcohol functions, bearing thio and other heteroatomic groups, having aromatic or aliphatic forms, with the potential of incorporating heteroatomic constituents in the aromatic structures. Odorants may be even-chained or branched, may be saturated or exhibit different degrees of unsaturation, and can contain double bonds or steric centers that can dictate the odor character and potency according to their steric properties. Even minimal differences can induce altered smell properties, as is encountered between certain enantiomers of the same molecule, thereby requiring that the exact structure and its formation pathways must be thoroughly resolved in order to be fully understood. Moreover, the complexity of possible combinations may be increased further by the combination and formation reactions of different structural moieties within one molecule.

A range of pathways have evolved in nature for communication purposes. The transmission of potent smells can elicit specific responses in recipients, and conversely, the latter have developed the means to detect these as signaling molecules. Odors generated and released in the plant kingdom, for instance, can serve as cues to insects and animals; fruity odors indicate a source of carbohydrate energy, and floral scents act as pollinator attractants. Animal-like smells can also induce specific responses in certain species, e.g., in conspecifics or in predator–prey relationships, and cell damage in plants, e.g., by herbivore feeding, may generate volatile compounds as a by-product of the plant's defense mechanism, which might further serve as a distress signal and attract predators of the insects damaging the plant. Apart from these biochemically driven routes, odorants may be also generated by predominantly chemical pathways. Thermal and pyrolytic processes or oxidation are amongst such reaction cascades that are often highly complex. We savor such aromas in baked and roasted foods, but specific burnt impressions tell us that heat treatment was too intense. Often, there is a complex interplay between several biochemical and chemical pathways, further increasing the number and combinatory complexity of odorous molecules being formed. This book section comprises contributions that compile numerous substance classes and their structural specifics, primarily in view of those that are of high importance to humans. Moreover, current knowledge of the most prominent pathways involved in their formation is provided, linking different mechanistic routes to present a fundamental understanding of how odorants come to exist in our world.

2. Biosynthesis of Plant-Derived Odorants

Matthias Wüst

Plants produce thousands of structurally diverse volatile signal compounds to attract pollinating insects and seed dispersing animals. These compounds are often perceived by humans as a specific fruit or vegetable aroma. Many of these volatiles serve also as defense substances against fungi, bacteria, viruses, and herbivores. The knowledge of precursors and pathways leading to the formation of volatiles in fruits and vegetables has considerably progressed during the last years because of the use of molecular and biochemical techniques. In vitro characterization of the heterologously expressed enzymes has helped clarify the pathways of volatile formation. This chapter will, therefore, provide an overview of biosynthetic sequences and construction mechanisms that are illustrated in most cases using detailed reaction schemes. The various compounds are predominantly ordered according to the biosynthetic pathway that is used in plants to synthesize them and are grouped into carbohydrate-, lipid-, and amino-acid-derived odorants, terpenoids, and glycosidically bound odorants.

2.1 Biosynthesis of Plant-Derived Odorants

The following chapter gives an overview on the biosynthesis of odorants, the metabolic sequences leading to various selected classes of plant natural products that can be perceived by humans due to their volatility and odor activity. Various odorants are predominantly ordered according to the biosynthetic pathway that is used in planta to synthesize them – a concept that has been adopted from several successful textbooks on natural product chemistry and biochemistry [2.1, 2]. Special emphasis was put on biosynthetic sequences and construction mechanisms that are illustrated in most cases using detailed reaction schemes. The molecular biology of the enzymes that catalyze these reactions, plant physiological aspects, and genetic engineering of biosynthetic pathways are clearly not within the scope of this chapter. Nevertheless, where appropriate, some remarks and references on these topics are given in the text, which allow the interested reader to gain more insight into these quickly developing fields of research.

2.1.1 Biological Functions of Plant-Derived Odorants

Plants produce thousands of structurally diverse volatile signal compounds to attract pollinating insects and seed dispersing animals and mediate interactions with other plants. Many of these volatiles serve also as defense substances against fungi, bacteria, viruses, and herbivores and are stored in specialized tissues like glandular trichomes or oil ducts [2.6]. Indeed, from a plant's point of view, human beings are nothing else than seed dispersers or herbivores that are able to perceive these compounds as a specific fruit or vegetable aroma. More recent studies have shown that some of these volatiles

Table 2.1 Groups of plant secondary metabolites (after [2.5])

Type of secondary metabolite[a]	Approximate number of known structures[b]
Alkaloids	21 000
Terpenoids, all classes	22 000
Monoterpenes (C_{10})	2500
Sesquiterpenes (C_{15})	5000
Diterpenes (C20)	2500
Triterpenes, steroids, saponins (C_{30}, C_{27})	5000
Tetraterpenes (C40)	500
Non-protein amino acids	700
Amines	100
Cyanogenic glycosides	60
Glucosinolates	100
Alkamides	150
Lectins, peptides, polypeptides	2000
Flavonoids, tannins	5000
Phenylpropanoids, lignin, coumarins, lignans	2000
Polyacetylenes, *fatty acids*, waxes	1500
Polyketides	750
Carbohydrates, organic acids	200

[a]Types in **bold** contain a large number of volatiles; types in *italic* serve as precursors for volatiles
[b]The Dictionary of Natural Products on DVD [2.4] contains more than 230 000 compounds contained in over 68 000 entries. An entry may contain variants and derivatives. Variants may include stereoisomers, for example (*R*)-form, *endo*-form; members of a series of natural products with closely related structures such as antibiotic complexes. Derivatives may include hydrates, complexes, salts, classical organic derivatives, substitution products and oxidation products etc.

also function as signal molecules in tritrophic plant-herbivore–carnivore interactions. The emitted volatiles may attract the herbivore's enemies, such as parasitoids or predators, which actively reduce the number of feeding herbivores [2.7]. This has often been termed as *plant's cry for help*.

Table 2.2 Common abbreviations for cofactors and substrates

ACP	Acyl carrier protein
ADP	Adenosine diphosphat
AMP	Adenosine monophosphat
Ara	Arabinose
ATP	Adenosine triphosphate
B	General base
CDP	Cytidine diphosphate
CMP	Cytidine monophosphate
CoA	Coenzyme A in structures
CoQ	Coenzyme Q (ubiquinone)
CTP	Cytidine triphosphat
Cys	Cysteine
Cyt	Cytochrome
DMAPP	Dimethylallyl diphosphate (pyrophosphate)
Enz	Enzyme
FAD	Flavin adenine dinucleotide (oxidized form)
FADH2	Flavin adenine dinucleotide (reduced form)
FMN	Flavin mononucleotide (oxidized form)
FMNH2	Flavin mononucleotide (reduced form)
FPP	Farnesyl diphosphate (pyrophosphate)
Fru	Fructose
Gal	Galactose
GF	Green fluorescent proteine
GFPP	Geranylfarnesyl diphosphate (pyrophosphate)
GGP	Geranylgeranyl diphosphate (pyrophosphate)
Glc	Glucose
Gln	Glutamine
Glu	Glutamate
GPP	Geranyl diphosphate (pyrophosphate)
GSH	Reduced glutathion
GSSG	Oxidized glutathione
HA	General acid
HMG-CoA	Beta-hydroxy-beta-methylglutaryl coenzyme A
HSCoA	Coenzyme A
IPP	Isopentenyl diphosphate (pyrophosphate)
Met	Methionine
NAD	Nicotinamide adenine dinucleotide (oxidized form)
NADH	Nicotinamide adenine dinucleotide (reduced form)
NADP	Nicotinamide adenine dinucleotide phosphate (oxidized form)
NADPH	Nicotinamide adenine dinucleotide phosphate (reduced form)
NPP	Neryl diphosphate (pyrophosphate)
P_i	Inorganic orthophosphate
P	Phosphate in structure
PEP	Phosphoenolpyruvate
PLP	Pyridoxal phosphate
PP_i	Inorganic pyrophosphate
PP	Pyrophosphate in structure
Rha	Rhamnose
SAM	*S*-adenosyl methionine
TPP	Thiamine pyrophosphate
UDP	Uridine diphosphate
UDP-gal	Uridine diphosphate galactose
UDP-gluc	Uridine diphosphate glucose
UMP	Uridine monophosphate
UTP	Uridine triphosphate
Xyl	Xylose

2.1.2 Primary and Secondary Metabolism

Most of the odorants described in this chapter are so-called secondary metabolites derived from building blocks that are generated by the fundamental processes in primary metabolism like glycolysis, Krebs cycle, pentose phosphate cycle, and others. These fundamental reaction sequences are not shown in detail in this chapter with the exception of the methylerythritol phosphate (MEP) pathway, which is surprisingly often not yet discussed in general biochemistry textbooks. As opposed to plant primary metabolites, plant secondary metabolites occur in a very high structural diversity as illustrated in Table 2.1. Several structural types of secondary metabolites are volatile as such (monoterpenes), while others serve as precursors that generate volatiles after enzymatic modification or degradation (glucosinolates). Despite this diversity, the number of corresponding biosynthetic pathways is surprisingly rather restricted. Figure 2.1 gives an overview on the metabolic pathways, leading to the biosynthesis of the various groups of volatile compounds that are shown in gray-shaded ovals and that are discussed in this chapter.

In the following presented reaction schemes, nonionized acids are usually depicted to simplify structures and to eliminate the need for counter ions. Likewise, amino acids are shown in unionized form, and not as zwitterions. The abbreviations **P** and **PP** represent the unionized phosphate and diphosphate group, respectively. Further common abbreviations for cofactors and certain substrates in enzymatic reactions that are used throughout the text are shown in Table 2.2.

2.2 Constitutive Biosynthetic Pathways

2.2.1 Carbohydrate-Derived Odorants

Carbohydrate-derived odorants, where the carbohydrate molecule is a direct precursor and is incorporated with the retention of the carbon chain without prior degradation, are very rare. The most prominent examples are furanones like furaneol (4-hydroxy-2,5-dimethyl-3(2*H*)-furanone – HDMF) and methoxyfuraneol (2,5-dimethyl-4-methoxy-3(2*H*)-furanone – DMMF) that are key aroma compounds in strawberry and pineapple fruits. HDMF and DMMF occur as natural racemic mixtures due to their oxo-enol structure and the resulting keto-enol tautomerism. The enantiomers smell different with either caramel-like to fruity-sweet odor notes ((*R*)-(+) enantiomers) or extremely weak to lactone-, coumarin-like ((*S*)-(−) enantiomers) [2.8]. D-Fructose-1,6-diphosphate is the biogenetic precursor of these substances and delivers the carbon chain of HDMF and DMMF [2.9]. The biosynthesis of both molecules is outlined in Fig. 2.2. The reaction sequence includes the intermediate 4-hydroxy-5-methyl-2-methylen-3(2*H*)-furanone (HMMF), and the products 4-hydroxy-2,5-dimethyl-3(2*H*)-furanone (HDMF) and 2,5-dimethyl-4-methoxy-3(2*H*)-furanone (DMMF). The enzymes so far characterized are Fragaria x ananassa enon oxidoreductase (FaEO) and Fragaria x ananassa *O*-methyltransferase (FaOMT).

Hexose diphosphate is converted by an as-yet unknown enzyme to 4-hydroxy-5-methyl-2-methylen-3(2*H*)-furanone (HMMF), which serves as a substrate for an enone oxidoreductase (FaEO), yielding furaneol [2.11, 12]. An *O*-methyltransferase converts furaneol to finally yield methoxyfuraneol [2.13]. It is interesting to note that HDMF is also generated in heated foods by a purely chemical reaction in the course of the Maillard reaction, and it has been suggested that this results in these foods appearing particularly attractive [2.14].

2.2.2 Terpenoids

Many of the compounds in plant-derived essential oils are biosynthesized from the *active isopren* C_5 units dimethylallyl diphosphate (DMAPP) and isopentenyl

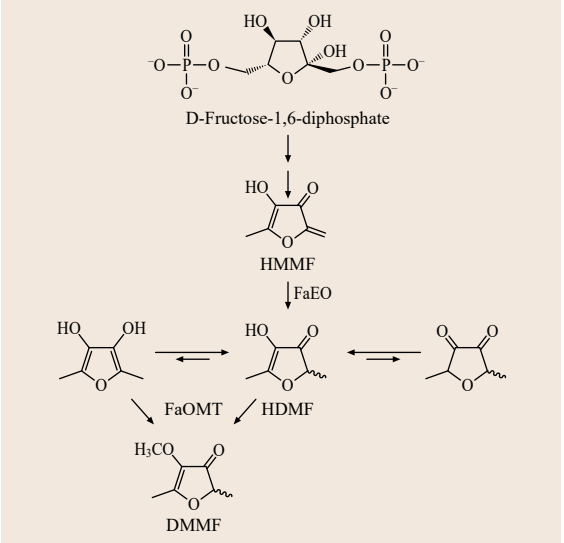

Fig. 2.2 Biosynthesis of the 3(2*H*)-furanones in strawberry (after [2.10])

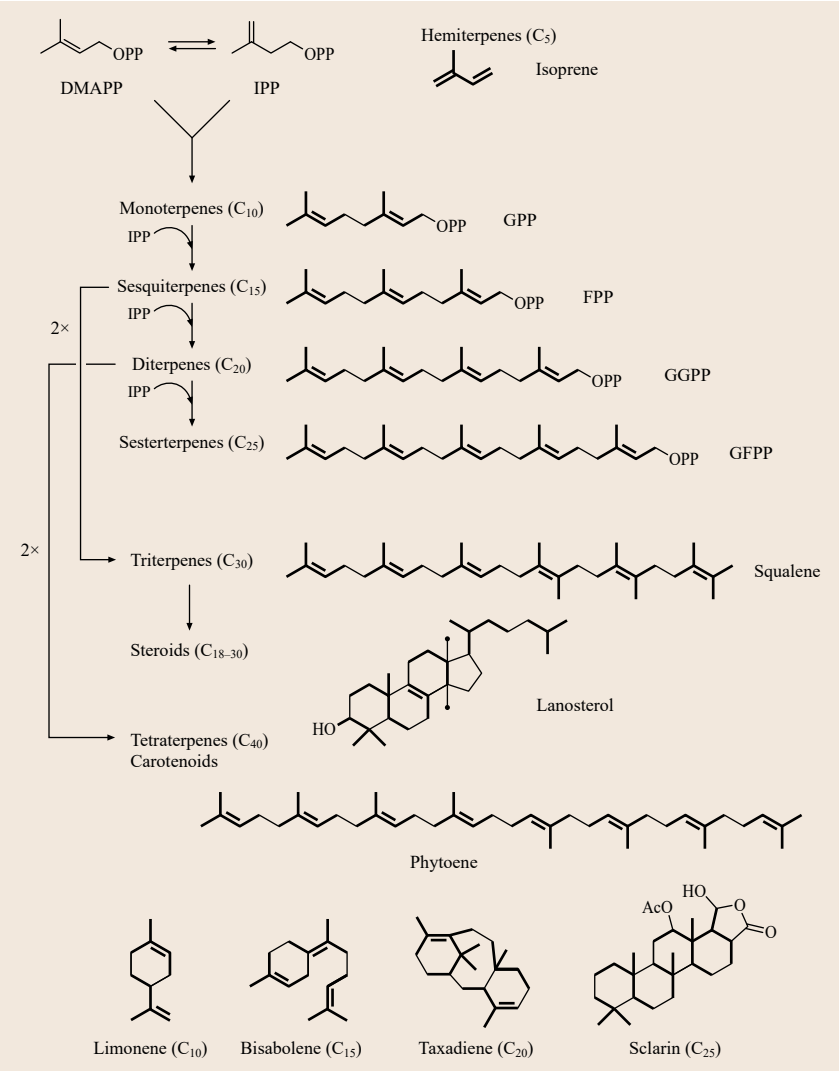

Fig. 2.3 Overview of the different terpenoid skeletons generated by head to tail addition of isoprene units. For each group the structure of a typical member is given. During the biosynthesis of lanosterol two Wagner–Meerwein rearrangements are observed so that two isoprene units are disassembled

diphosphate (IPP) and, thus, belong to the most diverse families of natural products – the terpenoids [2.15], also referred to as isoprenoids (Table 2.1). Essential oil-producing plants, among them are many herbs and citrus fruits, accumulate terpenoids in specialized tissues, such as glandular trichomes, oil ducts, or secretory cavities [2.16]. Terpenoids in low concentrations are also found in fruits and vegetables that do not accumulate essential oils. Nevertheless, they often contribute to the specific fruit and vegetable aroma due to their low-odor threshold values [2.17]. Terpenoids are classified according to the number of incorporated C_5-units and are distinguished into hemiterpenes (C_5), monoterpenes (C_{10}), sesquiterpenes (C_{15}), diterpenes (C_{20}), sesterterpenes (C_{25}, triterpenes (C_{30}), and tertraterpenes (C_{40}) (Fig. 2.3). Most of the volatile terpenoids are mono- and sesquiterpenes with only few diterpenes. The biogenetic precursor for all monoterpenes is geranyl diphosphate and for all sesquiterpenes (*E*, *E*)-farnesyl diphosphate, although exceptions from these rules have been described recently for the biosynthesis of terpenes in glandular trichomes of tomato [2.20]. Formally, all terpenoids are obtained by a head to tail addition of isoprene units (biogenetic isoprene roule by Ružička; 1939 Noble Prize winner in Chemistry). The biogenetic precursors of these isoprene units are IPP and DMAPP that are substrates for short-chain prenyltransferases, which produce geranyl diphosphate (GPP), farnesyl diphosphate (FPP), geranyl geranyl diphosphate (GGPP), and geranyl farnesyl diphosphate (GFPP) (Fig. 2.3) [2.21]. In plants, two independent routes are employed for the biosynthesis of IPP and DMAPP: the well-known

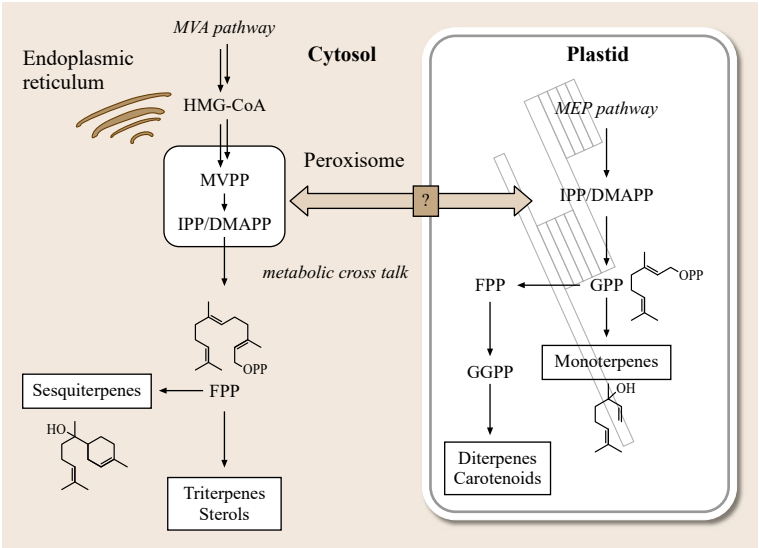

Fig. 2.4 Simplified scheme for the compartmentalization of terpene biosynthesis in higher plants. Metabolic cross talk is mediated by a yet unidentified metabolite transporter (after [2.18, 19]). IPP: isopentenyl diphosphate; DMAPP: dimethylallyl diphosphate; FPP: farnesyl diphosphate; GGPP: geranylgeranyl diphosphate; HMG-CoA: 3-hydroxy-3-methylglutaryl coenzyme A; MVPP: 5-diphosphomevalonat

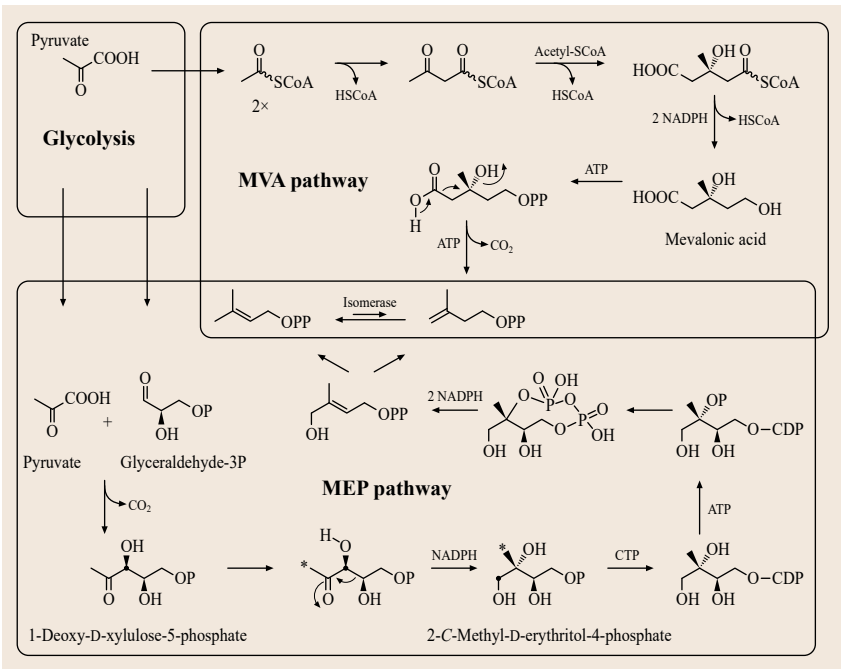

Fig. 2.5 Biosynthetic pathways to IPP/DMAPP in higher plants

cytosolic/peroxisomal mevalonic acid (MVA) pathway and the newly discovered plastidial methylerythritol phosphate (MEP) pathway [2.22].

In plant cells, both pathways are localized in different compartments. However, this compartmentalization is not absolute and some intermediates can be exchanged across the plastid membrane – a phenomenon that has been termed *metabolic cross talk* (Fig. 2.4). Insightful experiments with isotope labeled pathway-specific precursors and green fluorescent protein (GFP) labeled terpene synthases (TPS) have shown that the biosynthesis of monoterpenes is located in plastids and fueled by the MEP pathway, whereas the biosynthesis of sesquiterpenes is located in the cyctosol and is fueled by the MVA pathway and under certain conditions also by the MEP pathway via the above-mentioned metabolic crosstalk [2.23]. Exceptions from these rules could be demonstrated by feeding experiments using deuterium-labeled precursors and/or enzyme localization experiments using GFP fusion techniques for the

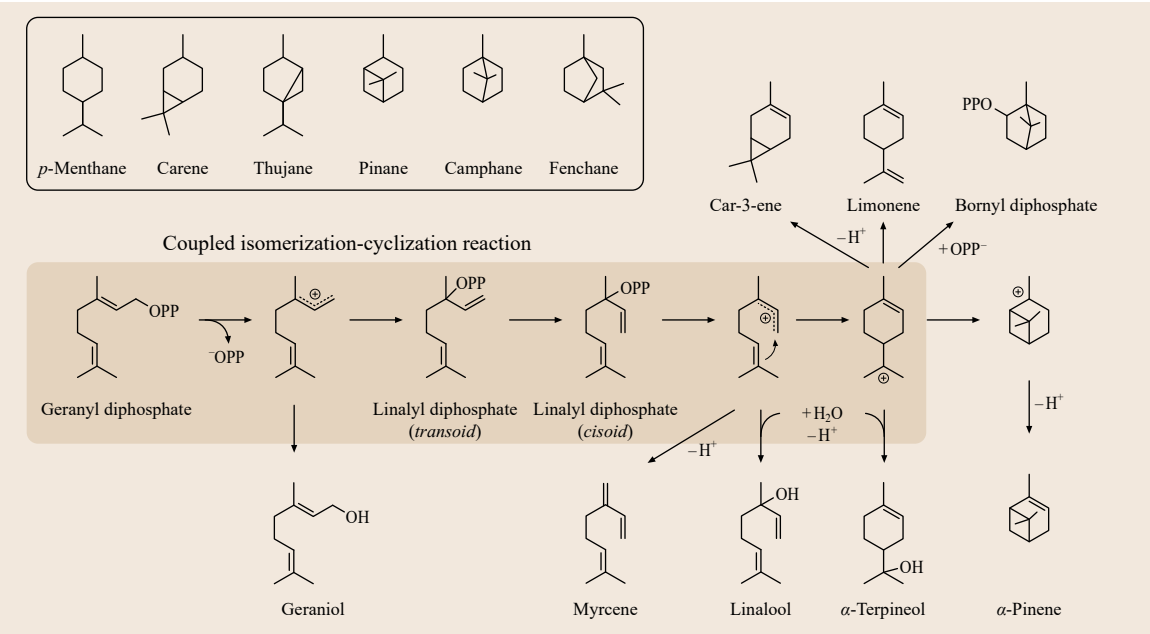

Fig. 2.6 Biosynthesis of acyclic (geraniol, linalool, myrcene), monocyclic (limonene, α-terpineol) and bicyclic (car-3-ene, α-pinene, bornyl diphosphate) monoterpenes from geranyl diphosphate. Cyclic monoterpenes are generated by TPS that share a coupled isomerization–cyclization reaction sequence. Carbon skeletons that are often found in plant-derived monoterpenes are shown in a box in the *upper left corner* of the figure

biosynthesis of monoterpenes in raspberry and strawberry fruits [2.24–26].

Figure 2.5 shows the reaction sequences of both pathways. The reduction of HMG-CoA to MVA has the highest degree of control over the metabolic flux through the MVA pathway. For the MEP pathway, it is now generally accepted that 1-deoxy-D-xylulose-5-phosphate synthase and 1-hydroxy-2-methyl-2-butenyl-4-diphosphate reductase, and to some extent 1-deoxy-D-xylulose-5-phosphate reductoisomerase, are the key enzymes that control flux [2.27].

Monoterpenes

Monoterpenes are generated by terpene synthases (TPS) that are capable of generating acyclic, monocyclic, and bicyclic products. The TPS gene family is a mid-size family, with gene numbers ranging from approximately 20 to 150 in sequenced plant genomes [2.28]. X-ray crystal structures of a limonene synthase from *Mentha spicata* [2.29] and a bornyl diphosphate synthase from *Salvia officinalis* [2.30] are now available and deliver a detailed picture of their reaction mechanisms. The reaction of all TPS starts with the stereoselective binding of GPP (or in some cases of NPP) at the active site followed by metal–ion-dependent ionization of the diphosphate ester to generate linalyl diphosphate (Fig. 2.6). A second ionization yields finally the universal monocyclic intermediate, the α-terpinyl cation, which can further react by deprotonation or nucleophilic capture of water following hydride shifts and other rearrangements. The formation of the acyclic monoterpenes geraniol, linalool, and myrcene might proceed either via the geranyl cation or via the linalyl cation.

The generated monoterpenes can be further modified by, for example, hydroxylations that are often mediated by cytochrome P450 monooxygenases [2.31]. The biosynthesis of the *p*-menthane-type monoterpenes menthone and carvone in glandular trichomes of peppermint and spearmint, respectively, is exceptionally well investigated and all enzymes of the respective pathways have been cloned and characterized (Fig. 2.7), which has facilitated the development of metabolic engineering strategies [2.32]. The regio-selectivity of the different cyctochrome P450 monooxygenases plays thereby a key role and determines which carbon atom at the limonene precursor is hydroxylated [2.33].

Sesquiterpenes

The diversity of sesquiterpene skeletal types is considerably greater than that of monoterpene types due to more double bonds and the longer, more flexi-

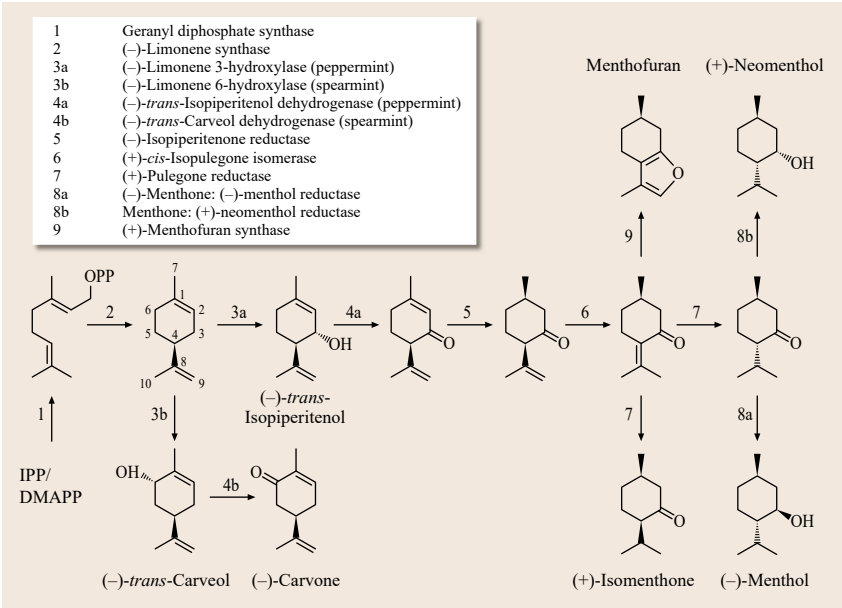

Fig. 2.7 Biosynthesis of (−)-carvone and and (−)-menthol in spearmint and peppermint, respectively

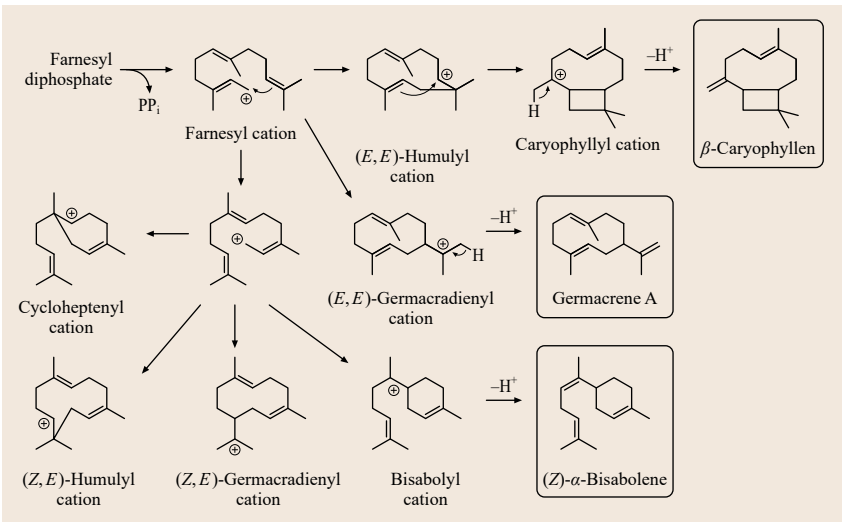

Fig. 2.8 A scheme of representative sesquiterpene cyclization reactions leading to volatile sesquiterpene hydrocarbons

ble chain in FPP. The cyclizations that are catalyzed by TPS as well may occur from the distal double bond to generate either the (*E*,*E*)-humulyl cation or the (*E*,*E*)-germacradienyl cation. Isomerization to the nerolidyl diphosphate permits the formation of the bisabolyl cation, the cycloheptanyl cation, the (*Z*,*E*)-germacradienyl cation, and the (*Z*,*E*)-humulyl-cation (Fig. 2.8) [2.34]. Further cyclizations, hydride shifts, methyl migrations, and/or Wagner–Meerwein rearrangements may occur prior to the termination of the reaction by deprotonation or nucleophile capture, thus producing a vast number of sesquiterpenoid carbon skeletons (over 80 skeletal types are currently known and used for structural sesquiterpene classification [2.35, 36]). One of the most unique traits of this enzyme class is their ability to convert FPP to diverse products during different reaction cycles. This property is found in nearly half of all characterized monoterpene and sesquiterpene synthases and may be attributed to the fact that the various reactive carbocationic intermediates can be stabilized in more than one way [2.37]. For example, the humulene synthase of grand fir (Abies grandis) generates 52 different sesquiterpenes [2.38]. Feeding experiments with deuterium-labeled precursors have shown that sesquiterpene biosynthesis in carrot roots and grape berry exocarp is supplied with IPP

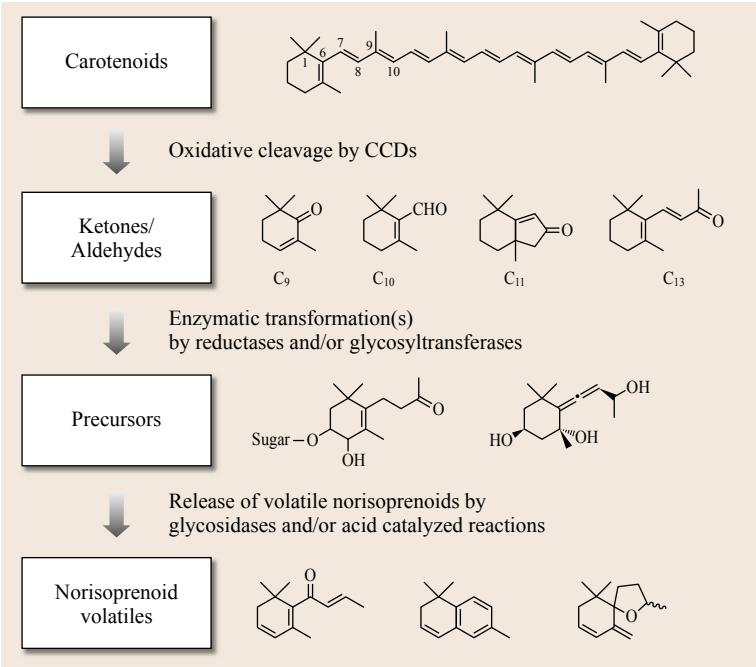

Fig. 2.9 Essential steps for the formation of carotenoid-derived volatiles (after [2.39])

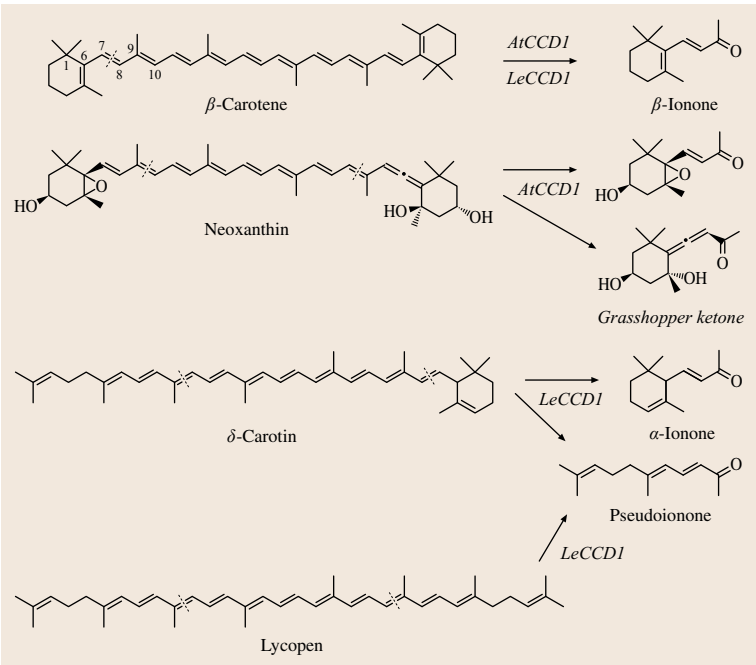

Fig. 2.10 Generation of the primary degradation products from different carotenoids by the action of carotenoid cleavage dioxygenases (CCDs) from tomato (*Solanum lycopersicum* – LeCCD1) and *Arabidopsis thaliana* (AtCCD1)

and DMAPP from both the MEP and the MVA pathway [2.40].

Norisoprenoids

The so-called norisoprenoids are volatiles that are generated from carotenoids by an oxidative cleavage that is followed by further enzymatic and nonenzymatic transformations. In most cases, the generation pathway consists of three essential steps [2.39] (Fig. 2.9). In the first step, the carotenoid is cleaved by the action of a so-called carotenoid cleavage dioxygenase (CCD). In the second step, the cleavage products

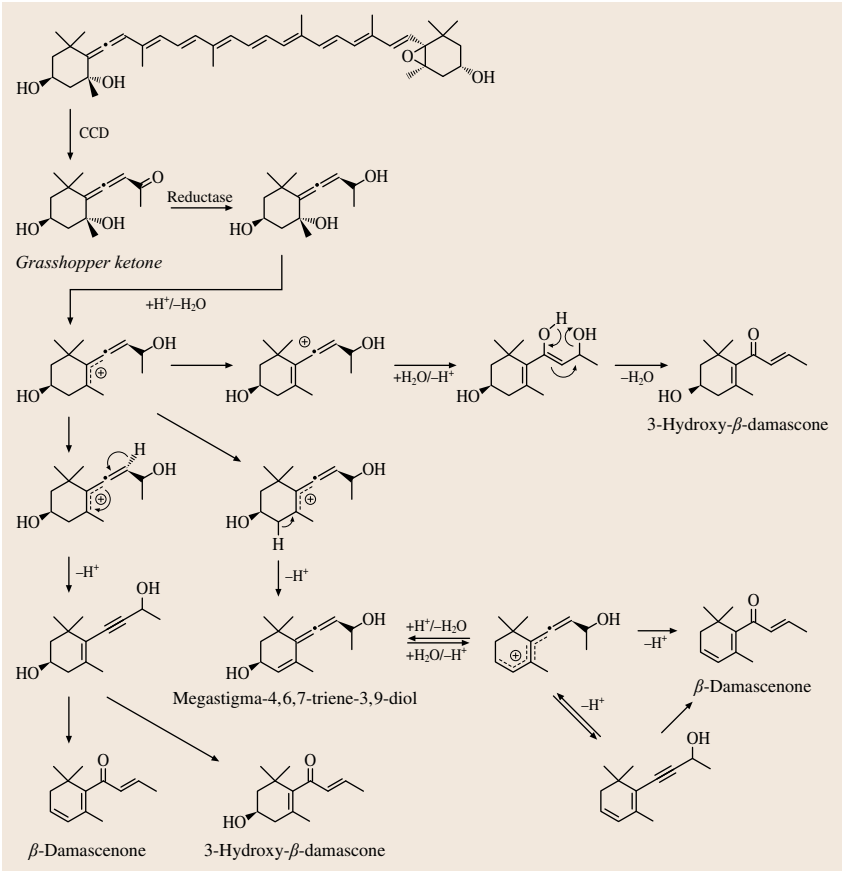

Fig. 2.11 Formation pathways of β-damascenone in grapes and wine starting from neoxanthin (after [2.39])

are further metabolized mainly by reductases and/or glucosyltransferases. In the third and last step, the volatile norisoprenoid is finally released by the action of a glycosidase and/or simply by acid catalyzed liberation.

In some cases, volatile norisoprenoids are directly obtained by the oxidative cleavage of carotenoids, α- and β-ionone (Fig. 2.10). In plants, CCDs are expressed in different tissues, such as roots, shoots, leaves, flowers, and fruits. Some of these CCDs show a rather broad spectrum of substrates and are capable of metabolizing structurally quite different carotenoids. CCD1 and CCD4 are the major families of carotenases found in fruits (so far functionally characterized: tomato, melon, grape, citrus, strawberry: CCD1; apple, peach: CCD4) [2.41]. Some reactions catalyzed by the CCD1 from tomato in comparison with the CCD1 from Arabidopsis are shown in Fig. 2.10.

Some of the norisoprenoids are powerful odorants with threshold values in the ppt-range and are, thus, key compounds for the aroma of several fruits and vegetables like tomato and watermelon [2.42]. Especially, C_{13}-norisoprenoids are important aroma contributors in both red and white wines [2.43], and their formation in grapes and wines has been extensively studied in the recent years [2.44]. The quite complex formation pathway of β-damascenone has been recently reviewed [2.45] and is illustrated in Fig. 2.11.

2.2.3 Fatty Acid Derived and Other Lipid-Derived Odorants

Fatty acids are biosynthesized from a plastidic pool of acetyl-CoA generated from pyruvate, the final product of the glycolysis. Fatty acids are stored in plants as triacylglycerides and are liberated by lipases before they act as direct precursors for various volatiles. In particular, the C_{18}-unsaturated fatty acids, linoleic and linolenic acid, are precursors for volatile straight chain alcohols, aldehydes, ketones, acids, esters, and lactones. They are found ubiquitously in the plant kingdom and are formed predominately by three processes: α-oxidaton, β-oxidation, and the lipoxygenase pathway [2.46].

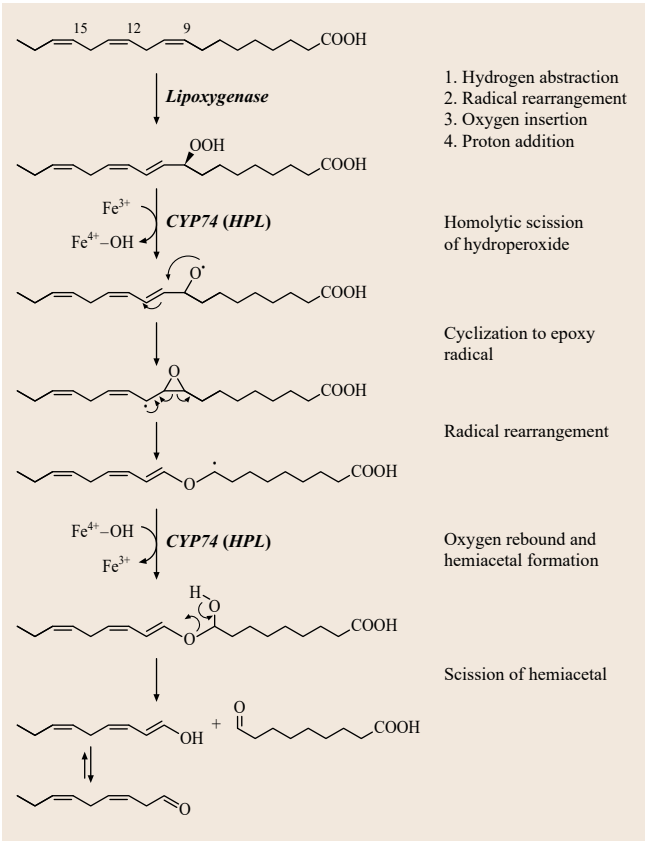

Fig. 2.12 Generation of an aldehyde and a ω-oxo acid from linolenic acid by the consecutive action of a type-1 9-lipoxygenase and a hydroperoxide lyase (HPL) ►

Lipoxygenase Pathway (In-Chain Oxidation)

The lipoxygenase pathyway (LOX pathway) is predominately active in green organs of plants in response to wounding, and it also gives rise to the formation of the so-called *green leaf volatiles* in fruits and vegetables, which are perceived as the characteristic *fresh green* aroma upon preparation in the kitchen or upon mastication. By the action of a nonheme, iron containing dioxygenase, the so-called lipoxygenase (LOX), unsaturated fatty acids are oxygenated regio- and enantioselectively to yield hydroperoxides [2.47]. Prerequisite is the presence of one or more (1*Z*,4*Z*)-pentadienoic moieties to yield the corresponding (1*S*,2*E*,4*Z*)-hydroperoxides that carry the hydroperoxy group either at position 9 or position 13 of the hydrocarbon backbone (9-LOX or 13-LOX) (Fig. 2.13). LOXs can be classified according to their subcellular localization: extraplastidial enzymes are designated as type 1-LOXs (ubiquitous cytosolic type-1 9-LOX and vacuole/lipid body type-1 13-LOX), and plastidial enzymes that harbor a chloroplast transit peptide are designated as type 2-LOXs (type 2-LOXs all belong to date to the subfamily of 13-LOXs) [2.48]. The generated hydroperoxides are substrates for hydroperoxide lyases (HPLs) that are enzymes of the cytochrome P450 family [2.49]. They catalyze in a multistep reaction sequence the homolytic isomerization of fatty acid hydroperoxides into short-lived hemiacetals that yield ultimately short-chain aldehydes and ω-oxo acids as scission products (Fig. 2.12) [2.51].

The short-chain aldehydes are further metabolized by isomerases and/or alcohol dehydrogenases to finally yield the so-called *green leaf volatiles* like (3E)-hexenol in olives [2.52]. Acyltransferases catalyze the formation

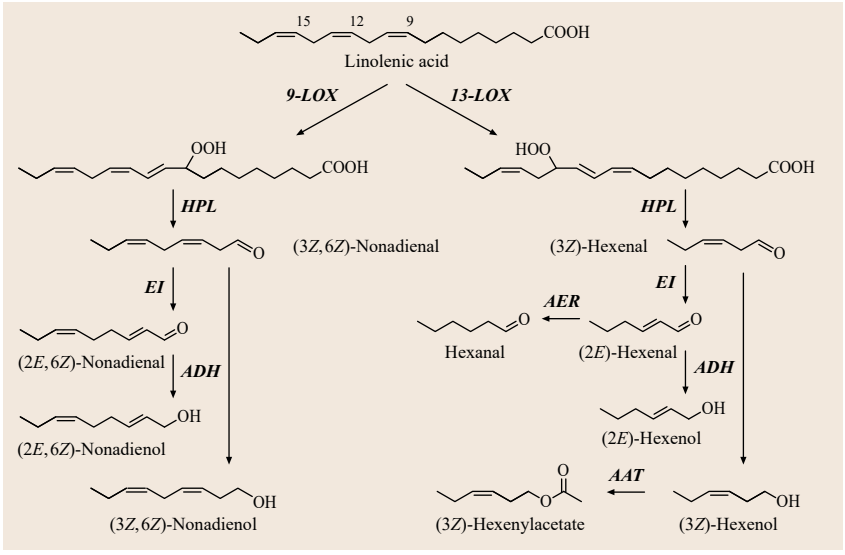

Fig. 2.13 Generation of linolenic acid-derived odorants (LOX: lipoxygenase; HPL: hydroperoxide lyase; EI: enal isomerase; AER: alkenal oxidoreductase; ADH: alcohol dehydrogenase; AAT: acetyl-CoA transferase) (after [2.50])

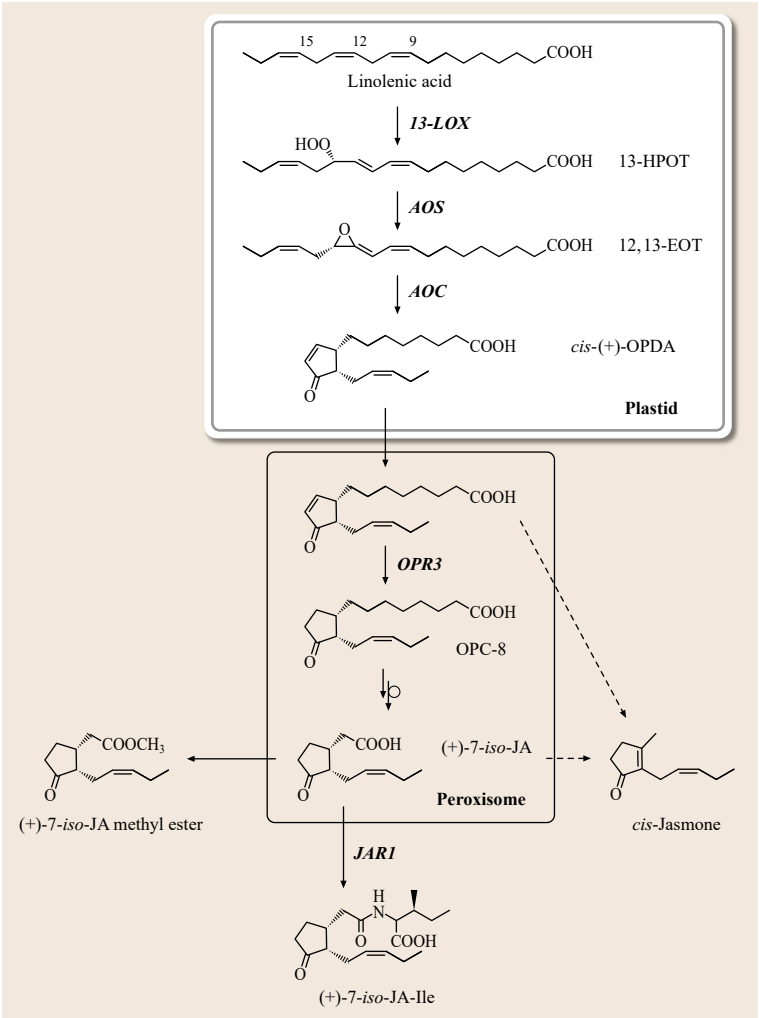

Fig. 2.14 Biosynthesis of jasmonic acid (JA)/ (+)-7-*iso*-jasmonoyl-L-isoleucine (JA-Ile) and further metabolites from linolenic acid. The biosynthetic route leading to the formation of *cis*-jasmone is still unclear as indicated by the broken arrows. AOC: allene oxide cyclase; AOS: allene oxide synthase; 12,13-EOT: 12,13(*S*)-epoxy-octadecatrienoic acid; 13-HPOT: (13*S*)-hydroperoxyoctadecatrienoic acid; JAR1: JA-amino acid synthetase; 13-LOX: 13-lipoxygenase; OPR3: OPDA reductase3; OPC-8: 3-oxo-2-(2-pentenyl)-cyclopentane-1-octanoic acid; *cis*-(+)-OPDA: *cis*-(+)-12-oxophytodienoic acid

of the corresponding esters and 2-alkenal reductases can reduce (2E)-hexenal to hexanal (Fig. 2.13).

Another branch of the LOX pathway gives rise to the formation of jasmonic acid (JA) and its derivatives [2.53] (Fig. 2.14). The key reaction is catalyzed by an allene oxide synthase that belongs to the CYP74 family and yields 12,13(S)-epoxy-octadecatrienoic acid [2.49]. β-Oxidation of the cyclization product 3-oxo-2-(2-pentenyl)-cyclopentane-1-octanoic acid yields finally JA. Jasmonates are important regulators in plant responses to biotic and abiotic stresses as well as to development [2.54]. Cis-jasmone (CJ) is a volatile compound and represents the main constituent of the floral bouquet of different plants thereby attracting insect pollinators. It is emitted in response to herbivory, application of insect oral secretions, or JA treatment. However, the biosynthetic route leading to the formation of CJ is still unclear. JA methyl ester is the main component of the scent of jasmine flowers.

α- and β-Oxidation

Fatty acids of short- and intermediate-chain length are generated in the course of fatty acid degradation by α- or β-oxidation. β-Oxidation in plants occurs primarily in the peroxisomes [2.55] and the reaction sequence is now well established [2.56]. One reaction cycle results in the successive removal of C_2-units (acetyl-CoA) yielding the C_{n-2} carboxylic acid. However, volatile acids can also be generated by de novo synthesis and hydrolysis of the conjugate between the acid moiety and the acyl carrier protein, that is, the acyl acyl carrier protein (acyl ACP), during fatty acid biosynthesis. Alcohols, esters, and aldehydes can be generated as further volatile metabolites by the action of alcohol dehydrogenases, alcohol acyl transferases,

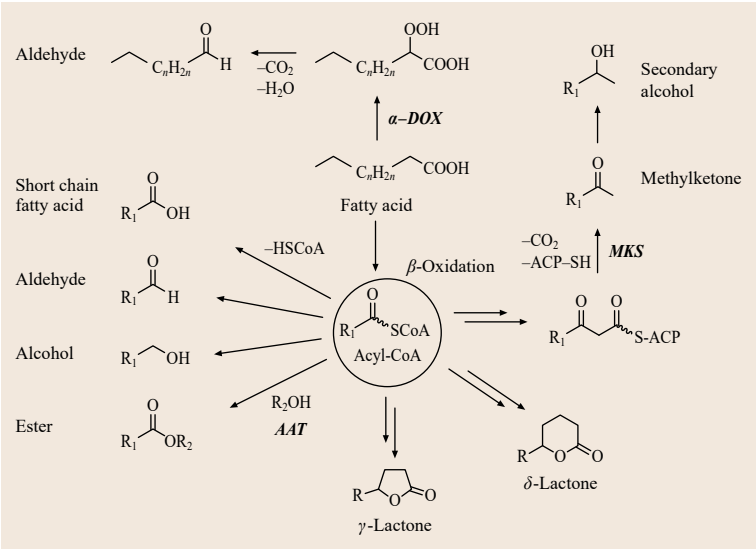

Fig. 2.15 Biosynthesis of volatiles from fatty acids. AAT, alcohol acyl transferase; MKS, methylketone synthase; ACP, acyl carrier protein; α-DOX, alpha-dioxygenase

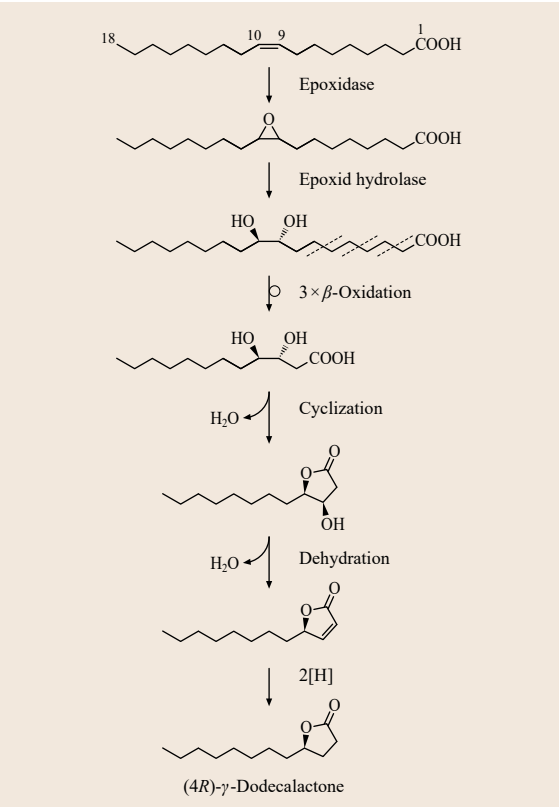

Fig. 2.16 Proposed biosynthesis of (4*R*)-γ-dodecalactone in ripening fruits (after [2.57]). The sequence was previously established by administration of deuterium labeled precursors to ripening strawberries and peaches (after [2.58])

or α-dioxygenases (α-DOXs) (Fig. 2.15). α-DOXs catalyze the formation of 2-hydroperoxy carboxylic acids that are unstable and yield the C_{n-1} aldehyde as product [2.59]. α-DOX from Arabidopsis resembles a *b*-type cytochrome, although with much more restricted access to the heme moiety. Methylketones are generated by hydrolysis and subsequent decarboxylation of β-ketoacyl ACPs [2.60] and are assumed to be precursors of aroma-active secondary alcohols like 2-pentanol and 2-heptanol in passion fruits [2.61].

Other important volatiles that are generated from fatty acids are alkanolides, which have 5- or 6-ring heterocyclic lactone structures, the so-called γ- and δ-lactones. Despite their importance for many fruit flavors, their biosynthesis in plants remained up to now largely obscure: no enzymes or genes associated with their biosynthesis have been characterized. However, it is generally accepted that all lactones originate from their corresponding 4- or 5-hydroxy carboxylic acids by nonenzymatic or AAT-catalyzed cyclization. Labeling studies with fatty acid epoxides and diols have shown that these precursors are efficiently incorporated into lactones in a stereoselective manner [2.57, 58] (Fig. 2.16). Expression profiling of genes and an integrative *omics* approach have recently identified new candidate genes that potentially impact aroma volatiles in peach fruit [2.62, 63].

2.2.4 Amino Acid-Derived Odorants

Branched chain and aromatic amino acids, cysteine and methionine, or intermediates in their biosynthesis, are very often precursors of odorants that are highly

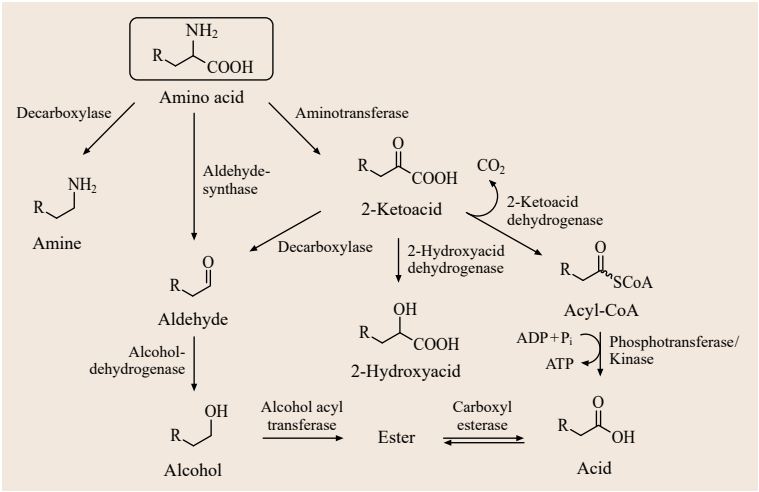

Fig. 2.17 Biosynthesis of amino acid-derived odor compounds (after [2.50])

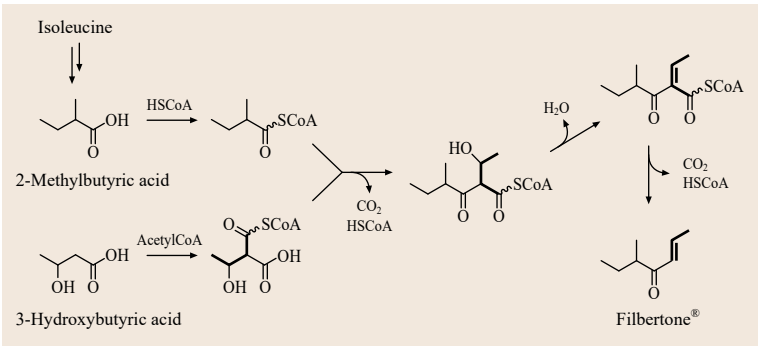

Fig. 2.18 Proposed biosynthesis of filbertone in hazelnuts

abundant in floral scents and fruit and vegetable aromas [2.17]. Especially important are branched-chain volatiles, derived from branched-chain amino acids, such as isoamyl acetate (banana), 2-methy-butyl acetate (apple) and methyl 2-methyl butanoate (prickly pear). The biosynthesis of these volatiles in plants is believed to proceed in a similar way to that found in bacteria and yeast, where these pathways have been studied more extensively [2.64].

Acids, Amines, Alcohols, Aldehydes, and Esters

The principal pathways to amino acid-derived odor compounds are shown in Fig. 2.17. The operation of these biosynthetic pathways is supported by numerous feeding experiments using intact plant tissues where the addition of intermediates enhanced the concentration of specific aroma compounds [2.65, 66]. An alcohol acyl transferase (AAT) from apple (cv. Royal Gala), MpAAT1, produces esters involved in an apple fruit flavor [2.67]. The recombinant enzyme can utilize a range of alcohol substrates from short-to-medium straight chain (C3–C10), branched chain, aromatic and terpene alcohols. A genomics approach has revealed that aroma production in an apple via the isoleucine degradation pathway is controlled by ethylene predominantly at the step in ester biosynthesis catalyzed by MpAAT1 [2.68]. In melon fruit tissues, the catabolism of amino acids into aroma volatiles can initiate through a transamination mechanism by branched chain amino transferases, rather than decarboxylation or direct aldehyde synthesis, as has been demonstrated in other plants [2.69]. A second route in melon apparently involves the action of an L-methionine-γ-lyase activity, releasing methanethiol, a backbone for the formation of thiol-derived aroma volatiles [2.70]. Exogenous L-methionine also generates nonsulfur volatiles by further metabolism of α-ketobutyrate, a product of L-methionine-γ-lyase activity. α-Ketobutyrate is further metabolized into L-isoleucine and subsequently other important melon volatiles, including nonsulfur-branched and straight-chain esters. In tomato fruits, the catabolism of branched chain amino acids supports respiration but not synthesis of volatiles, which are rather generated from keto acids as likely precursors [2.71].

One of the key aroma compounds in hazelnuts is 5-methyl-2-hepten-4-one (filbertone) whose biosynthesis

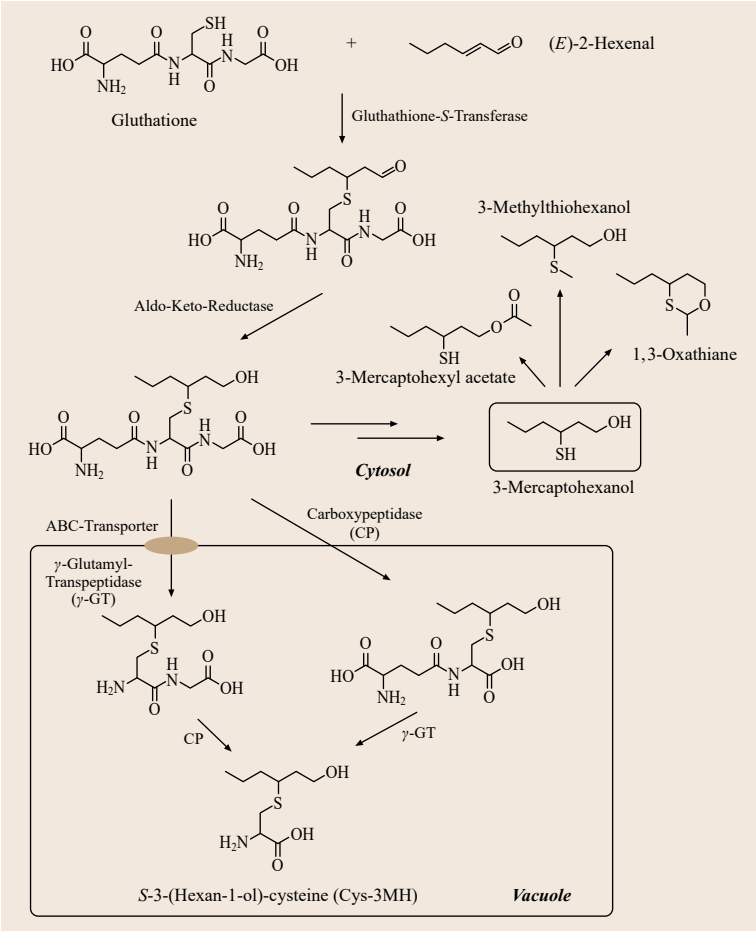

Fig. 2.19 Hypothetical pathway for the biosynthesis of 3-mercaptohexanol conjugates and their derivatives (after [2.73]). ABC-transporter, ATP binding cassette transporter

is believed to involve isoleucine as a precursor [2.72] (Fig. 2.18). Analysis of the volatile compounds during ripening and storage showed that the formation of methyl-branched ketones starts as soon as branched chain amino acids are catabolized. However, knowledge about genes and enzymes involved in this postulated pathway is still missing.

Aliphatic Thiols (Varietal Thiols)

Key compounds in explaining tropical fruit flavor like yellow passion fruit scent are volatile thiols. These molecules are generated from nonvolatile precursors like *S*-glutathionylated and *S*-cysteinylated conjugates, the latter being a degradation product of the former. A prominent example is 3-mercaptohexan-1-ol (3MH) that is a potent odorant in passion fruits [2.73] and certain grape varieties like Sauvignon Blanc and Petite Arvine [2.74]. It is believed that the first step of the precursor biosynthesis is the glutathionylation of (*E*)-2-hexenal, which is a product of the LOX-mediated fatty acid degradation [2.75]. After the reduction of the aldehyde moiety, the conjugate is gradually degraded by peptidases to yield the *S*-cysteinylated conjugate, which is stored in the vacuole or is further metabolized by a lyase that liberates 3MH (Fig. 2.19). The free thiol can undergo further transformations like esterification and formation of oxathians. However, no enzymes or genes associated with the biosynthesis of these metabolites have been characterized so far. Environmental stress enhances the biosynthesis of flavor precursors, *S*-3-(hexan-1-ol)-glutathione and *S*-3-(hexan-1-ol)-L-cysteine, in grapevine through glutathione *S*-transferase activation [2.76].

Phenylpropanoid/Benzoid Derivatives

Phenylpropanoid and benzoid compounds originate from the aromatic amino acid phenylalanine that is in turn generated by the shikimate/arogenate pathway [2.77]. The first committed step is the generation of cinnamic acid by the action of a phenylalanine ammonia lyase (Fig. 2.20). The formation of benzoids (C_6–C_1) requires shortening of the propyl side chain,

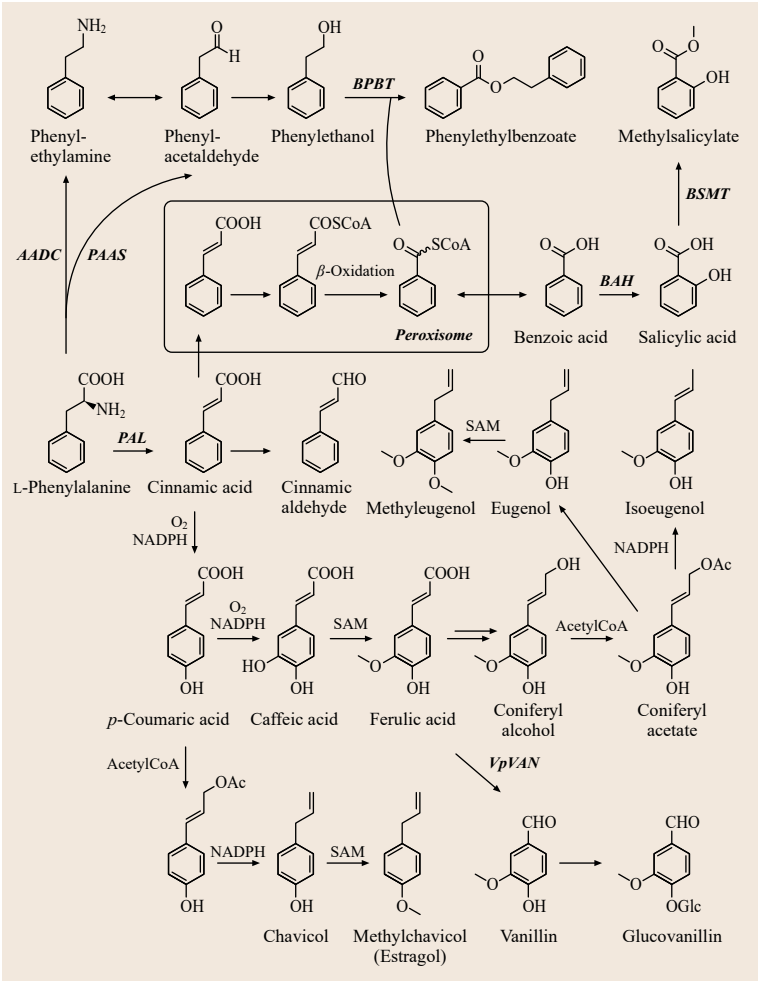

Fig. 2.20 Biosynthesis of benzoid and phenylpropanoid odorants (after [2.64]). AADC: aromatic amino acid decarboxylase; BAH: benzoic acid 2-hydroxlase; BPBT: benzoylCoA:benzylalcohol/2-phenylethanol benzoyltransferase; BSMT: benzoic acid/salicylic acid carboxyl methyltransferase; PAAS: phenylacetaldehyd synthase; PAL: phenylalanine ammonia lyase

which takes place in peroxysomes by the β-oxidation sequence [2.78]. Another non-β-oxidative reaction sequence to benzoic acid seems possible [2.79], but its biochemical steps are still in question. Volatile phenylpropenes (C_6–C_3) like eugenol and estragol require the elimination of the oxygen functionality at C-9 position, which is achieved by the reduction of the corresponding acetates (Fig. 2.20). Methyl anthranilate is generated in Concord grapes from anthranilic acid, which is an intermediate of tryptophan biosynthesis, by the action of an anthranilate-CoA ligase and a methanol acyltransferase [2.80]. However, herbivore-induced SABATH methyltransferases of maize that methylate anthranilic acid using *S*-adenosyl-L-methionine have been recently cloned and characterized [2.81]. The SABATH family is named after the first identified enzymes (SAMT, BAMT and Theobromine synthase) in this family.

Vanillin (4-hydroxy-3-methoxybenzaldehyde) is the most widely used flavor compound in the world. It is present as glucovanillin in the green pods of vanilla and is released only after fermentation, called *curing*, when the glucoside is hydrolyzed by an endogenous glucosidase in vanilla pods. Tracer experiments using ^{14}C-labeled precursors suggest that the biosynthetic pathway for vanillin is p-coumaric acid → feruclic acid → vanillin → glucovanillin (Fig. 2.20) [2.82]. A single enzyme designated vanillin synthase (VpVAN) catalyzes direct conversion of ferulic acid into vanillin.

Heterocyclic Odorants

Methoxypyrazines (MPs) are potent odorants and are responsible for the distinctive green and earthy aroma of some vegetables like 2-methoxy-3-isobutylpyrazine (IBMP) in bell pepper. 2-Methoxy-3-isopropylpyrazine (IPMB) is found in raw potatoes and peas [2.17]. The *vegetative* sensory attribute of Sauvignon Blanc and Cabernet Sauvignon wines is also due to the presence of MPs [2.84]. Little work has been done so far in de-

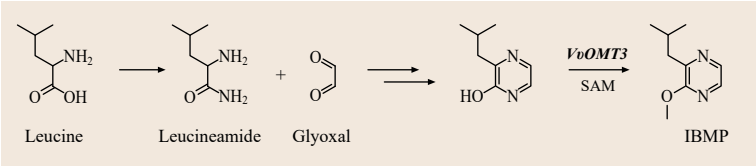

Fig. 2.21 Proposed pathway for 2-methoxyisobutylpyrazine (IBMP) biosynthesis (after [2.83])

termining the pathways of MP biosynthesis. A number of pathways have been proposed, which generally begin with an amino acid (leucine for IBMP or valine for IPMP) and an unknown 1,2-dicarbonyl compound leading to the formation of a 3-alkyl-2-hydroxypyrazine (HP) (Fig. 2.21). Recently, it could be shown that the final step of the methylation of HP is catalyzed by an *O*-methyltransferase that uses *S*-adenosyl methionin (SAM) as a methyl group donor [2.85, 86]. Interestingly, the corresponding gene is not expressed in the fruit of Pinot varieties, which lack IBMP, but is expressed in Cabernet Sauvignon at the time of accumulation of IBMP in the fruit [2.83, 88].

2-Acetyl-1-pyrroline (2AP) is a potent odorant that can be generated in the course of the Maillard reaction in heated foods like popcorn and white bread [2.90]. It

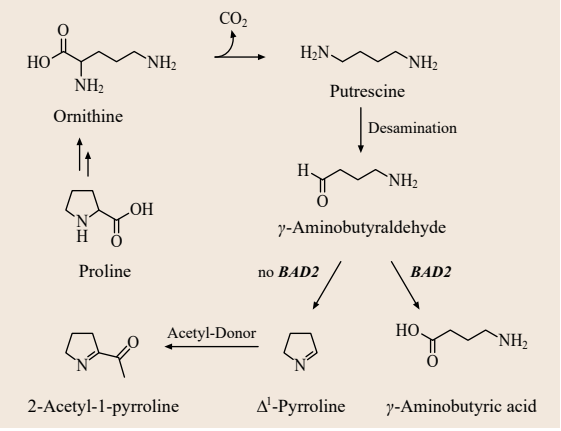

Fig. 2.22 Pathway from proline to 2-acetyl-1-pyrroline (2AP) (after [2.87])

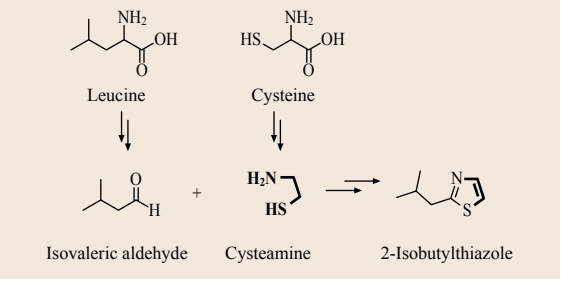

Fig. 2.23 Postulated biosynthesis of 2-isobutylthiazol in tomato (after [2.89])

can also be found in basmati and jasmine rice at higher concentrations and is biosynthesized there from proline [2.91]. Recent research has shown that a nonfunctional betain-aldehyde dehydrogenase (BAD2) leads to the enhanced generation of 2AP in these rice varieties due to the accumulation of pyrroline [2.87] (Fig. 2.22). The nature of the acetyl donor is still unknown.

2-Isobutylthiazole contributes to the aroma of tomato [2.92]. It is probably obtained as a product of the catabolism of leucine und cysteine (Fig. 2.23) [2.89].

S-Alk(en)yl Cysteine Sulfoxide-Derived Odorants

(+)-*S*-Alk(en)yl cysteine sulfoxides (CSOs) are nonprotein sulfur amino acids typically found in members of the family Alliaceae [2.93]. These molecules are precursors of volatile and reactive sulfur-containing odorants that cause the best known characteristic flavor of, *inter alia*, onion, garlic, and leek [2.94]. In onions, *S*-1-propenyl cystein sulfoxide is the main precursor of sulfur containing volatiles, whereas in garlic, *S*-allyl cysteine sulfoxide, better known as alliin, is most important. The biosynthesis of various CSOs from valine and glutathione is shown in Fig. 2.24. Alternative routes to CSOs imply the thioalk(en)ylation of *O*-acetylserine or the direct alk(en)ylation of cysteine. If both routes are active in all developmental stages of plant growth is not yet clear [2.95].

If onions or garlic are chopped, the typical aroma appears within seconds. Due to the disruption of the cells the enzyme alliinase comes into contact with CSOs and cleaves the C(β)-*S* bond, thus releasing ammonia, pyruvate and a series of unstable sulfenic acids (Fig. 2.25). These sulfenic acids yield, by purely chemical reactions, more stable volatiles like the well-known thiosulfinate allicin in garlic and further volatiles like disulfides [2.95].

Glucosinolate-Derived Odorants

Almost all vegetables that contain glucosinolates belong to the family of the Brassicaceae. Prominent examples are red and white cabbage, radish, mustard, and broccoli. Glucosinolates are thioglucosides whose basic structure is shown in Fig. 2.26. More than 100 different glucosinolates are currently known and can be grouped into aliphatic, indolic, and aromatic members [2.96].

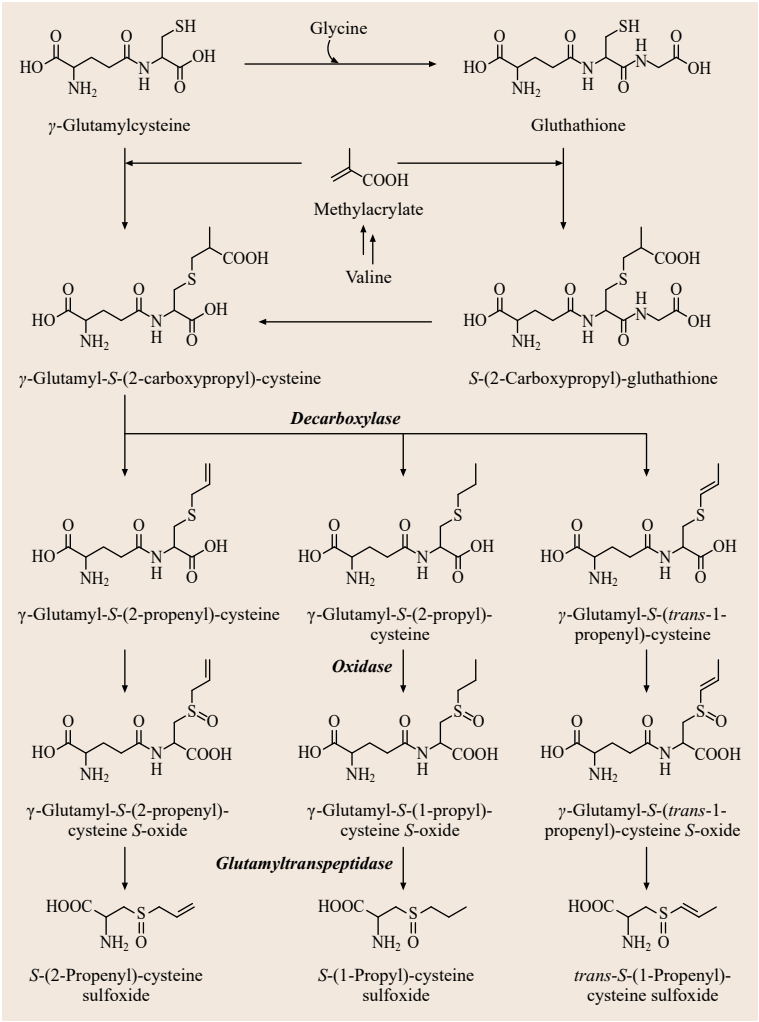

Fig. 2.24 Biosynthesis of flavor precursors in intact onion and garlic tissue (after [2.93])

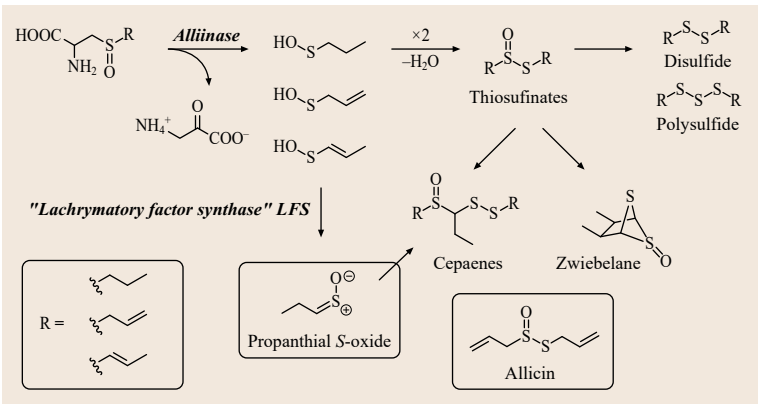

Fig. 2.25 The flavor volatiles resulting from the action of alliinase and lachrymatory factor synthase (in onions) (after [2.95])

Glucosinolate derivatives not only contribute greatly to the distinctive flavor and aroma of cruciferous vegetables and condiments, but also possess profound biological activities that range from their participation in plant defense and auxin homeostasis to cancer prevention in humans [2.97]. The biosyn-

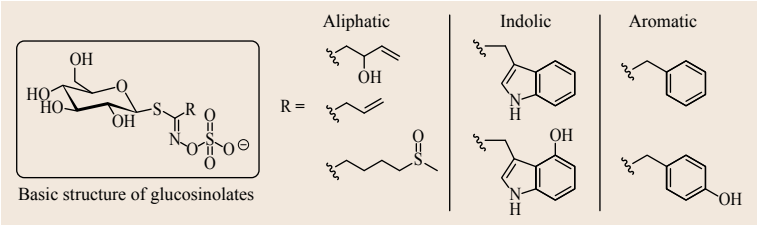

Fig. 2.26 Basic structure of glucosinolates and typical examples for members of the three groups

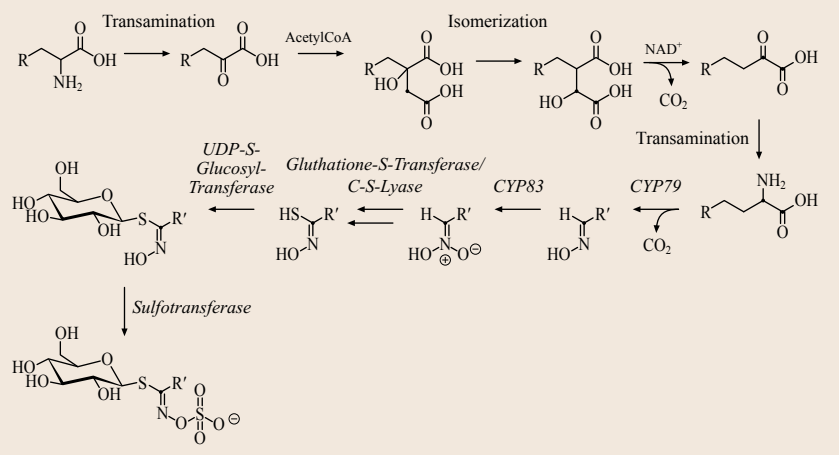

Fig. 2.27 Biosynthesis of glucosinolates (after [2.98]). Amino acid side chain elongation by one CH_2 group is shown and can be repeated up to 9 times. CYP83 and CYP79 are cytochrome P450 enzymes

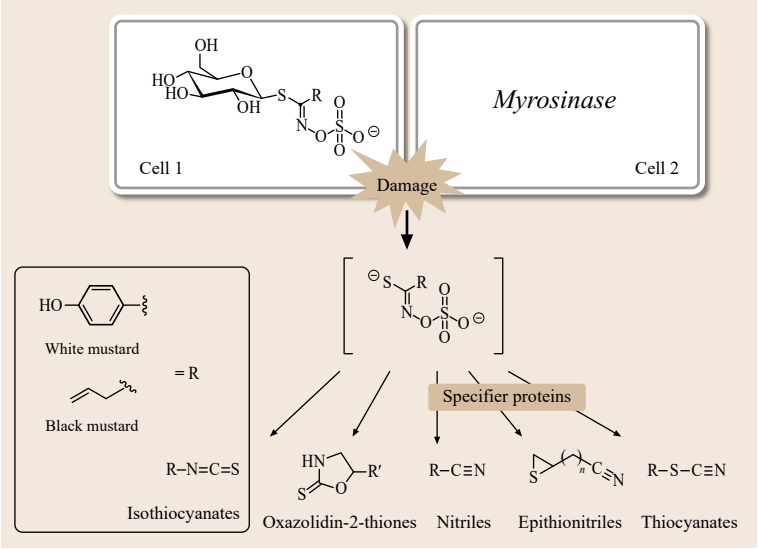

Fig. 2.28 Enzymatic degradation of glucosinolates by myrosinase and generation of further products. Allyl isothiocyanate (see lower left box) is a compound responsible for the pungent burning odor and taste of mustard. p-Hydroxybenzyl isothiocyanate is only slightly volatile and contributes significantly to the sharp pungent taste of mustard

thesis of glucosinolates can be divided into three steps:

1. Amino acid side-chain elongation
2. Glucone formation
3. Side-chain modification

and is shown in Fig. 2.27 [2.99].

If cells of cruciferous vegetables are disrupted glucosinolates come into contact with myrosinase, a thioglucosidase enzyme, which cleaves the thioglucosidic bond yielding glucose and an unstable aglycone that can rearrange into several final products (Fig. 2.28). The outcome is influenced by the structure of the side chain and the presence of so-called epithio-specifier

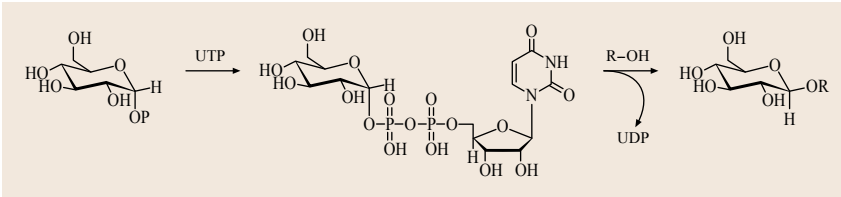

Fig. 2.29 Biosynthesis of β-glucosides by uridine diphosphate-glucosyltransferases (UGTs)

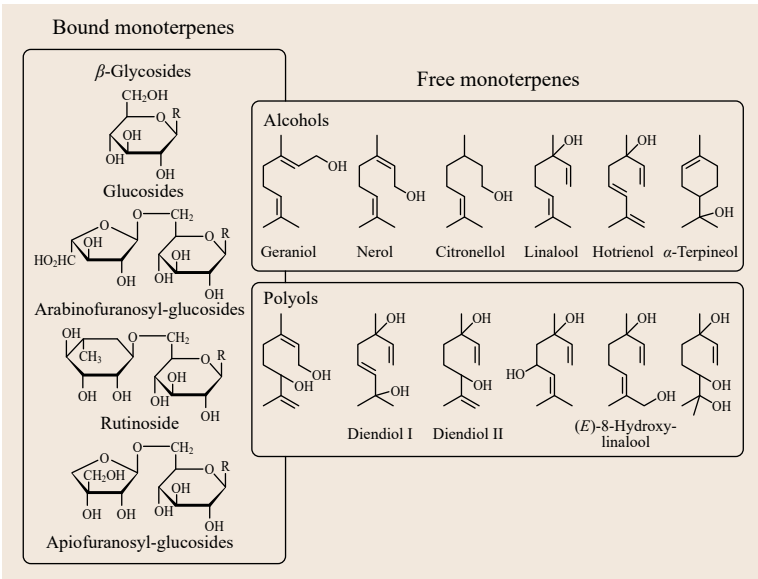

Fig. 2.30 Structures of typical monoterpene heterosides found in grapes

proteins (ESP) [2.95]. Isothiocyanates and nitriles are responsible for the pungent burning odor and taste and typical compounds in mustard oil.

Recent research has demonstrated that plant accumulation of glucosinolates and thus herbivore resistance are under circadian clock regulation. The simple stimulus of light is sufficient to entrain the clock not only of postharvest cabbage but also of diverse noncrucifer postharvest vegetables and fruits [2.100].

2.2.5 *O*-Glycosidically Bound Odorants

Plant volatiles are often *hidden* as glucosides whose glucose moiety is transferred from uridine diphosphoglucose by the so-called family 1 uridine diphosphate-glucosyltransferases (UGTs) [2.101]. Since the glucosylation process can be envisaged as a simple nucleophilic displacement reaction of S_N2 type, the product is a β-glucoside (Fig. 2.29).

By the sequential transfer of further activated sugar molecules, mixed disaccharides are generated (Fig. 2.30). A remarkably large array of different small molecules is glucosylated in fruits and vegetables and these include terpenoids, alkaloids, cyanogenic glucosides as well as flavonoids, isoflavonoids and other phenylpropanoids. It still remains an open question as to how this large number of structurally different flavor precursors is actually glucosylated in vivo because the in vitro activities of specific UGTs show large differences in the individual range of acceptors. Some UGTs are highly specific with respect to substrate-, regio-, and stereo-specificity, whereas others glucosylate a broad range of acceptors [2.102]. The latter phenomenon is called promiscuity and could decisively contribute to the immense structural variations of small plant secondary metabolites regarding their glucosylation pattern. Biochemical characterization of the substrate specificity of the UGTs is, therefore, a major challenge that scientists face when approaching the study of the actual biological function of these enzymes whose number of available sequences is rapidly increasing as a result of the expressed sequence tags (EST) and genome sequencing programs. In *Vitis vinifera* alone, more than 200 different glycosides have been identified, and there is a special interest in those glycoconjugates, which can contribute to wine flavor through the hydrolytic release of volatiles during the biotechnological vinification sequence leading from grape to aged wine [2.103]. These flavorless glycoconjugates accumulate in grape berries during maturation and can

be grouped into monoterpenes, C13-norisoprenoids, aliphatic alcohols, and shikimate-derived benzoids and phenylpropanoids [2.104]. Flavor enhancement in wine processing and in plant tissue products has nowadays become possible through the use of exogenous glycosidases [2.105].

2.3 Stress-Induced Biosynthesis of Plant Volatiles

Plants frequently emit volatiles upon feeding damage. The irregular acyclic homoterpenes 4,8-dimethylnona-1,3,7-triene (DMNT) and 4,8,12-trimethyltrideca-1,3,7,11-tetraene (TMTT) are among the most widespread volatiles produced by angiosperms with emission from vegetative tissues upon herbivore feeding. DMNT and TMTT have been implicated in attracting natural enemies of arthropod herbivores when released from damaged foliage [2.106]. This indirect defense strategy has been termed *plan's cry for help* and includes also the release of other volatiles like mono- and sesquiterpenes, aromatic compounds and fatty acid degradation products [2.7]. Today it is clear that jasmonates play a central role in signal transduction in plant stress response that leads ultimately to the emission of these volatiles by de novo biosynthesis [2.54]. The enzymatic steps in homoterpene biosynthesis are shown in Fig. 2.31. Key step is the oxidative C–C bond cleavage by cytochrome P450 enzymes from the so far uncharacterized plant CYP82 family [2.106].

2.4 Outlook

In the past decade, plant odorant research has witnessed a shift from studying odorant composition and identification toward the elucidation of their metabolic pathways [2.50, 64]. In particular, plant functional genomics that integrates genome sequencing, metabolomics, proteomics and high throughput biochemistry, will likely expedite the identification of genes and biochemical pathways of key odorants, whose formation in plant has been so far unknown. This will provide an expanded knowledge base for the genetic manipulation of biochemical pathways, which will ultimately lead to new crops with improved, altered or enhanced odor traits.

3. Natural Fragrant Raw Materials

Nicolas Baldovini, Jean-Jacques Filippi

The determination of the most important olfactory contributors of a fragrant natural raw material can be an extremely long and complex task which requires the combination of very efficient analytical techniques. Indeed, the characterization of these components is often difficult since the global odor of complex mixtures is not only due to the sum of the olfactory properties of each constituent, but also involves many synergies between each odorant constituents. In addition, the main contributors are often strongly potent odorants contained only in trace amounts, and therefore, their identification requires an exhaustive analysis of the whole mixture. Finally, since the olfactory sense is characterized by strong interindividual differences, a large number of panelists must be involved in such studies in order to bring generalizable data. Consequently, there is still lack of accurate knowledge about the main odoriferous constituents for many natural raw materials, and this situation is paradoxical when it concerns materials widely used for their odorant properties in the flavor and fragrance industry.

This chapter presents an overview of the published data about the main odor-active constituents of a selection of natural fragrant raw materials. It describes the chemical structures and olfactory properties of the main odorant components reported in the literature for 10 extracts and essential oils, after a brief description of the general analytical and sensorial issues concerning the determination of key odorants in a mixture.

The history of perfume is closely linked with that of natural raw materials. Indeed, before the birth of synthetic organic chemistry at the end of the nineteenth century, all of the materials used in perfume formulations were of natural origin, either vegetal or animal. Nowadays, even if modern perfumery is dominated by the use of synthetic substances, natural extracts are still considered prestigious ingredients. Moreover, fragrance chemists often use the vast pool of natural products as a source of starting materials for hemisynthesis [3.1] and the chemical structure of the most appreciated natural odorants also serves as inspiration for the creation of original synthetic fragrances. A large part of the artificial fragrant molecules used in modern perfumery has then a direct or indirect link with natural raw materials.

Therefore, the characterization of the odor-active constituents in natural raw materials is of crucial importance for the perfume industry. Paradoxically, the literature describing this type of analysis for a given natural odorant extract is generally limited compared to the number of publications focused only on its chemical composition. In the case of a raw material mainly used for its fragrant properties, such a situation is surprising, and is mainly due to the technical difficulty of giving some answers concerning the nature of the key

odorants of a complex mixture. Indeed, several issues will be encountered when trying to list the components which contribute to the odor of a fragrant mixture, especially in the determination of the relative importance of their contribution to the whole. However, this data is extremely useful, since it can help to formulate artificial reproductions of the raw material. In fact, many useful ingredients for the formulation of aroma and fragrances have been discovered in the frame of analytical studies devoted to the determination of impact odorants in natural raw materials [3.2]. A probably large part of the knowledge on the main odor contributors of the natural raw materials is not reported in the scientific literature for commercial reasons, but is rather stored in the archives of flavour and fragrance companies.

3.1 Identification of Odor Active Constituents in Natural Raw Materials

Two main types of natural raw materials are used in the flavor and fragrance industry for their odorant properties:

- The essential oils, obtained by hydrodistillation or steam distillation, are mixtures of volatile organic constituents with a low molecular weight (containing generally less than **20** carbon atoms). These components are usually phenylpropanoids, mono-, sesqui- and sometimes diterpenoids, but other types of constituents may also occur in these materials
- The solvent extracts (concretes, absolutes, resinoids, CO_2 extracts, etc.) usually contain the volatile constituents described earlier (with some differences), together with compounds of higher molecular weight which have dissolved in the solvent used during the extraction. These nonvolatile compounds generally have a weak impact on the olfactory characteristics of the mixture, but can modify significantly the evaporation rate of the volatile constituents. They act then as fixatives to increase the substantivity of their fragrance.

In both cases, the number of constituents of a raw material can be extremely important, with several hundreds of individual compounds present at a percentage higher than 0.1%. The odorants are contained in the volatile fraction of the extract, corresponding approximately to the essential oil; however, not all volatile compounds are odorants. Indeed, as detailed hereafter, distinct compounds can show huge differences in their olfactory properties, both in terms of quality and potency. The determination of key odorants in a natural raw material is a complex task which requires solving many classical issues of analytical chemistry, such as not only identifying accurately trace compounds, but also overcoming other difficulties related to the complexity of the human olfactory system. Some important points to consider are listed hereafter.

3.1.1 Physicochemical Issues

Sample Variability

The chemical composition of a given natural raw material is seldom uniform from one sample to another. As for any product obtained by transformation of living organisms such as foodstuff and beverages, several parameters can affect the chemical composition of an aromatic plant. The external issues (e.g., climate, nature of the soil) and the genetic factors of the species determine the nature of its secondary metabolites, which are also influenced by the harvesting and processing conditions (harvesting method, as well as storage, drying, cutting, cleaning conditions etc.). Eventually, the extraction process, which can also significantly differ from one producer to another, may also add another element of variability to the final composition of the extract. As a result, the odorant molecules present in two samples of a same essential oil or extract can strongly vary in terms of nature and content, and thus the overall olfactory properties of these samples will also differ. This situation is well known in the flavor and fragrance industry where a large part of the analytical activities is devoted to the quality control of natural oils and extracts. Therefore, any investigation on the determination of the odor-active constituents of a natural raw material should take into account that its results may not be generally valid to all samples of the same raw material.

Differential Volatility of the Constituents

When the odor of a natural extract is evaluated in a static mode (for instance on a smelling strip), the components of the mixture evaporate at a rate depending on their volatility. The most volatile constituents are perceived at the beginning of the olfaction, then quickly fade away to reveal the components of medium volatility, and eventually the less volatile odorants which can persist for a long time on the support (smelling strip, clothes, skin) [3.3]. The perfumers are familiar with

this phenomenon and commonly define the top, heart, and base notes of a composition or a natural extract. Hence, different components will contribute to different chronological parts of the general olfactory picture of the material, and accurate descriptions of the key odorants of a mixture sometimes mention if they are involved in the top, heart, or base notes.

3.1.2 Physiological Aspects

Sensitivity and Selectivity of the Olfactory System

The potency of an odorant molecule is usually expressed by its detection threshold, which is generally defined as the lowest concentration detected by at least 50% of a panel of evaluators. Large variations of detection thresholds exist between the known odorant substances, ranging from the ppt (parts per trillion) level (for the most potent odorants) to theoretical infinity (for a totally odorless compound like water). If we exclude such odorless substances, the human relative sensitivity ranges at least over 11 orders of magnitude [3.4]. At first sight, we may be tempted to use the detection threshold values to compare the contribution of different odorants of a mixture, and several analytical approaches detailed below are based on this intuitive principle. However, this reasoning would be valid only in the case of purely elemental processings, and is thus based on a false simplification (see below). Moreover, the published detection thresholds values should be considered carefully because a large number of different methods are used for their measurements; these methods often produce very different results for a same compound. Consequently, the comparison of threshold values compiled from different studies is not reliable [3.5, 6].

Interindividual Variability

It is well known that the detection threshold strongly depends on the person performing the evaluation [3.6, 7]. Individual sensitivity follows a log normal distribution in the population [3.6], and some cases of bimodal distribution are also known [3.8–11]. Hence, for some odorants, a significant proportion of the population can be either partially or totally anosmic, or on the contrary hyperosmic. For these reasons, the *typical odor* of a complex mixture can indeed be perceived differently from one individual to another. In extreme cases, two different individuals could then recognize different sets of odorant components among the main contributors to the global odor of the mixture. Finally, as in any sensory analysis, the most relevant data is obtained from averaged values collected from several evaluations realised by a panel as diverse as possible.

Synergies and Antagonisms in the Olfactory System

The perception of a mixture of odorants is the result of complex interactions at several levels in our olfactory system. In addition to the physical process of evaporation described above which delivers each constituent of the mixture at different times of the olfaction, a first set of synergistic and/or antagonist interactions might already occur when the odorants reach the olfactory mucus. Indeed, the odorant-binding proteins (OBP), a group of highly soluble proteins contained in high concentration in the nasal mucus, have been shown to bind odorant molecules with significant affinities. Although the function of the OBPs is still unclear, they may act as a primary filter which could modulate the perception of the odorant molecules [3.12], before the next step where they are delivered to the olfactory receptors (OR). Another complex interplay occurs then between all of these components and the different OR subtypes, and the discriminative power of the olfactory system is now considered to be mainly based on these interactions. Up to now, **396** genes coding for different functional human OR have been identified [3.13], but the mechanisms underlying the interactions of OR with the odorants are still not comprehensively understood. The same OR subtype can be activated by different odorants, and a single odorant can activate different ORs. Moreover, the binding of an odorant with an OR can occur with more or less high affinity [3.14], as is explained in detail in Chap. 27. Finally, another level of interaction appears when these combinatorial informations are processed by the brain to generate the olfactory perception. It has been demonstrated that a mixture of two components can be perceived either analytically with each component remaining identifiable, or as a single entity (*odor blending*). These processings are called elemental and configural, respectively [3.15]. *Zou* and *Buck* et al. have demonstrated the neuronal basis of the configural perception, by showing that a mixture of two components can activate cortical neurons that are not stimulated by any of these components taken alone [3.16]. For human naïve subjects, configural processing occurs with binary and tertiary mixtures, but trained subjects can perceive these mixtures in an elemental mode [3.17]. As a result, a mixture of several components can be perceived as something different than a simple arithmetical addition of each odorant. Complex mixtures such as natural raw materials often contain several hundreds of volatiles if one considers the trace constituents, but the number of odorants above their threshold level is much lower. Anyway, the level of perceptual odor blending between these active odorants is unknown, but is probably rather high.

3.1.3 Analytical Methods for the Characterization of Odor-Active Constituents in Mixtures

Direct Evaluation of Isolated Samples

The first answers concerning the odor-active constituents of natural raw materials were provided by analytical studies performed at the end of the nineteenth century, often by chemists working in the flavour and fragrance industry. Their methodology was based on the careful fractionation of the essential oils and extracts by physical and chemical methods, followed by the olfactory evaluation of the isolated substances. Despite the poor technical means of these times, several impressive characterizations could be achieved. Moreover, since no spectroscopic methods were yet available, all kinds of molecular characterization were exploited, and the olfactory properties of the purified substances were often reported in detail, as fragrance chemists were naturally open to olfactory evaluations.

The odor of a single compound can be determined with a sample obtained by fractionation of the raw material, but should then be considered with caution as it can be altered significantly by trace impurities [3.4, 18]. As mentioned above, the constituents of a natural extract can be totally odorless or on the contrary possess extremely low odor thresholds, because the human olfactory system is both extremely sensitive and selective. Even a few ppm of a strong odorant contaminant can completely modify the olfactory properties of another substance even if its purity is $> 99.9\%$. For this reason, the reliability of the evaluation depends on the purification method which provides the sample for evaluation. If it is based on the fractionation of the whole mixture, the efficiency of the separation is critical in order to avoid any remaining odorant contamination. The evaluation of the substance can also be confirmed by comparison with a sample of the same compound obtained from a different source, for instance a synthetic sample. In such a case, the probability of having the same odorant contamination in the sample is very low. However, for a complex mixture of many odorant compounds such as an essential oil or a solvent extract, it can be extremely time consuming to synthesize even a few of the most odorous components to prove their olfactory character, especially for some precious materials containing complex sesquiterpenic constituents.

Gas Chromatography–Olfactometry (GC-O)

Today, the most convenient method for the determination of odor impact constituents in a mixture is based on the use of gas chromatography-olfactometry (GC-O) (Fig. 3.1). This technique consists of a simple GC

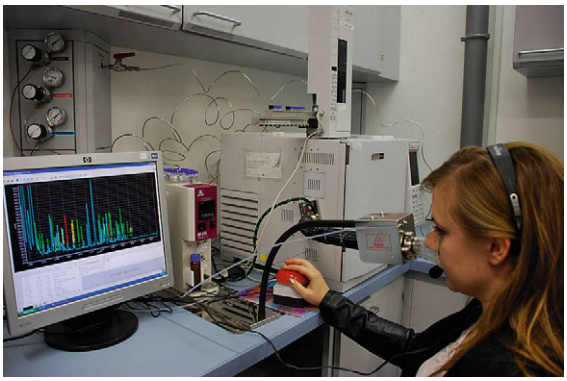

Fig. 3.1 A GC-O experiment. The panelist presses the *red button* when she perceives an odor at the olfactory port, and records the corresponding olfactory description via a voice recorder

experiment involving a human assessor who evaluates the effluent of the column, and describes the odor perceived in function of the retention time. The graphical result is named olfactogram (or aromagram). If a portion of the effluent is directed simultaneously to a conventional detector (mass spectrometer (MS), flame ionization detector (FID)), a correlation can be made between the olfactogram and the chromatogram, and for a given signal of the chromatogram, the odor of the corresponding compound(s) can be read on the olfactogram. GC-O is indeed as old as GC itself, because the first gas chromatographs equipped with a nondestructive thermal conductivity detector would release the effluent unchanged in the atmosphere, and it was then natural to perform olfactory assessments. Today, many technical evolutions have been proposed (multiple-port GC-O [3.19], GC×GC-O [3.20] etc.) and GC-O is the method of choice for the characterization of odor-active constituents, thanks to the high resolving power of modern capillary GC.

A single GC-O experiment can be used for a first overview of the odorant constituents in a mixture (GC-sniffing), but this technique is also used to determine the relative olfactory contribution of the odorants of a mixture. Several methodologies have been proposed for this purpose, and for the processing and interpretation of the data collected during the experiments [3.21–23]. They can be classified into three types:

1. Detection frequency
2. Dilution to threshold
3. Direct and posterior intensity.

Detection Frequency Methods

Detection frequency methods [3.24] are based on the comparison of the olfactograms realized by several dif-

ferent assessors. The constituents which are detected more frequently are concluded to have a greater relative contribution. This technique does not necessarily require trained panelists, but relevant results are obtained only with a large number of assessors (typically more than eight) and the determination of the relative olfactory contribution of the most potent components of a complex mixture can be problematic. Indeed, this method does not allow to rank the strongest odorants when they are detected by all the panelists [3.22]. *Pollien* et al. have proposed an improvement of the detection frequency method by taking into account the length of the stimulus [3.25]. However, many authors have reported that the end of the odor zone is often difficult to perceive accurately [3.26, 27] and that the importance of coeluting compounds is over-evaluated by this method [3.22, 28].

Dilution to Threshold Methodologies

In this approach, serial dilutions of an extract are prepared and analyzed by GC-O. The odorant constituents which are still perceived at the highest dilutions are considered to be the main odor contributors. The aroma extract dilution analysis (AEDA) takes into account the last dilution in which a constituent is still perceived, and attributes to this compound a flavor dilution (FD) factor corresponding to the dilution value [3.29]. In the CharmAnalysis, the duration of the stimulus is recorded, and peak areas can be calculated [3.30]. This last method has more discriminating power than AEDA, but presents also the limitations mentioned above for the measurement of the stimulus length. One of the drawbacks of the dilution to threshold method is the high number of experiments required per panelist, which precludes the possibility of handling a large population of evaluators. Consequently, many AEDA studies are based on the evaluations of only one or two assessors, which cannot then be considered as representative of the whole population since interindividual sensitivity differences are often important [3.7]. Moreover, the results of AEDA should be interpreted carefully, because such methods are based on the false assumption that the odor intensity increases linearly with the concentration. Indeed, the relation between odor intensity (I) and odorant concentration (C) follows the Stevens' psychophysical power law [3.31]. The sigmoid curve $I = f(C)$ is shown in Fig. 3.2. The saturation of the nose at high concentrations is visible, and the part of the curve before the saturation can be plotted in logarithmic scale ($\log(I) = f(\log(C))$, to give a line with a given slope. Different odorants are not necessarily characterized by the same slope [3.28, 32] and consequently, in a given mixture, a compound with a high FD factor may indeed induce a weaker olfactory stimulus than another

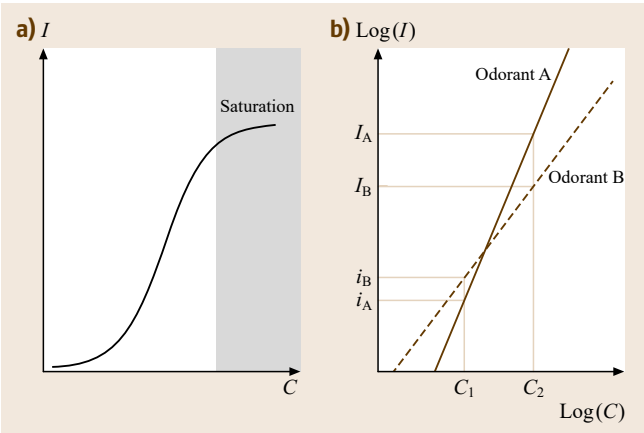

Fig. 3.2 Psychometric function. The intensity of the olfactory stimulus (I) is plotted against the concentration of the odorant (C), and gives either a *sigmoid curve* **(a)** or a *line* **(b)** if the scale is logarithmic

component showing a lower FD factor when this mixture is evaluated at a high concentration. In Fig. 3.2, an odorant A is perceived as stronger than an odorant B at a high concentration C_1 ($I_A > I_B$), but because of the differences in the slopes of their psychometric functions, the reverse is observed at lower concentrations C_2 ($I_A < I_B$).

Direct and Posterior Intensity Methods

Direct and posterior intensity methods [3.33–37] involve recording the stimulus with an evaluation of the intensity perceived by the assessor and the duration of the perception. An olfactogram similar to a classical chromatogram is then produced, and these methods give the most reliable results. However, they require a significant training of the assessors, and consequently, their application is not very frequent.

Some studies have demonstrated that for the same mixture of compounds evaluated by the same panel, each GC-O methodology gives different results in terms of odorant ranking [3.21, 28]. In consequence, any GC-O-based classification of the relative olfactory contributions of the constituents of a mixture should be considered with caution.

Odor Units

Once the concentration of an odorant in an mixture is determined, a calculation of its olfactory contribution has been proposed, by dividing its concentration by its odor threshold. This concept was first introduced by *Patton* and *Josephson* [3.38] and led to the definitions of aroma value [3.39], and odor unit (OU) [3.40]. The comparison of the OU of each odorant has been proposed to estimate their relative contribution to the over-

all odor, and was illustrated by Ohloff on the rose odorants [3.41] (Sect. 3.2.3). However, the same criticism as for AEDA can be applied to the OU concept, which assumes that there is a linear relationship between the perceived intensity of a compound and its concentration, with a same slope for all compounds. In addition, it does not take into account any synergistic/antagonistic effects that might occur between odorants [3.42, 43].

Reconstruction Experiments

The reliability of any kind of ranking of the main odor-active constituents of a mixture may be criticized, but despite this, it can be taken as a simple guide for a reconstruction of the mixture. Furthermore, it was the initial goal of the GC-O methods and the OU concept. If the odor of a mixture can be reproduced by blending a shortlist of some of its main odorant constituents in their original concentration, then it brings the ultimate confirmation of their role as key odorants. Omission experiments (in which a single constituent is withdrawn from the formula to evaluate if the overall odor is modified) are also very useful to determine if a given odorant has a real contribution [3.44]. Such an approach has been described for simple aromas [3.44], and wines [3.45] but is more tedious for complex essential oils or extracts, in which the key odorants are sesquiterpenic constituents that are not commercially available.

3.2 Odor-Active Constituents of Selected Natural Raw Materials

Several types of oils and extracts exist and can be classified regarding their odor-active constituents; thereby, *Petrzilka* and *Ehret* [3.46] have proposed to classify raw materials in three main categories, according to the following situations:

1. The typical odor of the material is due to one or a few major constituents and the minor constituents have almost no contribution.
2. The main components bring an essential olfactory base, but the typical and characteristic odor is created by their association with several key minor and trace constituents.
3. None of the main constituents has any olfactory importance, and the odor character is due to the minor and trace components.

Several important raw materials belong to the first category, and will be described hereafter. The last category is obviously the most problematic from the analytical point of view, and as an example, *Petrzilka* and *Ehret* mentioned the case of mimosa absolute (*Acacia dealbata*). The typical scent of this material is due to a complex interplay of constituents at a content below 1%, among which some trace compounds play a decisive role [3.46]. This observation was confirmed later by GC-O experiments which could not identify any single constituents possessing a typical mimosa odor [3.47]. In this review, a selection of some important natural raw materials is presented, with the data concerning their odor-active constituents, as reported in the scientific literature.

3.2.1 Jasmine

The extraction of jasmine flowers (Fig. 3.3) provides several types of extracts which were considered in the past as the most important natural perfume raw materials [3.48]. Still today, the jasmine absolutes and extracts are extremely precious natural floral ingredients for the preparation of high-grade perfumes. In the past, *Jasminum grandiflorum*, often grafted on *Jasminum officinale*, was cultivated mainly in the Grasse area in southern France, and contributed to the prosperity of the local fragrance industry [3.49]. Nowadays, most of the world production comes from India and North Africa.

Fig. 3.3 Jasmine (*Jasminum grandiflorum*) (courtesy of Céline Cerutti-Delasalle, *Albert Vieille*)

The first analytical investigations on the chemistry of jasmine fragrance appeared at the end of the nineteenth century, and were conducted by *Hesse* in Germany [3.50–54]. Because of the limited technical means, only few components could be characterized, with some inevitable errors. Among the substances which were confirmed by further studies, the most abundant constituents of jasmine absolute were characterized: (+)-linalool **1** and benzyl alcohol **2**, with their acetates **3**–**4** [3.54] (Fig. 3.4). Hesse also described the occurrence of some high impact odorant

constituents, and he pointed out the important contribution of indole **5** [3.53, 54] as well as those of jasmone **6**, a $C_{11}H_{16}O$ ketone with an *intense and pleasant jasmine odor* [3.54]. The structural determination of **6** was unattainable at that time, but in 1933, it was eventually elucidated simultaneously and independently by *Ruzicka* [3.55] and *Treff* [3.56]. Among the other jasmine constituents identified during this period, several important odorants were discovered: *p*-cresol **7** [3.57], eugenol **8** [3.58], benzaldehyde **9**, and creosol **10** [3.59]. *Naves* and *Grampoloff* also noticed the presence of lactones with a *tenacious potent fruity odor* but did not characterize their structures [3.59].

Nevertheless, the reconstitutions of jasmine odor with all these substances were still unsuccessful [3.58, 60], and it stimulated further analytical investigations. One of the missing links was discovered in 1962 by *Demole*, who identified methyl jasmonate **11**, a ketoester *playing an essential function in jasmine perfume* and structurally related to **6** [3.60]. Indeed, only the more potent **12** was detected in the headspace of jasmine flowers, but it epimerizes during the preparation of the absolute to give a 9 : 1 thermodynamic mixture of **11** and **12** [3.61]. Interestingly, (±)-**12** has an odor threshold **400** times lower than **11** [3.62]. *Demole* also described the occurrence of vanillin **13** and 6-methylhept-5-en-2-one **14** [3.63], and of (−)-(*Z*)-dec-7-en-5-olide **15**, a lactone with a *particularly sweet and fine, very floral odor* [3.64]. The dehydro, ethyl- and acetoxy-analogs of **11** (**16**–**18**) were also identified, as well as the peculiar bicyclic lactones **19**–**20** and other saturated and monocyclic ones (**21**–**26**) [3.49, 65]. **19** is odorless [3.65], and the olfactory contribution of **16**–**26** to the global odor of jasmine was not described, but is probably weaker than that of the much more abundant and strong odorant **11** and **12**.

Even if the presence of methyl anthranilate was already reported during *Hesse*'s pioneering investigations on jasmine oil [3.54], it proved to be indeed an artifact coming from the hydrolysis of methyl *N*-acetylanthranilate **27** [3.49] during hydrodistillation. Many other nitrogen compounds were also characterized, like methyl *N*-methylanthranilate **28** [3.66], and various pyridines and quinolines (**29**–**32**), as well as benzonitrile **33** and 2-phenylnitroethane **34** [3.67]. These compounds may participate in the olfactory character of jasmine, but the importance of their contribution is unclear. **29**–**32** possess pungent odors, **33** recalls benzaldehyde, and **34** has a cinnamic, phenylacetaldehyde-like odor. Their low amount might limit their olfactory importance, but **5** is probably the strongest nitrogenous contributor. Its amount in the headspace of living flowers is besides more substantial than in picked flowers [3.68]. Finally, maltol (**35**) should also be mentioned as an important odorant component of jasmine. This heterocyclic compound possesses a characteristic sweet caramel, fruity odor with baked bread undertones and is a well-known contributor to the aroma of many foodstuffs. It was isolated and identified in benzene extracts of Egyptian jasmine flowers [3.69], and was recently reported as a key odorant in an extract obtained by supercritical fluid extraction of an ethanolic infusion of French *Jasminum grandiflorum* flowers [3.70]. This latter study pointed out that the conventional hexane extraction produces an absolute which contains comparatively much lower amounts of **35**. These observations are consistent with the fact that **35** is significantly soluble in benzene and ethanol, but only poorly solubilized in hexane. **35** is indeed an actual constituent of jasmine, since it could also be detected in the headspace of living jasmine flowers [3.69]. In view of its significant percentage in the extracts, there is little doubt that its powerful odor certainly contributes substantially to the exquisite fragrance of natural jasmine.

Up to now, no published study has ever accurately described the relative contribution of the jasmine odorants, but the constituents unanimously [3.49, 61, 71] recognized as the most important elements of the typical beautiful jasmine fragrance are **15** and the two main jasmonoids: **6** and **11** [3.64]. Demole also reported that a significant portion of the absolute (more than one third) contained odorless heavy constituents acting as natural fixatives and synergists, and may then play a rather decisive role in the jasmine fragrance: phytol, isophytol, phytyl acetate, geranyl linalool, benzyl benzoate, fatty acids, and their esters [3.49, 72].

3.2.2 Tuberose

Tuberose (*Polyanthes tuberosa* L.) was one of the emblematic flowers (Fig. 3.5) cultivated in the Grasse area in the first half of the twentieth century, but the production of this delicate plant is now mainly located in India. By solvent extraction, the freshly harvested tuberose flowers furnish an absolute with a very typical sweet, heavy floral character [3.48]. Compared to jasmine extracts, tuberose absolute has a lower importance in perfumery, and consequently its composition has been much less investigated. Several constituents common to jasmine absolute have been reported. In the first investigations, methyl anthranilate **36**, eugenol **8**, geraniol **37**, nerol **38** and their acetates (**39**–**40**), benzyl benzoate **41**, farnesol **42**, methyl benzoate **43**, and methyl salicylate **44** have been characterized in tuberose solvent extract [3.73–75] (Fig. 3.6).

Later, *Kaiser* and *Lamparsky* identified coumarin **45** and several saturated δ- and γ-lactones **23**–**24**, **46**–**50** [3.76]. By preparative gas chromatography, they

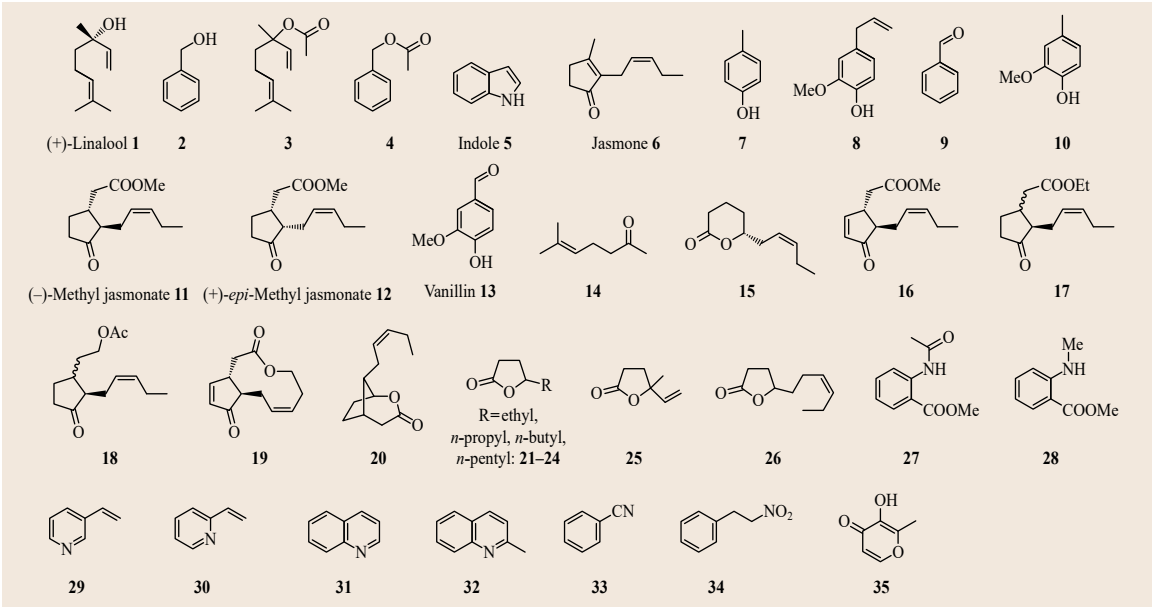

Fig. 3.4 Main constituents and key odorants of Jasmine absolute

Fig. 3.5 Tuberose (*Polyanthes tuberosa*) (courtesy of Céline Ceratti-Delasalle, Albert Vieille)

could also isolate some new δ-valerolactones **51**–**53** and *ent*-**15**, which is the optical antipode of one of the key odorants of jasmine, as mentioned above. *Maurer* and *Hauser* have subsequently identified **6** additional γ-butyrolactones **54**–**58** and the bicyclic lactone tuberolide **59** [3.77]. These components were detected in trace amounts (0.01−0.001%) but according to the authors, may contribute to the rich, heavy floral odor of tuberose absolute: **54**–**56** showed a strong smell reminiscent of the corresponding saturated γ-lactones, **57**–**58** displayed long lasting, slightly fatty aldehydic notes, and **59** had a tenacious lactonic odor.

Kaiser and *Lamparsky* also investigated the presence of nitrogen compounds [3.78], and identified *N*-formyl methyl anthranilate **60** and *N*-methyl methyl anthranilate **28** [3.79] in addition to **36**. Nitrogen heterocycles like **61** and the nicotinic acid esters **62**–**63** were also characterized, as well as 0.02% of indole **5** and traces of skatole **64**. The olfactory contribution of all these constituents is certainly quite significant: **62**–**63** bring a very special warm-tobacco like odor, and **5** also participates in the floral character. Besides, the presence of **5** has been measured in the concrete and absolutes of various strains of tuberose, and was shown to reach up to 2% [3.80]. Even if **64** is often designated as partly responsible for the odor of feces, it may bring, as a trace component, an important and interesting contribution to the pleasant odor of tuberose absolute [3.78].

3.2.3 Rose

With jasmine, rose is one of the major sources of natural ingredients for the flavor and fragrance industry. The *Queen of the flowers* is indeed an inescapable element in floral perfume compositions. Its beautiful shape and color makes it attractive also for horticultural purposes, and more than **13000** varieties have been created by crossings [3.81]. Many rose cultivars are odorous, with a large range of olfactory facets [3.82, 83]. Today, two main species are cultivated for the perfume industry: Damask rose (*Rosa damascena*) produced mainly in Bulgaria and Turkey, and *Rose de mai* (*Rosa centifolia*) (Fig. 3.7), grown in the past in the south of France, but cultivated now mostly in Morocco and Egypt.

The main aromatic extracts of rose are the concrete and absolute obtained by solvent extraction. By

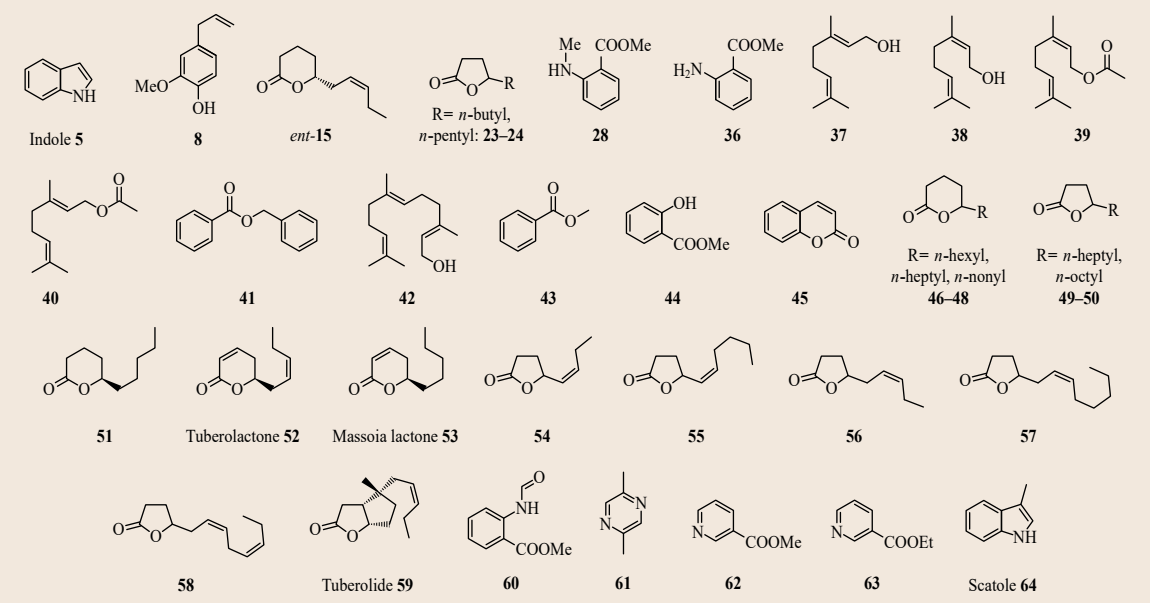

Fig. 3.6 Main constituents and key odorants of tuberose absolute

contrast, rose oil and rose water are produced by hydrodistillation of the flowers. Given the importance of these ingredients for the perfumers, the volatile part of these products has been extensively analyzed since the early times. Basically, the most abundant constituents of rose oil, which are also the main volatiles of concrete and absolute, are simple alcohols like phenylethanol **65**, (−)-citronellol **66**, geraniol **37**, and nerol **38** [3.84] (Fig. 3.8). Significant amounts of paraffins and olefins are often present as well, but their contribution to the overall odor is of little importance. A large variety of linear alcohols, aldehydes, acids, and esters can also be identified in rose solvent extracts [3.85].

Still today, the reproduction of the rose fragrance is a classical task for an apprentice perfumer. The determination of odor-active constituents of rose was thus a major concern for the fragrance chemists. **37**–**38** and **65**–**66** are often presented as necessary for the base note, and their odor is commonly described as *rose-like*, but their overall potency is low. Indeed, a simple mixture of these constituents is far from the typical rose fragrance. **65** is often presented as a key component, but rose reconstructions are possible without it [3.81]. Several key odorants contained at low percentages (< 1%) were discovered in extensive analytical investigations during the second half of the twentieth century. At first, *Seidel* and *Stoll* [3.86] identified the monoterpenic tetrahydropyranes **67**, which were named *rose oxides* and play a crucial role in the rose fragrance. The most abundant 2*S*,4*R* *cis*-isomer occurs at about 0.4% in the oil, twice more than its 2*R*,4*R* epimer [3.87]. **67** brings

Fig. 3.7 Rose de mai (*Rosa centifolia*) (courtesy of Céline Cerutti-Delasalle, Albert Vieille)

a powerful fruity odor essential for the floral green top-note [3.61].

An extensive analysis of Bulgarian rose oil was undertaken by Kováts at the ETH in Zürich between 1962 and 1967, in collaboration with the Firmenich company. This work remains a classic in the field of essential oil and fragrance chemistry, and its results started to be published only a decade later for commercial reasons [3.85]. Hence, **127** compounds representing 98.6% of the volatile part were isolated and identified, and the olfactory contribution of many minor constituents could be determined [3.88]. Kováts also gave an interesting account of a reconstruction of the rose oil. Hence, a rose base could be obtained by mixing **37**–**38** and **66** with some odorless paraffins and heavy natu-

ral constituents of rose oil acting here as fixatives. This base was described as possessing a pleasant rose odor, but it required to be strengthened by the addition of ethanol, hemiterpenic alcohols, hexenols, 2-alkanones, fatty alcohols, acids and aldehydes, and compounds **1**, **8**, **39**–**40**, **42**, **65**, and **69**–**72**. Finally, to obtain the sweet, powerful *honey note* of the oil, small amounts (0.05−0.2%) of **73**–**75** were added, but the full identity of rose was only revealed with the final adjunction of 0.1−0.2% of the key odorant **76** [3.89] which *changes the faint odor of this mixture to the well-known sweet odor of rose*. Several other constituents not included in this reconstruction (**2**, **9**, **77**–**78**) were nevertheless reported to be important for the organoleptic quality of the oil [3.88].

Ohloff exploited these results to illustrate the concept of odor unit (OU) [3.41] and proposed a quantitative estimation of the olfactory contribution of the main rose odorants [3.41, 61]. β-damascenone **76** was described as having *narcotic scent reminiscent of exotic flowers, and heavy fruity undertone* and showed the highest relative OU (70%) despite its low concentration in rose oil (0.14%) [3.61]. It was followed by β-ionone **79** (OU 19%, with a concentration of 0.03%), and the most abundant constituent (−)-citronellol **66** ranked only in the third position (OU 4%). The other contributors were, in decreasing order of OU: **67**, **1**, **37**, **42**, **8**, **38**, **80**, **65**, **68**, **81**, and several remaining odorants not included in this classification: nerol oxides **69** which, with **67**, contribute to the *geranium-like odor impression* and the hesperidin-like odorant *p*-menth-1-en-9-al **82** [3.90, 91]. Interestingly, β-damascone **83** was also reported to contribute to the overall character of rose oil with an odor resembling **76**, and even if its concentration in the oil was 0.0003%, it was still **10000** times higher than its threshold value [3.90].

Other experiments trying to reconstitute the rose fragrance reported that few additional natural components play an important role in the whole character: cis-3-hexenal (**84**) brought a *very lovely, fresh green and leafy aroma* whereas other C_5-C_9 aldehydes (especially mono- and di-unsaturated) which add fresh and spicy, or floral and fatty notes. Other facets sometimes recognized in the complex rose fragrance were attributed to specific components: minty (carvone **80** and methyl heptenone **14**), spicy (cinnamaldehyde **85**), woody (monoterpenes), and floral/fatty (alkanols) [3.81]. Başer has compared the compositions and odor properties of several Turkish *Rosa damascena* oils, and discussed the effect of **1**, **8**, **37**–**38**, **65**–**66** and **68** on the overall fragrance. He also pointed out that other compounds like **40**, **72**, and **86** create the typical fresh rosaceous character in the top note, which is boosted by nonanal **87** [3.92]. With the help of GC-sniffing experiments, a last class of highly potent odorant constituents has been discovered by *Omata* et al., who have reported the occurrence of **16** sulfur compounds such as mono-, di- and trisulfides, sulfur heterocycles and terpene sulfides like **88**–**94**. These trace constituents were described as important contributors to the characteristic odor of rose essential oil, with various notes like onion, green, smoky, and powdery [3.93, 94]. The actual natural occurrence of **93** in the plant is questionable, because this compound is a well-known constituent of crude oils and fuels [3.95] and might then be an artifact coming from the extraction process. Indeed, up to now, there are no established biosynthetic pathways related to the formation of such compounds in the plants, and attempts to identify traces of **93** in several rose extracts by other authors have been unsuccessful [3.69]. These last observations are obviously not a proof that **93** is not a natural constituent of rose. However, they justify a reinvestigation of the species where this compound was detected, using analytical procedures adapted to the detection of artifacts (involving instrument and procedural blanks).

To conclude this survey of the rose odorants, it should be considered that a great variety of garden roses have been created by multiple crossings during several centuries. Analytical studies on the chemistry of minor rose varieties have revealed a large number of constituents not common or even totally absent in *Rosa damascena* or *Rosa centifolia*, like for example 3,5-dimethoxytoluene **95**, 1,3,5-trimethoxybenzene **96**, dihydro-β-ionone **97**, theaspiranes **98** etc. [3.82, 83]. Many of these constituents are strong odorants, and therefore contribute to the rich palette of rose fragrances, which adds another layer of complexity to the aroma of the Queen of the flowers.

3.2.4 Cedars

The name cedar refers to several species rather distinct from the botanical and phytochemical point of view. In perfumery, the main types of cedars used for the production of fragrant raw materials are the Atlas cedar (*Cedrus atlantica*) and species of the *Juniperus* genus. The latter group is the most widely used, and is the source of the Texas and Virginian cedarwood oils, produced mainly in the United States by distillation of the woods of *Juniperus mexicana* and *Juniperus virginiana*, respectively [3.61].

The main constituents of *Juniperus virginiana* essential oil are (+)-cedrol **99**, (−)-α-cedrene **100**, and (−)-thujopsene **101** (Fig. 3.11). There seems to be a controversy about the key odorant constituents of *J. virginiana* essential oil, which recalls the case of patchouli. According to some sources, **99** is the principal odorant [3.61] but several authors have pointed

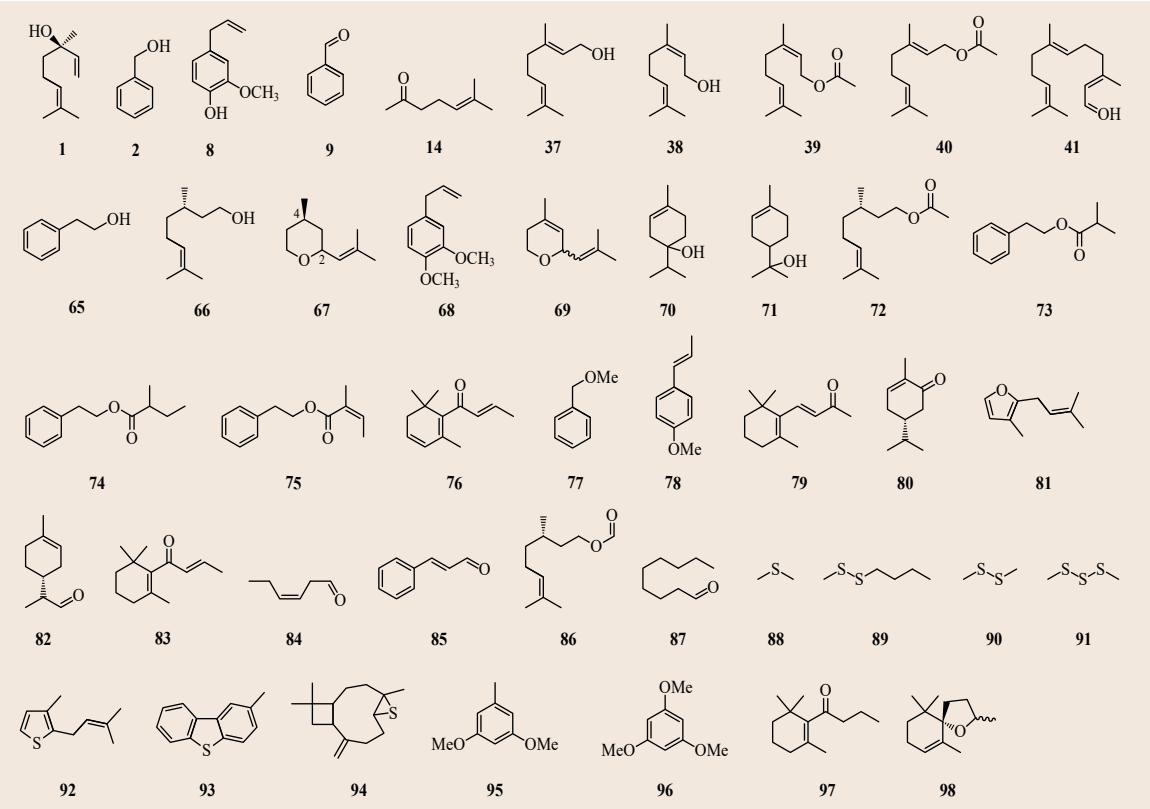

Fig. 3.8 Main constituents and key odorants of rose absolute and oil

out that crystalline **99** has a very weak woody odor, or is even odorless [3.48, 96, 97] so almost odorless, but small amounts of some odor-active components were reported in *J. virginiana* essential oils: cedrane oxide **102** (ambery) [3.61], (*E*)-betulenal **103** (sandalwood, acetylcedrene-like), funebrenal **104** (woody), 8-cedren-10-one **105** (musty, woody, mint myrrh-like), and nootkatone **106** (grapefruit) [3.96].

The second important cedar species is the Atlas cedar (*Cedrus atlantica*), native to the Atlas Mountains of Algeria and Morocco. It is botanically related to *Cedrus libani* (cedar of Lebanon) and also to its more distant Himalayan cousin *C. deodara* [3.98]. It is the main species of Moroccan forests used for timber production (Fig. 3.9), and the sawdust produced during the wood processing is often valorised by hydrodistillation to furnish an essential oil with a very particular sweet and tenacious woody odor, reminiscent of cassie and mimosa [3.48], and totally distinct from that of the above mentioned *Juniperus* oils. The main components of *Cedrus atlantica* essential oil are himachalane sesquiterpenoids **107**–**108** [3.99–106], and bisabolane sesquiterpenic ketones typical of this species, named atlantones **109**–**110** [3.99–107].

Fig. 3.9 Atlas cedarwood (Cedrus atlantica) trunks in a sawmill (courtesy of N. Baldovini)

Despite the large number of publications on the composition of Atlas cedarwood oil, the data concerning its odor-active constituents are scarce. As early as 1902, *Grimal* reported that the distillation of Atlas Cedarwood oil furnished a fraction *which possessed exactly the odor of the original essence* and which contained a ketone of the formula $C_9H_{14}O$ [3.108]. However, *Pfau* and *Plattner* [3.107] claimed later that

the mixture of **109** and **110** was *the true aromatic principle of the oils*. Recent sources confirmed this information [3.109] and also mentioned that deodarone **111** [3.110, 111] was an important contributor. Among the numerous other minor constituents identified in *C. atlantica*, vestitenone **112** was described as possessing an odor characteristic of the wood [3.112]. Recently, a GC-O investigation on Moroccan Atlas cedarwood essential oil was performed with eight panellists, following the AEDA methodology [3.113]. Interestingly, none of the panellists recognized **109** or **110** as strong and typical cedarwood odorants, and a purified sample of (*E*)-**109** was even very weak or odorless for most evaluators. The most potent odorant constituents were 4-acetyl-1-methylcyclohexene **113** (Atlas cedarwood-like), **112** (citrus-lemon), *p*-cresol **7** (phenolic, animal), 4-methylacetophenone **114** (almond-like), undecan-2-one **115** (aldehydic, coriander-like) and several non identified constituents. One of the strongest unknown components had a rather typical Atlas cedarwood note, but **113** showed the highest mean FD factor and possessed a very characteristic cedarwood odor for most of the panellists. **113** can then be reasonably considered as the principal key odorant of Atlas cedarwood essential oil, and probably corresponds to Grimal's ketone.

Fig. 3.10 Aerial parts of Vetiver (*Chrysopogon zizanoides*) (courtesy of Céline Cerutti-Delasalle, Albert Vieille)

3.2.5 Vetiver

Vetiver (*Chrysopogon zizanioides*) is a perennial plant of the Poaceae family (Fig. 3.10) that grows in tropical and subtropical countries. The hydrodistillation of vetiver roots produces an essential oil with a very characteristic and complex woody earthy, grapefruit odor, highly appreciated for the formulation of high grade perfumes. Vetiver essential oil has a very complex chemical composition, with a high number of constituents (mainly sesquiterpenoids) showing a huge structural diversity.

The first chemical studies of vetiver essential oil came up against the complexity of the oil, which proved particularly intractable for the poor analytical means available at the time. However, the precious scent of the oil stimulated the research on the nature of the odorants of vetiver, and as early as 1902, *Genvresse* and *Langlois* claimed that the typical vetiver odor was due to an ester: *vetivenyl vetivenate* [3.114], but it was only in 1939 that more solid analytical data permitted to *Pfau* and *Plattner* [3.115] (Givaudan) to report that the ketonic fraction was the most characteristic. The distillation of this fraction permitted to isolate two ketones, α- and β-vetivone, after purification by several successive recrystallizations of their semicarbazones. On the other hand, the alcoholic fraction was described as possessing a very weak odor. Because of the limited experimental methods for structural determination, the structures of these two ketones were wrongly described as isomers of **116** by deduction after tedious chemical transformations [3.116, 117] (Fig. 3.12). *Naves* and *Perrottet* (Givaudan) gave more details on their olfactory character: α-vetivone was described as possessing a characteristic potent and warm vetiver note, while β-vetivone was relatively weak, styrax, and vegetable like [3.116]. Their structures were definitely established as **117** and **118** by *Endo* [3.118] and *Marshall* [3.119], respectively (Fig. 3.12). Curiously, *Maurer* (Firmenich) described these ketones as ≪*relatively weak and uninteresting*≫ [3.120] but reported that in contrast, the norsesquiterpenic ketones **119**, **120**, and **121** possessed a characteristic vetiver note [3.121]. The important contribution of *Khusimone* **119** [3.122] to the characteristic scent of the essential oil was confirmed by *Büchi* [3.123] who also pointed out that another trinorsesquiterpenic ketone (**122**) *plays a significant role in the reconstitution of the essential oil* [3.124].

Jirovetz et al. applied GC-O to the study of vetiver essential oil [3.125]. A large number of olfactory zones were detected, but the correlation with the corresponding constituents was not clearly established, nor any kind of ranking of their relative contribution. However,

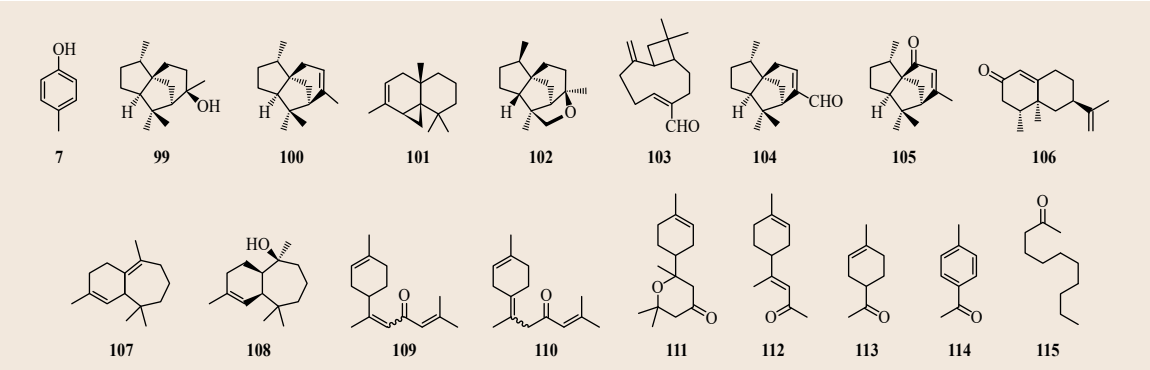

Fig. 3.11 Main constituents and key odorants of cedarwood oils (*Cedrus atlantica* and *Juniperus virginiana*)

some of the panelists involved in the study described as *typically vetiver* the elution zones of several constituents like **123–124** and **117–118**. The same team identified even more volatile compounds (monoterpenes and various light constituents), together with several known sesquiterpenic constituents, by purge and trap on the headspace of vetiver essential oil. They also analyzed these components by GC-O. The characteristic vetiver scent could not be associated with any of these constituents, but the authors affirmed that they were important for the top note of the oil, and *may have valuable synergistic effects with the other typical vetiver odor compounds* [3.126].

Mookherjee (International Flavors & Fragrances (IFF)) reported that **118** *undoubtedly plays the major role in contributing to the true odor of vetiver*, with several other carbonyl compounds (especially **117** and **119**) for which he gave an individual description of the olfactory character, and concluded that these other compounds *must also play some role to give the total precious woody note of vetiver oil* [3.127].

The controversies concerning the olfactory contribution of the vetivones continued, since *Spreitzer* et al. synthesized both enantiomers of **118** and described that the levorotatory form had a *quinoline-like, fruity (cassis, grapefruit) aroma with a woody by-note* but without *any odor reminiscent to the pleasant vetiver aroma*. Its antipode was characterized by an *unpleasant cresolic, medicinal note*. They concluded their article by hypothesizing that if most of the previous studies have attributed a typical vetiver scent to **118**, it was because of *traces of highly intensive odorous contaminations* [3.128].

The discrepancies of the literature on the odor-active components of vetiver led several authors to conclude in the mid-nineties that the constituents responsible for the true vetiver fragrance were still largely unknown [3.129, 130], and this statement probably stimulated some investigations like the outstanding work of *Weyerstahl*, published in a series of papers [3.131–133] which can up to now be considered as one of the most exhaustive analytical studies on a single essential oil. By a combination of distillations, chromatographic separations, chemical transformations, and structural analysis, he identified **155** constituents in a Haitian vetiver essential oil, and described numerous new structures. He also gave a detailed account on the olfactory properties of many isolated constituents and confirmed these data by synthesis for some of them [3.134, 135]. His contribution concerning the vetiver odorants is summarized at the end of his last publication [3.131] on the subject, and concludes that a large number of constituents possess strong odors with many different facets. Consequently, Weyerstahl claimed that the vetiver scent resulted from a complex sum of all these contributions, and he classified the constituents according to their olfactory notes. Three of the main alcohols were retained as the main contributors to the woody base note: khusimol **124**, (*E*)-isovalencenol **125**, and vetiselinenol **126**. Other olfactory notes related to the woody descriptor were mentioned for several compounds: sandalwood (**127–130**), ambery (**123**, **126–127**, **130–136**), and patchouli (**136–140**). One of the facets of the vetiver odor is often described as *aldehydic, very typical grapefruit-rhubarb*. Several carbonyl compounds (**135**, **139**, **141–146**) possessed this character, with **119** being the main representative, and **117** and **118** also falling within this category, with additional respective bitter and woody nuances. Many other constituents with various olfactory notes were also described: camphoraceous (**147–148**), fruity (**149–151**), musky (**152**), leather (**153**), floor-polish like (**154**), woody-peppery (**155**). *Weyerstahl* also wisely concluded that these olfactory evaluations had to be considered carefully, since even with the respectable GC purity of most of his samples, the presence of a strongly odorous minor constituent was still possible [3.4, 131]. Indeed, when he synthesized **145** for comparison with the natural

sample, he noticed slight olfactory differences that he attributed to the presence of odorous contaminants in the natural compound [3.133, 135].

In the work carried out by Weyerstahl, the relative contribution of the odorous components was not accurately established, but recently, Belhassen et al. performed a detailed analysis of Haitian vetiver oil using a combination of GC-O (AEDA), comprehensive two-dimensional gas chromatography (GC × GC)-MS, and chemical transformations. The AEDA conducted with five panelists underlined the importance of **142** and **144**, which showed the highest mean FD factor, accompanied by a typical vetiver character often mentioned for other zizaane derivatives such as **119** and **124**. Among the other constituents providing a high FD factor, **117** and **118** brought respectively rosy, lime-like and bitter grapefruit tonalities. β-vetivol (**156**) showed rosy-citrus aspects and **125** was perceived as strongly sandalwood-like. The other identified compounds with a lower FD are listed below in descending order of mean FD: dihydroeugenol **157** (dill-like, coconut, sweet), vanillin **13** (vanilla-like), 2-methylfurane-3-thiol **158** (meaty, nutty), β-damascenone **76** (fruity, sweet, plum-like), β-elemol **159** (carrot-like, pelargonium-like, green), *p*-vinylphenol **160** (metallic, phenolic), ziza-6(13)-en-3-α-ol **123** (Vetiver-like, cedarwood), nootkatone **106** (grapefruit-like, bitter, sour), cyclocopacamphanal **139** (marine, aqueous, calone-like), (*E*)-isoeugenol **161** (eugenol-like, smoky), guaiacol **162** (earthy, leek-like), *p*-vinylguaiacol **163** (smoky, warm, baked rice), spiroveta-3,7(11)-dien-12-ol **164** (baked apple, soft-fruit), khusimol **124** and khusimone **119** (both typically vetiver), 4-ethylphenol **165** (leather-like, smoky, burnt), khusian-2-ol **150** (fruity, sweet, woody), geosmine **166** (earthy-muddy), and β-vetivenene **167** (carrot-like, flowery). Strong variations were found between the five panelists for some constituents such as **118**, **117**, **150**, **156**, and **159** which showed significant deviations among their individual FD values. In contrast, the typical vetiver odorants **119**, and especially **142** and **144** displayed much more homogeneous FD values among the panelists. Since these two constituents possess a very characteristic woody vetiver note and were almost unanimously considered as the most potent odorants by the panel in this AEDA, they can then be recognized as the main vetiver key odorants [3.136].

3.2.6 Patchouli

Patchouli essential oil is produced by hydrodistillation of the dried leaves of *Pogostemon cablin*, a small plant (Fig. 3.13) cultivated mainly in Indonesia, Malaysia, and Philippines. Today, patchouli oil is the most important natural raw material in term of market size [3.61].

Fig. 3.13 Patchouli (*Pogostemon cablin*) leaves (courtesy of Sophie Lavoine, Charabot)

It possesses a very typical rich and strong odor, with woody, camphoraceous, spicy-balsamic and earthy tonalities [3.48, 61] (Fig. 3.14).

The main oil constituents are α- and δ-guaiene (**168–169**), and a specific sesquiterpenic alcohol, patchoulol **170**, which is almost systematically the major constituent. **170** is known since Gal's first analytical investigations on patchouli oil in 1869, since it can be easily obtained in crystalline form from fractional distillation, and was thus named *patchouli camphor* for this reason. Its history is also a famous example of a controversy about the key odor constituents of a raw material. Indeed, several authors claimed that **170** was odorless [3.137, 138] while most others maintained that it was the main odorant of the oil. The argument of the former was that crystalline **170** still contained trace amounts of a strongly odorous constituent, and for *Teisseire* et al., this compound was undoubtedly norpatchoulenol **171** [3.137]. Other analytical studies denied this assertion and the controversy eventually ended in 1981 when *Näf* et al. synthesized both enantiomers of **170** and demonstrated that the odor of the synthetic nature-identical levorotatory isomer was *practically indistinguishable* from the natural (−)-**170**. On the contrary (+)-**170** had a much weaker and completely different odor [3.139].

170 is now considered as the main odor donating constituent of patchouli essential oil, and according to many references, **171** has an important contribution [3.127, 140]. However, **171** shows a detection threshold three times lower than **170** but on the other hand, its typical content in patchouli oil is 70 times lower [3.61]. Anyway, specific individual anosmia for some of the patchouli odorants may have played a role in the controversies on the odor-active constituents of patchouli [3.61].

In 1988, *Nikiforov* et al. determined by GC-sniffing that **168–174** were the main odor-donating constituents

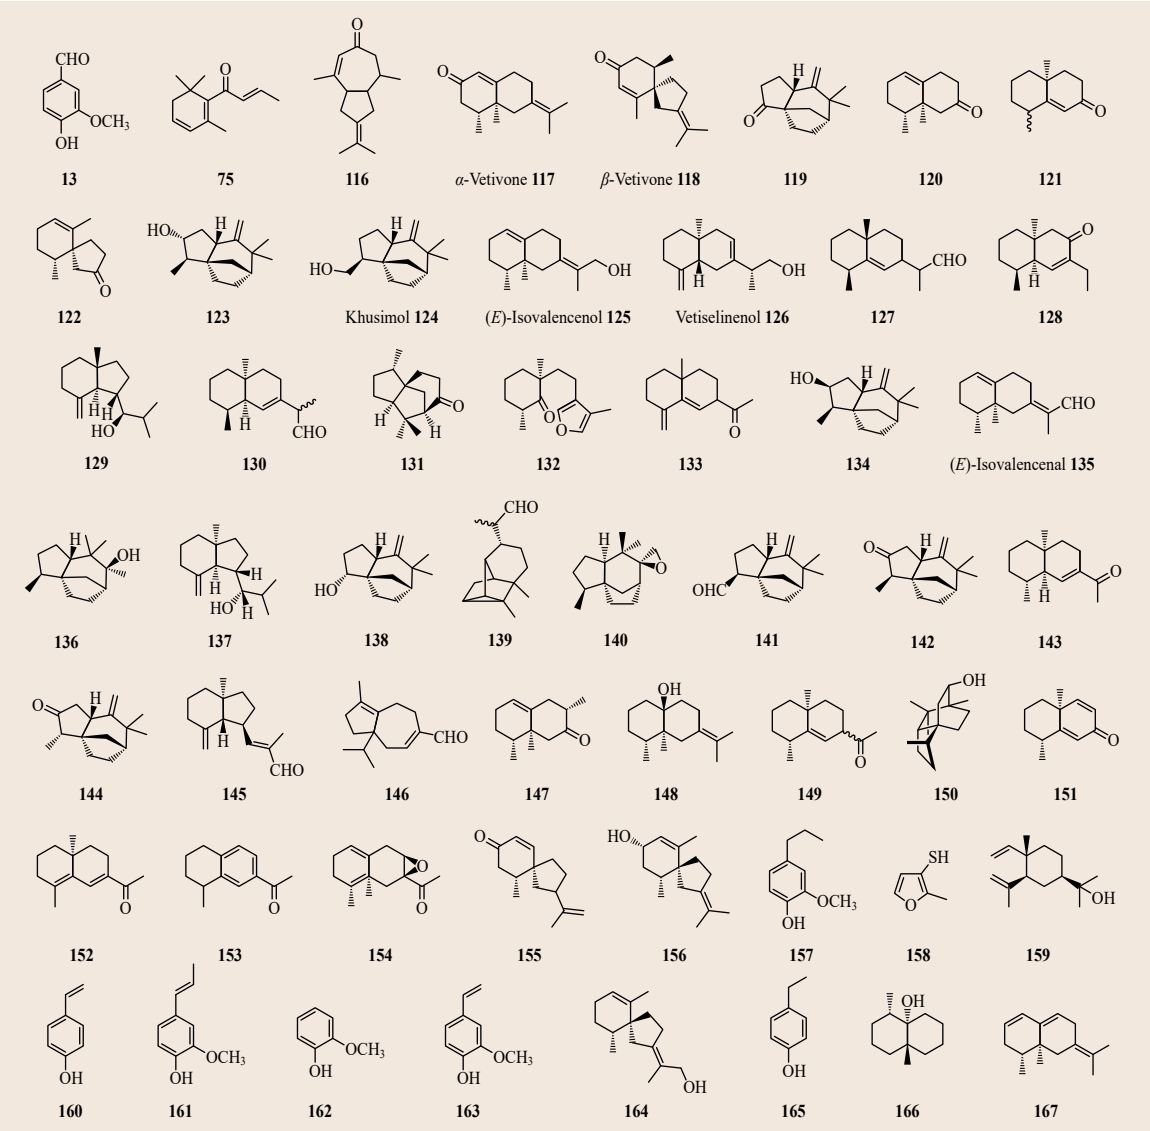

Fig. 3.12 Main constituents and key odorants of vetiver essential oil

of patchouli oil [3.141]. Thereafter, other minor constituents have been reported to contribute to the whole fragrance of patchouli, such as several nitrogen compounds: **175–176** [3.142], a series of pyrazines like **177–180** [3.142, 143] and some atypical sesquiterpene alkaloids **181–188** [3.127, 144]. Since these nitrogen compounds are contained in very low amounts, their olfactory contribution is probably limited, and rather negative [3.127]. *Mookherjee* performed a detailed analysis of patchouli oil and reported that it contained also acidic and phenolic fractions with respective *fatty, propionic* and *tarry, and phenolic* odors [3.127]. Several classical phenols and aliphatic acids had been previously isolated from patchouli oil [3.145], but their contribution to the odor of the whole oil was not determined. *Mookherjee* also isolated the following odorous constituents: cyclohexenones **189–191** and **192** (all possessing strong camphoraceous odors), **193** (strong woody, patchouli), **194** (ambergris), **195** (woody), **196** (celery), and concluded that these compounds contributed to the odor of patchouli oil, which was mainly due to the three sesquiterpenic alcohols **170–171** and the new tetracyclic potent patchouli odorant **197** [3.127, 146]. Researchers from Takasago recently reported the isolation of an isomeric structure **198** [3.147], which may be considered as the revised structure of **197**.

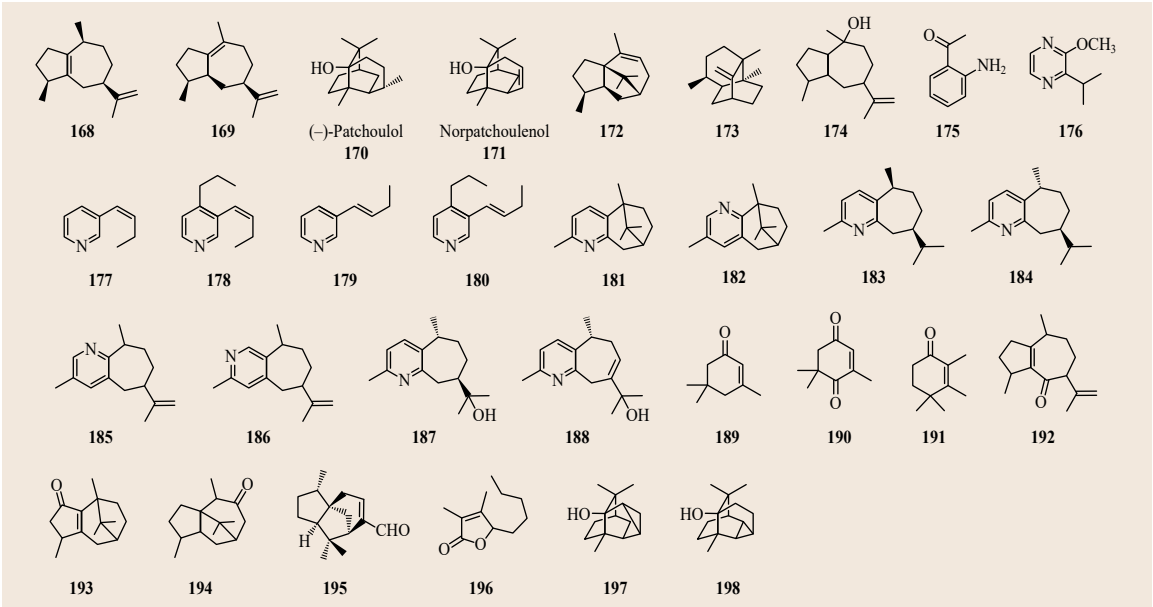

Fig. 3.14 Main constituents and key odorants of patchouli essential oil

3.2.7 Sandalwood

With its characteristic woody fragrance and its fixative properties, sandalwood essential oil is one of the most precious natural raw materials used in perfumery. This oil is produced by steam distillation of the heartwood and roots of various *Santalum* species. *S. album*, an evergreen hemiparasitic tree native from southern India [3.74, 148] is the most appreciated, and several other *Santalum* species are also cultivated for essential oil production, such as New Caledonian *S. austrocaledonicum* [3.149] or Australian *S. spicatum* (Fig. 3.15) [3.150–152].

The main constituents of sandalwood essential oil are (*Z*)-(+)-α-santalol **199** and (*Z*)-(−)-β-santalol **200** (Fig. 3.16), with typical amounts for *S. album* of about 40–50% and 20–30%, respectively. The structures of **199** and **200** were elucidated, respectively, by *Semmler* [3.153] and *Ruzicka* et al. [3.154] and these compounds were soon unanimously recognized as the most important contributors to the fragrance of *S. album* oil. (*Z*)-(+)-α-santalol **199** is described as slightly woody, reminiscent of cedarwood and α-cedrene [3.155], while its β-isomer **200**, usually contained with about half the amount of **199**, is more potent and is responsible for the highly prized typical warm-woody, milky, musky, urinous, animal aspects of sandalwood [3.127, 155–158]. Further minor constituents contributing to the odor of this material were then discovered in subsequent studies. *Demole* et al. analyzed distillation foreruns of *S. album* oil and identified many norsesquiterpenoids

Fig. 3.15 Australian sandalwood (*Santalum spicatum*) (courtesy of Céline Cerutti-Delasalle, Alvert Vieille)

and other constituents such as phenols **7**, **8**, **10**, **160**, **161–163**, and **201–203** which contribute to the smoky note of the sandalwood oil foreruns, as well the strong odorant **204** [3.159].

Nikiforov et al. [3.141, 160] performed GC-O experiments on *S. album* essential oil and described seven substances as the most intense odorous components in addition to **199** and **200**: α-santalene **205**, (*Z*)-α-santalal **206**, (*Z*)-β-santalal **207**, (*E*)-*epi*-β-santalal **208**, (*E*)-β-santalol **209**, α-bergamotol (isomer not specified) **210**, and spirosantalol **211**. The olfactory characterization of highly pure samples of some of these constituents was reported by *Brunke* et al. **209** (medium strength, woody to medicinal) and (−)-(*Z*)-α-*trans*-bergamotol **210** (bright, somewhat woody, waxy,

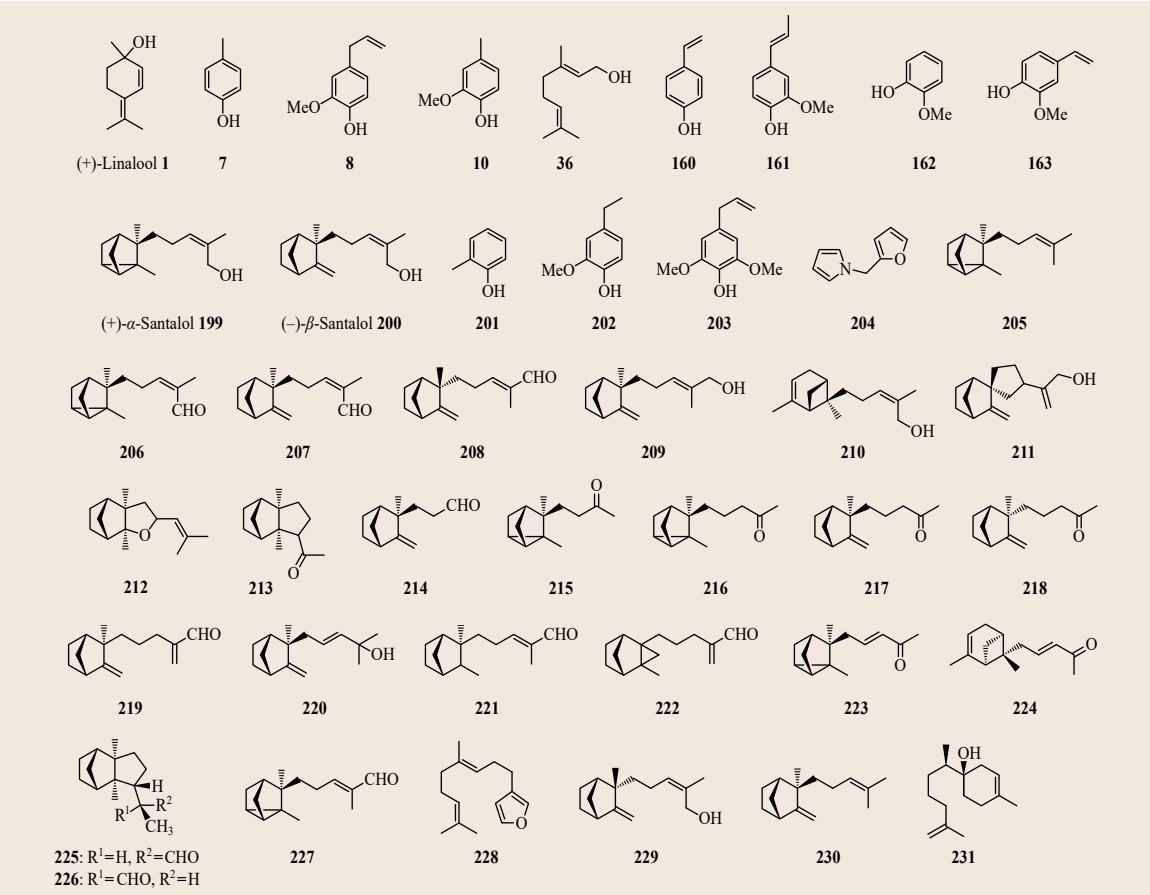

Fig. 3.16 Main constituents and key odorants of *Santalum album* essential oil

reminiscent of agrumen after-note, highly diffusive, and musky) [3.161].

Mookherjee later reported the olfactive properties of **19** additional constituents isolated after an extensive analysis of Javanese and Indian samples. Several of these components showed green, woody, melony and/or ambery tonalities (**212**–**219**) and five odorants were described as possessing very interesting woody odors: **213** (woody, ambery, ionone), **220** (fatty, sandalwood), **221** (sexy, sandalwood), **222** (woody, ambergris), and **223** (sweaty, sexy, woody) [3.127]. The most comprehensive study on the odorous components of sandalwood was published by *Brunke* and *Schmaus* who performed a GC-O (AEDA) of *Santalum album* essential oil [3.157, 158, 162]. Not surprisingly, the highest FD factor was attributed to **200**, followed by **199**. The third most important constituent was then identified as *nor*-α-*trans*-bergamotenone **224**, a trace constituent present in the essential oil at less than 0.01% [3.162]. This compound is responsible for the milky, nutty fatty tonalities perceived in the sandalwood fragrance. The fourth, fifth, and sixth contributors were respectively cyclosantalal **225**, *epi*-cyclosantalal **226** (both introducing green, aldehydic, aqueous, woody notes) and (−)-(*Z*)-α-*trans*-bergamotol **210** (sandalwood character, musky, with citrus tonalities). The next important constituents highlighted by this study were **1**, **7**, **8**, **37**, **204** (roasty, herbaceous), **205** (terpene-like), **220**, **221**, and **227** (all sandalwood), dendrolasine **228** (green, fatty, metallic), **229** (mild sandalwood) and **230** (terpene-like) [3.157, 158]. Finally, in a recent GC-O investigation on the odorous trace components of the *S. album* and *S. spicatum* essential oils, *Braun* et al. showed that **231**, present in less than 0.001% is also an important contributor to the fragrance of the oil, with a strong floral, muguet-like odor [3.163].

3.2.8 Myrrh and Frankincense

Myrrh and frankincense are among the oldest perfume materials known to mankind. They are oleo-gum-resins obtained from trees of the *Commiphora* species (for

Fig. 3.17 Myrrh gum-resin exuding from a *Commiphora myrrha* tree (courtesy of Céline Cerutti-Delasalle, Albert Vieille)

myrrh, Fig. 3.17) or the related genus *Boswellia* in the case of frankincense, which is also named olibanum. These trees grow in various parts of eastern Africa and southern Arabia [3.48]. Frankincense and myrrh gum-resins can be extracted or hydrodistilled to furnish an absolute or an essential oil.

Myrrh oils and extracts possess the characteristic warm-balsamic, sweet, and spicy odor of myrrh (Fig. 3.18). The main constituents of myrrh essential oil are furanosesquiterpenoids such as curzerene **232**, furanoeudesma-1,3-diene **233**, and lindestrene **234**. Compared to the other materials described before, the odorous compounds of myrrh have received much less attention. Wilson and Mookherjee have reported a detailed analysis on a sample of *Aden-Quality* myrrh essential oil. They noticed that the most volatile fraction of the oil contains common sesquiterpenes that have a low olfactory contribution, and that the typical odor of the oil was due to the components contained in the less volatile fraction. In order to characterize its key odorants, the sample was fractionated by column chromatography and preparative GC to furnish several furanosesquiterpenoids. The three main ones (**232**, **233**, **236**) were present at about 12% in the oil. **232** had a *green, woody, geranium odor of moderate intensity, but not characteristic of myrrh* but **234** was described as bearing a *deep rich leathery, incensey, warm, balsamic, sweet very typical myrrh character*. However, its olfactory evaluation was carried out on a fraction containing 25% of **234**. Together with these components, other minor (< 2%) furanosesquiterpenoids were also identified, and their olfactory properties were given. Several constituents showed an odor not particularly reminiscent of myrrh: **235** (relatively weak woody, balsamic odor), **236** (rose, tea, fruity-prunes), **237** (sweet, coumarin-like, tobacco-like), **238** (floral sweet, weak, hyacinth), **239** (weak, green, floral), and **240** (strong rose-tea, reminiscent of calamus). However, two components at 0.1% were reported to possess a strong resinous note: **241** (very heavy, subdued, resinous, compatible with myrrh, but not characteristic) and especially **242** (rich, sweet incense note, very characteristic of myrrh). The headspace of the myrrh gum was also investigated and did not contain these specific furanosesquiterpenes, which is consistent with the fact that the top notes are not characteristic of myrrh [3.164].

The olibanum resin is an uncommon example of a natural raw material in which each terpenic class is represented. Indeed, mono-, sesqui-, di-, and triterpenoids coexist in significant proportions in the resin, and its essential oil usually contains the three first classes. Two main types of compositions are known, distinguished by the main components: octanol **243**

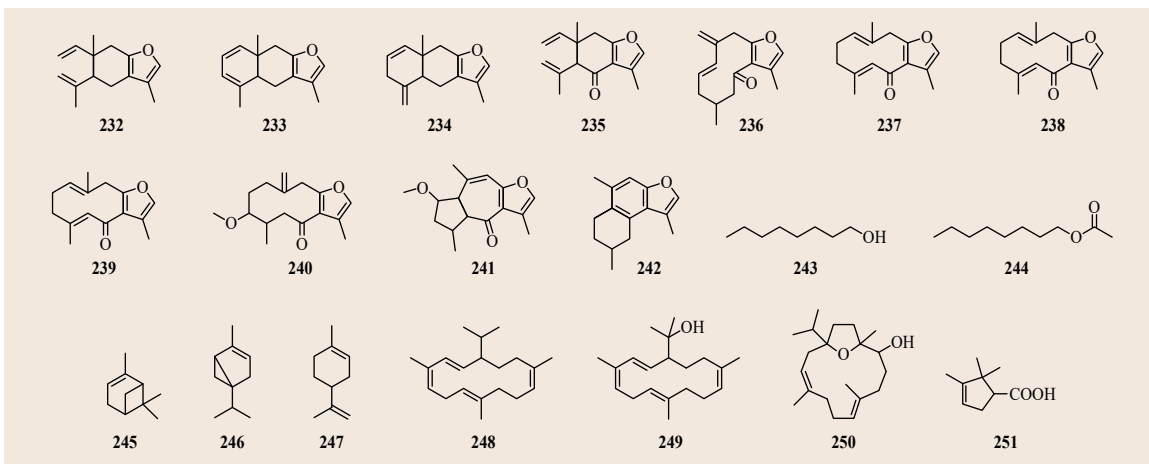

Fig. 3.18 Main constituents and key odorants of myrrh and frankincense essential oils

and its acetate **244** [3.165], or α-pinene **245**, α-thujene **246** and limonene **247** [3.166]. Specific diterpenic constituents are cembrane derivatives such as cembrene **248**, cembrenol **249**, and incensole **250** [3.167].

Paradoxically for a material which was often described as the oldest perfume known to mankind, very little is known about its main odor-active constituents [3.166]. The diterpenic components are odorless, and play no role in the characteristic old church-like base note, except maybe as fixative. However, the contribution of the carboxylic acids to this typical odor is certainly crucial [3.168, 169] and among these, α-campholytic acid **251** was reported to have *a rather strong odor reminiscent of the oil* [3.145].

3.3 Conclusion

For many natural raw materials used in perfumery, the published data concerning the most important odor impact constituents is often very scarce, even for extracts or oils which have been thoroughly analysed. *Weyerstahl* deplored that *synthetic chemists often do not smell their products* [3.131], and it is also regrettable that analysts who isolate pure constituents from fragrant raw materials seldom report their odorant characteristics. The characterization of the key odorants of natural raw materials is therefore still a vivid field of investigation, and as shown in this short overview, many discrepancies can still be found in the literature among the different studies, even on the most important raw materials. Anyway, the complexity of the olfactory system will certainly continue for a long time to supply new problems to the fragrance chemists working with natural extracts and oils, and many answers will be provided by the research studies trying to unravel the mechanisms of olfaction.

Acknowledgments. We would like to thank Daniel Joulain for his critical comments on the manuscript, and for many fruitful discussions and precious first-hand accounts. Lydia Ziegler (Robertet) and Clio André (UNSA) are warmly acknowledged for their precious bibliographical help.

4. Incense Materials

Johannes Niebler

Incense burning is probably the oldest perfuming method known to mankind. This chapter presents an overview of incense materials from different cultures and times, such as frankincense, myrrh, agarwood, palo santo, copal, and many more. Their botanical sources are given, and their chemical composition and odor properties are discussed. The methods of producing incense preparations are also briefly summarized. Incense use may pose certain health risks in the case of prolonged or repeated exposure, but may also have potential in medical applications. Incense use represents a special challenge to aroma research, as odorants can be newly formed during the process of burning.

The word *perfume* stems from the Latin *per fumum*, meaning *through smoke*. This indicates that incense burning was probably the first perfuming method available to mankind. Incense is, to put it simply, fragrant material meant for burning or smoldering, thereby releasing and/or generating the odorants and producing a pleasantly smelling smoke. In contrast to smoking and tobacco use, the smoke is usually not actively or directly inhaled. Such a simple procedure is easily discovered, and reports of incense rituals can be traced back as far as our written history can reach. They are found in varying extents in almost any culture and are still common even in modern times.

The use of incense materials is most often associated with rituals or religious ceremonies (Fig. 4.1). It adds an olfactory dimension to the experience and thus immerses the participants in a holistic manner. Nowadays, with perfumery, everyday scented products and flavored foodstuffs, incense has lost large parts of its attraction. Yet in former times, it can safely be assumed that everyday life was more often than not an olfactory nuisance. Incense use offered the simple (and only) way of scenting rooms, environments, and products, such as churches, ritual places and homes, including clothes, pillows, or hair.

Due to their ubiquitous importance, incense materials have been traded as precious commodities throughout the millennia. Perhaps the most prominent example is the Incense Route of antiquity, which refers to a main trade axis by land for camel caravans transporting frankincense, myrrh, and other goods from port towns in Hadhramaut (Yemen) up north along the Arabian Peninsula. Having passed numerous small kingdoms, tribe territories, and desert tracks, the road connected to Mediterranean trade routes in Petra, Gaza, and Alexandria. Trade by sea brought Arabian frankincense to India and Egypt [4.1, 2].

Even a brief account of cultures using incense and their rituals would easily fill a book on its own (e.g., *Fischer-Rizzi* [4.3]). A short description of its current or historical use in the world religions can perhaps give an impression of the variety of rites associated with incense.

Fig. 4.1 Woman praying with lit incense sticks (courtesy of szefei/iStock)

Fig. 4.2 An altar server with a typical censer (courtesy of Felipe Caparrós Cruz/digicomphoto/iStock)

In Christianity, mainly catholic and orthodox churches use incense for their services, whereas the protestant and other reformed churches have mostly abandoned it. Incense is seen as a symbol of prayers rising to God, and may have served to cover unpleasant smells in former times. Usually, a round metal censer hanging from chains (Fig. 4.2) is carried by altar servers

Fig. 4.3 Utensils for the Japanese Incense Ceremony (*left*), a traditional censer (*middle*) and two incense pieces wrapped in paper sheets (*right*). In the censer, a piece of charcoal is buried in ash and the incense wood is placed on a mica plate on the pile of ash (courtesy of Cristina Jaleru, www.LifeOfVenus.com)

Fig. 4.4 Depiction of the Japanese Incense Ceremony (courtesy of Nippon Kodo)

and the incense mixtures based on frankincense are placed on a glowing charcoal.

In Judaism, the priests performed extensive sacrificial offerings of a specially prepared incense mixture on the Altar of Incense in the Holy Temple in Jerusalem. The ingredients for the incense mixture, called ketoret, are given in the book of Exodus as stacte, onycha, galbanum, and pure frankincense. The Talmud lists several additional ones. However, the exact identity of the components is still a subject of discussion [4.4].

Islamic cultures use incense for pleasure and scenting rooms in their daily lives as well as for treating various medical conditions, but there is no ritualized, traditional use during worship. It is however mentioned as one of the smells that awaits people in Paradise.

In Buddhism, Chinese Taoism, and Hinduism incense offerings in temples are very common in the form of joss-sticks. A huge variety of scented and unscented incense raw materials is used in their production [4.5, 6]. In a nonreligious context, special incense sticks are also used as mosquito repellents in many tropical countries. Japanese high society in the Muromachi period (1336–1573 C.E.) developed Koh-do (香道, literally: Way of Incense, usually called Incense Ceremony, Figs. 4.3 and 4.4), a highly ritualized form of appreciating incense. *Listening* to incense was the central part in games during this Incense Ceremony and agarwood became the essential ingredient [4.7].

In almost all cases, incense use is closely interwoven with other effects, benefits, or interpretations apart from a profane scenting of the environment. Incense burning in the form of sticks or seals has even been used as a method of measuring time in ancient China and Japan [4.8]. Both the raw materials and the smoke could also be applied as a part of therapeutic treatments and medical procedures, for aphrodisiacal, cleansing, energetic effects, for inducing trance or hallucinations and connecting with ancestors, gods, or other spiritual entities [4.9, 10]. All these connotations make it hard to isolate the true potential for modern therapeutic applications, although some attempts have successfully been made. Frankincense, for example, shows promising anti-inflammatory properties due to its content in boswellic acids [4.11]. When looking at the odorant compounds, it is surprising that so few of these commonly available materials have been investigated by modern methods under an olfactory aspect. Quite probably, a large proportion of this knowledge has already been discovered but remains unpublished within the flavor and fragrance industry. Nonetheless, this chapter will try to gather basic information about common incense materials, preparations, and their olfactory properties.

4.1 Selected Incense Materials

All kinds of materials, from both plants and animals as well as occasionally even inorganic sources, have been used as incense in cultures around the world. This list can therefore only encompass a selection of the currently most common or renowned sources for incense materials. For an overview on incense in various culture areas, refer to *Fischer-Rizzi* [4.3], *Rätsch* [4.12], and *Mohagheghzadeh* et al. [4.10]. Common spices, like star anise, cinnamon, or cloves, are often part of incense mixtures. These will not be discussed here, but plenty of literature data is available on their composition and the relevant odorants in the general food chemistry literature.

Most chemical investigations on incense materials focus on the composition of the essential oil or the structural elucidation of new compounds. Investigations of odorant compounds and their specific contribution to the overall odor impression are rare, even for the essential oils. However, the established methodology in aroma research does not directly apply to the very special circumstances under which odorants are released during the burning of incense. High temperatures can lead to a variety of reactions and processes with potentially significant impacts on the odor, such as:

- Degradation or depolymerization of biopolymers (lignans, polysaccharides, proteins, etc.)
- Oxidation reactions, generation of pyrolysis products
- Vaporization of compounds of low volatility
- Release of odorants bound in precursors (glycosidic bonds, protein adducts, chromones).

Evidently, the study of these reactions involves many variables, such as the temperature (gradient), oxygen supply, grain size, or type of heat source. Furthermore, natural materials tend to vary in composition according to factors such as the climate, location, harvest, transportation, and storage conditions. Keeping track of all these influences is close to impossible.

A comprehensive investigation of any incense material would therefore have to involve reliably sourced raw materials and a realistic model of the burning process. A comparative, in-depth investigation of the smoke as well as the raw material would then (ideally) give trustworthy results. Unfortunately, such conditions are so far rarely achieved, and thus our knowledge on the aromas of many incense materials remains fragmentary.

Table 4.1 summarizes basic data on the various incense materials treated in the course of this chapter, and Table 4.2 gives additional odor descriptions of materials.

A study on tobacco additives [4.13] investigated several of the incense materials discussed in the following under pyrolytic conditions (temperature ramp from 300 to 900 °C). The authors only reported the five most abundant peaks in the chromatogram, often with uncertain identifications, but this is until now the only study comparing these materials or extracts

Table 4.1 Basic information on the incense materials treated in this chapter

Name	Alternative names	Botanical species or family	Main commercial source plants	Type of material	Countries of origin	Approx. price range[a] (US$/kg)	Main compound classes in the volatile fraction
Agarwood	Aloeswood, eaglewood, gaharu, oudh, jinkoh	*Aquilaria*	*Aquilaria sinensis, A. crassna*	Heartwood of infected trees	China, Vietnam, Cambodia, Indonesia, SE-Asia	100–100 000	Sesquiterpenoids, chromones
Asafoetida	Devil's dung	*Ferula*	*Ferula assa-foetida*	Gum resin	Iran, Afghanistan, Pakistan	30—100	Disulfides, monoterpenes
Benzoin	Benzoin Sumatra/ Siam, gum benjamin, benzoe, styrax	*Styrax*	*Styrax benzoin, Styrax tonkinensis*	Balsam	Thailand, Cambodia, Laos, Malaysia, Indonesia	20—200	Benzyl benzoate, cinnamic/benzoic acid derivatives
Bissabol myrrh	Scented/ perfumed myrrh, opopanax	*Commiphora*	*Commiphora guidotti, C. holtziana*	Gum resin	Somalia, Kenia	3—80	Monoterpenes, furanosesquiterpenes
Cedar-wood	–	*Cedrus, Juniperus, Cupressus*	*Cedrus atlanticus*	Wood	Morocco, Libanon, USA, China	1—50	Mono- and sesquiterpenoids
Copal manila	–	*Agathis dammara*	*Agathis dammara*	Gum resin	Philippines	3—80	
Copals	Copal blanco, santo Copal oro, amarillo Copal negro	*Bursera*[b] *Hymenaea courbaril*[b] *Protium*[b]	*B. bipinnata, jorullensis, microphylla* *Hymenaea courbaril* *Protium copal*	Gum resin	Mexico, Mesoamerica	–	Sesquiterpenes Monoterpenes Monoterpenes
Dammar	Copal dammar	*Shorea*	*S. wiesneri* (see text!), *S. javanica*	Gum resin	Indonesia	3—80	
Dammar	Black dammar	*Canarium*	*Canarium strictum*	Gum resin	India, South East Asia	3—80	
Dragon's blood	–	*Dracaena, Daemonorops, Croton*	*Daemonorops draco, Dracaena draco, D. cinnabari, Croton lechleri, C. draco*	Resin	Africa, India, Southeast Asia, South America	100—300	Flavonoids
Frankincense	Olibanum, Gum olibanum, Luban	*Boswellia* spp.	*Boswellia sacra, B. serrata, B. papyrifera*	Gum resin	Somalia, Oman, India, Ethiopia, Sudan, Eritrea	5—150	Monoterpenes, esters, diterpenoids
Galbanum	Mother resin	*Ferula gummosa (syn. F. galbaniflua)*	*Ferula gummosa (syn. F. galbaniflua)*	Gum resin	Iran, Turkey, Afghanistan	30—250	Monoterpenes
Guggul	Gugulu, false myrrh, bdellium	*Commiphora*	*Commiphora mukul, C. wightii*	Gum resin	India	5—100	Monoterpenes, furanosesquiterpenes
Juniper berries, leaves, wood	Red cedar, cedarwood	*Juniperus* spp.	*Juniperus virginiana*	Wood, berries, dried leaves	USA	–	

Table 4.1 (continued)

Name	Alternative names	Botanical species or family	Main commercial source plants	Type of material	Countries of origin	Approx. price range[a] (US$/kg)	Main compound classes in the volatile fraction
Labdanum	Ladanum, laudanum	*Cistus* spp.	*C. ladanifer, C. creticus*	Oleoresin	Mediterranean (Spain, Morroco, etc.)	40–400	Mono- and sesquiterpenoids
Mastic	Arabic/ Yemen gum, Chios Mastiha	*Pistacia lentiscus*	*Pistacia lentiscus (var chia)*	Gum	Greece, Mediterranean countries	100–500	Monoterpenes, sesquiterpenes
Myrrh	Heerabol myrrh	*Commiphora*	*Commiphora myrrha (var molmol)*	Gum resin	Somalia	5–100	Monoterpenes, furanosesquiterpenes
Opopanax	–	*Opopanax chironium*	*Opopanax chironium*	Gum resin	Mediterranean countries	–	
Palo santo	Holy wood	*Bursera graveolens*	*Bursera graveolens*	Wood	Mainly Peru, Middle and South America	10–150	Limonene, mono- and sesquiterpenoids
Palo santo	Holy wood, guaiac wood	*Bulnesia sarmienti*	*Bulnesia sarmienti*	Wood	Gran Chaco area (Argentina, Bolivia, Paraguay)	–	Sesquiterpenoids
Peru balsam	Balm of Peru	*Myroxylon balsamum*	*Myroxylon balsamum var pereirae*	Balsam	El Salvador, Central and South America	30–150	Benzoic/cinnamic acid and its esters
Sandalwood	–	*Santalum*	*Santalum album, S. austrocaledonicum, S. spicatum*	Heartwood	India, Sri Lanka, Australia, Indonesia	10–100	Santalols, sesquiterpene alcohols
Storax	Styrax, Levant storax, American storax, sweet gum	*Liquidambar*	*Liquidambar orientalis, L. styraciflora*	Balsam	Turkey, Honduras, Central America	30–100	Styrene, monoterpenes
Tolu balsam	Tolu balm	*Myroxylon balsamum*	*Myroxylon balsamum var balsamum*	Balsam	Columbia, Central and South America	30–150	Benzoic/cinnamic acid and its esters

[b] Attribution of common names to the species very tentative, multiple other species are traded as copal varieties.

thereof under pyrolytic conditions. Their main aim was identifying sources for harmful pyrolysis byproducts known as *Hofmann analytes*, for example, phenols and benzene. The reported compounds for incense materials treated in this chapter are given in Table 4.3. The data is therein compared to selected literature data, from which the five most abundant peaks were also listed.

It has to be noted that the study by *Baker* and *Bishop* [4.13] did not investigate their raw materials under nonpyrolytic conditions, so that no reliable conclusion can be drawn as to which compounds are newly formed by pyrolytic processes and which are just evaporated from the mixtures. For frankincense, for example, the data is in very good agreement with the literature data from a study by *Hamm* et al. [4.18], indicating that these major compounds evaporate unchanged from the olibanum oil. The same applies to galbanum and opoponax oil, whereas all other raw materials show distinct differences, which could either be attributed to changes occurring during the pyrolysis or simply be the result of natural variations in the raw materials or incorrect identification of compounds.

Many of the raw materials discussed in this section are plant exudations. A short note on their terminology [4.2] should help to clarify the expressions used in the following: Gums are water soluble, polysaccharide-based saps, whereas resins are

Table 4.2 Odor descriptions of a selection of incense raw materials, supplied by perfumers from Symrise AG (Germany)

Name	Source plant	Odor description
Agarwood	*Aquilaria*, species not stated	Rich sweet woody, wet wood-like, moist
Asafoetida	*Ferula assa-foetida*	Onion
Cedarwood	*Cedrus atlanticus*	Woody, dry, carrot, peppery
Dammar	Unknown	Smoky, birch tar-like
Frankincense	*Boswellia sacra*	Pine, woody, peppery
Galbanum	*Ferula gummosa*	Green, bitter, peas, earthy
Guggul	*Commiphora mukul*	Resineous, balsamic, spicy, olibanum
Gum benzoe Siam	*Styrax tonkinensis*	Balsam, powdery, cinnamic, ambra, slightly smoky, almond, prune
Gum benzoe Sumatra	*Styrax benzoin*	Balsamic, powdery, cinnamic, ambra
Labdanum	*Cistus ladanifer*	Waxy, incense, resin, ambra, animalic, fruity, prune
Myrrh	*Commiphora myrrha*	Liquorice, mushroom, hot and cold effect, wicker, undergrowth
Opopanax	*Opopanax chironium*	Mushroom, myrrh, nut, quinoline, tobacco, powdery
Palo santo	*Bulnesia sarmienti*	Greasy, pine, nut, tobacco, woody, powdery
Peru balsam	*Myroxylon balsamum var pereirae*	Balsam, vanilla, chocolate, powdery
Sandalwood	*Santalum album*	Woody, creamy, incense, powdery, smoky
Storax	*Liquidambar styraciflora*	Orange, animalic, almond, cinnamon, glycine, rose, peony
Tolu balsam	*Myroxylon balsamum var balsamum*	Tuberose, anise, balsam, vanilla, heliotrope, ciste, olibanum, tobacco, chocolate, powdery

lipid soluble and contain primarily terpenoid or phenolic compounds or a mixture thereof. The definition of balsams (balms) is not entirely specific, but it generally refers to soft, malleable exudations that are usually dominated by cinnamic and benzoic acid derivatives and are highly fragrant. Oleoresins are characterized by a high percentage of volatile terpenoids, and are therefore relatively fluid. It is evident that a clear distinction between them is not always possible, and many products are mixtures of these groups.

4.1.1 Agarwood

Agarwood, also called *gaharu* or *aloeswood* as well as *oud* in Arabic or *jinkoh* 沈香 in Japanese, is produced by tall, evergreen trees of the genus *Aquilaria* and, to a lesser extent also by *Gyrinops* and *Gonystylus*. They

Fig. 4.5 A large piece of agarwood presented during a Japanese Incense Ceremony. The dark color usually indicates a high oil content (courtesy of Cristina Jaleru, www.LifeOfVenus.com)

are typically found in southeast Asia, and most of the agarwood originates from *Aquilaria sinensis* Merr., *A. crassna* Pierre ex Lecomte, or *A. malaccensis* Lam. The trees respond to microbial infection by fungi or wounding with the secretion of a dark, resinous oil into the heartwood, roots, or branches; thus protecting it from further infection. The formerly lightweight and pale wood becomes dark brown to black and so dense that the best qualities of agarwood sink in water (Fig. 4.5). In nature, this process is rarely found, making agarwood an extremely luxurious commodity. In the recent decades plantations have been established, where artificial inoculation or wounding of the trees leads to the production of agarwood (an example can be found in *Liu* et al. [4.21]). In the wild, the trees have become rare due to overharvesting and exploitation [4.2]. Indeed, some species are now endangered, and their trade is regulated under CITES, the Convention on International Trade in Endangered Species of Wild Flora and Fauna. Agarwood is often reported as the most expensive wood in the world. Its price per gram for higher qualities often by far exceeds that of gold. The wood is highly valued as incense material, particularly in Arabic and Asian cultures. In Japan, agarwood is the essential ingredient for all incense rituals and ceremonies. Furthermore, steam distillation yields agarwood essential oil, which perfumers treasure for its unique *oud* character. In traditional medicine of various Asian countries, it is also a pharmaceutical drug for a large variety of purposes and generally considered an aphrodisiac.

Typical agarwood volatile constituents include a large variety of oxygenated sesquiterpenes, mostly based on the agarofuran, guaiane, selinane, and eu-

Table 4.3 Comparison of the top five constituents (by peak area %) for pyrolysate (data from [4.13]) and the volatile fraction (data from various literature sources, referenced in the table)

desmane skeleton. Notable is the complete absence of monoterpenes. Chromone derivatives are characteristic markers for agarwood, but have a low volatility and are not found in hydrodistillates [4.22].

A variety of sesquiterpenes in combination with smaller volatiles seem to be responsible for the typical, highly valued odor of agarwood [4.22], although this has not been satisfactorily investigated. Examples for potent sesquiterpenes are dihydrokaranone **1** and karanone **2** [4.23, 24] (Fig. 4.6). *Pripdeevech* et al. [4.25] identified many odor-active compounds in agarwood oils, but their study shows some irregularities and should therefore be considered with caution. For example, the presence of large amounts of isoamyl dodecanoate (13–55%) in all three investigated essential oils is rather surprising, as this compound has not been found in any other study on the essential oil of agarwood. Additionally, the authors reported a variety of monoterpenoids, whereas the review of the literature until 2010 by *Naef* states that *no monoterpenes at all have been detected* [4.22]. Moreover, the odorants detected were rated in intensity according to their relative peak area, which is not a valid conclusion to anyone familiar with flavor analysis. Nonetheless, this study showed a large variety of odor-active compounds being present in agarwood essential oils, their relative potency however needs further investigation.

In a different study by *Hashimoto* et al., chromones were shown to liberate aromatic compounds during burning (Fig. 4.7), a rare example of an investigation of the odorant generation in the process of incense burning [4.26]. As the review by *Naef* [4.22] summarizes, there are several other studies on the smoke of agarwood. Mostly, sesquiterpenes and a large vari-

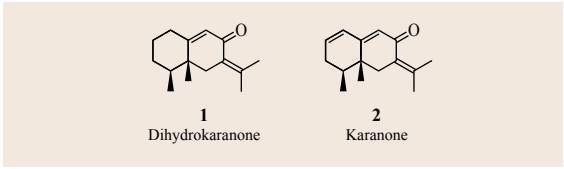

Fig. 4.6 Two odor-active sesquiterpenoids from agarwood

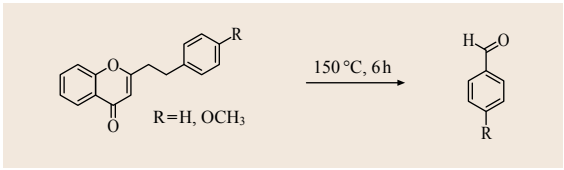

Fig. 4.7 Chromone derivatives were shown to release fragrant aldehydes, in this case benzaldehyde and 4-methoxybenzaldehyde during pyrolysis at 150 °C in the course of 6 h [4.26]

ety of aromatic compounds (e.g., phenol, anisole, or guaiacol) were detected, the former mostly unchanged except under high temperatures (500 °C), the latter presumed to be pyrolysis products from the chromones or from wood pulp (lignin). The pyrolytically generated compounds could be responsible for the change in the odor profile over a time period of 12 min from *floral*, *woody balsamic notes* to *heavy woody*, *phenolic*, *animalic notes* as observed by *Kaiser* [4.27].

4.1.2 Benzoin Siam/Sumatra

Firstly, some clarification on the naming of benzoin resins and storax (Sect. 4.1.13) is needed. Styrax is the resin derived from trees of the genus *Styrax*, whereas storax is obtained from *Liquidambar* species. However, some literature sources use the two names synonymously or interchangeably [4.2]. *Styrax* resins are also well-known under their other names: benzoin (resin), benzoe, or gum benjamin. For an easier reading experience, they will be treated here under the name *benzoin*, which is not to be confused with the chemical compound of the same name.

Two types of benzoin are traded on a larger scale: Siam benzoin from Thailand and Laos or Sumatra benzoin from the islands Sumatra, Java, and the Malay Peninsula. They are produced by repeated incisions made to the bark of *Styrax tonkinensis* Craib ex Hartwich for Siam benzoin and *Styrax benzoin* Dryand. for Sumatra benzoin. The latter product might also be obtained, though to a far lesser extent, from various other *Styrax* species occurring in the forests of Sumatra, such as *S. paralleloneurus* Perkins, *S. ridleyanus* Perkins and *S. subpaniculatus* Jungh. & de Vriese [4.2].

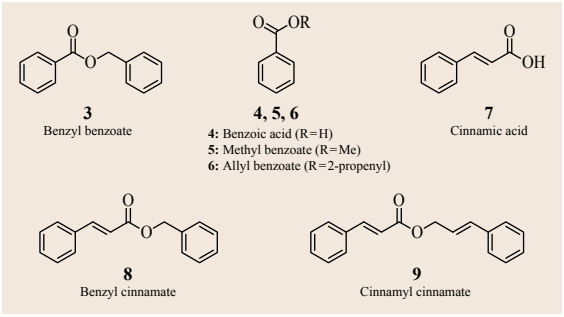

Fig. 4.8 Major constituents of *Styrax* resins

The volatile fraction of these two resins has been investigated in detail in a series of recent publications [4.14, 28, 29], in addition to several older studies summarized by *Langenheim* [4.2]. The two sorts can be well distinguished by their chemical composition: though both contain around 70–80% benzyl benzoate **3** in the volatile fraction, Siam benzoin contains benzoic acid **4** and its derivatives, like methyl or allyl benzoate **5**/**6** (Fig. 4.8). By contrast, Sumatra benzoin is, apart from **3**, dominated by cinnamic acid **7** and its derivatives like benzyl cinnamate **8** or cinnamyl cinnamate **9** [4.14]. Both balsams smell intensely balsamic [4.30, 31], and though their odorants have not been investigated in detail, it can safely be assumed that at least the aforementioned compounds contribute to the odor profile of benzoin. Siam benzoin is more valued in the flavors and fragrances industry due to its better aroma, whereas Sumatra benzoin is more commonly used in pharmaceutical applications [4.2].

4.1.3 Copal and Dammar

The designations *copal* and *dammar* (also spelled damar) are widely used for various resins, often with uncertain or unreliable botanical origin. Generally speaking, copal and dammar designate harvested as well as fossilized resins from trees of families Burseraceae, Dipterocarpaceae, Araucariaceae, and others. Historically, the distinction between dammars and copals was based on physical properties or local designations more than on botanical origin [4.32]. In colonial times, their export as nontimber forest products for the paint and varnish industries was introduced to many cultures in Southeast Asia [4.33].

Several sorts of copal, which are well-known incense materials, are commonly available on markets in Mesoamerica and have been used since precolonial times. They are frequently mentioned in literature and folklore as offerings to the gods in most Mesoamerican cultures in the form of incense or raw material. In Mayan cultures, copal is commonly known as *pom* and

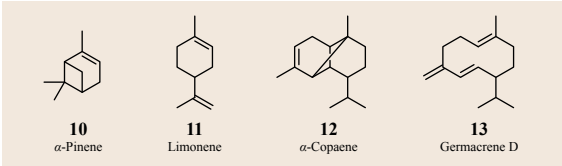

Fig. 4.9 Major compounds reported for various copals

transforms into *food for the gods* when it is burned as incense. Furthermore, the gums and resins from various trees were used as glue [4.34], medical ointments, and in modern times also for paint binders and varnishes.

Case et al. [4.35] investigated the three types of copal by performing an extensive literature search and GC-MS measurements and gives an excellent overview over the incense use of copals. They came to the tentative conclusion that copal blanco is commonly obtained from *Bursera bipinnata* Engl., copal oro from *Hymenaea courbaril* L. (from the family Fabaceae), and copal negro from *Protium copal* Engl. Considering the multitude of species from both *Bursera* and *Protium* growing in the area, it is highly unlikely that a solid attribution of trade names to a specific species will ever be possible. The authors also suggest that the color distinction between the copals comes from the tapping and processing techniques rather than from the source plants [4.35]. *Rätsch* [4.12], for example, lists 20 *Bursera* and 5 *Protium* species as sources of various copals. The samples depicted in this chapter (Sect. 4.1.15) were obtained from incense shops and claimed to be from *Protium copal* or *Bursera jorullense* for copal blanco and *Bursera microphylla* for Copal negro.

All three resins in the study by *Case* et al. [4.35] were dominated by mono- and sesquiterpenes. The main compounds in both copal oro and copal negro were α-pinene **10** and limonene **11** along with various other terpenes, whereas copal blanco was reported to contain mostly α-copaene **12** and germacrene D **13** and almost no monoterpenes at all (Fig. 4.9). *Stacey* et al. [4.34] used the triterpenic composition to categorize commercial and archaeological samples, and found that the commercial samples from local markets were probably *Bursera*-derived, but the inherent variability between the different *Bursera* species and lack of authentic reference material made it impossible to come to reliable conclusions.

Three additional products are also traded under the name copal or dammar. Firstly, copal manila is a translucent gum obtained from *Agathis dammara* (Lamb.) Rich. in the Philippines. Secondly, dammar usually comes from *Shorea wiesneri*, a species that does not exist in botanical literature and appears to be only a common trade name. Its exact botanical origin is therefore highly uncertain, but a potential major source of this dammar could be *Shorea javanica* Koord. & Valeton (Sumatra, Indonesia), reported in literature as economically important and tapped for its resin [4.2, 36]. Thirdly, black dammar from *Canarium strictum* Roxb. is, contrary to its name, a light yellowish to translucent, brittle resin. All three have multiple uses, as for instance paint binders and varnish, traditional medicine, medical glue components, or incense in the local cultures [4.37, 38].

4.1.4 Cedarwood

Cedarwood denominates a variety of woods from different trees and areas. Literature about its use as incense material is scarce. Cedarwood is mainly used as timber or for the distillation of essential oil for aromatherapy and perfumery (Chap. 3). In a strict sense, cedarwood comes from the genus *Cedrus*, with the most important species *Cedrus atlanticus* (Endl.) G. Manetti ex Carrière (Morocco, Algeria), *C. deodara* (Roxb. ex D. Don) G. Don (Himalaya) and *C. libani* A. Rich (Cedar of Lebanon). Commercial cedarwood (oils) often also originate from *Cupressus* spp. (Chinese cedarwood) and *Juniperus* spp. (Texan/Virginian cedarwood) [4.39]. Juniper berries, leaves, and wood, for example, from *Juniperus virginiana* L., were common incense materials in native American cultures [4.3].

4.1.5 Dragon's Blood

Dragon's blood is a bright to dark red resin, its name derived from medieval myths woven around it. However, the scholars of antiquity like the anonymous author of the *Periplus of the Erythrean Sea* already knew its true source to be a plant secretion from the island Socotra [4.40]. Today, three types of dragon's blood are known and traded: the resins from *Dracaena*, *Daemonorops*, and *Croton* species [4.2, 41].

Dracaena draco L. from the Canary Islands is closely related to *Dracaena cinnabari* Balf.f. from Socotra, both trees of extraordinary physical appearance. They exude a red oleoresin from small cracks in the trunk or from artificial woundings. *Dracaena* resins are characterized by a large variety of flavonoids and related polymers. The red color is caused by dracoflavylium **14** and other flavonoid colorants like dracorhodin **15** and dracorubin **16** [4.42] (Fig. 4.10).

Daemonorops draco Blume and other *Daemonorops* species are rattan palms native to parts of India and Southeast Asia (Sumatra, Borneo). The fruits of *D. draco* are covered in a red shell from which the resin is obtained; usually the harvested fruits are shaken to loosen the resin. This is the only type of

dragon's blood which enters world trade on a noteworthy scale [4.43].

Croton lechleri Müll.Arg., *C. draco* Schltdl. and several other *Croton* species are the source of South American dragon's blood, obtained from cuttings in the tree trunk. The main constituents of the essential oil from the bark of *C. lechleri* were reported to be sesquiterpenoids, namely sesquicineole **17**, α- **18** and β-calacorene **19**, 1,10-di-epi-cubenol **20** and epi-cedrol **21**, along with some monoterpenes like α-pinene **10**, p-cymene **22**, limonene **11** and borneol **23** [4.44, 45] (Fig. 4.11).

All types of dragon's blood have a large variety of medical uses in the local cultures, including treatment for open wounds and diarrhea. Like many other resins, it has also been used in some cases as lacquer in arts and crafts. As an incense material, it is particularly attractive for coloring mixtures, whereas its scent is neither particularly strong nor characteristic [4.12]. The attractive appearance as a dark red solid or bright red powder makes dragon's blood an interesting material for all kinds of scams. For example, it has been sold as *red rock opium* to drug users in the USA, although there is no evidence for any psychoactive substances in dragon's blood [4.46].

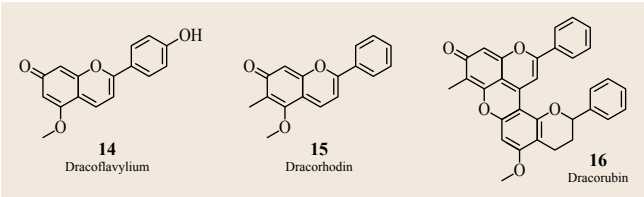

Fig. 4.10 Flavonoid compounds responsible for the intense red color of dragon's blood

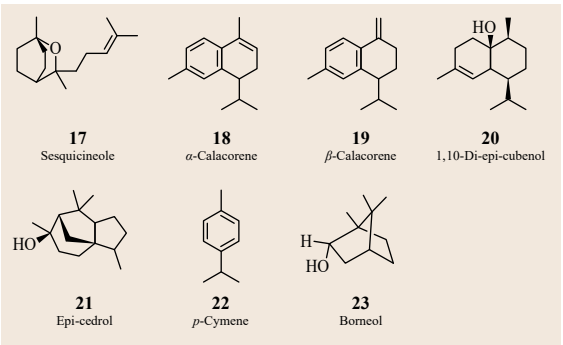

Fig. 4.11 Selected compounds from *Croton lechleri*

4.1.6 Frankincense

Frankincense is a central ingredient in many incense mixtures in Europe, Asia, India, and in Arabic countries. The frankincense trees of the genus *Boswellia* are tapped and their air-dried gum resin harvested, typically appearing as pea- to thumb-size grains of translucent, whitish-yellow to dark brown color. Four species are of economic relevance: *Boswellia sacra* Flueck. is native to Oman and Somalia, and *Boswellia carteri* Birdw. is generally considered to be the same species, differing only slightly in phenotype and habitat. Its gum resin (Arabian Frankincense) is said to be the highest quality available and was traded on the Incense Route since antiquity. *Boswellia serrata* Roxb. (Indian Frankincense) is found in parts of India and therefore deeply rooted in Ayurvedic medicine as well as in Hindu and Buddhist incense usage. *Boswellia papyrifera* Hochst. grows in coastal regions of Sudan, Eritrea, Ethiopia, and northern Somalia, and is often traded as Eritrea (or Ethiopia) type of incense. By contrast, *Boswellia frereana* Birdw. is of low commercial interest, typically found in Somalia and mostly used by locals [4.2, 47].

Applications typically range from direct use as incense, blending with other incense materials to therapeutic use in complementary and modern medicine. The so-called boswellic acids, pentacyclic triterpenic acids found in the resins, have been shown to possess anti-inflammatory properties [4.11]. The hydrodistillate of frankincense resins is a common perfumery raw material and often used in aromatherapy.

The volatile fractions of each species differ notably in composition and odor. Apart from *B. papyrifera*, which is dominated by *n*-octyl acetate **24** and *n*-octanol **25**, all other *Boswellia* resins mainly consist of mono-, sesqui- and diterpenes (Fig. 4.12). *Boswellia sacra* contains α-pinene **10** and limonene **11** and a variety of sesquiterpenes, whereas *Boswellia serrata* shows higher amounts of α-thujene **26** and a differing sesquiterpene profile. All three contain specific diterpenoid marker substances for frankincense, such as serratol **27**, incensole **28**, incensole acetate **29**, and others. Detailed compositions and a total of over 300 identified compounds in *Boswellia* resins are the result of a large number of chemo-analytical studies on the volatile constituents of frankincense, most of which have been summarized in the review by *Mertens* et al. [4.48]. Specific and comprehensive investigations concerning the odor-activity of these compounds are still missing. *Woolley* et al. [4.49] pointed out that differences in the enantiomeric ratios of α-pinene **10** and limonene **11** might allow to distinguish between *B. sacra* and *B. carteri* just by smelling the essentials oils, based on the olfactory differences for the enantiomers of both compounds. *Hasegawa* et al. [4.50] reported incensole **28** and several of its derivatives to be important contributors to the smell of *B. papyrifera* resins. Comprehensive investigations of the

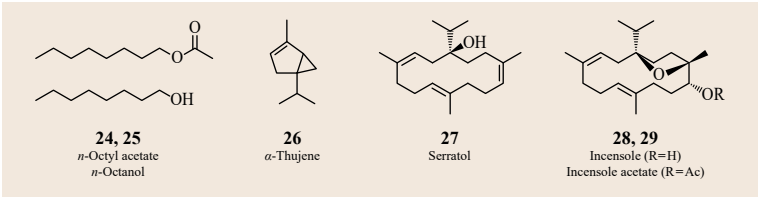

Fig. 4.12 Compounds found in *Boswellia* resins

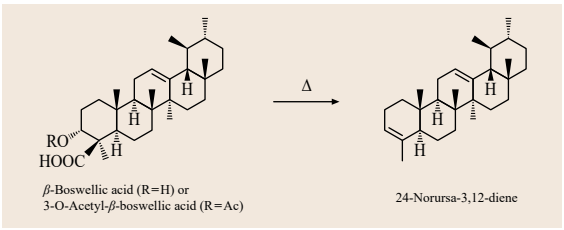

Fig. 4.13 Generation of 24-norursa-3,12-diene from boswellic acid precursors, an example of nortriterpenoids generated in the pyrolysis of frankincense (after [4.54])

odorant compounds in *Boswellia* resins that are currently conducted in our lab indicate that the different sorts of frankincense also differ extensively in their main odorants.

The smoke of frankincense has been investigated analytically with largely differing results. *Pailer* et al. analyzed pyrolysed fractions of the resins of *B. carteri* and found mostly newly generated compounds [4.51–53]. By contrast, *Basar* [4.54] observed mainly unchanged compounds, but was able to show the generation of nortriterpenic compounds in *B. carteri* pyrolysate by dehydration, deacetylation, and decarboxylation reactions of boswellic acids (Fig. 4.13). The apparent changes in the odor profile during pyrolysis have not yet been attributed to specific compounds or reactions.

4.1.7 *Ferula* Resins: Galbanum and Asafoetida

Some species of the giant fennels (*Ferula*) yield resins from their thick root when cut at the base. Two types have been known and traded for millennia: Asafoetida and Galbanum.

Asafoetida is the brown, sometimes greenish gum resin obtained primarily from *Ferula assa-foetida* L., a perennial plant of over 2 m in height with yellowish flowers and a large carrot-like root. Up to 17 other species like *F. foetida* Regel, *F. jaeschkeana* Vatke and *F. narthex* Boiss. yield a similar resin sold under the same name [4.55]. Typically, the plant is cut-off and incisions are made to the base of the root to collect the resin [4.2]. The essential oil of *F. assa-foetida* consists of over 40% but-2-yl-1-propenyldisulfide **30**, **31** (*E*-*Z*-ratio 7 : 3), accounting for its pungent, garlic-like, sulfurous smell. Its use is by far more common in traditional medicine applications and as a spice than as incense material [4.55].

Galbanum is a brown to yellowish, soft gum resin obtained from the lower stem or root of *Ferula gummosa* Boiss. (syn. *Ferula galbaniflua* Boiss. & Buhse). Some sources list *F. gummosa* and *F. galbaniflua* as distinct species based on chemotaxonomic evidence [4.15]. These plants grow in countries like Turkey, Afghanistan, and Iran and have been well-known since before biblical times. Galbanum is one of the ingredients in sacred incense from the Bible, has a multitude of reported uses for various medical conditions, and is also believed to be a contraceptive [4.2]. The chemical composition of the volatile oil, usually obtained by steam- or hydrodistillation, is dominated by α-**10** and β-pinene **32**, accounting for about 16–36% and 40–66%, respectively [4.15]. However, these are not major contributors to the characteristic odor of galbanum, which is generally described as powerful green, woody, fruity, and balsamic. Several authors investigated the odor of galbanum oil and found 1,3,5-undecatrienes (e.g., **33**) [4.56], alkoxyalkylpyrazines **34**, **35** [4.57], undeca-6,8,10-trienones **36**, **37** [4.58], and thioesters **38**, **39** [4.59] to be high-impact odorants [4.60] (Fig. 4.14).

Interesting to note is the occurrence of a large variety of sesquiterpene umbelliferone ethers [4.55, 61] in both gum resins, which could potentially serve as precursors for pyrolytically generated odorants; this has however not been investigated until now.

Another gum resin called silphium or silphion was highly sought after in antiquity and came from the Greek colony of Cyrene, located at the Mediterranean coast of modern Libya. It is generally believed to be a now-extinct *Ferula* species [4.2].

4.1.8 Labdanum

Labdanum is an oleoresin from *Cistus ladanifer* L. or *C. creticus* L. (common name: gum rock rose), a wild shrub growing in areas around the Mediterranean Sea, mostly in Morocco, Spain, France, and on islands like Cyprus and Malta. It exudes a dark brown to black, soft, and sticky oleoresin on its leaves and twigs. The lab-

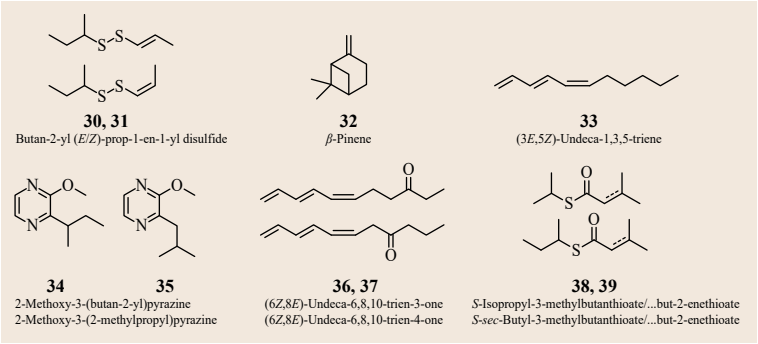

Fig. 4.14 Odorant compounds from asafoetida and galbanum

danum is obtained by extraction of plant materials with boiling water and the oil by steam distillation. Historically, shepherds scraped the resin off the pelt of their sheep or goats, who collected it by brushing through the shrubs of *Cistus* species. It used to be and still is a popular fragrance raw material, with documented use in ancient Egypt and discussed as the onycha of the ketoret incense mixture in Judaism [4.62]. Nowadays, it is prized for its ambergris-like tonalities and fixative properties [4.12, 63].

The essential oil is a highly complex mixture of over 300 compounds, mostly mono- and sesquiterpenoids, but also some diterpenoids. Among the main compounds reported in literature are α-pinene **10**, camphene **40**, bornyl acetate **41**, ledene **42**, viridiflorol **43** and cubeban-11-ol **44** (Fig. 4.15). Labdanum oil contains notable amounts (around 1%) of ambroxan **45** and is considered one of the very few natural sources of this important ambergris odorant [4.16, 64, 65].

4.1.9 Mastic

Mastic is the dried gum drops from *Pistacia lentiscus* L., gathered from the precleaned ground after incisions are made to the bark. The Greek island Chios with the variety *chia* is renowned for its long history of monopolistic mastic harvest and export. However, the shrub-like tree also grows in other areas around the Mediterranean Sea. It is reported to be an ingredient in the Egyptian incense mixture Kyphi and widely used in Orthodox churches in Eastern Europe. The predominant use, however, is as chewing gum and food additive in Greek recipes. The gum's oil consists of up to 90% α-pinene **10**, along with minor amounts of other terpenoids [4.2, 66].

4.1.10 Myrrh, Bissabol-Myrrh, Bdellium and Guggul (*Commiphora* Species)

The usually dark brown, resinous exudates from various *Commiphora* species are known since ancient times as myrrh, opopanax, bdellium, guggul, and locally also under many different names. They are small, shrub-like trees, usually with thorns, growing in countries in the Horn of Africa, Southern Arabia, and parts of India and Pakistan. With the number of different *Commiphora* species given in literature as ranging between 150 and over 200, it becomes evident that the exact terminology and botanical source of each resin is often inconsistent or contradictory in literature. Therefore, the descriptions given herein attempt to reflect the current state of consensus for the most important products.

Myrrh is the gum resin obtained by tapping *Commiphora myrrha* Engl. and *Commiphora molmol* Engl. ex Tschirch (sometimes used as synonyms). It is also known as heerabol myrrh, true, officinal, or bitter myrrh. The small, thorny tree grows in northern Somalia and Arabia; its resin is dark brown, sometimes reddish. Various authors report that the expensive true myrrh is often adulterated with other gums and resins, such as bissabol myrrh, gum arabic and bdellium. Myrrh typically contains a variety of furanosesquiterpenes, which serve as marker compounds for *Commiphora*. Most abundant in *C. myrrha* are furanoeudesma-1,3-diene **46**, furanodiene **47**, lindestrene **48**, and curzerene **49** (Fig. 4.16). Myrrh has a low content in monoterpenes, but is high in sesquiterpenes [4.47, 67].

The odor has not been intensively studied, or at least reported in the literature, but *Wilson* [4.68] isolated several furanosesquiterpenes and reported their olfactory properties. **46** and **48** as well as dihydropyrocurzerenone **50** resemble most closely the typical myrrh odor [4.69]. This publication is discussed in detail in Chap. 3.

There is plenty of literature on the therapeutic effects of myrrh in all forms – ingested, as extracts, lotions, mouthwashes, and so on. Most commonly known is the antimicrobial effect. The reviews by *El Ashry* et al. [4.67] and *Shen* et al. [4.70] present a good overview.

Bissabol myrrh, also named opopanax, habak haidi, or scented/perfumed/sweet myrrh (in contrast to the

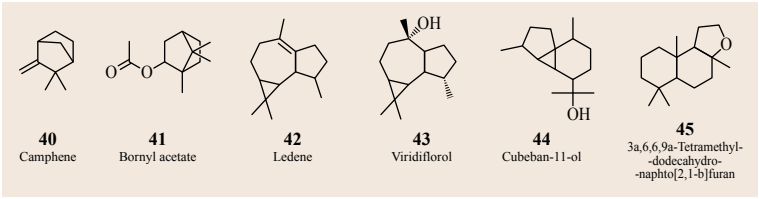

Fig. 4.15 Major compounds from labdanum

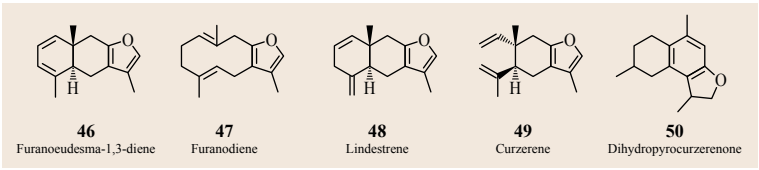

Fig. 4.16 Some furanosesquiterpenoids, characteristic compounds for *Commiphora* resins

true *bitter* myrrh), is the resin from the species *Commiphora guidottii* Chiov. Apparently, resins are sold under the same names from Kenia, but are derived from *C. holtziana*. Fomerly, *C. erythraea* Engl. (var *glabrescens*) and *C. kataf* Engl. were also given as source plants of bissabol myrrh, but *Thulin* and *Claeson* [4.71] convincingly showed that this was caused by historic misinterpretations of the herbarium specimens. Scented myrrh is generally considered inferior to heerabol myrrh, but is thought to be the myrrh in biblical times and Pliny's descriptions.

There is also a resin from *Opopanax chironium* (L.) Koch, a Mediterranean herb in the Apiaceae (carrot) family, called opopanax or sometimes falsely *sweet myrrh*. It is not to be confused with resins from *Commiphora* species and is in fact more closely related to asafoetida (Sect. 4.1.7). Nowadays, trade with *Opopanax chironium* material is almost nonexistent, so that it can safely be assumed that commercial opopanax is sourced from *Commiphora* species.

Indian Bdellium, guggul or guggulu is mainly obtained from *Commiphora mukul* Engl.; some authors additionally list *C. wightii* (Arn.) Bhandari, *C. caudata* Engl., or *C. roxburghii* Alston. *Commiphora africana* (A. Rich.) Endl. resin is called African bdellium and is harvested in Ethiopia, Eritrea, Sudan, and Kenya. Guggul is rich in plant sterols, the so-called *guggulsterols*, which were proposed to have positive effects on cholesterol levels, although more recent studies doubt these effects. The resin is still used as a traditional incense in India [4.72].

Commiphora opobalsamum (L.) Engl. is a small bush or tree without thorns, which yields the historic Balsam/Balm of Mecca (potentially identical to the Balm of Gilead). It grows along the coast of the Red Sea, yet it is nowadays insignificant as incense material. Its historical relevance as well as the botanical source of Balm of Mecca is, however, still a matter of discussion. Apparently, in ancient times, the tree's habitat extended even into Judea. The resin is still used in traditional Chinese Medicine [4.2, 73].

All sorts of *Commiphora* resins may be used as incense. It is not entirely clear which type of myrrh was more common in antiquity, although some claim that bissabol myrrh was more popular due to its sweeter, perfumed smell. Heerabol myrrh had a bigger significance in medical applications and for embalming the dead than as incense. Stacte, an ingredient of the incense mixture in Judaism, is often said to be an extract of myrrh or the spontaneous exudate of myrrh trees. In modern times, myrrh is still highly valued for its antimicrobial properties; for example, it is a common additive in toothpastes [4.2, 47, 70, 73].

4.1.11 Palo Santo

The indigenous people of Latin America have used fragrant woods as incense since precolonial times. Hence, the name Palo Santo (Spanish for *holy wood*) is ambiguous in its use. It commonly denominates either *Bursera graveolens* Triana & Planch. or *Bulnesia sarmienti* Lorentz ex Griseb. The name is sometimes also applied to wood from the genus *Guaiacum*, which is more commonly known as *lignum vitae* and lacks a reputation as incense.

Bursera graveolens yields a light, fragrant, and resinous wood typically found in tropical Middle and South America. Fallen branches can be collected from the ground, so that it is usually not necessary to fell the trees for their wood. It emits a pleasant odor when burnt in the form of shavings, but can also be distilled for its essential oil. The main constituents reported in the literature are limonene **11**, α-terpineol **51**, carvone **52**, as well as β-bisabolene **53** and other sesquiterpenoids, though in largely varying relative percentages (Fig. 4.17). GC-O analysis showed that **51**, **52**, mintlactone **54**, iso-mintlactone **55** and some sesquiterpenoids contribute to the characteristic odor, which

was described as woody, herbal, and minty [4.74, 75].

Bulnesia sarmienti is native to the Gran Chaco area in central South America (Argentina, Paraguay, Bolivia). Its fragrant wood is also burnt as incense, but it is better known for its essential oil, commonly named guaiac wood oil [4.63]. The wood is also often called guaiac wood, further complicating the distinction between true *Guaiacum* and *Bulnesia sarmienti* products. The main volatile compounds are sesquiterpene hydrocarbons and alcohols, including guaiol **56** and bulnesol **57** (Fig. 4.18). *Bulnesia sarmienti* is listed in CITES Appendix II.

4.1.12 Sandalwood

Sandalwood is the darker heartwood from *Santalum album* L., *S. austrocaledonicum* Vieill., and *S. spicatum* trees, which is rich in oil and highly fragrant. Native to India, Sri Lanka, Australia, New Caledonia and Indonesia, sandalwood has a long and rich history of use as incense, precious carving wood, and medicine. To harvest the wood, the tree is uprooted and the bark and sapwood separated from the heartwood. The essential oil, often used in perfumery, is typically extracted by steam distillation. Wood chips or powders are used as incense or in the preparation of joss sticks and incense mixtures. The volatile fraction is typically dominated by α- and β-santalol **58**, **59** (Fig. 4.19), along with many other sesquiterpene alcohols, aldehydes, and some phenolic compounds. The santalols are also the two key odorants, with other sesquiterpenoids modifying the odor (Chap. 3) [4.19].

4.1.13 Storax

Storax (often also styrax, Sect. 4.1.4) is a fragrant balsam from *Liquidambar* species, which exist as large deciduous trees in temperate zones. Two types are commercially relevant: the Levant/Oriental and the American variety, originating from *Liquidambar orientalis* Mill. in Turkey and from *L. styraciflua* L. in Honduras, Mexico, Guatemala, and the USA. Older descriptions of storax, for example, by Pliny and Dioscurides, give clear evidence that it was obtained from *Styrax officinalis* L. [4.4]. Nowadays, this species is still common in the eastern Mediterranean region, but of disputed relevance as a resin-producing species when compared to the *Liquidambar* balsams. *Hovaneissian* et al. [4.76], for example, state that solid storax comes from *Styrax officinalis* and the liquid storax from *Liquidambar* species. By contrast, *Zeybek* [4.77] tested wild-growing *Styrax officinalis* and was unable to induce any resin production, concluding that there must have been misconceptions in the botanical identification. To date, this question still remains unsettled. The lack of publications on the resin of *Styrax officinalis*, however, might favor Zeybeck's position.

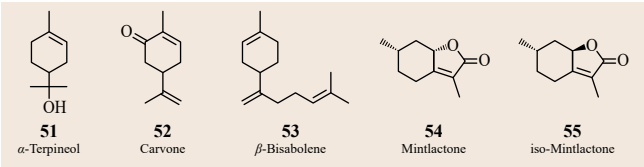

Fig. 4.17 Odorants from *Bursera graveolens*

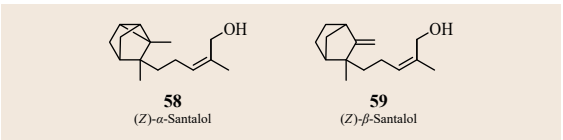

Fig. 4.19 Key odorants in sandalwood

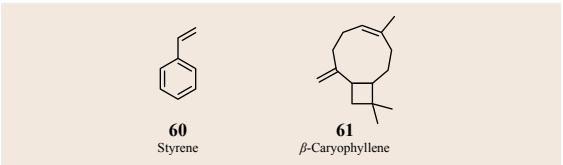

Fig. 4.20 Compounds from *Liquidambar* balsams

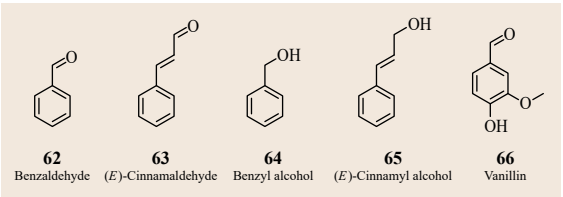

Fig. 4.21 Odor-active compounds found in Tolu and Peru balsam

The exudations of *Liquidambar* species were and to a lesser extent are still common in pharmacy, cosmetics, and perfumery [4.78]. The most prominent local, traditional use in Turkey is against ulcers [4.20, 79].

The balsams are usually grey-brown viscous liquids, and are most commonly traded either as charcoal chips or bark, both infused with the liquid resin. This allows easier handling and direct application for incense purposes. Essential oils and resinoids are also available.

Both balsams are characterized by a high content in styrene **60** (Fig. 4.20), with around 70–80% in the essential oil of *L. orientalis*. This compound was first isolated from storax and named accordingly [4.80]. Styrene is easily detectable by its distinctive sweet smell in the balsams. Additionally, the volatile fraction is mainly composed of α-**10** and β-pinene **32**, and in the case of *L. styraciflua* also β-caryophyllene **61** [4.20, 81]. Cinnamic acid **7**, its esters, and related compounds [4.82] might contribute to the balsamic, sweet smell, but this has not been properly investigated.

4.1.14 Tolu Balsam/Peru Balsam

Tolu balsam and Peru balsam are derived from *Myroxylon balsamum* varieties that are native to northern South America and Central America. Tolu balsam (*M. balsamum* Harms var *genuinum* Harms, some sources also: var *balsamum*) can either be a solid red-brown resin that melts at low temperatures or a thick yellow-brown fluid when fresh. Peru balsam (*M. balsamum* Harms var *pereirae* Harms) is a red-brown viscous fluid. Both smell strongly balsamic, with notes of vanilla and cinnamon. The organoleptic properties can be linked to high contents in benzoic acid **4** and cinnamic acid **7**, their esters (for example, **3**, **8**), aldehydes **62**, **63**, alcohols **64**, **65** but also vanillin **66** and related phenolic compounds (Fig. 4.21).

Tolu balsam is characterized by a lower content of the volatile fraction, historically named cinnamein, than the liquid Peru balsam. Both are known as components in incense mixtures, but are more commonly employed as fragrance raw material, for cosmetics, and medical applications. Due to the allergenic potential of the balsams, only the distilled essential oil is used in cosmetics and perfumes [4.63, 83, 84].

4.1.15 Overview of Incense Materials

These pictures are intended to give an overview of the physical appearance of the various incense materials mentioned in the text. The botanical species given below are based on suppliers' information and are not verified by chemical analysis.

Eritrean Frankincense
(*Boswellia papyrifera*)

Indian Frankincense
(*Boswellia serrata*)

Arabian Frankincense
(*Boswellia sacra*)

Labdanum
(*Cistus ladaniferus*)

Mastic
(*Pistacia lenticus*)

Myrrh
(*Commiphora myrrha*)

Bissabol/Sweet myrrh
(*Commiphora holtziana*)

Guggul
(*Commiphora mukul*)

Opopanax
(*Chironium opopanax*)

Palo Santo
(*Bursera graveolens*)

Guaiac resin
(*Guaiacum officinale*)

Sandalwood powder
(*Santalum album*)

Storax bark
(*Liquidambar orientalis*)

Tolu balsam
(*Myroxylon balsamum var genuinum*)

Peru balsam
(*Myroxylon balsamum var pereirae*)

4.2 Incense Preparations

Incense can be divided into two types: combustible and noncombustible. Combustible incense burns by itself after ignition, whereas noncombustible incense requires an external heat source, such as a glowing charcoal, although other hot surfaces can also be used. Examples are hot stones taken from or placed around a fire pit, or mica plates in the Japanese Incense Ceremony (Fig. 4.22), during which a thin sheet of this silicate mineral is heated by a glowing coal buried in ash [4.7, 85].

This chapter focuses on the preparation of combustible incense, as noncombustible incense, even in mixtures, does not require any special techniques. The components are simply mixed in whatever form preferred: ground to a fine powder, in granules, pieces, or chunks. Resin based mixtures can be melted and formed by gentle heating. Non-combustible incense encompasses the most famous mixtures from historical sources, such as Kyphi, an ancient Egyptian mixture and Ketoret, reported in Jewish tradition as the holy

Fig. 4.22 Mica plate placed on a glowing charcoal buried in a pile of ash, the typical form of heating incense materials during the Japanese Incense ceremony (courtesy of Nippon Kodo)

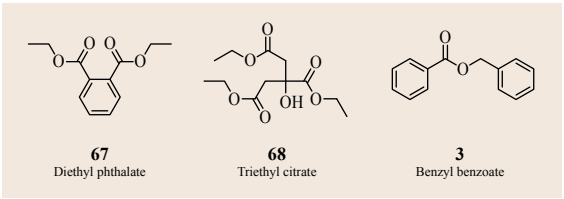

Fig. 4.23 Synthetic fixatives used in incense products

incense in the Jerusalem Temple. Many speculations circulate as to their exact compositions [4.12].

By contrast, combustible incense requires to be mixed with fuel, thereby making its preparation a lot more complicated. The mixtures typically contain the following types of ingredients, and the appropriate proportions need to be determined experimentally. The exact compositions are usually a closely guarded company secret, although examples for preparations can be found in the following sources, and many more are readily available on the Internet: *Fischer-Rizzi* [4.3], *Rätsch* [4.12], *Cunningham* [4.85], *Hsieh* [4.86], *Neumann* [4.87], *Newell* [4.88].

Firstly, a binding material is needed, which can be soaked in water to form a malleable paste, into which all other ingredients can be mixed. After forming and drying, this binder also serves as combustible material to keep the incense burning. Additional fuel can be included in the mixtures, such as powdered charcoal, incense woods, or barks. The most common binders in incense manufacture are gum tragacanth, gum arabic, makko powder (from the bark of *Machilus* spp.) or starch. Then, an oxidizing agent is usually introduced to keep the embers glowing more evenly. Most commonly, this is sodium or potassium nitrate. This dough is completed with pulverized incense ingredients to give the incense preparation the intended smell. Aside from

Fig. 4.24 Brightly colored incense cones from Thailand (courtesy of Johannes Niebler)

the aforementioned materials and many other natural products, essential oils can also be used to add fragrance notes otherwise unavailable. Care needs to be taken to ensure that the mixture still burns well, as too much essential oil or resin can impede an even combustion. In many industrial incense products, synthetic fragrances are used exclusively or additionally, for example, to include musk, vanilla, or patchouli notes. These would otherwise be unavailable or far too expensive, and can easily be included by adding synthetic musks, vanillin, or patchouli alcohol [4.89, 90]. Finally, most preparations include some form of fixative to avoid a strong loss of odor intensity during the drying and storage process. Traditionally, these fixatives were natural materials, including orris root (*Iris* spp.), ambergris, musk, resins (frankincense, myrrh, labdanum, etc.), balsams, and many others. Nowadays, synthetic fixatives are usually applied, including diethyl phthalate **67**, triethyl citrate **68**, benzyl benzoate **3** and others (Fig. 4.23). A study by *Tran* and *Marriott* [4.89] as well as similar studies performed in our laboratory (*Niebler* and *Buettner*, unpublished data) on the composition of incense sticks gave proof for this practice.

Combustible incense comes in many forms (Fig. 4.24 and 4.25). Powders can be flexibly used and allow exact dosage. Incense cones are popular around the world, and have a long tradition in the Ore Mountains in Germany. Incense sticks, also called joss sticks, come in various forms, depending on production method and intended use. They can be made from solid incense mixture or wrapped

Fig. 4.25 Various incense products. *Top row*: Incense cones from Germany (*left*) and Thailand (*middle*), a strip of folded Papier d'Arménie, ready to be lit (*right*). *Middle row*: reconstituted Kyphi, an ancient Egyptian incense mixture (*left*) and three different incense sticks (*right*). *Bottom row*: Incense mixtures used in Christian churches, rose scented incense (*left*), *Rhenish* mixture (*middle*) and *Original Arabic* mixture (*right*) (courtesy of Johannes Niebler)

around a wooden stick (mostly bamboo) in a layer. Methods of production include extrusion, dipping, pressing, coating, or rolling [4.5]. Additional forms of combustible incense include balls, coils, ropes and other specialized shapes [4.91]. It is also notable that in Asian countries particular cheaper, nonfragrant incense sticks are produced that are mainly used for offerings at the temples. These sticks only produce smoke and are not meant for scenting purposes [4.6]. Moreover, a special kind of combustible incense, the so-called Papier d'Arménie, is a French product that is essentially a strip of paper infused with an incense solution based on storax. Furthermore, many incense preparations are brilliantly colored by natural or synthetic dyes. The colorants can be included in the incense dough or applied externally on the finished product.

In conclusion, incense technology is not particularly sophisticated, even though some products require a certain experience and knowledge.

4.3 Benefits and Hazards of Incense Use

The use of incense products, in any form, does provide some benefits but it can also pose certain risks to human health. The next section includes a brief scientific review of documented positive and negative effects on humans.

The obvious benefits include a pleasant scenting of the room or environment, the aesthetical pleasure of watching incense smoke rise and curl in the air, as well as spiritual and psychological effects arising from such a ritualized experience. There are also numerous accounts of medicinal use of smokes in traditional medicine all over the world (for an overview, see *Mohagheghzadeh* et al. [4.10]). However, none of these have been investigated as medical incense treatments in clinical studies. This is probably caused by the fact that incense or smoke from plant materials is a virtually nonexistent form of application in modern medicine, and it is commonly associated with alternative treatments or drug abuse. Generally, inhalation of active compounds leads to a fast resorption and a sharp peak in the blood level. This can be beneficial in cases where a fast administration is intended, for example, in anesthetics or in the administration of anti-asthmatic drugs, but also in drug abuse (e.g., cannabis). Drawbacks are the lack of control over the exact dosage, side effects, and potentially harmful byproducts in the case of smokes. Another aspect to consider with inhalatory exposure is the metabolism of substances in the airways, which could generate a range of potentially bioactive derivatives [4.92]. A modern medical approach would therefore seek to isolate active substances from incense smoke and apply them in pure or enriched form through inhalator devices.

As an example, *Moussaieff* and *Mechoulam* [4.93] reviewed the scientific literature on the benefits of frankincense. Most of the trials were performed on extracts or isolated, nonvolatile compounds meant for oral administration. Only a few studies investigated the bioactivity of volatile compounds, which could also be found in the smoke of frankincense, and none were specifically targeted at an inhalative exposure. By contrast, several studies on adverse effects of frankincense smoke exposure are available (examples from the most recent literature: *Hussain* et al. [4.94], *Ahmed* et al. [4.95]). Furthermore, the nonvolatile fraction of incense materials can also be the source of promis-

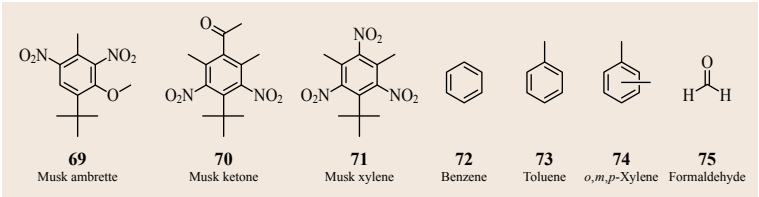

Fig. 4.26 Synthetic nitro-musks (**69**–**71**) and toxic byproducts from incense burning (**72**–**75**)

ing drugs, as exemplified by Crofelemer (SP-303), an oligomeric proanthocyanidine fraction from dragon's blood (*Croton lechleri*), that has recently been approved as an antidiarrheal drug by the Food and Drug Administration (FDA) [4.96].

Notably in the last decades, scientific investigations have increasingly raised awareness that incense burning should be considered as an activity with noteworthy risks to human health. Incense smoke is a complex mixture containing particulate matter, gases from the burning process, and organic compounds.

Particulate matter is a substantial health risk associated with burning of incense of all kinds. Highly elevated levels of particulate matter under 10 μm (PM_{10}) and under 2.5 μm ($PM_{2.5}$) in diameter from incense burning have been documented in numerous studies [4.97–104]. PM_{10} can enter and accumulate in the human respiratory system, whereas $PM_{2.5}$ can penetrate even further, as far as into the alveoli [4.105]. In a study comparing incense sticks and cigarettes, the former showed a 4.5-fold higher emission of particulate matter than a cigarette (45 mg/g compared to 10 mg/g, *Mannix* et al. [4.106]); another study stated that the indoor air pollution is comparable to cigarette smoking [4.101]. Particulate matter can carry mutagenic substances absorbed to the surface, and the mutagenic properties of incense smoke condensates have been documented by *Chen* and *Lee* [4.107] and *Löfroth* et al. [4.101]. Nevertheless, the distance from the source of particulate matter is surely quite different for both cases, cigarettes and incense; in any case, incense smoke is not as immediately and directly inhaled as is the case for cigarettes.

Polycyclic aromatic hydrocarbons (PAH) are generated during the burning process and quickly condense onto particulate matter [4.108]. Some PAHs are potent carcinogens and mutagens and have been repeatedly found in various kinds of incense smokes, in both field investigations and controlled laboratory measurements [4.97, 102, 109, 110].

Polychlorinated dibenzo-*p*-dioxins or dibenzofurans (PCDD/F) have also been found to be a notable risk factor associated with heavy incense use. Highly elevated levels were measured by *Hu* et al. [4.111] in a Taiwanese temple.

Additionally, volatile organic compounds (VOC) are heavily released. This is, obviously, part of the purpose of burning incense, as aromatic substances need to be vaporized or thermally generated. However, some compounds generated or released in the process can possess toxicological relevance. On the one hand, intentionally added substances like the nitro-musks (musk ambrette **69**, musk ketone **70**, musk xylene **71**, Fig. 4.26) were found in several incense preparations [4.90]. Musk ambrette **69** may cause photocontact dermatitis [4.112] and musk xylene **71** is listed as a substance of very high concern (SVHC) under REACH in the European Union (ED/67/2008), because it was rated as very persistent and very bioaccumulative (vPvB). Such risk factors can be eliminated by changing the formulation of the incense. On the other hand, in particular the slow and incomplete burning process releases toxic byproducts such as benzene **72**, toluene **73**, xylenes **74**, formaldehyde **75**, and many others (Fig. 4.26) [4.105, 113–115]. Furthermore, gaseous emissions from incense burning include toxic inorganic gases like carbon monoxide, sulfur dioxide and nitric oxides [4.106, 113].

Even though there is large variability between different samples, *Lee* and *Wang* [4.113] were able to show that incense use can lead to indoor air pollution at levels that are considered to have adverse effects on human health. *Lin* et al. [4.105] reviewed the available literature and stated that several epidemiological studies did not indicate any harmful effects of incense use, whereas other studies and reports showed that incense burning can be associated with negative effects on the respiratory tract, allergenic reactions, dermatological problems, cancer, neoplasms, and elevated IgE levels in cord blood. Overall, burning incense indoors or in insufficiently ventilated environments is, like cigarette smoking, a major cause of indoor air pollution and may pose adverse health effects, particularly in the case of prolonged and repeated exposure.

4.4 Conclusion and Outlook

The (aroma) chemistry of incense burning is a wide and complex topic of local and international relevance that cannot be adequately discussed in a few pages. The materials presented in this chapter were chosen to reflect aspects from several different culture areas. Nonetheless, it is obvious that some culture groups have barely been mentioned, even though they possess a rich history in incense use. For example, North American native people have used dried sage (*Salvia* spp.) as incense in their rituals.

Ethnobotanical studies like the one by *Staub* et al. [4.5] form the first step to understanding and investigating incense use in any culture. Unfortunately, these studies are rare, leading to a frequent uncertainty when talking about botanical sources of incense materials. In historical contexts, an exact identification of the plants described in the sources is for most cases impossible. Additionally, a considerable portion of the available literature is written by self-proclaimed experts in magic, rituals, and shamanism.

A better data basis is available on the chemical composition of many essential oils of various plant materials, even though the quality of the analysis varies considerably and several materials in this chapter would need a thorough reinvestigation. From the point of view of aroma research, this field still presents a largely undiscovered territory of new, potent odorants in complex mixtures. The highly dynamic and complex processes involved in incense burning represent an interesting challenge to established methodologies. The identification of thermolabile precursor substances might enable a better understanding of the apparent changes in the odor profiles of some incense materials during the burning process. To date, the aroma chemistry of incense remains a neglected subject; however it can offer promising and fascinating research opportunities for the future.

Acknowledgments. I would like to thank Benjamin Neumann of C.E. Roeper (Hamburg, Germany) for insights into trade prices of incense materials, Sabine Widder and Thierry Suong of Symrise (Holzminden, Germany) for supplying the odor descriptions and Cusanuswerk – Bischöfliche Studienförderung for funding.

5. Mechanistic Pathways of Non-Enzymatic Flavor Formation

Marcus A. Glomb

This chapter focusses on the formation of flavor active structures by mechanisms based on the degradation of reducing carbohydrates in the presence of amines. As model reactions have led to the elucidation of a confusing diversity of compounds, special attention is given to the understanding of the basic reaction pathways explaining the evolution of the most abundant odorants predominately shaping the aroma profile of most foods.

In 1912, the French chemist Louis Camille Maillard reported on chemical changes in amino acid sugar reaction mixtures with respect to browning and release of carbon dioxide. Since then the reaction of reducing sugars with amines is termed nonenzymatic browning or Maillard reaction [5.1, 2]. The colored high molecular weight products of the late reaction stages are called melanoidines. Although intermediates are similar in their basic reactive structure, the reaction has to be clearly differentiated from enzymatic browning processes. Here in contrast, the initial phase of the reaction of phenolic educts is catalyzed by enzymes, while nonenzymatic follow-up reactions then lead to late stage products like the browned high molecular weight melanines.

5.1 Maillard Reaction – General Considerations

Thus, in the historic sense the word Maillard reaction describes the reaction of two main constituents of foods. Not only reducing sugars glucose, fructose, maltose, and lactose, but also oligosaccharides are of importance. Pentoses are of interest for the processing of meat and meat products (Chap. 10), but can also be released from hemicelluloses, for example, under roasting conditions. Amino components are widely abundant in foods, most relevant are free amino acids, peptides, and proteins. The impact of the Maillard reaction on foods during processing, storage, and retail is of significant and very diverse importance. Other than browning, taste and aroma are changed, and not always just to yield better products but also to lead to off-flavors. However, these changes define our traditional perception of a specific food. Protein modifications not only lead to an irreversible loss of essential amino acids, but also to desired functional physical alterations. Not only some of the intermediates, but also late stage Maillard products are of significant antioxidative capacity and can prolong the shelf life of foods. On the other hand especially at very high temperatures, structures with strong carcinogenic and mutagenic properties are formed, for example, acrylamide and aromatic amines.

Reducing sugars in aqueous solutions are relatively stable within a pH range of 5–7. However, in the presence of amines this changes drastically. Amino components will degrade sugars by acid–base catalysis and by nucleophilic carbonyl reactions. For free amino acids the primary amine functions react, for peptides and proteins other than the N-termini the side chains of lysine and arginine are mainly targeted. Within the course of Maillard reaction α-hydroxycarbonyl and, most importantly, α-dicarbonyl structures are the key intermediates. Most, if not all follow-up structures can be mechanistically related to the latter group. Figure 5.1 shows established compounds relevant for the degradation of glucose [5.3, 4]. Exceptions are 1-amino-1,4-dideoxyglucosone and 1,4-dideoxyglucosone. Although these dicarbonyls show the typical C_6-carbon

backbone, they are formed in higher amounts specifically during the degradation of disaccharides. It is important to note that compared to the starting sugar, the dicarbonyls with the intact carbon backbone are of much higher reactivity. Other than these, the complete array of fragmentation from C_5- to C_2-products is found.

The understanding that α-dicarbonyl compounds are of central importance has changed the historic definition of the Maillard reaction. In the modern view this term is related to any amine-dicarbonyl reaction. This means that in addition to the classic degradation starting from intact sugars, the intermediate dicarbonyls can also stem from, for example, fat autoxidation, oxidation of phenolic structures, or from fermentative processes.

It is important to realize that the term Maillard reaction is not meant in the sense of a single reaction, for example, found in organic synthesis starting from educts A and B leading to products C and D. Instead, it is an extremely complex reaction cascade with multiple simultaneous processes. The main aspects can be described by cyclization, elimination, fragmentation, condensation, hydrolysis, rearrangement, and redox reactions, including both ionic and radical mechanisms. Owed to this complexity, today many Maillard products can still not be described by conclusive mechanistic pathways. The situation is even more difficult because many products are only formed in negligible amounts in the ppm range or even much lower. However, especially relevant for the aroma of foods, it is exactly these structures which due to their extremely low odor and taste threshold levels are of central interest to food industry.

In 2014, *Dunkel* et al. published a review on the chemical signatures of food odors and their relevance to human olfaction and to food biotechnology [5.5]. They screened literature from 1980 to 2013 for reports on aroma profiles of foods using very stringent inclusion/exclusion criteria. These were a bioactivity-directed approach based on coupled gas chromatography-olfactory analyses using the flavor dilution approach, unequivocal mass spectrometric, or retention index verification based on authentic reference standards, and a reliable quantitation by, for example, stable isotope dilution analyses. As a result, they selected 119 publications describing the key food odorants of 227 foods across the complete market basket with alcoholic beverages, meat products, fish and sea food, cereal and bakery products, dairy products, fats and oil seeds, fruits, vegetables, mushrooms, spices and herbs, cocoa and chocolate, coffee, tea, and many others. Surprisingly, the authors identified only 226 key odorants sufficient to describe the odor space of these foods. The authors even extrapolated from this observation that less than 230 main odorants, out of a total of about 10 000 volatiles assumed to be present in foods, might be enough to describe the total odorant space present in our foods and beverages. Out of the 226 odorants, the authors categorized three classes, namely 16 generalists with an abundance of more than 25% in the 227 food samples, 57 intermediaries with less than 25% but more than 5% abundance, and 151 individualists with less than 5% abundance. However most interestingly, many representatives of the generalist and also of the intermediaries can be related to the degradation of carbohydrates and amino acids, based on sole or alternative nonenzymatic pathways or a combination of both. This is especially true for the class of the generalists, where 10 out of 16 structures can be explained by Maillard reaction pathways. Table 5.1 lists these structures, and their abundances. Some of the compounds can evolve from both metabolic–enzymatic and nonenzymatic pathways. However, this chapter focuses

Table 5.1 Key odor structures in foods and beverages are formed by nonenzymatic pathways

Odorant *generalists*	**Abundance (%)**
3-(Methylsulfanyl)-propanal (methional)	54
2-/3-Methylbutanal	51
Butan-2,3-dione (diacetyl)	42
4-Hydroxy-2,5-dimethyl-3(*2H*)-furanone (furaneol)	41
3-Hydroxy-4,5-dimethyl-2(*5H*)-furanone (sotolone)	36
Acetic acid	29
Acetaldehyde	29
Ethyl-2/3-methylbutanoate	28
2-Acetyl-1-pyrroline	26
2-/3-Methylbutanoic acid	26
Odorant *intermediaries*	**Abundance (%)**
2-Methylpropanal	24
Phenylacetaldehyde	23
Ethyl-2-methylpropanoate	23
2-Ethyl-3,5-dimethylpyrazine	19
Dimethyltrisulfide	19
Phenylacetic acid	18
2,3-Diethyl-5-methylpyrazine	17
Furan-2-ylmethanethiol (2-furfurylthiol)	15
2-Methoxy-3-(propan-2-yl)pyrazine	14
Dimethylsulfide	14
Methanethiol	13
2-Acetyl-2-thiazoline	9
Propanal	7
2-Methylfuran-3-thiol	6
2-Ethyl-4-hydroxy-5-methyl-3(*2H*)-furanone (homofuraneol)	6
1,1-Diethoxyethane	6
Methyl-2/3-methylbutanoate	5

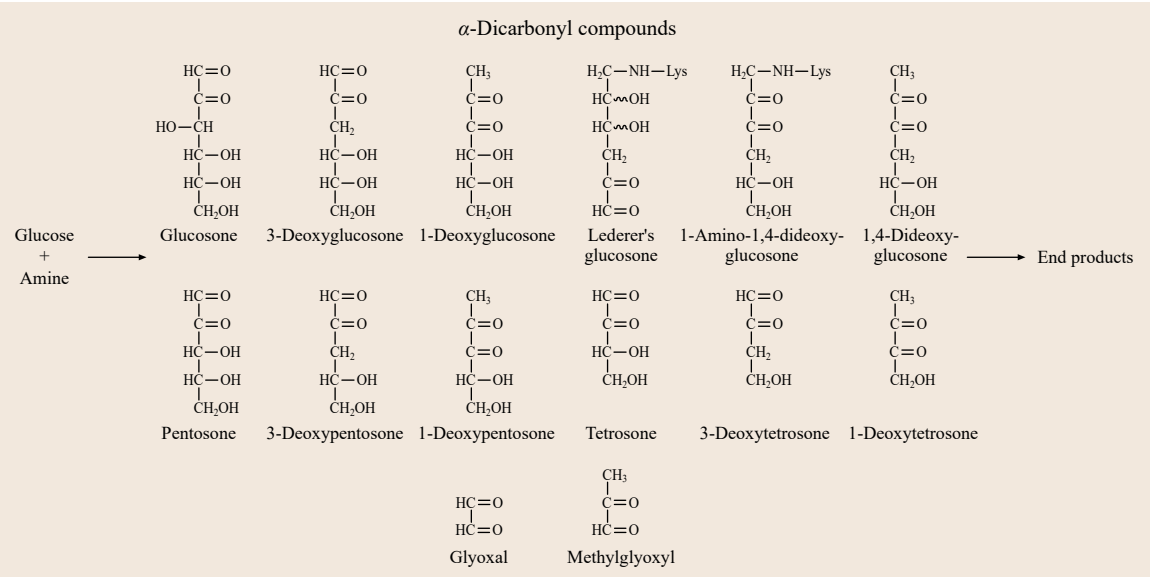

Fig. 5.1 Dicarbonyl compounds are the central Maillard intermediates

on the mechanisms explaining explicitly their nonenzymatic formation. Wherever possible, the following discussions are based on publications using isotopic labeling as the carbon module labeling (CAMOLA) approach [5.6] or using authentic intermediates for verification.

In general, both sugars and amino acids are too polar to contribute directly to the odor profile. This means that polar functionalities must get lost during the degradation process, which in most cases can be related to dehydration, elimination, fragmentation, and decarboxylation reactions.

5.2 α-Dicarbonyl Compounds

The early stage of the Maillard reaction is determined by the reactivity of the carbonyl function of the original sugar. In Fig. 5.2, glucose was chosen as a model compound. The structure is drawn in the open-chained form showing the native carbonyl function for simplification, although in aqueous systems carbonyl compounds exist mainly as hydrates or as half-acetalic structures. However, it is the availability of the free carbonyl function which determines the reactivity of the respective sugar. Reaction with the amine and dehydration leads to an imine, also called Schiff base or aldoimine. Keto-enol-tautomerism then gives an aminoketose via an 1,2-enaminol. This isomerization is also called Amadori rearrangement, the aminoketose termed Amadori product. The acid–base catalysis of the amino compounds basically allows the enolization to proceed along the complete carbon backbone of the sugar, which is prerequisite for the elimination of water or the amine. Starting from the 1,2-enaminol 3-deoxy-2-glucosulose (3-deoxyglucosone) is formed, the 2,3-enediol gives 1-deoxy-2,3-glucodiulose (1-deoxyglucosone). Substantial amounts of Lederer's glucosone verify that the enolization indeed proceeds to a 5,6-enediol intermediate [5.7]. In contrast, the formation of 2-glucosulose (glucosone) can only be explained by oxidation, that is, the amine catalyzed autoxidation of glucose, but mainly of the intermediate imine and of the Amadori product.

After enolization, 1-deoxyglucosone and glucosone show an α-oxoenediol motive. This means that these compounds are reductone structures, which are highly redox active and are easily degraded to give lower molecular weight fragments of even higher reactivity. Both, nonenzymatic reduction and oxidation in Maillard reaction systems can be explained by these intermediates. Oxidation leads to a 1,2,3-tricarbonyl compound. Thus, within the Maillard reaction it is exactly these structures with reductone character which direct the further course of reaction.

In Maillard literature, four main mechanisms of fragmentation have been proposed [5.8]:

1. Hydrolytic α-dicarbonyl cleavage
2. Retro-aldol cleavage

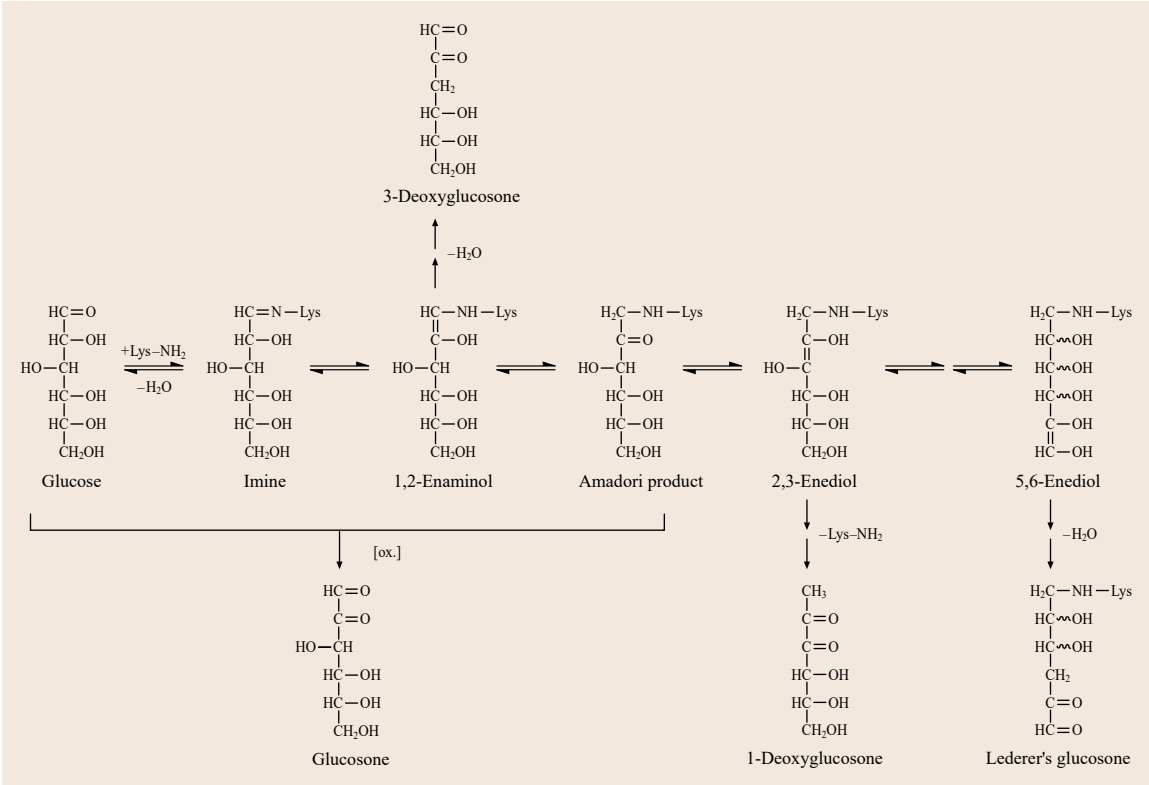

Fig. 5.2 Initial stage of Maillard reaction

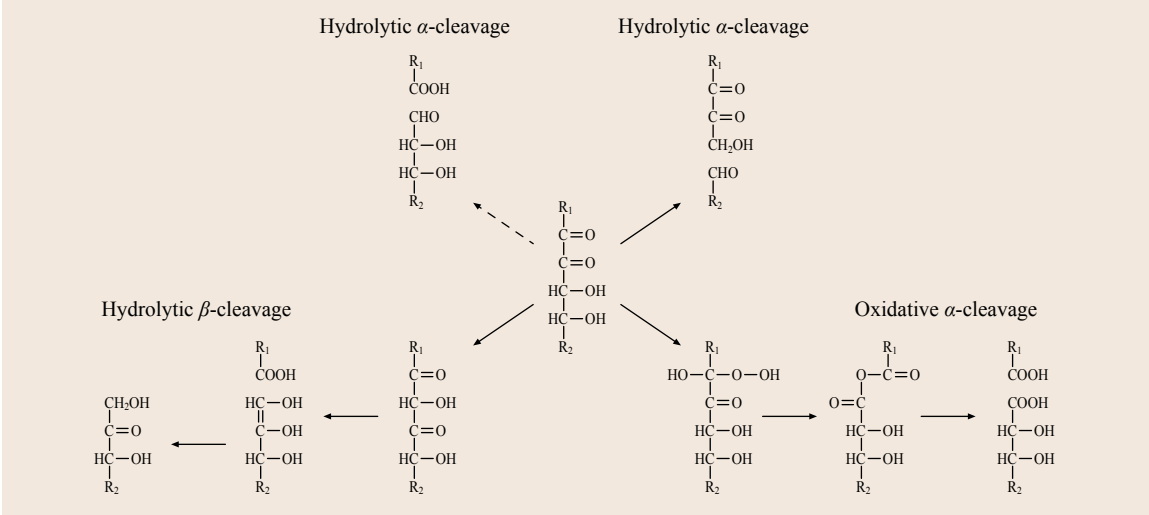

Fig. 5.3 Mechanisms of sugar fragmentation

3. Hydrolytic β-dicarbonyl cleavage
4. Oxidative α-dicarbonyl cleavage (Fig. 5.3).

Recently, the latter two have been refined by an additional amine-induced alternative route each.

The hydrolytic α-dicarbonyl cleavage describes the nonoxidative scission of an α-dicarbonyl motive to give a carbonyl and a carboxylic compound. It has been used very frequently especially in the older Maillard literature to explain the parallel formation of the two

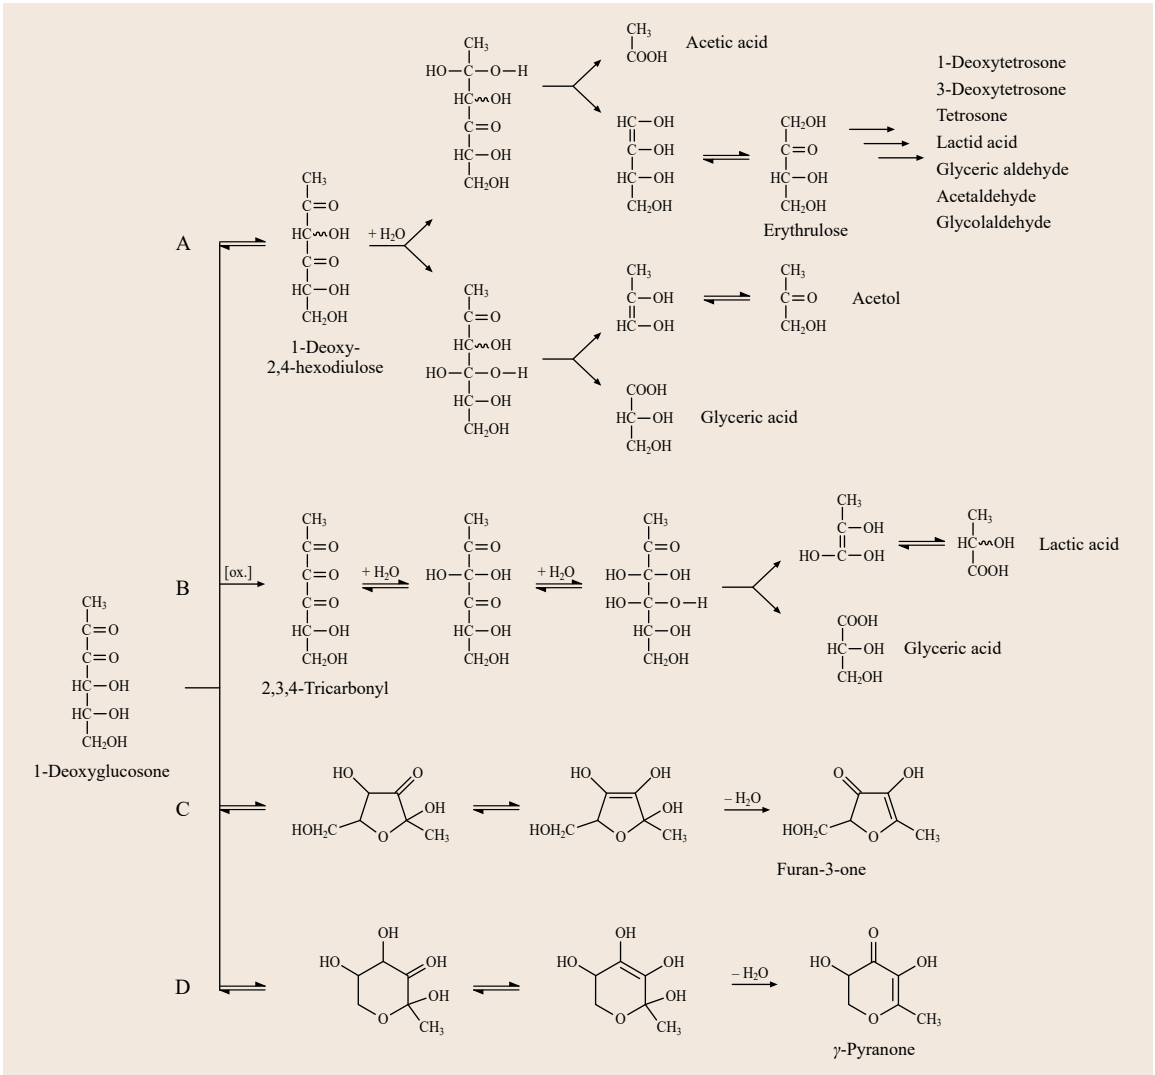

Fig. 5.4 1-Deoxyglucosone is the central intermediate of hexose Maillard chemistry: (A + B) β-dicarbonyl cleavage, (C + D) cyclization

molecule classes. However, recent investigations and also a comprehensive literature review have come to the conclusion that there is no experimental ground for this hypothetical mechanism and that its proposal is merely based on the coincidential, but non quantitative coexistence of structures with fitting complementary carbon backbone. Thus, this mechanism has to be excluded as void.

Retro-aldol cleavage is another mechanism that has been challenged recently. Any starting sugar shows the prerequisite β-hydroxycarbonyl moiety leading to two carbonyl fragments. Specifically from α-dicarbonyls, the mechanism leads to one α-dicarbonyl and one carbonyl molecule. This type of cleavage is commonly used to explain the generation of short-chained α-dicarbonyl compounds which are odor active as such, or are important intermediates involved in the formation of potent odor active compounds, that is, especially butane-2,3-dione (diacetyl), methylglyoxal, and 1-hydroxy-2-propanone (acetol). Aldol condensations are the reverse reaction and are frequently used in organic synthesis strategies under nonaqueous conditions. They have been also shown to proceed in aqueous systems at moderate temperatures, for example, leading from diacetyl and formaldehyde to 1,4-dideoxy-2,3-pentodiulose (1,4-dideoxypentosone) [5.9]. However, retro-aldol cleavages have been almost outruled for Maillard systems operated at moderate temper-

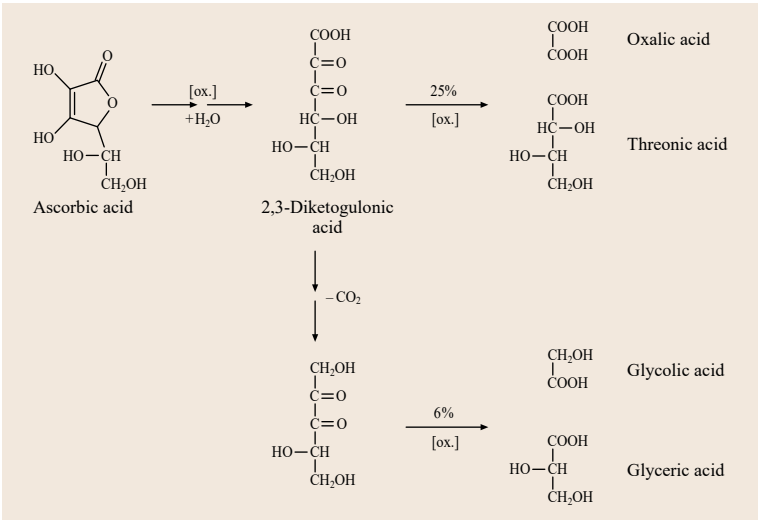

Fig. 5.5 Oxidative α-dicarbonyl cleavage is a major fragmentation mechanism during degradation of ascorbic acid

atures up to 50 °C. There was no scission of independently synthesized 1,4-dideoxy-2,3-hexodiulose (1,4-dideoxyglucosone) to give diacetyl and glycolaldehyde [5.4]. Instead, the educt was shown to be rather stable. In addition, incubations (< 50 °C) of authentic 1-deoxyglucosone and 3-deoxyglucosone both gave only negligible amounts of methylglyoxal [5.10, 11]. However, it is exactly these dicarbonyls which are frequently quoted as the main methylglyoxal precursors. Obviously, retro-aldol reactions are not favored at low temperatures and might require higher energy input found, for example, at boiling or roasting conditions.

β-Dicarbonyl cleavage reactions have evolved to one of the major fragmentation reactions already working at moderate temperatures. Although already mentioned in the earlier Maillard literature this mechanism has been studied first in detail by *Davidek* et al. in model systems using simple α- and β-dicarbonyl short-chained alkanes [5.12]. Later, these results were transferred by this and other groups to Maillard intermediates with a reductone motive. This allows an α-moiety to isomerize to a β-configuration, which is prerequisite for the β-scission. Figure 5.4 highlights reactions of 1-deoxyglucosone, which has to be evaluated as the major central intermediate of hexose chemistry with an exceptional high reactivity (e.g., half-life $\leq$ 30 min at 37 °C) [5.13]. Most important follow-up products can be rerouted to this structure. Detailed mechanistic studies were facilitated by a successful independent synthesis of 1-deoxyglucosone and allowed to explain about 70–80% of its total degradation under Maillard conditions. Path A starts from the isomeric 1-deoxy-2,4-hexodiulose. Hydration at the C_2-carbonyl function leads to acetic acid and an 1,2-enediol giving erythrulose. The yields of acetic acid were about 60% at 50 °C (up to 85% at 100 °C) independent of the presence of oxygen. This means that in hexose reactions this mechanism explains most if not all the acetic acid being formed. If the hydration proceeds at the C_4-carbonyl function glyceric acid and acetol result. While carboxylic acids have to be evaluated as stable Maillard endproducts the cleavage counterparts are α-hydroxycarbonyl intermediates which are prone to various follow-up reactions to give further carboxylic acids and dicarbonyls, but also important carbonyl structures as active odorants as such or as intermediates leading to odorants, for example, acetaldehyde, glycolaldehyde and glyceric aldehyde. Path B of Fig. 5.4 shows that β-dicarbonyl cleavage can also be facilitated from a double hydrated oxidation product of 1-deoxyglucosone (C_3 and C_4) to give lactic acid and as the counterpart glyceric acid in substantial yields. The putative cleavage starting from a C_2,C_3-dihydrate to give acetic acid and erythronic acid was experimentally disproven to be of importance. This also excludes a major alternative oxidative α-dicarbonyl cleavage reaction of 1-deoxyglucosone.

A forth cleavage reaction has been established only lately for Maillard systems, the oxidative α-dicarbonyl fragmentation. It was first evidenced from incubations of 2,3-pentandione to give acetic acid and propanoic acid in equimolar concentrations. The mechanism requires activated molecular oxygen stemming, for example, from UV irradiation or hydroperoxides. Incorporation at one of the carbonyl functions gives alkoxyradicals and after single-electron transfer reactions hydroperoxides. These rearrange via a Bayer–Villiger-type reaction to mixed asymmetric anhydride species, which are readily hydrolysed to two carboxylic acids (Fig. 5.3). Obviously, singlet oxygen is prerequisite

for the initial attack at the carbonyl function; however, if present, the reaction will also proceed at moderate conditions. This also must be the reason why during degradation of 1-deoxyglucosone this type of reaction is only of negligible importance. On the other hand, ascorbic acid is known to produce significant amounts of activated oxygen species. Consequently, *Smuda* and *Glomb* were able to verify 31% initiated by oxidative α-dicarbonyl cleavage out of a total of 75% of degradation related to fragmentation (Fig. 5.5) [5.14]. The remainder was attributed to decarboxylation and hydrolytic β-dicarbonyl cleavage. However, given the polarity of the resulting acids and the lack of carbonyl activity of the carboxylic acid function, it must be assumed that most products of the oxidative α-dicarbonyl fragmentation will not contribute to the odor profile.

5.3 Strecker Degradation

The Strecker degradation is by far the aspect of the Maillard reaction which accounts for most of the structures within the group of odor generalists and intermediaries listed in Table 5.1. 13 out of the 27 compounds can be explained directly from this mechanism, 7 by direct and indirect follow-up reactions. Basically, the term Strecker degradation describes the interaction of α-dicarbonyl compounds with amino acids including a decarboxylation step. This again underpins the importance of α-dicarbonyls as the central intermediates of Maillard reactions. After nucleophilic attack of the amino substituent at one of the carbonyl moieties and formation of an imine, the electron drawing second carbonyl function triggers the decarboxylation leading to an α,β-unsaturated imine, which hydrolyses to give the Strecker aldehyde and an eneaminol (Fig. 5.6, pathway A). This explains not only the formation of methional, 2-/3-methylbutanal, acetaldehyde, 2-methylpropanal, and phenyl acetaldehyde, but also formaldehyde from methionine, leucine/isoleucine, alanine, valine, phenylalanine, and glycine, respectively. Besides being aroma active with very low odor thresholds as such, these unpolar low molecular carbonyl structures are highly reactive and can perform, for example, aldol-type reactions to give further important aroma compounds. This also explains the spontaneous formation of 1,2-diethoxyethane from acetaldehyde in, for example, beer or wine. From the mechanistic point of view, the Strecker reaction represents a redox reaction. The amino acid is oxidized under decarboxylation, while the α-dicarbonyl gets reduced. This can be immediately realized from the comparison of the starting α-dicarbonyl to the α-hydroxycarbonyl structure, which is formed after tautomerism and hydrolysis of the resulting α-hydroxyimine to release ammonia already under moderate conditions (pathway B). If the tautomerism proceeds to an α-aminocarbonyl structure, condensation leads to dihydropyrazines, which spontaneously gets oxidized to give pyrazines (pathway C). These heteroaromatic structures contribute especially to the aroma profiles of baked and roasted foods. The basic reactions (A–C) have been continuously extended and have evolved today to a whole mechanistic cascade within the complex complete Maillard scheme. This is especially due to the fact that (I) many Strecker intermediates are very reactive, and that (II) the electronic isomerization reactions are reversible. In food systems of low water activity the intermediate hemiaminal prior to the release of the Strecker aldehyde cannot be formed (A) [5.15]. Instead, the α,β-unsaturated imine proceeds via ring formation to a 5-membered 4-oxazoline, which exists in an equilibrium to an 3-oxazoline (pathway D). Authentic synthesized oxazolines readily released the Strecker aldehyde upon addition of water (up to 56% at 37 °C). Other than by water content, the rate was strongly affected by pH and temperature. The existence of oxazoline derivatives was indeed verified in foods, for example, chocolate. Taken together, this alternative pathway explains the observation why especially from heat processed foods such as bread, snacks, and chocolates major amounts of odor active substances are formed during mastication and thereby add significantly to the retronasal perception.

In contrast to the α,β-unsaturated imine, the intermediate hemiaminal of pathway A represents an electron-rich eneaminol structure, which can be easily oxidized to give a heteroanalog α-dicarbonyl. Again, the electron-pulling carbonyl function initiates the intramolecular redox reaction to give the Strecker acid and the eneaminol after hydrolysis (pathway E) [5.16]. Thus, the ratio of formation of Strecker aldehyde to Strecker acid strongly depends on the reaction conditions. In-depth model reactions have indeed shown that in the presence of oxygen the ratio changed from about 1 : 1 under deaeration to 1 : 3–4 under aeration, that is, the formation of the Strecker acids represents a major mechanism for the processing of foods. The authors also excluded the notion that the formation of the acids might be an artifact of direct aldehyde oxidation by the use of stable isotopically labeled derivatives. Pathway E, therefore, explains the formation of the impor-

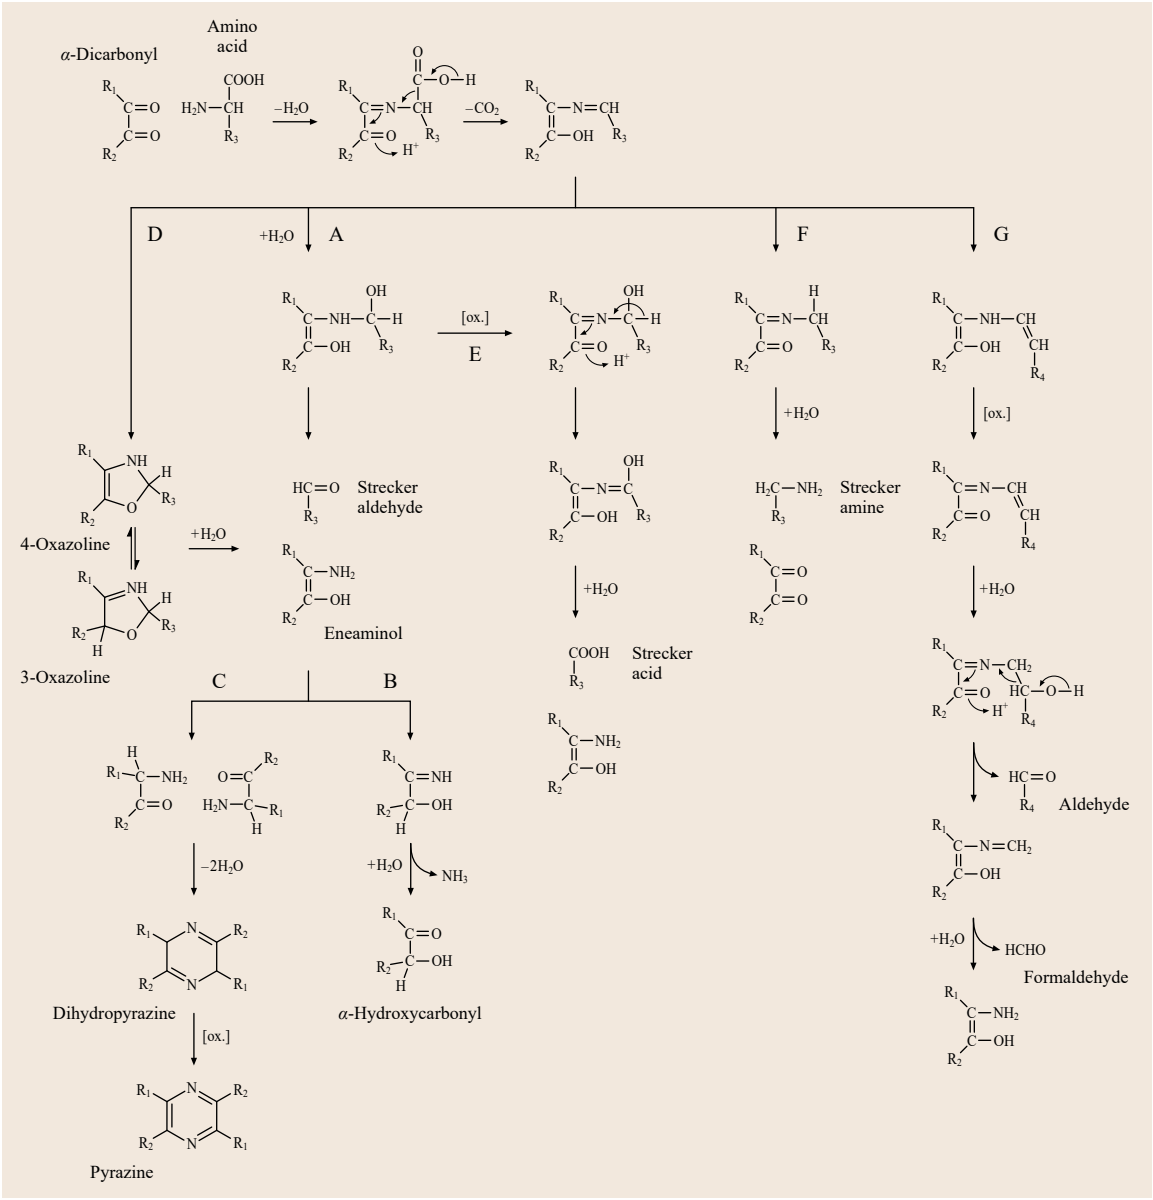

Fig. 5.6 The Strecker reaction cascade

tant odorants acetic acid, 2-/3-methylbutanoic acid, 2-methylpropanoic acid, phenylacetic acid from alanine, leucine/isoleucine, valine and phenylalanine, respectively. The acid formation also explains indirectly the detection of related methyl and ethyl esters in alcoholic beverages due to spontaneous esterification or transesterification from pectines induced, for example, under roasting conditions (ethyl-2,3-methylbutanoate, ethyl-2-methylpropanoate, methyl-2/3-methylbutanoate).

The reversibility of the above mentioned isomerization based on electronic rearrangement reactions is best envisioned by the detection of Strecker amines in amino acid/α-dicarbonyl mixtures (pathway F) [5.17]. This is obviously an alternative pathway to the pyridoxal phosphate-driven enzymatic generation of biogenic amines. However, the ratio of Strecker aldehydes to the respective amines ranged from about 1 : 100 (phenylalanine) to 1 : 1000 (other unpolar amino acids) in aqueous model systems. This and also the relatively high-odor thresholds might explain why Strecker amines are not found in above Table 5.1. The ratio might be related to the presence of electron pulling versus pushing groups,

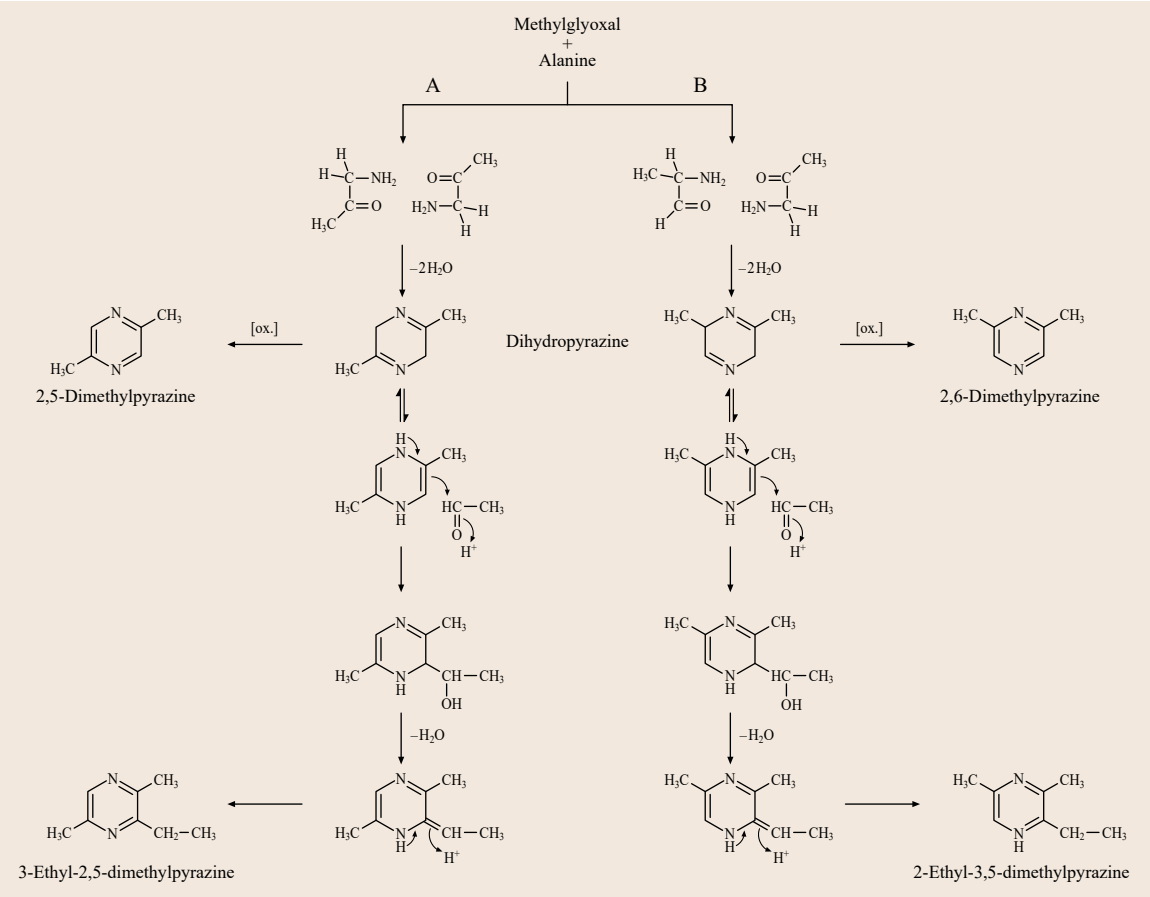

Fig. 5.7 Oxidative and nonoxidative formation of pyrazines

and also to a possible extension of unsaturation. This notion and also the reversibility were enlightened by the detection of substantial amounts of benzaldehyde (up to 7%) in reactions of 2-phenylethylamine in presence of methylglyoxal besides very small amounts of the respective Strecker aldehyde. Here (pathway G) after oxidation and addition of water, an intermediate half acetal was proposed to cleave off first benzaldehyde in a retro-aldol-type reaction and then formaldehyde to result again in the central eneaminol structure. Obviously, the cleavage of the half-acetal is strongly facilitated by the electron drawing dicarbonyl moiety.

It has to be mentioned that the Strecker pathways shown in Fig. 5.6 have been further extended today. One facet is that Strecker aldehydes have been detected in model systems of Amadori products [5.18]. This is expected, as Amadori products are transient intermediates in any Maillard system starting from carbohydrates leading to α-dicarbonyl compounds. However, the authors suggested a direct oxidative degradation route to explain different ratios of Strecker aldehydes to acids depending on the particular carbohydrate. On the other hand, Strecker-type reactions were identified in pyrolysis systems mimicking roasting processes [5.19] and in the interaction with fat autoxidation intermediates [5.20]. In contrast to earlier discussed reactions with a central eneaminol intermediate, here in both cases ylide intermediates were suggested as the important pivotal structures.

The oxidation of the dihydropyrazines to the aromatic derivatives in Fig. 5.6 occurs spontaneously in presence of atmospheric oxygen. In Fig. 5.7, this reaction is depicted in more detail for reactions with methylglyoxal and leads to 2,5-dimethylpyrazines in pathway A. Alternatively to 1-aminopropan-2-one, in pathway B condensation can also include 2-aminopropanal. However, this molecule is less abundant because the aldehyde function of methylglyoxal is more reactive than the keto moiety. After oxidation 2,6-dimethylpyrazine is formed. Thus in this oxidative pathway, the ring substituents must stem from the α-dicarbonyl compounds involved in the formation of the

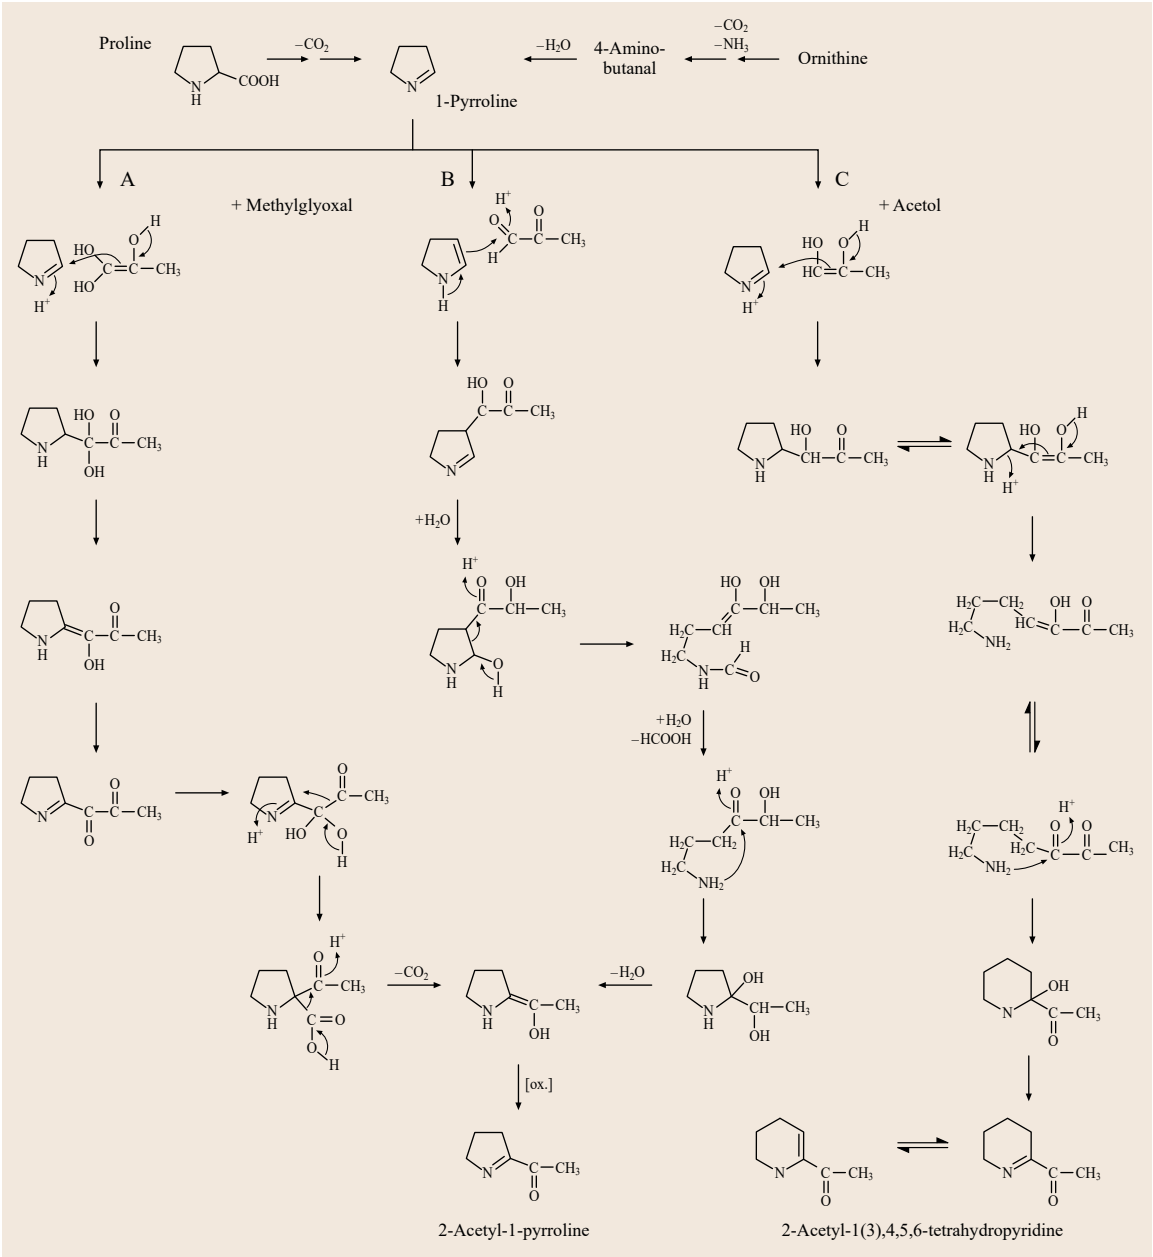

Fig. 5.8 Main routes of formation of 2-acetyl-1-pyrroline and 2-acetyl-1(3),4,5,6-tetrahydropyridine by Strecker degradation of proline with methylglyoxal

intermediate eneaminol [5.21]. As pyrazines are important agents of aroma profiles of baked, roasted, or fried foods with earthy odor qualities their mechanism of formation has been studied in detail and revealed additional nonoxidative pathways [5.22]. Here, the substitution pattern is argued by condensation of carbonyl structures to the electron rich dihydropyrazine ring system. As an example, the reaction with acetaldehyde is shown, which is the Strecker aldehyde of alanine, but may also originate from fermentative processes. Dehydration and tautomerization gives 3-ethyl-2,5-dimethyl- and 2-ethyl-3,5-dimethylpyrazine, respectively, without the need of an oxidative step. If the condensation reaction occurs with an α-dicarbonyl like methylglyoxal, the formation of acylated pyrazine derivatives can be explained.

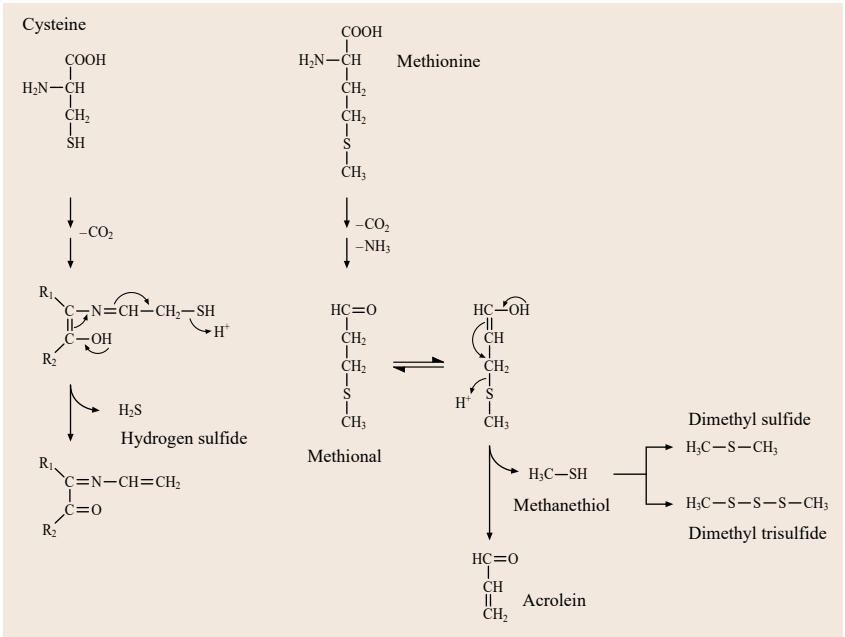

Fig. 5.9 Strecker degradation of cysteine and methionine leads to important odor active small nucleophiles

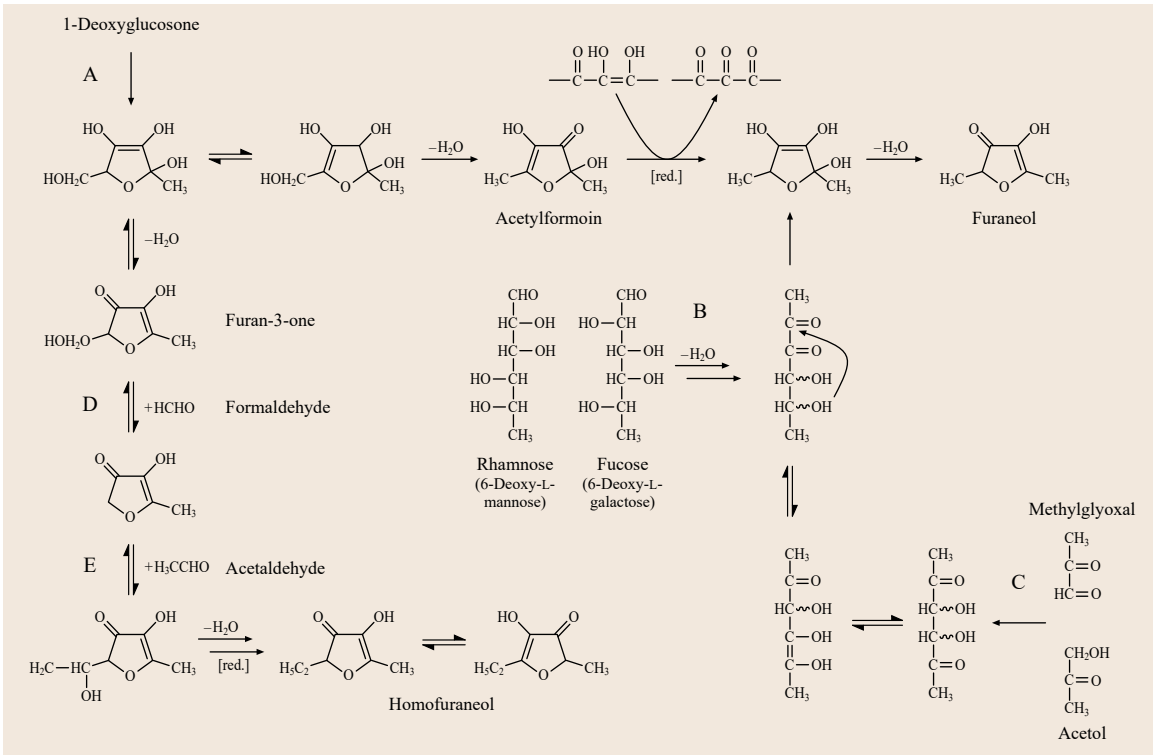

Fig. 5.10 Formation pathways of 4-hydroxy-2,5-dimethyl-3(*2H*)-furanone (furaneol)

2-Acetyl-1-pyrroline is the main representative of a class of N-containing heterocycles with roasty, popcorn-like odor notes and very low odor thresholds, especially for 2-acetyl-1-pyrroline which ranks 9 among the odorant generalists in Table 5.1 with 26% abundance. Central intermediate in the formation is 1-pyrroline,

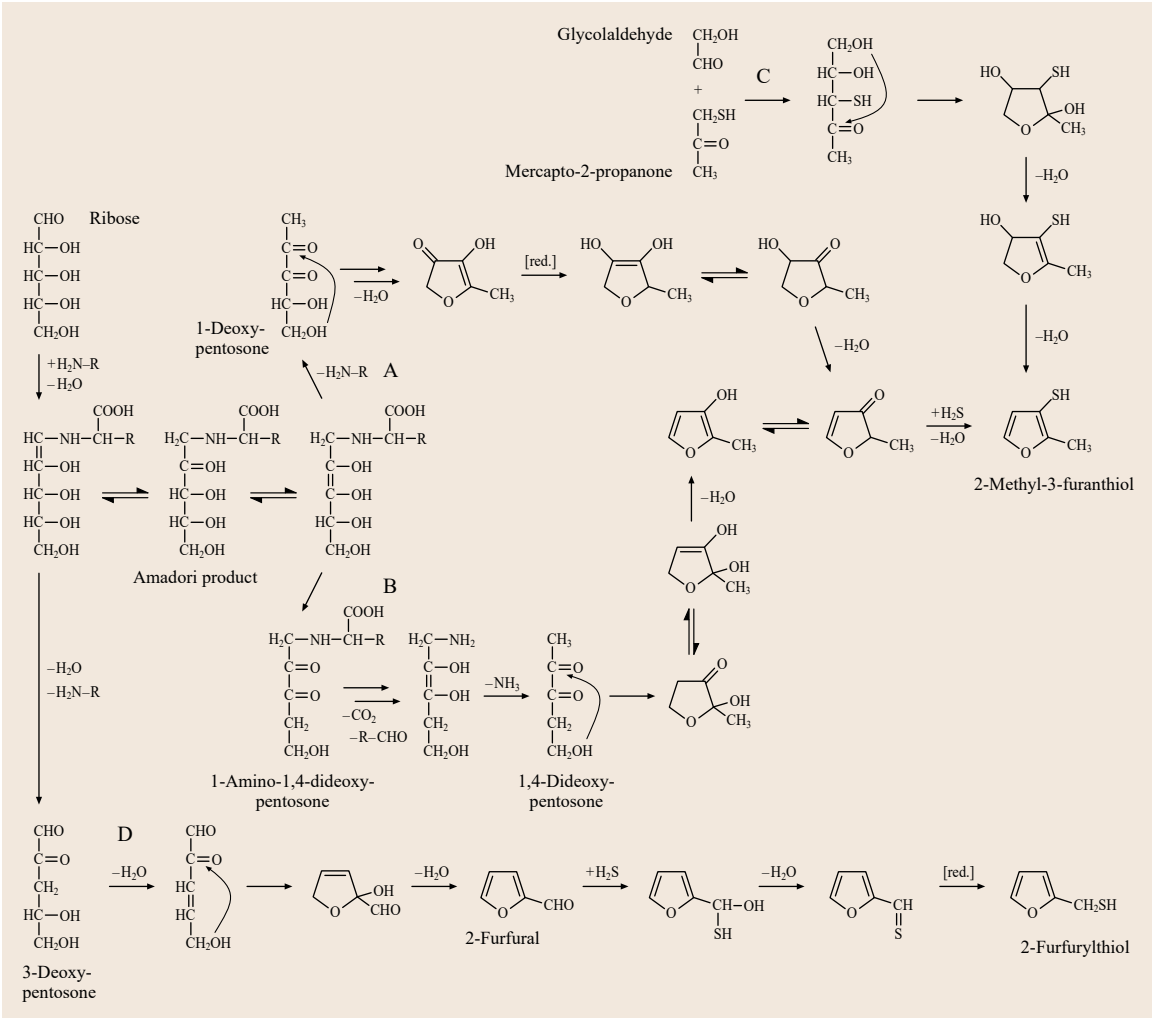

Fig. 5.11 Main formation mechanisms of 2-methyl-3-furanthiol and 2-furfurylthiol

which is the Strecker decarboxylation product of the amino acid proline [5.23]. Alternatively, but of less importance, 1-pyrroline can be formed by cyclization of the ornithine Strecker aldehyde 4-aminobutanal [5.24]. The reaction mechanism has been studied in-depth by the use of isotopically labeled educts elucidating two routes based on carbohydrate fragmentation C_3-products, that is, methylglyoxal and acetol (Fig. 5.8). The main course starts from the hydrate of methylglyoxal (pathway A) and thus allows a nucleophilic attack of the derivatized aldehyde function at 2-C of the pyrroline ring. Dehydration then leads to an N-analog reductone configuration, which can be easily oxidized to give a 1,2,3-tricarbonyl configuration. As known from other such configurations the central carbonyl function gets hydrated and allows the carbon backbone to rearrange to bring the carboxylic group in β-position to the carbonyl substituent of the acetyl group. Decarboxylation results in an electron rich eneaminol moiety that is oxidized to 2-acetyl-1-pyrroline. The loss of a C_1-fragment from the starting C_3-carbonyl has been independently verified by several authors using the CAMOLA approach to result predominately in the double labeled target compound [5.25]. However to a minor extent, a triple labeling was found too. This means that alternatively a second mechanism exists, which incorporates the intact C_3-carbon backbone of the starting carbonyl to the final pyrroline structure. The ratio of both pathways is 3/1 at pH 5.5 and changes to about 1/1 at pH 8.2, but is also influenced by other factors like the moisture content of the respective system.

Thus in pathway B, to explain the complete integration of the C_3 carbonyl, the reaction with native methylglyoxal is suggested. This allows the C,H-acidic

3-C position of pyrroline to nucleophilic attack the aldehyde function. Tautomerism and hydration lead to a hemiaminal function in β-position to the keto group of the former α-dicarbonyl backbone to enable a retro-aldol-type fragmentation. This means that in contrast to pathway A the C_1-fragment can now be cleaved off as formic acid. Cyclization, dehydration and oxidation give 2-acetyl-1-pyrroline. If the reaction starts at the oxidation level of acetol, the direct condensation of the hydroxymethylene function with the 2-C position of the ring can be realized (pathway C). In this case, the ring opening is facilitated by β-elimination of the amine function, which leads to ring expansion to a piperidine derivative, which after dehydration gives the tautomers 2-acetyl-1(3),4,5,6-tetrahydropyridine. These compounds can be found ranked under the individualists with 2.6% abundance in the earlier mentioned review on the total odorant space of foods.

The α-hydroxy carbonyl compound acetol is the result of the reduction of methylglyoxal during the Strecker cascade. As both carbonyls are common carbohydrate fragmentation products it was expected that both 2-acetyl-1-pyrroline and 2-acetyl-1(3),4,5,6-tetrahydropyridine were also found in reaction mixtures of higher sugars [5.26], but especially during the degradation of 1-deoxyglucosone and its follow-up product acetylformoin [5.27]. As explained in Figs. 5.4 and 5.10, acetol and methylglyoxal are immediate fragmentation products of these important sugar degradation intermediates. It has to be added that the described mechanisms have further been underlined by the detection of the propionyl pyrroline and propionyl piperidine analogs in reaction mixtures of proline with diacetyl and 1-hydroxy-2-butanone, respectively [5.28].

It is important to understand that the Strecker degradation leads to the production of very reactive small nucleophiles already under moderate conditions. This can be seen from the above described release of ammonia from the resulting α-hydroxyimine structure. However, even more important as educts for follow-up reactions leading to important odor active structures is the release of small sulfur compounds (Fig. 5.9). Cysteine is decarboxylated to the transient α,β-unsaturated imine. This brings the thiol substituent in β-position and leads to elimination of hydrogen sulfide. Besides being aroma active itself this potent nucleophile can condense with other Maillard-derived structures to give important odorants with extremely low thresholds like 2-methyl-3-furanthiol or 2-furfurylthiol (Fig. 5.11). Methionine gives the Strecker aldehyde methional, which easily eliminates methanethiol [5.29]. Oxidation and disproportionation then explains the formation of dimethyl sulfide and dimethyl trisulfide.

5.4 Other Mechanisms

Figure 5.4 depicts the main routes of degradation for 1-deoxyglucosone. Besides fragmentation, cyclization (C + D) leads to furanoic and pyranoic ring structures. 4-Hydroxy-2-(hydroxymethyl)-5-methylfuran-3(*2H*)-one (furan-3-one) is the main compound and reaches up to yields of 50% under moderate conditions. However, it is a nonstable intermediate and is quickly degraded at later stages. 3,5-Dihydroxy-6-methyl-2,3-dihydro-*4H*-pyran-4-one (γ-pyranone) shows the same reaction pattern, but at much lower levels (up to 8%). The formation of γ-pyranone within the 1-deoxy-route is closely related to the formation of 3-hydroxy-2-methyl-*4H*-pyran-4-one (maltol) from disaccharides, ranked within the individualists with 0.9% abundance in above odor signature study.

If alternatively to the formation of furan-3-one water is eliminated at the hydroxymethyl substituent of the furanoic half-acetal 2,4-dihydroxy-2,5-dimethylfuran-3(*2H*)-one (acetylformoin) results (Fig. 5.10, route A). This compound can easily react with nucleophiles to give, for example, pyrrol derivatives, but is also very redox active [5.30]. Disproportionation or reaction with other reducing structures or Strecker-type reactions followed by elimination of water then gives 4-hydroxy-2,5-dimethyl-3(*2H*)-furanone (furaneol) [5.31], which is one of the key generalist odorants with 41% abundance. The reduction step is prerequisite and explains why 6-deoxysugars like rhamnose or fucose are much more effective in generating furaneol [5.32]. Here, the 1-deoxy-route (B) directly leads to the target compound by repetitive water elimination without the need for a reduction step. The same accounts for the detection of furaneol in methylglyoxal or methylglyoxal-acetol incubations [5.33]. Aldol condensation gives the C_6-carbon backbone of the 1,6-dideoxy-hexodiulose intermediate (C). Interestingly, furan-3-one was reported to fragment to 4-hydroxy-5-methyl-3(*2H*)-furanone (norfuraneol), which is the pendant from the pentose 1-deoxy-route, and formaldehyde. This represents a retro-aldol reaction. Furaneol was also detected in pentose glycine reaction mixtures. Here, formaldehyde stems mainly from the Strecker degradation of glycine. Obviously, this is an equilibrium reaction, that is, formaldehyde condenses with norfuranol to result in furaneol via

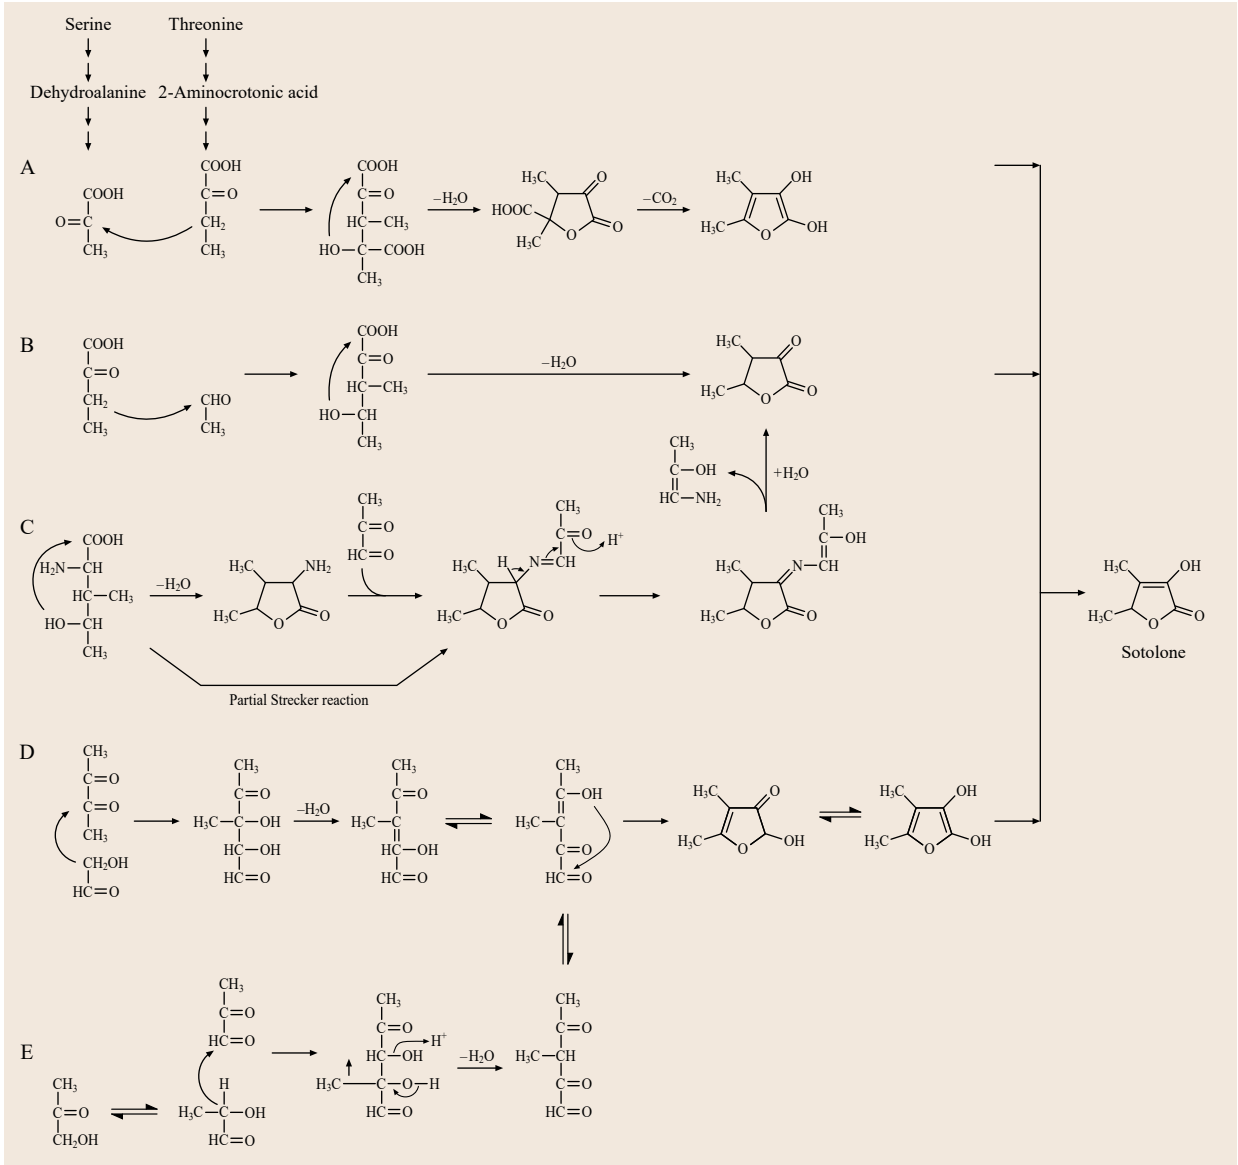

Fig. 5.12 Formation pathways leading to 3-hydroxy-4,5-dimethyl-2(*5H*)-furanone (sotolone)

furan-3-one and acetylformoin (D) [5.34]. This aldol condensation can also occur with acetaldehyde and thus explains the formation of 4-hydroxy-2(5)-ethyl-5(2)-methyl-3(*2H*)-furanone (homofuraneol) in pentose alanine Maillard systems (E). This compound exists in two tautomeric forms in a ratio of 2 : 1.

3-Hydroxy-4,5-dimethyl-2(*5H*)-furanone (sotolone) is another furane derivative, which is of major importance to the odor composition of many foods. Figure 5.12 summarizes nonenzymatic formation pathways that have been reported in the literature. Most mechanisms include an aldol condensation step to build up the branched six-membered carbon skeleton. Relevant to strong heating processes combined with acidic pH values found, for example, under roasting conditions or protein hydrolysis is the formation of pyruvic acid from serine via dehydroalanine, enolization, and loss of ammonia (A). Threonine gives 2-oxobutanoic acid via 2-aminocrotonic acid. Both carbonyl molecules condensate to give sotolone after cyclization, decarboxylation, and rearrangement reactions. This represents an aldol-driven C_3+C_4 route, where the carboxylic acid function at 5-C is then eliminated due to its β-position to the other ring carbonyl

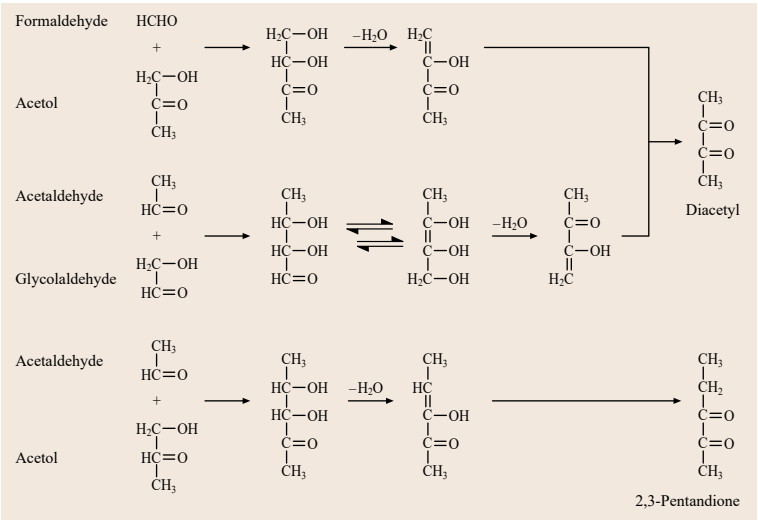

Fig. 5.13 Aldol condensation of short-chained carbonyl compounds explains the formation of diacetyl and 2,3-pentandione

functions. Alternatively, in pathway (B) for aged sake, a C_4+C_2 condensation product from 2-oxobutanoic acid and acetaldehyde was proposed to cyclize directly to the dimethyl substituted furanone [5.35]. Acetaldehyde may stem from acid degradation of threonine like the carboxylic acid or from alanine as the Strecker aldehyde. The positive correlation of acetaldehyde to the formation of sotolone was also reported for flor-sherry wines [5.36]. However, the most efficient pathway was reported for condiments as lovage and especially fenugreek (C) [5.37]. Here, the most abundant amino acid is 4-hydroxy-isoleucine, which already boasts the prerequisite functionalities. In-depth investigations of Blank et al. verified the intermediate 3-amino-lactone to be the most potent educt, to give sotolone in 40% yield at pH 6 in the presence of methylglyoxal. This unusual but very efficient deamination by a Strecker-type reaction can be argumented by the explicit C–H acidic position to give a conjugated 3-membered double bond system which is then hydrolyzed to give sotolone and the Strecker reaction typical eneaminol. On the other hand, incubations starting directly from 4-hydroxy-isoleucine were much less efficient, and a direct partial Strecker reaction was proposed eventually leading to the same ring intermediates in competition to the formation of high amounts of the Strecker aldehyde 3-hydroxy-2-methylbutanal. Alternatively, pathways D + E were proposed to explain the verified formation of sotolone in Maillard systems independent from the degradation of amino acids [5.38]. In (D), diacetyl (C_4) condenses with glycolaldehyde (C_2), dehydration then leads to a furanoic half-acetal to give sotolone after keto-enol-tautomerism. In case (E) of the condensation of acetol (C_3) and methylglyoxal (C_3) the methyl substitution pattern of the C_4-carbon backbone has first to rearrange to proceed via the same ring intermediates. In theory, this can be explained by a pinacol-pinacolone-type reaction. However to the best of our knowledge, such reactions have not yet been experimentally proven for food-relevant processing conditions.

It becomes obvious that aldol condensation reactions of short-chained Maillard intermediates play an important role in the generation of important flavor compounds. Alternatively to the above proposed retro-aldol fragmentation of 1,4-dideoxy-derivatives the formation of diacetyl was explained by the condensation of short-chained carbonyl structures, that is, formaldehyde or acetaldehyde with acetol and glycolaldehyde (Fig. 5.13) [5.28, 39]. This represents a C_1+C_3 and a C_2+C_2 route based on common sugar fragmentation products or Strecker aldehydes, respectively, to give the C_4 target structure after elimination of water and tautomerism. Aldol condensation of acetaldehyde (C_2) and acetol (C_3) also plausibly asserts the formation of 2,3-pentandione.

The Strecker degradation leads to the formation of very reactive small nucleophiles, that is, ammonia which can be released from the eneaminol intermediates, but especially hydrogen sulfide and methanethiol from the breakdown of cysteine and methionine, respectively. These nucleophiles can then easily react with carbonyl moieties to give odor intensive compounds of very low threshold, which are key agents of, for example, meaty aroma profiles. 2-Methyl-3-furanthiol was verified in incubations of 4-hydroxy-5-methyl-3(*2H*)-furanone, which is the main product of ribose via the 1-deoxypentosone route (Fig. 5.11, pathway A) [5.40]. However, this mechanism requires a reduction step to give a furan derivative of the ap-

propriate total redox level, which after elimination of water and substitution with hydrogen sulfide results in the aromatic target molecule. Although reduction steps in Maillard systems can be explained by the presence of reductone structures, this reasoning is a problem in this specific case, as the intermediate 4-hydroxy-5-methyl-3(*2H*)-furanone itself represents a cyclic reductone ether of explicit reducing capacity. Consequently, when *Cerny* and *Davidek* conducted an in-depth investigation based on the CAMOLA approach using ^{13}C-labeled sugars and authentic synthesized intermediates, they only observed very low amounts of 7% 2-methyl-3-furanthiol via this route in reaction mixtures of ribose, 4-hydroxy-5-methyl-3(*2H*)-furanone and cysteine at 95 °C and pH 5 [5.41]. Alternatively for the remaining 93%, they proposed that starting from the Amadori product the 2,3-enediol intermediate eliminates water at the position 4 to result in 1-amino-1,4-dideoxy-pentosone (pathway B). Although this α-dicarbonyl boasts an amino-reductone moiety, the prerequisite reduction step can in this case be explained by the Strecker reaction. Decarboxylation is here a strong driving force for the reduction to result in 1,4-dideoxypentosone after elimination of ammonia from the intermediate Strecker eneaminol [5.42]. Cyclization, water elimination, and incorporation of hydrogen sulfide then lead to 2-methyl-3-furanthiol. In their specific incubations starting from ribose the authors verified fragmentation and recombination reactions to be of negligible importance for the formation of the target furanthiol. However as stated earlier, sugar fragmentation is a general major aspect of Maillard sugar degradation. It is thus not unexpected that models with glycolaldehyde and mercapto-2-propanone lead to substantial amounts of 2-methyl-3-furanthiol (pathway C) [5.43]. Aldol condensation followed by cyclization and elimination of water directly leads to the target, while no reduction step is needed in this case. Mercapto-2-propanone represents an easily arguable acetol derivative. It has to be mentioned that in this study highest yields were obtained under extreme conditions of 180 °C in water-free systems.

A thiol furan structure of even higher importance to the odor space of foods is 2-furfurylthiol. For the pathway leading to this molecule above two studies were consistent with older literature [5.44], that is, the main precursor is 2-furfural, while fragmentation mechanisms were excluded. This means that starting from the *N*-glycoside of ribose the 1,2-eneaminol gives 3-deoxypentosone after elimination of water at the C-3 position and hydrolysis of the amine. Cyclization leads to 2-furfural, which condenses with hydrogen sulfide to result in 2-furfurylthiol after a reduction step (pathway D). To complete the discussion on both thiols, 2-methyl-3-furanthiol and 2-furfurylthiol, it has to be mentioned that minor pathways were reported to be valid in other reaction mixtures. This is owed to the fact, that (I) with, for example, thiamine or glutathione there are additional sources of sulfur than cysteine in foods [5.45], and (II) that hexoses and oligosaccharides can also generate substantial amounts of sugar intermediates with a five-membered carbon backbone following the fragmentation routes described earlier.

5.5 Conclusions

Major steps forward have been made in the elucidation of the complex Maillard reaction pathways resulting in nonenzymatic flavor formation. One major methodological driver was the use of stable isotopic labeled educts and intermediates to trace back their specific reaction pathways in the course of Maillard reaction. This has led to the characterization of 1-deoxyglucosone as the key reactive structure in hexose degradation systems based on insights into fundamental fragmentation mechanisms. Among others, short-chained molecules such as methylglyoxal, acetol, and acetaldehyde are thereby frequently found intermediates in the formation of major odorants. In this respect, hydrolytic β-dicarbonyl cleavage has evolved as the major scission reaction. In contrast, aldol and especially retro-aldol reactions were not substantiated to such an extent as would have been anticipated from the previous literature. Furthermore, it is important to note that the mechanistic degradation of higher sugars like disaccharides or oligosaccharides, which are much more relevant to many foods, is still not understood in full detail. On the other hand, the Strecker degradation as one aspect of the Maillard degradation of amino acids has been expanded from a simple decarboxylation and deamination reaction to a widely branched mechanism with all aspects of the general Maillard reaction scheme, including fragmentation, condensation, elimination, and redox reactions. Especially redox and rearrangement reactions are often important pieces in the puzzle of pathways explaining the formation of major odorants, but detailed insights into the underlaying mechanisms are still lacking and are awaiting to be uncovered.

Part B Food and

Part B Food and Flavors

Food consumption is arguably the most dominant exposure to odors that human beings encounter on a daily basis. This section of the handbook further extends the general considerations of the previous section, but additionally specifically examines the molecular structures that play a major role as potent aroma contributors in foods. Humans experience food from a multisensory perspective, yet their initial encounter with a food requires an immediate appraisal on edibility, which is based on sight and smell and leads to a yes/no decision: does the food look and smell fresh and healthy and appear not to be harmful, or are there odor notes that may indicate deterioration processes, spoilage, or contamination? In addition to a hedonic rating (do I like it?), the consumer further needs to decide if a specific food item fits their current physiological status or if they need specific nutritional requirements. When a person is hungry, smells associated with energy sources such as sugar and fat provide information on where to gain energy. Meat, fish, and other protein-rich sources, on the other hand, tell us via potent odorants originating from amino acid breakdown that this food can serve as building material for our body, later constituting important parts of our bodily cells.

The course of human evolution from hunter-gatherer to domestication and farming, and ultimately industrialization, has seen a concurrent evolution of the food we eat. Early humans consumed foods just as they found them in nature, but with the discovery of tools, fire, and organisms to modify, ameliorate, cook, and conserve food for later usage the aroma and flavor impressions of foods encountered became altered, at times to a major extent, dictating a need for people to learn to accept and appreciate these modified foods. Most interesting in this context is the increasingly extended usage of microbial conversions that led to the generation of novel products such as bread, fermented meat and milk products, and acidic or alcoholic fermentation products, to name but a few. These processing steps not only helped to achieve the intended improvements such as better preservation, prolonged storage, improved digestibility, or increased nutritional effects, but also resulted in the formation of modified or new aroma profiles. Even accidental discoveries, for example, that some spoiled food was actually not really off, led to a dramatic increase in the pool of aroma and flavor impressions encountered. This evolution of food is still ongoing, with fermentation and food processing continuously undergoing development and leading to flavors and preference of novel products that our ancestors never encountered. Still, our omnivorous nature has meant that we have always been exposed to sensory variance; thus our ability to further broaden our sensory openness is an inherent trait. Exploration in this direction will surely continue as sensory curiosity is a major driver of human nature.

6. Coffee

Chahan Yeretzian

Coffee is a relatively young beverage that has only been known about since the 17th century. Initially consumed by the aristocracy, coffee has developed since the early 20th century into one of the world's most popular beverages and is now part of our daily routine and lifestyle. It also represents a major source of income for many coffee-producing countries and is a significant business sector in consumer countries. The triumph of this beverage may have been driven by various factors, but there is no doubt that its unique flavor is the prime reason for its amazing success. Here we will review current knowledge on the aroma of coffee from a chemical and analytical perspective and outline future trends. It is believed that most coffee aroma compounds have already been identified and quantified. Yet little is understood about how these aroma compounds are generated from green coffee precursors during roasting. A true definition of the aroma of freshly roasted and/or brewed coffee is very elusive and some aroma compounds start to degrade the moment they form. Furthermore, research on interindividual differences in the sensation and perception of coffee aromas is still in its infancy. After reviewing our current knowledge on coffee aroma compounds, we will outline recent developments in time-resolved analysis in three fields:

1. Aroma formation during roasting
2. Aroma extraction during espresso preparation and
3. In-mouth release during consumption.

Finally, we will address predictive models for sensory profiles derived from instrumental measurements – possibly the holy grail of aroma sciences.

6.1 Coffee Aroma – From the Seed to the Cup

The aroma of a freshly prepared cup of coffee is the final expression and perceptible result of a long chain of transformations that link the seed to the cup [6.1]. Figure 6.1 outlines various factors that impact the aroma of coffee. The final cup is the result of the interplay between genetic predispositions, environmental and climatic factors, harvest and post-harvest practices, sorting, grading, storage and transport, processing steps such as roasting, grinding and extraction and finally consumption practices. This long journey can be condensed into three key factors: *Predisposition* → *Transformation* → *Consumption*. All three play a specific and important role in the aroma of coffee.

Predisposition: The green coffee variety (genetics) with its specific set of chemical precursors forms the basis for the aromas that will later develop during the subsequent transformation steps.

Transformation: Even the best coffee will be ruined if not properly processed. The art and science of creating an exceptional sensory experience is to master every one of these transformations. The agronomy,

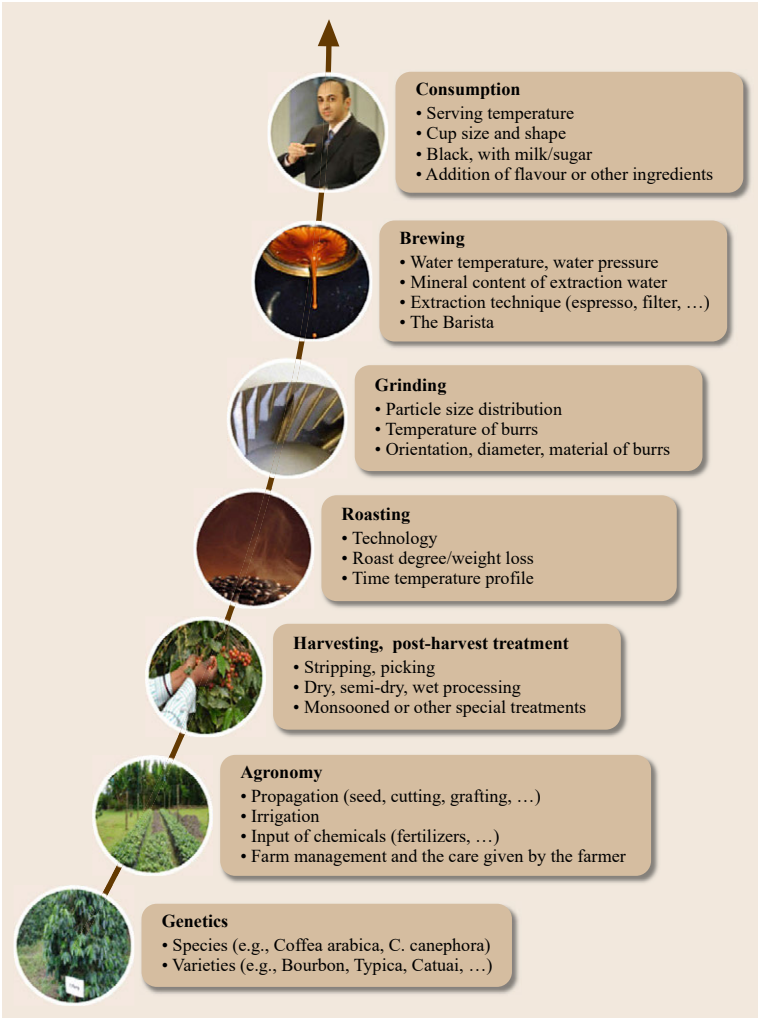

Fig. 6.1 The aroma of coffee is the final expression and perceptible result of a long chain of transformations, which link the seed to the cup. The aroma is influenced by genetic, agricultural, chemical and technical factors. However, the human factor in terms of the skill and care taken by all those involved in these transformations is just as important

climate, harvest practices and post-harvest treatment already start to modulate the genetic predisposition of the coffee beans. However, the smell and taste of green beans provide no cues as to what they might become once roasted. The most significant step in the transformation process is roasting. It unlocks the potential of the green bean and creates the coffee aroma.

Consumption: The way we prepare and consume our coffee greatly affects the flavor we perceive. However, beyond the perceptible quality in the cup, by choosing to buy a certain coffee, consumers show their support for all the work that has happened along the value chain and reward agronomic, ecological and business practices that they wish to reinforce.

6.2 The Sensory Experience of Coffee

There may be different reasons for the rapid and continuing rise of coffee's popularity. However, the prime driver for the increase is its unique set of sensory qualities. To better appreciate the multifaceted sensory experience elicited by a cup of coffee, one can schematically decompose it into four different components (Fig. 6.2).

1. *Chemical and physical properties*: This first and best understood factor of the sensory experience

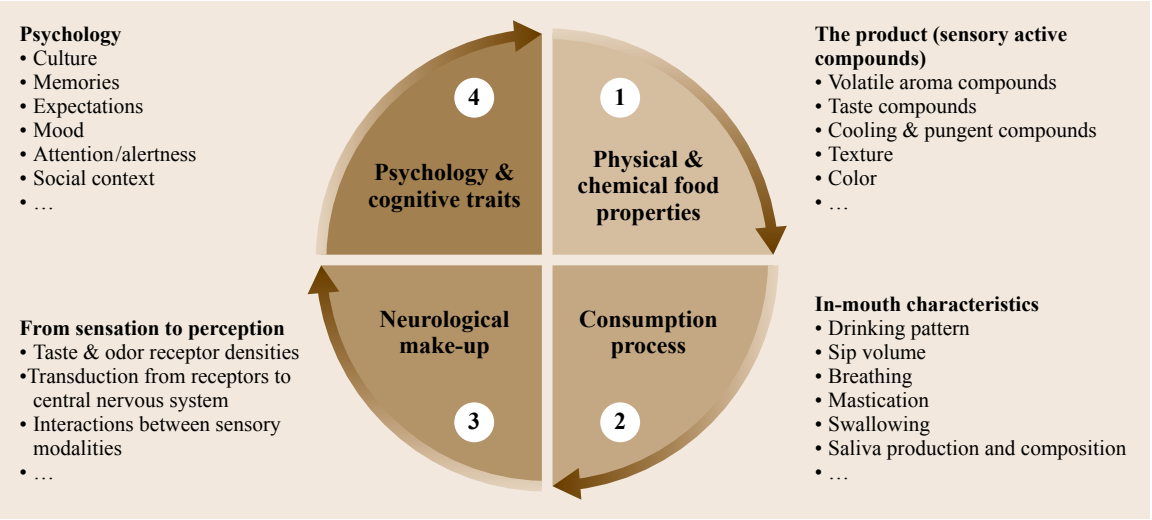

Fig. 6.2 The sensory experience of coffee is truly a holistic one. But, to understand it better, it can be schematically decomposed into four components

elicited from coffee is exclusively related to the product itself, without reference to how it is consumed and the actual consumer. These properties can be precisely measured by objective instrumental or analytical techniques and mainly focus on the concentration of aroma and taste compounds, temperature and texture (viscosity, % total solids, color). A lot of previous research into coffee aroma has focused on extracting, identifying and quantifying aroma active compounds in coffee.

2. *The consumption process*: A specific cup of coffee might have a precisely measurable composition of aroma compounds, yet these compounds may be released in-mouth and transported to the sensory receptors differently from person to person, leading to interindividual differences. Individual characteristics in consumption patterns (volume of sip, breathing rhythm, swallowing pattern, movement of the coffee in the mouth, etc.) and in-mouth physiognomy and physiology (shape of nasal cavity, amount and composition of saliva) will modulate the sensory experience and lead to interindividual differences in the sensory experience, even if consuming exactly the same coffee [6.2–10]. Indeed a given coffee will not *taste* the same for different people. This second factor therefore concerns the process of drinking and all aspects related to the physiological and physical environment in the mouth that leads to the liberation of the aroma and its transport from the oral to the nasal cavity, where the olfactory receptors are located. By recognizing the factors involved in a person's perception of coffee aroma, it has been possible to develop novel analytical approaches that open the way to individualized aroma science [6.11–13].
3. *The neurological make-up of individuals*: Besides individual differences in consumption patterns and in-mouth characteristics, the sensory experience is also modulated by individual differences in the initial sensation at the level of individual receptors as well as final and conscious perception. Sensation refers to the process of sensing our environment through touch, taste, sight, sound, and smell [6.14–16]. This information is sent to our brains in raw form where perception comes into play. Perception is the way we interpret these sensations and therefore make sense of everything around us. It is affected by a complex transduction process from activation of the multiple sensory receptors to the final response pattern at the level of the central nervous systems, where interactions from other senses may be integrated [6.17–19]. The individual sensory experience is therefore not only affected by the composition of sensory active compounds in the coffee and modulated by the individual's in-mouth characteristics and consumption habits. Individuals also differ in their neurological and physiological make-up. Like the in-mouth environment, this make-up will lead to an individually modulated sensory experience. Hence, the same coffee may elicit distinctively different sensory experiences for different people. Numerous reports have demonstrated the impact of anatomical and physiological differences on aroma perception [6.20–23]. A particularly well-studied case is bitter perception (sensitivity to 6-*n*-propylthiouracyl (PROP) or

phenylthiocarbamide (PTC). It has been established that individuals may vary in the extent to which they perceive bitter tasting compounds [6.24] and that this inheritable trait is related to the density of fungiform papillae on the tongue [6.25, 26]. There are reports that PROP sensitivity affects macronutrient selection [6.27]. Furthermore, the inability of some people to perceive specific odors, termed anosmia, is also well known [6.28, 29].

4. *Psychology and cognition*: Finally, individual history, past experiences, expectations, product familiarity [6.30, 31], psychosocial and cognitive factors such as culture, mood, and conditioning and social context can all affect the way a person experiences a cup of coffee [6.30, 32–39].

In Sect. 6.3, we will review the current status of *what makes coffee smell so good* [6.40, 41].

6.3 Coffee Aroma Compounds

Describing the sensory perceptions we experience whilst sipping a cup of coffee is not easy. It is the result of a complex multisensory experience involving all of our senses including olfaction, taste, touch, trigeminal sensation, vision, and possibly hearing.

Aroma is an odor; it is often referred to as a smell and is sensed by receptors in the nose. An important distinction is made between the orthonasal and the retronasal aroma. When we have coffee in front of us, we can smell it. We call this the orthonasal, or above-the-food aroma. VOCs, released from the coffee, enter our nasal cavity during inhalations and reach the olfactory epithelium. The olfactory centers reside very high along the roof of the nasal cavity just below and between the eyes. They cover an area of 5 cm^2 and contain some 10–20 million receptor cells. In order for these centers to be stimulated, the odor molecules have to be inhaled into the nose and carried up to the roof of the nose. The second type of aroma of significance to consumers is the aroma released in the mouth when drinking coffee. While coffee is in the mouth and also after swallowing, volatile compounds are released from the food and are transported by various airflows (mouth movement, respiration) from the oral cavity to the pharynx, passing the soft palate (*velum palatinum*). When exhaling, volatiles are swept up by the airflow coming from the oral cavity and the lungs and are released through the nose. During their transport from the oral cavity through the pharynx to the nasal cavity, VOCs pass along the olfactory epithelium and may trigger an olfactory perception. This aroma is termed the retronasal or in-mouth aroma, and is related to the aroma as perceived during eating or drinking.

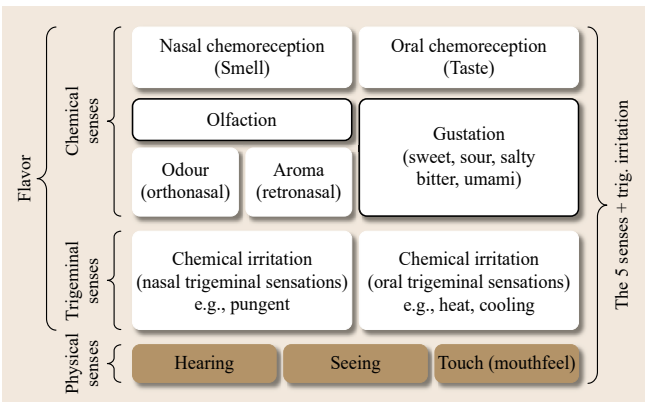

Fig. 6.3 Our senses represent our windows to the world and to our cup of coffee

Taste, or gustation, is the sensation of saltiness, sweetness, sourness, bitterness and umami (savoriness). Flavor is the combination of taste and smell. Another important additional sensation to describe the flavor of coffee is the body. It can be light, like a dry light wine, or it can be heavy, like a red wine. The perception of irritants is mediated not by taste and smell receptors, but by other chemosensitive receptors. The perceptual characteristics of chemical irritation, or chemesthesis, are mediated by nonspecific, multimodal somatosensory fibers and are a property of the skin [6.16]. These chemical senses are complemented by the physical senses of sight or vision, hearing and touch (somatosensation). Figure 6.3 summarizes the multidimensional space of the sensory experience.

Among the various sensory modalities, aroma (smell) is of paramount importance to the quality of coffee. Hence, in the remains of this chapter we will focus on volatile coffee aroma compounds. In order for coffee to be sensed by our nose (to have a smell) aromatic volatile organic compounds (VOCs) have to be released from the brew and reach the olfactory epithelium, a region in the upper part of the nasal cavity that contains the nerve endings that allow us to smell.

Scientific efforts to elucidate the origin of the rich and distinctive aroma of coffee, and ultimately to understand *what makes that coffee smell so good* [6.40, 41] can be traced back to 1880 when *Bernheimer*, a German scientist, identified the first few volatile compounds in coffee [6.72]. But the first significant progress can most

Table 6.1 Flavor active VOCs in Arabica coffee (after [6.42]). The first column lists 72 VOCs, classified into 15 different groups of chemical compounds (after [6.19, 30, 43–69])

Key odorant	CAS ID#	Concentration (ppb)[a]	Aroma descriptor	Sensory threshold (ppb)[b]
Aldehyde				
2-Methylbutanal	96-17-3	20 700	Rancid, almond-like, toasty	1.3
2-Methylpropanal	78-84-2	–	Toasty, caprylic, cheesy, dark chocolate, ethereal, fruity, malty, pungent	–
3-Methylbutanal	590-86-3	18 600	Fruity, almond-like, toasty, ethereal, chocolaty, peachy, fatty	0.35
(*E*)-2-Nonenal	18829-56-6	19	Fatty, green, cucumber, citrus	0.08
Acetaldehyde	75-07-0	139 000	Pungent, ethereal, fresh, lifting, penetrating, fruity, musty	0.7
4-Methoxybenzaldehyde	123-11-5	–	Sweet, powdery, vanilla, anise, woody, coumarin, creamy	27
Phenylacetaldehyde	122-78-1	–	Sweet, fruity, honey, floral, fermented	–
Propanal	123-38-6	17 400	Ethereal, pungent, earthy, alcoholic	10
Acid				
2-Methylbutyric acid	116-53-0	25 000	Acidic, fruity, dirty, cheese	10
3-Methylbutyric acid	503-74-2	18 060–32 180	Cheesy, dairy, acidic, sour, pungent, fruity, stinky	700
Ester				
Ethyl-2-methylbutyrate	7452-79-1	3.9	Fruity, berry	0.5
Ethyl-3-methylbutyrate	117442-70-3	14	Fruity	0.6
Furan				
Furfural	98-01-1	5880–19 370	Sweet, brown, woody, bread, caramellic	280
2-((Methylthio)methyl)furan/ 2-furfuryl methyl sulfurous	1438-91-1	–	Smoke, roast, onion, garlic, sulfurous, pungent, vegetable, horseradish	–
2-Furanmethanol acetate/furfuryl acetate	623-17-6	24 520–40 040	Onion, garlic, sulfurous, pungent, vegetable, horseradish	–
2-Methyl furan	534-22-5	–	Burnt, ethereal (mild), gasoline, acetone, chocolate	–
5-Methyl-2-furancarboxyaldehyde/ 2-methyl furfural	620-02-0	–	Sweet, caramellic, bready, brown, coffee-like	6000
Furfuryl formate	13493-97-5	–	Ethereal	–
Furfuryl methyl ether	13679-46-4	–	Roasted coffee	–
Furfuryl disulfide	4437-20-1	–	Sulfurous, coffee, roasted chicken, meaty, onion, cabbage	–
Sulfur-containing compounds				
Dimethyl trisulfide	3658-80-8	28	Sulfurous, cooked onion, savory, meaty, cabbage-like	0.001
Bis(2-methyl-3-furyl)disulfide	28588-75-2	–	Meaty, roasted scallion, onion, sulfurous	0.00076
Methional	3268-49-3	213–240	Boiled potato-like, musty, tomato, earthy, vegetable, creamy	0.2
Thiols				
3-Mercapto-3-methyl butyl formate	50746-10-6	130	Green blackcurrant, herbal, fruity, roasted, sweaty	0.0035
2-Furfurylthiol	98-02-2	1080–5080	Roasted (coffee-like), sulfurous	0.01
2-Methyl-3-furanthiol	28588-74-1	60–68	Sulfurous, meaty, fishy, metallic, boiled	0.007
3-Mercapto-3-methylbutylacetate	50746-09-3	7.5	Roasty, fruity, sulfurous, sweet	–
3-Methyl-2-butene-1-thiol	5287-45-6	13	Sulfurous, smoky, leek, onion	0.0003
Methanethiol	74-93-1	4550	Rotten eggs, meat or fish, cabbage, garlic, cheesy	0.02
Thiophene				
3-Methylthiophene	616-44-4	–	fatty, wine	–
Thiazole				
2,4-Dimethyl-5-ethylthiazole	38205-61-7	–	Nutty, roasted, meaty, earthy	–

Table 6.1 (continued)

Key odorant	CAS ID#	Concentration (ppb)[a]	Aroma descriptor	Sensory threshold (ppb)[b]
Furanone				
Dihydro-2-methyl-3(2*H*)-furanone	3188-00-9	7580–30 000	Sweet, bread, buttery, nutty	0.005
2-Ethyl-4-hydroxy-5-methyl-3(2*H*)-furanone (homofuraneol)	27538-10-9	16 800	Sweet, caramel, candy	20
3-Hydroxy-4,5-dimethyl-2(5*H*)-furanone (sotolone)	28664-35-9	1.1–11 470	Extremely sweet, strong caramel, maple, burnt sugar, coffee	20
4-Hydroxy-2,5-dimethyl-3(2*H*)-furanone (furaneol)	3658-77-3	10 930–112 000	Sweet, candy, caramel, strawberry, sugar	10
5-Ethyl-3-hydroxy-4-methyl-2(5*H*)-furanone (abhexon)	144831-60-7	104–160	Seasoning-like, caramel-like	7.5
5-Ethyl-4-hydroxy-2-methyl-3(2*H*)-furanone	27538-09-6	17 300	Sweet, caramel, bread, maple, brown sugar, burnt	1.15
Ketone				
1-Octen-3-one	4312-99-6	–	Herbal, mushroom, earthy, musty, dirty	0.0036
2,3-Hexadione	3848-24-6	–	Burnt, buttery, caramel, chocolate cream, creamy, fruity, oily, pear, sweet	–
2,3-Butanedione	431-03-8	48 400–50 800	Buttery, creamy, fatty, oily, sweet, vanilla	0.3
2,3-Pentanedione	600-14-6	3540–39 600	Buttery, caramel, creamy, penetrating, sweet	20
4-(4′-Hydroxyphenyl)-2-butanone	5471-51-2	1	Sweet fruity, berry, jam, raspberry, ripe, floral (raspberry ketone)	1–10
1-(2-Furanyl)-2-butanone	4208-63-3	–	Rummy	–
Norisoprenoid				
(*E*)-β-damascenone	23726-93-4	195–255	Honey-like, fruity, apple, rose, honey, tobacco, sweet	0.00075
Phenolic compounds				
Guaiacol	90-05-1	2000–17 970	Phenolic, burnt, smoke, spice, vanilla, woody	2.5
4-Ethyl guaiacol	2785-89-9	800–24 800	Spicy, smoky, bacon, phenolic, clove	25
4-Vinyl guaiacol	7786-61-0	8000–64 800	Spicy, dry woody, fresh amber, cedar, roasted peanut	0.75
Vanillin	121-33-5	2290–4800	Sweet, vanilla, creamy	25
Pyrazine				
2,3-Dimethylpyrazine	5910-89-4	2580–6100	Nutty, coffee, peanut butter, walnut, caramel, leather	800
2,5-Dimethylpyrazine	123-32-0	4550–11 730	Cocoa, roasted nuts, roast beef, woody, grass, medical	80
2,3-Diethyl-5-methylpyrazine (hazulnut pyrazine)	18138-04-0	73–95	Roasted nuts, musty, meaty, vegetable, roasted hazelnut	0.09
2-Ethyl-3,5-dimethylpyrazine	27043-05-6	55-330	Roasted nuts	0.04
2-Ethyl-3,6-dimethyl-pyrazine (3,6-cocoa pyrazine)	13360-65-1	2570–5980	Potato, cocoa, roasted, nutty	8.6
2-Methoxy-3,5-dimethylpyrazine (3,5-cocoa pyrazine)	13925-07-0	1.1	Earthy, burnt, almonds, roasted nuts, coffee	0.006
2-Methoxy-3,2-methylpropylpyrazine	24683-00-9	–	Green, pea green, bell pepper	–
2-Methoxy-3-isopropylpyrazine	25773-40-4	2.4	Earthy, pea, bean	0.002
3-Ethenyl-2-ethyl-5-methylpyrazine	181589-32-2	–	Earthy	–
6,7-Dihydro-5-methyl-5*H*-cyclopentapyrazine	23747-48-0	–	Roasted nuts, earthy, baked potato, peanut, roasted	–
Ethylpyrazine	13925-00-3	–	Peanut butter, musty, nutty, woody, roasted cocoa	4000
Pyridine				
Pyridine	110-86-1	21 280—65 520	Fishy	77
Pyrrole	109-97-7	–	Sweet, nutty, ethereal	–
1-Methyl pyrrole	96-54-8	–	Smoky, woody, herbal, negative notes; defective beans	–

Table 6.1 (continued)

Key odorant	CAS ID#	Concentration (ppb)[a]	Aroma descriptor	Sensory threshold (ppb)[b]
Terpene				
Linalool	78-70-6	–	Flowery, citrus, orange, terpene, waxy, rose	0.17
Limonene	138-86-3	–	Citrus, herbal, terpene, camphor	4
Geraniol	106-24-1	–	Sweet, floral, fruity, rose, waxy, citrus	1.1

[a] The second column shows the range of reported concentrations in ppb (μg/g) in roasted Arabica coffee. For some VOCs no information on concentrations could be found in the literature.
[b] In cases where different sensory detection thresholds were found, the one included in the table corresponds to the lowest one reported. All sensory thresholds were determined in water except:
1. Matrix unknown
2. Threshold measured by first diluting compounds in ethanol in a defined concentration and then dissolving them in water (for linalool → as R-linalool) 3. Determined in ethanolic solution 9.5%
4. Determined in cellulose
5. Determined in beer
6. Determined in air.

likely be attributed to *Reichenstein* and *Staudinger*, who, in 1926, identified and patented several important aroma active compounds in coffee [6.73, 74]. Mainly fueled by progress in analytical techniques, in particular gas chromatography (GC), the number of publications on coffee aroma and the number of identified coffee VOCs has rapidly increased since then. Today, around 1000 VOCs have been reported in coffee, which includes compounds from both green and roasted coffee [6.75].

For many years, scientists concentrated on identifying the VOCs in coffee. But already by the 1970s it had become clear that only a small fraction of these volatiles – perhaps 5% – are odoriferous and hence relevant to the aroma. As a result, the focus has shifted towards these few sensory relevant aroma-active compounds in the headspace (HS) of coffee (the airspace above the coffee).

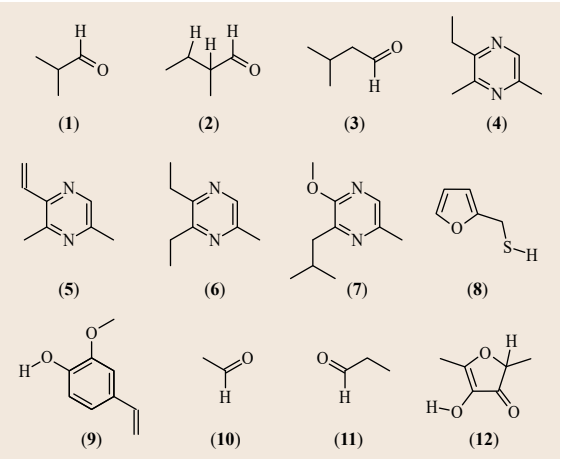

Fig. 6.4 These 12 compounds are considered of particular importance to the aroma of coffee. The numbers in brackets, below the formula, correspond to the numbers behind the names in Table 6.2 (first column)

Several instrumental methods have been developed to achieve the following objectives: to identify and quantify the odor-relevant volatiles, to assess their odor impact and note, and to recombine coffee aromas from the identified and quantified main aroma compounds. Given the extensive differences in coffee genetics, geographical origins, cultivation practices and processing techniques, it is not surprising that publications on coffee aroma composition differ in terms of the relative importance placed on the main aroma compounds. Consequently, while there has been extensive investigation into the main aroma volatiles in coffee, individual studies often report slightly different sets of volatiles that are representative of the particular aroma of the coffee being studied. Furthermore, the different methodological strategies and analytical approaches used for measuring VOC compositions are an additional source of variability in the ranking of the main aroma compounds. Hence, in order to *eliminate* variability due to differences between varieties for example, we have focused in Table 6.1 on just the Arabica variety.

In-depth studies by Grosch and his coworkers on the identification and quantification of flavor active VOCs, the determination of their odor thresholds and extraction yields, already concluded in the mid-1990s that less than 30 VOCs are important to the aroma of roasted coffee [6.44, 46, 48, 76–79]. Omission experiments further suggest that the actual number of indispensable coffee aroma compounds could be as small as nine [6.49, 51, 52, 80]. Based on this more focused and detailed work, a condensed list of coffee aroma VOCs has been com-

Table 6.2 Quantitative composition of roasted coffee, ground coffee and coffee extract/beverage, for the 28 most potent coffee aroma compounds, determined for a medium roasted Columbian Arabica coffee. (a) Mass fraction of the aroma compound in roast and ground coffee powder (after [6.70, 71]). (b) Concentration of aroma compounds in the extract/beverage (54 g of R and G extracted with 1 l of hot water) (after [6.70]). (c) Mass fraction of aroma compounds in the extract/beverage (calculated from [6.70]). (d) Extraction yield (after [6.70]). (e) Compounds whose absence was significant for most panelists when omitted from the aroma model (after [6.49]). The numbers in brackets, behind the compound names, correspond to the numbers of the structures shown in Fig. 6.4 (last column)

Compound name	Powder (µg/kg) (a)	Extract (µg/l) (b)	Extract (µg/kg) (c)	Extraction yield (%) (d)	Aroma model (e)

piled in Table 6.2, where compounds are grouped into sensory families. Besides concentrations in roast and ground coffee, concentrations in the liquid coffee extract and the extraction yields have also been included. The last column in Table 6.2 marks the 12 compounds that were considered by *Grosch* and his coworkers to be particularly important – shown in Fig. 6.4 [6.49, 51, 80]. Omitting these compounds from a coffee aroma model (individually or as groups) leads to a significant difference in the coffee aroma profile and so they are considered to be of particular importance in terms of coffee aroma.

6.4 Analytical Techniques for Coffee Aroma Analysis

6.4.1 Gas Chromatography

Without doubt the classical *work horse* in coffee aroma analysis has been gas chromatography (GC). Over the past 30 years it has led to the elucidation, characterization and quantification of the compounds that are relevant to coffee aroma. Two potential weaknesses of such an approach are that it is slow, making it unsuitable if fast processes need to be monitored in real time. Furthermore, it neglects possible interactions between aroma compounds, such as masking and enhancement. Yet, in spite of these and other drawbacks, GC analysis is still considered an excellent approach for understanding and reconstituting the flavor of coffee. The ultimate proof that we *understand* the aroma of coffee is when we are able to reconstitute this aroma [6.51, 80].

6.4.2 Olfactometry

Many aroma active compounds in coffee only appear in the HS at very low concentrations, some of which can hardly be detected by analytical detectors. The only detector capable of sensing these highly potent coffee aroma compounds is our nose. Hence, aroma chemists use their nose (or a panel of *sniffers*) to detect compounds that are eluted at the end of the GC column. Trained sniffers also provide a sensory description of the compound. In combination with the retention time and mass spectral profile, the aroma note often allows the compound to be unambiguously identified. Techniques that combine separation by capillary column chromatography and the human nose as a detector are called GC-olfactometry – GC/O [6.81] and are explained in the following section.

Two major GC/O screening techniques have been developed: one by *Grosch* and his coworkers (called aroma extract dilution analysis, AEDA) [6.52, 82] and the other by *Acree* and his coworkers (called comprehensive high-throughput arrays for relative methylation, CHARM analysis) [6.83–91]. These techniques are shown schematically in Fig. 6.5. Both evaluate a dilution series of an original aroma extract using GC/O. The occurrence of an aroma in each dilution is noted. As the dilution increases, the compounds with lower odor potency successively cease to be sensed, and only the most potent are detected at higher dilutions. The number of occurrences of each odorant across dilutions are then added together. The greater the number of dilutions in which an odorant is sensed, the higher is the odor potency in both AEDA and CHARM analysis. This leads to plots of dilution- or CHARM-values. Both AEDA and CHARM analysis originally proposed that the larger the dilution- or CHARM-value, the more important the contribution of the respective aroma compound to the overall aroma. While this interpretation has slightly evolved since its introduction, both techniques are still widely used to estimate the relative importance of various volatile aroma compounds to the aroma of coffee [6.1, 84, 86, 87, 89, 92]. An alternative technique, called gas chromatography – surface of nasal impact frequency (GC-SNIF), was introduced by *Chaintreau* and his coworkers [6.93]. In this method, the intensities of the aromagram peaks were based on the detection frequencies of the odorants perceived at the sniffing port by a panel of assessors. This approach allowed standard deviations to be calculated and hence led to more quantitative data analysis than previous GC/O methods. For a review of GC/O, with a specific discussion of coffee, please refer to [6.94].

An interesting application of GC/O was the identification of the chemicals responsible for the moldy/earthy off-notes found in lots of green Mexican coffees [6.1, 92]. GC profiles obtained from a reference sample – a sample free of off-notes – and a moldy sample, showed minor differences, and no indication of

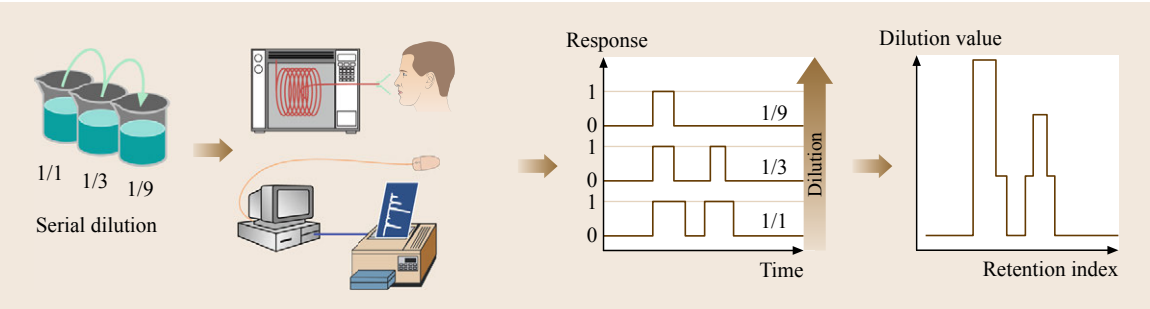

Fig. 6.5 Schematic description of gas chromatography olfactometry, GC/O. Aroma extract dilution analysis and CHARM analysis are the two most common realizations of GC/O

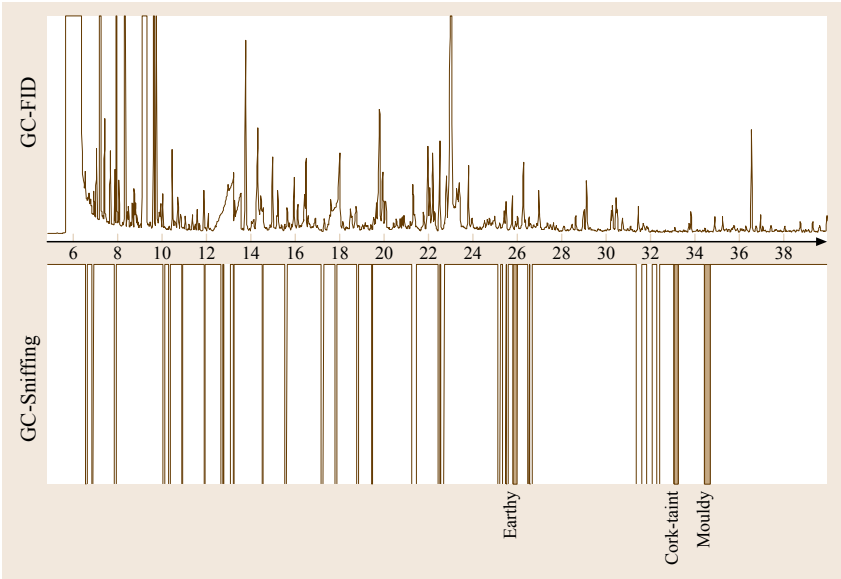

Fig. 6.6 Comparison of a GC chromatogram on the top with the GC/O profile analyzed by one sniffer on the bottom for a sample with a moldy, earthy defect. All sniffed signals without sensory descriptors represent signals that are typical to coffee and are not related to the off-note

the off-note was found. The same samples were then subjected to a GC/O sniffing analysis. This allowed several differences between the extracts that are related to the off-flavor to be identified (Fig. 6.6). In particular, earthy, green, chemical and moldy chromatographic zones were located that could be identified as 2-methyl isoborneol, 2,4,6-trichloroanisole, geosmin and various pyrazines.

The example in Fig. 6.6 demonstrates one of the strengths of GC/O: the identification of VOCs responsible for olfactory off-notes in a defective sample. It offsets the lack of sensitivity to low concentration flavor active compounds encountered with other detection systems. In this study, it was clear that instrumental detection failed to recognize the defects documented in the sensory profile [6.1, 92].

6.5 Trends and New Developments in Coffee Aroma Analysis

Through a sustained and concerted research effort over more than 30 years our understanding of the aroma of coffee has steadily grown. Today we believe that the list of aroma active compounds is essentially complete. Nevertheless, research into coffee aroma and aroma in general is still in its infancy. Major efforts are currently being made to develop a range of emerging technologies and analytical strategies. We would like to highlight three major trends that we believe will shape the future of (coffee) aroma research. These are: development of time-resolved analytical technologies (Sect. 6.5.1), progress on individualized aroma science (Sect. 6.5.2) and mathematical and statistical models to predict sensory profiles from instrumental measurements (Sect. 6.5.3).

6.5.1 Time-Resolved Analytical Techniques

Novel analytical technologies and strategies are currently being introduced, which go well beyond established chromatographic techniques and introduce time-resolved methods based on direct injection mass spectrometry using optical and laser ionization [6.95–101] and chemical ionization [6.11, 102–116]. Here we will discuss two applications of time-resolved approaches. In particular, we will present examples for coffee roasting and extraction. Both are dynamic processes requiring a time resolution of approximately one second. Both processing steps are also crucial to the transformation of coffee from the seed to the cup.

Aroma Formation During Roasting

One of the crucial steps for creating a good cup of coffee is the roasting process, where various physical and chemical changes lead to the formation of the desired coffee aroma molecules. One possibility for studying the formation of VOCs during roasting is to take samples at different times during the roasting process and analyze them offline with gas chromatography [6.70, 117–121]. However, these techniques are not only time-

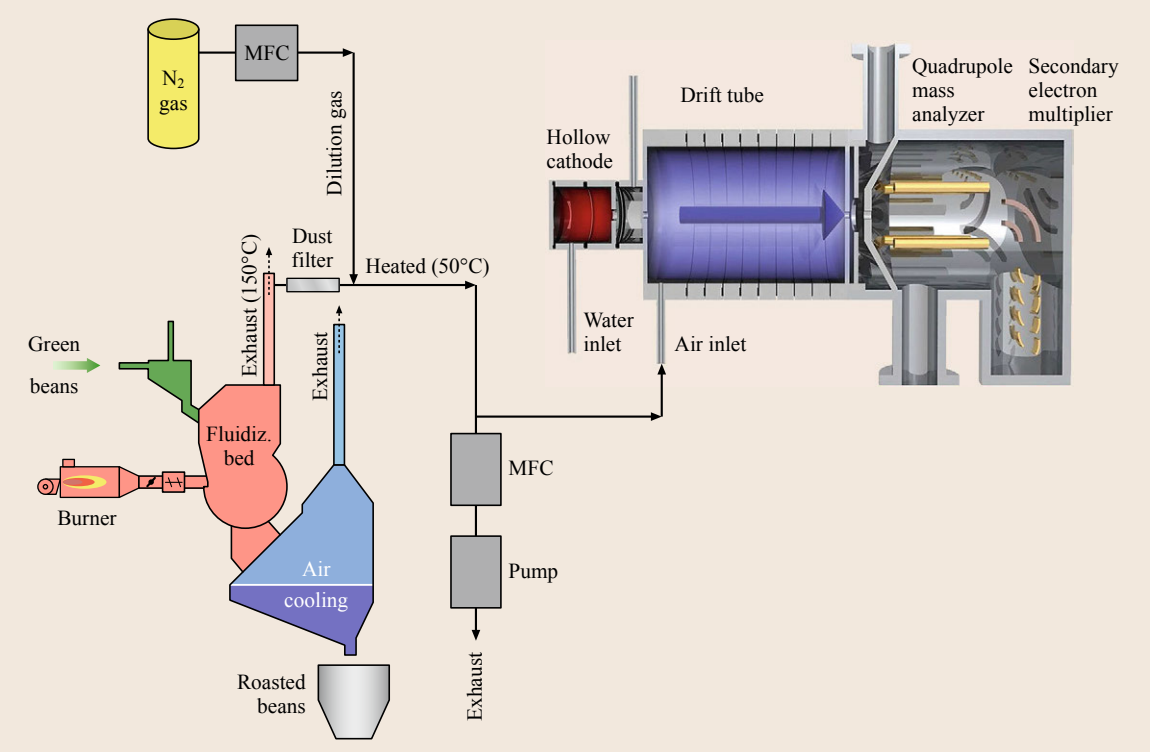

Fig. 6.7 Experimental setup for online measurements of the roaster off-gas during roasting on a 200 g/batch fluidized bed sample roaster from Neuhaus Neotec. The gas from the roaster off-gas is sampled through a dust filter and diluted with nitrogen gas to reduce the temperature and humidity of the sampled gas. All sampling lines are heated to 50 °C to prevent condensation. While most of the sampled gas is sent through the mass flow controller (MFC) and the pump to the exhaust, a small fraction is sampled via the air inlet into the drift tube of the PTR-MS. In the drift tube, VOCs are ionized by proton transfer from H_3O^+ and mass analyzed by a quadruple mass filter

consuming, but often require complex sample preparation processes before analysis, with the additional risk that irregularities in these processes might affect the outcome of the analysis. In contrast, direct online measurements of the roaster off-gas provide a direct insight into the dynamics of VOC formation in real time, are very sensitive and do not require sample preparation (hence avoiding potential distortion of information). An already well-proven technology for online analysis of coffee roasting, introduced by *Yeretzian* and his coworkers, is proton-transfer-reaction mass spectrometry (PTR-MS) [6.102, 122–125]. Furthermore, in collaboration with *Zimmermann* et al., alternative techniques based on resonant laser ionization coupled to time-of-flight mass analysis [6.95, 99–101], or ion trap mass spectrometry [6.126] have also been applied to explore the coffee roasting process. More recently, with single-photon ionization time-of-flight mass spectrometry (SPI-ToF-MS), single bean roasting has been performed on Arabica as well as Robusta beans [6.101]. Combining soft ionization via proton-transfer reaction with high mass resolution of a time-of-flight instrument (PTR-ToF-MS) [6.127] provides the advantage of a fast analytical technique to record information about VOCs formed during roasting in just one single mass spectrum. Online monitoring of coffee roasting with PTR-ToF-MS allows the formation dynamics of numerous VOCs to be followed in real time [6.114, 116, 128, 129].

Two examples of online analysis by PTR-MS of roaster off-gas during coffee roasting are provided below. The first example represents a Columbian Arabica coffee, roasted using different roaster gas temperatures to achieve the same dark roast degree (CTN 67 on the Neuhaus scale). The temperature of the roaster gas was set to 228, 238, 248 and 258 °C (isothermal roasting) for four roasting trials and more than 50 VOCs were measured simultaneously during each trial. Figure 6.7 shows the experimental setup, while Fig. 6.8 shows the time–intensity profiles for two selected compounds – furfural and 5-methylfurfural – during the four different isothermal roasting trials. While the cof-

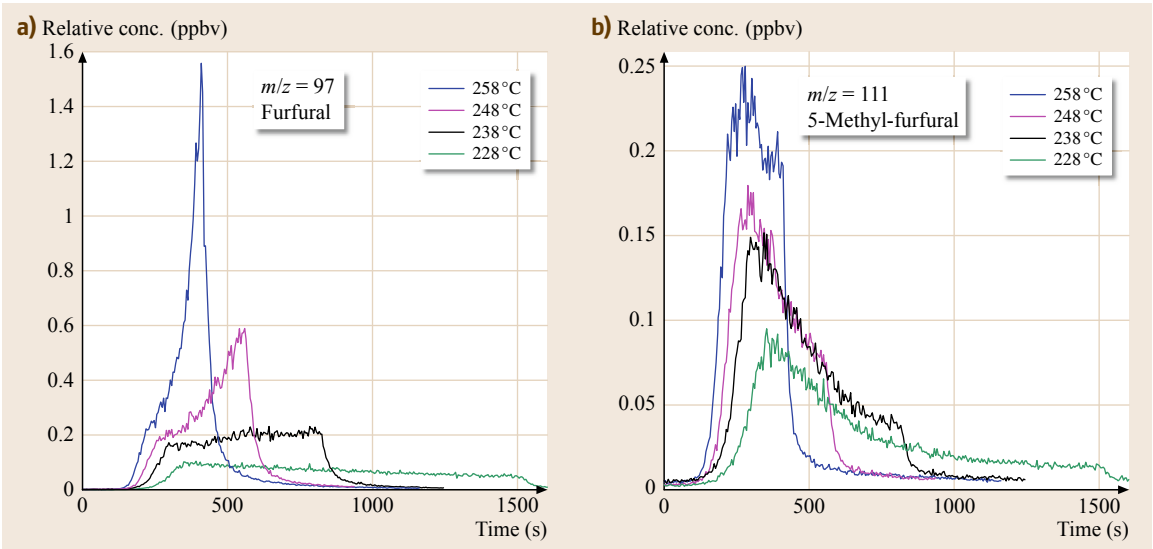

Fig. 6.8a,b The PTR-MS ion traces that are shown were monitored online and in real time in the off-gas of a fluidized bed sample roaster (200 g). Shown are two compounds (tentative assignment: furfural **(a)** and 5-Methyl-furfural **(b)**) during four different roasting trials for different hot air temperatures

fee reaches the same dark roast degree of CTN 67 in all four trails, the roasting times differed. At 228 °C (Fig. 6.8, green line), the roasting time corresponded to 25 minutes (1500 seconds). In contrast, roasting the coffee at 238, 248 and 258 °C (black, pink and blue lines), the time to reach CTN 67 was reduced to ≈ 14, ≈ 10 and ≈ 7.5 min respectively. Besides the obvious reduction in roasting time with increased temperature, the time–intensity profiles for the two selected compounds differed in two major aspects: (i) A strong increase in the intensity of the VOCs in the off-gas with increasing temperature, which corresponds to a concomitant increase in the compound's concentration in the roasted coffee [6.116]. Clearly short-time high-temperature (STHT) roasting generates coffee that exhibits significantly higher aroma intensity, in comparison to long-time low-temperature (LTLT) roasting to the same roast degree. The impact of the time–temperature profiles (for identical roast degree) has been confirmed in gas chromatographic [6.116] and sensory (to be published) studies. (ii) Modifying the time–temperature roasting profile may alter the dynamics of the compound formation and hence modulate the formation of intermediates. By exploring the formation of a range of phenolic compounds online, it has been possible to demonstrate the sequential formation of compounds, from precursors via various intermediate stages to the final VOC [6.101].

The second example examines the roasting of three distinct single-origin Arabica coffees. Figure 6.9 shows the time–temperature profiles of two example VOCs: formic acid as an example of a volatile organic acid formed during roasting and methanol as an example of a VOC with alcohol functionality. The coffees were always roasted to the same medium roast degree (103 Pt on the Probat scale), using either a medium or a low burner intensity/temperature. The left frame in Fig. 6.9 shows the PTR-MS ion traces of formic acid. Roasting at a medium burner intensity, the first to reach the target roast degree was the Central American coffee from Guatemala, followed by the coffee from South America (Colombia). The coffee that took the longest time was the Yirga Cheffe from Ethiopia. In a second series of experiments, the same coffees were roasted at a low burner intensity, which in general led to longer roasting times. However, besides extending the time to reach the target roast degree of 103 Pt, we also observed that the order (time) in which the coffee reached the target roast degree changed. The Yirga Cheffe, which clearly took the longest at the medium burner intensity, was the fastest at the lower burner intensity. This change in the order that the target roast degree was achieved for different burner intensities has been observed for many more VOCs other than those shown in Fig. 6.9. In a recent publication, the implication of such observations on split versus mixed roasting was discussed [6.116].

Extraction Kinetics of Coffee Aroma Compounds

Using proton-transfer-reaction time-of-flight mass-spectrometry (PTR-ToF-MS), we investigated the extraction dynamic of 95 ion traces in real time (time

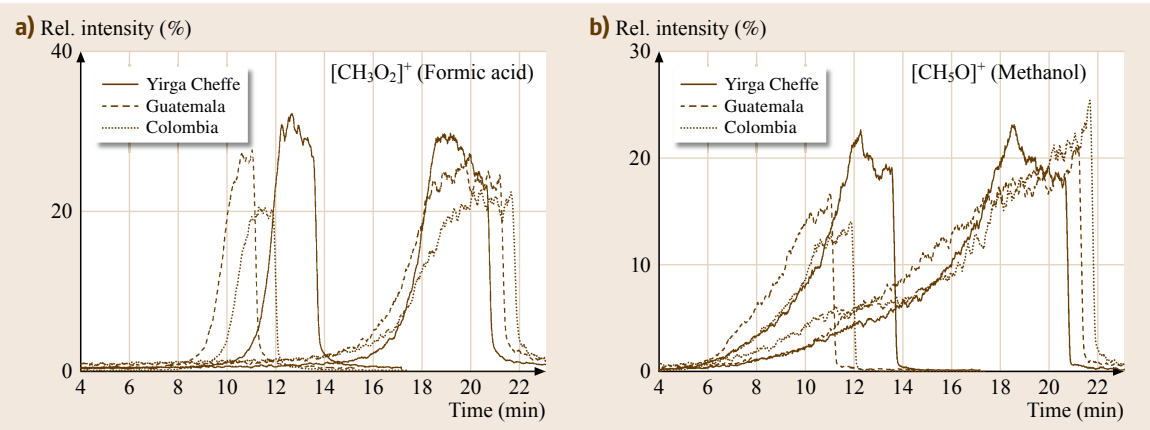

Fig. 6.9a,b Three different pure coffee varieties, all of the species Coffea arabica, were roasted to the same medium roast degree of 103 Pt on the Probat scale. Once, the three coffees were roasted by applying a lower roasting temperature (which corresponds to a lower burner intensity), which led to roasting times longer than 20 min. Alternatively, the same three coffees were roasted at the higher roasting temperature (which corresponds to a medium burner intensity), leading to roasting times between 11 and 14 min. Two example compounds are shown here: **(a)** formic acid and **(b)** methanol

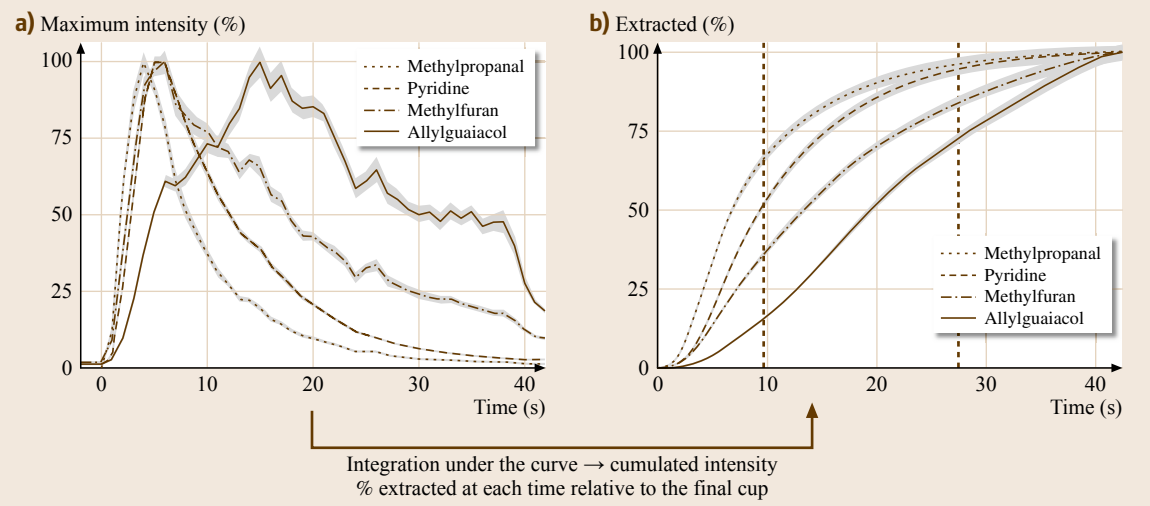

Fig. 6.10a,b Time–intensity profiles for one specific capsule (lungo, 42 second extraction time, 110 ml extraction volume) showing differences in extraction kinetics. **(a)** Data normalized to the maximum intensity of each of the four VOCs. **(b)** Integration of the area under the curve at each time point as a percentage of the total area at the end of the extraction. The shaded ribbons show the 95% confidence interval

resolution: one second) during espresso coffee preparation [6.130]. Fifty-two of these ions were tentatively identified. This was achieved by online sampling of the VOCs close to the coffee extract flow, at the exit of the extraction hose of the espresso machine (single serve capsules). The results show considerable differences in the extraction kinetics for different compounds, which led to a fast evolution of the volatile profiles in the extract flow and consequently to an evolution of the final aroma balance in the cup.

The time–intensity profiles in Fig. 6.10 show different extraction dynamics for the analyzed VOCs (Fig. 6.10a). Four example compounds are shown: methyl propanal, pyridine, methyl furan and a guaiacol. The time to reach the maximum intensity ranged from 2 to 20 seconds. Once the maximum had been reached, the intensity fell at different rates, depending on the compound. This decrease in intensity provides information on how the compounds are extracted. A fast decrease implies that the compound is extracted over

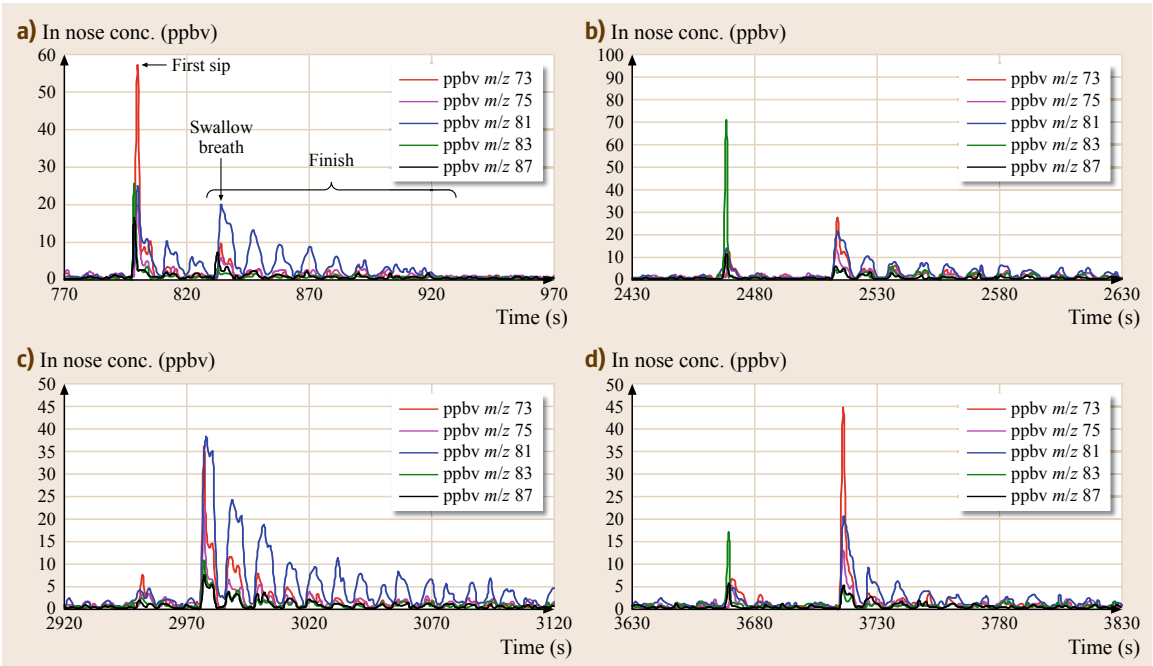

Fig. 6.11a–d Nose-space profile of four different assessors while drinking an espresso coffee. All four assessors drank the same coffee and the breath-air exhaled through the nostrils was measured online by PTR-MS. Three characteristic moments of the consumption process are outlined. *First sip* corresponds to the nose-space profiles of the exhalation just after taking coffee into the mouth. *Swallow breath* corresponds to the nose-space exhalation following just the swallowing of the coffee. *Finish* corresponds to the sequence of nose-space profiles after swallowing when the assessor no longer has any coffee left in their mouth

a relatively short time period while a slow decrease implies that the compound is extracted over a longer period. This approach will allow the extraction dynamics of VOCs to be explored under various extraction conditions, such as different pressures and temperatures and for different mineral contents.

6.5.2 Moving Towards an Individualized Aroma Science

By taking a closer look at the actual flavor experience that occurs whilst coffee is being drunk, it becomes clear that it is a highly dynamic experience, constantly changing and evolving in the mouth. In order to develop a better understanding of the aroma perceived by a consumer, it is important to develop techniques that capture the temporal evolution of the aroma during the actual process of consumption [6.11, 131–135].

Coffee aroma evolves in the mouth during drinking and leaves a typical after-odor or finish in the mouth for several minutes after swallowing – we have termed this dynamic evolution of the in-mouth aroma *the melody of coffee* [6.11, 12]. The nose-space technique allows these dynamic processes to be visualized, and provides a vivid insight into aroma release and its temporal evolution in the mouth.

Figure 6.11 shows the nose-space profiles from four different assessors (four male assessors aged 33–43 and labeled A to D when drinking the same coffee [6.11]. The time axis runs through all four experiments without interruption and shows the relative time of analysis for the four assessors. Assessor A drank the coffee first, from second 770 to 970; assessor B drank the coffee between seconds 2430 to 2630, and so forth. It is obvious that the four nose-space profiles are different. The main differences pertain to: (i) the absolute intensities of the three characteristic moments during the in-mouth consumption experience – the first sip, the swallow-breath and the after-odor, and (ii) the relative intensities of the individual VOCs (balance) for each of these characteristic moments. For assessors A and B, the first sip dominates, while assessor C perceives hardly any aroma during the first sip. For assessor C, the coffee aroma is essentially composed of the swallow-breath aroma and the persisting after-odor. Comparing assessors A and C with B and D, we notice that their first sip and swallow-breath aromas are different in terms of aroma balance. Five m/z ion traces are shown and qualified by their

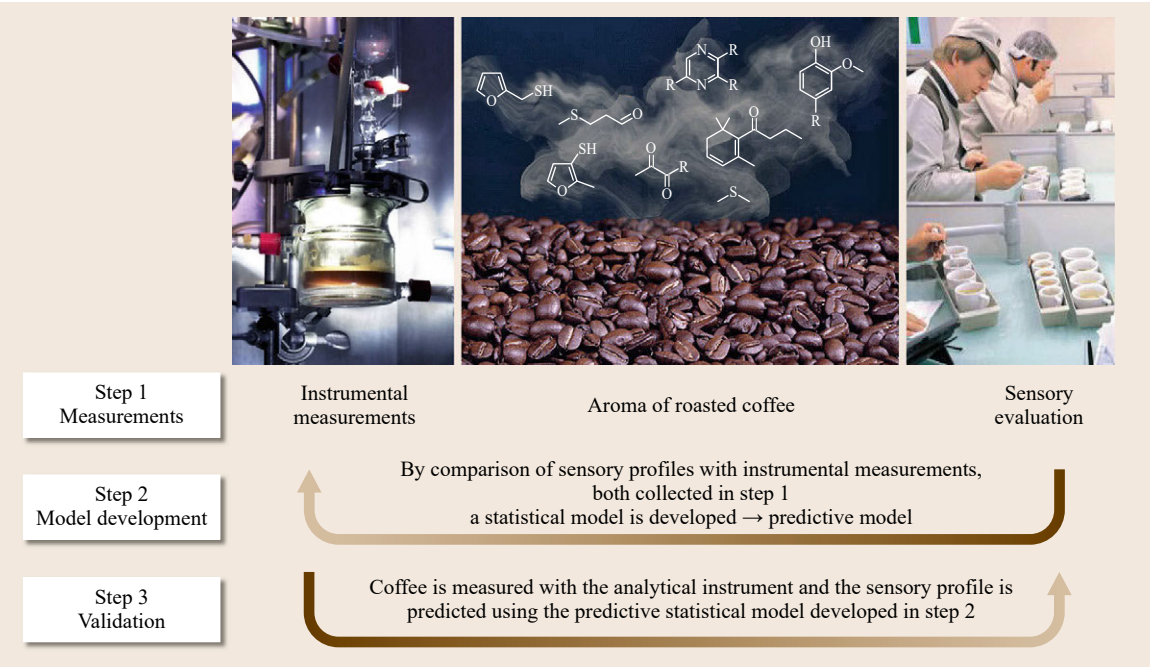

Fig. 6.12 Predicting sensory profiles from instrumental measurements: A three-step approach

m/z values. They have tentatively been assigned as: m/z 73: 2-butanone; m/z 75: methylacetate; m/z 81: furfurylalcohol; m/z 83: 2-methylfuran; m/z 87: 2-, 3-methylbutanal (57%); diacetyl (43%) [6.11]. The time resolution used for recording the nose-space spectra was 0.5 seconds.

This example demonstrates that the coffee aroma that reaches the olfactory receptors can vary over a large range between assessors. The fraction and composition of VOCs that are actually released from a food in the mouth and transported to the olfactory receptors depends not just on the composition of the food but is strongly modulated by anatomic and physiologic characteristics of the person, and may be further modulated by the person's consumption and breathing pattern. This is a demonstration of what we may already all know – a given coffee or food does not taste the same to everybody.

6.5.3 Predicting Sensory Profile from Instrumental Measurements

Improved strategies and methods for the correlation of sensory and instrumental analysis are being developed with the ultimate objective of predicting the sensory profile from instrumental measurements. While this represents a truly challenging endeavor, it is often considered the holy grail of flavor science [6.109–111].

The strategy presented in [6.109] can schematically be described as a three-step process, as outlined in Fig. 6.12. In the first step a range of coffees were analyzed by instrumental techniques (e.g., PTR-MS and/or GC-MS) and are profiled by a trained sensory panel. The second step concerns the development of a mathematical or statistical model that predicts the sensory profiles based on measured instrumental data. In the third step, in order to validate the predictive model, a se-

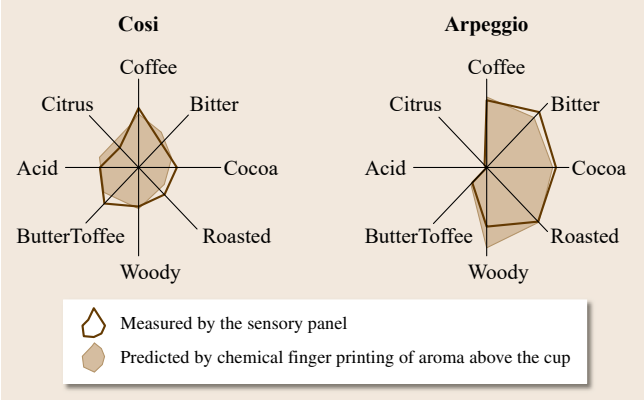

Fig. 6.13 Comparison of predicted sensory profiles, based on instrumental measurements (PTR-MS) and sensory profiles for two selected coffees. The coffees analyzed here were two single serve coffee capsules from Nespresso, a Cosi and an Arpeggio

ries of coffees were measured by instrumental methods and the sensory profiles predicted based on the model developed in step 2. Subsequently, the same coffees were profiled by the sensory panel and the profiles compared to the predicted ones. If the match was considered satisfactory, the model was successfully validated and can be applied to predict the sensory profiles of coffee, based on measured instrumental data.

In Fig. 6.13, the application of a model that was developed specifically for Nespresso single serve coffees was applied to two capsules [6.109, 110]. Predicted sensory profiles, generated using a formerly established predictive model based on PTR-MS measurements, are superimposed on the sensory profiles of the same capsules created by a sensory panel. Clearly, a very good match was achieved.

6.6 What Next?

For much of the past, research into coffee aroma focused on the identification, quantification and qualification of main coffee aroma compounds, and it is believed that essentially all relevant compounds have been identified. Consequently, the focus is shifting towards new fields. We see three major trends (among others) that we believe will dominate research into coffee aroma in the years to come.

Technological and analytical progress in instrumentation, and online techniques with high time resolution and very high sensitivity will certainly be one of the most prominent and relevant instrumental developments.

Understanding individual coffee flavor perception and preferences is a second major field of research that will attract significant attention. Novel tools and strategies will be developed to measure the volatile aroma compounds delivered breath-by-breath to the nose at an individual level. Understanding the basis of the differences in aroma delivery during coffee drinking and sensation/perception will contribute to the development of individualized aroma science.

Predicting the sensory profile of coffee from instrumental measurements is possibly the most significant challenge in flavor science and will certainly attract major attention and effort for many more years to come.

Today, flavor science is moving into a discipline that is truly multidisciplinary and that requires a new breed of scientists [6.12]. What was once the playground of food and flavor scientists and analytical chemists is today a complex scientific platform where experts from biology, psychophysics, psychology, organic chemistry, analytics, material sciences, physics, mathematics and health meet with food and flavor scientists to work in concert.

Acknowledgments. This work would not have been possible without the help and support of many colleagues and friends with whom I have been able to share my fascination for my work on the science of coffee aroma. They are: Werner Lindinger, Alfons Jordan, Martin Graus, Imre Blank, Philippe Pollien, Santo Ali, Christian Lindinger, Ralf Zimmermann, Ralph Dorfner, Alexia N. Gloess, Barbara Schönbächler, Flurin Wieland, Marco Wellinger, Samo Smrke, Sebastian Opitz, José A. Sánchez and many more.

7. Beer

Michael Dresel

This chapter presents some background information on the aroma-active volatiles in beer. It explains the evolution of the flavor-active compounds that are derived from the raw materials, namely water, malt, hops, yeast, and adjuncts. Especially the utilization of hops as well as hop itself as a key ingredient for the production of beer will be discussed. Furthermore, the flavor changes that occur during the most important manufacturing steps are summarized. Additionally, selected volatiles causing desired flavors as well as volatiles responsible for undesired off-flavors will be highlighted. Finally, this chapter will provide a detailed view on the impact of beer lagering and aging on the volatile profile of aroma-active compounds in beer.

With a worldwide production of approximately 2.0×10^9 l/yr, beer is one of the most consumed alcoholic beverages in the world. The most important beer-producing countries are Germany, the United States, and China [7.1].

Although beer is produced most of the times with only four ingredients (water, malt, hops, and yeast), it is an extremely complex mixture of aroma- and taste-active, volatile and nonvolatile components. The major constituents of traditional beer are water (91%), ethanol ($\approx$ 5.5%), carbohydrates (3%), proteins (0.5%), and carbon dioxide (0.5%). However, many minor compounds have been identified that are influencing the overall aroma perception of beer. These components can either originate from the raw materials, or can be formed de novo during the beer production or can be the result of the storage conditions of beer. Understanding the contributions of the raw materials and the processing conditions to the flavor of beer is essential for the brewers to ensure consistent product quality of existing products and to successfully introduce new products in the market. Although concentration of various flavor-active compounds in beer varies from g/l to ng/l, the importance of a compound for the flavor of beer is not its concentration but the impact that a specific component has on aroma and/or taste. In this context, consistent terminology to describe and compare the sensory properties of beer is essential [7.2].

Despite the fact that many compounds have already been identified and their origin has been elucidated, many volatiles still remain unknown; moreover, it is generally accepted that the flavor of beer depends on the balance between all theses sensorially active compounds. Also, the flavor profile changes during storage and aging of beer. These changes strongly depend on the storage conditions, rendering beer an extremely complex beverage. Reaction initiated by light, oxygen, and temperature can result in the de novo formation of volatiles or can lead to increasing or decreasing concentrations of aroma compounds. Although the phe-

nomenon of beer aging has been studied since decades, it was found to be extremely complex and is far from being understood.

This chapter deals with the origin and the evolution of the dominant volatile (off-) flavors in beer. Special attention will be drawn on hops as a raw material, as the hopping technology was found to influence the overall flavor perception of beer significantly. Furthermore, flavor changes that occur during storage and aging of beer will be highlighted.

7.1 Raw Materials

In order to obtain an insight into the aroma of beer, one must have a closer look at the respective raw materials used in brewing as the aromas are either present naturally in these materials or formed during the production. This section will especially deal with the brewing water, malt, hops, and yeast.

7.1.1 Brewing Water

Water accounts for around 90% of the beers volume. Its mineral content is of crucial importance for the brewing process: It influences the formation/degradation of bitter compounds and it contributes to the overall flavor of beer [7.3–7]. While the quality of brewing water depends on the respective local water supply, the mineral composition is nowadays very often adjusted in order to meet specific desired requirements. In this context, common treatments comprise pH and mineral adjustment, removal of iron and insoluble particles, as well as microbiological controls.

7.1.2 Malt and Wort

Next to water, malt is the most important ingredient from a quantitative perspective. It is rich in starch that will be transformed into fermentable sugars during wort production. The malt-derived aroma depends strongly on the type of malt used for wort production. Malt is rich in aldehydes but the majority of these compounds are already lost during the kilning process [7.8]. During this process, many other volatiles are formed, for example, phenolic acids [7.9, 10] and lipid-derived degradation products [7.11]. Especially, lipid oxidation products might remain in the final product and are believed to be involved in the evolution of typical staling aroma during beer aging [7.11]. Over the years, different methods of producing malt have been developed leading to a huge range of individual malt types meeting the demands of beer producers. Due to the formation of Maillard reaction products, a darker malt color results in a lower fermentable sugar content. However, most volatiles will be evaporated during wort production. Yet, studies proved that the flavor intensities of descriptors such as bread-, caramel-, burnt-like increased with an intensified malt color and that the flavor profile will be more divers [7.12, 13]. Compounds that were clearly connected to an increasing malt color and therefore wort color are furfural, 5-methyl-furfural, pyrazine, methylpyrazine, and 3-methylbutanal and its aldol condensation product 2-isopropyl-5-methyl-2-hexenal [7.12] (Fig. 7.1).

Another important compound that is formed during kilning and wort production is dimethyl sulfide (DMS; Fig. 7.2). This compound can be beneficial to the overall flavor of beer at concentrations above 30 µg/l but below 100 µg/l. Concentrations above 100 µg/l result in a flavor that is often associated with cooked vegetables or cooked sweet corn. Much research has therefore focused on the parameters that influence the formation and release of DMS during beer production [7.14–16]. Especially, two formation pathways are important that are significantly influenced by the brewing conditions [7.17]:

1. *S*-methyl-methionine (SMM; Fig. 7.2) can release DMS, under the temperature conditions necessary

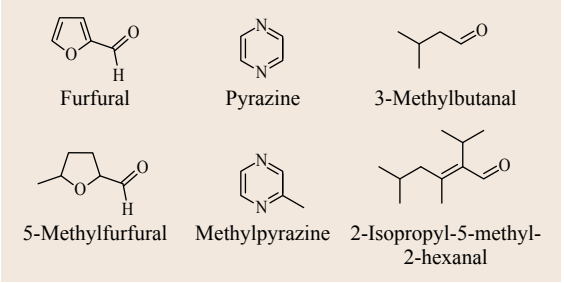

Fig. 7.1 Chemical structures of volatiles clearly influenced by wort color

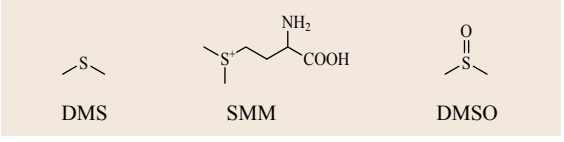

Fig. 7.2 Chemical structures of dimethyl sulfide (DMS) and two important precursors, *S*-methyl methionine (SMM) and dimethyl sulfoxide (DMSO)

during wort production. This precursor is present in grains which are relevant for the brewing industry such as barley, wheat, and oat.

2. DMS can be liberated from dimethyl sulfoxide (DMSO; Fig. 7.2) by both eukaryotic and prokaryotic microorganisms [7.18]. This precursor is especially produced during kilning at temperatures above 60 °C.

Both SMM and DMSO are very soluble in water and are therefore easily extracted during mashing. Especially DMSO is heat-stable and nonvolatile under these conditions and will be reduced during fermentation to give rise to DMS.

Besides these two, more than 100 compounds, among them sulfur compounds, alkenals, aldehydes, ketones, esters, alcohols, and furans, can be detected in wort [7.13]. However, their concentrations are comparably low and their contribution to the overall flavor of wort and beer remains unclear until today.

7.1.3 Hops

Although normally used in rather small quantities, hops play a major role for the beer aroma. Especially its essential oil is responsible for the unique aroma of hops and beer. The essential oil content typically ranges from 0.2–2.0 ml/100g for aroma hop varieties and 0.7–3.0 ml/100 g for bitter hop varieties.

Currently, over 450 volatiles have been identified in hop's essential oil [7.19], but estimations suggest that the hop oil actually comprises over 1000 compounds [7.20]. The most important compound classes are hydrocarbons, oxygenated compounds, and organosulfur compounds [7.21]. With a share of up to 75%, the hydrocarbon fraction is the most predominant group of the essential oil. Within this group, the monoterpene β-myrcene and the sesquiterpenes α-humulene and β-caryophyllene are the most important compounds (Fig. 7.3). β-Myrcene is only relevant for so-called dry hopped beers (Sect. 7.2.3), as it is almost completely lost during the wort boiling, due to its high volatility, and remaining levels will be further reduced during beer production. Despite the fact that the shares of these three compounds vary a lot between the different hop varieties, it is believed that a low β-myrcene and a high α-humulene content is connected to a pleasant aroma perception of beer [7.8].

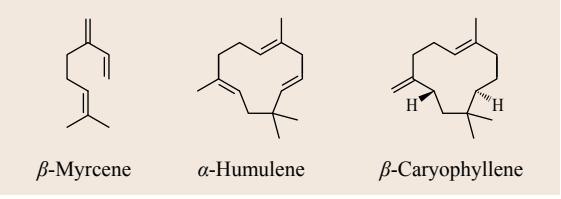

Fig. 7.3 Chemical structures of β-myrcene, α-humulene, and β-caryophyllene

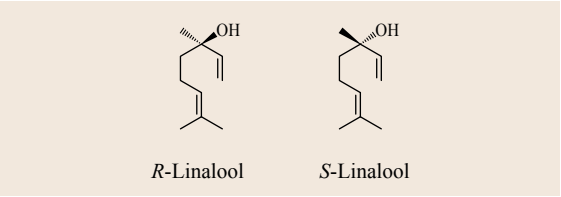

Fig. 7.4 Chemical structures of *R*-linalool and its stereoisomer *S*-linalool

The second largest group comprising up to 50% of the hop oil are the oxygenated compounds. Among them, many esters of straight and branched chain fatty acids and alcohols can be found. One important oxidation product of β-myrcene that is already present in hops is *R*-linalool (Fig. 7.4) and represents around 95% of the total linalool content. This compound has been suggested to be a marker compound to measure the hop flavor in beers, whereas its stereoisomer *S*-linalool (Fig. 7.4) is less flavor-active [7.22]. Like β-myrcene, other terpene and sesquiterpene hydrocarbons are sensitive toward oxidation (Sect. 7.2.1) and enzymatic biotransformation (Sect. 7.2.2).

Interestingly, it was recently shown that hop pellets that were slightly aged and used for dry hopping (Sect. 7.2.3) led to more pronounced fruity, floral, and herbal aroma impressions than a beer that was produced the same way with regular vacuum-packed hops [7.23].

Branched esters like 2-methylpropyl isobutyrate and 2-methylbutyl isobutyrate contribute to the fruity aroma of hops. Furthermore, free short-chain fatty acids such as 2-methylbutyric acid are responsible for a cheesy aroma perception when hops age.

Nowadays, with the discovery of 4-mercapto-4-methylpentan-2-one (4-MMP) (Fig. 7.5) [7.24, 25], organosulfur compounds moved into focus of interest [7.26, 27]. Especially 4-MMP polarizes brewers as this compound is characteristic for the blackcurrant-like aroma of especially American hops and beer. Unfortunately, this compound is perceived as catty, when

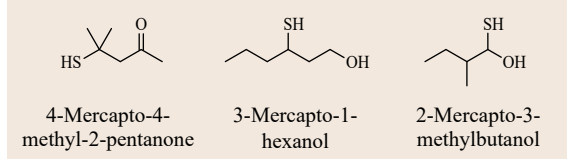

Fig. 7.5 Chemical structures of 4-mercapto-4-methyl-2-pentanone, 3-mercapto-1-hexanol, and 2-mercapto-3-methylbutanol

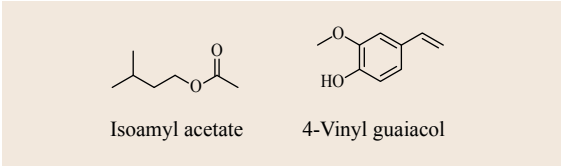

Fig. 7.6 Chemical structures of isoamyl acetate and 4-vinyl guaiacol

present in higher concentrations. The main problem in this context is the huge inter-individual variation of the odor threshold value. As a result, one will perceive the aroma of 4-MMP as pleasant in a beer, whereas another person will reject this beer. Currently over 40 polyfunctional thiols, for example, 3-mercapto-1-hexanol, 2-mercapto-3-methylbutanol (Fig. 7.5), are known. However, they seem to play a role only for a small number of hop varieties.

Yet, it is impossible to estimate the relevance of these compounds as they are only present in relatively low concentrations, but possess extremely low flavor threshold concentrations of a few ng/l [7.28]. Also, additive and synergistic effects might be of relevance for this substance group if different compounds are present in beer.

Besides the mentioned volatiles, hop aroma compounds are present in a glycosidically bound form in hops [7.29, 30]. The amount differs from variety to variety and also depends on the hop product. For example, a supercritical carbon dioxide extract of hops contain very little glycosidically bound compounds, whereas in ethanolic extracts, they will be present.

7.1.4 Yeast

Although yeast is vital for the production of beer, it does not contribute on its own to a specific beer aroma. Instead, due to its versatile metabolic pathways, yeast might generate specific volatile flavors that are characteristic for a specific beer style. A traditional German wheat beer will offer banana-like as well as clove-like and phenol-like flavors originating from isoamyl acetate [7.31] and 4-vinyl guaiacol [7.32], respectively (Fig. 7.6). These compounds are produced in elevated concentrations by specific yeast strains.

Furthermore, the nature of the yeast is of crucial importance, as it is known that ale strains (top fermenting yeast) naturally tend to produce more sensory-active esters and higher alcohols as lager yeast strains (bottom fermenting yeasts). In contrast, typical lager strains produce less of these sensory-active compounds [7.33]. However, the fermentation temperature plays a major role as studies gave proof that a higher temperature also results in an increased production of esters and higher alcohols [7.33]. These findings apply for both top- and bottom-fermenting yeast species. Traditionally, bottom-fermented beers are produced at temperatures around 10 °C, whereas top-fermented beers are fermented between 15 and 25 °C. This procedure favors clearly the production of esters and higher alcohols in ales. Yet, some beers are pushing the borders resulting in beers with special flavor characteristics, for example, German Kölsch (top fermenting at lower temperatures) or *German Alt* (bottom fermenting at higher temperatures).

7.1.5 Adjuncts and Other Additives

Whereas malts, which do not necessarily have to be derived from barley, are used to influence the overall aroma and taste perception, specialty malts can also contribute to the fermentable sugar content. In contrast to that, adjuncts are nonmalted materials and are mainly used to save costs or to enhance the brewhouse capacity. Furthermore they are used to influence color, foam stability, colloidal stability, flavor stability, and sweetness.

In order to create unique tasting experiences, other products might be used at different time points to introduce special flavors. The term *Gruit* refers to an old-fashioned herb mixture that can be used instead of or additionally to hops. These adjunct herbs commonly include sweet gale (*Myrica gale*), ground ivy (*Glechoma hederacea*), mugwort (*Artemisia vulgaris*), horehound (*Marrubium vulgare*), yarrow (*Achillea millefolium*), and heather (*Calluna vulgaris*). Sometimes other herbs as juniper berries, ginger, caraway seed, aniseed, nutmeg, or cinnamon are also used. Besides, other additives can be orange peel and coriander in Belgian Wit Beers or fruit beers, especially cherries, in case of Belgian-style Fruit Lambics.

7.2 Flavor Evolution of Hoppy Aroma

As the production scheme of the first wort, the unhopped wort, can hardly be altered in order to provide sufficient saccharification for the later fermentation step, the composition of flavor-active volatiles is barely affected by the technological steps. At this point, the flavor of the wort is influenced by the choice of specialty malts providing caramel-, biscuit-, toffee-, chocolate- and coffee-like as well as other roasted flavors. In con-

trast to that, not only the choice of the hop variety but also the precise hopping regime has a huge impact on the overall beer flavor.

7.2.1 Cooking

Traditionally, hops are added to the hot wort after the spent grain has been removed by filtration. During the following boiling step, the congeners of the humulones are extracted and isomerized to form the *cis*- and *trans*-iso-humulones (Fig. 7.7). These transformation products are addressed as the bitter principle in beer [7.34, 35]. In order to achieve sufficient isomerization of the humulones, boiling times over 60 min are required.

Accordingly, most hop-derived volatiles, especially terpenes like β-myrcene, β-pinene, and *cis*-ocimene, are almost completely lost during this production step [7.36]. Moreover, these compounds are very sensitive toward oxidation. Especially, the epoxidation of double bonds in compounds like α-humulene and β-caryophyllene leads to compounds that have been detected in beer and are believed to contribute to the flavor of beer [7.37]. However, it is not easy to estimate the transfer rate into beer, as those volatiles can also be formed during fermentation.

As mentioned before, *R*-linalool (Fig. 7.4) is believed to be a marker substance for hop flavor in beer [7.22]. However, it must be taken into account that the flavor-active *R*-isomer undergoes a racemization during boiling toward the less flavor-active *S*-isomer (Fig. 7.4), leading to a significantly lower amount of *R*-linalool and its concentration will decrease further during beer aging [7.38]. Nevertheless the absolute decrease of compounds like linalool is hard to estimate. *Kollmannsberger* et al. discovered that these compounds are present in hops in a glycosidically bound form and can be released later during fermentation due to glycosidase activity and liberation of the flavor-active aglycones. This could explain increasing concentrations of several hop-derived aroma compounds in beer over time [7.29, 30].

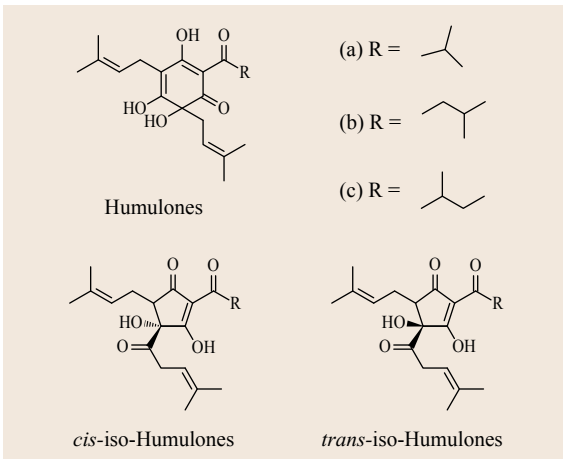

Fig. 7.7 Chemical structures of the co-(a), n-(b), and ad-(c) congeners of the humulones and their transformation products, the corresponding congeners of the *cis*- and *trans*-iso-humulones

7.2.2 Fermentation and Lagering

Another important process step, during which the hop-derived aroma profile significantly changes, is the fermentation. The most abundant terpene hydrocarbons β-myrcene, α-humulene, and β-caryophyllene are almost completely lost during fermentation. So far, no biotransformation products of these compounds have been detected in beer [7.39, 40]. Losses are believed to be caused by adsorption to the hydrophobic biomass and migration to the foam layer [7.39, 41]. The more hydrophilic oxidation products of those compounds that are already formed during wort boiling are more likely to remain in the final beer and have been proposed as potentially important flavor-active compounds [7.42]. Interestingly, humulol II might be an exception as it was produced in model fermentation studies with α-humulene, but not obtained during hydrolyzation experiments with humulene epoxides [7.37].

Several saturated and unsaturated aldehydes (e.g., neral, β-citronellal, and citral (= geranial) [7.43] (Fig. 7.8) and ketones (especially methyl ketones) occur in the hop essential oil. These carbonyl compounds will be transformed by the yeast due to various dehy-

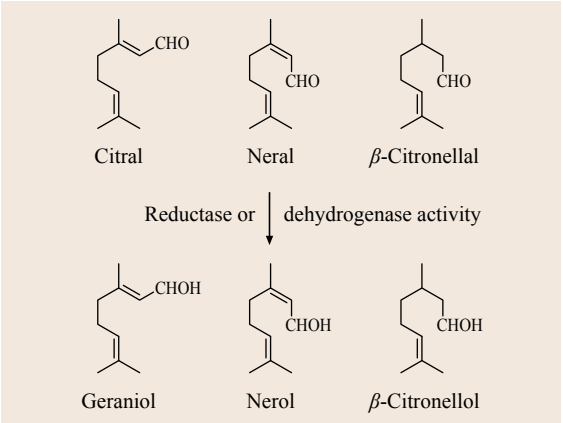

Fig. 7.8 Biochemical reduction of citral, neral, and β-citronellal to the corresponding alcohols geraniol, nerol, and β-citronellol

drogenase and reductase enzymes to the corresponding alcohols [7.44–46] .

Another important compound class are saturated and unsaturated esters. Especially methyl esters are found in hops and undergo both hydrolysis toward acids and transesterification toward ethyl esters during fermentation [7.46]. However, contradictory results are described for terpene-derived esters. While, *Peacock* and *Deinzer* found that geranyl acetate is hydrolyzed during fermentation [7.47], *King* and *Dickinson* describe that geranyl and citronellyl acetate are formed during fermentation with lager yeast but not during fermentation with ale yeast [7.42].

Interestingly, concentrations of geraniol and linalool decrease during fermentation, whereas the concentration of β-citronellol increases [7.48]. *King* and *Dickinson* [7.42, 49] reported earlier that during the fermentation, geraniol can be reduced to β-citronellol or can undergo a isomerization and give rise to linalool which reacts further to α-terpineol and terpin hydrate (Fig. 7.9). Furthermore, the cis–trans isomerization of nerol to geraniol is described as a nonstereospecific biotransformation during fermentation. Accordingly, it is generally accepted that terpenes do not transform spontaneously under the conditions occurring during beer production.

Norisoprenoids, such as β-ionone and β-damascenone (Fig. 7.10), are highly flavor-active degradation products of carotenoids. Yet, these two compounds are already present in hop oil. Nevertheless, β-ionone and β-damascenone have been found in beers at levels that might be relevant for the hoppy aroma [7.43]. Moreover, studies revealed a significant increase in β-damascenone during fermentation [7.50, 51] and it is believed that this phenomenon is due to the release of compounds from glycosidically bound aroma precursors [7.51]. *Biendl* et al. [7.30] and *Kollmannsberger* et al. [7.29] showed that the glycosidic fraction of beers produced with ethanolic hop extract or hop pellets, is susceptible to acidic and enzymatic hydrolysis. Moreover, a series of aroma-active compounds was obtained under these conditions: Aliphatic alcohols (e.g., 1-octen-3-ol, *cis*-3-hexen-1-ol), aromatic compounds (e.g., benzyl alcohol, phenyl ethyl alcohol, methyl salicylate, vanillin), monoterpene alcohols (linalool, *cis*- and *trans*-linalool oxide, α-terpineol, geraniol), and norisoprenoids (e.g., β-damascenone, 3-hydroxy-β-damascenone, 3-hydroxy-7,8-dihydro-β-ionol). Yet, another study indicates that the absolute concentrations of compounds released during the brewing process strongly depend on the hop variety [7.52]. However, knowledge on the evolution of hop glycosides during fermentation and the influence of the yeast type is fragmentary and more profound research is required to determine the impact of those compounds on the actual flavor perception of beer [7.53].

Finally, another group of oxygenated hop oil derived compounds are ethers (e.g., rose oxide), which are flavor-active compounds that have been detected in beer [7.54, 55] and might contribute to the hoppy aroma [7.43, 54]. Although major biotransformation pathways and biotransformation products have been revealed, it is not yet fully understood which volatile compounds are responsible for certain aroma impressions that are evolving during fermentation.

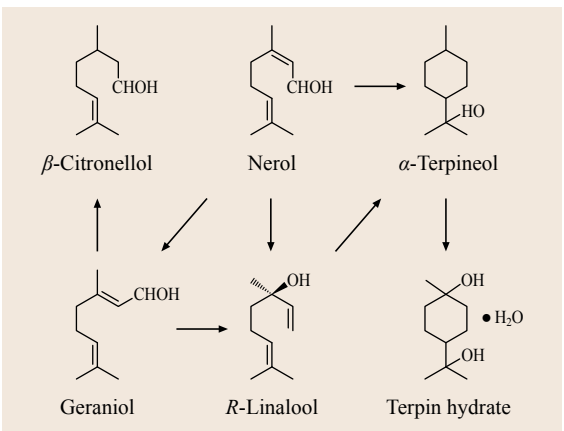

Fig. 7.9 Biochemical transformations of some monoterpenoids

7.2.3 Impact of Different Hopping Technologies and the Hop Variety

As mentioned before, the composition of the hop oil is quite divers and a lot of changes occur during beer production. Accordingly, different hopping technologies will have a huge impact on the flavor of the final beverage. Depending on the hop product, different flavor-active fractions might not be introduced into the beer. For example, a hop extract obtained by extraction with supercritical CO_2 contains rather unpolar compounds, mainly α- and β-acids, whereas the vast majority of flavonoids, polyphenols, and glycosides remain in the residue. In contrast to that, an ethanolic extract comprises to a certain extent polyphenols and

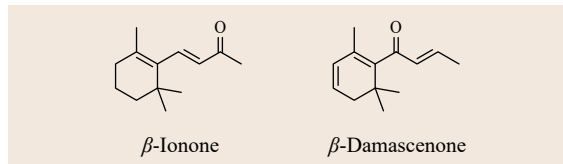

Fig. 7.10 Chemical structures of β-ionone and β-damascenone

glycosides [7.56]. However, such an extract does not reflect the original composition of hop cones or pellets and therefore lacks several flavor-active compounds. Accordingly, the flavor profiles of beers produced with those extracts will differ from a beer hopped with hop cones or hop pellets. However, it is not known if and how those compounds may influence the aroma of the final beer products.

Furthermore, the time point of adding hops has a great influence on the compounds transferred into beer. In order to reach an isomerization of the hops α-acids toward the better soluble iso-α-acids (Fig. 7.7), the bitter principle of beer, a sufficient boiling time is required. To achieve this transformation and depending on the recipe as well as the beer style, boiling times between 60and 120 min are necessary. It is easily conceivable that such a long process at high temperatures will affect hop-derived volatiles in many ways. Most vulnerable are compounds with low boiling points, such as short-chain ketones, aldehydes, and most importantly, monoterpene hydrocarbons (e.g., β-myrcene and β-pinene) and monoterpene alcohols (especially linalool and geraniol). A hop addition at the beginning of the boiling process will result in an almost complete loss of those compounds. Furthermore, during this so-called *early hopping*, sesquiterpene hydrocarbons will be oxidized. Especially, the oxidation products of α-humulene and β-caryophyllene have been studied thoroughly and many of those compounds have been suggested to be at least partly responsible for the spicy aroma of early hopped beers [7.44, 57, 58].

In order to counteract a complete loss of these compounds, an additional hop dosage can be applied toward the end of the boiling process. Such a hop addition is usually done during the last 5−15 min and does not essentially contribute to the formation of iso-α-acids. On the other hand, the more volatile compounds will at least partly remain in the hopped wort. However, all compounds that are introduced by *early* and/or *late hopping* might be metabolized during fermentation.

Besides, a hop addition toward the end of the fermentation or even in the lager tank is possible. This so-called *dry hopping* can be seen as an extraction of hop (oil)-derived compounds by an ethanolic solution. Accordingly, especially polar compounds (glycosides and monoterpene alcohols) will be extracted, influencing the overall flavor in a unique way.

In this context, not only the time point of adding hops is essential, but also the chosen hop variety. As the original hop oil content varies between 0.4 and 3.7 ml/100 g [7.59, 60], the amount of hops added during each hop addition is crucial regarding odor threshold concentrations. Furthermore, the hop oil composition strongly depends on the variety. For instance, farnesene, α-selinene, β-selinene, and aromadendrene are compounds whose occurrence is limited to certain varieties [7.61]. A strong varietal-dependency was also found for the release of glycosidically bound compounds during the beer production, such as linalool, β-citronellol, nerol, β-damascenone, geraniol, eugenol and terpinene-4-ol [7.52].

Moreover, sulfur-containing compounds have been found to be especially characteristic for hop varieties from America or New Zealand. For example, 4-mercapto-4-methylpentan-2-one (catty/black cassis-like aroma) and 3-mercaptohexan-1-ol (grapefruit-like aroma) enhance the hoppy aroma derived from the hop varieties *Tomahawk*, *Cascade*, or *Nelson Sauvin*, respectively [7.26, 62]. Another study suggests that β-citronellol might be characteristic for *dry-hopped* beers derived from particular flavor hop varieties in comparison to other hop varieties [7.63].

7.3 Special Flavors

Revealing the contribution of the raw materials on the final flavor is a necessity in order to understand how the flavor of beer develops and changes over time. This knowledge is the basis to understand how specific flavors are formed. This section deals with the development of wanted and unwanted flavor-active compounds during beer production, storage, and aging.

7.3.1 Desired Flavors

Ethyl alcohol is the most predominant alcohol in beer. However, ethanol is not considered to be an important odorant. While the production of ethanol is a common feature of practically all yeast strains used for beer production, the production of volatile, higher alcohols, so-called fusel alcohols, depends on the yeast strain. Yet, the vast majority of these compounds are only present in concentrations below their odor threshold concentration. Higher alcohols that might contribute to the overall aroma are 2-methylpropanol, 2-methylbutanol, 3-methylbutanol, and 2-phenylethanol. These compounds are often considered having a warming effect on the taste of beer [7.33].

More importantly, higher alcohols are direct precursors of esters found in beer. Considering the yeast metabolism, acetates and ethyl esters are the most

important esters produced during fermentation. Especially, ethyl acetate, 2-methylbutyl acetate, and 3-methylbutyl acetate (= iso-amyl acetate; banana-like aroma) are important esters as their concentrations are normally above their flavor threshold value. However, concentrations of the esters strongly depend on the yeast strain, the density of the wort (= original gravity in degree Plato) and the amount of oxygen available during fermentation [7.33]. As already mentioned in Sect. 7.1.4, ale strains tend to produce more fusel alcohols. Other esters commonly found in beer are, for example, ethyl hexanoate (sweet apple aroma), ethyl octanoate (sour apple aroma), and 2-phenyl ethyl acetate (roses and honey-like aroma impressions) [7.33]. All these esters are normally associated with fruity aroma impressions. During lagering and beer aging several new esters can originate from ethanol and organic acids, whereas the concentrations of other flavor-positive esters decrease. The formation of winy flavors for example has been related to ethyl 3-methylbutyrate and 2-methylbutyrate [7.64].

Another group of relevant volatiles are aldehydes, which are formed as reactive intermediates during various stages in the brewing process. The most important pathways are the degradation of malt-derived fatty acids and lipids as well as the oxidation of corresponding alcohols. However, only one aldehyde is of greater importance for the beer aroma. Acetaldehyde is found in concentrations between 2 and 10 mg/l and gives beer a typical green apple flavor, if the flavor threshold value is exceeded. This value strongly depends on the beer and varies between 5 and 50 mg/l [7.33]. Other aldehydes, so-called staling aldehydes, play an important role in the aging of beer [7.65].

7.3.2 Controversial Flavors

While the above-mentioned compounds are commonly described as positive attributes, the appreciation of some other compounds strongly depends on the beer style. A good example is 4-vinylguaiacol, typically found in especially German wheat beers. These beers are made with top-fermenting yeast strains as well as wheat or malted wheat and have a phenolic, clove-like flavor. During the manufacturing of German wheat beers, significant amounts 4-vinylguaiacol are mainly produced by an enzymatic decarboxylation of ferulic acid during fermentation. In contrast to that only low levels of 4-vinylguaiacol are liberated thermally induced from barley-derived ferulic acid during wort boiling (Fig. 7.11) [7.66]. Interestingly, the same flavor is considered to be an off-flavor in Pilsner-style beers. Moreover, levels above 10 µg/l are regarded as an indicator that the affected beer was probably contaminated with wild yeast strains [7.67].

The sensorial impact of vicinal diketones is also a controversial topic. While they are regarded as a defect in lager beers, they are desired in certain heavily hopped beers, such as British ales. The most important vicinal diketones are 2,3-butanedione (= diacetyl) and 2,3-pentanedione. Especially diacetyl causes a buttery, butterscotch-like aroma in beers. This compound is derived from α-acetolactate, which is excreted by the yeast cells and decomposes to diacetyl in the wort. Yet, healthy yeast has a great potential to reduce diacetyl to acetoin and subsequently to 2,3-butanediol. The same applies for 2,3-pentanedione, which is also metabolized to its diol. However, the reduction of vicinal diketones requires enough time and in almost every beer, diacetyl is detectable. The flavor threshold concentration varies for the different beer styles and was found to be as low as 0.03 mg/l for Pilsner-style beers. Although both, diacetyl and pentanedione are normally present in rather low concentrations in beer, they are supposed to contribute to the sensory sensation and flavor balance of the final product [7.68].

While most of the aroma compounds formed during fermentation are believed to have a positive effect on the aroma perception of beer, sulfur compounds, formed during the fermentation, can be a serious issue regarding off-flavors [7.43]. These sulfur-containing components are very often potent flavor-active substances with low flavor threshold values. Yet, a series of sulfur components present in beer might contribute positively to the overall beer flavor when present in small amounts.

The predominant sulfur-containing volatile is sulfur dioxide with concentrations up to 15 mg/l. It is naturally produced during fermentation and is able to counteract the formation of oxidation flavors due to its capacity to bind carbonyl compounds [7.69, 70] formed during beer aging. This ability is used to increase the shelf life of beer, by adding metabisulfite salts, which will release sulfur dioxide. However, the addition has to be in accordance with the legal requirements.

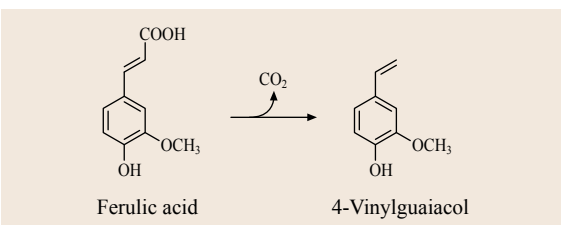

Fig. 7.11 Formation of 4-vinylguaiacol by thermal and enzymatic decarboxylation of ferulic acid

In contrast to that, hydrogen sulfide (H_2S) is a substance that should not be present in beer, because of its very unpleasant flavor. Fortunately, hydrogen sulfide normally is no serious issue, because of its high volatility; during fermentation its concentration will dramatically drop, due to the fact that the substance will evaporate from the fermentation tank together with carbon dioxide.

Another critical sulfur compound as already mentioned in Sect. 7.1.2 is DMS. Despite the fact that it will be evaporated during the wort boiling, it still remains a crucial compound. During the kilning step, DMS can be oxidized to DMSO. As DMSO is heat-stable and nonvolatile during wort boiling, it will be reduced during fermentation to give rise to DMS [7.17]. However, some people appreciate the sulfury note of DMS in beer, when it is present in a rather low concentration.

7.3.3 Aging Flavors

As mobility of our society increases, local products are no longer consumed regionally, but worldwide. Accordingly, products are transported over large distances before they reach the consumer. Flavor consistency and stability are therefore important criteria for the success of a product. Unfortunately, beer is not a static system and changes will occur in a time-dependent manner. Regarding the flavor of beer, those changes can either be the development of new flavor-active compounds or the degradation of initially present flavor-active compounds [7.71]. The decrease in positive flavors such as floral, fruity, and estery notes, and the evolution of staling flavors exceeding their odor threshold values, is further complicated by the interactions of single compounds [7.72, 73]. Furthermore, strong and dominant flavors as they occur for example in dark beers, can mask to a certain extend the perception of aging flavors. Accordingly, these products seem to have a better sensorial flavor stability. Yet, the concentrations of staling compounds are also increasing thereby going relatively unnoticed.

Aging of beer strongly depends on the beer style and the conditions under which the aging occurs, for example, temperature, oxygen content, or the presence of iron and other metal salts [7.74]. As beer is a mixture of many different compounds, many different reactions can occur depending on the aging conditions. An overview on the evolution of basic aging flavors in beer was given by *Dalgliesh* (Fig. 7.12) [7.75].

Yet, this figure is a generalization of the possible sensorial sensations occurring during beer storage. Accordingly, it is not applicable to every beer. For most beers, a constant decrease in the bitter intensity can be observed during aging. At the same time, a sweet, caramel, toffee-like aroma develops. Very often a rapid formation, followed by a fast decline in the so-called ribes flavor occurs, which reminds of blackcurrant leaves (*Ribes nigrum*) [7.76, 77]. Later, a flavor associated with wet cardboard can be perceived [7.74]. Experiments revealed that (*E*)-2-nonenal (Fig. 7.13) gives beer a cardboard flavor when added to beer [7.78]. Later it was shown, that (*E*)-2-nonenal is already present in wort as its Schiff bases and is transferred into the final beer, where it is steadily released until the compound exceeds its odor threshold concentration [7.79, 80].

Even if they usually remain below their odor threshold concentration, furfural and 5-hydroxymethylfurfural (Fig. 7.9) are thought to be marker compounds for beer staling and heat load during the brewing process [7.81]. Both compounds are typical Maillard reaction products that are formed during wort production; they can then be transferred into beer in a chemically bound state (as Schiff bases or SO_2-adducts). Especially, the Schiff base will release furfural and 5-hydroxymethylfurfural during beer aging contributing to a sweet, caramel-like flavor. Accordingly, the vast majority of furfural and 5-hydroxymethylfurfural is formed during beer aging. The formation rate has

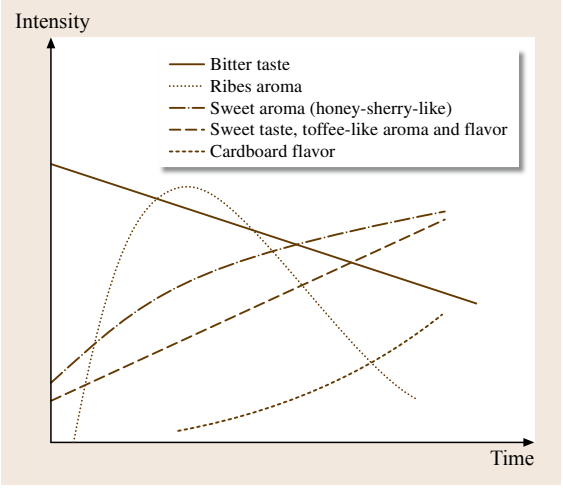

Fig. 7.12 Development of aging flavors of beer during time (according to *Dalgliesh* [7.75])

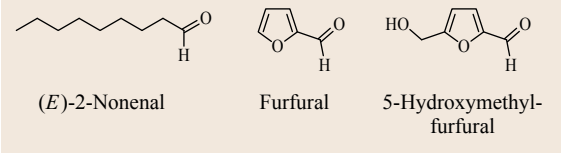

Fig. 7.13 Chemical structures of (*E*)-2-nonenal, furfural, and 5-hydroxymethylfurfural

been reported to be almost linear and to be temperature dependent [7.82].

Furthermore, several other staling aldehydes are formed during lagering [7.67, 74]. Thereby it is known, that the malt quality seems to be of essential importance regarding the formation of staling aldehydes. Yet, it is not clear which factors are responsible for significant differences in the brewing properties of malts [7.84].

In general, lipids are considered to be less important, as they are practically insoluble in water and lost to a large extent due to adsorption to solids. However lipid-derived oxidation products of aged hops are thought to be precursors for typical staling flavors [7.11]. In contrast to that, it is suggested that malt-derived polyphenols contribute to the flavor stability of beer [7.8].

When beer is exposed to sunlight, it quickly develops an unpleasant aroma, commonly referred to as the *sunstruck-flavor*. This off-flavor is predominantly caused by the skunky smelling 3-methyl-2-buten-1-thiol (MBT), formed in a light-induced reaction in the wavelength range of 350–550 nm involving isohumulone, riboflavin, and cysteine. The formation mechanism has been studied since decades (see [7.83] for a review) and even today, studies try to unravel the mystery of the respective conditions causing *sunstruck-flavor* [7.85]. The commonly accepted formation mechanism is shown in Fig. 7.14. A photosensitized cleavage of the C–C bond by light is suggested to be followed by a loss of carbon monoxide and a subsequent recombination with sulfur radicals.

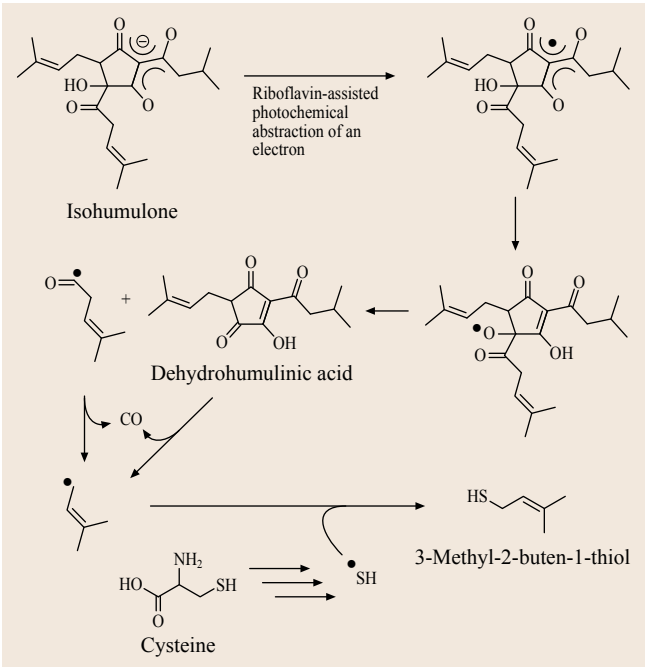

Fig. 7.14 Postulated mechanism of formation of 3-methyl-2-buten-1-thiol, responsible for the so-called *sunstruck flavor* (after [7.83])

As soon as beer is exposed to daylight, a rapid formation of MBT is initiated and due to its extremely low odor threshold (5–10 ng/l), even trace amounts of MBT usually have a noticeable effect on the aroma of beer.

In order to prevent this reaction, beer is either bottled in green or brown bottles, the latter being more effective. Naturally, full protection is only offered by metal cans. However, some beers are bottled in white glass. To prohibit the formation of MBT, either ultraviolet(UV)-filters must be embedded in the glass or the beer must be produced with so-called light-stable hop products. In these products, the unstable isohumulones are reduced to give rise to more light-stable dihydro-, tetrahydro-, and hexahydroisohumulones (Fig. 7.15) [7.34, 35]. However, it was shown, that tetrahydroisohumulones undergo the same reaction, as the α-hydroxy-keto function is still intact [7.83]. Furthermore, the authors reported that dihydroisohumulones are only partially light stable.

Other sulfur compounds can also be relevant for the aging flavor of beer, due to their very low odor threshold levels. Dimethyl trisulfide (fresh-onion-like) may increase above its flavor threshold of 0.1 µg/l [7.86, 87]. Other sulfur-containing volatiles that have been related to beer aging (catty, ribes-like aroma) include 3-methyl-3-mercaptobutyl formate [7.88] and 4-mercapto-4-methyl-pentane-2-one [7.89].

Although beer is a rather microbiologically stable beverage, a few microorganisms are able to grow in beer. Their growth can have a negative effect on

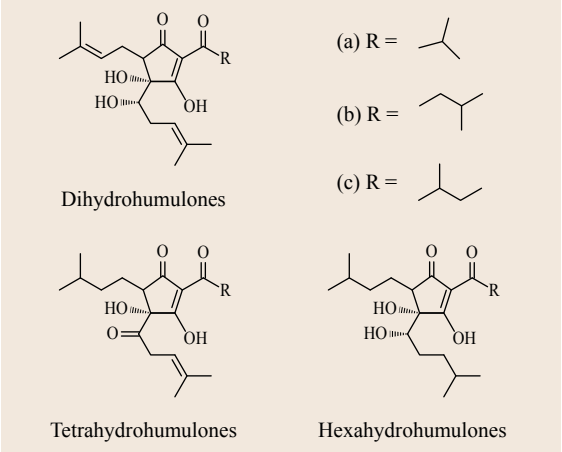

Fig. 7.15 Chemical structures of the co-(a), n-(b) and ad-(c) congeners of the dihydro-, tetrahydro- and hexahydroisohumulones

beer quality in general as well as on the flavor stability in particular. Possible infections include mycotoxin-producing fungi derived from the malting process, wild yeasts and bacteria, including certain lactic acid bacteria as well as anaerobic Gram-negative species [7.90].

7.4 Influence on the Sensory Sensation due to Other Constituents

As already mentioned, several hop-derived compounds can interact and cause synergistic effects. Moreover, even different compounds classes can influence each other. So far, studies have shown that carbon dioxide concentration influences the perception of the beer's bitterness, the warming perception of ethanol as well as the sweet taste [7.91]. Furthermore, studies indicated that the flavor complexity is mainly influenced by the ethanol concentration. These findings are supported by an investigation showing, that the ethanol concentration is crucial for the odor threshold concentration of several hop-derived volatiles, such as β-damascenone, β-carophyllene, and α-humulene [7.92]. But the concentrations of other nonvolatile compound classes, such as hop bitter acids or sweeteners, also influence the overall flavor complexity [7.91]. Another study provided evidence that the sourness plays a substantial role on how special flavors are perceived [7.93]. Interestingly, it was of great relevance which acid was used for the pH adjustment. Moreover, *Mojet* et al. found evidence suggesting that all tastants might also elicit a smell sensation [7.94], and therefore an influence on the overall aroma perception cannot be excluded. Such effects are strongly related to multisensorial perceptual effects as discussed in Chap. 47 of this book.

Finally, the temperature of beer obviously has a noticeable influence on the overall flavor perception, firstly due to the fact that the composition of volatiles in the head space above the aqueous layer will change, but also due to multisensorial interactions; for example, temperature can drastically influence the perception of tastants and this, in return, can again modify the perception of overall aroma of beer. Such considerations reveal that beer as a rather complex product is still far from being understood in view of its aroma and flavor properties; coming decades will surely unravel a multitude of knowledge in our attempt to understand why we savor beer for its unique flavor sensation.

7.5 Outlook

While many mysteries concerning the flavor of beer have been resolved, it is only partly possible to control and predict its flavor. Being an extremely complex beverage, many different compounds contribute to the overall flavor. Moreover, varying concentrations are making it almost impossible to fully characterize raw materials or even to link detectable, analytical changes to the sensorial perception elicited in the consumer. Although flavor thresholds and aroma impressions of single compounds have been studied thoroughly for certain compounds, interactions leading to flavor enhancement, suppression, or masking are not yet comprehensively understood. However, progress in analytical and sensorial evaluation methods will undoubtedly help to optimize and control the flavor evolution of the final beverage [7.95]. This information can also be used to adjust flavor profiles to the preferences of the consumers.

Flavor stability remains another problem that is not fully understood and, moreover, controlled. Yet, it is of major importance for a brewer to supply the consumer with consistent quality. Nevertheless, some mechanisms responsible for the aging of beer have been elucidated so that brewers will likely be able to increase the shelf life of beer in the near future. Possible sources of antioxidants that might be suited for this purpose are malts and hops as they are already naturally rich in antioxidants [7.61, 96].

Overall, increased efforts in multisensorial research will have most likely a strong impact on our common understanding of what specifically drives the complex perception of beer flavor.

8. Wine

Philippe Darriet, Alexandre Pons

Wine aroma is related to human cognition through multimodal stimuli, particularly in the case of volatile compounds detected by orthonasal and retronasal perception. In fine wines, aroma may be associated with associations of complexity, finesse, and elegance, sometimes attaining the level of uniqueness that makes them a source of a great pleasure. This chapter reviews the diversity of volatile components constituting wine aroma, including compounds originating from grapes, the metabolism of wine microorganisms during alcoholic and malolactic fermentations, implicating *Saccharomyces cerevisiae* and *Oenococcus oeni*, respectively, and oak barrels during wine aging. It will also address those associated with off-odors. The impact of all these compounds on wine aroma and quality is considered, including recently described perceptual interaction phenomena (i. e., masking, synergistic effects, and perceptual blending) and the influence of nonvolatile compounds in the wine matrix on aroma perception.

The quality of wine aroma is a matter of great importance. The first sensory impressions of a wine are color, followed by aroma, via orthonasal, then retronasal sensations. Tasters are capable of detecting a broad palette of aromas, including spicy, woody, flowery, and fruity components originating from the grape variety, soil, and climatic conditions, as well as vinification and aging processes [8.1]. Sometimes, tasting a wine is a source of great pleasure and represents such a unique experience that it may be considered a veritable work of art [8.1].

Wine tasters may use either hedonic or analytical criteria, depending on their preferences and knowledge of wine tasting. In this context, they also appreciate the intensity and complexity of the aromatic nuances and assess overall wine quality [8.1]. Analysis of the language used by a group of professional wine tasters revealed that they focused less on describing wines than categorizing them in relation to types they have already memorized [8.2]. Tasters unconsciously seek wine aromatic components related to specificity and originality, in order to associate each wine with an ideotype (stored reference). This aspect is related to the concept of typicality [8.3–5]. However, not all nuances are perceived in the same manner by different tasters; each taster has a unique personal sensitivity to aromas [8.6]. The context of the wine tasting may also have an impact on flavor perception [8.1, 7]. The perception of wine aroma and typicality is a complex cognitive process involving all the senses including somatosensory perceptions.

So, on what basis are a wine's aromatic nuances perceived? The aromatic palette is initially associated with the many – from one to several hundred – volatile compounds in the headspace above a glass of wine. Highly reputed wines usually have a complex composition consisting of a larger number of compounds. These compounds are stimuli for the human olfactory system, commencing with the olfactory epithelium before being transformed into nerve impulses in the olfactory bulb and becoming conscious sensations [8.8, 9]. However, volatile compounds do not contribute equally to wine aroma. Some, present in trace amounts (in the order of $\mathrm{ng\,l^{-1}}$ or $\mathrm{pg\,l^{-1}}$), have a very low olfactory

detection or recognition threshold, while others, detected at higher concentrations (several mg l^{-1}), have much higher detection or recognition thresholds [8.10, 11]. This paradoxical situation is due to the specificity of detection by the human olfactory system. However, the perceived intensity of a compound usually increases at higher concentrations [8.12]. Also, the presence of other wine compounds (ethanol, polyphenols, acidity, etc.) may affect the composition of the volatiles present in the headspace above the wine [8.13–15] and, potentially, the sensory perception of its aromas.

Nevertheless, the aroma perceived by the brain is not an algebraic sum of all the volatile compounds, but is related to a complex combinatorial process in the unconscious stage of perception [8.16]. Thus, the ultimate perception and verbalization of aromas involve complex, unconscious combinations of volatile compounds, as well as cognitive processes and memories of past experiences [8.10].

This chapter presents an overview of wine aroma components, including compounds originating from grapes (varietal compounds), those resulting from the fermentation metabolism of wine microorganisms, or associated with aging in oak barrels and bottles, and chemicals responsible for off-odors. The relationship between volatile compounds and their aromatic attributes in wine at each stage in tasting is discussed on the basis of recent research. The complex interaction of some key volatile compounds involved in overall perception is explored, focusing on combinatorial perception, as well as the impact of nonvolatile compounds on wine aroma.

8.1 Composition of the Wine Matrix

8.1.1 Fermentation Aroma

Compounds produced by the fermentation metabolism of yeasts (*Saccharomyces cerevisiae*, *Saccharomyces uvarum*) and lactic bacteria (*Œnococcus oeni, Lactobacillus* sp.) contribute first to the vinous character of a wine and thus its sensory specificity in comparison to other fermented beverages, as well as, in some cases, its fruity character. These compounds are primarily alcohols, particularly higher or fusel alcohols, esters formed by the esterification of higher alcohols with the acetic acid produced during fermentation, such as acetate esters of higher alcohols, esters formed from fatty acids and ethanol, such as ethyl esters of fatty acids, and, finally, carbonyl and sulfur compounds.

The key higher alcohols are 3-methyl-butan-1-ol (isoamyl alcohol) and 2-methyl-butan-1-ol (bug-like and heavy solvent odor), 2-methylpropan-1-ol (heavy solvent odor), 2-propan-1-ol (heavy solvent odor), 2-phenylethanol (rose flower, *pot pourri*), and 3-methylthiopropan-1-ol (cooked cabbage). These compounds with high-odor detection thresholds (ranging from mg l^{-1} to tens of mg l^{-1}) can affect wine aroma, as concentrations may be as high as several tens or hundreds of mg l^{-1}. Total concentrations of these compounds vary between 100 and 550 mg l^{-1} [8.11, 17]. Overall, with the exception of 2-phenylethanol, these compounds are considered to have a detrimental effect on quality, due to their pungent aromas when concentrations in wines exceed 300 mg l^{-1} [8.11, 17].

Esters of fatty acids (mainly butanoic, hexanoic, octanoic, and decanoic acids) and acetic esters of higher alcohols contribute through fruity and flowery nuances to the fermentation aroma of wines [8.11, 18]. The most significant acetic esters of higher alcohols in wine aroma are isoamyl acetate, responsible for the well-known banana aroma in some *primeur* wines, 2-phenylethyl acetate, which sometimes exhibits pungent, fruity, rose-like odors, and, less significantly, hexyl acetate (pear) and isobutyl acetate (banana). Globally, these compounds may be present at concentrations above the detection threshold (close to mg l^{-1}), sometimes masking the perception of varietal aroma nuances. Ethyl acetate (solvent *vinegar like*), also produced during alcoholic fermentation, may contribute to the fruity aroma of young wines at concentrations below 100 mg l^{-1}, while concentrations over 150 mg l^{-1} are always related to problems due to acetic or lactic bacteria, involving the esterification of ethanol with acetic acid [8.11].

Until 10 years ago, ethyl butanoate, ethyl hexanoate, ethyl octanoate, and ethyl decanoate, all known for their flowery aromas, were considered the most significant ethyl esters of fatty acids. The detection thresholds of these esters are in the μg l^{-1} range in water, and mg l^{-1} in young wines, significantly exceeding their individual detection thresholds. The amount of esters in young wines depends mainly on parameters related to alcoholic fermentation: *S. cerevisiae* yeast strain, and fermentation temperature, as well as composition and turbidity of the grape must [8.19–21].

More recently, the contribution of branched esters was identified, usually with higher concentrations in red wines. These compounds include hydroxylated ethyl esters, including ethyl 3-hydroxybutanoate [8.22, 23], ethyl 4-hydroxy butanoate (ethyl leucate) [8.24],

ethyl 2-hydroxyhexanoate, and ethyl 6-hydroxyhexanoate [8.22, 23], keto esters, such as ethyl 4-oxopentanoate (ethyl levulinate) [8.22, 23], and methylated esters, such as ethyl 2-methylpropanoate (ethyl isobutyrate), ethyl 2-methylbutanoate, and ethyl 2-hydroxy-4-methylpentanoate. While the individual olfactory detection thresholds of these compounds are similar to those of conventional esters, their contribution to the fruity aromas of red wines through perceptual interaction phenomena was recently reported [8.23]. Ethyl 2-methylpropanoate and ethyl 2-methylbutanoate are implicated with ethyl propanoate in blackberry aromas, while ethyl 3-hydroxybutanoate, together with ethyl butanoate, ethyl hexanoate, and ethyl octanoate contribute to red berry aromas [8.23]. Moreover, ethyl 2-hydroxy-4-methylpentanoate, only recently identified, was demonstrated to be involved in blackberry aroma via perceptual interaction phenomena [8.25]. The organoleptic impact of the enantiomers of this compound has also been studied [8.26]. Branched ethyl esters present lower olfactory detection thresholds than nonbranched compounds [8.22].

Globally, the contribution of the fermentation esters to wine aroma is limited in time, as these compounds are quite quickly degraded through hydrolysis during aging [8.27, 28]. However, contradictory results were recently reported in red wines by *Antalick* et al. [8.29], who observed high ester levels in aged red wines. In fact, other ethyl esters of branched acids may also be formed via chemical esterification during aging, including ethyl 2-methylpentanoate, ethyl 4-methylpentanoate, ethyl cyclohexanoate [8.30, 31], ethyl isobutyrate, ethyl 2-methylbutyrate, ethyl 2-methylpropanoate, ethyl 2-methylbutanoate, ethyl isovalerate, butyl acetate, and ethyl phenylacetate [8.32, 33]. Their contribution to wine aroma has not yet been precisely qualified.

Chemical esterification mechanisms may also affect various acids present in wine, such as cinnamic acid, chemically esterified to ethyl cinnamate (reminiscent of cinnamon, sweet-balsam, sweet-fruit, plums, and cherries), which is also formed during alcoholic fermentation [8.36, 37]. Ethyl phenylacetate has a strong, flowery flavor and is formed from phenylacetic acid, produced by the oxidation of phenylacetaldehyde [8.38, 39].

8.1.2 Other Fermentation Compounds

Other volatile sulfur- and carbonyl-based compounds, produced by wine microorganisms during alcoholic and malolactic fermentation, may significantly impact wine aroma (Sect. 8.1.5). Among the latter, diacetyl (2,3-butanedione) and acetoin, an intermediate in diacetyl formation, contributes to buttery, lactic aromas in both dry white and red wines following malolactic fermentation by *Œnococcus oeni* [8.11, 18]. The olfactory detection threshold of diacetyl is in the $\mu g\,l^{-1}$ range in water and $mg\,l^{-1}$ in model wine. A few $mg\,l^{-1}$ diacetyl ($2-3\,mg\,l^{-1}$ in dry whites and $5\,mg\,l^{-1}$ in reds) may contribute positively to wine aroma [8.11, 17, 40]. Another key volatile compound is acetaldehyde, but its contribution to wine aroma is generally limited, as it combines easily with the sulfur dioxide used as a preservative, except in oxidized wines. However, in specific situations, where wines are subjected to extreme oxidation during aging (e.g., Sherries from Xerez in southern Spain, Marsala, from Sicily, and *vin jaune* from the Jura region of France), acetaldehyde is present at concentrations of several hundreds of $mg\,l^{-1}$, contributing, with other volatile compounds (sotolon), to their typical oxidized apple and nut flavor [8.41].

8.1.3 Compounds Originating from Grapes

Methoxypyrazines

Methoxypyrazines are nitrogen heterocycle compounds belonging to the pyrazine group, largely represented in both animals and plants [8.42]. Among the various methoxypyrazines, some alkylated methoxypyrazines, such as 2-methoxy-3-isobutylpyrazine (IBMP), 2-methoxy-3-sec-butylpyrazine, and 2-methoxy-3-isopropylpyrazine (IPMP) are highly volatile with very low-odor thresholds, in the nanogram per liter range in water (Table 8.1). The odors of these methoxypyrazines are vegetable-like, reminiscent of pea pods, green peppers and, depending on the concentration and the compound, earthy nuances. These same substances have also been identified in bell peppers, pea pods, potatoes, and carrots as well as blackcurrants, raspberries, and blackberries [8.43–45].

These compounds, particularly 2-methoxy-3-isobutylpyrazine (IBMP), have been identified in various grape varieties such as Cabernet Sauvignon, Cabernet Franc, Sauvignon blanc [8.46–49], Merlot, Carmenère, and Verdejo [8.45, 50–52]. IBMP has also been found in Pinot Noir, Chardonnay, Riesling, Chenin Blanc, Traminer, Syrah, and Pinotage [8.53, 54], but in very low concentrations. Among the most odorous methoxypyrazines, IBMP is proportionally the most abundant compound in grapes and wine. Its concentration in Sauvignon blanc wines varies from 0.5 to $40\,ng\,l^{-1}$ and from 0.5 to $100\,ng\,l^{-1}$ in Cabernet Sauvignon wines. This compound can be detected at the highest concentrations (up to $160\,ng\,l^{-1}$) in Carmenère wines, which are frequently marked by herbaceous flavors [8.45, 50]. In Sauvignon blanc, as in Cabernet Sauvignon, the pea-pod, pepper-like aroma of IBMP

Table 8.1 2-Methoxy-3-alkylpyrazines identified in grapes and wines

Name	Structure	Descriptors	Detection threshold ($ng\,l^{-1}$)
			
2-Methoxy-3-isobutylpyrazine	R: $CH_2CH(CH_3)_2$	Greenpeper/pea pod	1[a]

[a] Determined in water at ISVV, University of Bordeaux
[b] Concentrations (after [8.34])
[c] Concentrations (after [8.35])

contributes to their herbaceous expression. A negative effect has been noticed on Cabernet Sauvignon wine flavor at concentrations as low as $15\,ng\,l^{-1}$ [8.55]. IBMP can also affect the flavor of Tempranillo and Grenache grown in Spain [8.13]. On the other hand, IBMP can contribute, to some extent, to desirable varietal aromas in Sauvignon blanc wines [8.56, 57]. As noticed by *Escudero* et al. [8.58] and *Pineau* et al. [8.59], perceptual interaction phenomena between 2-methoxy-3-isobutylpyrazine and other compounds, β-damascenone, dimethylsulfide can modulate the perceived herbaceous flavor of this compound by tasters (Sect. 8.2).

During vinification, IBMP is easily extracted during pressing or prefermentation maceration [8.60, 61]. Neither alcoholic fermentation nor aging modify the original concentration of IBMP in the must by more than 30% [8.60, 61]. This means that conventional winemaking techniques do not contribute to a decrease of IBMP in must, from the original amounts in grapes to the finished wine. However, the settling of must during the fermentation of white or rosés wines can reduce IBMP levels by about 50% [8.60, 61]. As for red wines, thermo-vinification can lead to a decrease of IBMP by evaporation [8.60, 61]. During aging, and because this compound is nonoxidizable, oxygenation has no impact on its concentration [8.60, 61]. Moreover, IBMP content is very stable during aging and can affect wine aroma for many years [8.60, 61].

Furthermore, other methoxypyrazines, such as 2-methoxy-3-methylpyrazine [8.48] and 2-methoxy-3-ethylpyrazine [8.62, 63], have been identified in Sauvignon blanc grapes, but these compounds are much less odoriferous than IBMP (Table 8.1).

Also, numerous studies have been published concerning the impact of natural (climate, soil) and viticultural factors on IBMP concentrations in grapes and wine. *Allen* et al. [8.54] first noticed lower IBMP concentrations in wines obtained from grapes ripened at higher temperatures, whereas *Falcao* et al. [8.64] discovered varying IBMP levels in wines obtained from grapes grown at different altitudes. The sensitivity of IBMP to UV light and its resulting degradation, leading to the formation of 2-methoxy-3-methylpyrazine, a much less odoriferous compound [8.45, 65, 66] should be noted. Climate-related variations in IBMP content in grapes and wine thus represent a key factor [8.55, 67–69]. Moreover, other physiological parameters of grape vines, such as yields and the availability of water and nitrogen [8.45, 70] also impact IBMP development. IBMP content in ripe grapes may also vary significantly, depending on the clonal origin of the vines [8.50].

Terpenic Compounds

Terpenes are a very large widespread group of compounds. Working from an early hypothesis by *Cordonnier* [8.71], various enological research teams have conducted research to learn more about these compounds [8.72–75]. There are 40 main monoterpene compounds in grapes. The most important in terms of odor are certain monoterpene alcohols and oxides, such as linalool, geraniol, citronellol, (*E*)-hotrienol, (*E*) and (*Z*)-rose oxide and nerol (3,7-dimethyl-2(*Z*),6-octadien-1-ol), which develop floral aromas. The detection thresholds of these compounds are quite low, ranging from tens to hundreds of micrograms per liter (Table 8.2).

The monoterpene alcohols mentioned above play a major role in the aroma of grapes and wines from the Muscat family (Muscat de Frontignan, also called Muscat à Petits Grains or Muscat d'Alsace, Muscat of Alexandria, also called Muscat à Gros Grains, Muscat d'Ottonel, White Muscat from Piemonte, etc.) as well as crosses between Muscat of Alexandria and other varietals (including such varietals as Muscat de Hambourg (crossed with Frankenthal [8.78]), and the Argentinian variety Torrontes (a cross with the Mission also called Pais variety [8.78]). The concentrations of

Table 8.2 Characteristics of some monoterpenes identified in grapes and wine

the main monoterpenes in these grapes and wines are much greater than the odor-detection threshold of these compounds. Monoterpenes also have a more or less pronounced impact in the flavor of Gewürztraminer, Albariño, Scheurebe, and Auxerrois grapes and wines, and to some extent those of Riesling, Muscadelle, and some clones of Chardonnay. These monoterpene alcohols are often found in many varieties (Sauvignon, Syrah, Cabernet Sauvignon, etc.) at levels generally below the olfactory perception threshold. In addition, as some monoterpenes have an asymmetric carbon, varying degrees of enantiomeric forms of monoterpenes can be found in grapes [8.79]. For example, linalool, hotrienol, cis-, and trans-rose oxide are predominantly present (88–97%) in a single enantiomeric form in the various varieties of Muscat that were analyzed (*S* form for linalool and (*E*)-hotrienol and (2*S*, 4*R*) and (2*R*, 4*S*) forms for (*Z*)-rose oxide, respectively). The abundance of one or the other enantiomer may contribute to modulating the strength of these odorous compounds in grape juice and wine, as well as aromatic expression. *R*-(−)-linalool, with an odor threshold of $0.8\,\mu g\,l^{-1}$, is described as having floral notes and overtones of woody lavender. It is more odoriferous than *S*-(+)-linalool, which presents a floral, sweet scent with a detection threshold of $17\,\mu g\,l^{-1}$ [8.76]. However, the proportions of enantiomeric forms may change over the fermentation process, the most fragrant enantiomer, cis-(2*S*, 4*R*)-rose oxide or (*Z*)-(−)-rose oxide, being for example, between 38 and 76% in wine [8.76]. Other than rose oxide, oxides present in grapes, such as the oxides of linalool and nerol, have little olfactory impact (i. e., high-perception thresholds of $1–5\,mg\,l^{-1}$). However, the presence of linalool oxide contributes to the increased perception of linalool [8.77, 80].

Botrytis cinerea development on grapes can also alter the composition of grape monoterpenes by degrading the main monoterpene alcohols and their oxides into generally less odorous components [8.73, 81]. Also, fermentation significantly alters the monoterpene composition of grapes through chemical and microbiological processes. The most pronounced transformation concerns the degradation of nerol and geraniol by the yeast *S. cerevisiae* via an enzymatic reduction to form citronellol, alpha-terpineol, and linalool [8.82, 83]. The proportion of the above compounds depends on the yeast strain and grape juice composition [8.84]. Also, during fermentation, the enzymatic reduction of 3,7-

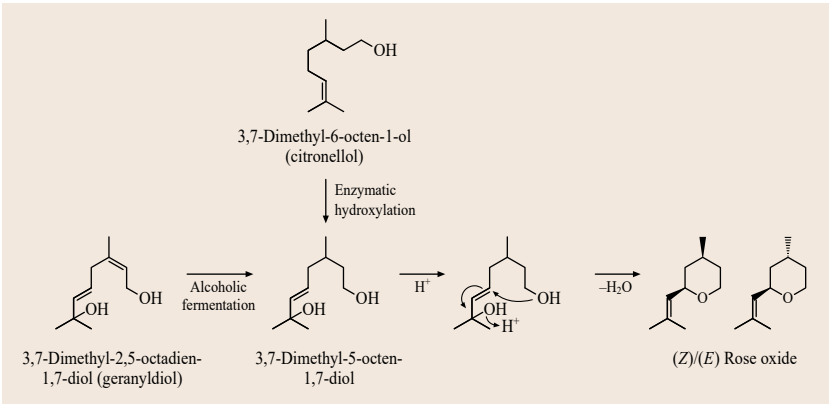

Fig. 8.1 Formation of rose oxide from various precursors in grape and during vinification (after [8.80])

dimethyl-2,5-octadien-1,7-diol or geranyldiol leads to the formation of a diendiol 3,7-dimethyl-5-octen-1,7-diol which is a precursor of rose oxide [8.80]. This diol is also derived from the enzymatic hydroxylation of citronellol in grapes [8.80]. These results illustrate the deep changes in the flavor of grapes that can result from the combination of fermentative metabolism of yeasts and wine acidic conditions (Fig. 8.1). Then during wine aging, the terpenols themselves may undergo rearrangements in acid to produce other monoterpene alcohols [8.85]. This is a classic chemical reaction involving the dehydration of alcohols in an acid medium. Thus, the alcohol dehydration of 3,7-dimethylocta-1,5-dien-3,7-diol, in the wine acidic medium, yields (*E*)-hotrienol, while (*E*)-2,6-dimethyl-6-hydroxyocta-2,7-dienoic acid has recently been identified as the precursor of the *wine-lactone* via stereoselective cyclization (Fig. 8.2) [8.86]. On the other hand, the concentrations of geraniol and nerol, which constitute part of the aroma of young wines, can rapidly decrease after 2–3 years of bottle aging (for instance in Muscat), and then no longer contribute in the same way to wine aroma. Linalool is more stable. Concentrations of this compound may even actually increase at the beginning of aging since it is formed from geraniol and nerol [8.87]. More specifically, cyclizing nerol produces α-terpineol; nerol is transformed into α-terpineol and linalool. Linalool is also converted into terpene hydrate over time [8.87]. These results account, at least partially, for the fact that the very intense young character of Muscat wine disappears during aging, acquiring a resinous odor.

Sesquiterpenoids

Sesquiterpenoids ((+)-aromadendrene, α-humulene, α-bisabolol, dehydro-aromadendrene, etc.) are secondary metabolites of grapes [8.88, 89] that do not generally contribute directly to wine flavor as their concentrations are usually in the $\mu g\,l^{-1}$ range, below the olfactory perception threshold of these compounds. Nevertheless, the characterization of pepper nuances in Syrah wines led to the successful identification of (−)-rotundone, a powerful sesquiterpene with an olfactory perception threshold in the $ng\,l^{-1}$ range (Table 8.3). Concentrations in Syrah range from 50 to $600\,ng\,l^{-1}$, and it is assumed that this compound can contribute to the black pepper flavor of this variety [8.88, 89].

C_{13}-Norisoprenoid Derivatives

The oxidative degradation of carotenoids, which belong to the family of terpenes with 40 carbon atoms (tetraterpenes), leads to many derivatives, including norisoprenoids with 13 carbon atoms (C_{13}-norisoprenoids) that may contribute to the aroma of wines. Three major groups each containing various volatile odoriferous compounds are concerned. The oxygenated megastigmane group includes powerful compounds, such as beta-damascenone [8.93, 94]. The smell of β-damascenone is reminiscent of apple sauce and tropical fruit. β-Damascenone has a very low-odor threshold in water ($2\,ng\,l^{-1}$) and a threshold close to wine in model solution ($60\,ng\,l^{-1}$) (Table 8.4). This compound, initially identified in grape juice from the Riesling and Scheurebe varieties by Schreier [8.93, 94] and then in many other varieties [8.93, 94] has maintained the myth of a major contribution to wine aromas given its very low olfactory threshold in water ($2\,ng\,l^{-1}$). In fact, the perception threshold of β-damascenone in wine is between 2 and $7\,\mu g\,l^{-1}$, although this com-

[c] Detection threshold in wine model solution and water, respectively

pound, usually found in concentrations of between 700 $ng\,l^{-1}$ and 2.5 $\mu g\,l^{-1}$ [8.93, 94], is rarely the only one involved in the aromatic composition of wines. However, β-damascenone can contribute by synergistic phenomena (Sect. 8.2). β-Ionone, with a distinctive smell of violet, has a perception threshold of 120 $ng\,l^{-1}$ in water, 800 $ng\,l^{-1}$ in model solution and 4 $\mu g\,l^{-1}$ in white wine, and its influence has been demonstrated in various grapes and wine varieties [8.90, 93, 94]. Other C_{13}-oxygenated norisoprenoids, such as 3-oxo-α-ionol (tobacco), 3-hydroxy-β-damascone (tea, tobacco), and β-damascone (tobacco, fruit) can provide only a very weak potential contribution to wine aroma. The second group consists of non-oxygenated megastigmane compounds, with 1-(2,3,6-trimethylphenyl)buta-1,3-diene (TPB) as a major representative. The detection threshold of this compound, presenting a typical geranium leaf odor, is 40 $ng\,l^{-1}$ in wine and 20 $ng\,l^{-1}$ in water. Concentration ranges in some old Sémillon wines can reach 200 $ng\,l^{-1}$ [8.93, 94]. The third group, composed of nonmegastigmanes, includes some odorous compounds as 1,1,6-trimethyl-1,2-dihydronaphtalene (TDN), which smells like kerosene and has a detection threshold of 1 $\mu g\,l^{-1}$ [8.91, 93, 94], (*E*) and (*Z*)-vitispirane which have camphor/woody nuances, riesling acetal (fruity descriptor), and actinidol (woody). TDN is considered to account in large part for the *petroleum* aromas of aged Riesling wines [8.93, 94] while (*E*) and (*Z*)-vitispirane, riesling acetal, actinidol are considered to have a limited contribution to wines aroma, particularly Riesling, as their concentration are usually much lower than their detection threshold [8.93, 94]. While megastigmane compounds from the first group can be detected in grape must and are present in the young wine, the representatives of the two other groups are only formed during wine aging. All these compounds originate from carotenoids present in grape, through enzymatic oxidative cleavage leading to hydroxylated C_{13}-norisoprenoid which then are submitted to several dehydration reactions in wine acidic media.

Impact of Volatile Thiols

In enology, many sulfur compounds in the thiol (sulfanyl) family are held responsible for olfactory defects. However, during the 1990s, several of these compounds were detected in wine and their positive contribution to wine flavor, particularly the varietal aroma of Sauvignon blanc wines and other white and red varietals, is now well documented. The three most important thiols in Sauvignon blanc aroma are 3-sulfanylhexanol (3SH), reminiscent of grapefruit flavor, 3-sulfanylhexyl acetate (3SHA), and 4-methyl-4-sulfanylpentan-2-one (4MSP) with box tree and broom aromas (Table 8.5) [8.95–98]. Descriptors, such as box tree and broom for 4MSP and grapefruit/passion fruit for 3SH match the occurrence of these compounds in box tree, broom, grapefruit, and yellow passion fruit, respectively. Several other odoriferous volatile thiols have also been

Table 8.5 Characteristics of some volatile thiols (sulfanyls) identified in wines

Name	Structure	Descriptors	Detection threshold[a] ($ng\,l^{-1}$)	Concentration in wines[b] ($ng\,l^{-1}$)
3-Sulfanylhexanol 3-SH		Passion fruit, grapefruit	60	100–10 000
3-Sulfanylhexylacetate 3SHA		Boxwood, passion fruit	4	0–1000
4-Methyl-4-sulfanylpentan-2-one 4MSP		Boxwood, broom	0.8	0–120
4-Methyl-4-sulfanylpentan-2-ol 4MSPOH		Citrus zest	55	0–150
3-Methyl-3-sulfanyl butan-1-ol 3MSB		Cooked leeks	1500	0–1500
3-Sulfanylpentan-1-ol 3SP		Citrus	900	0–400
3-Sulfanylheptan-1-ol $3SH_P$		Grapefruit	35	0–80
2-Methyl-3-sulfanyl butan-1-ol 2M3SB		Raw onion	nd	10–70

[a] Threshold determined in wine model solution at ISVV, University of Bordeaux

identified in Sauvignon blanc wine, such as 4-methyl-4-sulfanylpentan-2-ol, with a grapefruit zest flavor, and 3-methyl-3-sulfanylbutan-1-ol, smelling of leeks [8.97, 98]. Although these varietal thiols were first identified in Sauvignon blanc wine, they have also been found to contribute to the varietal aroma of wines made from other *Vitis vinifera* varieties, both red and white, such as Gewürztraminer, Riesling, Sémillon, Manseng, and Arvine [8.99, 100], as well as Merlot and Cabernet Sauvignon [8.101, 102].

More recently, 3-sulfanylpentan-1-ol (3SP), 3-sulfanylheptan-1-ol (3SHp), 2-methyl-3-sulfanylbutan-1-ol (2M3SB), and 2-methyl-3-sulfanylpentan-1-ol (2M3SP) were identified in Bordeaux dessert wines [8.103] and additive effects between them have been reported (Sect. 8.2). Due to their functional SH-group, thiol compounds sometimes occur in (*R*)- and (*S*)-enantiomer form. The enantiomeric distribution of 3SH, which contains one chiral center, was initially studied in passion fruit [8.97, 98], and later investigated in wines made from Sauvignon blanc and Sémillon grapes by *Tominaga* et al. [8.104]. The (*R*)- and (*S*)-enantiomer ratios of these two thiols in dry white Sauvignon blanc and Sémillon wines are approximately 30 : 70 for 3SHA and 50 : 50 for 3-sulfanylhexanol. However, in white dessert wines made from botrytized grapes, the proportion of the *R* and *S* forms of 3SH is in the vicinity of 30 : 70. The aroma descriptors of the two enantiomers of 3SH and 3SHA are quite different, although their perception thresholds are similar. Therefore, the enantiomeric distribution of 3SH and 3SHA in wine may have an impact on the perception and complexity of dry and sweet white wine aromas [8.104]. These varietal thiols originate from nonvolatile grape precursors, i. e., S-cysteine or glutathione conjugates, released during alcoholic fermentation [8.105]. 3-Sulfanylhexyl acetate (3SHA) is produced by enzymatic esterification of 3SH by *S. cerevisiae* yeast [8.106]. Accordingly, the formation of these compounds (thiols and esters) depends both on the yeast strain in alcoholic fermentation and the must matrix. Also, as thiols (sulfanyls) are highly reactive, they need to be preserved during winemaking and aging by protecting them from oxygen.

Lactones

Both γ- and δ-lactones are important aroma compounds, present in a wide variety of foods, beverages, and fruits. Many of them have been detected in wines, but one of the main cited is γ-nonalactone (Table 8.6). This compound has been identified in many different types of wine, including dry red and white, as well as botrytized and fortified wines [8.39, 107, 108]. Concentrations are low in white wines ($\approx 5.9\,\mu g\,l^{-1}$) and higher in botrytized and old red wines ($27–40\,\mu g\,l^{-1}$) [8.109, 110]. This compound, smelling of cooked peach when diluted, may con-

tribute to the characteristic prune flavor of these old red wines [8.111]. However, this substance is unlikely to contribute individually and directly to the aroma of most red wines, but probably has a greater impact in synergy with other γ- and δ-lactones. As γ-nonalactone is also found in oak wood, higher levels are found in wines aged in barrel [8.112].

This lactone is also a chiral compound, with enantiomers that differ slightly in their odor descriptors and strongly in their odor thresholds. Analysis of its enantiomeric distribution in wines revealed that, with few exceptions, the (*R*) enantiomer was more prevalent than its (*S*) counterpart in all the botrytized white wines analyzed, whereas neither isomer was overwhelming predominant in red wines [8.113].

This lactone is detected at low levels in grapes, depending on maturity or the development of noble rot (*B. cinerea*) [8.114], but is mainly produced by yeast (*S. cerevisiae*) during alcoholic fermentation [8.115]. *S. cerevisiae* yeast has been shown to produce γ-nonalactone from linoleic acid by two biosynthetic pathways [8.116]. The first features 13-lipoxygenation of linoleic acid to (*S*)-13-hydroxyoctadecadienoic acid, followed by four β-oxidation cycles and finally α-oxidation to (*S*)-γ-nonalactone (40–80% ee). The second features 9-lipoxygenation of linoleic acid to (*R*)-9-hydroxyoctadecadienoic acid, followed by a Baeyer-Villiger type oxidation to 3-(*Z*)-nonen-1-ol, which is further metabolized to the (*R*)-enantiomer (40–60% ee). Finally, this enzymatic mechanism exhibits an unsteady optical purity. Another odoriferous lactone, 2-nonen-4-olide, implicated in perceptual interaction phenomena, was recently identified in dessert wines [8.117].

Furanones

The flavor of 4-hydroxy-2,5-dimethyl-3(2*H*)-furanone (Furaneol, HDMF) is influenced by its concentration; the pure compound is reminiscent of caramel, while it is described as cooked strawberry at low concentrations. This compound has a pK_a of 8,56 (20 °C) and, like many structurally related compounds, 3(2*H*) furanone is highly soluble in water (0.315 g mL^{-1}, 25 °C) [8.118]. It was first identified in grapes and wines made with certain fungus-resistant cultivars obtained by cross-breeding wild American vines (*Vitis labrusca*) with European cultivars (*Vitis vinifera*), marked by an intense strawberry flavor. For example, furaneol levels as high as 10 mg l^{-1} have been measured in wines made from the Castor cultivar [8.119]. Since then, it has frequently been reported as contributing to the complexity and quality of red wines, while the lowest levels were found in dry white wines (10–40 µg l^{-1}). On the contrary, concentrations may reach 60 µg l^{-1} in young Cabernet Sauvignon wines and even 150 µg l^{-1} in Merlot. These values are well correlated with the caramel note found in certain Merlot wines [8.120]. High concentrations have also been reported in sweet fortified wines, reaching more than 620 µg l^{-1} in young wines but decreasing during aging suggesting that this compound is unstable at wine pH, degrading to form acetylformoin [8.121], buta-2,3-dione, and acetoin [8.122]. In wines, this furanone exists in free and odorous form, as well as bound to sulfur dioxide and catechols (mainly nonpolymerized forms). According to *Ferreira* et al. [8.123], this finding may explain the low free furaneol levels found in white wines.

As demonstrated by *Guedes de Pinho* et al. [8.124], furaneol levels can be increased by using pectolytic enzymes with β-glucosidic secondary activities, suggesting the existence of glycosylated precursors. Also, while it is absent from grapes at maturity, high levels have been found in overripe grapes. As furaneol may be formed from pentose or hexose by a Maillard reaction, its presence in grapes may also be enhanced by high temperatures around maturity [8.125]. Besides these aspects, *Sarrazin* et al. [8.39] highlighted the fact that most of the furaneol found in wine is released or produced thanks to the yeast metabolism during alcoholic fermentation [8.39]. The use of toasted oak wood may also provide an additional source of this furanone.

Homofuraneol, HEMF (5 (or 2)-ethyl-4-hydroxy-2(or 5)-methyl-3-(2*H*)-furanone), like furaneol, has a planar enol-oxo-configuration, but, due to the asymmetry of the molecule, both tautomeric forms have been identified and separated by GC on polar phase [8.126]. This compound was detected at the end of the 1990s in wines [8.77] and, like furaneol, is reminiscent of caramel and cooked strawberries. Concentrations in wines are lower compared to furaneol, ranging from 10 to 70 µg l^{-1} in dry red and white wines, and thus rarely exceed its perception threshold (Table 8.6) [8.39]. The lowest levels (a few µg l^{-1}) were found in sweet fortified wines, whereas the highest values, around 320 µg l^{-1}, were determined in botrytized wines. Moreover, owing to a strong synergistic effect between HDMF and homofuraneol, the fruity caramel note was increased, as evidenced in some rosé wines [8.127].

C_6 Aldehydes and Alcohols

Unsaturated fatty acids with 18 carbon atoms, such as linoleic acid and linolenic acid, are converted during prefermentation operations into the C_6 aldehydes hexanal and 2- and 3-hexenal with the aid of grape lipoxygenase [8.128, 129], and then further reduced to alcohol during fermentation. These C_6 aldehydes and

Table 8.6 Main furanones and lactones in wine

Name	Structure	Descriptors	Detection threshold
Racemic γ-nonalactone		Coconut, cooked peach	30 $\mu g\,l^{-1}$ [b]
(*R*)-form soft coconut with fatty-milky aspects strong, sweet[c]			284 $\mu g\,l^{-1}$ [a,c]
(*S*)-form fatty, moldy, weak coconut note[c]			91 $\mu g\,l^{-1}$ [a,c]
2-Nonen-4-olide		Minty and fruity	4.3 $\mu g\,l^{-1}$ [b]
Furaneol		Cooked strawberry, caramel	60 $\mu g\,l^{-1}$ [b]
Homofuraneol		Cooked strawberry, caramel	10–40 $\mu g\,l^{-1}$ [b]

[a] Wine, [b] Wine model solution determined at ISVV, University of Bordeaux, [c] *Cooke* et al. [8.113]

alcohols smell like freshly cut grass, but, considering their detection thresholds in the mg l^{-1} range, when taken separately, they rarely contribute directly to the herbaceous character of musts and wines.

8.1.4 Aging Aroma and Oak Related Flavor Compounds

Aging of wine is an important aspect of wine connoisseurship and one which distinguishes wine from almost every other drink. Already, in Antiquity, Falernian, and Surrentine wines required 15–20 years aging before they were considered at their best and were sometimes kept for decades in sealed earthenware jars or amphorae. Moreover, the Greek physician Galen was probably the first to note that an *aged* wine need not necessarily be old, but might simply have the characteristics of age. In other words, it was possible to age wines prematurely by heating or smoking them.

Nowadays, when we age wine, we hope for changes that will cause the wine to mature well by gaining a complex mix of complementary flavors. This is why the reputation of white and red wines is always strongly associated with their aging potential. These wines are able to retain the flavor nuances of young wines while developing specific varietal nuances. This kind of aging results in what is known as a reduction *bouquet*. While this specific organoleptic character is highly prized by connoisseurs, ideal aging does not occur in every wine. Most of the time, wine flavor develops quickly, resulting in a loss of complexity and personality, i. e., the flavor found in every oxidized wine. This phenomenon, known as premature aging, is well known in white wines and has more recently been found in red wines. Prematurely aged (Premox) white wines are reminiscent of honey, cider, and in certain cases, cooked vegetables, while red wines develop several aromatic nuances reminiscent of prunes and figs. In our experience of red wine tasting, the presence of these overriding odors affects the quality and subtlety of the wine flavor and may shorten its shelf life.

Wine aging generally consists of two phases: maturation (oxidative aging) and bottle aging (reductive aging). During maturation, wine is often stored in oak barrels. Continued aging in bottle is known as reductive aging, due to the small amount of oxygen inside the bottles.

Oak Wood Volatile Compounds in Wine Aroma

Oak (*Quercus* sp.) is currently the only wood used in making barrels for fermenting and aging quality wines. A fundamental aspect of aging wines in oak concerns the aromatic compounds extracted from the wood. When these compounds marry perfectly with a wine's intrinsic aromas, they make a significant contribution to the richness and complexity of the bouquet, as well as improving the flavor. Volatile extractive compounds from oak wood are responsible for important olfactory notes, such as coconut, wood, vanilla, caramel, and spice that play an essential role in wine aging in oak casks. They generally have low-aroma thresholds and may thus be detected by tasters in mature beverages at very low concentrations. Volatile content is strongly affected by natural factors, as well as botanical species (*Quercus robur*, *Quercus petraea*, *Quercus alba*), geographical origins, and cooperage techniques, such as seasoning and toasting (also known as hydrothermolysis). Hundreds of oak-derived volatile compounds have

Table 8.7 Oak volatile compounds

Name	Structure	Descriptors	Detection threshold[a]
(*Z*)-Oak lactone		Coconut, earthy	20 $\mu g\,l^{-1}$
(*E*)-Oak lactone		Spicy, coconut	110 $\mu g\,l^{-1}$
Vanillin		Vanilla	65 $\mu g\,l^{-1}$

[a] In wine model solution determined at ISVV, University of Bordeaux

been identified in alcoholic beverages. One group of compounds is formed by the degradation of oak lignin. This releases a range of phenolic odorants, the most important being eugenol, guaiacol, and 4-methylguaiacol, which give wine smoky and spicy aromas. Many other odorants are also directly or indirectly associated with wood aging, increasing the complexity of wines aged in oak barrels [8.130–133].

Of all the volatile compounds in oak wood, oak lactones, (*E*)/(*Z*)-β-methyl-γ-octalactone, particularly the cis-isomer, are considered the most important oak-derived compounds in wine. The structure of oak lactone, which is reminiscent of coconut, features two stereocenters, giving a total of four possible stereoisomers and two enantiomeric pairs of diastereoisomers. However, it has been established that oak wood contains only the (4*S*, 5*S*)-cis-1 and (4*S*, 5*R*)-trans-2 isomers of oak lactone [8.134]. The concentration of oak lactone (*cis*+*trans*) in untoasted wood ranges from 30 to 150 $\mu g\,g^{-1}$. In wines, the concentration of *cis*-oak lactone (the most odorous compound, Table 8.7), was found to be greater (under 20 $\mu g\,l^{-1}$ to over 1000 $\mu g\,l^{-1}$) than that of the trans-isomer (under 20 $\mu g\,l^{-1}$ to over 400 $\mu g\,l^{-1}$). The two isomers may be present at levels considerably higher than their perception thresholds [8.134]. Above a certain concentration, excessive amounts of this lactone may have a negative effect on wine aroma, giving it a strong woody or even resinous odor. Even when alcoholic fermentation takes place in barrels, the yeast metabolism has no impact on concentrations in wine. By analyzing the ratio of cis- and trans-isomers, it is possible to determine the source of wood used for barrel aging. This finding has been supported by results showing that American oak (*Quercus alba*) has only approximately 10% of the trans-isomer, while French oak (*Quercus robur, Quercus sessilis*) was found to have an almost equal amount of both stereoisomers. Moreover, this lactone is specific to oak wood. Only trace levels have been found in acacia, cherry, and chestnut woods, other species potentially used by coopers [8.135]. Detected in fresh oak woods, the two isomers of β-methyl-γ-octalactone are also formed during the air-drying process and during toasting at high temperature (150–200 °C) through dehydration of several precursors naturally present in oak wood. The precursors identified in oak wood are *cis*-3-methyl-4-galloyloxyoctanoic acid (ring-opened *cis*-oak lactone gallate, $R=4$), (3*S*,4*S*)- and (3*S*,4*R*)-3-methyl-4-*O*-β-D-glucopyranosyloctanoic acid (ring-opened *cis*- and *trans*-oak lactone glucoside $R=1$) [8.136], (3*S*,4*S*)-3-methyl-4-*O*-(6′-O-galloyl)-β-D-glucopyranosyloctanoic acid (ring-opened *cis*-oak lactone galloylglucoside, $R=2$) and 3-methyl-4-*O*-(6′-*O*-α-*L*-rhamnosyl)-β-D-glucopyranosyloctanoic acid ($R=3$) [8.137, 138] (Fig. 8.3). Concerning the glycoconjugate precursors, *Wilkinson* et al. [8.138] reported concentrations of the galloylglucoside ($R=2$) in French oak woods ten times higher (110–354 $\mu g\,g^{-1}$) than those of the others forms ($R=1$, $R=3$). Finally, knowledge of precursors indicated that the formation of oak lactone from oak lactone precursors could occur in two steps: liberation of the ring-opened oak lactone from oak lactone precursor by either pyrolysis (toasting) or enzymic activity and acid hydrolysis, followed by ring closure (lactonization) to yield oak lactone [8.139].

Vanillin plays an active part in the oaky and vanilla odors that barrels release into wine. However, its organoleptic contribution is a matter of debate. It may be direct or indirect according to its concentra-

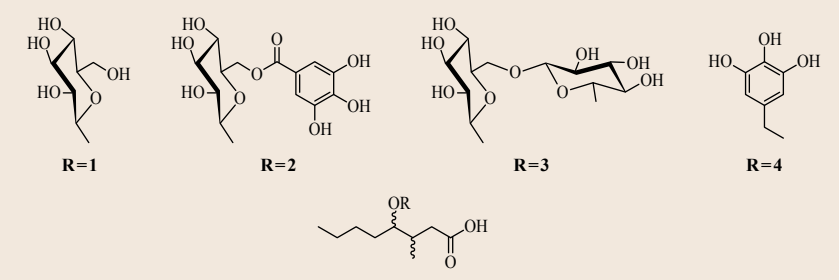

Fig. 8.3 Structure of the precursors of oak lactone identified in oak wood

tion and, more importantly, the type of wine (white or red) [8.140]. Only traces of vanillin are detected in grapes and wines, but much higher concentrations are released by toasted oak wood into wines during barrel aging. Though it is detected in nontoasted wood, toasting significantly increases the concentration. Vanillin accumulates quickly in wine: 70% of the final concentration of a 9 month storage period is reached during the three first months [8.141]. According to the aging period ($\approx$ 6–24 months) and the type of wood, the highest level ($\approx 5\,mg\,l^{-1}$) was systematically found in red wines. Indeed, traditionally, white wines undergo alcoholic fermentation in oak barrels to limit the organoleptic impact of wood compounds. This is mainly due to a biochemical transformation of vanillin into the barely fragrant vanillyl alcohol (perception threshold: $50\,mg\,l^{-1}$), vanillyl ethyl ester ($2.5\,mg\,l^{-1}$), and, finally, flavorless vanillyl ethyl ether. Moreover, yeast lees are capable of fixing and continuing to transform certain volatile compounds as they are released from the wood [8.142]. In general, the extraction of vanilllin from wood is greater than its conversion, so it accumulates in the wine. During malolactic fermentation (MLF) in wood barrels, an increase in vanillin is associated with the secondary metabolism of lactic acid bacteria (*O. oeni*) [8.143]. It has been demonstrated that these bacteria are able to hydrolyze glycosylated compounds released by oak wood; but, to date, specific precursors have not yet been identified. Ferulic acid was demonstrated to produce vanillin in the presence of *O. oeni*, but yields were low, resulting in amounts too small to explain the concentrations found in wines after MLF [8.144].

Reduction-Related Flavor Compounds: Reduction *Bouquet*

Empyreumatic aromas originate from greek empyreume, $\varepsilon\mu\pi\upsilon\rho\varepsilon\upsilon\mu\alpha$ (which is burned), the reminiscent of smoke and burnt wood odors, often feature in descriptors used by wine tasters. *Tominaga* et al. [8.145, 146] investigated the sensory impact of several volatile thiols on the reduction bouquet of wine aroma.

One potent thiol, 2-furanmethanethiol (2FM), develops a strong roast-coffee aroma and has been identified in Jurançon white dessert wines made from Petit Manseng grapes, as well as red Bordeaux wines (made from Merlot, Cabernet Franc, and Cabernet Sauvignon). These wines contain a few several dozen $ng\,l^{-1}$ 2FM (Table 8.8). The highest amount ($500\,ng\,l^{-1}$) was assayed in red wines at the end of 12 months aging in new oak barrels. Taking into account its very low-perception threshold ($0.4\,ng\,l^{-1}$), 2FM can therefore contribute to the roast-coffee aroma of certain barrel-aged red and white wines [8.145, 147]. This compound has also been reported in some old Champagnes, where it may be produced during bottle aging [8.148].

Traces of 2FM have been found in toasted oak used in barrel-making [8.149]. Furfural, released by toasted oak wood, plays a major role in 2FM formation in barrel-fermented white wines, where it is closely related to the yeast's (*S. cerevisiae*) sulfur metabolism. In barrel-aged red wines, a biochemical pathway involving furfural and a secondary metabolism of lactic bacteria (*O. oeni*) may promote a chemical route, involving furfural and H_2S. However, its formation mechanisms in bottle have not yet been elucidated.

Benzenemethanethiol (BM) contributes to the smoky/gunflint odor in several varietal wines. BM was detected systematically in white wines, including young ($20–30\,ng\,l^{-1}$) and old Champagnes ($200–400\,ng\,l^{-1}$), Sauvignon blanc ($10–20\,ng\,l^{-1}$), and Chardonnay ($20–40\,ng\,l^{-1}$). The lowest levels were found in red wines ($< 10\,ng\,l^{-1}$) [8.146]. This sulfur-containing compound has an extremely low-detection threshold ($0.3\,ng\,l^{-1}$) and makes a significant sensory contribution to the aroma of white wine. Together with 2-furanmethanthiol, these thiols contribute to the empyreumatic nuances in the bouquet of old Champagne wines [8.148]. The precursors of this thiol have not yet been identified.

2-Methyl-3-furanthiol (2M3F), the reminiscent of cooked meat, was identified for the first time in wine by *Bouchilloux* et al. [8.150]. Despite its instability, assaying 2M3F demonstrated its ubiquitous properties in young, as well as older wines (3–8 years old). It was detected systematically in red and white wines from different appellations at concentrations up to $100\,ng\,l^{-1}$, i. e., significantly above the olfactory perception threshold for this compound in model dilute alcohol solution ($2–8\,ng\,l^{-1}$). The highest values (reaching $200\,ng\,l^{-1}$) were found in Champagnes. At this level, it contributes to the overall *toasty* aroma in these wines [8.147]. The formation mechanisms of this compound, produced by Maillard reactions when food is cooked, have been studied in food, as well as in a model medium containing cysteine and pentose [8.151, 152]. In wine, its origin remains unclear. It has not been detected in must and is probably produced by yeast during alcoholic fermentation or brought in by dry yeasts [8.153].

Another important sulfur compound in the flavor of aged wines is dimethyl sulfide (DMS), identified by *Marais* [8.154]. It elicits odors described as *asparagus*, truffles, and molasses and plays an ambiguous role in wine aroma. Indeed, its influence on wine aroma was perceived either positively or negatively, depending on the DMS content and type of wine [8.155]. For example, it produces synergistic effects for fruity odors at subthreshold concentrations

Table 8.8 Volatile sulfur compounds related to aging aroma

Name	Structure	Descriptors	Detection threshold[a]
Dimethyl sulfide		Quince, truffle	25 $\mu g\,l^{-1}$ (white wine) and 65 $\mu g\,l^{-1}$ (red wine)
Benzenemethanethiol		Gunflint, smoky	0.3 $ng\,l^{-1}$
2-Furanmethanethiol or 2-Furfurylthiol		Roasted coffee	0.4 $ng\,l^{-1}$
2-Methyl-3-furanthiol		Cooked meat	2–8 $ng\,l^{-1}$

[a] In wine model solution determined at ISVV, University of Bordeaux

($10\,\mu g\,l^{-1}$) in mixtures containing fruity esters, C_{13}-norisoprenoids, and linalool [8.156, 157]. Moreover, DMS is considered a beneficial compound at low concentrations, contributing to the aroma of bottle-aged wines. DMS concentrations found in wine range from a few $\mu g\,l^{-1}$ to $480\,\mu g\,l^{-1}$, well above the sensory threshold ($27\,\mu g\,l^{-1}$) [8.158]: levels in freshly bottled wines are low and increase during aging, depending on storage temperature [8.159]. The DMS formation mechanism in wine is not clear. It may be formed in a similar way to other mercaptans. It appears during aging, via a yeast mechanism, by cleavage of *S*-methyl-*L*-methionine to form homoserine and dimethyl sulfide, and is also variously linked to the cysteine, cysteine, or glutathione metabolism in yeast.

Recently a strong correlation was established between the appreciation of reduction bouquet in aged great Bordeaux wines with the level of abundance of 2-methanefuranethiol and DMS [8.160]. Also, other thiol (sulfanyl) derivatives associated with ageing bouquet have been identified as vanillylthiol resulting from vanillin transformation and several thiopyrroles in aged Chardonnay wines from Burgundy [8.161].

Oxidation-Related Flavor Compounds

Sotolon (4,5-dimethyl-3-hydroxy-2(5)H-furanone) is an important five-branched lactone belonging to the isotetronic acid family (Table 8.9). The pure compound possesses an intense odor of curry, but develops honey and nutty flavors when diluted. NMR revealed that only the enolic tautomer of sotolon was observed in aqueous solution [8.162]. It is stable at the pH of wine, but unstable under basic conditions and in apolar organic solvent. Furthermore, this thermolabile, highly polar compound is susceptible to irreversible adsorption in GC-MS and is difficult to extract from wine samples (poor yields). However, methodologies have been optimized for its quantification and SIDA approaches (^{13}C label) gave the best results [8.162, 163].

Sotolon contributes to the aromas of *vins jaunes* from the Jura and sherries [8.164, 165], as well the *dried fig* and *rancio* nuances in French fortified wines (Vins doux naturels – VDN) and port [8.166, 167]. Concentrations in white wines made from grape varieties like Savagnin increase during aging with yeast *flor*, as well as during the barrel aging of sweet wines [8.167–169]. Wines of this type, over 20 years old, may contain up to $1\,mg\,l^{-1}$ sotolon that contributes to the typicality of these wines, made under oxidative conditions.

This furanone has also been detected in white wines made from botrytized grapes [8.170] but is rarely found in red wines. More recently, several authors determined the contribution of sotolon to the oxidation aromas of prematurely aged dry white wines [8.171–173]. The highest concentration found in these dry wines was $15–20\,\mu g\,l^{-1}$. Oxidation phenomena are involved in generating sotolon in wine. In wines that are made traditionally under reductive conditions, sotolon is considered an off-flavor.

Both enantiomers are detected in white wines, but due to its low-perception threshold, only (*S*)-sotolon contributes to the characteristic aroma of prematurely aged (premox) dry white wines. According to the wines, the maximum enantiomer excess (ee) ranged from 56 to 50 for the *R* and *S* forms, respectively [8.174, 175].

According to several studies, amino acids and, more precisely, threonine constitute a potential source of this furanone in wines. Its enzymatic or chemical deamination to 2-ketobutyric acid, followed by an aldol condensation with acetaldehyde, led to the formation of racemic sotolon (Fig. 8.4) [8.177]. Acetaldehyde and 2-ketobutyric acid are found in every wine as by-products of *S. cerevisiae*. 2-Ketobutyric acid has also been identified as an oxidative degradation product of ascorbic acid, a natural antioxidant present in small quantities in grapes and added during white wine vinification as well as at bottling (from 50 to $100\,mg\,l^{-1}$) to protect the wine from oxidative phenomena. A stereoselective pathway producing enantiopure sotolon has

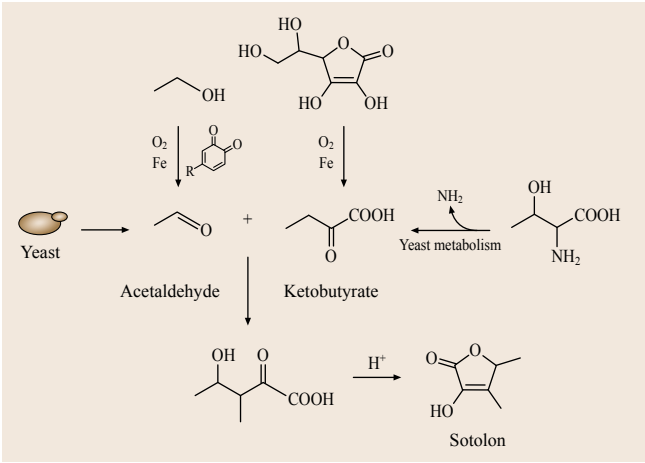

Fig. 8.4 Chemical and biochemical production of sotolon in wines (after [8.166, 176, 177])

not yet been identified. However, such a mechanism is not ruled out; low enantiomeric excess (ee) may be partly explained by the slow racemization kinetics (20 months) of optically active sotolon. Abhexon, an analogue of sotolon, with very similar organoleptic properties, has been identified in old Sauternes and flor sherry wines [8.178].

Among the oxidation-related aroma compounds, aldehydes, methional, and phenylacetaldehyde have attracted the most attention, due to their supposedly greater aroma impact and possible contribution to the aromas of red and white wines [8.179]. Reminiscent of boiled potatoes and old rose, respectively, their perception thresholds in wine model solution are 0.5 and $1\,\mu g\,l^{-1}$ [8.180]. These aldehydes are commonly found in all wines: white and red, port and sherry. Methional concentrations range from a few hundred $ng\,l^{-1}$ to $4.9\,\mu g\,l^{-1}$ in white wines and, in exceptional cases, $140\,\mu g\,l^{-1}$ [8.179], according to the oxidation level. Phenylacetaldehyde concentrations range from a few $\mu g\,l^{-1}$ to $53\,\mu g\,l^{-1}$ in white wines, sometimes exceeding $90\,\mu g\,l^{-1}$ in red [8.180] and botrytized white wines [8.39]. These compounds contribute directly to the flavors of oxidized white wines and are the reminiscent of cooked vegetables, cider, liquor, and honey. In oxidized red wines, they add nuances of figs and dried prunes and their direct contribution is not so clear. For example, *San-Juan* et al. [8.181] showed that the addition of methional to a young red wine transformed fresh fruit nuances into dried fruit aromas. According to these authors, this effect is particularly strong in the presence of C_{13} norisoprenoids.

It has been proposed that these aldehydes are formed from methionine and phenylalanine amino acids, respectively, via the Strecker reaction, involving the presence of a dicarbonyl compound. Wine contains two possible sources of dicarbonyl compounds able to induce the Strecker reaction. The first requires a reaction involving wine ortho-diphenols, forming ortho quinones [8.182] and are, in turn, able to induce the Strecker reaction with the amino acid [8.183]. Wine also contains dicarbonyls produced by microbial metabolisms. These include diacetyl, glyoxal, and methylglyoxal. The formation of aldehydes involving these carbonyls and the corresponding amino acids has been demonstrated in a wine-like medium and may play a role in the formation of aldehydes during bottle aging [8.184].

Another ketone involved in red wine flavor modifications is 3-methyl-2,4-nonanedione (MND) (Table 8.9). This β-diketone, the reminiscent of hay and anise, was recently identified in prematurely aged red wines with a marked prune flavor [8.111]. These descriptors may be concentration dependent. Indeed, at low concentrations, MND smells different from the pure compound (i. e., fruit pit, prune) and is rather reminiscent of prematurely aged (premox) red wine. Its perception threshold in wine model solution is $16\,ng\,l^{-1}$ [8.185]. MND content was shown to be lower in nonoxidized red wines than oxidized red wines, where it systematically exceeded the perception threshold ($62\,ng\,l^{-1}$). The keto-enol equilibrium, in which tautomers with the same odor and perception threshold in air [8.186] are only partially interconverted according to the temperature and polarity of the solvent, was first described by *Guth* [8.187].

Concentrations up to $340\,ng\,l^{-1}$ were determined in most oxidized red wines. High concentrations of this compound can be found in various wines i. e., rosé, botrytized wines and fortified wines made with overripe grapes. The lowest levels ($2.9\,ng\,l^{-1}$) were found in nonoxidized white wines and the highest concentrations in oxidized botrytized wines ($293.8\,ng\,l^{-1}$). From a sensory standpoint, the presence of MND alone significantly modifies the flavor of a red wine. The fresh fruit flavor in unadulterated red wine contrasts with the aromatic expression of *rancio* (old walnut flavor characteristic of oxidative aged Port wine) in wines spiked with high concentrations of MND ($308.9\,ng\,l^{-1}$). Oxidation mechanisms are responsible for its presence in wines. Guth found that certain furan fatty acids (10,13-epoxy-11,12-dimethyloctadeca-10,12-dienoic acid and 12,15-epoxy-13,14-dimethyleicosa-12,14-dienoic acid) were precursors of this compound in soybean oil [8.188]. These fatty acids have not previously been identified in wine, so the origin of 3-methyl-2,4-nonanedione in red wine is still unknown.

Table 8.9 Characteristics of volatile compounds involved in oxidation-related wine flavors

Name	Structure	Descriptors	Detection threshold[a]
Sotolon		Curry	Racemic 2 µg l^{-1}. (*S*) 0.8 µg l^{-1} (*R*) 89 µg l^{-1}

Other Age-Related Flavor Compounds

TDN (1,1,6-trimethyl-1,2-dihydronaphtalene), previously described (Sect. 8.1.2) as grape-derived C_{13}-norisoprenoid, sometimes imparts an undesirable *petroleum* or *kerosene* note to Riesling wine during aging (Table 8.10). Despite that, TDN is found in several red and white varietals, e.g., Cabernet Sauvignon, Cabernet Franc, and Sauvignon blanc, and is considered to have a strong, specific impact on Riesling wines. *Sponholtz* et al. [8.189] reported that TDN concentrations below 20 µg l^{-1} were considered to make a positive contribution to the varietal aroma of young Riesling wines and Riesling wine quality in general, up to a maximum of 4 µg l^{-1}, but recent work by *Schüttler* et al. [8.92] did not find any link between TDN concentrations in Riesling wines and the appreciation of their aroma uniqueness. TDN may be formed during alcoholic fermentation, but develops mainly during bottle storage. TDN is chemically stable in wine. Lutein, a carotenoid was shown to be a possible precursor for TDN via chemical thermal degradation in a sulfuric acidic medium. It is also generated from megastigm-4-ene-3,6,9-triol and megastigm-4,7-diene-3,6,8-triol, possibly bound as glycosides, by hydrolytic cleavage in acidic media [8.190, 191]. More recently, *Daniel* [8.192] demonstrated that Riesling acetal is a precursor of TDN in wine.

2-Aminoacetophenone is known as the aroma impact compound responsible for *untypical aging off-flavor* (UTA) in *Vitis Vinifera* wines [8.193]. This off-flavor may develop in bottle or in barrel within a few months after fermentation. UTA is associated with descriptors such as furniture polish, mothballs, or acacia blossom, combined with a loss of varietal character. Below its odor threshold in grape berries, must, and wine after alcoholic fermentation [8.194], 2-AAP concentrations increase significantly during storage. It has been detected in all wines irrespective of the grape variety, at concentrations ranging from 0.02 to 10 µg l^{-1} [8.195]. Concentrations in Sauvignon blanc range from 0.05 to 0.9 µg l^{-1}, rarely exceeding its sensory threshold, between 0.7 and 1 µg l^{-1}. Red wines contain the lowest concentrations. The 2-AAP content in wines without UTA is below 0.3 µg l^{-1}. Indole-3-acetic acid (IAA), a naturally occurring grape phyto-hormone, is considered a potential precursor of 2-AAP in wines [8.196]. A nonenzymatic mechanism is involved in its formation, when IAA reacts with sulfite, which requires superoxide radicals [8.197], generated by the aerobic oxidation of sulfured wine during storage. UTA has not yet been detected in red wines; the degradation of IAA to 2-AAP is probably blocked due to the presence of phenolic radical scavengers (Table 8.10).

8.1.5 Off Flavors in Wine

Many examples show how wine tasting can be affected by volatile compounds associated with organoleptic deviations. Also, it is important to characterize the com-

pounds responsible for off-odors in order to develop control strategies, as well as protocols to address the problem and improve wine quality. Acetic spoilage, resulting in the production of acetic acid and ethyl acetate, constitutes an historical example where deviation due to sugars being metabolized by acetic bacteria, converts wine into an unpleasant-tasting vinegary beverage [8.11]. Other off-odors in wine aroma can be traced back to the pollution of wine by contaminated materials, such as a cork stoppers (cork taint due to the release of 2,4,6-trichloranisole and 2,3,4,6-tetrachloroanisole, formed by *Ascomycetes* fungi (*Penicillium* sp., and *Trichoderma* sp.)) [8.11] or bushfire smoke [8.198], as well as undesirable metabolic by-products of grape and wine microorganisms, and, finally, chemical mechanisms responsible for transforming non-odorous compounds into defects. These off-odors may originate from grapes, as well as during winemaking and aging in tanks, oak barrels, and bottles.

Concerning the contribution of each compound to the off-odor, it is necessary to bear the following three points in mind:

1. Firstly, the perception of an off-odor depends on both the concentration of the compound responsible and its olfactory detection (or recognition) threshold. However, at a given concentration, the perception of an off-odor is highly dependent on individual sensitivity.
2. Secondly, the perception of an off-odor may be modulated by the presence of other volatile compounds.
3. Thirdly, the recognition of an off-odor depends on the wine tasters' capacity, depending on their level of experience, to distinguish a particular odor among the complex aromas of wine (*Tempere* et al. [8.199]).

Off-Odors Related to the Metabolism of Wine Microorganisms

Many unpleasant odors in wine result from the development of unwanted microorganisms or are related to metabolic modifications in wine microorganisms. Among the microorganisms concerned, over the past 20 years, spoilage due to *Brettanomyces sp* contaminant yeast has increasingly deteriorated the aromatic appreciation of red wines [8.200]. This off-odor is due to volatile phenolic compounds, mainly 4-ethylphenol and 4-ethylgaiacol, which originate from the decarboxylation of hydroxycinnamic acids in grapes, ferulic, and p-coumaric acid, respectively, by *Brettanomyces sp*. [8.201, 202]. The development of *Brettanomyces sp*. is favored, particularly in oak barrels, when wine is not sufficiently protected by sulfur dioxide due to high pH.

4-Ethylphenol and 4-ethylgaiacol present a heavy phenolic flavor likely to spoil red wine aroma, particularly attenuating their fruity character, with horse sweat, leather, and phenolic descriptors, all recognized as *Brett* character [8.181, 201–203]. In model solution similar to wine, the olfactory detection thresholds of 4-ethylphenol and 4-ethylguaiacol are $440\,\mu g\,l^{-1}$ and $135\,\mu g\,l^{-1}$, respectively. They are usually present in a ratio of around 10 : 1. As *Brett* character is not always clearly detected at concentrations above the detection threshold of ethylphenols in red wines, several studies have reconsidered the sensory perception implication of these compounds in red wine aroma [8.6]. A psychophysical study with 134 wine professionals highlighted that the distribution of individual olfactory detection thresholds for a mixture of 4-ethylphenol and 4-ethylgaiacol (in a 10 : 1 ratio) varied by a factor of 100 between the persons with the lowest and highest sensitivity. Moreover, the detection threshold of these compounds in red wine may be modulated by the presence of other wine volatile constituents (Sect. 8.2). In recent studies, *Tempère* et al. [8.199] investigated the analysis of perceptual skills and socio-professional parameters implicated in the recognition of *Brett* character. An initial experiment tested the hypothesis that expertise in terms of age and qualifications could affect the assessment of *Brett* character.

Vinyl phenols also affect the *finesse* of dry white and rosé wines [8.204]. These compounds originate from the decarboxylation of hydroxycinnamic acids by *S. cerevisiae*. 4-Vinylphenol has a strong odor, described as phenol, pharmaceutical, or gouache, that is, heavy odor of painting used by painters-, while 4-vinyguaiacol elicits the smell of cloves. Various enological parameters influence vinylphenol formation in white and rosé wines, particularly the strain of *S. cerevisiae* yeast used for alcoholic fermentation.

Lactic acid bacteria belonging to *O. oeni* and *Lactobocillus sp* contribute to wine stabilization by fermenting malic acid during malolactic fermentation, a key step for numerous premium red and white wines. However, the development of these bacteria in wines may sometimes result in off odors detrimental to the aromatic quality of the wine. This is the case when sorbic acid (2,4-hexadienoic acid), a fungistatic agent used in some dessert wines to reduce the risk of refermentation, is degraded by lactic bacteria to form 2-ethoxyhexa-3,5-diene, a strongly odoriferous compound reminiscent of geranium leaves (*Pelargonium sp* [8.205]. Also, *L. hilgardii* and *L. brevis* may be implicated in the production of potent nitrogen-heterocylic compounds (2-acetyltetrahydropyridine, 2-acetyl-1-pyrroline, or 2-ethyltetrahydropyridine) that contribute to an off odor in red wines identified as mousy taint [8.206–208].

Fungal, Mushroom, and Herbaceous Off-Odors

Some of these off-odors in wines are related to fungal notes, the reminiscent of damp earth, camphor, mold, and fresh mushrooms (Table 8.11). The presence of these aromatic nuances is sometimes attributed to contact between must or wine and materials (tanks, oak-barrels, or stoppers) that have been polluted during vinification, or barrel or bottle aging. These off-odors may originate from grape bunch rot when the harvest is spoiled by poorly timed rain, persistent morning mists, or hail. Analysis of these off-odors has led to the identification of several compounds with detection thresholds in the ng l^{-1} range, including 1-octen-3-one and 1-nonen-3-one (fresh mushroom odors), (−)-geosmin (powerful *damp earth* and *beetroot* odor) and the less common 2-methylisoborneol, with its camphor and earthy off-odors [8.209, 210]. These fungal off-flavors are related to grapes with bunch rot complexes involving *Botrytis cinerea* and secondary saprophytic invaders belonging to various species especially the *Penicillium* genus [8.211, 212]. Due to the potent odor of (−)-geosmin (perception threshold in water: 10 ng l^{-1}), less than 1% infection of a plot in the vineyard is enough to contaminate the entire harvest [8.209]. Particular care in the prevention and control of gray mold caused by *B. cinerea* in the vineyards concerned, together with careful sorting and removal of affected grapes, is recommended, in view of this compound's strong sensory impact [8.209]. Herbaceous off-odors have been shown to originate from the presence of high concentrations of 2-methoxy-3-isopropylpyrazine, due to the contamination of grapes during harvesting by the Asian Lady Beetle, *H. axyridis*, an insect introduced for the biological control of aphids [8.213].

Reduction Defects Caused by Volatile Sulfur Compounds

The impact of trace amounts of highly odorous volatile thiols on a wine's varietal aroma was established in the early 1990s (Sect. 8.1.3, *Impact of Volatile Thiols*), and in the wine aging bouquet. However, in enology, sulfur compounds are first considered to be responsible for organoleptic defects due to the irritating odor of sulfur dioxide or the *reduced* character related to the presence of some thiol or sulfide compounds. Winemakers have, therefore, always sought to minimize the impact of these compounds.

Historically, the first sulfur compound used in the elaboration of wine likely to cause a deterioration in quality is sulfur dioxide. This compound, naturally produced during alcoholic fermentation by *S. cerevisiae* at concentrations around 10 mg l^{-1}, is added to grape must and wine after fermentation and during aging, to prevent the development of undesirable microorganisms (bacteria and yeasts) and limit oxidative phenomena. Sulfur dioxide has been used systematically for its protective antioxidant and antimicrobial properties since at least the early 17th century. Its irritating odor, rarely perceived today in commercial wine, is considered detrimental to wine quality.

Off-odors known as *reduction* defects, evocative of rotten egg, garlic, onion, rubbery, or sometimes metallic character, are associated with volatile sulfur compounds:

1. Sulfides
2. Thiols
3. Thiophenes
4. Thiazoles.

Two groups of compounds have been distinguished according to their volatility: Highly volatile sulfur compounds (VSC) (boiling point $< 90\,^{\circ}C$), including hydrogen sulfide (H_2S), methanethiol (MeSH), ethanethiol (EtSH), dimethyl sulfide (DMS), diethyl sulfide (DES), dimethyl disulfide (DMDS) and *heavy* sulfur compounds, with boiling points above 90 °C. VSC compounds have a strong impact on wine aroma, due to their high volatility and low-odor thresholds. The main *light* sulfur compounds hydrogen sulfide, methyl mercaptans, and, less frequently, ethanethiol, dimethyl disulfide, and carbon disulfide, play a key role in reduction defects. In *reduced* wines, levels of these compounds are always above the olfactory detection threshold [8.214, 215]. The origins of these compounds are diverse, depending on vinification and aging conditions, as well as grape and wine contaminants. However, on the other hand, the absence of a small amount of oxygen, either enclosed at bottling or as a result of oxygen seeping through the closures, results in undesirable *reduction* aromas. Nitrogen deficiency in grape must and the presence of sulfur residues from pesticide treatments may also have a significant effect on the formation of these compounds

by *S. cerevisiae* yeast, as well as photochemical degradation during the wine aging (degradation of vitamin B2) [8.11].

Among the many *heavy* VSCs identified in wines, only a few contribute significantly to reduction defects. The most important of these is 3-methythiopropan-1-ol or methionol, which smells strongly of fermented cabbage (odor threshold $1200\,\mu g\,l^{-1}$). The 2-mercaptoethanol content in some *reduced* wines may also approach the odor threshold. Thiophene and 2-methyl-tetrahydro-thiophenone, act rather as odor-masking substances at concentrations exceeding $90\,\mu g\,l^{-1}$, thereby masking other aroma compounds with positive impact on the global wine aroma [8.216]. Recently, a malodorous sulfur metabolite perceived as *baked beans* and *Fritillaria sp. bulbs*, affecting dry white and rosé wine aroma, was identified as ethyl 2-sulfanylacetate [8.217]. This compound is not associated with the sulfur metabolites produced during alcoholic fermentation of grape juice containing solids, nor excessive addition of sulfur dioxide in the must. It is produced during alcoholic fermentation, particularly in wines made from hard-pressed juices and oxygenated musts. Depending on the wine matrix, concentration at which aroma is affected in dry Sauvignon blanc wines doted with this substance varies from 300 to $500\,ng\,l^{-1}$, while the detection thresholds of ethyl 2-sulfanylacetate in water and hydro-alcoholic solution are $70\,ng\,l^{-1}$ and $200\,ng\,l^{-1}$, respectively. Moreover, concentrations of this compound increase during bottle-aging of white wine. The knowledge of this compound facilitates informed choice of pressing and juice selection, as well as white wine vinification techniques that preserve aroma. Particular care is recommended in situations where this malodorous compound is likely to be produced, with grape pressing under a nitrogen atmosphere as a key strategy for minimizing the oxidation of the grape juice [8.217].

8.2 Perceptual Interaction Phenomena

The uniqueness and complexity of wine aroma depends on the presence of key volatile compounds. Characterization of these volatile compounds constitutes the heart of research into wine aroma. Indeed, the chemical characterization of impact aroma compounds and analysis of their contribution to wine aroma provides an opportunity to consider various aspects of winemaking technology, including wine microorganisms and grape ripening conditions. Despite substantial progress toward identifying unique varietal aromas, the construction of olfactory *images* in the brain is so complex that the key compounds alone are often unable to explain all the nuances perceived in wine aromas. Well-known experiments by the *Laing* group [8.218, 219] revealed the limited capacity of human beings to identify odors correctly in a mixture consisting of only three or four compounds. In fact, in considering wine aroma perception, at least two main types of perception should be considered: analytical and elemental perception, where the odors of specific compounds are clearly perceived in the wine among other volatile odoriferous compounds and synthetic or configural perception, involving perceptual interaction phenomena, where the perceived odors result from a combination of several volatile compounds, modified by masking phenomena and additive or synergistic effects, possibly resulting in new aromas.

8.2.1 Masking Effects

In enology, research into wine volatile compounds, conducted mainly in the last decade, has shown the importance of such sensory phenomena. Thus, it seems that the detection of off-odors in wine is likely to be related to analytical perception, while specific wine aromas more generally result from combinatorial effects involving several volatile compounds. In fact, empirical observations concerning the perception of *Brett* off-odor have indicated an indirect relation between the ethylphenol content in wines and the perception of this defect [8.199, 202]. For example, *Romano* et al. [8.220] showed that the detection threshold of a mixture of 4-ethylphenol and 4-ethylguaiacol (in a 10 : 1 ratio) in wine was higher (i. e., reduced perception) when other volatile compounds related to *Brettanomyces* sp. metabolism, such as isobutyric and isovaleric acids, were present, indicating that a masking phenomenon was involved.

8.2.2 Additive and Synergistic Effects

In contrast, as early as 1970, *Ribéreau-Gayon* and *Boidron* demonstrated that a mixture of the main terpenols had a significantly lower odor-detection threshold than each one taken separately, thereby highlighting a synergistic action [8.74]. This effect was also observed for wine γ-lactones by *Jarauta* et al. [8.221], who reported that the detection threshold of a mixture of wine lactones was four times lower than that expected on the basis of their individual thresholds. *Sarrazin* et al. [8.103] also noticed that chemically similar sulfanylalcohols, for example, 3-sulfanylpentan-1-ol, and 3-sulfanylheptan-1-ol, which have a similar cit-

rus aroma to 3-sulfanylhexan-1-ol, may contribute to dessert wine aromas at concentrations lower than their olfactory detection thresholds through additive phenomena.

More recently, the additive properties of some ethyl esters of fatty acids and fusel alcohol acetates in the fresh, fruity aromas of red wine have been extensively studied by several authors [8.22, 23, 26, 222, 223]. In combination, these compounds make a significant contribution to red wine fruity aroma, even at concentrations below their odor-detection thresholds, while each one added separately has no effect [8.13, 23, 23]. Ethyl butyrate, ethyl hexanoate, and ethyl octanoate were found to enhance the expression of *fresh fruit* and *red fruit* aromas, while ethyl propionate was implicated in the notion of *candied fruit* and *black fruit* [8.13, 23, 23]. By way of example, ethyl 2-hydroxy-4-methylpentanoate, also known as ethyl leucate, was recently demonstrated to enhance the fruity aroma of red wine [8.25, 26].

Both ethyl esters of fatty acids and fusel alcohol acetates are considered to impact the typical fruity character of red wines, through synergistic effects and perceptive interactions [8.13, 23, 23]. Using omission tests in model media (dilute alcohol solutions), *Lytra* et al. [8.223] highlighted the importance of ethyl propanoate, ethyl-3-hydroxybutanoate, butyl acetate, and 2-methylpropyl acetate in a fruity mixture containing 12-ethyl esters of fatty acids and fusel alcohol acetate, although these compounds were only present at subthreshold concentrations. Also, ethyl esters of fatty acids, such as butanoic, hexanoic, octanoic, decanoic, and, to a lesser extent, dodecanoic acids are involved in perceptive interactions with other aromatic compounds, including β-damascenone [8.13, 23, 23], β-ionone [8.13, 23, 23], and dimethylsulfide [8.13, 155, 157] even at concentrations below their odor thresholds.

Synergistic effects have also been revealed between monoterpenes and β-damascenone; for example, the orthonasal detection thresholds of linalool and geraniol are lowered by the presence of β-damascenone. This phenomenon has also been identified and measured with lab mice in the Pasteur Institute through psychophysic tests using a specific behavioral methodology [8.224]. Moreover, β-damascenone contributes, via synergistic phenomena, to reducing the detection thresholds of ethyl hexanoate and ethyl cinnamate and raising the detection threshold of 2-methoxy-3-isobutylpyrazine [8.59].

8.2.3 Perceptual Blending

Not many examples in the literature report the situation where a mixture of compounds triggers the perception of a different aroma from those of the compounds taken separately. A 30/70 mixture of ethyl isobutyrate (strawberry flavor) and ethylmaltol (caramel) induced the perception of pineapple [8.225]. In another situation, a mixture of six compounds (β-damascenone, β-ionone, frambinone, vanillin, isoamyl acetate, and ethyl acetate) had a flavor reminiscent of red cordial (grenadine), unlike any of the compounds taken individually [8.226].

Another example of perceptual interaction phenomena was revealed during a study on compounds involved in the *candied citrus* and *orange* aromas of dessert wines [8.117]. Emphasis was placed on the study of the phenomenon of perceptual interactions; consequently, *aromatic recovery* was an important research approach: while fractionating an extract of premium Sauternes dessert wine, one fraction was recognized as having these characteristic citrus aromas. This fraction was not present in lower quality wines. Analytical chemistry coupled with sensory analysis identified the compounds present in the fraction associated with this odor as whisky lactone (*coconut*), eugenol (*clove*), and a newly identified lactone, 2-nonen-4-olide, associated with noble rot, which has *minty* and *fruity* odors. None of these compounds considered alone at concentrations close to those assayed in wines produced an orange aroma. Subsequent omission and reconstitution tests demonstrated that these four compounds together, particularly the two lactones (one originating from oak wood and the other from botrytized grapes), generate the perception of *orange* aroma. Moreover, the importance of enantioselective distribution of 2-nonen-4-olide on this perceptual phenomena was recently evidenced (*Stamatopoulos* et al. [8.227]) The correlation of whisky lactone with wine fruitiness has also been reported [8.228, 229]. This sensory phenomenon, well known in perfumery, appears to contribute substantially to the uniqueness and complexity of wine and opens up new perspectives for understanding wine aroma perception.

8.2.4 Interactions Between the Wine Matrix and Aroma Compounds

The wine matrix contains numerous nonvolatile compounds, at concentrations in the $g\,l^{-1}$ range, that may have a significant impact on aroma perception during wine tasting. Those compounds include acids (tartaric, malic, citric, and acetic acids), ethanol (at concentrations ranging from 70 to 160 $g\,l^{-1}$), polysaccharides, proteins, and polyphenols (pigments, such as anthocyanins, and flavonoids). One aspect of this subject concerns the impact of pigments (anthocyanins) on the

appreciation of aromatic nuances. Briefly, when nonexpert wine tasters were asked to assess a dry white wine colored with anthocyanins, they used red wine descriptors [8.7].

Another aspect of the impact of wine matrix composition on aroma compounds concerns physico-chemical interactions between volatile compounds and other key compounds in wine (glucose or fructose, polyphenols, polysaccharides, proteins, etc.) and in vivo retronasal perception in the mouth. Specifically, several authors have reported the impact of interactions between nonvolatile and volatile compounds in wine on the partitioning of volatile compounds [8.10, 15, 230, 231]. First, *Dufour* et al. described the impact of (+)-catechin ($2-10\,g\,l^{-1}$) on reducing the volatility of several fermentation esters:

1. Isoamyl acetate (banana flavor)
2. Ethyl hexanoate
3. Benzaldehyde.

The sensory effect of such phenomena, studied more recently [8.14] regarding other esters (ethyl butyrate and ethyl octanoate), indicated that their olfactory detection threshold increased (at least doubled) in the presence of (+)-catechin ($2\,g\,l^{-1}$), but not in the presence of another phenolic compound, gallic acid ($2\,g\,l^{-1}$) [8.14]. Also, the attenuating impact of ethanol on the volatility and fruitiness of several wine components has been illustrated by several authors [8.13, 15]. Considering a range of volatile compounds in wine [monoterpenes (linalool, nerol), C_{13}-norisoprenoids (β-damascenone, β-ionone), and ethyl esters], *Robinson* et al. [8.15] reported an increase in volatility in the presence of glucose ($160-320\,g\,l^{-1}$) and the reverse for ethanol (> 10% vol.), whereas proline had no effect. Also, the presence of ethanol affected perceptual interaction phenomena in binary odor mixtures of isoamyl acetate and whisky lactone, [8.232]. The effect of these phenomena on the aromatic profile of wines has not yet been investigated in detail. The impact of (+)-catechin supplementation at concentrations ranging from 25 to $200\,mg\,l^{-1}$ on the aromatic profiles of three Sauvignon blanc wines was studied through triangular tests. The experiment revealed significant differences between supplemented and non-supplemented wines at concentrations between $50\,mg\,l^{-1}$ and $200\,mg\,l^{-1}$ but not at lower levels [8.233].

The perception of volatile compounds during wine tasting is not only orthonasal but also retronasal. One recent study used an in vivo approach to measure aroma compound concentrations directly in exhaled breath after wine consumption, revealing the importance of the wine matrix, particularly the presence of polyphenols, on the volatility of odoriferous compounds, such as isoamyl acetate, ethylhexanoate and linalool and also the impact of oral mucosa [8.234–236]. Further research is required to elucidate the importance of these phenomena during wine consumption.

9. Fruits

Anne Plotto, Jinhe Bai, Elisabeth Baldwin

In a botanical sense, fruits are the developed part of the seed-containing ovary. Evolutionarily speaking, plants have developed fruits presumably to attract insects, birds, reptiles, and mammals and hence to spread the seeds. Fruits can be dry such as the pod of a pea, or fleshy such as a peach. As humans, we enjoy fleshy fruits for their flavor and nutritional value. In this chapter, we will review the common volatiles that are produced by the major fruits with commercial value: tomato, citrus, apples, and strawberries. Some volatile compounds are commonly produced by all crops, simply by the fact of common biosynthetic pathways, while other compounds are specific to certain fruit species. Fruit-specific aroma depends on species, cultivar, growing conditions, and developmental and maturity stage. In the end, however, what gives a fruit its specific flavor is the combination of volatile and nonvolatile compounds, including sugars, acids, and other water-soluble and insoluble compounds.

9.1 Fruit Volatiles

Because volatiles are derived from primary metabolites from common pathways, as described in this book, Chap. 2, many odorants are common to many fruits. However, some pathways are more active in some plant species than others, resulting in different flavor profiles. Apples and pears are characterized by a dominance of aliphatic esters, alcohols, and aldehydes, while berries (strawberries, blackberries, and raspberries) may have similar volatiles, with additional ketones or lactones that give them their characteristic flavor. Citrus fruits are usually characterized by large amounts of terpenes, but different citrus species differentiate from each other by producing more or less of other compounds: esters and sesquiterpenes are predominant in oranges relative to mandarins, sulfur compounds are found in large amounts in grapefruit, the aldehydes neral and geranial (both isomers of citral) are characteristic of lemon flavor. Tropical fruits, with a wide spectrum of genera and species, have in common sulfur compounds that give a fruity/sweet aroma when in low concentrations and combined in a matrix with high sugars/low acids such as in mango, papaya, passion fruit, durian, or guava.

9.1.1 Common Volatiles Found in Fruit

Esters

Most temperate fruits owe their fruity flavor to straight- or branched-chained esters, derived from fatty acid and amino-acid pathways, respectively (this book, Chap. 2). Esters have been reported in almost all fruits, including muskmelon [9.1], apple [9.2, 3], strawberry [9.4, 5], pineapple [9.6], oranges [9.7], to name a few. As a matter of fact, when flavorists need to add a *fruity* note to a flavor, they would first turn to esters [9.8]. Most esters have a fruity quality [9.2, 9–11], although higher concentrations may be perceived as *solvent* or *ether*, for example in the case of gas chromatography-olfactometry (GC-O) [9.11, 12], or impart a *fermented* or *spoiled fruit* and musty flavor to a fruit or juice [9.10, 13]. In

general, branched esters have a much lower threshold than their straight chain counterpart, as determined by classical odor thresholds in water [9.14] or observed by GC-O [9.15–17]. Thereby, threshold concentrations have been used by the flavor industry as indicators of the relative contribution of a compound to a food [9.8, 18, 19]. Branched chain esters with a mercapto- or hydroxyl-group were found to have higher odor thresholds than branched chain esters with methyl and ethyl groups in the acid part of the ester [9.14]; a methyl group at the 1-position of the alcohol did not have a consistent effect in increasing or decreasing thresholds [9.20]. Ester thresholds in water vary as low as 0.008 ppb (ethyl 3-methylpentanoate) to 2500 ppb (ethyl 3-hydroxybutanoate), and up to 13 500 ppb (ethyl acetate), and they all have a fruity odor [9.14, 20].

Lactones are cyclic esters with characteristic coconut or peach flavor [9.21], and were found in peach [9.22], mango [9.23], apricot [9.24, 25], and strawberries [9.26, 27]. Their odor thresholds are usually very low, and often more easily detected by GC-O than by GC-MS (gas chromatography-mass spectrometry) or GC-FID (flame ionization detector) [9.26, 27]. Wine lactone (3a,4,5,7a-tetrahydro-3,6-dimethyl-2(3H)-benzofuranone) and furaneol (2,5-dimethyl-4-hydroxy-3(2H)-furanone) are two potent lactones with a sugary/sweet odor and odor thresholds of 0.008 and 60 ppb, respectively [9.9, 28]. Wine lactone was found in fresh oranges [9.29], while furaneol is quite ubiquitous in fruit: tomatoes [9.28], strawberries [9.30], pineapples, and mangoes [9.31], to name but a few.

Aldehydes and Alcohols

Aliphatic aldehydes and alcohols are produced upon cutting or chewing plant tissue from the lipoxygenase pathway (this book, Chap. 2). Most common compounds produced are hexanal, 1-hexanol, (2*E*)-hexenal, (2*E*)-hexenol, (3*Z*)-hexenal, (3*Z*)-hexenol, all having a *green* odor, like cut grass, leaf, or woody, and with odor thresholds varying from 0.25 ppb ((3*Z*)-hexenal) to 500 ppb (1-hexanol), with the most common aldehyde, hexanal, having a threshold of 4.5 ppb [9.32]. These compounds tend to be in greater amount in unripe fruit [9.1, 33]. Straight- and longer chain aldehydes such as octanal, nonanal and decanal are present in citrus oil more than in fruit vesicles [9.34], and have typical citrus aroma [9.7]. Longer chain aldehydes, whether saturated or not, are present in citrus and have fatty or soapy characters [9.34]. Terpene aldehydes and alcohols such as neral (nerol) and geranial (geraniol) (both isomers of citral), linalool, sinensal, and citronellal (citronellol) occur in citrus juice with characteristic citrus flavors. The phenolic aldehyde, benzaldehyde, has a typical cherry or almond flavor. It is found in many fruits, including peaches [9.22, 35], strawberry [9.36], oranges [9.34], tomato [9.37], blueberry [9.38], and of course in cherries [9.39–41].

Ketones

Like alcohols and aldehydes, ketones may belong to various chemical groups. Some ketones have characteristic odors and are character impact compounds in some fruits. An example is the raspberry ketone, 4-(4-hydroxyphenyl)-butan-2-one, with an odor threshold of 0.001–0.01 ppb [9.42]. Others have very low odor thresholds and are ubiquitous in the fruit kingdom: for example, β-damascenone, α- and β-ionone are derived from carotenoid degradation when fruit ripens. β-Damascenone, with a low odor threshold, is found in mostly all fruit extracts by GC-O, without often being detected by classical GC methods. It is described as sweet, honey, tobacco, and is believed to contribute to the general fruitiness of a fruit product [9.24, 43–47]. α- and β-Ionones are found in berries [9.48], oranges [9.45], tomato [9.49], and lychee [9.50].

1-Octen-3-one and 1-octen-3-ol are two other compounds that are found in many fruits by GC-O, but instead of having a fruity or green odor, have a very characteristic mushroom odor. Their odor thresholds are 0.005 ppb and 1 ppb, respectively [9.9], and they are often detected by GC-O but not by the FID or MS detectors. Nootkatone is a terpene ketone and has a characteristic grapefruit odor [9.51, 52].

Terpenes

When talking about chemistry of terpenes, two plant groups come to mind: Labiateae, containing the mint species, and Rutaceae, containing the citrus species. Terpene biosynthesis has been studied in both groups, as they have important economic values [9.53, 54]. Terpenes occur not only in citrus, but are found in many tropical fruits and berries. Terpenes were detected in blueberries [9.55], blackberries [9.56], strawberries [9.36], and mango [9.57, 58]. In general, the high molecular weight sesquiterpenes have little odor in comparison with the low molecular weight and highly volatile monoterpenes [9.59]. Depending on their oxygenation level, their odor threshold and quality might vary considerably. Limonene is the main volatile produced by citrus fruit, but only accounts for a fraction of the odor activity. On the contrary, the oxygenated linalool has a characteristic citrus and floral odor. Odor thresholds in a deodorized orange juice matrix for both compounds are 13 700 and 113 ppb, respectively [9.60].

Table 9.1 Odor-active sulfur volatile compounds detected by gas GC-O in selected tropical and subtropical fruit

Fruit	Compound	Odor characteristic	Reference
Lychee	Hydrogen sulfide	Sulfur, fetid	[9.50]
	Dimethyl sulfide	Cabbage	
	Diethyl disulfide	Moldy, sulfur	
	2-Methyl thiazole	Garlic	
	2,4-Dithiopentane	Burning tire, cabbage	
	Dimethyl trisulfide	Cabbage, sulfur	
	Methional	Cooked potato	
	2-Acetyl-2-thiazoline	Dry fruit, nutty	
Mango	2-Methyl-3-furanthiol	Nutty, medicinal, oily	[9.61]
	4-Mercapto-4-methyl penten-2-ol	Green, grapefruit	
Guava	Methanethiol	Sulfury	[9.61]
	2-Methyl-3-furanthiol	Nutty, roasted	
	Mercaptomethylbutyl formate	Cat urine, sweet	
	4-Mercapto-4-methylpentan-2-ol	Grapefruit	
	3-Mercapto hexanol	Grapefruit, sulfury, tropical	
Strawberry	Methyl thioacetate	Sulfurous, cheesy	[9.62]
	Methyl thiobutanoate	Sulfury, cheesy, cabbage	
Melon	Methyl 2-(methylthio)acetate	Baked potato, pungent, rancid	[9.17]
	Ethyl 3-(methylthio)propanoate	Clean, fresh, melon	
Muskmelon	Ethyl (methylthio)acetate	Cucumber	[9.63]
	Ethyl 3-(methylthio)propanoate	Fruity, green	
Orange	Methional	Cooked potato	[9.29]
	p-Menth-1-ene-8-thiol	Grapefruit-like	

Sulfur Compounds

Sulfur-containing compounds are usually very potent with low odor thresholds, their odor quality varies with concentration [9.64, 65], and they are very labile and difficult to separate from other compounds for analysis [9.34]. Some tropical fruits, such as durian, are well-known for their sulfury, garlic, or onion-like odors, combined with sweet flavor; indeed, 24 sulfur-like compounds were detected by GC-O in three durian cultivars [9.66]. *Mahattanatawee* et al. [9.61] detected seven and two sulfur-like components in guava and mango, respectively, and 11 compounds in lychee [9.50] (Table 9.1). *Du* et al. [9.67] identified 19 volatile sulfur compounds in 12 Florida strawberry cultivars, with methanethiol and methyl thioacetate being the most abundant and with the presumably highest odor activity. Methyl thioacetate and methyl thiobutanoate, produced in the largest amount in Strawberry Festival [9.67], were detected by GC-O in this cultivar and in Florida Radiance [9.62] (both are strawberry cultivars) (Table 9.1). Thioesters are the type of sulfur compounds produced in melons [9.68–70] and some were found to be important contributors to the characteristic melon note [9.17, 63, 71] (Table 9.1). In citrus, most sulfur compounds occur in grapefruit [9.72], with 4-mercapto-4-methylpentan-2-one and 1-*p*-menthene-8-thiol contributing to the typical sulfurous, grapefruit-like odor [9.73]. However, a few sulfur compounds were reported in fresh squeezed oranges [9.29, 74] (Table 9.1) and in tangerine [9.59], although none were identified in the latter research. Even though consumed as a vegetable, tomato is a fruit and its flavor has been widely studied. Isobutylthiazole is a sulfur compound with important contribution to tomato flavor [9.75] and contributes to the *viney*, *green*, *earthy*, and *musty* descriptors [9.37].

9.1.2 Effect of Genetic and Environmental Factors

While each fruit species has its own flavor signature, flavor types may greatly vary within a species. For instance, within the sweet orange species, *Citrus sinensis*, the blood orange types are very different from blond oranges commercially used in orange juice (*Valencia*, *Hamlin*) [9.76] (Fig. 9.1). Not only the volatile profile is different, but also blood oranges are the only types of oranges that produce anthocyanins. Generations of breeding for growing fruit adapted to certain climatic zones have brought about commercial strawberries (*Fragaria* × *ananassa* Duch.) that have quite different volatile profiles between those grown in subtropical Florida and those grown in temperate European climates [9.62]. To further complicate the matter, interspecific breeding has resulted in new species and continues to be a source of diversity for modern breed-

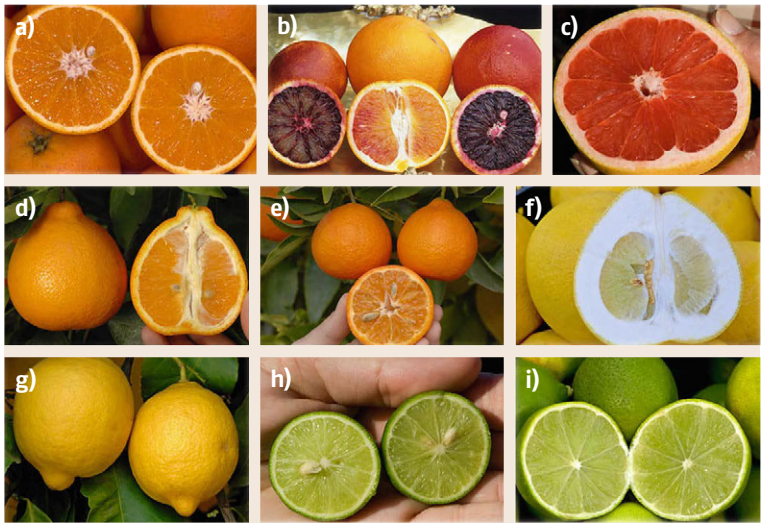

Fig. 9.1a–i Diversity in the genus *Citrus*: **(a)** Valencia orange (*Citrus sinensis* [L.] Osbeck); **(b)** Blood oranges (*Citrus sinensis* [L.] Osbeck); **(c)** Star Ruby grapefruit (*Citrus paradisi* Macf.); **(d)** Minneola tangelo (hybrid of Duncan grapefruit and Dancy mandarin); **(e)** Mandarin, *Algerian clementine* (*Citrus clementina* hort. Ex Tanaka); **(f)** Reinking pummelo (*Citrus maxima* (Burm.) Merr.); **(g)** Foothill Lisbon lemon (*Citrus limon* [L.] Burm. f.); **(h)** *Mexican* lime (or *Key* lime) (*Citrus aurantiifolia* [Christm.]); **(i)** *Bearss* lime (*Citrus latifolia* Tan.), Photos courtesy of David Karp, University of California, Riverside

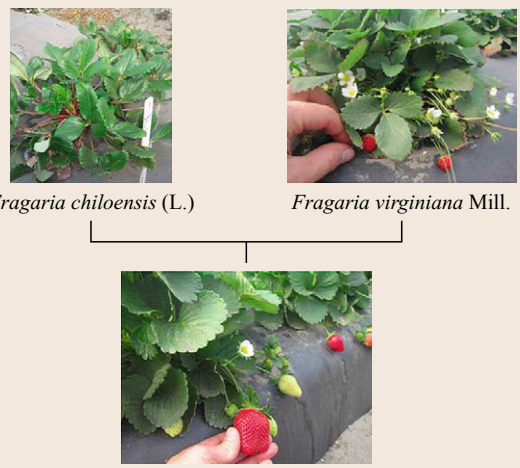

Fig. 9.2 Modern commercial strawberry, *Fragaria* × *ananassa* Duch., and its parents, *Fragaria chiloensis* (L.) Mill. and *Fragaria virginiana* Mill. Photos courtesy of Vance Whitaker, University of Florida

ers. For example, the modern cultivated strawberry, *Fragaria* × *ananassa* Duch., is the result of spontaneous hybridization between *Fragaria chiloensis* (L.) Mill. and *Fragaria virginiana* Mill. [9.77] (Fig. 9.2). *F.* × *ananassa* inherited its large size from *F. chiloensis* and its bright red color from *F. virginiana*. However, breeding for commercial production has emphasized traits such as fruit size, disease resistance, and ability to withstand handling and transportation, and as a result, flavor diversity has narrowed. This effect is observed over and over in many crops, including tomatoes, apples, and strawberries. For strawberries, current research interest is in reintroducing methyl anthranilate, a sweet and grape-like volatile component, in new cultivars. Methyl anthranilate is only produced in wild-type species of *F. vesca* and *F. moschata* [9.77]. New varieties (or cultivars) are released when the traits remain stable over several years. For example, the strawberry selection *FL-00-51* was always sweeter and produced more esters and lactones than other selections, regardless of weather pattern [9.36]. That selection has been released with the name of *Florida Elyana* [9.78].

Once new varieties are released and adopted commercially, growers learn how to optimize their growing conditions. Maturity is an important factor affecting fruit quality, and harvest maturity is crucial in determining the storage potential of some fruit such as tomatoes, apples, and pears. Fruit accumulate sugars and acids as they develop, and acids usually decrease upon ripening. Volatiles also change accordingly. Volatile changes with fruit ripening, together with sugars and acids, were documented in tomatoes [9.79, 80], oranges [9.81], apples [9.33, 82], and strawberries [9.67, 83, 84].

Handling and storage also affect fruit volatile production. In apples and tomatoes, reducing fruit respiration rate after harvest maintains fruit firmness and acidity, but lower volatile production ensues. Lower respiration rate is traditionally achieved with cold storage, with the risk however to induce chilling injury, especially in tomatoes that are susceptible to temperatures below 10–13 °C. One of the symptoms of chilling injury in tomatoes is reduction of volatile production [9.37, 75]. Reducing metabolic activity has commercially been done using controlled atmosphere storage in apples, where atmospheric oxygen is reduced

to 1–2% and carbon dioxide increased to 1–2%. Nowadays, the ripening inhibitor 1-methylcyclopropene (1-MCP) has accomplished the same purpose. For each technique, there is a compromise between extending fruit visual qualities in storage and optimizing eating quality [9.85].

Processing also induces changes in fruit volatile profile. Disrupting fruit cells release enzymes that are otherwise membrane bound. Further heating for pasteurizing may release volatiles that are glycosylated. C6 aldehydes and alcohols are typical volatiles that are released upon disruption of the plant cell. β-Damascenone is an example of compound released upon heating and only found in processed tomatoes [9.86]. Reviews of the effect of processing on tomato and orange flavor have been published [9.87, 88].

9.2 Impact of Volatiles on Fruit Flavor

Flavor is an important component of internal fruit quality and volatiles are responsible for specific fruity characters. However, it is the interaction of volatiles with nonvolatile compounds that truly contributes to the sensory perception of a food. *Baldwin* et al. [9.37] showed how some volatiles could increase or decrease the perception of sweet and, sour taste in fresh tomatoes. Sweetness and sourness in fruit are due to the presence of sugars and acids, with minerals that may affect buffering capacity and modulate perception of sourness [9.89]. Phenolic compounds, anthocyanins, alkaloids, and amino acids may elicit other sensory responses such as astringency, bitterness, and umami. The presence of long-chain polysaccharides, such as pectin and other cell wall polysaccharides, can affect the mouth feel of a fruit or fruit beverage. All these nonvolatile compounds interact with aroma volatile compounds within the intact fruit, and in the mouth upon chewing, which determines the overall sensation of aroma and taste, which comprise flavor.

9.2.1 Volatile Analysis of Fruit Commodities

Fresh produce, both fruits and vegetables, once removed from the plant, continue to undergo metabolic activities. Choosing the appropriate time for sampling is critical for flavor analyses: volatiles fluctuate during maturation, new volatiles are produced while others are metabolized, and they interact with nonvolatile components (sugars, acids, phenolics) which also change upon fruit maturation. Further, fruit-to-fruit variation makes flavor studies complicated, and sampling criteria must be rigorous to minimize this variation [9.90]. Sample preparation is also critical, as once a fruit is cut, homogenized, or macerated, enzymatic reactions occur that can affect flavor components, and need to be controlled, depending on the purpose of the study [9.91]. One well-known chain of enzymatic reactions that occur upon cutting, macerating or blending plant tissue results in C-6 aldehydes formed from oxidation of lipids (this book, Chap. 2). *Buttery* and co-workers [9.87] proposed adding an equal volume of saturated salt (sodium chloride or calcium chloride) to the homogenate in order to denature enzymes. In our laboratory, we found that sodium chloride was a better denaturant than calcium chloride for some fruit that contained high levels of pectin such as mango, apple or strawberry. The calcium ion from calcium chloride bonded with pectin, making a gel, and retarded the release of volatiles into the headspace to varying degrees, depending on the amount of pectin in the fruit [9.58]. Other methods, such as using solvent extraction, vacuum distillation, or heat would achieve the same purpose of stopping enzyme activity, each method having its advantages and disadvantages. Many reviews and book chapters are written about sampling and analytical techniques for volatile analysis [9.92, 93]. When using solvent extraction, it is usually best to compare the odor of the extract after removing the solvent, with the initial sample [9.94]. Direct GC-O, where the sample extract does not go through an analytical column and is directly sniffed by a panel and compared to the original sample, has been useful to optimize extraction techniques of headspace volatiles by direct headspace or solid phase microextraction (SPME) [9.95–98].

Once volatiles are identified analytically, contribution of compounds to the food flavor has traditionally been determined by two approaches: threshold-based and GC-O. Correlations and models to predict sensory quality from volatile compounds can be further developed using sensory evaluation.

9.2.2 Specific Sensory Tests

Thresholds

Contribution of volatile compounds to a food flavor can be estimated after calculating the compound concentration in the food divided by its odor threshold to determine its odor activity value (OAV) or odor unit [9.18, 19]. Compounds that are present in a food at a concentration greater than their threshold are deemed to contribute to that food flavor. Volatile thresh-

olds have been compiled in several databases [9.9, 99], and have been helpful to flavorists and food scientists to formulate new flavors [9.8]. By using the same methodology [9.100], researchers at the United States Departement of Agriculture (USDA), Agriculture Research Service (ARS), Western Regional Research Center have measured thresholds of hundreds of pure compounds [9.101], which have been extensively used to determine volatile contributions to fruit and food products from GC data. However, odor thresholds vary with the dilutant in which the compound is prepared [9.13, 60, 102]. Due to interactions with larger nonvolatile molecules, odorant thresholds are usually higher in complex matrices than in water: they were about twice as much and up to 600 times higher in a deodorized apple juice or orange juice matrix [9.13, 60]. While knowing the threshold value in a matrix has helped reassess the contribution of certain odor volatiles in orange juice [9.10, 60], measuring thresholds of flavor compounds is time consuming. Also, data are more robust when they are obtained with the same panelists, using the same method. Therefore, *Cliff* et al. [9.13] proposed a model to estimate thresholds in apple or orange juice matrices based on known thresholds in water, and current knowledge of thresholds in the juice matrices. These data and approach would be useful to flavorists and food scientists in quality control and research and development for the beverage industry including orange and apple juice.

GC-O

Researchers have smelled the effluent of the gas chromatograph since the inception of gas chromatography. However, very soon, two approaches considering the human factor were developed: (1) using thresholds, where the sample is diluted and sniffed repeatedly until no odor is perceived (aroma extraction dilution analysis AEDA, [9.103]; and CharmAnalysis analysis, [9.104]), and (2) using the dose–response characteristics of each compound (*Osme* the Greek word for smell, [9.105]). Having criticized these techniques for the small number of panelists used to determine odors in a GC run (one to four panelists), other authors developed the detection frequency analysis, using up to 10 panelists [9.106, 107]. Studies comparing different methods showed similarities between them in the overall results [9.108–110], with some differences observed in detection reproducibility or discrimination between levels of compounds sniffed [9.108, 110]. An excellent critical review of the methods is given by *Delahunty* et al. [9.111]. In the end, *Grosch* [9.112] demonstrates the necessity of reconstituting the sample with the odorants having odor activity in order to confirm their contribution to the food. For the study of fruit flavors, AEDA followed by the reconstitution model was published for strawberries [9.5], grapefruit [9.73], oranges [9.29], and apricot [9.24]. Reconstitution of fruit flavor based on thresholds and odor activity of volatiles in the food of interest were published for apples [9.15], orange juice [9.113], and guava [9.114].

Another way to interpret GC-O data is by comparing statistical analyses of both GC-O and sensory data, when GC-O data are amenable to statistical analysis (for instance as in the OSME or the frequency detection methods). *Miyazaki* et al. [9.59] compared OSME profiles of five tangerine juices with their sensory characteristics by a trained panel: they found that the hybrid with the highest amount of esters and β-damascenone, all compounds having fruity odors, was characterized as having an orange-like flavor by a taste panel. Conversely, a hybrid with the most GC-O descriptors with citrus/fruity, terpeney, and metallic/rubber categories had a typical tangerine flavor with sulfury and woody notes, as described by a taste panel. More complex statistical analyses may be used for interpreting GC-O data. Partial least square (PLS) regressions [9.115, 116] with sensory as a dependent variable and GC-O peak intensity as explanatory variables were used to model strawberry [9.27] or wine [9.117] flavor. Alternatively, PLS regressions could be performed using the quantified volatiles with olfactory qualities to explain sensory data [9.118–120].

9.2.3 Effect of Nonvolatile Compounds

Eating a fruit involves the experience of texture and taste. While biting into a fruit gives the first mouthfeel impression (juiciness, crunchiness, hardness, softness), the volatile components are released upon biting, then chewing the pulp. Besides the physico-chemical interactions between volatile and nonvolatile components in a fruit or fruit juice, interactions exist at the cognitive level; the brain processes information from stimuli received through the mouth and the olfactory bulb (retronasally) to produce flavor [9.121]. Studies pairing taste and odor stimuli showed that the perception of sweetness from a sweet tastant (sucrose or saccharine) could be enhanced by the presence of a volatile with fruity or sweet odor [9.122–124]. In a series of studies, it was shown that volatile perception in the mouth could be enhanced in the presence of a congruent taste stimulus (such as a volatile associated with fruitiness presented together with sugar) [9.124–126]. When the same volatile was presented without any tastant, it was mostly perceived in the nasal cavity. Studies with complex mixtures of fruit drinks or fruit puree also showed that increasing sugar (sucrose and/or glucose) generally increased the perception of aromatics associated with

fruity/ripe fruit flavor [9.127–129]. However, increasing acidity (with citric acid) had inconsistent results, depending on the study: citric acid increased orange peel flavor in a mango puree [9.127]; it increased *apple cider* but decreased *pear-candy* flavors in an apple drink, and increased grapefruit and lemon flavor in an orange drink [9.128]; and it increased citrus flavor and decreased fruity flavors in a tomato puree [9.129].

Sugars (sucrose, glucose, fructose) and acids (citric in citrus, malic in apples, tartaric in grape) are the main nonvolatiles driving fruit eating quality, with the proper balance of sugars and acids indicating the ripeness level. But also bitter components play an important role in citrus. For example, the flavanone glucoside, naringin, is the main bitter component in grapefruit. Limonin is a bitter limonoid known to increase in some cultivars, such as *Navel*, upon disrupting the vesicles in the juicing process [9.130], and has recently become a problem in juice made from oranges affected by the greening disease due to *Candidatus* Liberibacter asiaticus [9.131–133]. Bitterness was not perceived in juice made from *Valencia* oranges because the limonin level was low, but also likely because the total content of volatiles in that cultivar is much greater than in earlier season cultivars, possibly helping to mask the bitterness. Juice processors are well aware of the effects of volatiles on the taste perception of drinks, and may be able to adjust flavors to modulate taste perception. Finally, polysaccharides such as pectin have an effect on volatile release, and effect flavor perception. This was shown with mango puree [9.127] and orange juice [9.134].

9.3 Flavor of Specific Fruits

Tomato is by far the most produced fruit crop worldwide, followed by citrus, all species combined. World tomato and citrus fruit annual productions were 140−160 and 115−118 million tons, respectively, between 2008 and 2012 [9.135]. Both crops are consumed fresh or processed in can, paste, juice, and concentrate. On the other hand, the most popular fruit flavors for use in food or pharmaceutical preparations are strawberry, citrus (orange and lemon) and apple. The flavor of these specific fruits is reviewed in this section.

9.3.1 Tomato

Fresh market tomatoes sold in supermarkets garner much criticism concerning their lack of flavor or presence of off-flavor. Consumers find that fresh tomatoes lack that *homegrown* taste [9.136] and are willing to pay a premium price for full-flavored tomatoes [9.136]. Tomatoes have a characteristic sweet-sour flavor accompanied by a complex mix of aromatic volatiles that interact with the sugars and acids [9.137]. Unfortunately, most tomatoes on the market today are bland in aroma, and the aroma present is generally green, viney, earthy, and musty, while low in fruity and floral notes [9.138]. Domestication events in Central America and Europe created genetic bottlenecks that led to a low level of diversity within the cultivated tomato [9.139, 140]. Thus, lack of flavor is likely due to the lack of genetic flavor diversity as well as the fact that it is difficult for breeders to select for this complex trait. Then environmental conditions during plant cultivation, harvest practices that do not allow the fruit to initiate ripening on the mother plant [9.80, 141], and postharvest practices that include chilling the fruit to prolong stored shelf life [9.80, 142, 143] all can contribute to poor or bland flavor. Genetics are the most important as this holds the flavor potential for a variety; however, the full flavor potential inherent in the genetics of a tomato may not be realized due to less than optimal environmental conditions, harvest maturity, and postharvest handling practices etc. Nevertheless, if the genetic potential for good flavor is not there, then no amount of careful cultivation, harvesting, and handling can make up for the lack of genetic flavor potential. For this reason, tomato breeders are adding flavor analysis to their screening programs for advanced lines to compare with standard commercial cultivars using sensory consumer panels combined with chemical analyses of flavor compounds. One success story has been the recent release of *Tasti-Lee*, now popular in supermarkets, that was bred for hot Florida conditions [9.144], the state in the US where most fresh tomatoes are grown. This tomato is also harvested with some red color to avoid the green tomato harvest that results in *immature green* tomatoes that never ripen with good quality [9.80, 141].

Of the hundreds of volatiles present in tomatoes, odor threshold studies have identified around 30 to be important contributors to fresh tomato flavor based on the odor unit concept [9.75, 87, 145] (Table 9.2). Studies spiking deodorized tomato homogenate with volatile standards with or without added sugars and acids determined the important contribution of various volatiles, known to be present in tomatoes, to overall flavor [9.37, 129]. Among them and consistent with earlier studies, β-ionone, furaneol, 6-methyl-5-hepten-2-one, and geranylacetone contributed to sweet and

fruity flavor, while C6 aldehydes, isobutylthiazole, *E*,*E*-2,4-decadienal contributed to earthy and green/viney flavor. Other approaches to determine which volatiles contribute to specific sensory descriptors or consumer liking include tasting fruit with a wide range of flavors and modeling the response with chemical components [9.49, 140, 146]. Some fruity/floral volatiles were found to enhance the perception of sweetness, whereas other volatiles associated with green notes enhanced perception of sourness [9.49]. Volatiles derived from carotenoids contributed to overall tomato flavor: geranial, geranylacetone, 6-methyl-5-hepten-2-one and β-ionone, confirmed by tasting tomatoes lacking this specific group of compounds [9.140]. In another study, spiking tomato homogenate with either sugar or acid found that, generally the sweeter the tomato, the more acceptable, whereas the acceptability of acid concentration reached a peak in acceptability and then declined, depending on the amount of sugar present [9.147].

9.3.2 Citrus

Citrus fruits are produced in most of the subtropical and tropical regions of the world and provide many uses: fresh fruit, juice, canned mandarin/orange segments, marmalade, even the peel can be used in spices and condiments. Further, citrus peel oils have their own market and are widely used in the fragrance and flavor industries, as well as having industrial applications as solvents, paint, resins, etc. Contrary to all other fleshy fruits that produce volatiles in the cell vacuoles, citrus fruits have a largely developed peel that contains the oil glands. Consumers experience citrus flavor when they peel a fresh fruit, hereby splashing the peel oil into the atmosphere and transferring it to the edible segments, and by incidentally or purposely adding peel oil to the juice. Volatiles contributing from peel oil are usually water insoluble and very rich in the monoterpene limonene: 90–96% in sweet orange (*Citrus* × *sinensis* [L.] Osbeck), grapefruit (*C.* × *paradisi* Macfayden), and bitter orange (*C.* × *aurantium* L.); 60–80% in lemon (*C.* × *limon* [L.] Burm); 49–60% in lime (*C. aurantifolia* [Christm.] Swing., and *C. Latifolia* Tan.) and 23–50% in bergamot (*C. bergamia* [Risso] Wright & Am) [9.148]. Cultivars of mandarin/tangerine (*C. reticulata* Blanco) are numerous and present a great diversity of volatile components in peel oil, some contain as high as 90–96%, and others contain as low as 60–80% of limonene [9.148]. Other abundant components include β-pinene (high in lemon, lime, and bergamot); γ-terpinene (high in lemon, lime, bergamot and mandarin); citral (mixture of isomers of geranial and neral, high in lemon and lime); linalool and linalyl acetate (both predominant in bergamot); valencene and α-sinensal (high in bitter and sweet oranges, clementine and mandarin); β-sinensal (high in bitter and sweet oranges, clementine and grapefruit); nootkatone (high in bitter orange and grapefruit, and trace in lemon and bergamot); δ-3-carene (a key component at trace level in most of the citrus oils except sweet orange); and methyl N-methylanthranilate, thymol, and its methyl ether (only in mandarin/tangerine) [9.148]. For most citrus, peel oil is a by-product of juice processing, such as in orange and grapefruit, while some citrus are cultivated exclusively for their peel oil, such as bergamot and bitter orange. Not only being used for food and drink, citrus peel oils are also widely used in cosmetics, perfumes, detergents, body care products, and pharmaceutical preparations [9.149]. The most recent compilation of citrus oil composition and analytical techniques can be found in [9.150].

In addition to sweetness and sourness, bitterness is an important component of flavor in some citrus such as grapefruit or bitter orange. Bitterness may be brought out by limonoids or flavonoids, depending on the sugar moiety attached to the aglycone structure. Naringin in grapefruit and sour orange, as well as neoeriocitrin, neohesperidin, and poncirin in sour orange are all neohesperidose flavanone glycosides [9.151, 152]. Limonoids (limonin and nomilin) are bitter compounds that impart bitterness to orange juice made with some cultivars such as *Navel* [9.130], or to juice made with fruit affected by the citrus greening disease [9.132]. Both, flavonoids and limonoids, are mainly present in the fruit peel. From the taste features, citrus can be easily divided into four types: *sweet and sour* sweet oranges, *sweet* mandarins (low acid), *mild sour with variable bitter taste* grapefruit, *acidless* sweet limes, and *sour* lemons and limes [9.153]. Volatile compounds may increase perception of sweetness or bitterness when present above threshold in a juice matrix [9.10]. However, modulating sweetness or bitterness with volatile compounds such as in tomato [9.37] has not been published, and may only be a trade secret of juice processing companies.

Fruity, citrus, tropical (mango, passion fruit), fruity-non-citrus (apricot, peach), floral, terpeney, chemical, green/grassy, fatty, soapy, metallic, herbal, and mushroom are most often used in GC-O and sensory descriptions for citrus aroma [9.10, 34, 154]. They are the result of volatile terpene hydrocarbons, aldehydes, alcohols, esters, ketones, sulfur compounds, and other minor components in the juice sacs and oil glands.

Oranges and mandarin/tangerine flavor consists of more than 200 or 300 volatiles, respectively, although only about 36–49 volatiles had aroma activity and essentially contributed to citrus odor [9.34]. There is not just one or few specific character im-

Table 9.2 Concentration and odor thresholds of major components in fresh ripe tomatoes (after [9.87])

Compound	Concentration (ppb)	Odor threshold (ppb in water)	Odor activity value[a]	Log odor units[b]

pact compound(s) imparting typical orange or mandarin/tangerine flavor, but instead a combination of multiple different volatiles [9.7, 59, 155]. In fresh *Valencia* and *Navel* oranges, the two main commercial cultivars, ethyl butanoate, ethyl 2-methylpropanoate, and (*S*)-ethyl 2-methylbutanoate were the esters with the greatest aroma activity by GC-O, together with wine lactone, (*Z*)-3-hexenal, and decanal [9.29], while in blood oranges, limonene, linalool, and nootkatone had the greatest concentration to odor threshold value (odor activity value) [9.156]. Granted that the differences between these two studies may be due to sample preparation, blood oranges have quite a different flavor than blond oranges (*Navel* and *Valencia*). In another study, methyl butanoate and ethyl octanoate were detected only in the blood orange cultivars (*Moro* and *Tarocco*) by GC-O, while linalool was only in the blond oranges (*Washington Navel* and *Valencia Late*) [9.76]. *Miyazaki*, et al.'s [9.157] data show that tangerine hybrids with sweet orange in their pedigree contain more esters and sesquiterpenes than mandarins/tangerines. Other generally recognized contributors to orange juices, are decanal (green, fatty, soapy), nonanal (floral, citrus), and (*Z*)-3-hexenal; (*S*)-ethyl-2-methylbutaboate (fruity), α-pinene (pine tree), β-myrcene (metallic, geranium-like), acetaldehyde (pungent, ethereal), and β-damascenone (cooked apple) [9.34]. Usually, commercially processed oranges contain more peel oil and, thus, more volatiles associated with peel oil flavor such as terpenes (α-pinene, myrcene, limonene, valencene) and straight chain aldehydes (octanal, nonanal and decanal) in contrast with hand squeezed juice or fresh fruit volatiles that are richer in esters, short chain aldehydes (C2 to C7) and ethanol [9.88, 158].

Volatiles reported across studies in mandarins/tangerines (easy to peel) include linalool, α-terpineol (floral), terpinen-4-ol (woody, earthy), nonanal, decanal, carvone (spearmint, caraway), limonene, α-pinene, and β-myrcene [9.159]. Although thymol and

methyl-N-methylanthranilate differentiate mandarins/tangerines from oranges and may play important roles in flavor of some mandarins/tangerines [9.160], no typical volatile production pattern was found in mandarin/tangerine flavor [9.59, 161, 162].

Unlike oranges and mandarines/tangerines, grapefruit juice consists of a few character impact compounds – nootkatone, 1-*p*-menthene-8-thiol and 4-mercapto-4-methylpentan-2-one [9.51, 73, 163], which provide typical grapefruit-like odor. Other major aroma contributors include ethyl 2-methylpropanoate, ethyl butanoate, (*S*)-ethyl 2-methylbutanoate, wine lactone (sweet note), (*Z*)-3-hexenal, and (*E*)-4, 5-epoxy-(*E*)-2-decenal [9.72].

Citral is considered as a key character impact compound of lemon odor [9.164], and other major constituents are limonene, α-terpineol, terpinen-4-ol, neral, geranial, neryl acetate, geranyl acetate, linalool, and 2-methyl-3-buten-2-ol [9.165, 166].

Harvest maturity and postharvest storage affect fruit flavors. Citrus fruit usually have wide harvest windows, from a few weeks to a few months. After reaching harvest maturity, sugars keep increasing slowly and acids decrease quite fast over the harvest season [9.81]. *Bai* and co-authors [9.81] observed that *Valencia* oranges harvested in April and May had more terpene hydrocarbons, aldehydes, and esters and total volatiles in comparison with fruits harvested in February and March. Compounds that increased dramatically were β-myrcene, γ-terpinene, valencene, ethyl butanoate, ethyl acetate, hexanal, (*Z*)-3-hexenal, octanal, nonanal, geranial, and terpinen-4-ol. Meanwhile linalool, (*E*)-2-octenal, and β-ionone decreased in late harvested fruit. Total and important volatiles decreased after reaching a peak in April [9.81].

Numerous storage experiments of mandarins show that flavor quality of fruit decline for the following reasons: decrease in acidity and unbalanced sugar:acid ratio, decrease in typical aroma components, and accumulation of fermentation related off-flavor [9.34]. According to *Tietel* et al. [9.167] and *Obenland* et al. [9.168], many volatiles except acetaldehyde, ethanol, and ethyl esters, especially terpene hydrocarbons, terpene alcohols, and aldehydes which impart pleasant, desirable, fruity and citrus-like notes, decrease during storage. In contrast, volatiles derived from the ethanol fermentation metabolism and amino acid and fatty acid catabolism pathways, significantly increased during storage.

9.3.3 Apples

Apple is the third fruit produced worldwide (70–75 million metric tons, 2008–2012) after tomato and banana, and is in par with orange and table grape production [9.135]. Apple flavor has been extensively studied in the 1960s and 1970s. Initial studies aimed at identifying volatile compounds and their contribution to apple flavor [9.3, 44, 169–171]. Later, volatile profiling according to cultivar, or volatile production in fresh fruit as affected by maturity and storage were the emphasis of apple research [9.12, 33, 172–176], together with understanding the biochemical control of production of specific volatiles or volatile classes [9.177–182]. Current research aims at understanding the genetic control of volatile production [9.183–187] (Fig. 9.3).

Apple flavor is a typical example where the flavor is the combination of many volatiles without a specific character impact compound. Esters are particularly well represented in analysis of volatiles emitted by this fruit. In reviews of apple flavor, *Paillard* [9.2] listed 92 esters and *Yahia* [9.190] more than 100. Esters can account for 78–92% of the total volatiles adsorbed by activated charcoal [9.3, 191, 192]. However, the amount and type of esters depend on apple cultivar. *Paillard* [9.3] classi-

fied cultivars grown in France according to the predominant esters emitted by the fruit: acetate esters (*Calville blanc*, *Golden Delicious*), butanoate esters (*Canada Blanc*, *Belle de Boskoop*), while other cultivars produced an equal amount of acetate and butanoate esters. In comparing publications with similar sampling methods, *Golden Delicious* and *Gala* apples, two related cultivars (*Gala* is a hybrid of multiple crosses that have *Golden Delicious* as a parent, [9.193]), produced mainly butyl acetate, hexyl acetate, and 2-methylbutyl acetate [9.12, 187] (Table 9.3). Likewise, *Bisbee Delicious* produced, in decreasing order, 2-methylbutyl acetate, butyl acetate, and hexyl acetate (Table 9.3). In contrast, *Granny Smith* apple produces very little amounts of volatiles [9.187, 188]. Those two studies report different esters in *Granny Smith*: in the *Lavilla* et al. [9.188] study, propanol or propanoic acid esters were dominant, while in the *Zhu* et al. [9.187] study,

esters derived from hexanol (hexyl acetate and hexyl butanoate) were the main volatiles (Table 9.3). *Fuji* apple mostly produced ethyl 2-methylbutanoate and 2-methylbutyl acetate [9.189] (Table 9.3). Table 9.3 also illustrates an earlier observation by *Paillard* [9.3], that esters with even-numbered carbon chains from acetic, butanoic and hexanoic acids, and with ethyl, butyl and hexyl alcohols are more frequently found in apples than odd-numbered ones. In another study where volatiles were extracted by vacuum hydro-distillation, the main ester (and volatile) in *Golden Delicious* was butyl acetate, and in *Fuji*, it was butyl acetate and 2-methylbutyl acetate [9.82]. In that study like in others where authors are seeking the impact of odor-volatile compounds by GC-O, 15 compounds, out of a total of 36 detected, were selected as contributors to apple flavor. Out of these 15 compounds, 9 were esters, and butyl propanoate was detected only in *Braeburn* apple [9.82].

Other volatiles produced in large amount by apples include straight- and branched-chain aliphatic aldehydes and alcohols [9.2]. Alcohols include ethanol, propanol, butanol, pentanol, hexanol, 2-methyl-1-propanol, 2-methyl-1-butanol, 2-ethyl-1-hexanol [9.174, 187, 188]. C6 aldehydes have been reported by many authors, as well as heptanal, nonanal, and decanal. Only a few ketones have been reported in apples [9.2, 190]. They are mostly straight-chain aliphatic ketones including acetone, or the hydrocarbon 6-methyl-5-hepten-2-one. 6-Methyl-5-hepten-2-one was perceived as fruity by GC-O [9.12]. Some volatiles were found only by GC-O, as they have low odor-thresholds and are produced in very small amounts. Examples are β-damascenone and 4-methoxyallylbenzene, with characteristic sweet/grape juice/cooked apple and anise/spicy odors, respectively [9.12, 44, 194]. While β-damascenone contributes to the underlying fruity/cooked note in a fruit [9.12], 4-methoxyallylbenzene is believed to impart a characteristic spicy note to *Gala* [9.12], *Cox's Orange Pippin*, *Ellison's Orange*, and *Kidd's Late Orange* apples [9.194]. An early study of apple flavor by GC-O using CharmAnalysis [9.44] clearly summarized the fact that apples do not have volatiles that qualify as character impact. Further, the variation among the 40 cultivars tested was such that no odor-active compound was found common to all samples. In that study, β-damascenone had the most intense odor, followed by esters: ethyl butanoate, hexyl hexanoate, hexyl butanoate, and ethyl-2-methyl butanoate. *Plotto* et al. [9.15] also found hexyl acetate, butyl acetate, 2-methylbutyl acetate, methyl-2-methyl butanoate, and hexanal to contribute the most to *Gala* apple aroma by mixing volatiles in a model solution.

9.3.4 Strawberries

Strawberry is a popular fruit of temperate climates, among others because it is one of the first to be on the market in the spring. In fresh strawberries, sweetness was shown to have the highest correlation with overall liking in consumer studies, much more so than other attributes such as firmness or sourness [9.195]. In general, consumers overall liking for strawberry fruit was positively correlated with total soluble solids, total sugars (sucrose, fructose, glucose), or the ratio of total soluble solids (TSS) with titratable acidity (TA) [9.36, 195, 196]. Even though total volatiles contribute to strawberry flavor, which of the volatiles affect consumer liking is less clear and depends on the studies [9.36, 195, 196]. In GC-O studies, compounds with high odor activities are esters, furanones, some lactones, alcohols, aldehydes, and acids. Most frequently cited esters are methyl and ethyl butanoate, ethyl and methyl hexanoate, and ethyl 2-methyl butanoate, all having fruity aroma [9.4, 5, 27, 62]. Interestingly, in one consumer study, the cultivar that had the lowest amount of esters was the least preferred, in spite of its highest sweetness and TSS/TA level [9.36], showing the important contribution of fruity esters to strawberry flavor. Compounds with the greatest aroma activities by GC-O are by far furaneol (2,5-dimethyl-4-hydroxy-3(2H)-furanone (DMHF)) and mesifurane (2,5-dimethyl-4-methoxy-3(2H)-furanone (DMMF)) [9.5, 62, 197]. These two furanones were identified early on because of their strong sweet and pleasant odors [9.198, 199]. However, because they are highly water soluble and thermally instable, their quantification may not always be accurate when analyzed and reported together with other volatiles [9.30, 83]. It may explain why furaneol was not reported as a contributor of strawberry flavor or sweetness-enhancing volatile in two studies [9.195, 197]. Lactones (γ-decalactone, δ-decalactone, γ-dodecalactone) were identified in strawberry with high odor-activity in some cultivars [9.4, 62, 197], and positively contributing to consumer liking [9.36, 195]. In fact, furaneol and γ-decalactone were chosen as target compounds to enhance strawberry flavor in a breeding program [9.200]. Among aliphatic alcohols, aldehydes, and acids, (*Z*)-3-hexenal had the highest odor activity value in one study [9.5], but (*E*)-2-hexenal and hexanal are also reported [9.27, 62, 197]. As mentioned earlier, these volatiles are the result of sample preparation, and may vary greatly between studies [9.36]. They nevertheless contribute to green, fresh flavor when chewing the fruit. Hexanoic acid, high in *Senga*, had a negative effect on strawberry flavor in spite of high mesifurane and γ-decalactone levels in that cultivar [9.4]. Few terpenes were reported,

with linalool, geraniol, and/or nerolidol contributing to odor activity [9.27, 62, 197] and overall strawberry flavor [9.77, 195]. Sulfur compounds were also reported in strawberries, mostly methyl thioacetate and methyl thiobutanoate [9.62, 84, 195, 201]. Their contribution to strawberry flavor has not been precisely defined; however, they might enhance overall fruitiness.

Like in all horticultural crops, volatiles in strawberries depend on species, cultivar, maturity, and environmental factors. Commercial cultivars are the result of generations of crosses that have improved production yield, disease resistance, fruit size, handling and storage, to the detriment of flavor quality [9.4]. Recently breeders are trying to introduce *old* flavors (flavor from wild type species) into new cultivars. With that goal in mind, *Ulrich* and co-workers analyzed the volatiles of cultivated and wild-type strawberries, and then evaluated them by GC-O and sensory taste panels [9.4, 77]. In summary, the old European wild strawberry, *Fragaria vesca* (Fig. 9.4), is unique in that it produces high amounts of methyl anthranilate, a compound with typical grape flavor. High amounts of methyl anthranilate (greater than 1 ppm) can impart an unpleasant perfumey and soapy flavor [9.77]; however, in combination with furaneol and mesifurane, smaller amounts of methyl anthranilate produced fruit with highly desirable flavor [9.4]. Another wild species, *F. moschata* (Fig. 9.4), with pleasant aroma and taste, was characterized by large amounts of esters and terpenes, contrary to some commercial cultivars that had a much lower quantity of these fruity volatiles. These studies and others [9.202] are building blocks to understand the distribution of volatiles in different species and intra- and interspecific crosses. Modern genomic tools will identify genes that control volatile production, and together with the knowledge of genetics, make breeding for enhancing fruit flavor more efficient [9.203–205].

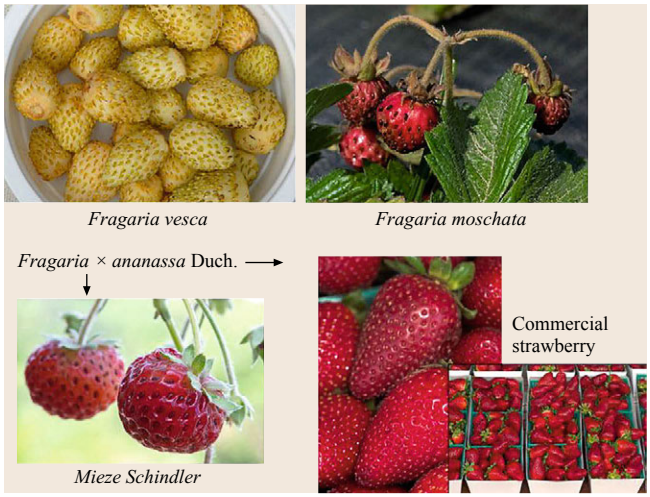

Fig. 9.4 Strawberries producing high (*Fragaria vesca*) or medium (*F. moschata* and *F.* × *ananassa* Duch., *Mieze Schindler*) amounts of methyl anthranilate, in comparison with the commercially cultivated strawberry (*F.* × *ananassa* Duch.) which produces no methyl anthranilate. 9.4 Conclusion

Considering the diversity of fruits on earth, it is expected to find a wide array of volatile chemicals producing very diverse flavors, together with nonvolatile compounds. If there are some common volatiles across plant species, their quantities will vary with the species and variety. Further, for horticultural crops, fruit composition will be greatly dependent on cultivar, maturity, postharvest handling, and environmental factors during fruit development. The authors of this chapter hope they have succeeded in conveying the complexity of a biological commodity such as a fruit, and how fruit quality must be studied across multiple facets.

10. Meat

Jane K. Parker

The delicious aroma of freshly cooked meat is highly attractive, stimulating the gastric juices, and giving us early indications that the meat and its eating experience are likely to be enjoyable. Consequently, there is much interest from the food industry in understanding how to control and optimize meat aroma. The aroma profiles of cooked and cured meats are extremely complex, comprising several thousand volatile compounds, of which only a few impart characteristic meaty notes. This chapter covers the characterization of meat aroma, identifying those compounds that impart meaty aromas and those that give species character, as well as those which generate off-notes. The formation pathways of these compounds are reviewed, and the role of pre- and post-slaughter conditions in altering the aroma profile of the meat is discussed. Production of optimum meat flavor involves careful selection of diet and breed, good control over pre- and post-slaughter conditions, and choice of appropriate processing conditions to maximize the formation of taste and aroma compounds.

10.1 Introduction to Meat Flavor

The aroma of meat is one of the attributes which, in conjunction with others such as color, taste, texture, juiciness, and tenderness, combine to give us the overall sensation of meat flavor, and ultimately determine the consumer enjoyment and acceptability of the meat. Meat aroma is the subject of a vast number of journal articles and patents, with several thousand published within the last decade alone. It is the topic of many reviews [10.1–5] and, although much has already been discovered about the chemistry of meat flavor, its complexity means that it continues to challenge both academics and industrialists who seek to accurately imitate, manipulate, and control meat flavor, whether it be in roast beef, soups, or snack seasonings. The challenge for the flavor chemist is to understand which compounds are important for meat aroma (Sect. 10.2), how they are formed (Sect. 10.3), and what factors are important in influencing and optimizing the flavor of meat (Sect. 10.4).

10.1.1 Sensory Aspects

The taste and flavor of meat is hard to articulate, and many groups have drawn up standard lexicons for use with sensory panels. One such standard lexicon [10.6], developed for cooked beef, included words such as brothy, umami, roast beef, juicy, browned, fatty and salty, and these descriptors were generally regarded as positive, whereas words such as barny, bitter, gamey, and grassy had negative connotations. When beef, lamb,

and pork were compared by a sensory panel [10.7], beef and lamb were described with similar terms including barny, bitter, gamey, grassy, livery, metallic and roast beef, whereas pork and turkey were described using words such as brothy, fatty, salty, sweet, and umami. A pork lexicon [10.8] contained additional words such as nutty, green and fatty as odor terms, and bloody, metallic and piggy as overall flavor terms. Inevitably, terms such as lamby or mutton, beefy, chicken-like, and pork-like are often included in sensory lexicons as sensory panels struggle to describe the differences between species using other terms.

The aroma profile of fresh raw meat is limited to a blood-like flavor [10.1] and the characteristic flavor of cooked meat only develops during thermal processing, whilst the more delicate flavor of cured meats develops during extended storage. The volatile profiles of both cured and thermally processed meats are complex, increasingly so, as technological advances produce instruments with greater and greater sensitivity. Roast beef has been reported to contain almost 5000 individual volatile compounds [10.9], but not all these have been identified and, more importantly, only a fraction contribute to the aroma of cooked roast beef.

10.1.2 Analysis of Volatile Compounds in Meat

Over 1000 compounds have been identified in thermally processed meat, and those reported are very dependent on the techniques used for extraction and analysis. Extraction of volatile compounds from the complex matrix of muscle and fat is a challenge, since most aroma compounds are present at the mg/kg level and below. Extraction techniques can be exhaustive (i. e., they strip out all (or most of) the volatile components from the entire sample) or semi-quantitative where only the headspace above the sample is analyzed. Exhaustive extraction techniques are preferable for quantitative analysis but tend to be time consuming. Solvent-assisted flavor extraction (SAFE) developed by *Engel* et al. [10.10] is currently the exhaustive extraction technique of choice, using high vacuum and low temperatures to distill the volatiles from the food, or from a solvent extract of the food. This is particularly useful for complex matrices, particularly fatty ones, where the volatiles are often difficult to separate from the fat, but the downside is loss of the highly volatile compounds during the concentration procedures. It has replaced the use of the Likens–Nickerson simultaneous distillation extraction method [10.11] which employed higher temperatures and was susceptible to the formation of artifacts. Solid phase extraction (SPE) can be used quantitatively for meat extracts, and is particularly useful for the analysis of more polar aroma compounds that are not readily extracted using headspace techniques.

Currently, a range of headspace extraction techniques is available. Solid phase microextraction (SPME) [10.12] is the most frequently used, but there are many other variants emerging. During SPME, the headspace volatiles are concentrated onto a fiber coated in a combination of adsorbing and absorbing polymers, and the fiber is then desorbed directly in the injection port of a gas chromatograph (GC). Dynamic headspace extraction (DHE) is also popular. The advantage of this technique is that more concentrated extracts can be obtained as the volatiles are continuously swept onto a trap containing an adsorbent resin. Traps can be desorbed using a solvent, or in a bespoke injection port. Both SPME and DHE are more suitable for routine analysis than SAFE, but are only semi-quantitative, unless used in conjunction with stable isotope dilution analysis (SIDA) [10.13]. These extraction techniques are reviewed by *Elmore* [10.14, 15].

After extraction, the volatile compounds are separated by gas chromatography and detected using a mass spectrometer (GC-MS) and/or an odor port (GC-olfactometry or GC-O) where the effluent is sniffed by a trained assessor. Two-dimensional GC (Chap. 17), in combination with time-of-flight MS, is a particularly powerful technique which has been used to identify trace components in meat [10.9].

10.2 Characterization of Meat Aroma

It is important to realize that only a subset of the 4700 volatiles found in the headspace of oven-roast beef [10.9] are perceived as odorous and only a fraction of those are present in cooked or cured meat at levels above their odor threshold. Those which are odor-active are generally determined using GC-O with aroma extract dilution analysis (AEDA) [10.13]. In this technique, the odor-active components of an aroma extract are identified by GC-O and then the extract is serially diluted and reanalyzed by GC-O at each dilution. Those compounds with the highest dilution factor (FD) (those being detected in the most dilute extracts) are deemed to make an important contribution to the aroma profile of the cooked meat. However, FDs are derived from a liquid extract and do not account for the relative partitioning of the components into the headspace.

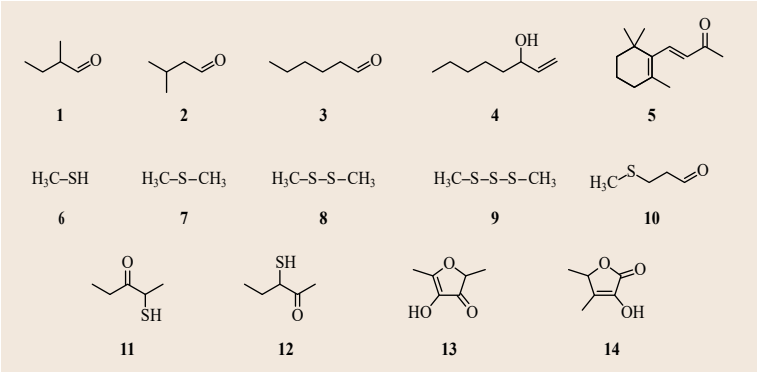

Fig. 10.1 Odor-active compounds in meat: complementary or incongruent aromas

Therefore, AEDA is often followed by quantification of the compounds with the highest FDs and formulation of a recombinate by mixing the appropriate concentrations of the most odor-active components, in the correct proportions, into a bland but representative base. The contribution of each component can be assessed by systematically removing single compounds (or pairs, or groups) from the recombinate and reassessing. Odor activity values (OAVs) can be calculated by dividing the concentration of each component in the system by the respective threshold value, and this is sometimes reported as the logarithm of the ratio. The OAV and the FD give complementary information, so those compounds with the highest FD are not necessarily the same as those with the highest OAV. Note that the result is only as good as the original extract and the proficiency of the assessors but, despite this and the natural variation in meat flavor (discussed below), there is remarkable agreement within the literature as to the compounds responsible for meat aroma.

Cerny [10.5] has compiled from the literature a list of odor-active compounds present in beef, pork, and chicken, roasted, boiled, or stewed. This list contains 100 compounds representing many classes of compounds, the majority of which are straight chain aliphatic compounds including aldehydes (C_5–C_{10}) and most of the corresponding 2-alkenals, C_9 and C_{10} alkadienals, and the branched Strecker aldehydes. The list also contains heterocyclic compounds: lactones, pyrazines, thiazoles, phenols, and sulfur compounds, all contributing a range of aromas to the overall profile which, when present in the correct proportions, gives a rounded and characteristic meaty flavor. These compounds can be classified according to their odor character, in order of increasing specificity:

1. Those compounds which are complementary or incongruent (they do not resemble meat, but are still odor-active and contribute to the overall meat aroma)
2. Those compounds which give the impression of cooked or savory aroma, but not specifically meat
3. Those which give a meaty character and
4. Those which impart species character, thus distinguishing beef from lamb, pork, or chicken.

Those in categories 3 and 4 are termed *character impact compounds* and make up only a small proportion of the odor-active compounds.

10.2.1 Complementary or Incongruent Aromas

A large proportion of odor-active compounds in meat do not, when smelt individually, resemble meat, although quantitatively they can often be major components of the volatile profile. Most of the aldehydes, alcohols, and ketones listed by *Cerny* [10.5] fall into this category, typical examples being 2,3-butanedione (buttery), the Strecker aldehydes methylpropanal, 2-methylbutanal (**1**) and 3-methylbutanal (**2**, malty, bitter cocoa), hexanal (**3**, green), phenylacetaldehyde (honey) and decanal (orange) (Fig. 10.1). These carbonyl compounds, as well as 1-octen-3-ol (**4**, mushroom), tend to be present and odor-active in most cooked foods. Other less encountered examples are 2-octanone (fruity or blue cheese) and β-ionone (**5**, floral or cooked carrots), and some are character impact compounds of other foods, for example, (*E*,*E*)-2,6-nonadienal (cucumber) and (*E*)-2-decenal (coriander), yet still appear on lists of odor-active compounds in meat.

One important contribution is made by the group of sulfur compounds that have objectionable, sulfury, rotting aromas when sniffed alone, but often play a vital role in recombinates [10.9]. These are methanethiol (**6**), dimethyl sulfide (**7**), dimethyl disulfide (**8**) and dimethyl trisulfide (**9**), as well as 3-methylthiopropanal (methional, **10**) which imparts a strong baked or dried potato note. Mercaptoketones impart a sulfury, hydrogen sulfide note, yet both 2-mer-

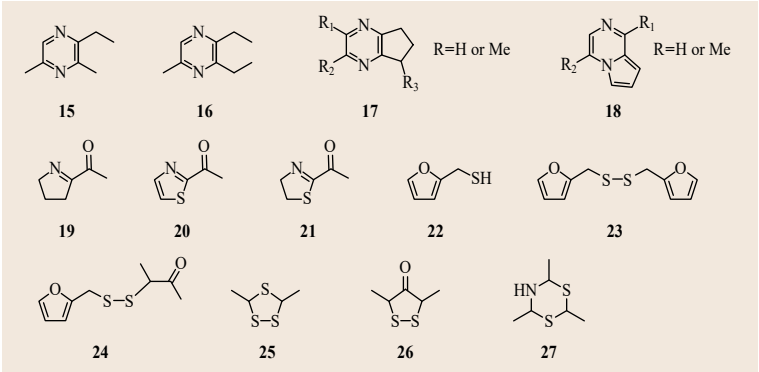

Fig. 10.2 Odor-active compounds in meat: savory and cooked aromas

capto-3-pentanone (**11**) and 3-mercapto-2-pentanone (**12**) play a significant role in the odor profile of beef, pork, and chicken [10.5].

Another exceptionally important contributor to meat aroma is 2,5-dimethyl-4-hydroxy-3[2*H*]furanone (furaneol, **13**). This compound has been found to be essential in volatile recombinates of a range of cooked and uncooked foods, particularly strawberries [10.16], pineapple [10.17], tomatoes [10.18], tea [10.19], and beer [10.20]. Alone it imparts a burnt sugar, candy-floss aroma, but it has been found to be one of the most powerful odorants in beef extracts [10.21]. Its isomer, 3-hydroxy-4,5-dimethyl-5*H*-furan-2-one (sotolone, **14**), is also important for meat flavor, imparting savory, curry and spicy notes, but also turning caramellic and maple on dilution.

Although it is not immediately obvious why these compounds are important for meat flavor, some have been shown to be vital. It is likely that these compounds are involved in interactions which may suppress or alter the more objectionable or incongruent aromas, or enhance the positive aromas. The basis for these interactions is not fully understood and is likely to be multimodal. The interactions could be physical (changes in flavor release), chemical (reactions occurring in the food), biochemical (enzymatic changes in the mouth or mucosal surfaces), physiochemical (interactions at receptor level), or psychological constructs [10.22]. The overall effect is to provide a rounded, balanced meaty flavor.

10.2.2 Savory and Cooked Aromas

Many compounds impart generic roasty, toasted, cooked (and burnt) notes, not only to thermally processed meat, but also to a range of cooked foods such as roasted nuts, french fries, potato snacks, popcorn, bread crust, biscuits, and so on. These compounds are predominantly derived from the Maillard reaction (Sect. 10.3.1), a complex process involving the reaction between reducing sugars and an amino nitrogen, and they are usually heterocyclic, belonging to chemical classes such as furans, oxazoles, pyrroles, pyrazines, thiophenes, thiazoles, thiazolines, and sulfides (Fig. 10.2). Pyrazines play an important role in cooked aromas, particularly the tri-substituted pyrazines such as 2-ethyl-3,5-dimethylpyrazine (**15**, roasty, nutty, cocoa) and 2,3-diethyl-5-methylpyrazine (**16**, potato-like, roasty) which are present in meat at low levels compared to the less substituted pyrazines, but have much lower odor thresholds (1 and 0.05 µg/kg, respectively [10.23, 24]). Two series of bicyclic pyrazines, one based on the 6,7-dihydro-5(*H*)-cyclopentapyrazine structure (**17**) and the other a group of pyrrolopyrazines (**18**), have been found in grilled, roasted, and burnt meat, imparting the characteristic roast note to their flavor profile [10.25, 26]. 2-Acetyl-1-pyrroline (**19**), which is a character impact compound in bread crust, is often found to be odor-active in meat products.

The role of sulfur compounds is of paramount importance in roasted flavors. 2-Acetylthiazole (**20**, nutty, popcorn note) and 2-acetyl-2-thiazoline (**21**, biscuit cracker note) are crucial for bakery products like biscuits, but are also found to contribute to meaty aromas, particularly beef.

2-Furanmethanethiol (**22**) is incredibly important in meat flavor and imparts a slightly meaty or roasted coffee note depending on the concentration. *Kerscher* and *Grosch* [10.27] have reported this compound in meat at 2–40 µg/kg, well above its reported threshold value of 0.005 µg/kg [10.28]. Related disulfides also give savory aromas, e.g., bis(2-furanmethyl) disulfide (**23**) which gives a roast, nutty, and baked aroma, and has been found to be odor-active in boiled chicken, and 3-[2-(furanmethyl)dithio]-2-butanone (**24**) and homologues which are reported to impart onion and burnt rubber aromas [10.29]. This last reference lists the odor properties of 30 sulfur compounds formed in a model system, mostly mer-

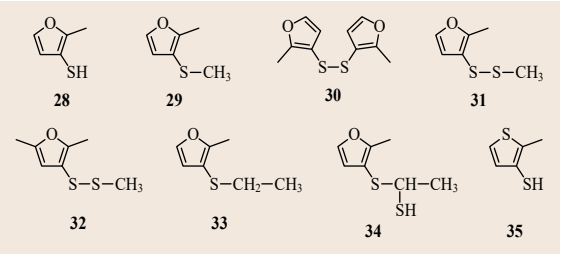

Fig. 10.3 Odor-active compounds in meat: meaty character impact compounds

captoketones, many of which impart sulfury, savory, or cooked aromas.

A series of cyclic sulfides, either thiolanes or thiolanones, was extracted from meat using Likens–Nickerson extraction [10.1]. They are not as potent as some of the compounds discussed above, but their characteristic cooked aroma (roasty, vegetable or nutty) with meaty tendencies makes them potentially important in meat flavor. Of these, 3,5-dimethyl-1,2,4-trithiolane (**25**) is the most frequently encountered, imparting a fatty, oniony, and nutty aroma which has been described as slightly meaty. A series of related disulfides, for example, 3,5-dimethyl-1,2-dithiolan-4-one (**26**) was synthesized [10.30] and most were found to have spicy, roasty, and savory character. *Werkhoff* also discusses the role of 1,3,5-dithiazines (e.g., thialdine **27**) which he believes are important for meat flavor and which tend to impart roasty, oniony, nutty, and occasionally meaty aromas [10.1]. Although these cyclic compounds have been found in model meat reactions [10.31], they are rarely found in meat, other than in SDE or Likens–Nickerson extracts. More recent studies have shown that they are formed during these extraction techniques, so their quantities can be overestimated [10.32]. Although this suggests that their contribution to meat aroma is perhaps minimal, their formation in model systems is important for the generation of meaty aroma in process reactions.

10.2.3 Meaty Character Impact Compounds

The majority of compounds that provide the characteristic meaty note are sulfur compounds (Fig. 10.3). They are also derived from the Maillard reaction, specifically from cysteine and ribose (Sect. 10.3.1), although there are alternative formation pathways from thiamine (Sect. 10.3.3) and ascorbic acid. These precursors are relatively abundant in meat, compared to cereals and vegetables. A breakthrough in the flavor chemistry of meat was made in 1976 by *Evers* et al. [10.33] who isolated, identified, and synthesized a family of meaty sulfur compounds based on the 2-methyl-3-furanthiol moiety (**28**), which included sulfides, di-, tri-, and tetrasulfides as well as analogs substituted with a methyl group on the 5 position. This was followed by the isolation of 2-methyl-3-(methylthio)furan (**29**) from cooked beef by *MacLeod* and *Ames* [10.34]. The most powerful of this family, determined by *Gasser* and *Grosch* [10.35], is the bis(2-methyl-3-furan) disulfide (**30**) that imparts a characteristic meaty flavor and is one of the most powerful aroma substances known, with an odor detection threshold in water of 0.00002 µg/kg [10.36]. The parent thiol (**28**) also has an exceptionally low threshold of 0.0004 µg/kg [10.37], whereas both the methyl sulfide (2-methyl-3-(methylthio)furan) (**29**) and the methyl disulfide (2-methyl-3-(methyldithio)furan) (**31**) impart meaty notes at low concentrations, but have odor thresholds several orders of magnitude higher (0.05 and 0.01 µg/kg, respectively [10.28, 34]). The analogs with an additional substituent on the furan ring can also impart meaty notes 2,5-dimethyl-3-(methyldithio)furan (**32**) which has an odor threshold of 0.01 µg/kg [10.28]. This family of compounds is consistently found to contribute to meat flavor, particularly the parent thiol (**28**) and the bis-disulfide (**30**) which are generally believed to be the character impact compounds of meat.

Werkhoff et al. [10.1] isolated a further 100 sulfur compounds from Likens–Nickerson extracts of cooked pork and some of these were also present in beef or lamb. Some of these are of particular interest because of their meaty aromas, although they are not

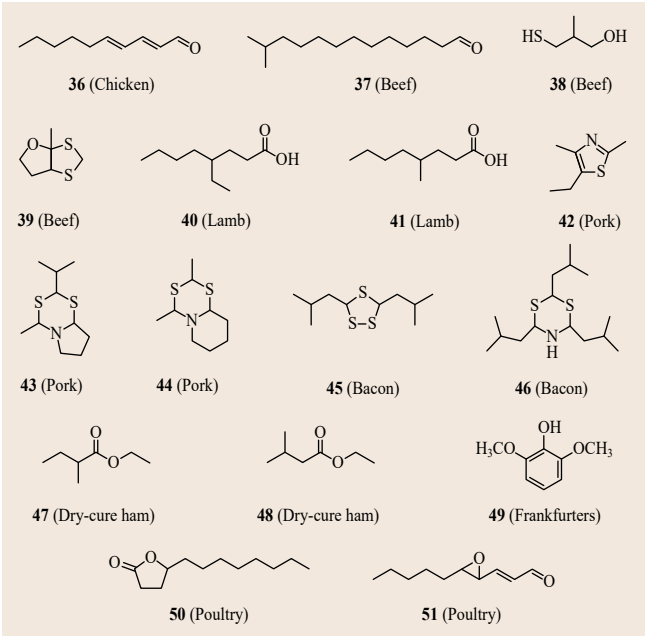

Fig. 10.4 Odor-active compounds in meat: species-specfic aromas

often detected by GC-O. The more odor-active ones are closely related to 2-methyl-3-furanthiol (**28**). For example, 2-methyl-3-(ethylthio)furan (**33**), which was found in chicken, imparts fatty and rubbery notes, but at low concentrations has a meaty, brothy aroma. This is typical of many sulfur compounds that impart meaty, vegetable or even fruity notes at concentrations close to their thresholds, but quickly develop particularly offensive sulfury, rubbery notes as the concentration increases. The ethanethiol analog (1-(2-methyl-3-furanthio)ethanethiol) (**34**) was isolated from pork and reported to have a powerful meat-like aroma, and replacement of the furan ring with a thiophene ring also produced a meaty note (2-methyl-3-thiophenethiol (**35**)).

10.2.4 Species Character

Species character is usually (but not exclusively) provided by the lipid-derived volatiles (Fig. 10.4). This was demonstrated in the 1960s by *Hornstein* and *Crowe* [10.38] who showed that aqueous extracts of lean beef and pork produced a similar meaty flavor, whereas heating beef and pork fat produced the characteristic species-specific aromas.

Beef

Beef is a popular meat, with a global consumption of over 5×10^7 t/a, typically boiled, roasted, or stewed. *Gasser* and *Grosch* [10.35] determined 40 odor-active compounds in an SDE extract of boiled beef. The most potent of these (with dilution factors of 512) were the two meaty compounds (2-methyl-3-furanthiol (**28**) and bis(2-methyl-3-furan) disulfide (**30**)), two savory compounds (methional (**10**) and one unidentified roasted compound), two fatty compounds ((*E*,*E*)-2,4-decadienal (**36**) and (*E*)-2-nonenal), and β-ionone (**5**) (violet). However, the compounds that provided the species character were bis(2-methyl-3-furan) disulfide (**30**) and 12-methyltridecanal (**37**). The disulfide contributes to the meaty aroma of all species of meat but, in beef, where it is present at higher concentrations, it imparts the characteristic aroma of aged prime-rib of beef. The aldehyde (**37**) that was found in stewed beef [10.39] is derived from plasmalogen lipids and has a distinctive beef tallow aroma with an odor- threshold of 0.01 µg/kg. The longer chain analogs have subsequently been identified in cooked beef.

The most potent aroma compounds in stewed beef were reported by *Guth* and *Grosch* [10.40]. Using AEDA on an ether extract, furaneol (**13**) was found to have the highest dilution factor, followed by butanoic acid and acetic acid. After quantification and determination of the odor thresholds, those with the highest odor activity were found to be methanethiol (**6**), followed by 12-methyltridecanal (**37**), furaneol (**13**), and acetaldehyde. 2-Methyl-3-furanthiol (**28**) was not reported as odor-active in this study, although 2-furanmethanthiol (**22**) was detected at the lower end of the odor-activity scale. Twelve of these components were required to make up a recombinate (in a base containing oil, gelatine, potassium hydrogen phosphate, lactic acid, and glutamate) which was judged by five panellists to be similar to the stewed beef juice. By systematic elimination of one single component at a time, removal of either methanethiol (**6**), furaneol (**13**) or 12-methyltridecanal (**37**) was found to have the biggest impact on the quality of the match. 12-Methyltridecanal (**37**) was found to be one of the most odor-active components of a beef broth recombinate [10.5], followed by 2-methyl-3-furanthiol (**28**), 2-furanmethanethiol (**22**), methanethiol (**6**), nonanal and furaneol (**13**). However, removal of 12-methyltridecanal (**37**) from the recombinate on this occasion did not change the aroma of the recombinate significantly and its contribution to beef aroma is debatable.

In a novel experimental set-up, *Rochat* et al. [10.9] extracted the volatiles of roast beef directly onto an SPME fiber placed in the headspace of the tubular oven as the beef was roasting, thus minimizing the formation of artifacts and capturing the more labile compounds that may not survive more exhaustive extraction procedures. The sulfur compounds that were perceived most frequently at the GC-O sniffer port (i. e., had the highest nasal impact frequency (NIF)) were dimethyl trisulfide (**9**), methional (**10**), 2-methyl-3-furanthiol (**28**), 2-methylthiophene, methanethiol (**6**), and 2-acetyl-2-thiazoline (**21**). In this study, the compound that provided the species character was 2-methyl-3-mercapto-1-propanol (**38**) which was described as beefy, but the NIF was only 11% (i. e., it was only detected in 11% of the GC-O analyses). This compound is important because it is one of few which have been described as *beefy* which have been identified in cooked beef.

Other compounds have been reported to have beef aromas. 3[(2-Methyl-3-furan)dithio]-2-pentanone is described as meaty [10.29] and, in a compilation of the sensory properties of Maillard-derived volatile compounds, *Fors* [10.41] reported boiled beef characteristics for 3,5-dimethyl-1,2,4-trithiolane (**25**), 3-methyl-1,2-dithiolane, 2,4,5-trimethyl-3-oxazoline, and 2,4,5-trimethyloxazole. 1-Methylbicyclo[3.3.0]-2,4-dithia-8-oxaoctane (**39**) has been reported by *Etiévant* [10.42] as smelling like cooked beef, but also chicken and boiled milk. Although characteristically beefy, these compounds do not appear to be particularly odor-active and it is likely that the odor thresholds are higher than for the other sulfur compounds that are consis-

tently found to be important in beef. The threshold of 3,5-dimethyl-1,2,4-trithiolane (**25**) has been reported as 10 μg/kg, which is several orders of magnitude higher than the other sulfur compounds reported, particularly the furanthiols.

Sheep and Goat Meat

Worldwide consumption of sheep meat is about a fifth of that of beef, and its unique flavor is not as universally accepted as that of beef. A recent review of sheep meat [10.43] includes a meta-analysis incorporating all recent GC-O studies. The two furanthiols (**22** and **28**) were amongst the list of 28 odor-active compounds, but the list was dominated by lipid-degradation products. The meta-analysis demonstrated that the compound contributing the most to lamb flavor was 4-ethyloctanoic acid (**40**), a compound with a fatty, mutton flavor. Branched-chain fatty acids are believed to give the characteristic mutton notes to sheep products, and the presence of both 4-ethyl- and 4-methyloctanoic acid (**41**) is unique to ovine species when compared to beef, pork, and poultry. The homologous 4-methylnonanoic acid also has a muttony note, but has been found in other species. These acids are present at relatively high concentrations in both the cooked and raw lamb fat [10.44] and do not accumulate during processing. 4-Methyloctanoic acid (**41**) was found at 3–5 mg/kg in the adipose tissue of lambs [10.45], just above the estimated threshold value.

The meta-analysis shows that for most of the other odor-active compounds, the contribution to the headspace in both lamb and beef was similar. The exceptions were (*Z*)-2-nonenal (grass/plastic), 2-acetyl-1-pyrroline (**19**, popcorn), (*E*,*E*)-2,4-hepteadienal (fried potato), and 4-methylphenol (stable, animal) which all made a far greater contribution to the aroma profile of lamb than they did to beef. (*Z*)-4-Heptenal is often considered to be very characteristic of lamb fat.

Goat meat has been compared to lamb in a recent study by *Madruga* et al. [10.46]. Although the profiles were similar, goat meat was found to contain more compounds derived from (ω-3) fatty acids such as linolenic acid (2-ethylfuran, 1-penten-3-ol, (*Z*)-6-nonenal), whereas the lamb contained much higher levels of compounds derived from (ω-6) fatty acids such as linoleic acid (pentanal, hexanal (**3**), 1-octen-3-ol (**4**) and 2-pentylfuran). It was suggested that these differences gave lamb the much stronger flavor; however, no character impact compounds have been reported for the distinctive goaty note that distinguishes goat from lamb.

Pork

The worldwide consumption of pork is almost twice that of beef, and it is the most popular meat in Europe, consumed both cooked and cured, in many different forms.

Cooked Pork. A comparison of boiled beef and pork [10.47] showed that many of the same compounds were present, with the exception of the beef-specific aldehyde (**37**) and dimethyl sulfide (**7**) which were not found in pork. The importance of the two furanthiols (**22** and **28**) in pork aroma was confirmed [10.5] and Kerscher reported a contribution from methanethiol (**6**), acetaldehyde, methylpropanal, furaneol (**13**), octanal, nonanal and 1-octen-3-one – all compounds which have also been found to be odor-active in beef. The only distinguishing compound was 2,4-dimethyl-5-ethylthiazole (**42**) which gives a roasty earthy note.

Several meaty compounds have been found in cooked pork. Many of the cyclic sulfides were found by *Werkhoff* et al. [10.1] in cooked pork: 3-methyl-4-oxo-1,2-dithiane was described as meaty, bloody, and sulfury; 3-methyl-1,2,4-trithiolane was described as oniony and meaty; and 3-methyl-5-isobutyl-1,2,4-trithiolane was described as onion, roasty, and meaty. The bicyclic dithiazines such as tetrahydro-4-methyl-2-isopropyl-4*H*-pyrrolo[2,1-d]-1,3,5-dithiazine (**43**) and tetrahydro-2,4-dimethyl-4*H*,6*H*-pyrido[2,1-d]-1,3,5-dithiazine (**44**) are unique to cooked pork and believed to be important for pork flavor, but they are described with more generic terms such as fatty, onion, roasted, and nutty. However, a typical pork-rind aroma has been reported from two compounds isolated from a model system: 3,5-di-isobutyl-1,2,4-trithiolane (**45**) and 5,6-dihydro-2,4,6-tri-isobutyl-4*H*-1,3,5-dithiazine (**46**) [10.48].

Aroma extract dilution analysis (AEDA) has been carried out on a pork and vegetable gravy prepared *a la chef* [10.49], and 50 odor-active compounds were reported. Of these, 2-methyl-3-mercapto-1-propanol (**38**), described previously as beefy, was the compound with the highest dilution factor (4096) in both pork/vegetable and beef/vegetable gravies and was described in this study as a characteristic gravy aroma. However, it was only present in the beef or pork gravy prepared with vegetables, and not with beef alone.

The volatile profile of wild boar has been compared to that of a domestic pig [10.50]. No character impact compounds of boar were identified, and the difference in flavor was attributed to changes in the concentration of a range of potent aroma compounds.

Cured Pork Products. The curing of pork meat is a tradition going back many centuries when it was a vital method of preservation. Records start as early as Cato (234–149 BC) who described the process for dry-cure ham. Cured cuts of pork, which are not subse-

quently cooked, have quite a different aroma profile to cooked pork products. Dry-cured hams are speciality products that are aged or ripened for several months to generate the delicate flavor associated with such products. Over 600 compounds were identified in Bayonne ham [10.51], using DHE, of which 29 were odor-active. Although many of the compounds detected have also been found in cooked meat, they tend to be the compounds that contributed fruity, green, and sweet notes belonging to the chemical classes of aldehydes, esters, alcohols, and acids, rather than the thermally derived heterocyclic compounds. Other authors using dynamic headspace showed that the most odor-active compounds in Iberian ham were hexanal (**3**), (*Z*)-3-hexenal, 3-methylbutanal (**2**), 1-octen-3-one, 1-octen-3-ol (**4**), and methylpropanal [10.52], but this group also found five meaty or toasty compounds amidst those which were odor-active (2-methyl-3-furanthiol (**28**), 2-furanmethanethiol (**22**), 3-mercapto-2-pentanone (**12**), 2-acetyl-1-pyrroline (**19**), and 2-propionyl-1-pyrroline). The odor-active compounds in Parma ham [10.53] were shown to include 2-acetyl-1-pyrroline (**19**), methional (**10**), 1-octen-3-one, furaneol (**13**), 4-methylphenol, and sotolone (**14**).

The odor-active compounds reported in the volatile profile of fermented sausages [10.54] were hexanal (**3**), heptanal and 1-octen-3-ol (**4**), and a salty meat, dry-cured ham aroma which was attributed to (*E*)-2-hexenal. When the volatile profile was monitored over time using SPME [10.55], the most odor-active compounds at the beginning of the process were 3-methylbutanal (**2**), 2-methylbutanal (**1**), octanal, 2,3-butanedione, and ethyl 2-methylbutanoate (**47**), whereas propanal, pentanal, hexanal (**3**), ethyl 3-methylbutanoate (**48**), 1-octen-3-ol (**4**), 3-ethylbutanoic acid, methylpropanoic acid, ethyl hexanoate, and nonanal developed during storage.

It is clear that, to date, no single compound has been identified which gives a characteristic cured meat note and the typical flavor is derived from low levels of meaty compounds and relatively high levels of short chain aldehydes, esters, and alcohols.

Other Pork Products. Bacon is a traditional product which is prepared using different methods around the world. It is both cured and cooked to generate a unique flavor. The volatile profile of green bacon (uncooked) [10.56] contains similar classes of compounds to dry-cured ham, e.g., 3-methylbutanal (**2**), and 1-octen-3-ol (**4**). An SPME extract of Chinese sweet cure bacon [10.57], which is also smoked, contained a range of odor-active compounds, including those already discussed for cooked meat, and in addition a range of phenols derived from the smoke. Bacon aroma has been generated by *Shu* et al. [10.48] in a model system containing 3-methylbutanal (**2**) and ammonium sulfide. 3,5-Di-isobutyl-1,2,4-trithiolane (**47**) and 5,6-dihydro-2,4,6-tri-isobutyl-4*H*-1,3,5-dithiazine (**48**) were identified in the model system, synthesized, and the pure compounds were described as having typical fried bacon and pork-rind aromas.

Frankfurters are a more complex product involving the addition of spices and smoking. The odor-active compounds in frankfurters prepared from a blend of pork and beef, with and without spices (mostly pepper, mint, ginger, nutmeg, and cardamon) and smoke flavoring (hickory smoke flavoring D402V, Dalgety Food Ingredients, Dublin, Ireland), have been compared [10.58]. The odor-active compounds derived from the meat component were found to be very similar to those discussed previously (furanthiols and sulfides (**22–23** and **28–31**)), whereas those derived from the spices (α-pinene (green), 1,8-cineole (medicinal) and linalool (flowery)) were found in the commercial frankfurters and those prepared with the spice mix. A group of methoxyphenols, derived from the smoke, were highly odor-active. Of these, 2-methoxyphenol, 2-methylphenol, and 2,6-dimethoxyphenol (**49**) were found to be character-impact compounds, described by the assessors as smoky and frankfurter-like.

Poultry. Poultry flavor has been reviewed by *Dawson* and *Spinelli* [10.59], *Cerny* [10.5], and most recently by *Jayasena* et al. [10.60]. Chicken aroma has been shown to involve many of the savory and meaty compounds already discussed. However, in red meat, the meaty, sulfury notes dominate, whereas in chicken, it is the lipid-derived compounds that are more odor-active and the sulfury, meaty compounds, although still present, are far less important. *Kerler* and *Grosch* [10.61] found that the compounds with the highest dilution factor in an ether extract of boiled chicken were (*E*,*E*)-2,4-decadienal (**36**) and furaneol (**13**) (FD = 1024), followed by butanoic acid (FD = 512), sotolone (**14**), 2-furanmethanethiol (**22**), 2-acetyl-2-thiazoline (**21**), and acetic acid. Although present and odor-active in most other meat aromas, (*E*,*E*)-2,4-decadienal (**36**) is present at higher concentration in chicken aroma and is considered to contribute the species character to roast chicken. It was found to be the compound with the highest dilution factor in chicken broth [10.62] followed by the furanthiols (**22, 28**) and γ-dodecalactone (**50**). 2,4-Decadienal (**36**) is derived from linoleic acid that is present in chicken fat at higher concentrations than in pork and beef, and its oxidation product ((*E*,*E*)-4,5-epoxy-2-decenal, **51**) is also believed to contribute to fried chicken aroma.

When compared to boiled beef and pork [10.47], the odor-active compounds that distinguish chicken from beef or pork were hydrogen sulfide, hexanal (**3**), (*E*,*Z*)-2,6-nonadienal, the lack of 12-methyltridecanal (**37**), and there was a much smaller contribution from the meaty furanthiols (**22**, **28**). After quantification and formulation of a recombinate to match boiled chicken, the most odor-active compounds were methanethiol (**6**), (*E*,*E*)- and (*E*,*Z*)-2,4-decadienal, (*E*,*E*)-2,4-nonadienal and 2-furanmethanethiol (**22**).

Several alkyl-substituted trithiolanes and dithiazines have been isolated from fried chicken [10.1, 63]. They are derived from the interaction between hydrogen sulfide and aldehydes generated either from the Strecker degradation or lipid oxidation. A comparison of roasted and fried chicken by *Shi* and *Ho* [10.63] showed an increase in lipid degradation volatiles with roasting, but a decrease in 2,4-decadienal (**36**), and the Maillard reaction compounds increased significantly with frying cf. roasting. The most odor-active compounds in a fried chicken skin recombinate were found to be acetaldehyde (**64**), methanethiol (**6**), methional (**10**), and the Strecker aldehydes.

The volatile components of turkey [10.64] are similar to those of chicken and no character impact compounds have been identified which distinguish the two meats. However, turkey is more susceptible to the development of lipid oxidation and warmed-over-flavor (WOF).

Similarly, duck meat contains many of the same compounds and the list of most odor-active compounds in Bejing duck [10.65] determined by AEDA contained the same compounds as chicken, although it was particularly rich in the fatty fried alkadienals. The lipid-derived volatiles in an SPME extract of Chinese Nanjiing water-boiled salted duck [10.66] were found to be very high, accelerated by the combination of curing, brining, and roasting. *Lesimple* et al. [10.67] have reported volatiles on smoked duck fillet.

Organ Meats. Organ meat, particularly liver, is highly nutritious, low in fat, and full of vitamins and minerals, but many consumers find liver unpalatable. The first of only a few papers reporting volatiles in cooked liver was published by *Mussinan* and *Walradt* in 1974 [10.68] who identified 179 volatile compounds from a distillation extract of cooked pork liver. The classes of compounds were similar to those found in cooked meat, but the range of pyrazines and furans was far greater, probably as a result of the high glucose content of liver. Interestingly, among the 23 sulfur compounds identified, derivatives of 2-furanmethanethiol (**22**) were identified, but no derivatives of 2-methyl-3-furanthiol (**28**) were reported. One explanation is the lack of ribose, which is a key precursor, but liver contains up to 1 mg/100 g thiamine, which is also an effective precursor of (**28**). *Werkhoff* et al. [10.69] isolated 120 sulfur compounds from cooked beef liver, and reported sensory properties and MS data for several mercapto- and methylthio-substituted aldehydes and ketones. Of these, 3-mercapto-2-pentanone was described as cooked liver. *Lorenz* et al. [10.70] identified 108 compounds in different fractions of a Likens–Nickerson extract of sheep liver. No furanthiols were detected in this study, and it was suggested that the thiazoles were the most odor-active compounds. AEDA on roasted beef, pork, and duck livers [10.71] found that 2-acetyl-1-pyrroline (**19**) and 2-acetyl-2-thiazoline (**21**) had high FDs in all three roasted livers, imparting the toasted notes associated with cooked liver. A third toasty note, 2-acetyltetrahydropyridine, had a high FD only in the roasted duck liver, possibly contributing to its unique aroma.

A comparison of fried beef and pork liver from both young and old animals [10.72] using several extraction methods (Tenax trapping, SPME and steam distillation) demonstrated that the significant difference between the sheep and beef liver was the presence of unidentified methyl-branched C14, C15, and C16 aldehydes that were present in the aged and fattened beef liver, but not in the more delicately flavored calf liver or the sheep liver. These aldehydes have subsequently been identified as the group of iso- or anteiso-methylbranched aldehydes, of which 12-methyltridecanal (**37**) was identified as a character-impact compound of beef. GC-O was carried out on these extracts, and a liver-like aroma was reported in the beef liver extracts, but no compound could be assigned to that aromatic region. *Parker* et al. [10.73] recently reported the volatiles present in SPME extracts of pressure-cooked beef, pork, lamb, and chicken liver, confirming the presence of the branched aldehydes in the beef liver and showing that, analytically, the species differentiation was driven by the lipid degradation products.

Other authors have focused on the off-notes and negative attributes of cooked liver. 1-Octen-3-one (metallic), hexanol (weak metallic), 1-octen-3-ol (**4**, mushroom-like), (*E*)-2-nonenal (cardboard-like), and (*E*,*E*)-2,4-decadienal (**36**, fatty, oily) were shown by *Im* et al. [10.74] to be responsible for metallic and fishy off-notes when oxidation was induced in pork liver using oleic, linoleic, linolenic, and arachidonic acids in the presence of $FeCl_2$. These compounds can be reduced by the addition of rosemary extract [10.75].

Finnish liver sausages and liver pâtés have been compared [10.76], particularly with a view to the minimization of undesirable lipid-derived volatiles. The volatile profiles were highly characteristic of the additional ingredients, particularly the commercial products that had high levels of terpenes, derived from added flavorings, that could potentially mask the off flavors due to lipid oxidation.

One major use for cooked liver is in pet food with a global annual production of over 20 million tons. There are very few publications on pet food volatiles with only one study reporting a list of volatile compounds found in dry dog food using SPME [10.77]. There was some overlap between the compounds found in pet food and those found in meat or liver, particularly the lipid-derived aldehydes, ketones, and pyrazines, but there was a noticeable lack of sulfur compounds, reflecting the low meat content and high cereal content of many of the products. Most of the literature is in the form of patents reporting the chemical composition of palatability enhancers. Notably, butanoic acid and 3-methylbutanoic acid are reported to increase the palatability of dog food [10.78], and a range of different α-cyclic enolones can be used as palatability enhancers for dry dog food [10.79]. Various combinations of Maillard and lipid-derived products have been patented [10.80–82] and the use of herbs and spices [10.83]. Several inventors have patented particular processes, based on the Maillard reaction, for the generation of meaty aromas for use in pet food [10.84] and a multistep process has been patented by *Davidek* et al. [10.85].

10.2.5 Taste Compounds

Aroma compounds do not work in isolation. The flavor of meat is also characterized and modified by the presence of nonvolatile tastants in the meat. Those which contribute to the flavor are salts, acids (sour), sugars (sweet), and both glutamic and aspartic acid contribute to the savory/umami perception of meat flavor. The role of nucleotides such as inosine 5′-monophosphate (IMP) is essential in our perception of meaty flavor, contributing the savory and umami sensation detected on the tongue and acting as a flavor enhancer. More recently, multimodal taste enhancers have been isolated from cooked meat that have been shown to be vital in recombinates to reproduce the respective meat flavor. Alapyridaine was isolated from beef bouillon [10.86] and found to enhance sweet and umami character, whilst β-alanyl peptides identified in chicken broth gave a thick white-meat orosensation [10.87] to the broth.

10.2.6 Off-Notes

Warmed-Over-Flavor

All meats are susceptible to the generation of WOF, a distinctive off-note associated with reheated meat and particularly prevalent in re-heated poultry. In freshly boiled chicken [10.61], (*E*,*E*)- and (*E*,*Z*)-2,4-decadienal, (*E*,*E*)-2,4-nonadienal, 2-furanmethanethiol (**22**), hexanal (**3**), octanal, and acetaldehyde were found to be the character impact components; however, after refrigeration and reheating of the chicken, there was a loss of sweet chicken notes and an increase in the green, cardboard aromas. These were attributed to the sevenfold increase in hexanal (**3**) and a decrease in (*E*,*E*)-2,4-decadienal (**36**) and 2-furanmethanethiol (**22**). It is the combination of accelerated lipid oxidation and the loss of desirable notes that make the WOF so striking in reheated meat, and there are clear implications for the cook-chill industry. The mechanism is discussed in Sect. 10.3.2.

In pork, WOF was characterized by words like fishy and rancid flavor [10.88], as well as linseed oil, rubbery, and cardboard aroma, which increased as the length of storage increased. An increase in the development of WOF was also observed when the animal's diet was supplemented with iron.

The susceptibility toward the development of WOF was investigated in meat from turkey and chicken, both breast and thigh meat, and from pork longissimus dorsi muscle [10.89]. Ground meat samples from these five sources were heated for 30 min in a water bath at 60, 70, or 80 °C and stored at 5 °C for up to four days. Measurement of thiobarbituric acid-reactive substances (TBARS) and sensory evaluation showed that turkey was more susceptible to WOF than chicken, thigh meat more susceptible than breast meat, and pork was the least affected.

Pastoral Aroma in Lamb

The flavor of meat from pasture-fed sheep has a pastoral aroma to it which has been attributed to 3-methylindole (skatole, **52**) and 4-methylphenol (*p*-cresol, **53**) (Fig. 10.5). The pastoral diet, particularly when it contains lucerne and clover, contains a higher proportion of protein compared to concentrates, which is readily broken down to free amino acids by the microflora in the rumen, and subsequent anaerobic metabolism of L-tryptophan results in the production of skatole (**52**), a highly potent odor compound with a faecal farmyard aroma. Similarly, *p*-cresol is formed from the metabolism of L-tyrosine and has a manure-like aroma. Both these odor-active compounds are lipophilic and tend to deposit in the fat tissue. Addition of forage

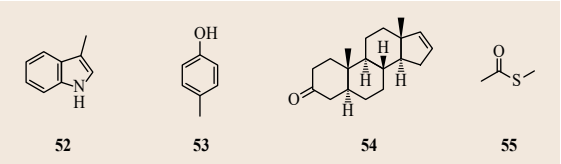

Fig. 10.5 Odor-active compounds in meat: off-notes

legumes containing high levels of polyphenols (condensed tannins) [10.90] or grape-seed extract [10.91] to the diet was found to reduce the formation of indole and skatole (**52**). In a study by *Priolo* et al. [10.92], skatole (**52**) and indole were monitored in the rumen of lambs which had been fed either herbage or concentrate with, and without, tannins. Both skatole (**52**) and indole were present at significantly higher amounts in the rumen of lambs fed on herbage, but skatole (**52**) was reduced if the feed was supplemented with tannins. The caudal fat of herbage-fed animals tended to have higher levels of indole and skatole (**52**), but this was not reflected in the sensory evaluation. Sensory evaluation did, however, show that supplementation with tannins significantly reduced the sheep meat odor.

Boar Taint

Boar taint is a problem associated with the meat from uncastrated male pigs [10.93, 94]. The compound 5α-androst-16-en-3-one (androstenone, **54**) (Fig. 10.5) is produced in the testes and transported to the sub-maxillary glands in the mouth by the blood stream. It is then released into the saliva, along with the corresponding alcohol, and volatilized into the boar's breath where it is sensed by the female who responds to the boar's advances if she is ovulating. Androstenone (**54**) accumulates in the fat of boars and this causes a taint in cooked meat. Although, amongst consumers, about 30% of males and 20% of females show anosmia to the compound, many find it extremely objectionable. In general, females are more sensitive than males, but sensitivity varies from country to country [10.95]. Those who perceive it, find the odor of androstenone (**54**) unpleasant, sweaty, urinous, and fecal. Consequently, boars for meat are slaughtered before maturity or, in some countries, they are surgically castrated usually without any pain relief. The alternative immunocastration, where vaccination against gonadotropin releasing hormone suppresses androstenone synthesis [10.96], is costly and therefore less commonly used. In the EU, due to animal welfare concerns, there has been a voluntary declaration since 2012 which, in the short term, dictates that if surgical castration is necessary, it should be carried out with prolonged analgesia and/or anaesthesia. However, in longer term (2018), it suggests that the practice of castration should be abandoned entirely and that in the meantime, research should be devoted to understanding how boar taint (and the sexual and aggressive behaviors associated with adult entire males) can be managed through breeding [10.97] and production management [10.98].

Skatole (**52**) and indole are also implicated in boar taint but, unlike androstenone (**54**) which is formed during puberty, skatole can be manipulated using the diet. Addition of fermentable carbohydrates to the feed prior to slaughter reduces the skatole in the colon [10.99]. Skatole (**54**) causes rejection at 0.2 μg/g of fat.

Others

Some off-notes in poultry are generally believed to be due to gram negative psychrotrophic bacteria and the production of H_2S [10.59] and other small sulfur molecules such as dimethyl sulfide, methyl trisulfide, and methyl thioacetate (**55**).

10.3 Mechanisms of Aroma Generation

Aroma compounds in meat are generated from the pool of precursors that exist in raw meat and develop post-slaughter. In cooked meat, the Maillard reaction is of paramount importance in generating the characteristic meaty flavor, but other pathways are also known to contribute to meaty flavor such as degradation of thiamine and ascorbic acid. Species character is generally given by the thermal degradation of lipids, and the interaction of the two can also have an impact on flavor generation. In cured products, flavor is generated via fermentation reactions which are based on the catabolism of amino acids. Again, lipid degradation is also extremely important. These pathways are discussed in the following sections.

10.3.1 The Maillard Reaction

The Maillard reaction is the basis for flavor generation in all cooked foods. It involves the reaction between a reducing sugar and an amino compound, initially forming a Schiff base, which breaks down in a cascade of parallel reactions to form not only flavor, but also color and antioxidants [10.100], as well as less desirable compounds such as acrylamide [10.101] and

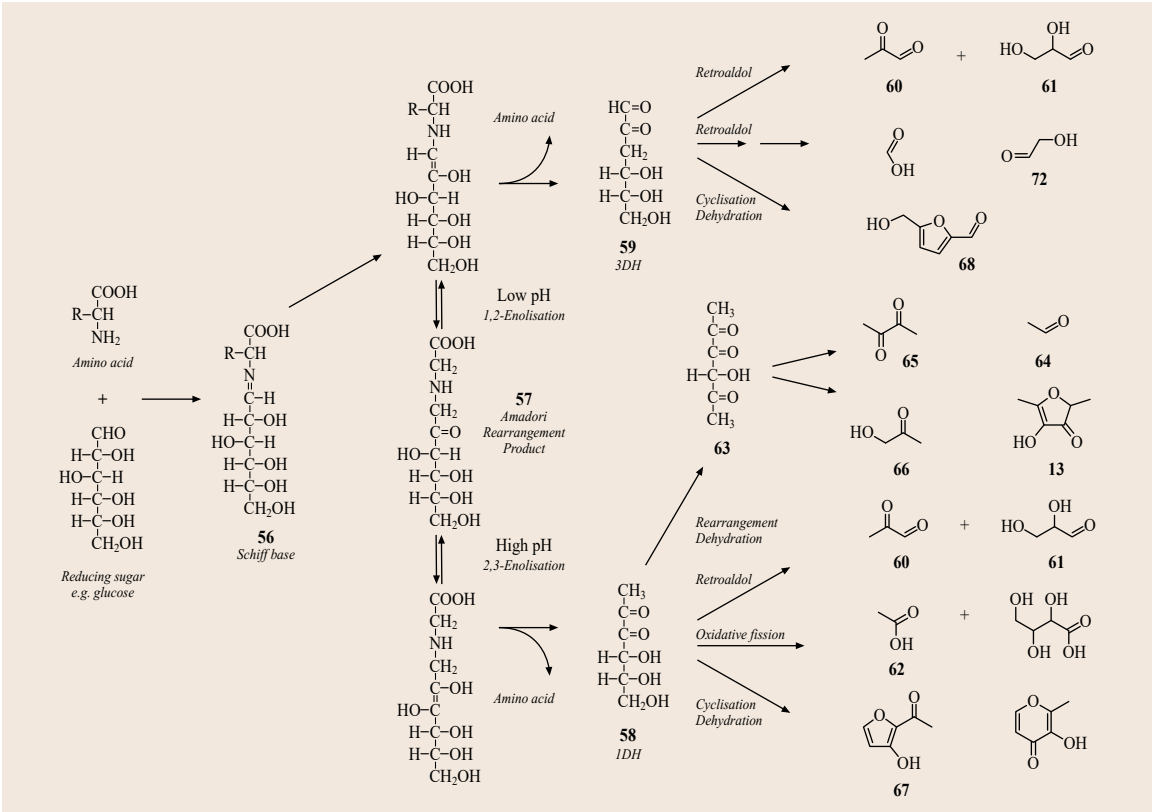

Fig. 10.6 Formation of reactive intermediates via the Maillard reaction

heterocyclic aromatic amines [10.102]. Further details of the Maillard reaction are given in Chap. 5.

The Early Stages of The Maillard Reaction

The first step involves the nucleophilic attack of the amino group on the reducing sugar to form a Schiff base (**56**) which rearranges to form the Amadori Rearrangement Product (ARP) (**57**) if the sugar is an aldose, typically ribose or glucose in meat, or a Heynes rearrangement product if the sugar is a ketose. The Maillard reaction between an amino acid and glucose is summarized in Fig. 10.6. The ARP breaks down, regenerating the amino acid and, depending on pH, forms either the 1-deoxyhexosulose (1DH, **58**) at high pH or the 3-deoxyhexosulose (3DH, **59**) at low pH [10.103]. At high pH, the deoxyhexosuloses breakdown by retroaldol or oxidative fission reactions, providing a pool of highly reactive dicarbonyl and hydroxycarbonyl compounds. For example, with glucose, retroaldolisation produces pyruvaldehyde (**60**) and glyceraldehyde (**61**), whereas oxidative fission produces acetic acid (**62**) [10.104]. Rearrangement and dehydration of the 1DH give diacetylformoin (**63**) which is the precursor for the formation of other reactive intermediates such as acetaldehyde (**64**), 2,3-butanedione (**65**), and hydroxypropanone (**66**). Some of these are odor-active in their own right (e.g., 2,3-butanedione imparts a characteristic creamy, buttery note), but they all undergo further reactions. Cyclization and dehydration of diacetylformoin give the highly odor-active 4-hydroxy-2,5-dimethyl-3(2*H*)-furanone (furaneol) (**13**). The high pH route is also important in the formation of odor-active furanones and pyranones such as 2-acetyl-3-hydroxyfuran (isomaltol) (**67**) and 4-hydroxy-5-methyl-3(2*H*)-furanone (norfuraneol) is formed by the corresponding route from pentoses. Low pH tends to favor the formation of 5-hydroxymethyl-2-furfural (HMF) (**68**) or 2-furfural (from pentoses) [10.105].

Although glucose is the major sugar present in raw meat (7–10 mmol/kg) [10.106], the aromas that it generates tend to be the cooked, roasted notes such as pyrazines and thiazoles. It is ribose, which is present at one-tenth of the concentration (0.6–1 mmol/kg), that forms the basis for the generation of characteristic meaty aromas. Pentoses can participate in the Maillard reaction, and do so faster than their hexose counterparts, certainly when color formation is considered [10.107]. When the rate constants for the first step of the Maillard

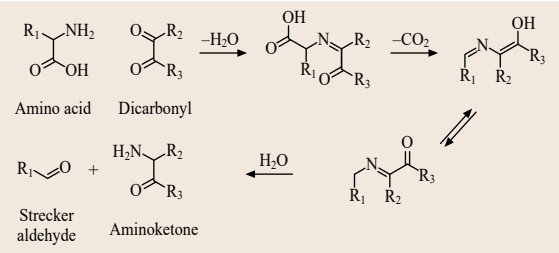

Fig. 10.7 The Strecker degradation

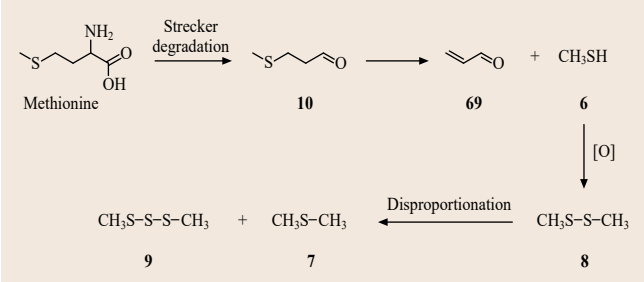

Fig. 10.8 The Strecker degradation of methionine

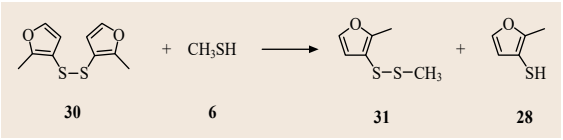

Fig. 10.9 Exchange reaction between thiols and disulfides

reaction were determined in an aqueous extract of meat heated at 130 °C, it was found that the participation of ribose was ten times faster than glucose (rate constants of 0.007 and 0.05 min^{-1}, respectively). Pentoses are less sterically hindered than hexoses and, in aqueous solution, equilibrium lies in favor of the reactive open-chain form. However, *Mottram* and *Nobrega* [10.108] showed that in unbuffered aqueous model meat systems, the major product after heating was 2-furfural, and it has been suggested from the kinetic model that 2-furfural may form directly from earlier intermediates, such as the ARP [10.109]. As a consequence, with ribose, there is a reduction in the availability of sugar fragmentation products which are critical for the Strecker degradation and for the formation of heterocyclic compounds such as pyrazines and thiazoles, and the major products are cyclization products such as 2-furfural or norfuraneol.

The Strecker Degradation

The role of the early stages of the Maillard reaction is to break down sugars into more reactive intermediates such as dicarbonyls and hydroxycarbonyls. These undergo an array of reactions which include addition reactions with H_2S and NH_3, aldol condensations, dehydration, and cyclization reactions. However, one of the most important reactions for generating flavor is the Strecker degradation, in which a dicarbonyl reacts with an amino acid to provide the corresponding aminoketone and a Strecker aldehyde, derived from the parent amino acid, but containing one carbon less (Fig. 10.7). The aminoketone, which is derived from the sugar moiety, reacts further, forming pyrazines (see below). The Strecker aldehyde, which is directly related to the amino acid, provides a characteristic aroma to the food. For example, the reaction with proline gives a toasted, bread crust aroma, whereas reaction with leucine or isoleucine gives a malty or cocoa aroma. The two most important amino acids for the generation of meat flavor are methionine and cysteine.

Methionine breaks down in the Strecker degradation to form methional (**10**) (Fig. 10.8), a compound which imparts a very characteristic baked or boiled potato aroma, but has also been found to be odor-active in beef and chicken. It subsequently breaks down to form 2-propenal (**69**) and methanethiol (**6**), and the latter readily oxidizes to dimethyl disulfide (**8**). These are all reactive intermediates: propenal (**69**) readily undergoes aldol condensation reactions and addition reactions; methanethiol (**6**) can undergo oxidation, addition reactions, and exchange reactions with disulfides such as the bis(2-methyl-3-furan) disulfide (**30**) to give the related methyl sulfide (**31**) and 2-methyl-3-furanthiol (**28**) (Fig. 10.9), thus altering the meaty profile of the sample; dimethyl disulfide (**8**) can undergo disproportionation reactions to form dimethyl trisulfide (**9**) and dimethyl disulfide (**7**) (Fig. 10.8), again altering the aroma profile.

Cysteine Degradation

Cysteine is one of the most important precursors for the generation of meat flavor. Breakdown of cysteine, via the Strecker degradation, produces a number of highly reactive intermediates with flavor generating potential (Fig. 10.10): ammonia, hydrogen sulfide, acetaldehyde (**64**), mercaptoacetaldehyde (**70**). Ammonia and the hydrogen sulfide react with the pool of reactive carbonyl compounds to form heterocyclic aroma compounds such as pyrazines, thiophenes, and thiazoles which are important for the development of cooked notes. The formation of thiazoles requires the substitution of ammonia into an aldehyde, and hydrogen sulfide into a dicarbonyl or hydroxycarbonyl (Fig. 10.11). Condensation of the resulting mercaptoketone and the imine produces a thiazoline which undergoes oxidation to form the corresponding thiazole.

Hydrogen sulfide and acetaldehyde (**64**) combine to form dimethyltrithiolanes, or when ammonia is involved, dithiazines can be formed (Fig. 10.12) [10.110].

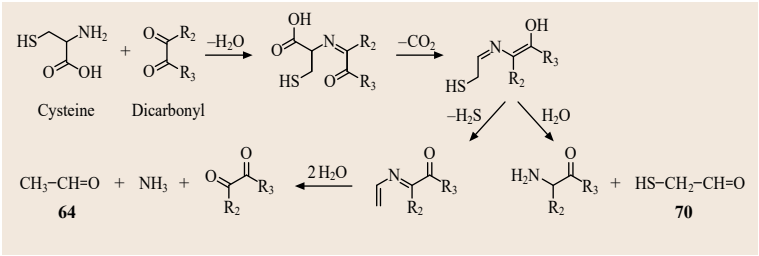

Fig. 10.10 The Strecker degradation of cysteine

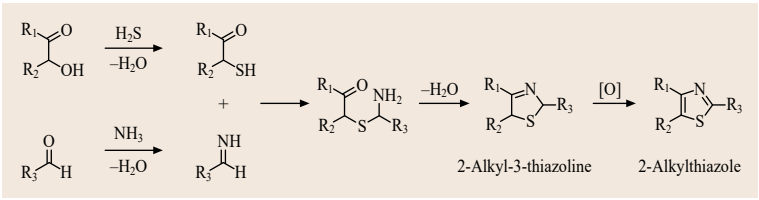

Fig. 10.11 Formation of thiazoles

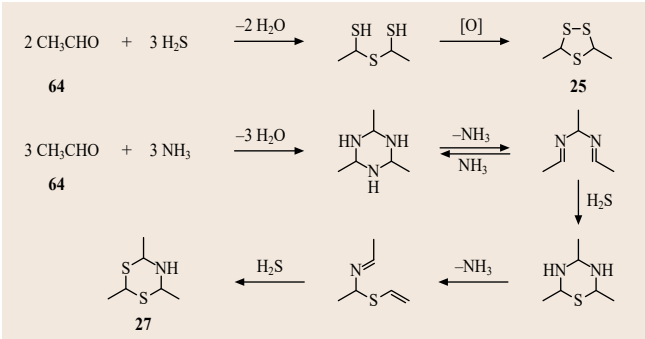

Fig. 10.12 Formation of 3,5-dimethyl-1,2,4-trithiolane and thialdine

Other aldehydes can participate in the reaction so, for example, if 3-methylbutanal is present, one or more of the methyl groups can be replaced by a methylpropyl group. Mercaptoacetaldehyde (**70**), which retains part of the carbon skeleton of the cysteine, is also highly reactive and forms thiophene, whilst the nitrogen analog cysteamine produces thiazoles [10.111].

One critical role of cysteine is to provide H_2S for the formation of the furanthiols (**22, 28**). 2-Methyl-3-furanthiol (**28**) is formed from a number of routes, and one of those is from a pentose sugar [10.112]. The early stages of the Maillard reaction give 1-deoxypentosulose, which in its tautomeric form, cyclizes losing water to form norfuraneol (**71**). *Whitfield* and *Mottram* [10.113] reported the formation of 2-methyl-3-furanthiol (**28**) in a model system containing cysteine and norfuraneol (71) at pH 4 and proposed that norfuraneol was a key intermediate (Fig. 10.13). The first step in the generation of (**28**) from norfuraneol involves a reduction and thereafter a dehydration step followed by the addition of H_2S and removal of water. However, *Cerny* and *Davidek* [10.114] carried out a similar reaction in the presence of $^{13}C_5$ ribose and demonstrated that 93% of the 2-methyl-3-furanthiol (**28**) was derived from ribose, rather than from the unlabeled norfuraneol, and proposed an alternative route via a 1,4-deoxypentosulose (**72**). Furthermore, low levels of 2-methyl-3-furanthiol (**28**) can be found in glucose/cysteine mixtures [10.112]. One possible route is via norfuraneol which can be produced from the aldol condensation of pyruvaldehyde (**60**) and hydroxyacetaldehyde, both of which can be derived from glucose. However, *Hofmann* and *Schieberle* [10.112] demonstrated in a model system that the aldol condensation between these two aldehydes preferentially formed 2-furfural rather than norfuraneol, and there was a more favorable route to (**28**) via the condensation of hydroxyacetaldehyde (**73**) and mercapto-2-propanone (**74**) which can be formed from H_2S and pyruvaldehyde (**60**). The initial step is an aldol condensation which can produce two isomeric mercaptoketones. One cyclizes and dehydrates to form 2-methyl-3-furanthiol (**28**) (Fig. 10.13), whereas the other forms 2-furanmethanethiol (**22**). In this model system at pH 5, the formation of (**28**) from thiamine was not favored.

However, reactions in meat are influenced by the other components of the matrix. Ho has looked at incorporating other sources of nitrogen such as other amino acids, urea, and carnosine. Addition of urea, which is naturally present in beef and pork at 20–40 mg/kg [10.115], releases ammonia into the system and raises the pH, thus favoring pyrazine formation and producing more roasted and buttery notes. Addition of carnosine had a similar effect [10.116], decreasing the formation of meaty sulfur compounds such as 2-methyl-3-furanthiol (**28**) and increasing pyrazine formation. Alternative sources of sugars have also

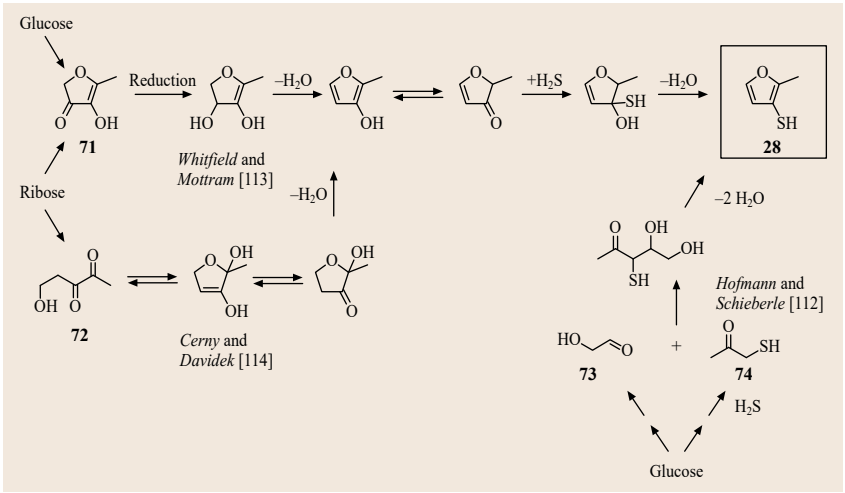

Fig. 10.13 Formation of 2-methyl-3-furanthiol from sugars

been studied. *Nobrega* and *Mottram* [10.117] included both inosine-5′-monophosphate (IMP) and ribose-5-phosphate in a cysteine-containing model system and showed that the IMP was relatively unreactive but ribose-5-phoshate contributed to the formation of the 2-methyl-3-furanthiol (**28**). Ribose phosphate provides a direct route to norfuranol, bypassing the first stage of the Maillard reaction [10.118].

Whitfield and *Mottram* [10.113] also reported the formation of 26 different disulfides, several containing the 2-methyl-3-furan moiety. These require an oxidation step, but given that the conditions in the model were highly reducing (H_2S), they proposed that the redox system involved in the formation of the disulfides was 2,3-butanedione, which could be reduced to 3-hydroxybutanone, providing the oxidation required for the formation of disulfides. However, *Baines* et al. [10.119], based on the large number of disulfides found in a cysteine/ascorbic acid model system compared to ribose/cysteine model system, suggested that it might be dehydroascorbic acid providing the oxidative step.

Pyrazine Formation

Simple pyrazines are formed from the condensation of two amino ketones (generated during the Strecker degradation) and subsequent oxidation (Fig. 10.14). However, the more substituted pyrazines, which are important in meat flavor, are more likely to be generated from the nonoxidative route in which one of the substituents comes from an aldehyde [10.120]. In the case of 2-ethyl-3,5-dimethylpyrazine (**15**), it may be that the methyl group is derived from formaldehyde or the ethyl group from acetaldehyde. One important source of these aldehydes is the Strecker degradation, with formaldehyde being derived from glycine and acetaldehyde from alanine and cysteine. Acetaldehyde can also be generated from lipid oxidation.

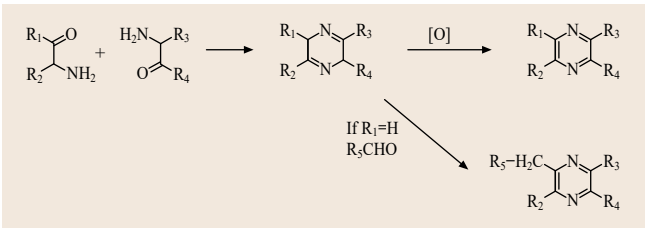

Fig. 10.14 Formation of pyrazines

Ascorbic Acid

The nonenzymic browning of ascorbic acid is well known and is partly due to Maillard-type reactions. Degradation of ascorbic acid can provide a pool of intermediates containing reactive dicarbonyls and hydroxycarbonyls – amongst these are glyoxal, pyruvaldehyde (**60**), and 2,3-butanedione [10.121]. *Vernin* et al. [10.122] has shown a pathway for the degradation of ascorbic acid to 1-deoxyopentosulose (**58**). These compounds are typical of those formed during the Maillard reaction and react further to form hundreds of odor-active compounds. Recently, *Yu* and *Zhang* [10.123] reported the volatiles generated when ascorbic acid and cysteine were heated in aqueous buffer at 141 °C at different pHs ≥ 5. Many of these were compounds that can contribute to meat flavor such as thiophenes, thiazoles, pyrazines, and cyclic sulfur compounds. However, using DHE rather than SPME, *Parker* et al. [10.124] showed that 2-methyl-3-furanthiol (**28**) and many related disulfides were formed in buffered model systems containing ascorbic acid and cysteine. She suggested that these are formed directly from ascorbic acid via 1DO, bypassing the early stages of the Maillard reac-

tion and avoiding the possible formation of the semistable 2-(1,2,3,4-tetrahydroxybutyl)thiazolidine-4-carboxylic acid which is readily formed between ribose and cysteine [10.125].

Process Reactions

Process reactions are designer Maillard reactions performed outside the food environment from highly tailored precursors, chosen to target specific compounds, groups of compounds and aromas. They are carried out using typical Maillard precursors under carefully controlled conditions of time, temperature and pH which mimic conventional cooking but have been optimized to maximize the desired flavor. They are widely used in the food industry, particularly to flavor meat products and meat-flavored soups and snacks. Meat process reaction flavors typically contain a pentose (or a source of pentose, such as ribonucleotides) and cysteine, but often contain other amino acids which catalyze the early stages of the Maillard reaction and can also modulate the flavor. The first such system was patented by *Morton* et al. [10.126] and, since then, hundreds have followed. Their complexity has developed over the years as significant advances have been made in understanding the chemistry of meat flavor and the interactions of aroma compounds with other components of the food matrix. Process reactions have become quite sophisticated with the use of phospholipids, nucleotides, thiamine, protein hydrolysates, yeast extracts, hydolyzed vegetable proteins (HVPs) and even specific Maillard intermediates, spices, flavor enhancers, and glutamic acid or monosodium glutamate (MSG). Often carried out in highly concentrated format, these give rise to hundreds of sulfur-containing compounds, many of which are highly potent odorants. *Hofmann* and *Schieberle* [10.127] used AEDA to identify the most potent odorants in a buffered ribose cysteine process reaction. The most potent in the extract were the two meaty thiols (**22**, **28**) and 3-mercapto-2-pentanone (**12**) and the remaining 25 were either sulfur compounds or one of the potent sugar degradation products (furaneol (**13**), norfuraneol, and sotolone (**14**)). Process flavors have been reviewed recently by *Cerny* [10.128].

10.3.2 Lipid Oxidation

Quantitatively, the volatile profile of cooked meat is dominated by lipid degradation products, but the odor thresholds tend to be much higher than those from compounds derived from the Maillard reaction. They do, however, play a major role in meat flavor and tend to give the species character to cooked meat. Subcutaneous fat is one obvious source of lipids, but the lean tissue also contains intra- and intermuscular triglycerides and structural phospholipids [10.129] which also contribute to flavor formation. Lipid oxidation contributes to the desirable aroma of meat, but also causes many of the off-odors associated with reheated meat (or WOF) and rancidity developed during the prolonged storage of either the raw or cooked meat.

Lipid Oxidation Mechanism

The mechanism of lipid oxidation has been reviewed by *Frankel* [10.130, 131] and more details are given in Chap. 11. It is generally believed to occur via a free radical-induced chain reaction that occurs in three phases: initiation, propagation, and termination. During the initiation phase, hydrogen is abstracted from the lipid to leave a lipid radical, which reacts with molecular oxygen to form a lipid hydroperoxide (Fig. 10.15). Hydrogen abstraction from unsaturated fatty acids forms more stable radicals due to conjugation of the radical with the double bonds, and unsaturated fatty acids are, therefore, more prone to oxidation, particularly at low temperatures. Saturated lipids are relatively stable by comparison, and their degradation becomes more important at higher temperatures, that is, during thermal processing.

The second phase involves the breakdown of the lipid hydroperoxides by the cleavage of the C–C bond on one side or other of the radical. Because there is no double bond to guide the initial abstraction of hydrogen, saturated fatty acids degrade to form series of alkanes, alkanals, and alcohols with a range of chain lengths; however, the major products from triglycerides such as tristearin are medium chain (C6–C10) aldehydes, alcohols, alkanes, carboxylic acids, and lactones.

With monounsaturated fatty acids (MUFAs), the degradation is more directed. In oleic acid, for example, the abstraction of the hydrogen can happen more readily at the position alpha to the double bond at either carbon 8 or 11 (Fig. 10.15). At carbon 8, the resultant allylic radical can tautomerize across the conjugated double bond to form the radical on C10. Likewise, both C11 and C9 radicals can be formed from abstraction at C11 and the corresponding hydroperoxides are formed at C8, C9, C10, or C11 in approximately equal amounts [10.130]. Each of these peroxides can cleave on either side of the hydroperoxide (A or B), resulting in the formation of medium chain aldehydes, 2-alkenals, alkanes, and alkenes. The dominant pathways are influenced by the reaction conditions and by the relative stability of the lipid radicals and the compounds that are formed. Model systems [10.132] showed that the major degradation product of oleate at ambient temperatures was nonanal (40–60 wt %), whereas at temperatures more relevant to roasting and frying (192 °C), nonanal (22%), 2-decenal (17%), and

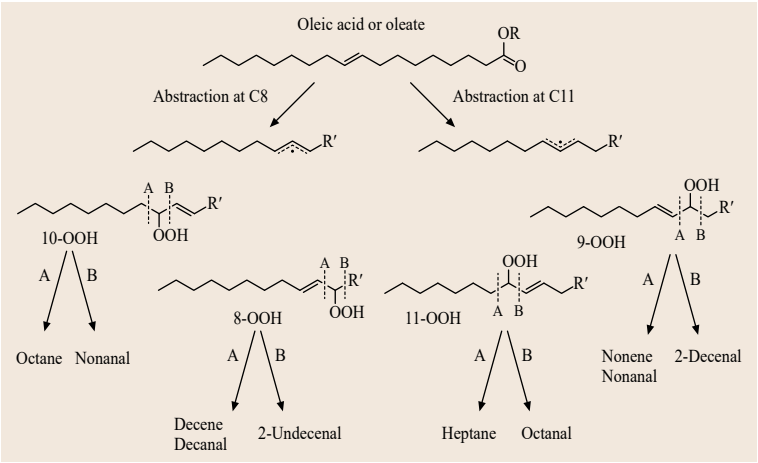

Fig. 10.15 Oxidation of oleic acid

2-undecenal (11%) were the major products which all impart fatty, but fruity notes, atypical of cooked meat. These three aldehydes are formed from the β cleavage of the 10-OOH, 9-OOH, and 8-OOH hydroperoxides, respectively (Fig. 10.15).

The most reactive fatty acids are the polyunsaturated fatty acids (PUFAs), estimated to be about 10 times more reactive than the MUFAs which, in turn, are 100 times more reactive than the fully saturated fatty acids. For PUFAs such as linoleic acid, there are more possibilities for the abstraction of the hydrogen, but abstraction at C11 is much more favored because it is alpha to two double bonds. Tautomerism of the resulting radical gives stable radicals at both C9 and C13 so this is the favored position for the formation of hydroperoxides. Subsequently, cleavage can occur at A or B, resulting in the formation of alkanals, 2-alkenals, 2,4-alkadienals, and cyclization products such as 2-alkylfurans. In the model system [10.132] at moderate temperatures, hexanal (**3**) (formed from β cleavage of the 13-OOH) was the major product quantitatively from trilinolein (50%) and linoleic acid (66%), although organoleptically the most important was the (*E*,*Z*)-2,4-decadienal (6%), which imparts a fatty fried note. However, when the methyl linoleate was irradiated under similar conditions, both (*E*,*E*)- and (*E*,*Z*)-2,4-decadienal were formed in greater amounts (9 and 19%, respectively), formed from the B-cleavage of the 9-OOH. At 192 °C, trilinolein produced similar amounts of pentane, hexanal, 2-heptenal, and 2,4-decadienal, emphasizing the point that under different processing conditions, the balance of the lipid degradation pathways changes.

Linolenic and arachidonic acids provide yet more possible pathways, leading to several unsaturated aldehydes. Under moderate conditions, the major oxidation product of linolenic acid (ω-3) was (*E*,*Z*)-2,4-heptadienal (40%) followed by (*Z*)-3-hexenal (11%) and 2,4,7-decatrienal (11%), but in the presence of haem, propanal, (*Z*)-2-hexenal, and 3,5-octadien-2-one were the major products. At 250 °C, ethyl linolenate formed 2-ethylfuran and a range of ethyl esters. The degradation products of arachidonic acid (ω-6) were similar to those of linoleic acid (hexanal, (*Z*)-2-heptenal, and (*E*,*Z*)-2,4-decadienal). Given the relative reactivity of PUFAs compared to their more saturated counterparts, and the high odor activity of many of the compounds formed, it is often degradation of the PUFAs that has the greatest impact on the volatile profile. The free fatty acid profile of the raw material, therefore, has a major role in the development of the aroma profile, and this is particularly relevant for the aroma of meat where many factors, particularly species, diet, and breed, can influence the fatty acid composition of the animal.

The Role of Phospholipids

The PUFA content of triglycerides of both the lean muscle and the fat of lamb and beef is only 1–2% [10.133] although pork is relatively rich in linoleic acid (14%) [10.134]. However, the PUFA content of phospholipids is much higher. Phospholipids contain a triglycerol backbone with just two ester linked alkyl chains, the third position being occupied by a polar phosphate group. They are an integral part of cell membranes and the increased unsaturation renders them more prone to oxidation, especially when released from the cell membrane into an aqueous environment where they come into contact with potential catalysts (iron). In pork, the phospholipids contain about 30% linoleic acid and 10% arachidonic acid (C20 : 4 (n-6)), whereas the figures are 22 and 10%, respectively, for beef and 12 and 5% for sheep. Hence, the phospholipids play a far greater role than the triglycerides in the development of flavor in cooked meat.

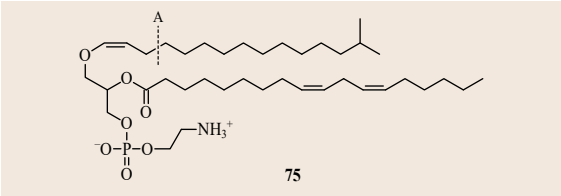
The role of phospholipids in flavor generation has been reviewed by *Mottram* [10.129]. He showed that removal of the polar lipid fraction containing the phospholipids resulted in a significant decrease in the aliphatic lipid degradation products, indicating that the phospholipids were a major source of lipid oxidation products – many of which are odor-active. Many studies since have confirmed the role of the phospholipids [10.135, 136].

Warmed-Over-Flavor

The phospholipids are also believed to play a role in the development of warmed-over-flavor (WOF), the distinctive off-note associated with reheated meat. In raw meat, the phospholipids are still contained within the cell membranes, and are only released as the meat is heated. Thus, when the meat is heated a second time, they can readily undergo further oxidation, catalyzed by traces of iron released from haem pigments during the initial cook [10.129].

Mitigation strategies have been reviewed by *Mielche* and *Bertelsen* [10.137]. Generally, the use of the freshest possible meat minimized oxidation processes in the raw material, and the addition of antioxidants in the form of free-radical scavengers or chelators reduced the development of WOF. Chelating agents such as polyphosphates and pyrophosphates are also effective, acting by chelating the metal ions, particularly haem-derived, that initiate the oxidation reactions. The reduction of storage time and temperature reduces the development of WOF; however, the use of high temperatures during processing seems to retard the development of WOF, and this is believed to be a result of the antioxidant properties of Maillard reaction products which are formed at higher temperatures. Excluding oxygen and light is an important factor to consider, and the addition of antioxidants such as butylated hydroxytoluene (BHT) and butylated hydroxyanisoles (BHAs) effectively extend the induction period by absorbing free radicals. However, tighter regulations means that natural antioxidants such as ascorbate, tocopherols (Vitamin E), β-carotene, and rosemary extract are often applied. Application of rosemary extract was found to suppress both lipid oxidation and the Maillard reaction in a cooked beef extract, and this antioxidant activity was attributed to carnosic acid and rosemanol [10.138]. Addition of ground canola seeds to ground pork patties significantly inhibited WOF [10.137]. Application of natural smoke can also prevent oxidation and imparts additional flavor.

There are many instances where these natural antioxidants have been fed pre-slaughter; for example, a study carried out by *O'Sullivan* et al. showed that by incorporation of vitamin E into the feed of hogs, the freshness was maintained for longer and the development of WOF was reduced [10.88].



75

Fig. 10.16 Structure of a beef plasmalogen

Role of Plasmalogens

Plasmalogens are also important for flavor generation. They are phospholipids that are based on phosphatidylethanolamine (rather than phosphatidylcholine which is the major component of lecithin), and contain a vinyl ether linkage in place of one of the ester linkages (**75**) (Fig. 10.16). As with the oxidation of unsaturated ester linkages, hydrogen abstraction occurs at the position alpha to the double bond and cleavage of the ensuing hydroperoxide produces acetaldehyde (**64**) and a branched aldehyde, such as 12-methyltridecanal (**37**) and the longer chain analogs. They are predominantly found in the internal organs of animals, but high levels of 12-methyltridecanal (**37**) have been found in the rumen of cattle [10.139] where it is reabsorbed by the animal and transported to the muscle tissue and incorporated into the phospholipids. In pork, the ether linkages lack the methyl branch and the corresponding straight chain aldehydes are formed.

Interactions Between Lipid Oxidation and the Maillard Reaction

Additionally, in cooked meat, the interaction between the Maillard reaction products and the lipid degradation products is important for moderating the flavor [10.140–143]. *Mottram* and *Edwards* [10.144] initially showed that when phospholipids were removed from meat before cooking, pyrazine levels increased in the cooked meat, suggesting that the products of lipid oxidation were interfering with the progress of the Maillard reaction. In model systems containing phospholipids and Maillard precursors (ribose and cysteine), fewer aldehydes were formed when the Maillard precursors were present, but there was no effect on other classes of lipid degradation products [10.145]. This reduction in aldehydes was attributed to their removal from the system by reaction with free amino groups, H_2S, or free thiol groups. Later work in model systems [10.141] confirmed that long-chain alkylthiophenes and alkylthiazoles could be generated from phospholipids, cysteine, and ribose model systems, and these compounds have been reported in cooked meat. *Elmore* et al. [10.143]

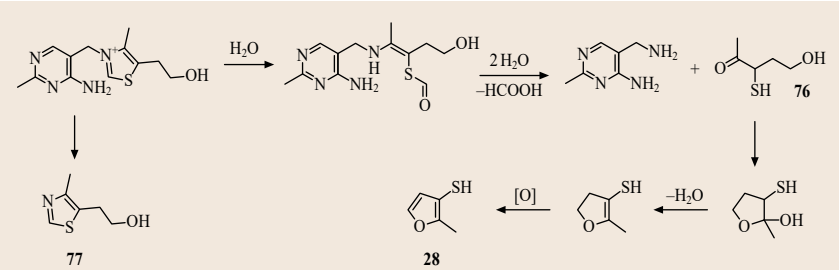


Fig. 10.17 Thermal degradation of thiamine

confirmed the role of the PUFAs in generating a series of 2-alkyl-substituted thiazoles and thiazolines, which were present at much higher levels in beef steaks from animals fed fish oil supplements compared to the control diet. Model systems confirmed that these could be formed from reactive Maillard intermediates, such as dicarbonyl and hydroxycarbonyls in the presence of ammonium sulfide and C3–C9 aldehydes. Thus, an increase in lipid oxidation could effectively remove reactive intermediates from the system which would otherwise participate on the Maillard reaction to form roasty, meaty aromas. Likewise, alkyl substituted thiophenes and thiapyrans were found in cooked beef and lamb, present at higher levels in meat from animals which had been fed a diet high in n-3PUFAs [10.146]. Model reaction confirmed that these were formed from the reaction of 2,4-alkadienals with H_2S, thus removing the H_2S from the system and reducing the amount of H_2S available to participate in the Maillard reaction, and in key flavor forming reactions. Neither the alkylthiapyrans/thiophenes nor the alkylthiazoles/thiazolines were found to be particularly odor-active.

10.3.3 Thiamine Degradation

Thiamine is present in raw meat at relatively high concentration (0.1−1 mg/100 g) and is prone to thermal degradation. Under acidic conditions (Fig. 10.17), the thiazole ring opens and 5-hydroxy-3-mercapto-2-pentanone (**76**) is released [10.147]. This is a particularly reactive molecule, but its presence in model systems was confirmed by *Cerny* and *Guntz-Dubini* [10.147]. It generates a number of low molecular weight sulfur-compounds [10.148, 149] many with rubbery, sulfury odors and some with vegetable, meaty aromas. One of the most potent is 2-methyl-3-furanthiol (**28**), the key meaty thiol, which is formed from the cyclization of 5-hydroxy-3-mercapto-2-pentanone (**76**) followed by loss of water and an oxidation step. This is a third route by which this highly potent meaty compound can be formed. *Grosch* et al. [10.150] showed the importance of the thiamine route compared to the ribose/cysteine route by directly comparing the two in model systems. An aqueous solution of L-cysteine (0.65 mM) and ribose (1.34 mM) produced only 0.2 µg/L of 2-methyl-3-furanthiol (**28**), whereas when ribose was replaced with thiamine at a very low concentration (0.06 mM), the yield increased 1500 times to 300 µg/L. *Güntert* also studied the compounds formed when meat model systems containing thiamine, ribose, cysteine, and ascorbic acid in various combinations were heated together [10.148]. Over 60 sulfur compounds were identified including thiophenes, thiols, sulfides, mercaptoketones, thianes, dithianes, thiolanes, dithiolanes, and three fused ring compounds including 1-methylbicyclo[3.3.0]-2,8-dioxa-4-thiaoctane. Of these, mercaptopropanone, 2-methyl-2-tetrahydrothiophenethiol, 3-acetyl-1,2-dithiolane, and 1H-pyrrolo[2,1,c]-1,4-thiazine were described as meaty. Details of the formation pathways have been elucidated by *Cerny* [10.151] using isotopically labeled starting materials.

Under acidic conditions, the thiazole ring remains intact, and 5-(2-hydroxyethyl)-4-methylthiazole (sulfurol, **77**) is produced [10.152]. Although this is reported to have meaty qualities, pure sulfurol has very little odor and the meaty notes are likely to be due to the presence of impurities, such as 4,5-dihydro-2-methyl-3-furanthiol [10.153].

10.3.4 Fermentation

In contrast to thermal generation of flavors in cooked meat, flavor formation during fermentation is controlled by enzymic processes [10.154–157]. The curing of meats is time consuming, and understanding the flavor formation is critical to the industry in order to shorten ripening periods in aid of more efficient processes [10.158]. The ripening or curing process is susceptible to changes in time, temperature, starter culture [10.159], position in the joint [10.160] and curing agents [10.161].

Amino Acid Catabolism

Post slaughter, the major components of muscle meat undergo proteolysis (14.4.2) generating small peptides and free amino acids. The first stage in amino acid

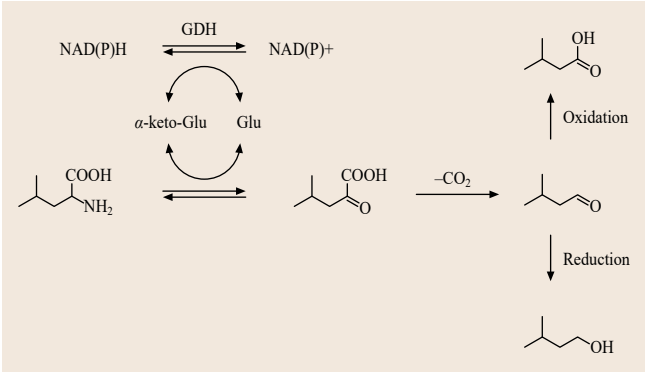

Fig. 10.18 Catabolism of leucine during fermentation

catabolism is the removal of the amino group by aminotransferases and the formation of the corresponding α-keto acids (Fig. 10.18) [10.162]. Further loss of CO_2 produces the aldehyde (which corresponds to the Strecker aldehyde) and this can be oxidized to the corresponding acid or reduced to the corresponding alcohol. During the processing of dry-cured ham [10.163], the free amino acid pool comprises predominantly alanine (Ala), leucine (Leu), valine (Val), arginine (Arg), lysine (Lys), glutamic acid (Gla), and aspartic acid (Asp). In the case of Leu and Val, catabolism gives the respective Strecker aldehyde – 3-methylbutanal or methylpropanal, compounds which contribute to the delicate aroma of cured meats. Further oxidation gives the respective acids, known more for their cheesy characteristics. However, the conversion of acids to esters gives the fruity notes which are a desirable characteristic of the final product. Catabolism of methionine produces methanethiol which can react with carboxylic acids to form potent thioesters which are desirable and fruity at low levels. Catabolism of tyrosine and tryptophan can produce the exceptionally potent compounds *p*-cresol (**53**) and skatole (**52**), respectively. At very low levels, these can be desirable but, if their formation is not halted, they can impart highly objectionable medicinal, phenolic and fecal, farmyard notes, respectively. Addition of cocktails of free amino acids prior to the fermentation of sausages was shown to increase the catabolism of amino acids and increase the concentration of the respective aldehydes. Use of just valine, isoleucine, and leucine produced a sausage with better sensorial quality [10.164].

Lipolysis and Lipid Oxidation

In subcutaneous fat and intramuscular fat, lipases are responsible for the breakdown of triglycerides into free fatty acids, and subsequent oxidation, initiated by lipoxygenases, results in the generation of aroma compounds, such as hexanal (**3**), 3-hexenal, 1-octen-3-one, and 1-octen-3-ol (**4**). The mechanism is a three-phase radical reaction, similar to those shown for the thermal degradation of lipids, but the dominant pathways will be different. The formation of the radical in the initiation stage is catalyzed by muscle lipoxygenases as well as light, moisture, and metal cations. In the structural phospholipids, a similar process is carried out by phospholipidases. Lipolysis occurs with the endogenous enzymes, but *Hierro* et al. [10.165] demonstrated in fermented sausages that the application of various starter cultures, such as *Lactobacillus plantarum* 4045 or *Staphylococcus* sp., enhanced the process. Enzymic reactions are influenced by time, temperature, pH, water activity, redox potential, salt, and ascorbic acid [10.166]. One example is the role of calcium chloride which has been shown to inhibit the formation of lipid-derived volatiles but promote the formation of branched alcohols and ethyl esters, thus reducing off-notes and increasing the desirable aroma [10.167].

10.4 Factors Affecting Meat Flavor

The factors affecting meat flavor are numerous, and this section can only begin to summarize some of the extensive literature in this area, focussing on those studies where there are volatile data to back up the sensory and consumer results.

10.4.1 Pre-Slaughter Handling – Diet and Breed

Pre- and post-slaughter factors play a major part in flavor generation and have been the subject of many papers and reviews. Pre-slaughter factors, such as diet, age, gender, slaughter weight, fat levels, stress and conditioning all have an influence on consumer acceptability and sensory evaluation [10.168] and these differences can be correlated with changes in the volatile profile of the meat.

The Evolution of Flavor in Animal Husbandry

Ever since the domestication of animals 10 000 years ago, communities have sought to improve the flavor of meat by selective breeding and a careful choice of pastureland. During the agricultural revolution of the eighteenth century, improvement focused primar-

ily on yield and other elements of efficiency (such as increasing herd survival rates and maximizing the value of by-products such as tallow). However, even at the height of the movement to use breeding to improve output, there was an interest in improving the flavor of meat. The great breeding experimenter Robert Bakewell for instance, whilst interested principally in breeding sheep able to yield more wool, was not indifferent to the claims of breeding to improve flavor [10.169]. *Young* [10.170], noting the impact of Bakewell's work on mutton quality in 1804, commented on the fact that the effect of selective breeding on flavor was understood even in the kitchens of Eton College. Later writers, such as *Low* [10.171] reflected that the most successful of the new sheep breeds of the period (the Southdown cross, which with a broader back and deeper carcass produced more meat, tallow, and wool) was conspicuously improved in meat flavor too.

It was not until the 1850s that flavor became a dominant element in breeding and husbandry [10.172], and then largely due to the declining significance of non-meat animal products in domestic trade. The science of breeding, such as it was, began to take an interest in the effect on meat quality and meat flavor, and – through the new agricultural chemistry of the 1860s – in minimization of taints and off-notes, the kinetics of cooking, and the effect of preservation techniques on flavor. By the last quarter of the nineteenth century and into the twentieth, as *Perren* has shown [10.173], selective breeding for flavor in the extensive hacienda and prairie farms of the New World was responding increasingly to flavor requirements, and flavor fashions, in European dining rooms. By the mid-twentieth century, with the development of new forms of preservation and canning alongside better transportation and logistics for shop and, ultimately, supermarket delivery, flavor became a vital element in competitive meat production systems across the world.

This prompted activity amongst the research institutes, where laborious derivatization techniques and column chromatography were used to characterize the aroma of cooked meat from different breeds of sheep [10.174] and other animals [10.175]. A review was published by *Lawrie* [10.176], and thereafter, the number of publications escalated as advances in technology provided capillary GC and an increase in the sensitivity of several orders of magnitude. The influence of diet and breed continues to challenge the scientific community and is often used as a marketing opportunity by retailers and restaurateurs to denote premium products. Grass-fed beef, corn-fed chicken, and saltmarsh lamb often feature on more exclusive menus and the flavor of the finest Iberian ham, jamón ibérico de bellota, is attributed to the acorn diet of the free-roaming pigs. In the UK, there is a return to the more flavorsome traditional breeds of pig such as Hampshires, Gloucester Old Spots, and Tamworth, and rare breeds of lamb are often selected for their superior flavor. Understanding the chemistry underpinning the differences in flavor produced by the different breeds, or diet, helps to optimize nutritional and organoleptic quality whilst maintaining efficient production systems.

Beef

Sensory and consumer trials [10.168] indicate that the breed of animal plays a part in the flavor of beef steaks, and most of this is attributed to differences in fat. The age of the animal plays a bigger role, with animals over 30 months old tending to have too intense a flavor and the acceptability decreases. Diet has a significant impact, and this is attributed to changes in the fatty acid profile. Forage-based diets, such as grass and hay are high in ω-3 fatty acids, such as linolenic acid, whereas cereals tend to have higher levels of ω-6 fatty acids (linoleic acid). Comparison of the volatile profile of grilled steaks (*M. longissimus lumborum*) from animals fed either concentrate or silage [10.177], showed that typical ω-6 lipid-derived compounds, such as hexanal (**3**), 1-octen-3-ol (**4**), and 2-octen-1-ol were four times higher in the meat from animals fed concentrate. This correlates well with the higher concentration of ω-6 fatty acids in the meat from the same concentrate-fed animals. Linoleic acid increased from about 60 to 140 mg/100 g in both Aberdeen Angus and Holstein Friesian.

Lamb

The acceptance of lamb flavor is influenced by previous exposure and the accepted norm. In Australia, where animals are pasture fed, there is a distinctive skatole (**52**) note derived from the feed, which is considered desirable in Australia but unacceptable in other countries where the normal diet is concentrates. The results of consumer studies are, therefore, not always in agreement, but descriptive sensory panels have consistently found differences between feeding regimes [10.43]. Sheep meat flavor and odor are higher in meat from pasture-fed animals compared to grain-fed, and are correlated with high levels of skatole (**52**), 2,3-octanedione, terpenes, and diterpenoids, whereas the grain-fed have higher levels of lipid-degradation products and branched-chain fatty acids, the latter formed in the rumen from the propionate-rich grain diet. A sensory study, using grilled meat from 96 castrated male Corriedale lambs [10.178] fed finishing diets with different proportions of pasture and concentrate, revealed a preference among Euro-

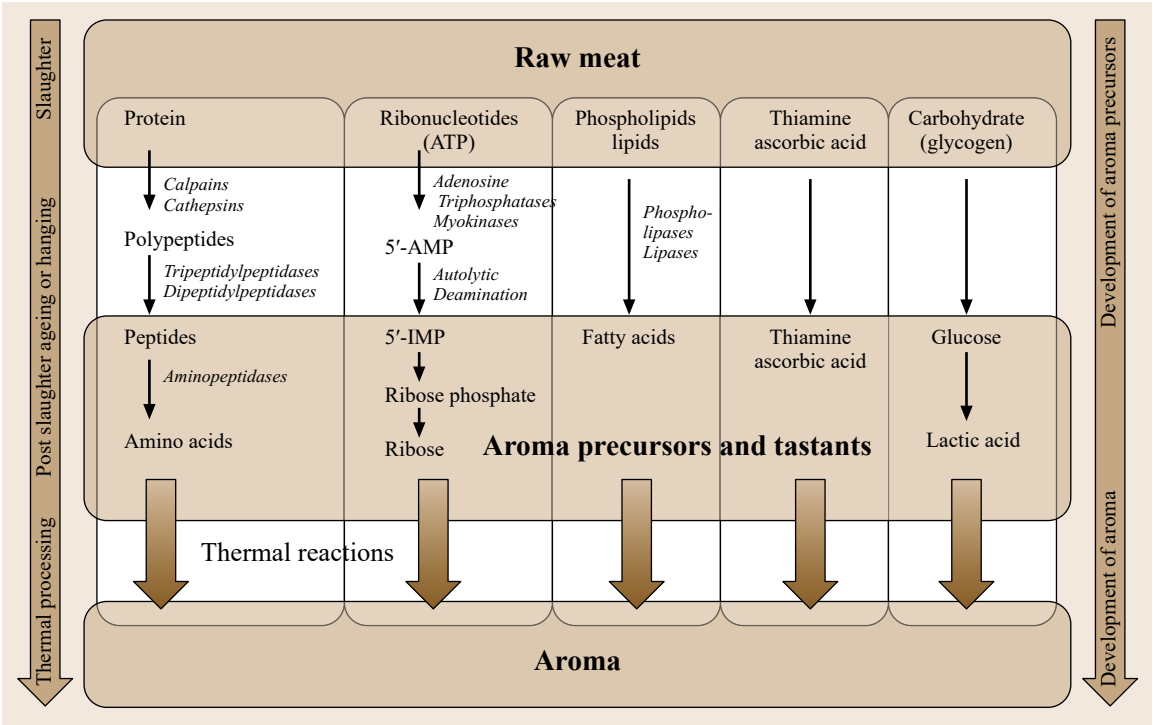

Fig. 10.19 Generation of tastants, aroma precursors, and aroma from raw meat

pean consumers, for the meat from the concentrate-finished animals. There was a corresponding reduction in rancid notes and an increase in typical lamb flavor. Volatile analysis of these samples showed an increase in lipid oxidation in the meat from the concentrate-fed animals (and, therefore, no correlation with the rancid aroma), but 2,4-heptadienal, derived from ω-3 fatty acids was higher in the meat from pasture-fed animals.

The pasture species can also influence flavor and acceptability [10.43]. Sensory panels have found stronger flavors linked to white clover and lucerne (cf. rye grass) and alfafa (cf. corn and soybean), and these flavors become objectionable at high concentrations. A strong meat odor was produced from a perennial diet of ryegrass which was acceptable only to some consumers, and a diet of green oats produced a pungent meat flavor [10.179]. Feeding brassica and rape tend to get low acceptability scores.

Dietary supplements are often incorporated in feed to enhance the nutritional properties and can have a substantial influence on the aroma profile of sheep meat. *Elmore* et al. studied the effect of five dietary supplements on aroma generation in lamb [10.180]:

1. Linseed oil
2. Fish oil
3. Protected lipid high in linoleic acid (C18 : 2 (n-6)) and α-linolenic acid (C18 : 3 (n-3))
4. Fish oil/marine algae (1 : 1), and
5. Protected lipid/marine algae (1 : 1).

The fatty acid profile of the supplements was reflected in the fatty acid composition of the meat and in the volatile profile of the grilled meat. Volatile compounds, such as (*E*)-2-heptenal, 1-octen-3-ol (**4**), and 2,3-octanedione, derived from ω-6 fatty acids, were highest in the meat from the lambs fed the protected lipid diet, whereas those derived from ω-3 fatty acids (e.g., 1-penten-3-ol, (*E*)-2-hexenal, 2-(2-pentenyl)furan) were highest in the meat from the lambs fed the fish oil/algae diet. The linseed-fed lamb was the most preferred, whereas the meat from those fed fish oil had a fishy flavor and those fed the protected lipid had a green note.

Poultry

It has long been established that corn-fed poultry has a superior flavor to those fed on barley, oats, and wheat [10.59]. Addition of beans, peanuts, and dried poultry-waste has been shown to have little effect on flavor, and the major dietary influence in poultry is the use of dietary fish meal or supplementation with fish oil, which results in meat with a fishy off-note, attributed to the oxidation of the PUFAs.

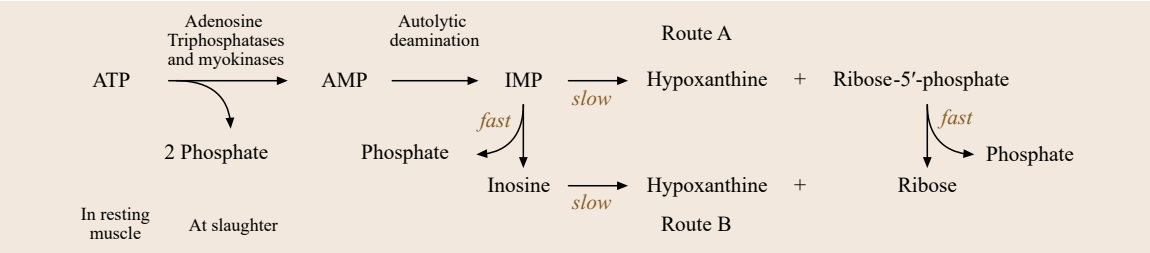

Fig. 10.20 Breakdown of ATP

Pork

Supplementation of pig feed with unsaturated fatty acids to reduce the levels of saturated fats resulted in a favorable change in the fatty acid profile with minimal change in flavor, but under less controlled conditions where lipid oxidation is allowed to proceed unhindered, a rancid off-note is readily detected.

10.4.2 Post-Slaughter Handling – Generation of Precursors

Post-slaughter conditions, such as chilling method, irradiation, storage conditions, and particularly processing or cooking techniques also exert a significant influence on the flavor of the meat. Aside from texture differences, many of the differences between breed, diet, and handling can be attributed to changes in the profile of the flavor precursors, and the challenge is to understand the origin of the precursors and how best to manipulate them for optimum flavor. Based on the knowledge of the formation pathways, sugars, amino acids, fatty acids, thiamine, and ascorbic acid have been identified as the key precursors of meat flavor. Many of these are generated post-slaughter from the breakdown of fat and muscle tissue. At slaughter [10.179], blood circulation ceases, oxygen supply fails, and under these conditions, proteolysis, lipolysis, glycolysis, and breakdown of ribonucleotides (Fig. 10.19) all start to occur, generating a pool of precursors, many of which have taste-active properties. Subsequent thermal processing is responsible for the generation of aroma.

Breakdown of Ribonucleotides

Of particular importance in the generation of meat flavor is the breakdown of adenosine 5′-triphosphate (ATP) to inosine 5′-monophosphate (IMP), and subsequent degradation to form ribose and ribose 5′-phosphate (key Maillard precursors), hypoxanthine (the constituent base in IMP), and inorganic phosphate (Fig. 10.20). In the living animal, ATP is found in resting muscle. In practice, almost invariably the animal is in a state of some exercise or stress at the point of slaughter so the labile phosphate residues are lost by the actions of the tissue adenosine triphosphatases and myokinase systems to form adenosine 5′-monophosphate (AMP). This usually happens very fast – the disappearance of ATP within a few hours post slaughter has been shown in pork [10.181] and chicken breast [10.182]. Within 24 h, AMP undergoes rapid autolytic deamination to form IMP, which is converted by the action of 5′-nucleotidase or nonspecific phosphomonoesterases to inosine and inorganic phosphate. Inosine is then converted either autolytically or under the intervention of a developing spoilage microflora to form hypoxanthine and ribose. The hypoxanthine degrades further to xanthine, uric acid, and ring cleavage products. This process provides both IMP, which is essential to the taste of meat, ribose, and ribose 5′-phosphate which are vital precursors for the development of meaty aromas (Sect. 10.1).

It has been shown that IMP, when compared to ribose and ribose 5′-phosphate, does not contribute greatly to the formation of meat aroma [10.108], unless the pH drops to 4.2 or below. Hydrolysis of the *N*-glycoside link between the sugar and the base is required for the ribose to participate in the Maillard reaction. During heat treatment, there are potentially two IMP degradation pathways as outlined in Fig. 10.20. In route A, the base is lost before the phosphate, whereas in route B, the phosphate is lost before the base. In both cases, the loss of the base is the rate-limiting step. Once formed, both ribose and ribose 5′-phosphate readily participate in the Maillard reaction and both were equally efficient (under model conditions [10.108]) at producing 2-methyl-3-furanthiol (**28**), but the more acidic conditions (pH 4.2) produced 3-4 times more than pH 6.5.

Proteolysis

Post slaughter, the muscle proteins denature and undergo proteolysis. Calcium-dependent proteases (calpains and cathepsins) act upon the myofibrillar and sarcoplasmic proteins to form polypeptide chains (≈ 30 kDa) [10.166]. Further breakdown of these by di- and tri-peptidyl peptidase releases small peptides that are broken down into free amino acids by amino pep-

tidases. The small peptides and free amino acids can provide taste characteristics to fermented meats, but they are also precursors of many of the important flavor compounds [10.183]. Amino acids, in general, catalyze the Maillard reaction, and many aroma compounds, particularly Strecker aldehydes, are generated from specific amino acids so it is both the nature and quantity of the free amino acids that are important for meat aroma.

Lipolysis

Although triglycerides can undergo oxidation, the fatty acids are far more reactive after they have been cleaved from the triglyceride backbone. This process requires the action of muscle lipases on muscle or adipose tissue, or phospholipases on membrane phospholipids. These lipolytic enzymes are sensitive to changes in pH, time, and temperature of storage or processing conditions, water activity and the presence of curing agents which are summarized by *Toldrá* [10.166]. Lipases remain active during freezing, and their activity increases greatly during the initial stages of cooking. Salt can partly inhibit some lipases, and ascorbic acid present at 500 ppm slightly inhibits all lipolytic enzymes. There is also limited evidence to show that some fatty acids are released quicker than others. Once released, the free fatty acids are the precursors for further enzymic or autolytic activity forming species characteristic aroma compounds. This process is, therefore, vital for flavor generation, but in excess leads to rancidity, off-notes, and WOF.

Glycolysis

Post slaughter, blood circulation stops, and in the absence of oxygen, muscles turn to anaerobic glycolysis, a process that breaks down glycogen without oxygen, to generate ATP and lactic acid. The intermediates, which are glucose and fructose phosphates, are precursors of the Maillard reaction. High levels of glucose and fructose have been demonstrated in beef muscle from animals fed sucrose prior to slaughter [10.184].

Precursor Studies

Koutsidis et al. investigated the effect of breed and diet on levels of precursors [10.106] and showed that diet had a greater effect than breed. Animals fed with concentrates rather than silage tended to have slightly higher levels of sugars. Changes in post-mortem conditioning were more substantial. A steady decline in IMP was observed during the 21 days post-mortem storage of meat (*M. longissimus lumborum*) from Charolais steers fed on concentrate. Ribose phosphate remained constant throughout the period, but ribose increased from 0.25 to 1.67 mmol/kg. This was concomitant with a rise in cysteine levels from 0.05 to 0.16 mmol/kg and in methionine from 0.05 to 0.35 mmol/kg. These are essential precursors for meat flavor and these changes are likely to have an impact on the final volatile profile.

In chicken breast, *Aliani* and *Farmer* [10.185] systematically increased by 2–4-fold the concentration of natural precursors (ribose, ribose 5′-phosphate, cysteine, thiamine and IMP) in raw chicken prior to cooking. Sensory evaluation showed that only ribose had an effect, and the chicken breasts with a higher concentration of ribose had an increase in cooked chicken aroma. This was attributed to the increase in 2-methyl-3-furanthiol (**28**), and possibly 2-furanmethanethiol (**22**), thus demonstrating that ribose concentration is a limiting factor in the development of chicken aroma.

10.4.3 Processing Conditions

The effect of processing or cooking conditions on any meat is significant, as any cook can testify. For example, the use of dry heat (roasting, grilling) favors the Maillard reaction and produces quite different aromas to moist heat (boiling, steaming, poaching). There are also distinct differences between roasted, grilled, pan-fried, or barbecued meat [10.59], and more complex flavors can be generated by combining two methods, or by the use of marinading and brining. The meat processing industry requires a consistent product and uses tight controls over the processing parameters.

Boiled, roasted, and stewed meats contain many of the same odor-active compounds, but they are present in very different proportions [10.5]. Boiled chicken, for example, has much higher levels of hexanal (**3**) than either roasted or stewed chicken. 2-Methyl-3-furanthiol (**28**) is reported in boiled beef and pork, but not in the corresponding roasted or stewed meats. 2-Ethyl-3,5-dimethylpyrazine (**15**) is found in roasted and stewed beef, but not in boiled where the mild conditions are not conducive to the formation of Maillard reaction products. Under boiling conditions, the contribution from the Maillard reaction is minimal, but under roasting conditions, it is the major pathway for flavor formation. A systematic sensory evaluation of cooked pork [10.186] has shown the increase in brown roasted notes and the decrease in metallic blood-like notes as the end-point temperature increased. Time, temperature profiles for thermal processing of beef muscle extract [10.109], and beef liver extract [10.187] show the progression of the Maillard reaction and the formation of 2- and 3-methylbutanals, indicating that after a certain time, levels of 3-methylbutanal start to decrease as the degradation (or condensation) pathways exceed the rate of formation. Overcooking produces high levels of Maillard reaction products which produce a burnt flavor when present at high concentrations.

The pH of the system also has an impact on the flavor. One major consequence of pH change is on texture. As lactic acid builds up in the muscle tissue post mortem, the pH drops, and if it is allowed to accumulate, the meat loses its water-binding ability and becomes pale and watery. If the acid is too low, the meat will be tough and dry. The Maillard reaction is also highly sensitive to pH changes. High pH tends to favor the formation of pyrazines giving roasty notes, whereas the meaty thiols are preferentially formed at lower pH where thiol groups exist as reactive thiolate anions.

As we move toward a predicted global population in excess of 8 billion, increased food demands, reductions in water and energy, and changes in land-use, meat production is under threat and methods to optimize meat quality or produce meat flavorings for alternative proteins become highly sought after. The production of optimum meat flavor involves the careful selection of diet and breed, good control over pre- and post-slaughter conditions and the choice of appropriate processing conditions to maximize the formation of aroma compounds.

11. Fats and Oils

Eric Frérot

Foods that contain fat are generally well liked by consumers. Fats and oils contain a large variety of aroma compounds. These aroma compounds are either trapped within the oil phase of the food matrix or can be formed from the lipids themselves. The analysis of aroma compounds in fat is difficult. This chapter discusses the analytical techniques used to identify the lipid-associated odorants and presents some comparisons of the results obtained from these techniques. Insights into the main families of chemicals imparting specific flavors to fat-containing foods and their formation pathways are presented, with a special emphasis on the compounds that are formed from lipids. Based on this premise, the aroma compositions of selected vegetable oils and animal fats are reviewed with a focus on the specific compounds that have been discovered during the last decade and their proven or postulated formation pathway. Finally, odor descriptions of many of the main compounds and their relative contribution to the overall flavor of fats and oils are given.

Food preferences are predominantly guided by taste, aroma, and texture, although other variables – genetic, physiological, educational, and metabolic – also play a role [11.1]. Sweet and fat tastes generally drive preferences in children and adults [11.1]. This is likely to be linked to the nutritional value of sugar and lipids in food. Despite this, however, it is still unknown whether human receptors for fat taste actually exist. In rodents, CD36 and GPR120 have been shown to be lingual receptors able to recognize free fatty acids [11.2]. Such receptors are also present in humans, and GPR120 in particular, might be involved in the perception of fat taste [11.3]. Certainly, the perception of fats in food relies primarily on smell and texture [11.4]. Thereby, there is an intricate and complex relationship between fat content, flavor release, and viscosity [11.5]. In view of this intrinsic interaction, flavor release as a function of the fat content or composition has been intensively studied, in model emulsions [11.6] and in model margarine [11.7]. Besides its physicochemical behavior and nutritional value, fat is highly desirable because it is a source of aroma compounds, formed either by the reaction of fat compounds or simply trapped within the lipid phase of the food. This chapter outlines the analytical techniques used to characterize the odorants in fats and oils and provides insights into the chemicals that impart the specific flavor to fat-containing foods and how these chemicals are formed. The aroma composition of selected vegetable oils and animal fats is then reviewed.

11.1 Analytical Techniques Used to Study Aroma Compounds in Fats and Oils

The analysis of flavor compounds in foods in general is a complex task. The aroma compounds are almost always analyzed by gas chromatography-mass spectrometry (GC-MS) (or GC-flame ionization detection (FID)) and as such they must be separated from the nonvolatile matrix prior to analysis to prevent damage to the GC column and the formation of artifacts within the GC injector. Odorant compounds in foods are typically present in low quantities, generally in the order of parts-per-million (ppm; or mg/kg) or parts-per-billion (ppb; μg/kg) levels, and even down to parts-per-trillion (ppt; ng/kg) for the most potent odorants. Therefore, food flavor analysis requires an isolation of the volatile flavor compounds from the matrix and an enrichment of the extract for subsequent analysis by GC-MS. The reader may refer to a comprehensive review by *Chaintreau* on the different techniques in flavor analysis [11.8] or Chap. 17 within this book. In particular, the analysis of aroma compounds in high-fat foods can be considered as one of the most complex and challenging tasks in flavor science. This is mainly due to the hydrophobic character that the fat flavor molecules share with the lipid molecules, thus making the odorants difficult to isolate with good recoveries. The techniques used for the isolation of odor molecules from fat can be classified on the basis of separation: distillation, headspace techniques, extraction, or size-exclusion chromatography. Overall, one needs to be aware of the fact that there is not *the* perfect isolation technique for aroma compounds, and that each procedure imparts discrimination and incomplete recoveries for some compounds, depending on the nature of each individual aroma compound and the matrix that is involved. Accordingly, it is important to know what each technique can achieve and to be familiar with the respective measures of compensation and correction for such discrepancies (e.g., Chap. 20 on stable isotope dilution analysis), especially when aiming at a precise quantification of the target odorants.

In view of the most commonly applied isolation techniques, each of these techniques is briefly described here and compared with each other by way of examples taken from the field of oil analysis. Odor compounds can be identified and their odor contribution assessed by using classical GC-MS and GC-olfactometry (GC-O) techniques, respectively.

11.1.1 Distillation

High Vacuum Transfer (HVT) and Cold Finger Molecular Distillation

The principle of the high vacuum transfer (HVT) and cold finger molecular distillation techniques is to evaporate flavor compounds from heated oil, commonly at 50 °C, by applying a high vacuum in two steps [11.9]. The two techniques are applied sequentially in the same apparatus (Fig. 11.1). The first step (HVT) takes place at 10^{-1} torr whereby the volatile compounds of the sample placed in a heated flask (3) are collected in a trap at −196 °C. A second trap (10) prevents contamination from the pump oil. After the content of this trap (6) is recovered, the second step (cold finger molecular distillation) can be carried out. The volatile odorants are collected on the surface of the cold finger (5), which is loaded with liquid N_2 and a higher vacuum of 10^{-2}–10^{-4} torr is applied. *Forss* and *Holloway* studied the recovery of aliphatic alcohols and ketones from butter oil using this technique [11.9]. They spiked butter oil with known amounts of alcohols and ketones of increasing carbon chain length. The volatile alcohols (C_2–C_5) and ketones (C_3–C_7) were recovered to more than 50% by HVT, whereas alcohols (C_6–C_{10}) and ketones (C_8–C_{10}) were recovered on the cold finger during step two. Total recoveries were

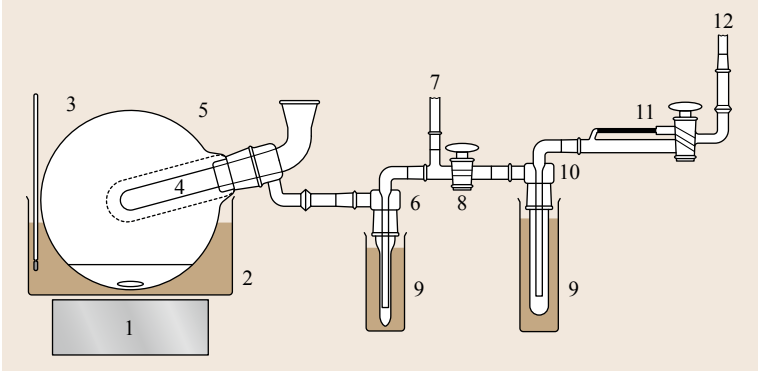

Fig. 11.1 Scheme of HVT and cold finger molecular distillation according to [11.9]

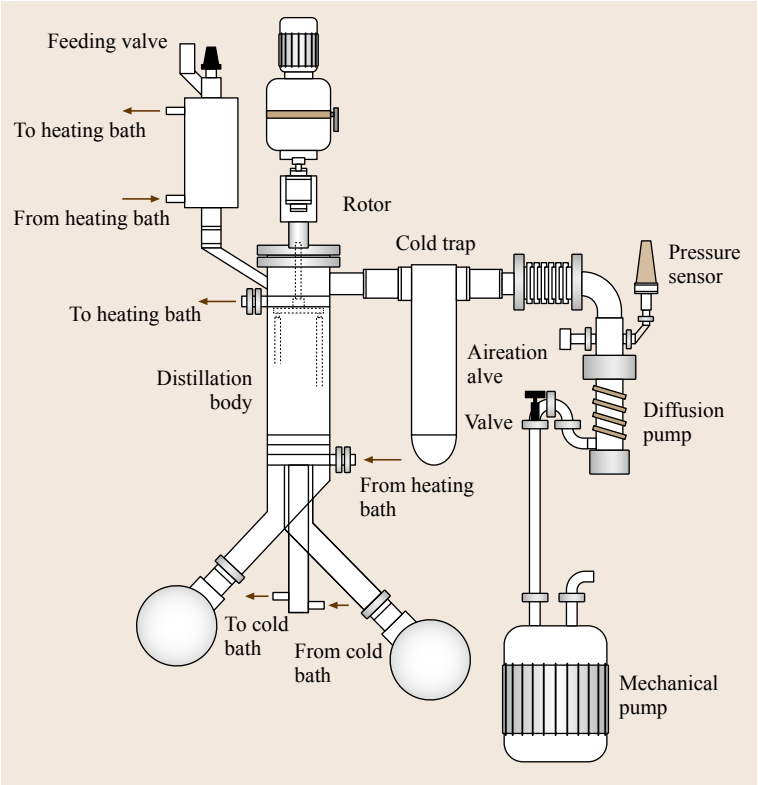

Fig. 11.2 Scheme of short-path distillation (after [11.10])

predominantly good (72–97%) or moderate for higher alcohols (C_8–C_{10}, 55–61%). Many other setups based on the same principle have been summarized by *Weurman* [11.11].

Short-Path Distillation

Also called falling-film, wiped-film, or thin-film distillation, short-path distillation is a continuous low-pressure distillation process [11.12]. In this technique, the oil is introduced drop-wise into the high-vacuum distillation body, where it forms a thin film by falling or is spread to form a thin film under the action of Teflon-coated rolling wipers (Fig. 11.2). The sample is introduced from the feeding flask (upper left) which may be heated. The falling oil forms a thin film in the distillation body. Most of the volatile compounds are collected in the cold trap. An additional cold trap (not shown) may be used to prevent contamination from the pumps. Odorants are collected on the surface of the cold finger located inside the distillation body, while the remaining oil flows to the receiving flask (bottom left). The volatile compounds are collected on the surface of a cold finger located inside the distillation body, or in the cold trap for the most volatile ones. As the residence time of the oil in the distillation chamber at 50 °C is less than a few seconds [11.12], the formation of artifacts is greatly minimized. In contrast to solvent-assisted flavor evaporation (SAFE; see below), short-path distillation is performed without the assistance of a solvent, thus yielding a more concentrated extract. At the end of the distillation, the cold finger is rinsed with a volatile solvent to recover and dilute the odorant extract and avoid it remaining in its concentrated form as it warms up. Using falling-film short-path distillation on a model mixture in synthetic oil, *Krings* et al. [11.13] measured recovery factors of many aroma compounds. For most compounds, the recoveries were in the range of 60–90% and were linearly correlated with the product of the boiling point and log P. For lactones recoveries were much poorer, for example with 57.4% for octan-4-olide and only 5.1% for dodecan-5-olide.

Reduced Pressure Steam Distillation

Steam distillation is a very old technique used for the production of essential oils. The product to be extracted is brought into contact with steam. Generally, the volatile compounds are distilled at a much lower temperature than during normal distillation because of the formation of azeotropes. After condensation, the organic compounds can be recovered from the water phase by decantation or by solvent extraction. In their

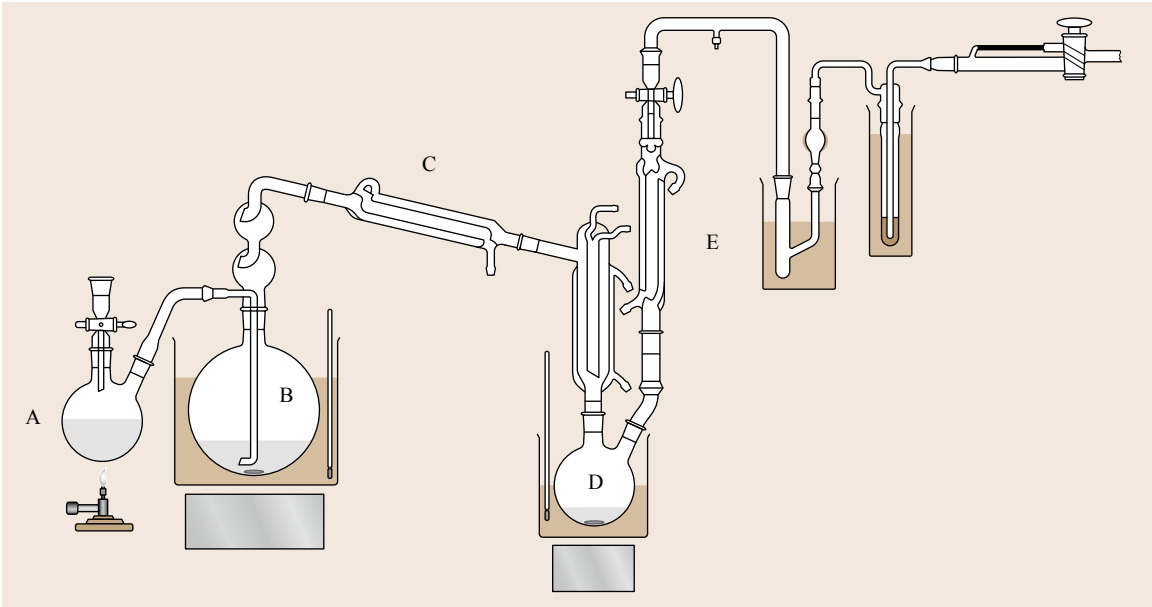

Fig. 11.3 Reduced pressure steam distillation

study on butter oil, *Forss* and *Holloway* applied this technique under reduced pressure [11.9] (Fig. 11.3). Butter oil in a heated flask (B) was percolated by steam from the steam generator (A). The aroma compounds together with water that condensed in the flask (D) could be further enriched (Fig. 11.3, E). Thereby, the recoveries of alkan-2-ones ranged from 75–90% (C_3–C_9) down to 48–12% (C_{10}–C_{12}).

As a modification of the previous setup, a simpler glassware arrangement can be used in some cases: thereby, the oil and water phases are mixed in a flask and subsequently distilled. This operation, often called hydrodistillation, can be carried out, for example, in a rotary evaporator. The flavor compounds that are soluble in the water phase can subsequently be recovered by adsorptive or solvent extraction techniques, by solid-phase extraction (SPE; Sect. 11.1.3). This combination was previously used for the analysis of sesame oil flavor and led to the identification of more than 150 compounds [11.14].

Simultaneous Distillation Extraction

In analytical scale steam distillation, the flavor compounds are extracted from the condensed water phase by using an organic solvent or by adsorptive techniques such as SPE. In simultaneous distillation extraction (SDE) the steam distillation and the continuous extraction are performed at the same time by using a Likens–Nickerson apparatus (Fig. 11.4). The solid or liquid fat product is placed in a flask attached to the left branch (A). The extractive solvent (ether, pentane) is placed in a flask attached to the right branch (B). The steam and the solvent vapors are brought into contact, decanted in the bottom loop of the device, and return to their original respective flasks. If the extractive solvent is denser than water (dichloromethane), it should be connected to the left branch (A). A comprehensive review of this technique is given in the literature [11.15].

To provide some examples, beef and lamb/mutton fat were comparatively analyzed by SDE and solid-phase microextraction (SPME; Sect. 11.1.2) of the headspace. Fewer aroma compounds were detected by SDE, but no trend could be drawn regarding the influence of the chemical class or the extraction efficiencies [11.16]. The same two techniques were compared for the analysis of dry-cured ham and gave more expected results: SPME was far better for the recovery of highly volatile compounds (acetaldehyde, dimethylsulfide, butanal), whereas compounds of lower volatility (C_{10}–C_{12} aldehydes, lactones) were more abundant in SDE samples [11.17]. In addition, SDE can lead to artifact formation not observed in SPME, such as di-unsaturated aldehydes formed by autoxidation of fatty acids [11.17]. The same observations were reported in a study of olive oil [11.18].

Solvent-Assisted Flavor Evaporation (SAFE)

Solvent-assisted flavor evaporation (SAFE) is a mild technique for the recovery of volatile flavor compounds from difficult liquid, solid, or heterogenous matrices, including high-fat foods [11.19]. The SAFE apparatus

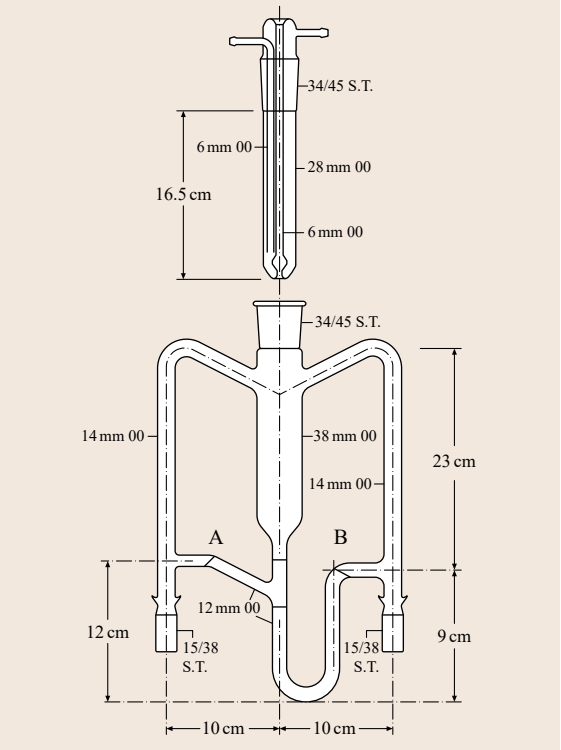

Fig. 11.4 Likens–Nickerson apparatus for SDE

consists of a complex assembly of especially constructed glassware (Fig. 11.5). The food sample is diluted or suspended in an organic solvent, usually dichloromethane or diethyl ether. This is then placed into the *addition funnel* (A) and then added drop-wise into the heated flask (B) in which a high vacuum (10^{-5}–10^{-4} torr) provided by a diffusion pump is applied. The solvent and the volatile flavor compounds are volatilized concomitantly before the vapors are trapped at −196 °C (C and D). Careful temperature regulation minimizes the freezing of material in unwanted zones of the apparatus. The use of a high vacuum allows very moderate heating (20–35 °C), thus minimizing odorant degradation during extraction. A model flavor containing seven aroma compounds with different functional groups diluted in synthetic triglycerides (TGs) demonstrated recoveries in the range of 37–13% (3-methylbutanoic acid, phenylacetaldehyde, phenylethanol) or considerably lower (Furaneol 4%, vanillin 0.5%). The recoveries were slightly higher than with HVT (Sect. 11.1.1). SAFE has the reputation of providing olfactively representative extracts. Therefore, it is one of the most often used preparative techniques in flavor research; interestingly, a few chefs who have embraced the *molecular gastronomy* trend also use SAFE [11.20].

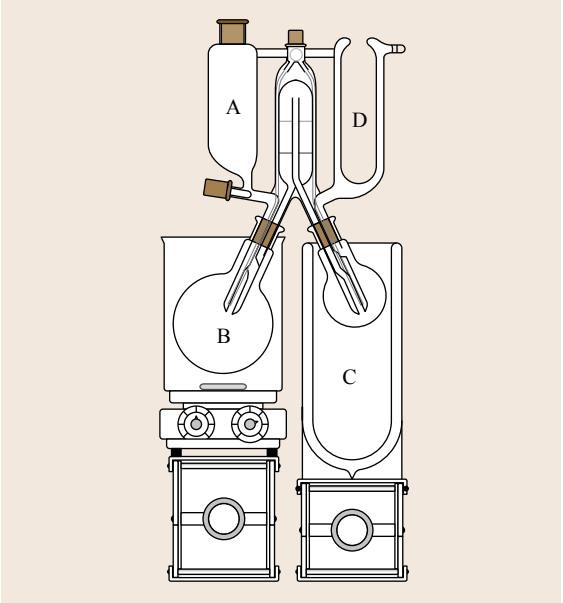

Fig. 11.5 Scheme of the SAFE apparatus (after [11.19])

11.1.2 Headspace Techniques

Headspace analysis is of great interest in flavor analysis since it requires little or no sample preparation and as odorants collected by this technique are believed to represent the initial olfactory impression of a sample, for example, when smelling a dish. The volume above the sample, called the headspace, is collected in many different ways and injected onto the GC column. Alternatively, it can be analyzed directly by online chemical ionization mass spectrometers (Chap. 18). The many variants of headspace analysis are reviewed in [11.21]. In view of fats and oils, one needs to keep in mind that, overall, the partitioning behavior of the fat-associated odorants commonly does not favor the gas phase due to the strong affinity of the odorous molecules to the rather nonpolar matrix. Another crucial step in headspace analysis, especially when working under static conditions, may be the application of incubation steps to achieve the equilibrium of odorant distribution between the sample matrix and the gas phase. In the case of sensitive fats and oils, this introduces the necessity to carefully consider and avoid potential artifact formation, for example, due to fatty acid oxidation. In such cases, working under a protective atmosphere, as well as careful adjustment of the temperature and time parameters during incubation might be required.

Static or Dynamic Headspace

In classical static headspace analysis, a certain volume above a sample is collected by using a gas-tight

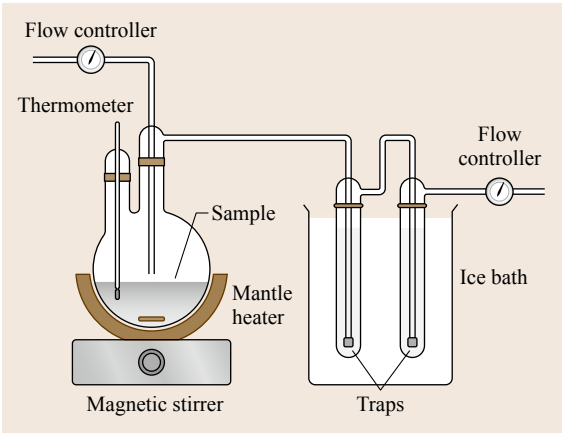

Fig. 11.6 Trapping of volatile compounds in the headspace of pork fat. Reprinted from [11.22] with permission from Elsevier

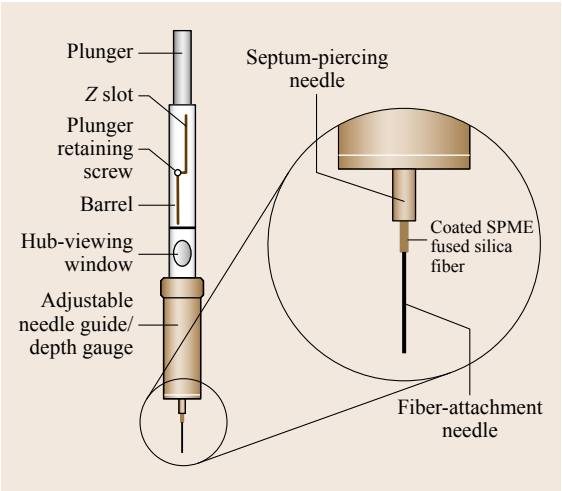

Fig. 11.7 Solid-phase microextraction (SPME) assembly

syringe and is subsequently analyzed by GC, commonly coupled with FID or MS detection. In dynamic headspace analysis, the headspace volume is continuously purged by a flow of a purified gas and the volatile compounds are collected in a cold trap, either in cold solvent or by using an adsorbent, or by pure cryo-focussing, for example, using liquid nitrogen. Dynamic headspace is often preferred over static headspace in the analysis of fats and oils because it leads to much more concentrated volatile extracts. Figure 11.6 shows the setup used for the analysis of heated pork fat [11.22] whereby the respective volatiles were collected in cold dichloromethane for 6 h. The trapping of the volatiles over adsorbent-containing cartridges, such as Tenax, has gained much popularity because it can be applied in a fully automated process. For example, blue cheese was studied by using this technique, and its simplicity, reliability, and high level of automation were highly appreciated [11.23].

Solid Phase Microextraction and Related Techniques

Solid phase microextraction (SPME) is a static headspace sampling technique introduced by Pawliszyn in 1993 that achieves a high level of volatile enrichment [11.24]. An adsorbent, polydimethylsiloxane (PDMS), polyacrylate, or Carboxen, coated onto a fused silica fiber, forms the end of a needle assembly as is shown in Fig. 11.7. The SPME fiber is exposed to the headspace of the sample and the volatile analytes are adsorbed. The amount of a given analyte adsorbed on the fiber results from its partitioning between the sample matrix, the headspace, and the adsorbent. This phenomenon creates huge discrimination between different analytes. Also, the choice of the fiber material, extraction time and temperature are of crucial importance. The accumulated volatiles are desorbed thermally into a conventional split/splitless GC injector. SPME analysis is perhaps the simplest and most easily automated technique described in this chapter, which explains its huge popularity. To increase the concentration capability of SPME, various techniques with thicker sorbent films have been developed. In headspace sorptive extraction (HSSE) the headspace volatiles are collected onto a bar that is coated with at least 100 times more sorbent, commonly PDMS. It should be noted that HSSE is a special case of stir bar sorptive extraction (SBSE) whereby the bar is just suspended in the headspace of the sample instead of being stirred in the solution. All of these sampling techniques were recently assessed using two-dimensional GC-MS [11.25]. The physicochemical properties of the adsorbent are similar to those of oils and fats. Therefore, the partitioning between the oil phase, the headspace, and the rather low amount of SPME adsorbent for the most hydrophobic and less volatile compounds is not favorable. However, high-concentration capacity sampling techniques, such as HSSE or SBSE showed good results, even for whole milk samples [11.25]. HSSE and SPME have been compared for the analysis of olive oils [11.26] and HSSE gave slightly better results at the expense of the need for a special desorption/GC-injection device. It should be noted that most of the compounds analyzed in this study were volatile, weakly hydrophobic aldehydes and alcohols (C_5–C_{10}).

11.1.3 Extraction

Solvent extraction is perhaps the oldest technique in flavor analysis. It is still used, but new techniques that are

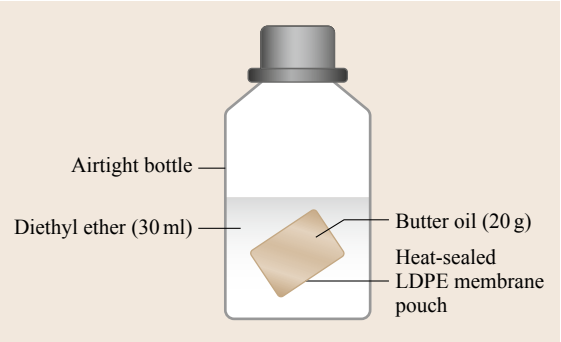

Fig. 11.8 Membrane-assisted solvent extraction (after [11.28], courtesy of John Wiley & Sons, Ltd)

claimed to be more ecological, such as SPE and supercritical fluid extraction (SFE), have recently gained popularity.

Solvent Extraction (or Liquid–Liquid Extraction (LLE))

Solvent extraction is used to extract the oil from fat-containing food samples, for example, chicken adipose fat tissue [11.27]. Since most of the solvents also dissolve TGs and other nonvolatile lipid constituents, which prevents direct GC analysis, liquid–liquid extraction of aroma volatiles from oils is never used alone. An attractive technique called membrane-assisted solvent extraction was reported on recently [11.28]. Butter oil was placed in a sealed low-density polyethylene membrane pouch in a closed bottle containing the organic solvent (Fig. 11.8). The membrane acted as a molecular sieve, allowing the volatile flavor molecules to reach the solvent side, whereas TGs did not diffuse through it. Spiking experiments were performed to determine recovery factors. These were modest (1–2% for acids, 10% for lactones), but very reproducible. Interestingly, lactones with higher molecular weights (C_{14}, C_{16}) could also be recovered by using this technique.

Solid Phase Extraction

Solid phase extraction (SPE) is extensively used for the extraction of aroma volatiles from water-based foods and drinks. The sorbent is generally composed of C_{18}-bonded silica or polymers of the same lipophilicity. SPE cannot be used for the direct analysis of fats. The polar flavor compounds of butter were previously recovered by SPE, but only after the water phase was first separated from the butter oil [11.29].

Supercritical Fluid Extraction (SFE)

Besides its *green chemistry label*, SFE, mostly performed with carbon dioxide, offers many advantages over solvent extraction. First, its selectivity toward solutes can be modulated by variation of the applied pressure. Second, CO_2 evaporates easily at ambient pressure, whereas it is difficult to separate liquid solvents from extracts without losing the volatiles. Supercritical CO_2 extraction was used in an extensive analysis of raw beef volatiles [11.30]; thereby, a lipid-like fraction was produced under high pressure of CO_2 (400 bar). By reducing the pressure to atmospheric pressure, the gaseous CO_2 was forced to pass through a cartridge that contained Tenax adsorbent. The condensed fraction remaining after CO_2 evaporation was primarily composed of lipids. Thermal desorption of the Tenax cartridge and GC-MS analysis led to the identification of more than 120 compounds [11.30].

11.1.4 Gel Permeation Chromatography (GPC)

Gel permeation chromatography (GPC) has long been used for the determination of contaminants, such as phthalates [11.31] or pesticides [11.32] in vegetable oils by GC. Despite this technique being able to separate semivolatile compounds, such as fatty acid esters from TGs [11.33] it has been rarely used for aroma compound analysis. *Fröhlich* described the separation of fat and flavor compounds by using a column of Bio-Beads SX-3 eluted with dichloromethane [11.34]. The analysis of a chocolate with coconut filling spiked with various amounts of ethylvanillin gave recoveries from 92 to 108%.

11.1.5 Comparison of Techniques

It is difficult to objectively compare all of the techniques described above because no extensive systematic study has been conducted to determine the recoveries of different aroma compounds from the same fat or oil by each approach. Table 11.1 shows the main features of each technique. Distillation techniques are seemingly best suited for in-depth analysis because a large quantity of oil can be processed. The extracts thus obtained can be further fractionated by flash chromatography. High-vacuum distillation may be considered best for semivolatile compounds, such as long-chain lactones. On the other hand, these techniques require expensive hardware, such as a high-vacuum pumps or dedicated glassware, in addition to a longer operation time. SDE may be a good technique but compounds of lower volatility or those that are heat sensitive may induce biases. Also, artifact formation from nonvolatile precursors might be an issue that needs to be considered. Solvent extraction is often difficult because the physic-

Table 11.1 Pros and cons of each sampling technique for the analysis of fat/oil volatiles

Technique	Price	Ease of use	Advantages	Drawbacks
HVT	$$$	−	Prep scale, good recoveries of volatiles and semivolatiles	Tedious, solid fat analysis not possible
Short path distillation	$$$$	−	Continuous, prep scale, good recoveries of low and high boiling chemicals	Tedious, solid fat analysis not possible, dedicated glassware, difficult to clean
Steam distillation	$	+	Prep scale	Artifacts, poor recovery for polar compounds
SDE	$	+	Prep scale, easy use, low cost	Artifacts, difficult under vacuum, dedicated glassware
SAFE	$$$$	−	Prep scale, versatile	Needs solvent, price, dedicated glassware, difficult to clean
Headspace	$	++	Easy use, sensitivity	Small scale only, semivolatiles not recovered
SPME	$	+++	Choice of fibers, easy use, sensitivity, quantification	Small scale only, semivolatiles not recovered
LLE	$	++	Prep scale, large choice of solvent	Difficult to eliminate TGs
LLE with membrane	$	+	Prep scale, easy use	Not much data in the literature
SPE	$	+++	Choice of sorbent, easy use	Difficult to separate lipophilic molecules from TGs
SFE	$$$	−	Prep scale, *green technique*	Dedicated instrument, needs skilled technician
GPC	$	+	Mild technique, no artifacts	Not much data in literature

ochemical properties of glycerides are not sufficiently different from those of certain classes of aroma compounds. Nevertheless, the complete removal of nonvolatile molecules before GC analysis can subsequently be performed by size exclusion chromatography (SEC) or with the help of membrane separators. For studies requiring a larger number of sample analyses, headspace techniques offer substantial advantages, but the downside here is that semivolatile compounds are discriminated or omitted.

11.2 The Different Chemical Classes of Aroma Compounds Found in Fats and Oils, and How They Are Formed

Aroma chemicals present in the fat phase of foods can either originate from lipids or can simply be trapped in the fat phase because of their lipophilicity. Flavors derived from fat have been reviewed extensively by Urbach and Gordon, who focused on milk fat products [11.35]. The most typical molecules are shown in the following subsections; their odor qualities and thresholds, when available, can be found in the literature [11.36]. A valuable source of information used in the present article is the Volatile Compounds in Foods database, which contains more than 7000 compounds present in 675 types of foods, together with their corresponding literature [11.37]. The data entries in this database are updated every year by the Netherlands Organisation for Applied Scientific Research. In Sect. 11.3, only the most common members of each class of aroma compounds are presented. Their described mechanisms of formation may be generalized to other aroma chemicals to understand how they are formed from lipid products.

11.2.1 Acids

Free fatty acids are formed by lipolysis of TGs. Long-chain fatty acids are not potent odorants, which is in contrast with short-chain fatty acids (C_4–C_{10}). Short-chain acids, such as **(1)–(4)** (Fig. 11.9) are more abundant in animal fats than in vegetable oils. *Frerot* et al. analyzed butter TGs by ultra-performance liquid chromatography coupled with mass spectrometry (UPLC-MS) [11.38]. Most of the identified TGs contained a butanoyl moiety in position 1 (or 3) of the glycerol. In contrast, none of the diglycerides present in butter oil contained a butyric acid residue. The enzymatic hydrolysis of the primary ester bond positions (1 or 3) of TGs is easier than that of the secondary ester bond (position 2). Furthermore smaller, less sterically hindered fatty acids are cleaved first. This explains why rancid butter and good cheese contain a substantial amount of short-chain fatty acids, such as **(1)** and **(2)**.

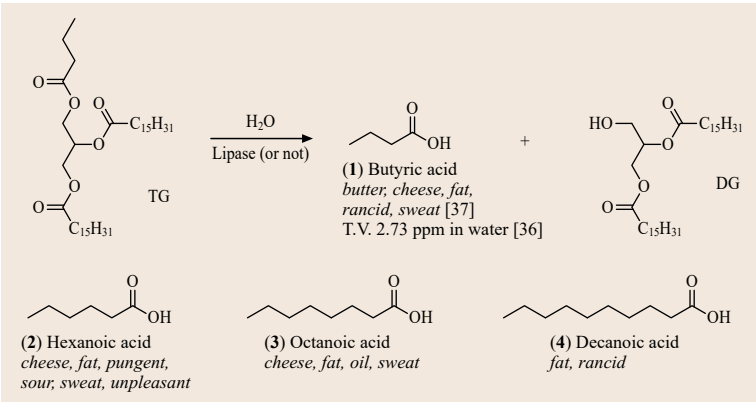

Fig. 11.9 Short-chain fatty acids from triglycerides

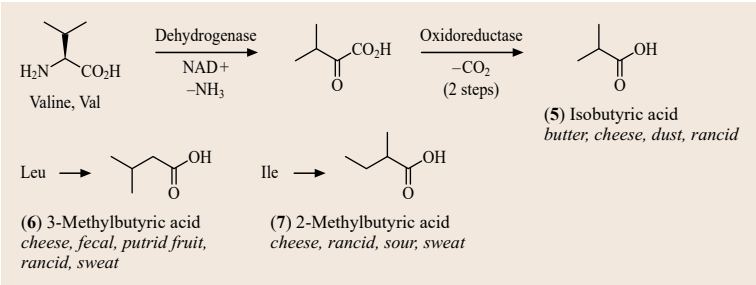

Fig. 11.10 Short branched-chain fatty acids from amino acids

Small branched-chain fatty acids do not originate from TGs, but from the degradation pathways of the amino acids valine, leucine, and isoleucine (Fig. 11.10), as can be found in the Kyoto Encyclopedia of Genes and Genomes (Kegg) database [11.39].

Short-chain fatty acids constitute a chemical class of high aroma importance in many fat-containing foods, in particular milk fat products. These acids generally impart the character of the food and its initial flavor impact, and are primarily quality markers in ripening processes but also arise due to deterioration (as in over-ripening).

Short-chain fatty acids and long-chain fatty acids are also the biochemical precursors of many other important aroma compound classes, such as aldehydes (Sect. 11.2.3), ketones (Sect. 11.2.4), and lactones (Sect. 11.2.5).

11.2.2 Esters

Esters do not constitute an important class of odorants in fat-containing foods, in contrast to their overwhelming importance in fruits. They are not abundant in fats and oils, as compared with acids or aldehydes, and they do not contribute much to their overall flavor profiles. Ethyl-2-methylbutyrate **(8)** was described as contributing to the odor of olive oil to a moderate extent [11.40]. A noticeable exception is ethyl butyrate **(9)** (Fig. 11.11), which plays an important role in the aroma profile of many cheeses (Cheddar, Pecorino, Gorgonzola), as reviewed by *Curioni* and *Bosset* [11.41].

11.2.3 Aldehydes

Aldehydes have tremendous importance in fat-related aromas and, accordingly, in the flavor industry. In particular, many aroma-impact compounds in vegetable oils and meat fats belong to this chemical class. Most of the aldehydes identified in foods are produced by the oxidation of unsaturated fatty acids. In plants, this process can be enzymatic and is called the lipoxygenase (LOX) pathway (Fig. 11.12, Chap. 2). Hydroperoxides, specifically 9-HPOT or 13-HPOT, are first formed from linolenic acid upon the combined action of a lipase and of a lipoxygenase (9- or 13-LOX). A hydroperoxide lyase, 9-HPL or 13-HPL, then cleaves the hydroperoxide to give C_9 or C_6 aldehydes, respectively. In olive

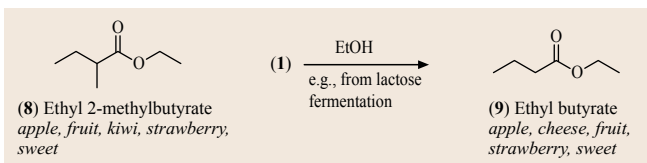

Fig. 11.11 Esters in olive oil

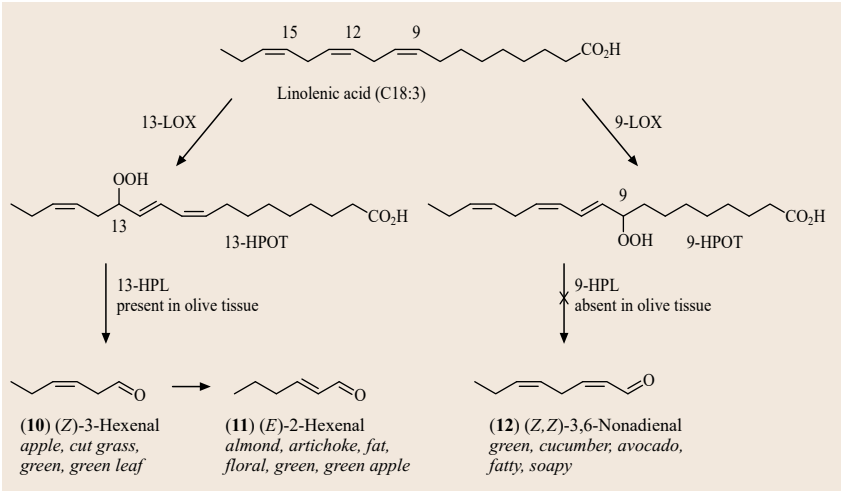

Fig. 11.12 Lipoxygenase (LOX) pathway to *green* aldehydes in olive oil

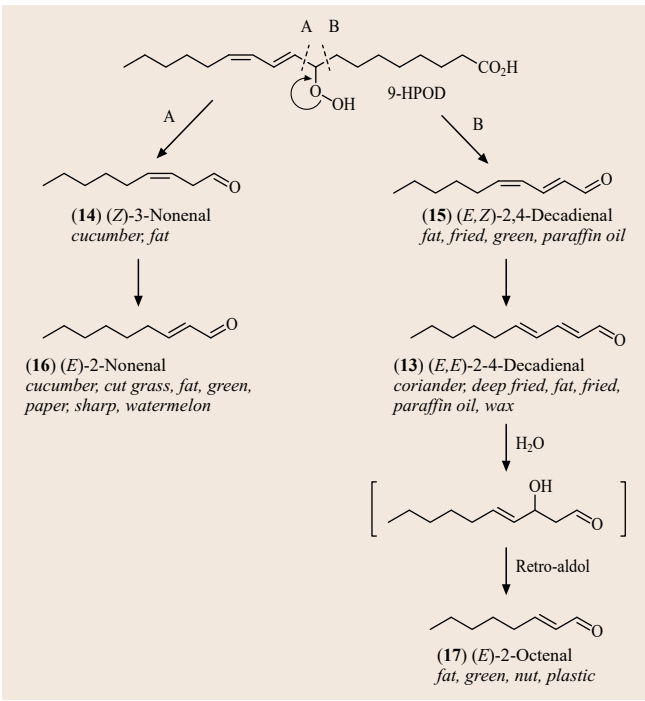

Fig. 11.13 Autoxidation of linoleic acid

oil, only C_6 aldehydes, such as (*Z*)-3-hexenal **(10)** and (*E*)-2-hexenal **(11)**, which are responsible for the *green* odor of olive oil, are formed [11.42]. Whereas 9-HPOT was more abundant in the reaction of linolenic acid with olive fruit tissue, the corresponding C_9 aldehydes, such as **(12)** were absent because the hydroperoxide lyase present in olive is highly specific toward 13-HPOT (Fig. 11.12) [11.42].

However, the enzymatic pathway to aldehydes is not the only one and also not the most common in foods. Autoxidation during cooking or storage forms a large variety of potent odorant aldehydes. Thereby, it is important to note that no enzyme is needed for the thermal cleavage of fatty acid hydroperoxides. Thus, (*E,E*)-2,4-decadienal **(13)** is formed from 9-HPOD, as is shown in Fig. 11.13 [11.43]. Unsaturated aldehydes may also react with water and degrade through a retro-aldol reaction to give (*E*)-2-alkenals with two fewer carbon units. The mechanistic aspects of flavor compound formation from lipids have been reviewed in detail by *Fitz* et al. [11.44]. Table 11.2 lists the most important aldehydes in fats and oils, most of which are used as flavor ingredients in the food industry. The possible precursors according to *Fitz* et al. [11.44] are also shown. A recent study of olive oil put the aldehydes and the fatty acids in perspective, thereby allowing the confirmation of the origin of certain aldehydes [11.45]. The occurrence of less common branched-chain fatty aldehydes in beef has been described in the literature [11.46, 47]. These aldehydes are believed to originate from microorganisms in the rumen of bovine animals [11.48]. They are then incorporated into the lipid phase of the muscular tissue in the form of plasmalogen, which is a special kind of phospholipid (Fig. 11.14). Aldehydes, including unusual branched-chain aldehydes, are bound to glycerol by an enol ether bond and are subsequently released by hydrolysis during cooking [11.48]. 12-Methyltridecanal **(30)** is the most important member of this family of aldehydes.

Note that the occurrence information indicated in the right column of Table 11.2 is not exhaustive. Only those foods are listed in which the compound has been discovered in the highest quantity, when this information is available.

Another class of aldehydes can be found in fat-containing food forms from Maillard reactions [11.50]

Table 11.2 Important odorous aldehydes and their occurrence in fat-containing or fat-based foods

Aldehyde	Precursors [11.44]	Odor [11.37]	Occurrence [11.37]
Hexanal **(18)**	13-LOOH	Apple, fat, grass, green, green fruit, oil	Common
(*Z*)-3-Hexenal **(10)**	13-LnOOH	Apple, cut grass, green, green leaf	Olive oil
(*E*)-2-Hexenal **(11)**	Isomerization of **(10)**	Almond, artichoke, fat, floral, green, green apple	Olive oil
(*Z*)-4-Heptenal **(19)**	Retro aldol of **(24)**	Biscuit, cream, fat, tallow	Chicken, milk
Octanal **(20)**	11-OOOH	Citrus, fat, green, oil, pungent, soap, sweet	Beef, chicken, cheese, olive oil
(*E*)-2-Octenal **(17)**	Retro aldol of **(13)**	Fat, green, nut, plastic	Butter oil
(*E*)-2-Nonenal **(21)**	9-LOOH, 12-AnOOH	Cucumber, fat, green, paper	Chicken

or by enzymatic degradation reactions. They originate from amino acids and form through Strecker degradation (Fig. 11.15). These aldehydes can be considered as minor compounds in fat-containing foods, as compared with lipid-derived aldehydes. However, they can impart a distinctive odor (Table 11.3).

11.2.4 Ketones

Ketones have less importance than aldehydes in the flavor of fat-containing foods (Table 11.4). They are usually found in lower quantities, and only a few ketones can be considered as key odor components of meat fat or vegetable oils. A notable exception is mold-ripened cheese, such as blue cheese. The formation of methylketones (2-alkanones) is the result of the β-oxidation of fatty acids [11.51]. Fatty acids appear to slow down the growth of *Penicillium roquefortii* and their oxidation in carefully controlled conditions in cheese making may be a detoxifying mechanism used by the mold [11.52]. By feeding *P. roquefortii* spores with uniformly labeled lauric acid, Dartey and Kinsella showed that a homologous series of C_3–C_{11} methyl ke-

tones was produced [11.53], which demonstrated the mechanism of Fig. 11.16.

1-Octen-3-one **(40)** and (*Z*)-1,5-octadien-3-one **(42)** are found in only trace quantities in fat-containing foods. However, these compounds are such potent odorants that they may contribute to the overall flavor, as shown in butter oil by GC-O [11.55].

(*E*)-5-Methyl-2-hepten-4-one, filbertone **(44)**, is a characteristic and potent odorant of hazelnut [11.56]. It is likely to be formed during the roasting of the nuts in the course of the Maillard reaction, which involves sugars and amino acids, but not lipids. Thus, raw hazelnut was shown to contain only trace amounts of **(44)**, whereas the boiling of the defatted paste in water continuously generated this ketone. It also formed continuously during the roasting of hazelnuts and is found in the oil [11.54].

11.2.5 Lactones

Lactones are ubiquitous in foods. In 1976, Maga exhaustively summarized the occurrence of lactones in many foods, along with their levels and sensory properties [11.57]. The lactones are well-known key aroma compounds in fruits, such as peach, apricot, and coconut, but they are also important in fat-containing foods: vegetable oils (coconut, soybean, cottonseed) or meat fat (beef, chicken, pork, lamb/mutton). Lactones identified in foods possess either a five-membered ring (γ-lactones = 4-olides) or a six-membered ring (δ-lactones = 5-olides). Many γ- and δ-lactones are used by the flavor industry, as reviewed in the literature [11.58]. Interestingly, the annual 1987 world consumption of lactones was 125 t of their native form in foods and 20 t as a flavor additive. Figure 11.17 and Table 11.5 list the most abundant saturated lactones in fat-containing foods, which are also the most important lactones used by the flavor industry [11.58].

γ- and δ-lactones bear a stereogenic center at C(4) or C(5), respectively. Many studies have been performed to determine the enantiomers of lactones in natural products. *Palm* et al. used GC analysis with chiral columns [11.62] and *Lehmann* et al. used multidimensional GC [11.63] for the analysis of dairy lactones. There is not much difference in odor quality between the (*R*)- and (*S*)-enantiomers of the same lactone, but

Octan-5-olide **(54)**	δ-Oxidation	Coconut, hay, goat [11.58]	Beef, chicken, pork, butter, cream, milk
Nonan-5-olide **(55)**	δ-Oxidation	Fat, cream, milk, butter, oily [11.58]	Beef, chicken, pork, butter, milk
Decan-5-olide **(56)**	δ-Oxidation	Peach, oily, coconut [11.58]	Beef, chicken, pork, lamb, milk, butter, cream
Undecan-5-olide **(57)**	δ-Oxidation	Cream, fat, peach [11.58]	Butter, cream, milk
Dodecan-5-olide **(58)**	δ-Oxidation	Strong, peach, butter, coconut [11.58]	Cheese, butter, beef, chicken, pork
Tetradecan-5-olide **(59)**	δ-Oxidation	Creamy	Beef, chicken, pork, butter
(*Z*)-6-Dodecen-4-olide **(60)**	Linoleic acid [11.61]	Coconut, fruity, peach [11.49]	Butter

the perception threshold may be different. The (*R*)-enantiomer predominates in milk, cream, butter, and cheese for most of the lactones ($R/S > 80/20$ for **(50)**, **(52)**, **(56)**, **(58)**, **(59)**), with the surprising exception of octan-5-olide **(52)**. The high enantiomeric excess is evidence for an enzymatic pathway. As early as 1969, TGs containing 4-hydroxyoctanoic and 4-hydroxynonanoic acid were isolated from butterfat and were shown to give the corresponding lactones **(48)** and **(49)** when heated in water [11.64]. Based on the findings obtained after radiolabeled [1-^{14}C] lauric acid (C_{12}) was infused into the lactating glands of goats, a δ-oxidation pathway was proposed to occur in saturated fatty acids. These experiments eventually yielded radiolabels only in γ–C_{12} and δ–C_{12} lactones, thus proving that C_{12} hydroxy acids had been produced [11.60]. This interesting work has been overlooked, in consideration of the low number of subsequent citations. Another pathway implies the hydration of unsaturated fatty acids combined with the β-oxidation degradation of fatty acids (Fig. 11.18) [11.61]. This mechanism explains why only even carbon number lactones are present in milk. It is in agreement with the observed enantiomeric excessof lactones and also the configuration of the double bond found in (*Z*)-6-dodecen-4-olide **(60)**, as shown in Fig. 11.18. An industrial fermentative process for the synthesis of lactone provides further evidence in favor of this mechanism [11.65].

Table 11.5 shows the major lactones usually found in fat-containing foods. Although they may not all be potent, they are important in many foods. They provide sweet, fruit, peach to fatty, coconut, and creamy notes. For saturated lactones, the fatty character increases with the chain length.

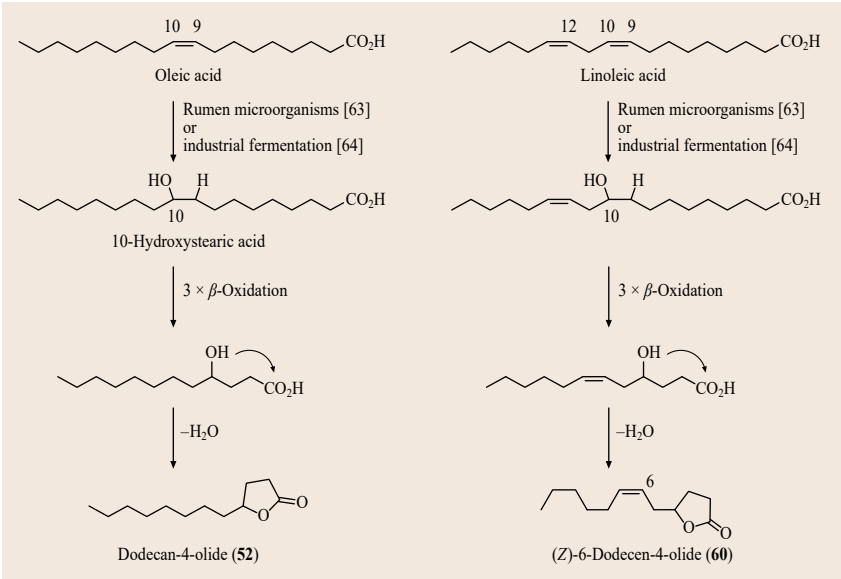

Fig. 11.18 Lactone formation in milk products (after [11.61])

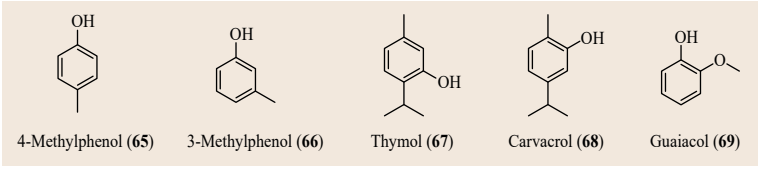

Fig. 11.19 Odorous phenols in fats and oils

11.2.6 Alcohols

Alcohols are not important contributors to the flavor of fat-containing foods (Table 11.6). The thresholdlevels of alcohols are one or two orders of magnitude higher than those of the corresponding aldehydes [11.44]. However, hexanol **(61)**, (*Z*)-3-hexenol **(62)**, and (*Z*)-2-pentan-1-ol **(63)** have been shown to contribute to the green odor of olive oil [11.40]. Alcohols in oils are formed through the same LOX pathway as the aldehydes shown in Fig. 11.12, but a reductase acts as the next step. Natural leaf alcohols, such as **(62)** or (*E*)-2-hexen-1-ol **(63)** are produced industrially in high yield from linolenic acid or linseed oil, using cloned lipoxygenase, HPL, and baker's yeast [11.66]. Phenylethanol **(64)** is not a lipid-derived compound. It is the reduction product of the Strecker aldehyde phenylacetaldehyde **(31)**, as shown in Fig. 11.15.

11.2.7 Phenols

Phenols constitute a class of powerful odorants in foods. They are rarely found in fats and oils, but may contribute to the overall aroma when present. Their odor ranges from woody, smoky to medicinal or animalic and fecal. Table 11.7 and Fig. 11.19 present a few phenols that were identified in fat-containing foods.

11.2.8 Furans

Furans are ubiquitous in fats and oils [11.37]. They are products of the autoxidation of polyunsaturated fatty acids. Thus, 2-pentylfuran **(70)** can form from linoleic acid. Thefirst steps are shown in Fig. 11.20. Aldehyde **(14)** can react with singlet oxygen to give a peroxide that eventually cyclizes upon loss of water [11.67]. 2-Pentylfuran **(70)**, 2-ethylfuran **(71)** of Fig. 11.20, and higher 2-alkylfurans were identified in beef, chicken and pork, or heated butter [11.37]. In many foods, furans such as furfural or 2-acetylfuran are the result of sugar degradation and are important flavor compounds [11.37]. Generally, however, furans that are formed from lipids are not important odor compounds because their concentrations are around or below their odor thresholds in lipophilic matrices.

11.2.9 Nitrogen-Containing Heterocycles

Most of the aroma-active nitrogen-containing compounds, such as pyrazines, are Maillard reaction products. This reaction of amino acids and sugars also

Table 11.6 Odorous alcohols in fats and oils

Alcohol	Precursors [11.44]	Odor [11.37]	Occurrence [11.37]
1-Hexanol **(61)**	Linoleic acid	Banana, flower, fruit, grass, green	Beef, cheese, butter
(*Z*)-3-Hexenol **(62)**	Linolenic acid	Banana, grass, green fruit, green leaf	Butter, olive
(*E*)-2-Hexen-1-ol **(63)**	Linolenic acid	Fat, grass, green, leaf, pungent, sweet, walnut	Olive
Phenylethanol **(64)**	Phenylalanine	Floral, herb, honey, lilac, pungent, rose, spice	Chicken, cheese

Table 11.7 Odorous phenols in fats and oils

Phenol	Precursors	Odor [11.37]	Occurrence [11.37]
4-Methylphenol **(65)**		Fecal, medicinal, phenol, smoke, spice, stable	Fish, cheese, chicken
3-Methylphenol **(66)**		Fecal, medicinal, phenol, plastic, sharp, smoke, spice	Cheese, pork
2-Isopropyl-5-methylphenol **(67)**	Terpene pathway [11.39]	Medicine, wood	Cheese, fish, olive
5-Isopropyl-2-methylphenol **(68)**	Terpene pathway [11.39]	Caraway, spice, thyme	Cheese
2-Methoxyphenol **(69)**	Lignans	Burnt, medicine, smoke, sweet, wood	Olive

produces low molecular-weight amines, such as ammonia, which may subsequently react with lipid oxidation products to yield the nitrogen-containing heterocycles found in heated fats. Thus, model thermal reactions between an amino acid and 2,4-decadienal **(13)** invariably give 2-pentylpyridine **(72)** as a major volatile compound (Fig. 11.21), together with an extensive list of other compounds [11.68]. A series of homologous 2-alkyl pyridines **(72)–(75)** was recently identified in chicken fat [11.69]. Table 11.8 gives their odor description when tasted at a concentration of 10 ppm in water. These compounds are potent odorants whose role in fats and oils has been overlooked.

Similarly, pyrroles, such as **(76)** of Fig. 11.22 can be found in the fat phase of cooked meat. Pyrroles are not considered to be potent flavor components, which is in contrast with pyrrolines such as 2-acetylpyrroline **(77)**. 2-Acetylpyrroline is formed from the amino acid proline, not from lipids. However, it is found in chicken and beef [11.37]. It is an extremely potent compound with an odor threshold of as low as 0.02 $\mu g/m^3$ [11.39].

Pyrazines (Fig. 11.23) are important aroma compounds in foods and are formed by the Maillard reaction. They are found in oils made from roasted seeds or from nuts. In this case, they play a major role in the respective flavors of these foods (Sect. 11.3.1).

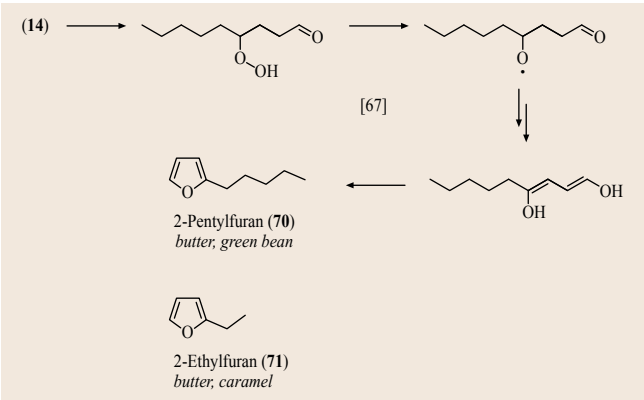

Fig. 11.20 Odorous furans in fats and oils

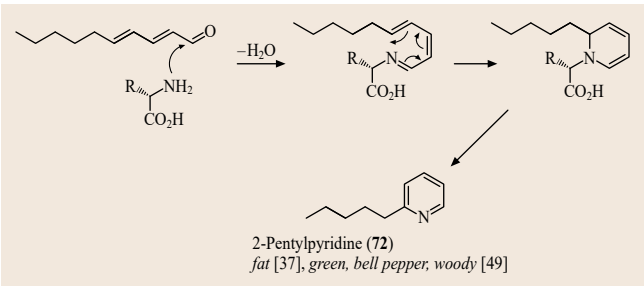

Fig. 11.21 Formation of 2-pentylpyridine (72)

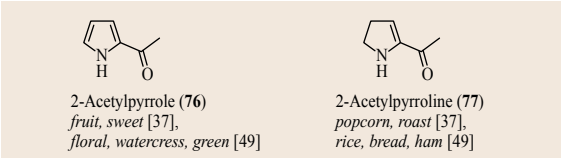

Fig. 11.22 Odorous pyrroles in fats and oils

11.2.10 Other Heterocycles

Sulfur heterocycles, such as thiophenes (Fig. 11.24) and thiapyrans may originate from lipids. Thus, the reaction of hydrogen sulfide with 2,4-decadienal forms either 2-hexylthiophene or 2-pentyl-2*H*-thiapyran [11.70]. Thiophenes are not regarded as important odor contributors to food flavors.

Thiazoles and thiazolines (Fig. 11.25) can also form in fatty and roasted foods through the reaction of cysteamine with a lipid-derived aldehyde or acid [11.70]. These heterocycles may greatly contribute to the flavor of oils such as sesame (Sect. 11.3).

Table 11.8 Odorous pyridines in fats and oils

Pyridine	Precursors	Odor [11.69]	Occurrence [11.37]
2-Pentylpyridine **(72)**	2,4-Decadienal	Fruity, green, woody, vegetable, licorice, aniseed	Beef, chicken, lamb, peanut
2-Butylpyridine **(73)**	2,4-Nonadienal	Fruity, green, fatty, chemical	Chicken, lamb
2-Hexylpyridine **(74)**	2,4-Undecadienal	Fruity, green, fatty, oily	Chicken [11.69], lamb

11.3 The Aroma of Fats and Oils

The aroma of foods can be studied for many purposes. For the flavor industry, the creation of a flavor that is the closest to a genuine cooking recipe is the main goal. For agronomists, understanding which compound is a key aroma compound or is detrimental to the overall flavor will help in selecting the right plant hybrids or modifying cultivation practices. The food industry also benefits from knowledge about aroma compounds. Understanding the stability of key aroma compounds during storage or cooking is important to maintain good quality even under cost constraints.

GC-MS analysis of a food extract does not provide sufficient information to fully understand a food's flavor. The key compounds, many of which are found in trace amounts, have to be sorted out from hundreds of components. The identification of key aroma compounds is often done by GC-O [11.71]. In the following section, a selection of the most important fats and oils of the human diet is reviewed. Their odor-contributing compounds, based on recent GC-O studies, are given in the form of tables wherever possible.

The odor activity value (OAV) is often additionally used to evaluate the contribution of individual compounds to the odor profile of food extracts. It represents the ratio between the quantity of a compound divided by its odor threshold in the same matrix. When the OAV is greater than 1, the compound is considered to have an important odor contribution. In aroma extract dilution assay (AEDA) analysis, the analytes are not quantified. The aroma extract is diluted stepwise and each diluted solution is then analyzed by GC-O. The flavor dilution (FD) factor corresponds to the last dilution step of the extract in which the analyte is still perceived. The higher the FD factor, the more the compound contributes to the overall flavor of the extract. The nasal impact frequency (NIF) method uses more panelists, whose task is to report the detection of odorants eluting from the GC and, if possible, provide a description of the odor. The compounds are then classified by the number of panelists that detected each compound. It is hoped that all of these GC-O data will be helpful in understanding the flavor of foods. However, such data are never sufficient to perfectly re-create a natural flavor (personal experiences of this author). Quantitation of the most contributive odorants may help greatly, but the flavorist has to *interpret* the data and use his/her own skills to create a flavor composition that is close to the real food product.

11.3.1 Vegetable Oils

The vegetable oils presented here can be used as such, for example, in salad dressing. They can also be used for cooking or frying, a process during which certain molecules will degrade and others will form. Such processes are not discussed further here.

Olive Oil

Table 11.9 summarizes recently obtained GC-MS and GC-O qualitative and quantitative data [11.17, 40, 72–76]. *Reiners* and *Grosch* [11.76] used distillation for the preparation of the extract and GC-MS and GC-O analysis. After having identified the main odorants, the oil was spiked with deuterated reference compounds for the accurate quantitation [11.76]. There are many differences in the results of these studies. However, it is clear that C_6 aldehydes constitute the key elements of the odor of fresh olive oil, whereas a few ketones and esters may give fruity undertones. Terpenoids and hydrocarbons are found in high quantities, but do not contribute much to the odor.

Peanut Oil

The contribution of flavor compounds to the aroma of peanut oil was analyzed by GC-O using AEDA [11.77]. Table 11.10 shows the compounds that possessed an FD of more than 1. Although numerous aldehydes were found amongst the most important compounds, other chemical classes, not only those that are lipid-derived, contributed to roasted or sweet notes. In particular, pyrazines in aromatic roasted peanut oil were shown to increase upon roasting [11.78]. Many of these pyrazines have a very low odor threshold level when tasted in oil: 2,5-dimethylpyrazine **(79)** is detected at 2 ppm, 2,3-dimethylpyrazine at 50 ppb, and 2,5-dimethyl-3-ethylpyrazine **(80)** at 24 ppb.

Hazelnut Oil

Table 11.10 (see the previous section on peanut oil) shows the result of AEDA analysis for hazelnut oil. Aldehydes were of less importance, whereas one ketone, filbertone **(44)** (Fig. 11.26), gave the specific odor to the oil. This ketone was accurately quantified using the deuterated analog **(44)** as an internal standard and was much higher in roasted hazelnut oil (316 ppb) than in unroasted hazelnut oil (6 ppb) [11.54].

Sesame Oil

Sesame oil has a very characteristic odor and is used for seasoning, particularly in East Asian dishes. In the manufacture of sesame seed oil, the seeds are roasted to develop the roasty odor. In 1996, *Shimoda* et al. identified and quantified 100 flavor compounds in sesame oils made from different roasting processes [11.14]. They used hydrodistillation (Sect. 11.1.1) followed by GC-MS analysis to show that the amount of all of the chemical classes of aroma compounds was increased by a factor of 4–6 upon deep roasting as compared with light roasting [11.82]. Table 11.11 shows the quantitative data expressed in ppb.

Fig. 11.28 Two new thiazolines in sesame oil (after [11.81])

In 2010, the roasting of sesame seeds was studied by *Tamura* et al. [11.79]. Dichloromethane extraction of the ground roasted seeds, followed by SAFE (Sect. 11.1.1), was used to isolate the volatile compounds. Remarkably, 11 thiols were firmly identified, including previously unknown 1-alkenyl-1-thiols **(86)–(89)** (Fig. 11.27). These thiols have not yet been shown to occur in sesame oil. It is likely that high-sensitivity GC-MS or GC-O methods will eventually show their odor contribution, especially when considering their very low odor thresholds [11.80].

Apart from that, flavor scientists recently identified two thiazolines **(90)** and **(91)** (Fig. 11.28) in sesame oil [11.80], which might also contribute to the odor.

11.3.2 Animal Fats

Milk and Butter

A thorough analysis of the flavor of milk was published by *Bendall* in 2001 [11.83]. The extraction of milk was performed by using SAFE (Sect. 11.1.1) and more than 60 aroma compounds were identified by GC-MS and GC-O using the NIF method (Table 11.12 and Fig. 11.29). The nitrogen-containing heterocycles indole **(92)** and skatole **(93)**, as well as phenol **(94)** and 4-propylphenol **(95)**, added the animalic notes to milk. γ-Lactones **(50)**, **(52)**, **(60)**, **(96)**, and **(97)** and δ-lactone **(56)** had high NIF factors.

Butter aroma has been the subject of numerous GC-O studies [11.55, 87]. These were reviewed in 2008 by *Mallia* et al. [11.85]. The list of aroma-

Table 11.12 Aroma compounds in milk products

Phytol	Bitter; oats				

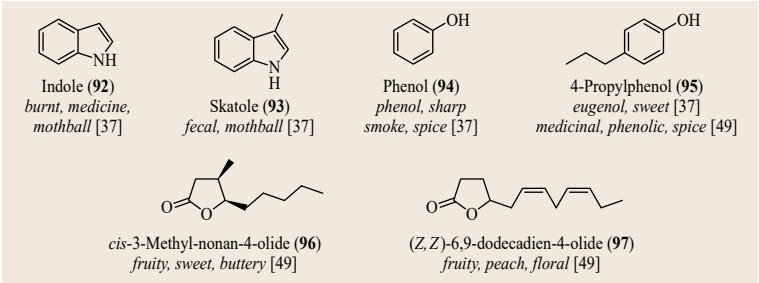

Fig. 11.29 Selected key aroma compounds in milk (after [11.83])

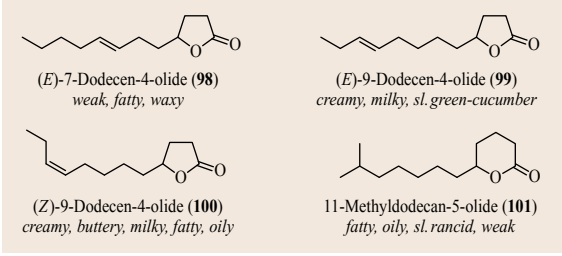

Fig. 11.30 New lactones in butter oil (after [11.84])

active compounds shown in Table 11.12 is adapted from this review. In sweet cream butter, the quantities indicated in Table 11.12 were obtained by static headspace analysis (Sect. 11.1.2) carried out in a large glass vessel [11.86]. Less quantitative data are available on the lone butter oil [11.55]. Recently, *Sarrazin* et al. carried out a study focused on the lactones in butter oil [11.84]. They distilled 1 kg of butter oil (Sect. 11.1.1) and discovered a series of new γ-lactones after systematic chemical synthesis [11.88]. Reconstitutions based on the lactone fraction and diluted in sunflower oil were carried out. The first reconstitution was only composed of the major lactones, **(50)**, **(54)**, **(56)**, **(58–60)** in the ratio actually found in butter oil. In addition to the major lactones, a second reconstitution also contained the minor lactones **(98–101)** of Fig. 11.30. The odor difference of the two reconstituted solutions were clearly perceived and the lactones **(98–101)**, although found in lower quantities, brought a more creamy and coconut character to the overall odor [11.84].

Cheese

The aroma of cheese has been exhaustively reviewed by *Curioni* and *Bosset* [11.41], who compiled the GC-O data from about 100 references in nine tables. They provided a comprehensive overview of the odor qualities and thresholds of many compounds sorted according to chemical class. In this review, thirteen different cheese types were taken into consideration and the main odorants were summarized based on the GC-O studies carried out in the cited references. The main odorants in Gongonzola, a typical blue cheese made from cow's milk in Italy, were found to be 2-heptanone **(37)**, 2-nonanone **(38)**, 2-heptanol (green, earthy), 1-octen-3-ol (mushroom-like) and ethylhexanoate (fruity, apple). In Camembert, a typical mold-ripened cow's milk cheese from France, a larger variety of compounds were identified as the main odorants, namely 1-octen-3-ol, 3-methylbutanal **(34)**, 2-undecanone **(39)**, 1-octen-3-one **(40)**, 2,3-butanedione (buttery), phenylethyl acetate (floral, rose-like), decan-5-olide **(56)**, methional **(35)**, methanethiol (sulfurous), dimethylsulfide (sulfurous), butanoic acid **(1)**, and 3-methylbutanoic acid **(6)**. In Gruyère, a typical hard cheese made from cow's milk in Switzerland, the main odorants were 2-methylbutanal **(33)**, (*Z*)-2-nonenal (fatty, tallowy), phenylacetaldehyde **(31)**, methional **(35)**, methanethiol, dimethyltrisulfide (cabbage-like, sulfurous), propanoic acid (fruity, pungent), butanoic acid **(1)**, 2-methylbutanoic acid **(7)**, and 3-methylbutanoic acid **(6)**. 2-Ethyl-3,5-dimethylpyrazine (earthy) and 2,3-diethyl-5-methylpyrazine (earthy) are also impact odorants formed during the cooking steps (34−54 °C) involved in the preparation of Gruyère cheese. In goat cheese, acids are the main odorants: nonanoic acid (goat-like), 4-ethylnonanoic (goat-like), and 3-methylbutanoic **(6)**.

Beef Fat

Most of the publications on beef flavor describe the analysis of roast beef with the meat being minced and roasted before extraction of the volatile compounds [11.89]. *Um* et al. analyzed heated beef fat flavor compounds isolated by supercritical CO_2 extraction (Sect. 11.1.3) [11.91]. Besides hydrocarbons, they identified 15 aldehydes, three ketones, four phenols, 10 carboxylic acids, six esters, and seven lactones, which are summarized in Table 11.13. *Umano* and *Shibamoto* used the headspace technique (Sect. 11.1.2), resulting in the identification of a greater number of more volatile compounds on average [11.92]. However, the absence of esters and lactones shows the inability of the technique to extract compounds of lower volatilities. An interesting setup was used by *Rochat*

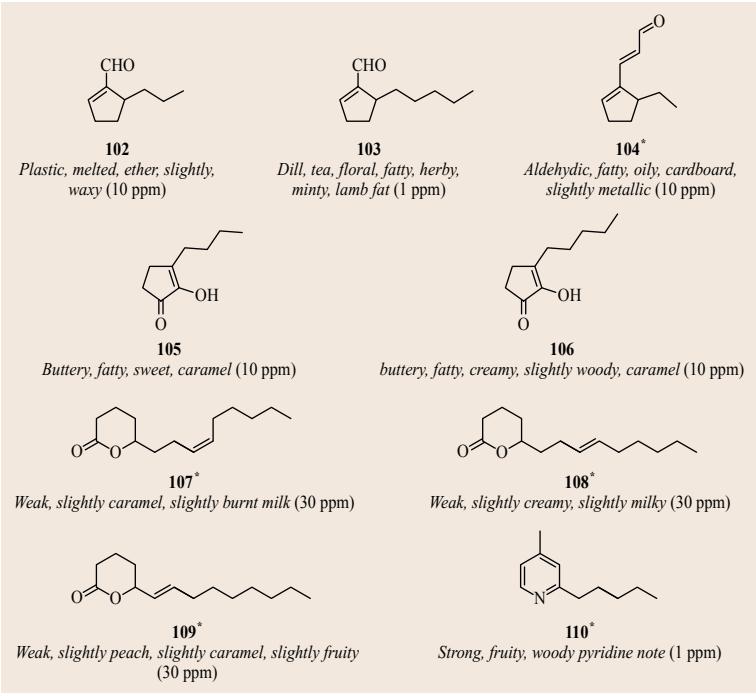

Fig. 11.31 Aroma compounds newly found in chicken (after [11.90]). Asterisks denote compounds not previously known in nature. Odor qualities given from tasting the compounds are shown at the indicated dosage in salted water

and *Chaintreau* for the analysis of roast beef [11.93]. They placed a Tenax cartridge to extract the headspace of the oven during cooking. It can thus be considered that the volatile compounds came from the fat being exuded during roasting. The study focused on carbonyl compounds; more than 50 of them were identified, among which were straight and branched-chain aldehydes, 2-alkenals and 2,4-alkadienals, and 2-alkanones. Their flavor impact was assessed by GC-O with the NIF method (see Sect. 11.3 above); these substances are also presented together with the obtained data in Table 11.13. Another GC-O study of beef fat headspace found the same key compounds, with 4-heptenal, 2,6-nonadienal, indole, and decan-5-olide also being considered as important aroma chemicals [11.94].

Pork

The volatile compounds identified in pork fat do not differ much from those of beef fat. The reader is referred to the review of *Werkhoff* et al. [11.47] for a comparison of beef, pork, and chicken meat, with an emphasis on sulfur compounds and long-chain aldehydes. A careful qualitative and quantitative analysis of roasted pork by GC-MS and GC-O provided detailed results (amounts, odor quality, NIF factors) [11.95].

Chicken

Considering the topic of the present chapter, that is, the flavor of fats, chicken perhaps constitutes the most interesting example because the fat resides in a precise location near the meat and skin. Therefore the chicken can be roasted and a different part, in particular the fat, can be analyzed separately. *Noleau* and *Toulemonde* published a thorough piece of work in which they identified and quantified nearly 200 compounds in the skin and meat of roasted chicken, 80 of which were new [11.96]. For skin and meat, they used the Likens–Nickerson apparatus (Sect. 11.1.1). The dripping fat was also analyzed with short-path distillation (Sect. 11.1.1) and more than 200 compounds were identified by GC-MS and quantified by GC-FID [11.97]. Again, the volatile part was composed of aldehydes (51 chemicals, accounting for 120 mg/kg of fat), ketones (34, 10 mg/kg), acids (19, 40 mg/kg), and lactones (24, 8 mg/kg) as the major components. *Delort* et al. subsequently followed the same approach to analyze distinct parts of cooked chicken, including its fat [11.90]. Short-path distillation was used to produce the fat aroma extract, which was fractionated further by chromatography over silica gel, and many new compounds could be identified (Fig. 11.31). The role of these compounds in the overall aroma remains to be assessed.

Table 11.13 Aroma compounds in beef

Compound	Concentration in heated beef fat ppm [11.91]	Amount in heated beef fat (GC FID %) GC-FID peak area % [11.92]	GC-O NIF, detection frequency % [11.93]	GC-O Odor quality [11.93]	GC-O Odor quality [11.94]

11.4 Conclusion

The analysis of aroma compounds in fats and oils is a difficult task. Understanding the aroma of fat-containing foods requires many analytical skills, from the preparation of a good extract to the GC-MS identification of hundreds of chemical compounds. GC-O and/or quantitative studies are then needed to assess the role of each component. Many extraction methods are available and may be adapted to the needs of the analysis. Further fractionation can provide the identity of even more products that can play a role in the flavor. Aldehydes, acids, lactones, and ketones are common key contributors to the aroma of fats and oils. However, the sensory importance of sulfur compounds and nitrogen heterocycles should not be overlooked. Finally, it should be noted that the many components can be desirable or undesirable, such as in frying oil, which imparts good taste to foods but may also be responsible for deterioration in quality if not properly used [11.98]. A fundamental understanding of the diverse mechanisms of formation of these chemicals is thus the key prerequisite to maximizing or preventing the formation of certain compounds.

12. Aroma Encapsulation and Controlled Delivery

Gary Reineccius

The area of protecting and delivering aroma compounds in a food application is most challenging. At this time, well over 8000 aroma compounds have been found in nature and they vary widely in physical and chemical properties which makes their protection and delivery very problematic (evaporation and chemical reactivity). Thus, one attempts to design encapsulation systems that protect the key aroma compounds but yet deliver them when needed using cost-effective and legally approved materials and methodologies. This chapter provides strategies used to accomplish these goals. Overviews of materials and methods used in encapsulation and controlled delivery are presented. The final section offers insights into unmet needs in this area.

There is no question that volatile compounds that contribute to sensory perception (aroma compounds) are extremely important to characterizing the flavor of a food. Until fairly recently, it was felt that they were the only chemicals contributing significantly to flavor perception. Food manufacturers treated taste as if was an afterthought, that is, if a product needed a sweet taste, one could use any sweet compound (most likely the cheapest) and flavor character would be satisfactory. We have since learned that taste and aroma are intimately linked and the human brain has certain expectations of congruency to elicit a true flavor (Chap. 47).

The long held belief that aroma was the only consideration in creating a flavor resulted in a great deal of research on identifying, determining the importance of, stabilizing and delivering aroma compounds on eating. This chapter will focus on stabilizing and controlling the release of flavor compounds in foods. Stabilizing is very important since aroma compounds are often chemically reactive and are, by definition, volatile. They need to be protected from loss from manufacture to consumption; this is often done by employing some process of encapsulation. To deliver these protected aroma compounds they must be released from the encapsulant. This brings us to the topic of controlled release, that is, when do we want them released. Ideally, they should be released from the encapsulant just as the food goes in the mouth so they may be protected until the very last moment and then be released into the food to create the desired perception when masticated or simply swallowed. This chapter will discuss the concepts of encapsulation to provide the protection of aroma compounds and then their controlled release at some step in the food preparation process.

12.1 Diversity in Aroma Compounds

In order to address the topic of aroma encapsulation, it is worthwhile to set the stage by discussing what compounds one wants to protect, what we want to protect them from, and what the issues are in terms of controlling their delivery. This book is focused on odor compounds: those compounds found in foods that stimulate the sense of smell. Essentially, this must consider all volatile compounds present in a food that are transferred to the breath during eating at adequate concentrations to influence perception.

At this time, more than 8000 volatile chemicals, and thus potential contributors to odor, have been identified in food products. These compounds differ tremendously in terms of volatility, solubility, and reactivity. Volatility, expressed as boiling point, can range from temperatures of ca. −60 °C (e.g., hydrogen sulfide) to ca. 285 °C (e.g., vanillin). An aroma compound can be totally immiscible in water or totally insoluble; others can easily be dissolved in water. In terms of reactivity, some aroma compounds are extremely stable to normal temperatures, acidities, ambient light or the presence of oxygen. Others are very labile. If a food flavor was composed of only one known compound and we had to protect it from one known reaction, our task would be simple. Unfortunately, nature has chosen to make our world much more complicated and also much richer. While one aroma compound may reproduce a specific food flavor, the perceived flavor is poor and not true to nature. Nature uses many compounds to provide depth and character. The result is we must protect many, often very different, aroma compounds to deliver a quality flavor. The breadth of physical and chemical properties as well as reactivity displayed by aroma chemicals makes designing encapsulation processes extremely challenging.

12.2 Chemical Reactions that Lead to Flavor Loss

Aroma chemicals, by their nature, are subject to loss during storage due to chemical reactions or evaporation. As noted earlier, encapsulation is a method used to protect aroma compounds from these losses. While numerous different chemical reactions can occur within a flavoring or between the flavoring and the environment, we will focus only on the major chemical reactions. These are oxidation, the Maillard reaction, and some miscellaneous reactions. Note, we are not attempting to deal with the development of off flavors in foods (see Chaps. 5, 10), but only a narrow discussion of how flavors added to a food might be lost during storage or preparation. Each of these reactions will be briefly discussed.

12.2.1 Oxidation

While essential oils will undergo numerous degradation reactions (e.g., polymerization, isomerization, dehydration, and thermal rearrangements), the primary degradation reaction is oxidation (Fig. 12.1, [12.1]). Mono terpenes tend to be the most liable compounds in essential oils (limonene in citrus oils). The pathway shown in Fig. 12.1 illustrates that limonene oxide and carvone tend to be major oxidation-end products. These two compounds are primarily responsible for the off flavor associated with limonene-free radical oxidation.

Other essential oils, such as phenolic oils (clove, savory, thyme, and origanum), mint, and aldehyde-based oils (e.g., oil of bitter almond) will also deteriorate due to oxidation. Oil of bitter almond has benzaldehyde as a characterizing component which will oxidize to benzoic acid that has a harsh, biting effect in the back of the throat. The sensitivity of essential oils to oxidation is often the primary reason for the encapsulation of a flavoring, limiting the exposure of the flavoring to oxygen.

A different cause of deterioration in essential oils is light exposure. For example, anise oil will readily degrade on light exposure to give off notes. The first step in degradation is the isomerization of *trans*-anethole to *cis*-anethole followed by subsequent oxidation to anisaldehyde (vanilla-like odor; Fig. 12.2a). An additional reaction, the reaction of anethole with anisaldehyde will readily occur to form 4,4-dimethoxystilbene (Fig. 12.2b; no odor reported).

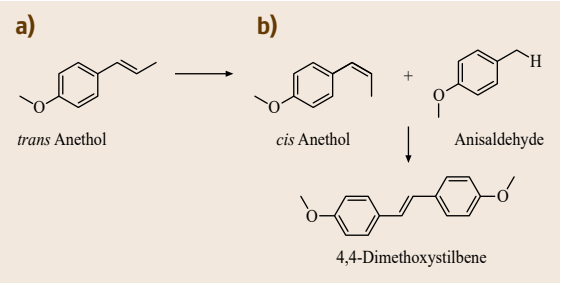

Fig. 12.2 **(a)** Oxidation of *t*-anethol to anisaldehyde. **(b)** Reaction product of *t*-anethol and anisaldehyde to form 4,4-dimethoxystilbene (after [12.1])

12.2.2 Maillard Reaction

While in food chemistry we tend to think of the Maillard reaction as a reaction between amino acids and reducing sugars, in flavor chemistry, this definition is broadened to the reaction of any amine with any carbonyl compound. With this broadened definition, we become very concerned about the unsaturated carbonyls and amines used in flavorings and their opportunity for reaction. This reaction does not necessarily result in the formation of off flavors, but the loss of desirable flavoring components.

Unsaturated carbonyls (most often aldehydes)
+ amines (may be from several sources)
→ Schiffs base (no flavor)

Unsaturated carbonyls are fairly common while few amines are used as flavoring components. The most common amines used in flavoring are methyl or ethyl anthranilate (grape flavoring and some essential oils). Due to differences in amount and frequency of use, we are most commonly concerned about the loss of the aldehydes. Figure 12.3 illustrates the sources of reactants that lead to the loss of carbonyls.

A statement was made earlier that the primary result of the Maillard reaction in this context is a loss of flavor (as opposed to the formation of an off flavor), in the case of reaction with the high potency sweeteners, not only the flavoring agents (the unsaturated aldehydes) are lost but also the sweetener. This is a primary reason that aspartame is not used in some chewing gums (lemon [citral] or cinnamon [cinnamic aldehyde] flavored gums; [12.2]).

If we decide to encapsulate our flavoring to offer some protection against such reactions, we must choose our flavor encapsulation system carefully. The primary consideration here is to not use a protein in the encapsulation wall system. If so, the carbonyl components of the flavoring will react with the free amino groups in the protein encapsulant and will lead to complete losses of the flavoring in a short time [12.3].

12.2.3 Miscellaneous Reactions–Internal Reactions

By internal reactions, we are considering reactions that can occur within a given flavor formulation. When one prepares a complex mixture of organic chemicals (creates a flavoring) many reactions may occur (dimerization, aldol condensations, ester formation, sulfide formation, etc.). A reasonable question is why these reactions do not occur in nature resulting in flavor degradation and the answer is they do. However, in many cases flavor is formed enzymatically, very rapidly on chewing (vegetables), so little time is available for the chemical reaction to occur prior to eating. In another instance such as during the roasting of coffee beans, the flavor is created during heating but gets locked into a dry matrix where diffusion to other reactants is not allowed (within the bean). A final example is the natural flavor is very dilute and thus reactions take place very slowly; however, this is not the case in a concentrated commercial flavoring.

To meet this particular challenge, a unique form of encapsulation is used: molecular encapsulation. Molecular encapsulation is often called inclusion complexing and involves the interaction of individual flavor molecules with an encapsulating material such as a cyclodextrin or amylose. These encapsulating materials possess unique structures that *tuck* individual flavoring compounds into a safe place in them where they are protected from the environment and each other. This method will be discussed in some detail later in this chapter.

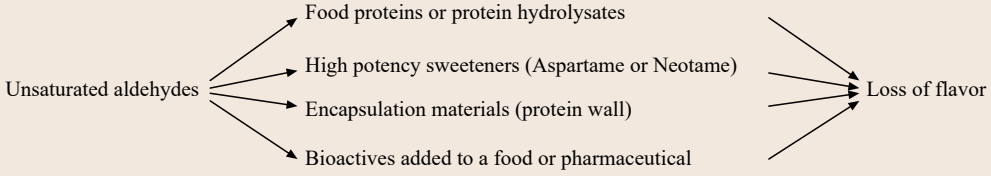

Fig. 12.3 Components that contain amines that may react with carbonyl-containing flavoring materials

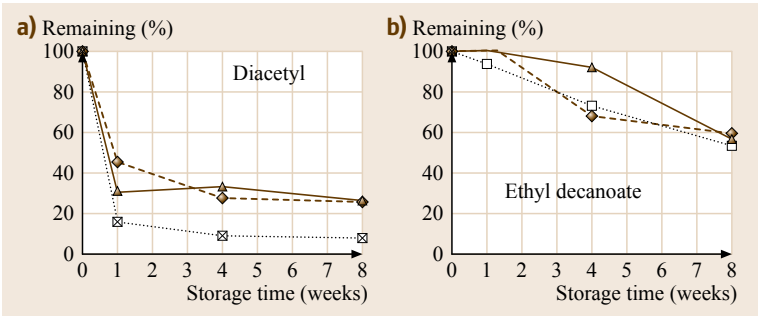

Fig. 12.4a,b Retention of two model aroma compounds when put in microwave popcorn package prepared as a liquid flavoring (*dotted lines*), spray dried in N-Lok (*dashed lines*) and spray dried in gum acacia (*solid lines*) **(a)** diacetyl **(b)** ethyl decanoate (after [12.4])

12.2.4 Reaction with the Food Matrix

This mechanism of flavor loss has already been partially presented above when discussing Maillard reactions (carbonyl flavor compounds with free amino groups on proteins). As noted, this reaction can be a very significant means of flavor loss. Beyond Maillard-type reactions, proteins also offer other reactive sites for flavor reaction. An example is the formation of sulfides from any thiol-based flavor compounds reacting with the free sulfhydryl groups on cysteine. One could envision acetal formation again involving protein side chains and aldehydes. Anyone working in the high protein bar business appreciates how difficult it is to form and keep a desirable flavor in high protein food products.

12.3 Evaporation as a Mechanism of Flavor Loss

Thinking back to the earlier description of the physical properties of aroma compounds, some aroma compounds have extremely low boiling points (e.g. hydrogen sulfide has a boiling point of −60 °C, methanethiol boils at 5.95 °C, and acetaldehyde at 20.2 °C) and thus, would be readily lost due to evaporation if not adequately sealed into some encapsulated structure. There are numerous aroma chemicals that boil close to or just above room temperature. The high vapor pressure and small size of some aroma chemicals make it nearly impossible to keep them in any system – even our best encapsulation systems: This is illustrated in Fig. 12.4 where model aroma compounds were encapsulated by spray drying, put in a model microwave popcorn package (oil, popcorn, and salt) and then stored. In a matter of one week, the diacetyl concentration had dropped by 85% when not encapsulated but still lost 55–70% when encapsulated (Fig. 12.4a). Despite diacetyl being a reasonably large molecule with a boiling point of 88 °C and it was encapsulated, it was readily lost from the capsules. This is likely due to the high polarity of the molecule. For comparison purposes, data are also shown for a much less volatile and larger compound, ethyl decanoate. Losses for this compound differed little whether encapsulated or added as a liquid (Fig. 12.4b).

12.4 Techniques for Preserving Flavor

Understanding that all aroma compounds are volatile and many are reactive, the industry searches for ways to make them more stable to extend shelf-life. This typically involves protection from oxygen, light, and reactions within the flavor system or with the encapsulation or food matrix. Various encapsulation processes have been developed for these purposes. The major methods will be touched upon (detailed reviews are available on the methods – see reviews [12.5–8]).

12.4.1 Plating

Plating of flavorings involves adding a flavoring to a dry carrier of some type and simply mixing the system to spread the flavoring across the surface and into any pore structure of the carrier. This is often done simply to better distribute a potent flavoring (perhaps a spice oil) in a final food product (e.g., sausage). Some early work by *Bolton* and *Reineccius* [12.9] demonstrated that one could offer substantial protection to flavor compounds

if they were plated on a silica substrate. The very porous silica was able to adsorb the flavoring into very small pores and thereby offer significant protection against evaporation and oxidation. This approach has found some application in the industry most recently for the delivery of savory flavorings.

More recent work on silica has focused on sol–gel approaches [12.10–12]. The sol–gel techniques involve allowing the polymerization of silica monomers to form a structure around pockets (or droplets) of flavor. Sol–gel approaches have found some application in the fragrance industry but not the flavor industry [12.13].

12.4.2 Encapsulation

Encapsulation is a very general term for any process that puts some type of protective *shell* around an active material (flavoring). When one goes through the literature, one notes that many different materials and processes are proposed for flavor encapsulation. With that said, only four processes find broad application in the food/flavor industry. They are spray drying, extrusion, inclusion complexing and coacervation: the largest volume of dry, encapsulated flavorings is done by spray drying. Each of these processes offers unique benefits and weaknesses. Since all of these methods are discussed in the review articles cited above, only brief statements will be made for each.

Spray Drying

Spray drying (Fig. 12.5) starts by preparing an aqueous emulsion consisting of the flavoring material (generally water insoluble) and the encapsulating material (water soluble; generally a gum acacia, modified starch, or maltodextrin-based dispersion) in a mix tank. The material is solubilized and then homogenized to make a very fine dispersion of the flavoring in the solution. This emulsion is atomized into hot air (e.g., 200 °C) where the particles dry rapidly. The powder is separated from the exhaust air stream in a *cyclone*, collected, screened and bagged. The flavoring material is in the form of a dry emulsion called matrix encapsulation – droplets of flavoring dispersed in the dry encapsulating material (Fig. 12.6). This process is very popular for several reasons including low cost, equipment readily available, high flavor load (ca. 20%), and the process/product performs well (retention of flavoring and barrier to oxygen). The down side includes secondary processes are required to modify physical properties (instantize or afford controlled release) and not well suited to very low boiling compounds.

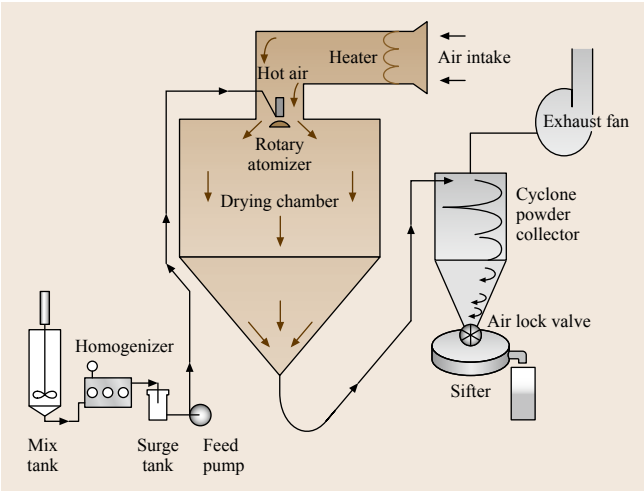

Fig. 12.5 Spray dryer used to encapsulate flavoring materials

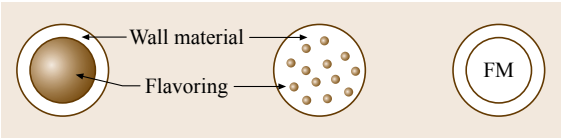

Fig. 12.6 Particle structures occurring in encapsulation systems. (*left* – shell and core structure; *middle* – matrix structure; *right* – molecular inclusion (one flavor molecule in a cyclic glucose structure))

Extrusion

The extrusion process for flavor encapsulation originated from a very simple process of making a flavored hard candy (sucrose and water). The flavored hard candy was ground to provide a powdered flavoring. The traditional commercial process (Fig. 12.7a) involves dispersing a flavoring into a hot, extremely viscous carbohydrate melt. The melt is forced through a small orifice (die) into a vat of cold isopropanol where it rapidly forms a glassy matrix on cooling. Mixing in the vat breaks the extruded strands into small pieces and allows some dehydration. Further air drying results in stable, dry particles. The final particles have a matrix structure and are much larger than those produced in spray drying (ca. 500 μm vs. 10–50 μm). The most recent innovations in this process are to use a twin-screw extruder to form the carbohydrate melt and flavor emulsion (Fig. 12.7b). Substantial work has been devoted to finding alternatives to the cold isopropanol bath. The use of an extruder has provided opportunities to reduce moisture content, reduce the time the flavor is held at high temperatures, and develop a continuous process. Lowering moisture content is particularly valuable in that the less moisture put into the product, the less effort

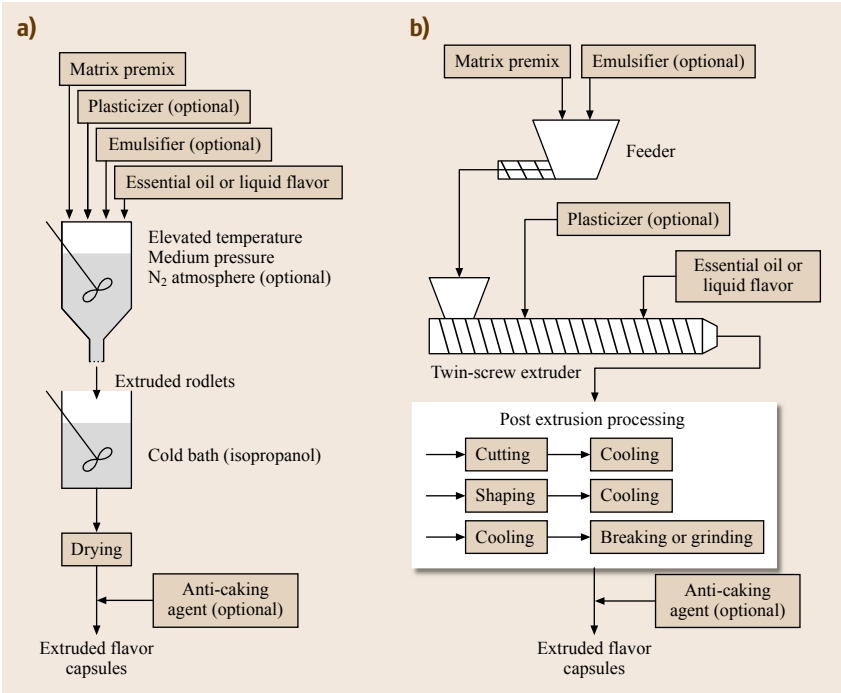

Fig. 12.7a,b Systems for producing extruded flavoring materials: **(a)** traditional system; **(b)** modern extruder system (after [12.7])

is needed to remove it to produce a dry, stable, glassy particle. Advantages of this process (in all configurations) tend to be a long shelf-life (excellent oxygen barrier properties) and large particles. The negatives may be low load (typically ca. 10%), large particles (can also be a positive), slowly soluble in cold water, high temperature process, less than ideal emulsion quality and cost. Despite the list of negatives being longer than positives, it is an important process in the industry.

Molecular Inclusion

Molecular inclusion involves the use of very specific host molecules (cyclodextrins and/or amylose) that offer sites that protect any molecules included in them [12.14]). Figure 12.8 shows the structure of the most commonly used cyclodextrin, the beta form. It is interesting that a cyclic structure composed of glucose forms a very hydrophobic core when placed in water. Flavor molecules tend to be hydrophobic and thus move into the center of the cyclodextrin where they are well protected from oxidation or other chemical reactions. The amount of flavoring that can be loaded into cyclodextrins depends upon the molecular weight of the flavoring material: One molecule of cyclodextrin includes one molecule of flavoring. Thus the loading typically ranges from ca. 9% to 15% by weight.

Amylose, and amylopectin in certain cases, also offers opportunities for forming inclusion complexes [12.15]. Amylose will form a single helix in the presence of aroma compounds that offers a hydrophobic central cavity (hydrophilic exterior) for including aroma compounds. There is evidence that aroma compounds may also be bound in between the helices. There is potential for initiating flavor release using enzymes (amylase), temperature, or moisture. While there are numerous patents on using amylose for this purpose, it has found less use for this purpose than cyclodextrins due to several factors including the physical properties of the amylose (solubility, clarity in solution, etc.)

Coacervation

The process of (complex) coacervation, as applied in flavor encapsulation, originated with carbonless papers in mid-1950s [12.15]. Complex coacervation involves making a coarse emulsion of a flavoring in an aqueous solution of edible food polymer (must have emulsifying properties) and then the addition of a second oppositely charged edible polymer (typically use a combination of a protein, such as gelatin and a hydrocolloid, such as gum acacia). The pH is controlled such that the polymers form a coating around the droplet. The coating typically has to be hardened by crosslinking. This can be done in various ways, for example, chemically using glutaraldehyde or enzymatically using *trans*-glutaminase.

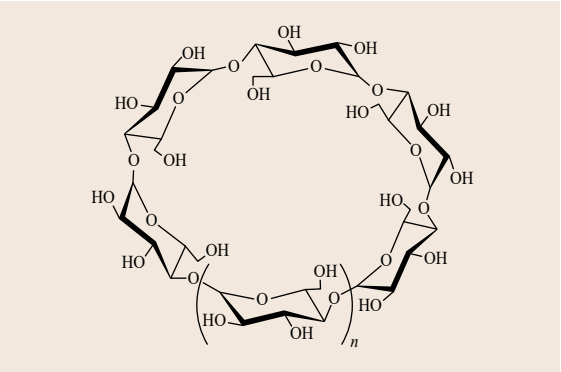

Fig. 12.8 Structure of β-cyclodextrin (after [12.14])

Coacervation is the only encapsulation process that makes a true core and shell structure (other processes result in matrix or molecular encapsulation structures, Fig. 12.6). Coacervation offers some unique advantages not imparted by other encapsulation processes including a wide range of particle size, high loadings, good oxidation stability, having a unique release mechanism (diffusion), and high recovery of flavoring. There are numerous weaknesses to the use of coacervation for flavor encapsulation which include: 1) Water soluble flavor components are lost to the process water; 2) aggregation of the coacervate particles makes control of particle size problematic; 3) process and materials costs are high relative to competing processes; and 4) the protein wall component raises issues of reactivity, allergenicity (labeling) and vegetarian status. As will be discussed later, this process has a unique controlled release mechanism.

Microbial Cells

The potential for using yeast cells for the encapsulation of sensitive materials has been recognized for nearly 40 years [12.16]. The preferred material is empty yeast cells, that is, those that have been treated to remove most of their cytoplasmic cell interior and then spray dried [12.17, 18]. The cells are loaded with flavoring materials by diffusion.

Substantial work has been published on defining the encapsulation and release mechanisms of flavorings from microbial cells [12.19–21]. As one would expect, the movement of flavoring compounds into the cells is dependent upon compound hydrophobicity. *Dardelle* et al. [12.18] reported that compounds with a $\log P > 2.0$ will achieve an encapsulation efficiency of more than 50%. Encapsulation efficiency decreases as $\log P$ decreases.

This method is particularly attractive for imparting thermal stability to flavoring for it has been reported that flavors are not released from dry yeast cells until temperatures approaching 250 °C are attained [12.20, 21]. As with most food polymers, the cell permeability is dependent upon water activity. However, while most encapsulation materials become permeable at water activities around 0.3, the yeast cells were impermeable below a water of ca. 0.7 [12.21].

Other Methods

There are numerous other encapsulation methods listed in the patent and scientific literature. However, they see very limited to no commercial usage and thus they are not going to be discussed in this book chapter.

12.5 Controlled Delivery of Food Aroma

As was mentioned in the introduction to this chapter, one purpose for encapsulating a flavoring material is to impart controlled release properties to it. Looking at the processes used in flavor encapsulation, one can see that the most commonly used processes for flavor encapsulation (spray drying, extrusion and molecular encapsulation) release the flavoring compounds on dissolution. This follows since all of the wall materials used in these encapsulation processes are water soluble. There is a substantial need in the industry to develop processes that afford the controlled release of flavorings, that is, protect the flavoring as long as possible from undesirable reactions and then release for sensing during eating.

Capsule dissolution (flavor release) can occur during manufacturing, home preparation, or during eating depending upon the product and processing. For example, water may be added to the flavoring when making a batter, dough, sauce, broth, or some other item for consumption. Adding water to a dry encapsulated flavor immediately releases the flavoring: the flavor was protected during storage until use but not during further processing or preparation.

The goal may be to delay the release of flavor (protect it) during the baking or frying of a food product. Developing a process that is based on temperature (thermal release) could protect the flavoring from chemical reactions with the food, or losses due to evaporation resulting in a food with better flavor, or more realistic flavor. An issue to keep in mind when approaching this goal is that flavorings are largely lipophilic. Thus, if one puts flavor into a lipophilic shell so that it is not released on water contact, the flavor will be permeable to the wall and over time the flavor will be lost from

the particle to the product environment. The alternative is to put the lipophilic flavor into a hydrophilic shell and coat the final capsules with a water barrier to slow release. The first process provides a wall that is impermeable to the flavoring and most often, oxygen. Then a secondary coating is applied to make the initial particle slowly soluble. These processes are discussed in the following sections.

12.5.1 Diffusion-Controlled Release

It is often assumed that to achieve controlled release (delayed release), one must have particles that are perfectly impermeable to the flavor in any environment – humidity, or contact with water or oil. That is not the case for this is an impossible goal. The only encapsulation process that one might apply to flavorings that would meet that requirement would be to put the flavor into glass or metal shells. One cannot make a particle out of any food ingredient that would not leak flavor, given enough time, or when put into water. The problems are the flavoring materials (high vapor pressures and small molecular size), and the approved wall materials cannot provide a barrier to water over significant time periods. Thus, we do not seek (the impossible) to develop capsules that are totally impermeable but those that minimally will delay flavor release on contact with water or on heating.

One can delay flavor release in various ways. The simplest is to entrap the flavoring in an insoluble matrix: One that will not dissolve on contact with water, for example, corn protein (diffusion controlled release). That limits applications to those products where insoluble particles are acceptable (texture issue on eating). The release rate would be dependent upon the diffusion rate through the matrix and the particle size (smaller particles yield a faster release). This approach has found application in chewing gum applications [12.22, 23]. The fact that the particle is not soluble limits its applications in many other products.

An alternate means of imparting diffusion-controlled release is to use coacervated particles. If one crosslinks the capsule wall matrix, the capsules become insoluble and flavor can be released only by diffusion through the capsule wall. One has some control over the flavor-release properties of these particles. Since this is a diffusion controlled release, flavor release starts slowly and becomes constant for some time. The rate of flavor release is dependent upon several factors including the capsule size, flavor-loading level and both the flavoring composition and the capsule wall material. Particle size influences the flavor release rate since the smaller the particle, the more surface area it has per unit weight. Surface area determines the opportunity for the flavoring to reach the food matrix. The flavor loading level (amount of flavor in the capsules) determines the proportion of the particle that is wall material – the barrier against diffusion. Capsules with low flavor loadings have a large proportion of wall material (thick walls with small central cores of flavoring) and thus, the flavoring only slowly is released. The type of flavoring also determines the release rate. A very light, volatile flavoring (such as a butter or a fruit flavoring) tends to be made up of low molecular weight, highly volatile components. These types of compounds readily diffuse through food polymers resulting in high release rates. Finally, the wall material used in flavor encapsulation may be more or less dense (or cross linked) thereby providing a stronger barrier to flavor release (diffusion).

12.5.2 Controlled Release Using Coatings

It is fairly common to encapsulate a flavoring using one of the traditional methods (spray drying, or extrusion) and then apply a secondary process to afford controlled release properties to it. The primary encapsulation may be used to impart oxygen-barrier properties and decrease the volatility of the flavoring so that a secondary process can be applied. The secondary process may be to slow the particle dissolution or add thermal release properties. As one would expect, there are various materials to use in coating and ways to apply the desired coating.

Coating Materials

The materials used depend upon the application purpose. Coatings can be based on nearly any food material and can be either water soluble or fat soluble. The most common lipophilic coatings are lipids (hydrocarbons, beeswax or solid fats), a shellac or a modified cellulose (e.g., ethyl cellulose). If lipids are used, they´ must have a high enough melting point so that they do not melt in storage so the product cakes, but yet melt in the final application (e.g., baking or frying) to allow hydration of the core flavor capsule that results in flavor release.

The coating may function to provide protection to the flavoring and/or controlled release properties. An example of the coating providing both functions is the patent of *Patel* [12.24]. *Patel* [12.24] encapsulated high potency sweeteners (e.g., aspartame) in a shellac coating using fluidized bed or roller bed coating techniques. The shellac limited water uptake by the sweetener and protected it from other undesirable reactions (e.g., aldehydic flavor components) both providing a longer shelf-life to the product and controlled release properties. The patent of *Castro* and *Witke* [12.25] used coating techniques to offer a chew-

ing gum that changed flavor during chewing. A core flavoring particle was prepared with one flavor type and then a second flavoring was coated around that core. The two encapsulating materials, the core and the coating placed around it differed in polarity (solubility). Thus, the outside layer might be very water soluble and release its flavor quickly and then the inner layer which would be a less soluble material would slowly release its flavor to give a different flavor character to the gum.

Shellacs are often suggested in the patent literature as coating materials. A shellac is a resinous material obtained primarily from Thailand and India that is secreted by the female lac bug (Wikipedia). It is soluble in ethanol and forms a very good water barrier when dry. *Song* et al. [12.26] used shellac to impart controlled release properties to a chewing gum flavoring that was initially loaded into porous beads. The porous beads carried the flavoring and the shellac provided controlled release. The largest deterrent to using a shellac is the need to dissolve it in ethanol for application. Ethanol is a controlled substance, expensive and flammable.

Coating Methods

Fluidized bed – one of the most common techniques used to apply coatings in the industry (Fig. 12.9). As the name suggests, a bed of material (e.g., spray dried flavor) to be coated is suspended in an air flow and a coating material (e.g., lipid) is sprayed onto the powdered flavoring. (There are numerous possible configurations for such a process.)

The coated material is either cooled (if it is a molten lipid coating) or dried if the coating is applied in a solvent (water or alcohol) to form a durable shell. While this sounds fairly simple, it is not. The primary problem is that the preferred starting material is a spray-dried flavoring (due primarily to cost). Unfortunately, the spray-dried flavoring generally is a fine powder ranging in size from 10 to 50 μm (depending upon the spray dryer used). It is difficult to coat a very small particle since the coating material is also delivered as a spray and thus has similar dimensions: one is attempting to coat a particle with another particle of the same size. One tends to get agglomerates that eventually offer an effective barrier but one delivers a lot of coating and not much flavor. It is very difficult to coat particles less than 100 μm in diameter.

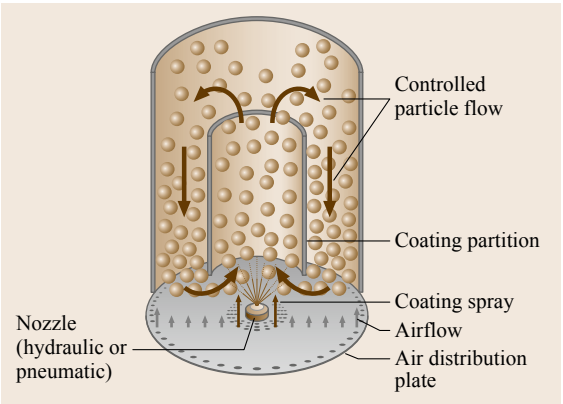

Fig. 12.9 Fluidized bed coating system

Granulation

Granulation is a term that tends to be used very broadly in the industry. In effect, it may be any process that results in a granular product. In the pharmaceutical industry, it is more limited describing a process in which powder particles are forced to agglomerate to form larger, multi-particle structures called granules (Wikipedia). Granulation can be done by wet or dry processes. The dry process involves compaction followed by grinding to the desired size. This is most often used to increase the particle size. The wet process involves spraying a liquid into an initial spray-dried material while tumbling or fluidizing the initial powder. If we wish to coat the initial powder, the liquid would contain a coating material which when dry serves to impart controlled release properties.

A different but somewhat similar process also shows up in the patent literature: one where a flavor-containing emulsion is sprayed into a chamber containing a dry (unflavored) powder. The emulsion *adsorbs* the dry neutral powder onto each droplet thereby providing a *coating*. An example of this process is given by *Johnson* [12.27]. He made an initial emulsion of modified starch, water and a perfume formulation. Corn starch was then placed in a small agglomerator and the starch was fluidized by hot air. The emulsion was sprayed into the chamber using a two-fluid atomizer. The resultant product was a relatively large particle (> 700 μm).

12.6 Unmet Needs

The materials and processes available for imparting controlled release properties to food flavorings are very limited. The primary limitations are imposed by both cost constraints and legal usage. One cannot help but look with envy at the pharmaceutical industry. The fundamental processes and materials available to the food flavor industry have changed very little over the last 50+ years. Having said that, innovations are occur-

ring which offer incremental improvements. The three largest flavor companies have been granted ca. 100 patents since 2000 on encapsulation (SciFinder search on key words *flavor* and *encapsulation*). We would expect this innovation to continue.

Three innovations that would be valuable in this author's view are:

1. The development of a positively charged food polymer
2. The ability to produce large particles by spray drying (ca. 100 μm)
3. The ability to apply uniform, hydrophilic and/or hydrophobic, nano-thickness coatings.

The need for a positively charged food polymer relates to needs in coacervation: a protein usually serves as the positively charged food polymer for complex coacervation. Proteins tend to be relatively expensive, must be labeled (allergens), and are reactive. Chitin has been used in place of protein but this polymer also has functional drawbacks. We need an inexpensive, positively charged food polymer to make coacervation more cost-effective and less problematic.

The desire for producing large particles in spray drying stems from our need for an inexpensive method to produce a primary flavored particle that is large enough to easily coat for imparting controlled release properties. Furthermore, it would be desirable that the particles have a core and shell structure rather than the typical matrix structure. Core and shell structures permit higher flavor loadings to partially offset the dilution due to using coating material.

The last need this author suggests is a better way to coat particles: A method that can uniformly apply a very thin coating to the small particles we can produce economically today. That would likely be a vapor phase coating process. One could certainly expand upon this short list of needs but innovations in these three areas would be very helpful.

12.7 Conclusions

The volatility, permeability, and reactivity of aroma compounds make them problematic to maintain in a food product during storage, distribution, and preparation. These needs have resulted in several methods of encapsulation being practiced in the food/flavor industry including spray drying, extrusion, coacervation, and inclusion complexing. These processes are fairly old and despite innovation, cannot provide the stability often needed to satisfy market demands. A similar statement can be made for our ability to obtain the desired controlled release properties to these encapsulated materials. We simply lack the materials and processes required to adequately accomplish controlled delivery. That is not to say that we have made not progress but that there is still a great deal of unmet need in the field.

13. Physico-Chemical Interactions in the Flavor-Release Process

Anne-Marie Seuvre, Andrée Voilley

The perception of flavor is induced by the release of aroma compounds in the vapor phase. The olfactory perception is not only related to the nature of aroma compounds initially present in the food, but also to their distribution between the different phases. After a description of the interactions established between the aroma compounds and different constituents of food, this chapter looks at physico-chemical characteristics of aroma compounds and at the composition and properties of food matrices. Then, in order to understand the behavior of aroma compounds in the matrices, study methods of interactions are described. The assessment of the release is done by determining the partition coefficients and mass transfer between phases. The conclusion opens the way on the preservation of aroma compounds.

Foods are complex products containing volatile and nonvolatile compounds. Among the volatile compounds, flavor compounds may be naturally present in foods or added to compensate, for example, loss or damage arising either during the manufacturing process or during storage.

Aroma results from the balance between the different aroma compounds and will depend, in particular, on the concentration and composition of the food matrix. The chemical nature of aroma compounds, the composition and the structure of a food are the main characteristics influencing both the transfer of aroma compounds in the food and their release. Food matrices are often multiphase, containing liquid (aqueous or lipid) solid and vapor phases. The distribution of an aroma compound in a food depends on its affinity for the different phases, and its ability to be released into the vapor phase. This distribution, responsible for the availability of aroma compounds, will modify sensory perception when smelling a food or during consumption. This distribution is characterized by the partition coefficient of vapor versus matrix which determines the maximum amount of each odorant available in the vapor phase for perception and indicates the presence or absence of the type and extent of interactions between aroma compounds and the respective matrix.

The nature of the different nonvolatile constituents such as proteins, lipids, carbohydrates and salts has a great impact on the retention of aroma compounds in food matrices. Indeed, physico-chemical interactions can be established between flavor compounds and food constituents, and can modify the distribution of

aroma compounds in the food. So they can increase or decrease the release of aroma compounds and thus modulate their availability, thus influencing their sensory perception.

In recent years, interest in low-sugar or low-fat products has increased, and to satisfy the wishes of consumers, the industry has had to change the formulation of a food in several cases. However, the change in composition of the food may, consequently, cause a change in its structure and its sensory properties, particularly in terms of the overall aroma intensity and the individual aromatic notes perceived in the nose and in the mouth.

To predict the release of aroma compounds from a food matrix, instrumental and sensory studies are needed to develop mathematical models to describe and predict this complex process. These mathematical models are based on physico-chemical properties such as diffusion, transfer rate and volatility of each odorous molecule. Some models are dedicated to the partitioning of flavor compounds between the different phases of the food and the vapor phase, others are directed to the release of aroma compounds in the mouth by taking into account the physiological parameters.

The understanding of the phenomena of release/retention of aroma compounds from the physico-chemical point of view, in particular through the study of vapor-liquid equilibria between the food matrix and the gas phase using thermodynamic and kinetic approaches, is thereby an essential step. These equilibria are governed by the particular interactions that take place between the components of the matrix and the volatile compounds. The amounts of released aroma substances will depend not only on the concentration of aroma compounds in the matrix, but also on the nature of both odorants and matrix. The chemical functionalities, the conformational aspects and the structural features of the food matrix have to be considered. The interactions between the food matrices and the odorous molecules thus appear as a determinant of the balance between retention and release.

In the food sector, the aroma compounds are distributed between the different phases (vapor, liquid and/or solid phases, aqueous or lipid phases) according to their affinity and taking into account the possibility of the mixing of several phases. The objective of the thermodynamic equilibrium between the phases is to quantitatively describe the distribution of each compound present in the different phases (vapor, liquid or solid) of the food by the determination of the respective partition coefficients. The two coefficients most commonly used are the partition coefficient of vapor-medium, where the medium can be a liquid, a solid or a food matrix, and the coefficient of liquid-liquid partition between two immiscible liquids. The kinetic approaches study the rate of distribution of compounds within the food, their distribution in each phase at different times and their transfer from one phase to another.

13.1 Nature of the Interactions Aroma Compounds–Matrices

One of the essential variables in the study of the thermodynamic equilibria is the chemical potential μ_i of a component i. Indeed, a single or multiphase system is in equilibrium when μ_i is the same at any point in each phase of the system for a given temperature and a given pressure. The chemical potential μ_i is by definition

$$\mu_i = \left(\frac{\delta G_i}{\delta N}\right)_{\mathrm{P,T}} , \tag{13.1}$$

where G_i is the free enthalpy of the phase in question and N the total number of moles in this phase.

In a mixture of perfect gases and in isothermal and isobaric conditions, the chemical potential μ_i of a constituent i is a function of its partial pressure in the system

$$\mu_i = \mu_i^{0\,\mathrm{vap}} + RT \ln \frac{p_i}{p^0} , \tag{13.2}$$

where $\mu_i^{0\,\mathrm{vap}}$ is the reference chemical potential of the component i in the gaseous state under standard conditions of temperature and pressure, R is the gas constant, T the temperature (K), P the pressure (Pa), p_0 the reference pressure (101 325 Pa), p_i the partial pressure of component i in the gas mixture.

In general, in food systems, the vapor phase above a product is considered as an ideal gas mixture consisting of water vapor and volatile compounds.

In solution, the chemical potential of a component i is a function of its activity a_i (dimensionless number)

$$\mu_i = \mu_i^{0\,\mathrm{liq}} + RT \ln a_i , \tag{13.3}$$

where $\mu_i^{0\,\mathrm{liq}}$ is the chemical potential of the pure component i in the liquid state in standard conditions of temperature and pressure.

In an ideal solution, $a_i = x_i$, so the chemical potential μ_i of component i is a function of its molar fraction

Table 13.1 Activity coefficients of aroma compounds in water at 25 °C

Aroma compound	[13.1]	[13.2]	[13.3]	[13.4]	[13.5]	[13.6]
Isoamyl acetate	5016	4650	4400			
Acetaldehyde	3.3	3.0	3.4	4.2		
Benzaldehyde	1436		1040		1456	
D-Linalool	8631		14 000	25 000		
cis-3-Hexenol	381					
D-Limonene	86 631	33 400	47 000	77 500		
Acetophenone	1689		1200			
2-Heptanone	5629		4700			
2-Octanone	9452		11 300	13 200		
2-Nonanone	58 036		43 000			16 300

in the liquid phase, x_i

$$\mu_i = \mu_i^{0\,\mathrm{liq}} + RT \ln x_i \,. \tag{13.4}$$

In a real solution (not ideal), $a_i = x_i \gamma_i$, and the equation is

$$\mu_i = \mu_i^{0\,\mathrm{liq}} + RT \ln x_i + RT \ln \gamma_i \,, \tag{13.5}$$

with γ_i the activity coefficient of component i.

The application of the equations given above requires the definition of a reference state for all the constituents of the mixture. The pure liquid solute i is the reference state: for $x_i = 1$, $\gamma_i = 1$ and $a_i = 1$. The chemical potential of the reference is that of the pure compound at a given temperature and pressure.

The activity coefficient γ_i depends on the temperature, pressure and composition of the system. However, in the pressure range of interest, the activity coefficient varies little with pressure.

For any component i in an ideal solution, γ_i is constant and equal to 1 (Raoult's law). This solution corresponds to the mixture of molecules having a very similar structure or interactions having the same nature.

For any component i of a real solution, γ_i is not equal to 1 (Henry's law) and represents the deviation from ideality. Molecules have very different structures. In addition, the nature and the number of solute-solvent interactions differ by comparison to solute-solute interactions and solvent-solvent interactions.

Two factors are involved in the deviation from ideality:

- Taking two components, A_1 and A_2, the interactions between these components in a solution are of a much lower order of magnitude compared to the interactions between A_1 and A_1 and between A_2 and A_2: then the partial pressure of component i in the vapor phase is greater than the ideal case, therefore the activity coefficient is greater than 1 (positive deviation).
- The interactions between components A_1 and A_2 in solution are of an order of magnitude higher than the interactions between A_1 and A_1 and between A_2 and A_2: then the partial pressure of component i in the vapor phase is lower than in the ideal case, therefore the activity coefficient is less than 1 (negative deviation).

In the case of an infinitely diluted solution, interactions between solute molecules can be neglected and the activity coefficient of component i noticed γ_i^{∞} is constant.

Table 13.1 presents some value examples of activity coefficient of aroma compounds in water at 25 °C.

Interactions are due to attractive or repulsive forces between groups. Their range and intensity vary according to their nature (Table 13.2).

13.1.1 Attractive Forces

These forces include several types of interactions: Coulomb forces, van der Waals forces, hydrogen bonds and hydrophobic interactions. They depend, in particular, on the presence of electric charges and on the polarity of the different bonds of the interacting molecules. A bond is called apolar if the electrons participating are divided equally between the two polar nuclei and polar if one of the two atoms, more electronegative than the other, attracts the electron cloud more strongly.

Coulomb Forces

The Coulomb forces apply to a charged molecule, that is, an ion and another ion or a dipole. Their intensity depends on the nature of the second dipole involved. The forces between ions are intense and long-range, and their energy is an inverse function of the distance between charges. Interactions between ion and dipole are also long-range but decrease as the square of the distance between the ion and the center of the dipole. It should be noted that the intensity depends strongly on the orientation of the dipole. The interactions play

Table 13.2 Intensity and range of the physico-chemical interactions (after [13.7])

	Origin	Intensity	Range	Energy (kJ/mol)
Attractive forces	**Coulomb forces**			
	Ion-ion	Very intense	Very long $\frac{1}{r}$	≈ 750
	Ion-fixe dipole	Intense	Long $\frac{1}{r^2}$	≈ 250
	Ion-mobile dipole	Medium	Medium $\frac{1}{r^4}$	$\approx 2,5$
	Van der Waals			
	Dipole-dipole	Weak	Short $\frac{1}{r^6}$	$< 2,5$
	Dipole-apolar molecule	Weak	Short $\frac{1}{r^6}$	$< 2,5$
	Apolar molecule-apolar molecule	Medium	Short $\frac{1}{r^6}$	$\approx 2,5$
	Hydrogen bond	Intense	Medium	< 40
	Hydrophobic interaction	Intense	Long	< 25
Repulsive forces		Very intense	Very short $\frac{1}{r^n}$ with $n < 9$	

r: intermolecular distance

an essential role in the orientation of the dipoles especially for their solvation. Finally, interactions between ions and mobile dipoles are less intense and decrease with the distance at exponent four between the ions and the dipole center. Moreover, these interactions are independent of the orientation of the dipole which remains in a state of thermal rotation.

Van der Waals Forces

Under this designation are grouped orientation, polarization and induction forces. They all involve a dipole, either permanent or instantaneous. Orientation forces, also called dipole-dipole interactions or Keesom forces, result from the interaction of two permanent dipoles.

Polarization forces arise from the interaction between a permanent dipole and the dipole that it induces on a neighboring molecule and correspond to the term called Debye.

Dispersion forces, also called London forces, occur between nonpolar molecules and are created by the interaction of instantaneous dipoles. They come from the movement of electrons whose momentary configurations may correspond to a nonuniform charge distribution, that is, a dipole. In turn, this dipole induces a dipole in a neighboring molecule resulting in a force of attraction. In vacuum, the energy of all these interactions decreases with the distance between the centers of the dipoles at exponent six.

Hydrogen Bonds

These are the bonds between electronegative atoms such as oxygen or nitrogen and hydrogen atoms involved in a covalent bond with other electronegative atoms. They are of a very special nature because they only, and specifically, involve hydrogen atoms whose small size and tendency to positively polarize allow interaction with the neighboring electronegative atoms. This type of bonding only occurs in limited cases, but is of great practical importance. In fact, it participates in the stabilization of macromolecules such as proteins, nucleic acids or polysaccharides such as amylose, and gives them their spatial structure (ternary). Their energy is between 10 and 40 kJ/mole.

Hydrophobic Interactions

In biochemical and pharmacological fields, hydrophobic interactions are often described as a type of interaction in itself, although they result from the combination of several elementary interactions (polar, electrostatic, dispersive and repulsive) in addition to entropic effects of hydrophobic hydration [13.7]. They concern molecules or portions of apolar molecules which therefore have only very low affinity for water. The hydrophobic effect comes from the nonaffinity of these solutes for water and results in a collection of apolar molecules and a reorganization of solvent molecules.

13.1.2 Repulsive Forces

Repulsive forces result from the electronic orbital overlap when the molecules get closer to a very short distance. Then the positively charged nuclei repel each other. These forces have a very short range and an extremely important growth when molecules get closer.

13.2 Physico-Chemical Characteristics of Aroma Compounds

The aroma compounds are organic molecules of low molecular weight (< 400 Da) whose vapor pressure at atmospheric pressure and at room temperature is sufficiently high so that they are partially in the vapor state in the gas atmosphere and can cause an olfactory stimulation when they come into contact with the olfactory mucosa [13.8].

Aroma compounds are present in very small amounts in food; their concentrations vary from a few milligrams per ton (ppb) to a few milligrams per kilogram (ppm). On the other hand, they are generally present in very large numbers [13.9], especially for food produced by thermal processes (coffee) or in combination with fermentation (bread, beer, cocoa, tea) that contain more than 500 flavor compounds. Among these aroma compounds, only a limited number are of importance for the overall food aroma; these are the substances whose concentrations in the food exceed the thresholds of their sensory perception. The threshold of perception of an aroma compound depends on its vapor pressure, which changes depending on the temperature and the environment.

Aroma compounds in foods belong to all chemical classes [13.8–10] with several examples being presented in the following):

- Terpene compounds: hydrocarbons (limonene, myrcene), alcohols (linalool, menthol), aldehydes (geranial), ketones (menthone, carvone)
- C_{13}-norisoprenoids compounds: damascenone, 3-hydroxy-β-ionone
- Esters: isoamyl acetate (3-methylbut-1-yl ethanoate), ethyl butanoate, etc. (fruity flavor)
- Lactones: γ-decalactone (peach), δ-decalactone (coconut), etc.
- Carbonyl compounds: benzaldehyde, C_6 aldehydes (green notes: hexanal, trans-2-hexenal, ...), methyl ketones (2-heptanone and 2-nonanone as characteristics of blue cheese), butanoic acid (rancid butter), 2-methyl-butanoic acid (Roquefort)
- Phenols: raspberry ketone (fruit), eugenol (clove), thymol (thyme) and vanillin (vanilla), etc.
- Sulfur compounds: which represent about 10% of the compounds identified in the volatile fraction of food (sulfides, disulfides or trisulfides, thiols, ...)
- Heterocyclic compounds: pyrazines (coffee, cocoa, chips and meat), furanones (smell of caramel, bread, beef broth, ...), thiazoles and benzothiazoles, especially isobutylthiazole (fresh note of tomato).

Commonly, food flavors are mixtures of volatile compounds with different physico-chemical properties; consequently, this phenomenon leads to the preferential retention of some of them in a specific food matrix and thus to a change in sensory properties of a specific food product [13.11, 12]. Several physico-chemical characteristics of the aroma compound are involved in their retention by a food matrix. They include molecular dimensions, chemical functions, polarity of the odorous compound, hydrophobicity, volatility and diffusivity.

13.2.1 Molecular Dimensions

This parameter has a direct impact on the diffusivity of aroma compounds but also plays a role in the establishment of interactions with matrices. For example, starch, which is a mixture of amylose and amylopectin, interacts in aqueous solutions with aroma compounds. This retention is mainly attributed to the inclusion of the odorous molecules in the amylose helix and, to a lesser extent, in those helix structures being formed by amylopectin [13.13–16]. The interactions are of low energy and the dissociation constant varies according to the length of the carbon chain of the solute [13.14].

The effect of the molecular size of the volatile compound has been studied in the case of interactions with polysaccharides and especially with glucose polymers. These polymers seem to interfere in the number and nature of interactions, essentially determining the importance of contact with the hydrophobic regions of these polysaccharides, and thus the importance of hydrophobic interactions and/or van der Waals forces.

In the case of the interaction between the volatile compound and β-cyclodextrins, the molecular dimensions of the ligand are also a parameter determining the stability of the complexes. The β-cyclodextrins have the shape of a torus with a diameter of 0.78 nm and an internal volume of 262 $Å^3$ [13.17–19]. Molecules with a size of the same order of magnitude can therefore be included. However, it was observed that smaller molecules were less well retained [13.11]. The affinity constant of alcohols evolves in the direction methanol < ethanol < 2-propanol < 1-butanol [13.20]. Similar results were obtained for acids or ketones [13.21, 22].

According to *Kano* [13.23], the nature of the predominant interactions between a volatile compound and β-cyclodextrin depends on the size of the compound included. If its size is close to the size of the cavity, van der Waals interactions would predominate, whereas if the compound has a size substantially smaller than that of the cavity, hydrophobic interactions dominate.

The shape of the molecule determines the importance of contact with the cavity of cyclodextrins and thus the strength of the bonds [13.24]. The nature and strength of the interactions are also determined by the nature of the chemical functions carried by the aroma compound.

The conformation of polysaccharides also affects the ability to interact with the flavor compounds [13.25]. For example, amylose or starch hydrolysates retain aroma compounds in solution unlike dextrans [13.26]. These polysaccharides are glucose polymers but in the case of the first two, the glucose units are linked by connections $\alpha 1 \rightarrow 4$ whereas they are connected by links $\alpha 1 \rightarrow 6$ in the case of dextrans. The presence of ramifications can also affect the ability of aroma fixation. The volatile compounds have a greater affinity for the amylose constituted of linear chains as amylopectin, having ramifications. However, it was shown that interactions may exist between the polymer and the volatile compounds if the length of the linear portions is sufficient [13.14, 15].

However, the most outstanding effect of the conformation on the polysaccharides ability to interact with volatile compounds arises from the cyclization of the chain dextrins to lead to the formation of cyclodextrins.

13.2.2 Chemical Functions

The chemical functions of the aroma compounds affect their retention by the matrices. For example, it seems that the polysaccharides retention follows the order: alcohols > ketones, esters > acids. These functions influence the distribution of the electric charges of the compound and therefore its polarity, whose characteristic is also affected in the nature of the interactions established by the aroma compound with the polysaccharides.

Alcohols are generally better retained than the other components. It has thus been observed that 1-hexanol and 2-propanol are better sorbed by β-cyclodextrins and starch hydrolysates with dextrose equivalent (DE) 20, 31 and 61.5 than diacetyl (diketone) or ethyl acetate [13.27]. Their proportion among the sorbed compounds represents 17 and 7.5% of the total moles of sorbed compounds against 6.9 and 4.8% for diacetyl and ethyl acetate, respectively. Another study on freeze-dried starch hydrolysates reported a retention rate of benzyl alcohol higher than those of fifteen other volatile compounds [13.28]. The retention rate of benzyl alcohol varies between 45 and 83% depending on the nature of the carrier (freeze-dried starch hydrolysates) while that of the esters does not exceed 49.5% and that of the acid is less than 7%.

Regarding ketones, they seem to be less retained than alcohols and as much as esters. *Maier* [13.29] observed a lower sorption of ketones by starch compared to that of alcohols with the same chain length.

When the retention of ketones is compared to that of esters, few differences were noted. However, there are too few studies comparing the effect of these functions to draw conclusions [13.25].

Esters also appear to be less well retained by polysaccharides than alcohols but are better retained than acids. Thus the study of the retention of a mixture of 16 aroma compounds by lyophilized starch hydrolysates showed a lower retention of esters compared to alcohols, and very low retention of acids (Fig 13.1) [13.28]. Less than 7% of the acids were retained, regardless of the considered support, whereas the esters and alcohols were retained at more than 10% and in certain media up to 83%.

However, there are exceptions to the preferential retention of alcohols by the polysaccharides. For example, only 21% of initially added amounts of oct-1-en-3-ol and 33% of 1-octanol were retained during the spraying of starch hydrolysates DE 36.5 while 41% of octanal was retained [13.30]. This example shows that the chemical functions are not sufficient to explain the differences in retention depending on the nature of the volatile compound.

13.2.3 Polarity

The polarity of the volatile compound further plays a role in establishing interactions with the matrix. For example, during the dehydration treatment of polysaccharides, the polarity of the volatile compounds affects their retention: the most polar aroma compounds are generally less retained. The polarity of the volatile compound plays a role in establishing interactions with polysaccharides and in the stability of complexes between aroma compounds and the matrix, as is the case for complexes between aroma compounds and β-cyclodextrin. But the nature of the support is also to be considered: β-cyclodextrins have a hydrophobic cavity in which the flavor molecules are included. The strength of the bonds increases with increasing contact of the hydrophobic part of the compound included within the wall of the cavity of β-cyclodextrin [13.23].

The polarity also affects the interactions with mono- or disaccharides: *Roberts* et al. [13.31] suggested that the interaction of the volatile compounds with sucrose or glucose depends on the polarity of the volatile compound. The polar compounds are excluded from aqueous solutions of sucrose or glucose because of the structuring effect of these sugars on the water. The apolar compounds are retained through interaction with the

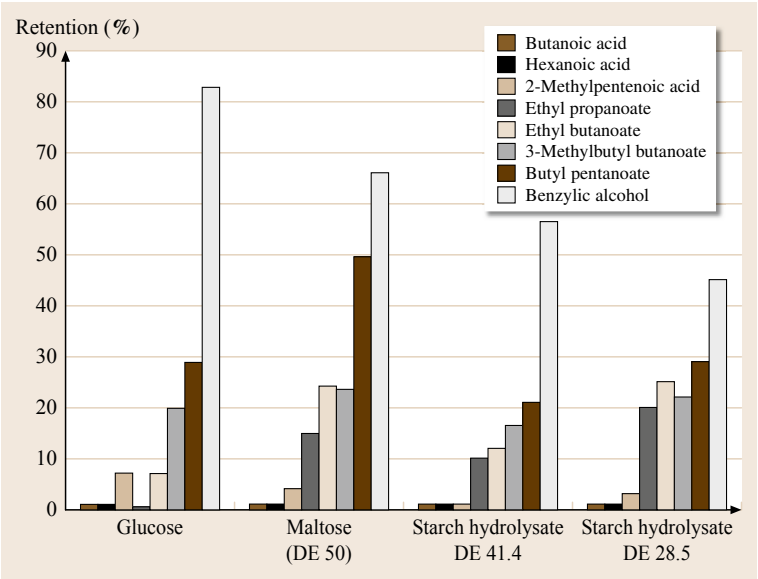

Fig. 13.1 Influence of chemical functions of aroma compounds on their retention in mixtures containing freeze-dried starch hydrolysates and glucose (after [13.28])

hydrophobic regions of the sugars. However, there are some exceptions to this trend.

Aroma compounds have generally a hydrophobic nature and have rather different physico-chemical characteristics. The water solubility and hydrophobicity allow the evaluation of their affinity for the organic and aqueous phases. Another physico-chemical characteristic is the saturated vapor pressure which represents the volatility of the molecule in its pure state. It can be measured or estimated. A static method, suitable for measuring low saturated vapor pressure, is to measure the pressure above the pure product when the thermodynamic equilibrium is reached. Different methods of estimation of the saturated vapor pressure are described in the literature [13.32–40].

13.2.4 Hydrophobicity

The hydrophobicity is represented by the log P value which corresponds to the logarithm of the partition coefficient of one compound between water and n-octanol. This value can be calculated with the help of the gas chromatography (GC) experimental determination of the concentrations of the chosen aroma compound in the two phases, or estimated [13.41]. The value of log P may be estimated by a group contribution method [13.42] but it does not take into account the position of the chemical groups in the molecule and the intramolecular interactions. Aroma compounds having a log P of less than 1 are considered polar and are relatively soluble in water (Fig. 13.2) [13.1]. This characteristic is important to consider: a hydrophilic compound readily diffuses through a matrix of the same nature, unlike a hydrophobic compound [13.43, 44]. A polar carrier is better for apolar compounds, as are most of the aroma compounds and vice versa for polar compounds.

Hydrophobicity and volatility are characteristics that predict the ability of a flavor to reach the gas phase, but the release of volatile compounds also depends on kinetic phenomena that additionally must be taken into account when regarding their transfer from one phase to another.

13.2.5 Volatility

A physico-chemical characteristic to consider is saturated vapor pressure which represents the volatility of the molecule in its pure state. It can be measured or estimated [13.32]. Saturated vapor pressure can partly explain the differences of the aroma compound ability to transfer to the vapor phase. But even more than this characteristic, the value of the volatility in solution needs to be taken into account [13.30]. This value characterizes the behavior of a diluted compound: the higher it is, the more easily it evaporates. It depends on the boiling temperature, on the molecular weight and on the solubility in the dilution medium. It can be modified by the existence of interactions with the components of the matrix [13.45–48] since the aroma compounds establish low energy bonds with nonvolatile molecules. For example, the addition of a 15% (m/m) glucose solution to a 1-propanol solution increases its volatility whereas the addition of starch hydrolysate (DE 5) reduces the volatility of this compound [13.49, 50].

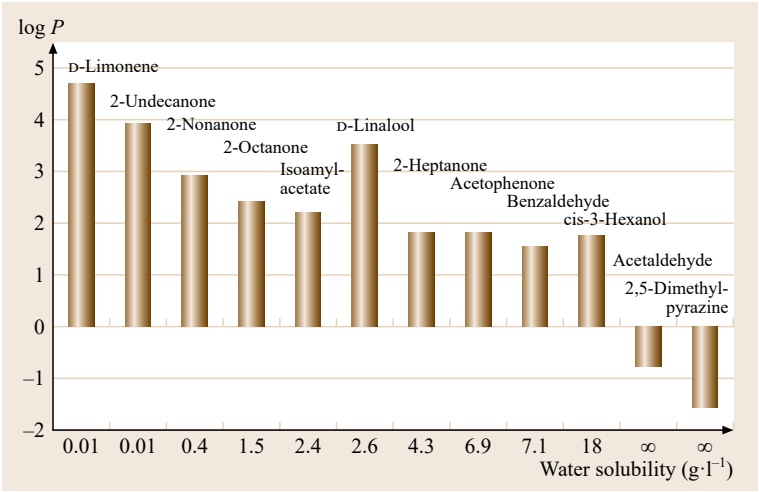

Fig. 13.2 Comparison between hydrophobicity and water solubility of aroma compounds at 25 °C (after [13.1])

13.2.6 Diffusivity

The ability of the volatile compounds to be retained by a matrix depends on their solubility and on their diffusion coefficient in this matrix [13.28, 43, 51]. The more soluble a compound may be, then the higher the diffusivity in the matrix may be and, accordingly, the more facilitated the transfer is. This is why the molecular volume, which is indirectly related to the molar mass, helps to predict differences between diffusivity of aroma compounds. The greater the volume is, the lower the release rate is [13.52, 53].

13.3 Composition and Properties of the Matrices

The release of aroma compounds of a food depends on several factors. Studies from model environments have shown that the aromatic quality of volatile compounds in the vapor phase depends on their physico-chemical properties, their initial concentration and their interactions with the media components. Several authors have studied the behavior of aroma compounds in relatively simple systems such as water, in the presence of carbohydrates, proteins and lipids. The authors have demonstrated the effect of the medium composition on the retention of aroma compounds. In foods, lipids play a dominant role in the behavior of aroma compounds. Thus, when a product is reduced in fat content, strong changes in the aromatic quality of the product are caused. This problem can be solved by a new and specifically adapted formulation of the aroma. However, the use of ingredients such as polysaccharides and proteins capable of binding aroma molecules is desirable.

Most foods are relatively structured media (emulsions, gels, foams). Conformational changes of the various ingredients (especially proteins) caused by treatments during the manufacturing of the product play a role in the physico-chemical behavior of aroma compounds.

13.3.1 Carbohydrates, Proteins, Lipids, Salts

Carbohydrates

In general, the presence of carbohydrates in an aqueous solution induces a decrease in the relative volatility of compounds compared to that in water. However, carbohydrates such as mono-and diosides cause an effect of *salting-out* that is to say, an increase in volatility compared to that in water [13.16].

Interactions between carbohydrates and aroma compounds are generally low energy and depend on many factors such as the nature and concentration of volatile compounds and carbohydrates [13.54–57]. These interactions can be of different types: adsorption, formation of inclusion complexes and modification of the solute diffusivity in the system [13.58], they result in changes in the volatility and diffusion coefficient of the solute. Thermodynamic and kinetic approaches have been conducted on the retention of various aroma compounds by gels and solutions of polysaccharides [13.59–61].

Carbohydrates have a particularly important role in the formulation of new products. Indeed, in the food industry, carbohydrates are used as substitutes for conventional ingredients. For example, carboxymethyl

cellulose and starch preparations are used as substitutes for fat [13.16].

Carbohydrates are most commonly used by the food industry [13.53, 62]. They consist mainly of sucrose, starch and starch derivatives, gums.

Oses. Sucrose, one of the most common ingredients in the food industry, is also used as a textural sensory agent and flavor carrier, either alone or in mixture. Some studies have been conducted on the sweetness-texture interactions [13.63, 64]. Alone, it is a medium on which volatile aromas are sorbed or encapsuled. The very low cost of this method of retention is its main advantage. However, the compounds are not encapsulated and then evaporate or oxidize easily. But, when the encapsulation is performed by co-crystallization, the aroma compounds are retained in the pores formed between the microcrystals of sucrose pellets and only those located on the surface are exposed to evaporation or degradation [13.65].

Finally, sucrose mixed with starch hydrolysates is very commonly used as a matrix for encapsulation by extrusion [13.66–68]. In all cases this support is inexpensive and readily dissolves in water. However, it has a sweet taste that may limit its utilization. Carbohydrates are the most common encapsulation materials in the food industry but also some proteins are interesting flavor carriers. The behavior in sucrose solutions depends on their concentrations. *Roberts* and *Acree* [13.69] showed that the presence of sucrose in aqueous solution at high concentration induces a decrease of the release of aroma compounds by an increase in the viscosity of the solution and a decrease of the water activity in the solution. *Lubbers* and *Guichard* [13.70] also showed a decrease in the release of aroma compounds in sugar syrups containing 60% dry matter. *Mei* [13.71] observed that the addition of sucrose and fructose to yogurt has a suppressive effect on the release of certain aroma compounds. But in sucrose solutions at lower concentrations, other authors [13.72, 73] showed an increase in the release of aroma compounds in the presence of sucrose, described as *salting-out* [13.73, 74].

Starch and Starch Hydrolysates. Many studies have focused on the interactions between aroma compounds and starches [13.75–78]. The retention is influenced by numerous factors such as the botanical origin of starches, the applied treatment as well as the nature of aroma compounds [13.79]. Different mechanisms are involved, such as hydrogen bonds and hydrophobic interactions, and also the formation of inclusion complexes [13.55, 75, 76]. The higher polarity and solubility of aroma compounds, as well as their shape and size, influence the structure and stability of such complexes. It may even be a competition between the compounds for a binding site [13.80].

Starch hydrolysates are obtained from the partial hydrolysis of starch by enzymatical or acidic treatment, or by using a combination of these two ways. The resulting products are mixtures of oligo-and polymers of glucose, characterized by their DE. Those having a DE between 3 and 20 are called maltodextrins, while those having a DE greater than or equal to 20 are called glucose syrups.

Their hydrophilic nature does not allow them to form stable emulsions in the early stages of encapsulation and requires the addition of an emulsifier to ensure the retention of flavors [13.53, 62]. An alternative is to use them in combination with other compounds having emulsifying properties (arabic gum or proteins) [13.81, 82].

For a similar solid content, their viscosity and their ability to retain aroma compounds decrease with the increase of their DE [13.53, 83]. These retention differences are explained by the highest diffusivity of aroma compounds in starch hydrolysates solutions with high dextrose equivalent [13.53, 84] and also by the greater mobility of the insoluble fraction of flavors in such environments [13.84]. However, the assumption of the existence of interactions between volatile compounds and starch hydrolysates was also issued [13.15]. It is based on the fact that these materials cause a color reaction with iodine, thus revealing the existence of a complex, and is further reinforced by the discovery of complexes between dextrins over nine glucose units and sulfate dodecyl and sodium [13.85]. This study also demonstrated a greater ability to form complexation with increasing degree of polymerization and consequently lowering the DE. Interactions between aroma compounds and starch can arise from two kinds of interactions. First, by the involvement of hydrogen bonds between the hydroxyl groups on the outside of the amylose helices and aroma compounds, and secondly, the inclusion complexes where the aroma compounds are trapped inside the amylose helices through hydrophobic interactions [13.86–88]. Some authors explain the retention and the release rate of aroma compounds in part by the crystal structure (Type-V) of amylose [13.89]. Increasing the concentration of starch in dairy gel models generally results in a decrease in the release of aroma compounds [13.90].

In contrast, the protection against oxidation increases with dextrose equivalent as the high dextrose equivalent products have a high content of reducing sugars. This property is a major advantage of these media, as a protection against oxidation is carried out without the addition of antioxidant, with starch hydrolysates

being not considered as food additives [13.91]. Associated with their low prices and their neutral taste, these properties make it one of the most common flavoring materials in the food industry.

Modified Starches. Modified starches have been developed to combine both the emulsifying properties of arabic gums and the low cost of starch hydrolysates. To improve its functional properties, starch can be crosslinked or grafted, but only grafted starch is used as a flavor carrier. Modified starches, although they are more expensive than starch hydrolysates, have the advantage of being able to form stable emulsions with aroma compounds, often with hydrophobic compounds [13.81, 92, 93]. They are obtained by grafting lipophilic groups such as octenyl succinate (0.3%) on starch, which is a hydrophilic substance. These molecules are therefore amphiphilic and have excellent emulsifying properties, which gives them a very high retention capacity. In addition, after rehydration, the reconstituted emulsions are stable and their droplet diameter is in the micrometer-range, giving the product an attractive appearance [13.92]. These materials are considered as food additives, designated by the code E1450, unlike starch hydrolysates [13.94].

β-Cyclodextrins. Among the derivatives of starch used as aroma carriers, there are also β-cyclodextrins (Fig. 13.3).

Although known since the beginning of the 20-th century, they have been used in the food industry only since the 1970s. They are now allowed as aroma carriers in USA, Japan and in the European Union [13.95]. The European regulation of 11 November 2011 allows their presence (additive E459) at a concentration of 1000 mg/kg in the final food. They are homopolymers of seven D-glucose units linked by $\alpha 1 \rightarrow 4$ (Fig. 13.3). They have the shape of a truncated cone having two outer rings of hydroxyl groups. Primary hydroxyl groups are located at the narrow end of the torus formed by these polysaccharides, while the wider end is lined with secondary hydroxyl functions. These OH functions provide the β-cyclodextrins solubility of 18.8 g/l in water at 25 °C [13.19]. Their ability to retain aroma compounds is related to the hydrophobicity of their cavity whose dimensions are compatible with the inclusion of numerous aroma compounds [13.19, 62, 96]. Upon the considered compounds, one or two molecules or a portion of the flavor molecules may be included in the cavity. *Sanemasa* [13.97] studied the molar ratio of aroma compounds and β-cyclodextrins after encapsulation for twenty-two volatile compounds, and found that it varies between 0.8 and 2. *Szejtli* [13.95] noted in a journal devoted to these molecules that the stoichiometry of the complex aroma/β-cyclodextrin compound ranges between 0.5 and 2.

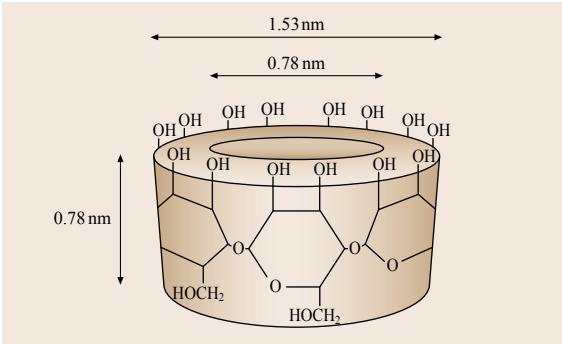

Fig. 13.3 Representation of a β-cyclodextrin molecule

The ability of these materials to reduce the volatility of aroma [13.25], their chemical or thermal degradations and their desired application are factors which can compensate for their higher prices than starch hydrolysates [13.17, 98, 99].

Gums. Gums are also widely used as flavor carriers and among them, arabic gum is the most common [13.100]. It is obtained from the exudate of Acacia Senegal and some other species of acacia. Its supply and its price are subject to the vagaries of the harvest. However, its large storage capacity makes it an interesting medium. This ability is due to its composition. Arabic gum consists of polymers of glucuronic acid, rhamnose, galactose and glucose. It also includes 5% of proteins that give it its emulsifying properties and thus higher retention capacity than starch hydrolysates at which it is sometimes added during atomization.

Xanthan gum is also widely used in food industries because it is both soluble in hot or cold water. Its structure consists of a main chain of β-D-glucose residues. One molecule of glucose out of two carries a side chain of trisaccharides (α-D-mannose, β-D-glucuronic acid and β-D-mannose terminal). Xanthan is stable under acidic medium (an advantage compared to starch and its derivatives), it supports cycles of freezing and thawing without notable syneresis and it also has an excellent compatibility with many compounds and salts. Finally, Xanthan has good emulsifying properties (a vinaigrette to 60% of oil is stable for over a year by the addition of 0.3% xanthan). *Bylaite* et al. [13.101] aimed at better understanding the release of aroma compounds from xanthan-thickened food model systems. The viscous food model was developed by increasing xanthan concentration to vary the *macroscopic viscosity* of the food model. The aroma release was evaluated in the xanthan-thickened solutions by assessing the partitioning and mass transfer behavior of 20

selected aroma compounds (5 aldehydes, 4 esters, 5 ketones, 3 alcohols, and 3 terpenes) having a wide range of physico-chemical properties. Interactions between flavor compounds and xanthan were assessed by measuring air-liquid partition coefficients K of aroma compounds in pure water and in the xanthan solutions by static headspace gas chromatography. The mass transfer of aroma compounds was estimated by dynamic headspace gas chromatography. To specifically understand the influence of viscosity on molecular diffusion of aroma compounds and thus abolish the effects of eddy diffusion, the dynamic headspace analyses were carried out with solutions under stagnant conditions. Their results had shown that limonene and some of the esters and aldehydes exhibited decreased K values in the presence of xanthan, indicating that the release of these volatile aroma compounds was reduced due to interaction with the xanthan matrix. They observed that the degree of interaction depended on the physico-chemical characteristics of the aroma compounds. A similar tendency was observed at nonequilibrium with the decreases in release rates being most pronounced for limonene, followed by the esters and aldehydes, with no effect for ketones and an apparent *salting-out* effect for alcohols. They concluded that the reduction in flavor release by xanthan was thus dependent on the physico-chemical properties of the aroma compounds and was apparently a result of the aroma-xanthan interactions and not influenced by the viscosity of the system itself.

Other gums, such as guar gum, are also largely used in the food industry. Guar gum consists of a polysaccharide composed of galactose and mannose. The backbone is a linear chain of β 1,4-linked mannose residues to which galactose residues are 1,6-linked at every second mannose, forming short side-branches. *Jouquand* et al. [13.57] have studied two guar samples differing mainly in their mannose/galactose ratio but with a similar molecular weight. The impact of these variations on aroma retention was determined by measuring the partition coefficient of ethyl butanoate, ethyl hexanoate, ethyl octanoate and ethyl decanoate in polysaccharide solutions prepared at 0.1% (w/w). They observed that the ethyl hexanoate retention depended on the mannose/galactose ratio. A high density of galactose residues induced a release of this nonpolar compound. A competition between galactose residues and ethyl hexanoate to bind water molecules could explain this *salting-out* effect. This result pointed out the impact of H-bonds on the retention of this compound. On the contrary, the high retention of ethyl decanoate was clearly linked to the molecular weight of guar samples involving hydrophobic interactions with the macromolecules.

Proteins

The knowledge of aroma-protein interactions is essential to the food industry. Indeed, several proteins used for their functional properties can bring unwanted flavors (off-flavors) and cause problems of acceptability of the product [13.102]. Furthermore, proteins can selectively retain the components in a mixture of flavorings and cause an imbalance in the perceived flavor. The binding capacity of aroma compounds by proteins may also be useful in the formulation of new products, especially for the flavor of low-fat foods. For this reason, the retention of flavors, and the factors that affect flavor release in media containing proteins are widely studied [13.88, 102, 103].

The fixation of flavors to food proteins (and likewise of off-flavors) must be considered by the food industry in the use of functional ingredients such as proteins. In formulating new products, several parameters must be evaluated and determined such as the binding affinity and the degree of release of flavor, and the partitioning of each aroma compound between the various components of the food. Although the functional properties of the protein are those requested, in some cases the protein preparations have undesirable aromas and the release of these compounds limits the use of these preparations [13.104].

The protein materials are mainly represented by gelatin, a water soluble protein derived from collagen [13.62]. Together with water, it forms a semi-solid colloid gel. Gelatin thereby firstly forms a solution of high viscosity in water which sets to a gel on cooling. Gelatin is also soluble in most polar solvents. It can be associated with starch hydrolysates to improve their emulsifying properties and thus their retention capacity. Mixed with arabic gum, it is the material used for encapsulation by coacervation. Other proteins such as gluten, casein, albumin or soy protein can also be used as an encapsulation support, but are less common [13.105].

Various bonding mechanisms are possible between the flavor compounds and proteins such as reversible bonds whose nature is probably hydrophobic and/or electrostatic as suggested by the influence of the temperature, the length of the carbon chain and the force ion [13.102, 106]. Many authors have highlighted the existence of hydrophobic binding sites [13.58]. A chemical reaction between the substrate and the volatile compound is also possible, giving rise to a covalent bond, for example, the formation of a Schiff base between the lysine or cysteine moieties and an aldehyde [13.107].

Proteins are capable of binding with aroma compounds by specific interactions. In most cases, they cause a decrease in their volatilities [13.108]. *Weel* et al. [13.109] specified that the perception of flavor

from flavored whey protein is determined by texture rather than by release. The retention of apolar flavor compounds by proteins depends on the existence of hydrophobic regions in the macromolecule which must be accessible to the ligand. The protein denaturing agents cause the unfolding of the tertiary structure of the protein and alter the structure of the hydrophobic regions. These agents are useful to highlight the role of the conformation of the hydrophobic interactions between small molecules and proteins.

In most cases, interactions between proteins and flavor compounds are reversible, they are of hydrophobic type or employ hydrogen bonds [13.110, 111]. However, there are also irreversible covalent interactions such as between aldehydes and available NH residues. A nonreversible binding has been demonstrated with the fixation of (E) hex-2-enal on milk proteins [13.112]. Numerous model media have been studied to reveal the importance of proteins (notably dairy proteins such as caseins, lactoglobulin and bovine serum albumin) in the retention of aroma [13.113–115]. *Hansen* [13.116] showed early on that milk proteins cause a decrease in perceived intensity for vanillin, benzaldehyde and D-limonene.

The heating of proteins usually causes unfolding. Indeed, when increasing the temperature, the bonds, in particular hydrogen bonds which stabilize the protein structure, become lower thus causing the unwinding of the polypeptide chain. This unfolding induces the exposure of hydrophobic side chains that become available for the formation of molecular associations [13.117, 118]. *Burova* et al. [13.119] observed that the bovine serum albumin (BSA) denaturation by acid or thermal treatment acted negatively on the covalent binding between vanillin and native bovine serum albumin. More recently, *Tavel* et al. [13.120] confirmed the strong affinity of β-lactoglobulin to β-ionone and also an affinity for guaiacol. Both aroma compounds showed greater retention by partially denatured (heated) β-lactoglobulin than by native β-lactoglobulin. The less tightly packed structure of the heated protein promotes a binding with aroma compounds, especially with the central cavity; this cavity becomes more accessible by heating that induces the favorable conformational change which in turn results in the retention of aromas.

The effects of heating on the protein and the related impact on the release or retention of aroma compounds directly impact the formulation of foods. Accordingly, the heat treatment of products containing proteins sensitive to heat can change the suitability of the product [13.104]. However, this phenomenon depends on the composition of the food process conditions and on the nature of aroma compounds.

The nature and strength of interactions between aroma compounds and proteins are influenced by physical or chemical treatments which alter the conformational status of the protein and cause significant changes in ligand binding properties. This results in increased or decreased binding of a given compound by the proteins according to the intensity and duration of treatment.

The final result of the retention of volatile compounds by proteins may be a change in the sensory perception of flavor. For example, *Hansen* and *Heinis* [13.107] observed a decrease in the intensity of the flavor by using benzaldehyde and limonene in the presence of milk protein, but in the case of citral no difference in perception was noted. Other dairy products were studied such as yogurt; data on the release of aroma compounds in such systems are available in the literature [13.121–124].

The β-lactoglobulin was used as a model for the study of protein-ligand interactions because its conformation and physical properties have been relatively well studied [13.103]. Interactions between aroma compounds and β-lactoglobulin depend on the conformational state of the protein, temperature, pH and the presence of other ingredients such as salt, lactose and residual lipids [13.125].

Espinosa-Diaz [13.1] and *Seuvre* et al. [13.126–128] also used β-lactoglobulin as a model to study the interactions between the protein and the aroma compounds. Their results show that physico-chemical interactions between aroma compounds and β-lactoglobulin depend on the nature and on the initial concentration of the flavor compound and on the pH of the protein solution. The influence of protein conformation on flavor retention has also been shown, with monomers having a greater affinity than dimers. Moreover, water has been shown to be necessary to the formation of aroma-protein hydrophobic interactions. The volatility of the aroma compounds can be altered by the structure of the food matrix; in dispersed systems (water-lipid), β-lactoglobulin is less available to interact with flavor molecules because of its partial adsorption at the lipid-water interface. The physical barrier formed by β-lactoglobulin at this interface also modifies the aroma transfer. This phenomenon further depends on the respective pH. Flavor release from food matrix likewise depends on the nature of the aroma compounds. Their behavior as a function of the food matrix structure and composition shows that flavor release is influenced basically by the presence or absence of interactions with the nonvolatile constituents of the medium.

Proteins and carbohydrates do not exert any barrier properties to water. When such properties are desired, lipids are preferably used.

Lipids

This substance class includes mono-and diglycerides, and hydrogenated oils and phospholipids which are also called lecithins [13.62, 82]. As emulsions, they are used to flavor many beverages. As coatings, they are used to control the release by increasing the temperature or to obtain water barrier properties. Their melting temperature is determined both by the length of their carbon chains and their degree of unsaturation (Table 13.3). The shorter and the more unsaturated fatty acid chains are, the lower the melting point is. The judicious choice of the type of used lipid allows controlling the release of aromas. In addition, their hydrophobicity makes them little permeable to hydrophilic compounds, which gives them a large retention capacity for these substances in comparison to protein and carbohydrate matrices.

The fat content of a food strongly affects the perception of flavor [13.130]. *Ebeler* et al. [13.131] studied the influence of lipids on the release and on the sensory perception of menthone and isoamyl acetate. Their results show a decrease of the concentration in the vapor phase and of the perceived intensity of these two compounds in the presence of soybean oil compared to the values obtained in water. In general, the perception thresholds of aroma compounds are higher with a dissolution in oil than with a dissolution in water. For example, the detection limits of octanoic acid and γ-decalactone are 60 times higher in oil compared to those in water. For 2,4-decadienal this factor is 600 [13.58]. A decrease in the concentration of volatile compounds in the vapor phase was observed when the amount of lipid increases in the medium: water, skim milk, whole milk and vegetable oil [13.132]. The addition of lipids in an aqueous medium causes a redistribution of aroma between the water, the lipid molecules and the vapor phase. Aroma compounds are generally hydrophobic, their concentration is often high in the lipid phase of the food and reduced in aqueous and vapor phases [13.133]. These factors should be considered when formulating new products with reduced fat. *Brauss* et al. [13.134] observed that altering the fat content affected flavor release in a model yogurt system and *van Ruth* et al. [13.135] pointed out the influence of the lipid fraction on the release of 20 aroma compounds from oil-in water emulsions.

Several authors consider that the decrease of the volatility of aroma compounds in lipids is mainly due to a phenomenon of solubilization [13.58]. Regarding the nature of interactions between aroma compounds and lipids, *Plug* and *Haring* [13.136] revealed the existence of hydrophobic interactions and van der Waals forces. *Le Thanh* [13.137] showed the presence of hydrogen bonds between fatty acids and volatile compounds.

Even in a small proportion, lipids strongly influence volatile aroma compounds: 1% of vegetable oil added to the aqueous phase substantially reduces the concentration of aliphatic C4 to C8 aldehydes in the vapor phase [13.138]. This trend is even more important for higher chain length or generally a higher number of carbon atoms constituting the aroma molecules: *Jouenne* [13.3] observed that the activity coefficient of 2-octanone decreased by a factor of 4 in the presence of 1% miglyol while for 2-nonanone this factor was 10. When the compound is hydrophilic, the opposite effect is observed: *Land* and *Reynolds* [13.139] showed that the concentration of diacetyl in the vapor phase is higher above oil than water. The effect of fat on the retention of hydrophobic aroma compounds is higher than that of proteins [13.126] or that of carbohydrates [13.140].

The nature of the fat moiety, especially the length of the carbon chain and the degree of saturation of the fatty acids constituting the lipid, also influences the coefficient of vapor-liquid partitioning of aroma compounds [13.137, 141]. The melting point depends on the composition of fat; accordingly, small changes in temperature around the melting point of the lipid affect the solid/liquid ratio. This solid/liquid fraction can affect the coefficient of vapor-liquid partition. Sorption of volatile compounds in liquid food lipids is greater than that of solid [13.29]. The amount of sorbed substance depends on the length of the carbon chain of the triglyceride fatty acids: moreover retention increases with the degree of unsaturation of the fatty acids [13.29]. The behavior of solutes in liquid lipids obeys Henry's Law which is not the case for solid lipids [13.142].

The influence of different chemical groups of solutes on their partition coefficients between an organic solvent and an aqueous phase is highlighted from the coefficients of liquid-liquid or vapor-liquid partitioning. In the homologous series of aliphatic alcohols, the coefficients of liquid-liquid partitioning (cyclohexane/water and hexadecane/water) increases with the number of carbon atoms [13.143]. The same trend was observed by analyzing the vapor of solutions of homologous series of aldehydes and ketones in oil: the

Table 13.3 Melting temperature of lipids (after [13.129])

Lipid		Melting temperature (K)
Fatty acids	Stearic acid C_{18}	344
	Oleic acid $C_{8:1}$ Δ^9	286
	Linoleic acid $C_{18:2}$ $\Delta^{9,12}$	368
	Linolenic acid $C_{18:3}$ $\Delta^{9,12,15}$	262
Triglycerides	Trimyristin (C_{14})	330
	Tripalmitin (C_{16})	339
	Triolein (C_{18})	346

vapor pressure decreases with the length of the aliphatic chain [13.144]. The comparison between liquid-liquid partition coefficients of two aroma compounds with the same chain length but with different chemical function shows significant differences. For example, the partition coefficient in cyclohexane/water of 2-hexanol was 1.68 [13.145] while that of 2-hexanone has been reported to be 11.10 [13.146]. This difference is explained by the difference of polarity of the chemical groups. The hydroxyl group is more polar than that of the carbonyl group.

The flavor-lipid interactions must be considered especially in the use of fat substitutes. Indeed, in addition to the consequences related to texture, the removal of fat in most foods causes an imbalance in the aroma and the appearance of off-flavors, which causes a decrease in the acceptability of the product by the consumer [13.147].

Salts

The effect of salts on the volatility of aroma compounds must also be taken into account. *Voilley* et al. [13.148] showed a significant release phenomenon of octanol and acetone in the presence of calcium chloride (20%). The same trend was observed by several authors with sodium chloride [13.137, 149]. This effect of *salting-out* of odorants in the presence of salts can be explained by a change in the structure of water causing an increase in the effective concentration of aroma compounds in the solution thus increasing their volatility [13.150]. Based on the fact that consumption of salt is too high (9–10 g/day in France for example) compared to the values that are recommended for daily intake (6–8 g/day), there is an increasing interest in the production of low sodium-content foods. However, salt perception interacts with aroma perception. *Lauverjat* et al. [13.151] studied the physico-chemical properties involved in the mobility and release of salt and aroma compounds in model cheeses. They determined the values of NaCl water/product partition coefficients to highlight interactions between proteins and NaCl. They observed that

> *these interactions were not modified by the product composition or structure. On the contrary, the composition and the structure of the studied model cheese influenced diffusion of NaCl and both the partition and the diffusion of aroma compounds.*

These authors also concluded that *both physiochemical and cognitive mechanisms contributed to perception*.

Moreover, salt (sodium chloride) is also used as a carrier for flavors. Sodium chloride may retain flavors by impregnation. This process, though economical, is not a real flavor encapsulation and then aromas evaporate or oxidize easily.

13.3.2 Macro- and Microstructure

An emulsion is a heterogeneous system containing a liquid dispersed in another in the form of droplets of microscopic size or colloidal [13.152]. Two main types of emulsion are found in food:

- *Lipid-in-water* emulsion which is a dispersion of fat in the form of lipid droplets (diameter of 0.1 to a few tens of micrometers in average) in water (continuous phase).
- *Water-in-lipid* emulsion, in which case the fat (in high concentration) is the continuous phase and water is the dispersed phase. Butter and margarine belong to this type of emulsion [13.153].

The aroma is determined by the presence of volatile molecules in the vapor above the emulsion [13.154]. The perception of aroma depends on the precise location of aroma inside the emulsion components. Most odorants are perceived more intensely when they are present in the aqueous phase rather than in the oil phase [13.155, 156]. An emulsion may be divided into four phases. The flavor molecules will be distributed within each of them: inside the droplets, in the continuous phase, in the oil-water interfacial area and the vapor above the emulsion [13.157]. The relative concentration of aroma compounds in each of these phases depends on their molecular structure, the affinity of the aroma compound for each phase and the respective phase properties [13.141].

Two factors influence the release of odorants from the emulsion: their partition coefficients at equilibrium (liquid-liquid, vapor-liquid) that determine the degree of the odorant concentration gradients at the interface, and their mass transfer coefficients that determine the rate at which the molecules move from one phase to another.

Influence of the Nature of the Continuous Phase of an Emulsion

The physico-chemical characteristics of aroma compounds largely determine the partition coefficient between the vapor phase and different solvents in which they are present (water or oil). If an apolar flavor compound is added to an apolar solvent, then the volatility decreases as the molecular weight increases (the value of the partition coefficient vapor-apolar solvent decreases). Indeed, the number of favorable attractive interactions increases between the flavor compounds and the nonpolar solvent with the increase in the size of the

compound that is to say with the length of the carbon chain in the case of homologous series [13.138]. However, if a nonpolar compound is added to a polar solvent, the volatility increases as the molecular weight increases [13.158]. Nonpolar compounds are less volatile in apolar solvents than in polar solvents [13.138]. Indeed, when a nonpolar compound is introduced into a polar solvent, a relatively large number of hydrogen bonds between water molecules must be replaced by relatively weak interactions of van der Waals-type, which is energetically unfavorable due to the hydrophobic effect. Polar compounds are less volatile in polar solvents than in apolar solvents, because the hydrogen bonds formed in the polar solvent are stronger than the van der Waals interactions formed in a nonpolar solvent [13.157].

Thus, the nature of the continuous phase of the emulsion, oil or water, can have an influence on the release of volatile compounds in the vapor phase. *Salvador* et al. [13.159] showed that for diacetyl the transfer rate towards the vapor phase is greater for an oil-in-water emulsion than for a water-in-oil emulsion with the same oil content (50% v/v) and emulsified with the same type and amount of emulsifier (0.5%, v/v sucrose ester). This variation of the transfer rate of the flavor compounds from the dispersed phase towards the continuous phase would be due to structural differences of the oil-water interface.

Influence of Droplet Size and Interface of an Emulsion

In the case of an oil-in-water emulsion, the release rate of aroma compounds from the emulsion increases as the droplet size decreases. The rate is highest for droplets smaller than 10 micrometers [13.157]. If the droplets are coated with an interfacial membrane, the release rate can be significantly reduced and will depend on the type of emulsifier [13.160].

However, no difference was observed by *Druaux* et al. [13.161] with the variation of the size of the lipid droplets of an oil-in-water emulsion for the volatility of diacetyl and 2-nonanone if the size of the fat globules is multiplied by 12 (0.5–6.1 μm). *Charles* et al. [13.162] showed an increase of the release of hydrophobic compounds and a decrease of the hydrophilic compounds when the size of fat globules in a salad dressing decreases. The higher viscosity of the salad dressing with a fine granularity could explain the lower release of hydrophilic compounds (transfer through the aqueous phase is a limiting factor). Hydrophobic compounds are more easily released through increased contact between the small globules and air (direct transfer from the fatty phase towards the vapor phase) and by reducing the thickness of emulsifiers at the globule surface (transfer towards the aqueous phase). *Van Ruth* et al. [13.135] also showed that the particle size has a very important effect on the vapor-emulsion partition coefficient, since the partition coefficient of 18 out of 20 compounds was affected. Generally, a decrease of the vapor phase concentration is observed when the particle size increases. The droplet diameter change modifies the concentration of the emulsifier on its surface, and the ratio *interface volume/emulsion volume*. The diameter also affects the kinetics of the aroma compounds release, which is in relation with the viscosity change. *Miettinen* et al. [13.163] studied the effects of the composition and structure of a rapeseed oil-in-water emulsion on the release of a nonpolar compound, linalool and a polar compound, diacetyl by static headspace and sensory evaluation by smelling. The lipid content strongly affected the release of linalool but not diacetyl. They also found a small effect of the type of emulsifier both by means of headspace and sensory analyses. For diacetyl, the release is more pronounced from emulsions at 5 and 50% rapeseed oil containing modified potato starch as emulsifier compared to those containing sucrose stearate. For linalool, the same trend was found for the 5% rapeseed oil emulsion, but the opposite trend was observed for the 50% emulsion. In addition, they observed that the decrease in the size of the oil droplets, obtained by high-pressure homogenization, increased the release of linalool but had no effect on diacetyl liberation.

Emulsifiers

To obtain a stable emulsion, a surfactant substance must be present to protect newly formed droplets against immediate recoalescence. This substance is the emulsifying agent [13.152].

In food, there are two major classes of emulsifying substances: emulsifiers with low molecular weight and macromolecular emulsifiers. Among the low molecular weight emulsifiers ($\leq 1000\,g/mol$), monoglycerides are the most commonly used emulsifying additives besides lecithins and other synthetic molecules such as polysorbates. Macromolecular emulsifiers are proteins, mainly from egg or milk [13.164].

The amphiphilic emulsifiers are often classified according to what is called hydrophilic-lipophilic balance (HLB). It is a semi-empirical concept which depends on the ratio between the hydrophilic and hydrophobic groups. If the HLB value is high, the emulsifier has a predominant hydrophilic character and therefore a preferential solubility in water. For a low HLB value, solubility in oil is higher [13.152]. The amphiphilic character of these molecules allows them to stabilize a naturally unstable system such as two immiscible phases such as oil and water.

To be effective, an emulsifier must, first, facilitate the creation of a new interface by lowering the interfacial free energy and, secondly, provide some stability to the droplet, that is, by forming a protective adsorbed layer on its surface [13.152]. The emulsifier is adsorbed at the oil-water interface, which has the effect of reducing the interfacial tension [13.165]. At the oil-water interfaces, surfactants tend to orient themselves so that their hydrophilic polar head (for example, carboxyl or hydroxyl group) is in the aqueous phase and the hydrophobic chain (lipophilic hydrocarbon chain in general) in the lipid phase [13.152]. An emulsion can be characterized by the size and distribution of its droplets, its density, the ratio of volume fractions of the two phases and viscosity.

Milk proteins are used to stabilize *lipid-in-water* emulsions [13.166]. The proteins form an interfacial membrane and thus stabilize the system against flocculation, coalescence and creaming, through electrostatic repulsions and/or steric hindrance [13.167, 168]. However, during adsorption at the oil-water interface, the conformation of the protein can be modified. Thereby β-lactoglobulin can partially unfold and the sulfhydryl groups which are commonly buried in the protein monomer become available to react with other sulfhydryl groups and form disulfide bridges [13.169]. This change of conformation can, in turn, induce a modification in the retention of aroma compounds.

It was also observed that salts can also change the emulsifying properties of β-lactoglobulin. In fact, these properties decrease with increasing NaCl concentration in the presence of calcium ions. The effect of calcium is dominant and can be reduced by the additional presence of NaCl in the solution [13.168].

13.4 Methods to Study Interactions and Their Role on Transfers

By studies on the macroscopic scale, it is possible to highlight these interactions to determine the number of binding sites and the affinity of aroma compounds for these sites. The first approach to the study of the interactions is therefore to characterize them at the macroscopic scale.

13.4.1 Experimental Highlight and Characterization of the Interactions

The detection of physico-chemical interactions between flavors and other components is based on the measurement of the equilibrium vapor-liquid or liquid-liquid, with or without the involvement of changes of state in the aroma compound [13.170]. The used methods are static or dynamic, depending on how the thermodynamic equilibrium is reached at the time of measurement (Table 13.4). But whatever the method (static or dynamic), the interactions are quantified by determining a retention percentage or a fixed aroma amount on the carrier.

For Low Water Contents

The sorption of aroma compounds in a chamber at controlled water activity allows to detect the retention of aroma compounds in relation to the hydration of the carrier and, therefore, synergies or competitions between aroma and water. Water as a plasticizer may actually promote the fixation of volatile compounds but by interacting with the polar sites of the macromolecules, water also competes with the ligand. In low water content media, few interactions between nonvolatile components and aroma compounds can occur.

In Aqueous Solution

The vapor analysis or headspace analysis consists in analyzing the vapor phase above the liquid phase (or solid) when the equilibrium between the two phases is reached. The sampling step of the vapor phase is im-

Table 13.4 Methods to study the physico-chemical interactions at the macroscopic scale

State of hydration of the support	Method	Equilibria	
		Static	Dynamic
Low water content	With change of state of the aroma compound	Sorption [13.1, 27, 171]	
Solution	With change of state of the aroma compound	• Headspace [13.60, 150, 158, 172, 173]	• Exponential dilution [13.174–177]
	Without change of state of the aroma compound	• Liquid-liquid partition [13.178] • Dialysis at equilibrium [13.179–182]	• Liquid chromatography [13.183] • Dynamic liquid chromatography with coupled columns [13.3, 176]

portant: indeed, the vapor-liquid equilibrium should not be modified by sampling. After a variable time to reach equilibrium, sampling can be done with a gas-tight syringe and injected into the gas chromatograph [13.131, 150, 184] by overpressure in the vial connected to the chromatograph [13.133, 158] or by driving the vapor with an inert gas [13.27, 148]. The advantages and disadvantages of the different types of sampling are known [13.185]. To underline the retention of the aroma compounds by the medium, the comparison of the vapor-liquid partition coefficients obtained in water and the considered medium is achieved.

The method is called dynamic when one of the two phases (liquid or vapor) circulates (equilibrium is displaced). The exponential dilution consists in following over time the depletion of aroma compounds in the vapor phase. An inert gas is bubbled through the liquid phase and causes the depletion of the vapor phase. The kinetic analysis is realized on the vapor phase [13.3, 49, 174, 175].

It is possible to combine the static headspace with a trapping system that does not require calibration [13.185]: the liquid and vapor phases reach equilibrium inside a syringe by moving the piston. The gas mixture is trapped on porous polymer (such as Tenax) and then desorbed and analyzed by gas chromatography (purge and trap method). Reverse gas chromatography is another technique to study the interactions between aroma compounds and macromolecules such as starch or β-cyclodextrin [13.87, 186, 187]. The column is filled with the macromolecule to be studied, which constitutes the stationary phase, and is placed in the oven of the gas chromatograph. At t_0, a known amount of flavor is injected onto the column, the carrier gas then further drives the aroma compounds. The interaction between the ligand and the macromolecule increases the retention time of the ligand. The free aroma compounds are analyzed by a flame ionization detector. This technique permits the determination of the partition coefficient, but also other thermodynamic parameters such as the coefficient of solubility, the adsorption enthalpy and the free energy of adsorption, and also permits quickly the determination of sorption isotherms.

These above methods require the volatilization of aroma compounds. Other methods to study the interactions do not require a change of state of the compound. The static techniques are based on the equilibrium between the two immiscible or partially miscible liquid phases. The partition coefficient depends on the interactions between the compound and the components of each phase. The methods applied to highlight the interactions do not allow determining the nature of the bonds. To validate the assumptions made on the basis of observations at the macroscopic scale, it is necessary to use spectroscopic methods and molecular modeling. Spectroscopic methods such as infrared spectroscopy [13.137, 188] or Raman [13.188], nuclear magnetic resonance (NMR) [13.188, 189] or electron paramagnetic resonance [13.188, 190] allow achieving this objective. These methods are based on the absorption of energy by molecules during their irradiation but differ in the energy level of the electromagnetic radiation. They provide information on the mobility and the molecular conformation of the respective molecules.

13.4.2 Modeling and Prediction of the Release of Aroma Compounds

Modeling can help in predicting the release (or retention) of aroma compounds and can be generally considered in two ways. Firstly, mathematical models based on the physico-chemical properties, and secondly, molecular models giving the conformational aspects of molecules based on the interactions of the atom groups.

Mathematical Models

Physiological factors influencing the release and aroma perception during the consumption of solid food can be quantified both instrumentally and sensorically. Such investigations are useful to predict the release of aroma compounds in a food matrix. To achieve this aim, mathematical models based on physico-chemical properties such as diffusion, transfer rate and volatility have been developed. The models can be classified in two groups. Some authors [13.138, 172, 191] focused on the partitioning of flavor between the different phases of the food and the vapor phase compounds. Other authors [13.31, 154, 192–200] oriented their research towards the investigation of the release of aroma compounds in the mouth, taking into account the respective physiological parameters.

The first model was proposed by *Buttery* et al. [13.138]. This equation was used to estimate the volatility of aroma compounds in three-phase systems, oil/water/air, taking into account the partition coefficients of oil/air and water/air, and the volume fractions of oil and water in the mixture. Using this model, *Guyot* et al. [13.201] found a good correlation between experimental and theoretical values of the vapor-liquid partition coefficients when the oil content of the emulsion increases. *Carey* et al. [13.191] measured the vapor-emulsion partition coefficients for 39 aroma compounds. The experimental values were correlated to 72 physico-chemical parameters determined by the software CAChe (Computer-Aided Chemistry and Biochemistry) to define the parameters playing an important role in the release, such as water

solubility, log P or dipole moment. As a result, an empirical model has been developed predicting the effect of lipids based on these three physico-chemical parameters and on lipid concentration.

Marin et al. [13.172] modeled the liberation of aroma compounds from a nonstirred aqueous solution. The system is initially at thermodynamic equilibrium. At time t_0, an air flow passes through the vapor phase to simulate the opening of a package containing food. Thereby, the aroma compounds present in the vapor phase above the food are diluted by the air flow. In the course of these studies, the model was also validated by experimental measurements. Overall, the authors showed that the release of aroma compounds depends on the vapor-liquid partition coefficient, on the mass transfer coefficients in the two phases (liquid and vapor) and also on the gas flow.

For the release of aroma compounds in the mouth, other parameters, such as chewing, temperature, dilution with saliva, should be considered. *McNulty* and *Karel* [13.192] considered odorant transfer from the lipid phase into the aqueous phase when the equilibrium between the two phases is modified by dilution with saliva. They hypothesized that only the aroma compounds in the aqueous phase contribute to the perception and that the volatile lipophilic compounds are transferred from oil to water upon dilution by saliva. Their model predicted that the release of volatile compounds increases with the oil/water partition coefficient, with the volume fraction of the lipid phase and with the dilution of the emulsion.

Overbosch et al. [13.154] underlined that partition between phases is not the only factor to take into account and highlighted the importance of the degree of flavor release, defined as the flow of matter from one phase to another per unit of time and surface area. *Roberts* and *Acree* [13.69] developed a model based on the parameters temperature, viscosity, fat content and liquid-liquid partition coefficient to take into account the composition and the texture of the product. *De Roos* and *Wolswinkel* [13.193] defined a model of multiple extractions to simulate the effects of mastication. This model takes into account both the distribution of aroma compounds in different phases and the resistance to mass transfer at interfaces. *Brossard* et al. [13.202] suggested that in viscous systems, the aromatic perception of lipophilic compounds would depend on a combination of factors such as the maximum concentration of flavor in the lipid phase, the rate of transfer from the lipid phase towards the aqueous phase and the possibility of release of aroma compounds of the lipid phase to the vapor phase.

The team of *Harrison* and *Hills* studied these factors from a theoretical point of view and developed predictive models of release [13.196, 200, 203]. These models include both the resistance to mass transfer at interfaces and the volatility, as well as the effects of the salivary flow and the breath [13.194, 195, 198, 199]. *Hills* and *Harrison* [13.203] basically developed a theoretical model to calculate the release of aroma compounds from a homogeneous solid food, using the theory of the double layer (*two-layer theory*) to simulate the mass transfer of the food compound to the saliva in the mouth. Their model proposed that the rate-limiting step in flavor release (from a boiled sweet) was the presence of two liquid films. One was adjacent to the boiled sweet, where solubilization of the sugar matrix occurred and one related to the bulk liquid layer. The model covered the release of flavor from the solid phase (the boiled sweet) to an aqueous phase and some experimental evidence was obtained by monitoring the release of a dye from a sweet sample into the liquid phase. *Harrison* and *Hills* [13.196] further developed a mathematical model describing the release of aroma compounds from gels of gelatin and sucrose. They showed that the release of aroma compounds from these gels depends on the melting point of the gel which is related to the concentration of sucrose and gelatin in the respective gel. For a low concentration of sucrose, the limiting step is the heat transfer allowing melting of the gel, but for high concentrations of sucrose, sucrose must diffuse out of the gel to reduce the melting point. *Harrison* et al. [13.199] also developed models to take into account release of aroma compounds from emulsions into the gas phase in the mouth. They considered that the limiting step of the aroma compounds transfer from food towards the vapor phase is the resistance at the food-air interface. They incorporated the partition coefficients into their calculation model, and the influence of viscosity on the transfer coefficient, as well as the lipid fraction and the size of fat globules. The model predicted that the initial release of the odorants is linearly dependent on time and is proportional to their initial concentration, and to the transfer coefficients of the respective odorants. *Harrison* and *Hills* [13.197] further incorporated the effects of the gas flow into their model. They observed that with a longer mastication time, the degree of flavor release becomes very sensitive to the gas flow. According to these authors, this observation may partly explain the differences in perception between individuals. *Harrison* [13.195] also considered the effect of salivary flow on the release of aroma, thereby showing the great importance of the level of salivary flow on the release processes in the vapor phase. In the same study, *Harrison* et al. [13.200] further developed a computer simulation describing flavor release from solid foods in the mouth. Saliva flow, mastication, and swallow-

ing were incorporated into their model. These authors showed that the initial rate of flavor release primarily depends on the mass transfer coefficient of the respective odorant and on breakage mechanisms of the food which depends on the food's structure and composition. They also specified that an individual's mastication and swallowing pattern greatly influenced the rates of flavor release at longer times.

For foods in which the interactions exist between aroma compounds and macromolecules, the release rates mainly depend on the affinity constant. It has been demonstrated that most of the time, the limiting step for aroma release is the mass transfer across the interface liquid-vapor [13.199, 204].

Molecular Models

Molecular modeling provides information on the conformation and the mobility of macromolecule chains (such as polysaccharides) and on the characteristics of their binding sites. These models use data obtained by spectral methods such as X-ray diffraction or NMR spectroscopy to determine inter-atomic distances and call on NMR, infrared or Raman spectroscopies to know the value of the bond angles. Molecular modeling reveals deformations not detectable by use of spectroscopy, or hydrogen bonds that are difficult to observe in the presence of a solvent. It also enables to quantify the importance of each type of interaction. The combined use of spectral techniques and modeling leads to obtain additional information on the nature of the interactions between host and ligand, the latter may be an aroma compound. Modeling is widely used to better understand the interactions between active principles and macromolecules, especially the interactions with polysaccharides and proteins.

By varying the value of the bond angles, for example between glucosyl residues, and searching the energy minima, it is possible to determine the most stable conformations. Molecular modeling demonstrated the high flexibility of polyosides in solution [13.205]. *Neszmélyi* and *Hollo* [13.206] have shown by a combination of NMR spectroscopy and molecular modeling that oligomers or polymers of α 1-4 glucose have a high mobility in solution. It was also observed that molecules such as β-cyclodextrins can deform when these molecules are in solution [13.207]. Cyclodextrin deformation during the inclusion of a ligand in the cavity was also visualized by molecular modeling. The importance of the deformation is related to the volume of the ligand [13.208, 209]. The conformation of the complexes between amylose and fatty acids was also determined using this technique [13.206, 210]: the lipids are included in a helix of seven glucose units per turn. The interior of the amylose single helix, somewhat hydrophobic, is sufficiently large to be able to accommodate a linear hydrocarbon chain, although charged headgroups can disrupt the helical conformation. These results agreed with the chemical shift changes observed by NMR signals due to amylose molecules. Molecular modeling further allows to highlight that fatty acids are included at the end of the helices, the polar head remaining outside [13.210].

Lichtenthaller and *Immel* [13.211] were interested in the hydrophobicity of polysaccharides. They showed that the internal cavity of β-cyclodextrins is hydrophobic and that secondary hydroxyl groups, located at one end of the molecule, form a highly polar ring while the other end bordered with primary hydroxyl groups, is less hydrophilic. The determination of these characteristics allows a better understanding of the nature of interactions and in this aim, the macromolecule ligand complexes were also modeled. In the case of complex p-iodoaniline/β-cyclodextrin or butane-1,4-diol/β-cyclodextrins, it is clear that the hydrophobic ligand areas are included in the cavity of cyclodextrins [13.212].

Among food proteins, β-lactoglobulin is the most widely studied for its interactions with aroma compounds involving hydrophobic interactions and hydrogen bonds in relation to the perception of flavor [13.111, 113]. This protein interacts with many flavors such as aldehydes, ketones and esters. It has been shown that in the same chemical class of aroma compounds the affinity for β-lactoglobulin increases with the length of the carbon chain, except for terpenes [13.213]. With the help of the 3D-QSAR (Quantitative Structure–Activity Relationship) molecular modeling, *Tromelin* and *Guichard* [13.214] suggested the existence of several types of binding, confirming the presence of at least two binding modes and highlighting the role of hydrogen bonds. *Guichard* [13.111] made the assumption that during the aroma release process in the mouth, not only are free aroma compounds released but also those reversibly bound by the protein, pointing out the fact that flavor perception is only affected if strong binding occurs.

Recently, *Golebiowski* et al. [13.215] compared molecular modeling approaches (pharmacophore, docking and molecular dynamics) to biophysical data (fluorescence spectroscopy). The combination of molecular modeling and fluorescence spectroscopy is used to study the affinity of an odorant binding protein towards various odorant molecules. These authors were interested in the interactions between odorants and proteins involved in the perception of smell and they focused on the capability of molecular modeling to rank odorants according to their affinity with the protein, which is involved in the sense of smell.

13.5 Flavor Release or Retention

13.5.1 Partition Coefficients

Vapor–Liquid Equilibrium (or Solid)

In a vapor-liquid system, the component i is present in both phases. When the system is at equilibrium, the chemical potentials in the two phases are equal: $\mu_i^{\text{liq}} = \mu_i^{\text{vap}}$.

What is written as

$$\mu_i^{0\,\text{liq}} + RT \ln a_i = \mu_i^{0\,\text{vap}} + RT \ln \frac{p_i}{p^0} , \tag{13.6}$$

$$\ln \frac{p_i}{p^0 a_i} = \frac{\mu_i^{0\,\text{liq}} - \mu_i^{0\,\text{vap}}}{RT} . \tag{13.7}$$

The second member of this equation is constant at a given temperature, the activity of component i in the solution and its partial pressure are proportional.

In the case of an ideal solution, $a_i = x_i$, and the partial pressure of component i follows Raoult's law

$$p_i = P_i^{\text{S}} x_i , \tag{13.8}$$

where P_i^{S} is the saturated vapor pressure of pure component i. It only depends on the temperature and nature of i.

If the vapor is an ideal gas, the relationship between the partial pressure of the component i and its molar fraction in this phase follows the law of Dalton

$$p_i = y_i P_{\text{T}} , \tag{13.9}$$

where y_i is the molar fraction of the constituent i in the vapor phase and P_{T} the total pressure in the system (Pa).

For a real solution, where $a_i = x_i \gamma_i$, and if the vapor is perfect, the vapor-liquid equilibrium of component i follows Henry's law

$$p_i = P_i^{\text{S}} x_i \gamma_i . \tag{13.10}$$

This law is applicable only for pressures less than 10 times the atmospheric pressure and for temperatures far below the critical temperature of the solvent [13.216]. Henry's constant H_i is defined by

$$H_i = P_i^{\text{S}} \gamma_i . \tag{13.11}$$

From (13.9) and (13.10), the activity coefficient is defined by

$$\gamma_i = \frac{y_i}{x_i} \frac{P_{\text{T}}}{P_i^{\text{S}}} . \tag{13.12}$$

The vapor-liquid partition coefficient K_{mol} expressed as molar fraction of the constituent i is

$$K_{\text{mol}} = \frac{y_i}{x_i} . \tag{13.13}$$

The molar fraction x_i of the liquid phase is present in this equation, which requires knowledge of the total number of moles in this phase. However, the total number of moles is only accessible for simple media models where the molecular weights of each component are known. With complex food matrices, the results of the vapor-liquid partition coefficient are expressed in terms of mass fractions rather than molar fractions. The determination of the activity coefficient of aroma compounds in these matrices requiring knowledge of the partition coefficient expressed in molar fraction is not accessible. The thermodynamic constants H_i and K_{mol} represent the volatility of component i. When the component i is at infinite dilution, constant H_i, K_{mol} and γ_i do not vary for a given temperature and a given pressure.

Liquid–Liquid Equilibrium

In a liquid-liquid system containing an organic phase and an aqueous phase, immiscible or partially miscible, the partial pressures for each phase are

$$p_i^{\text{org}} = P_i^{\text{S}} x_i^{\text{org}} \gamma_i^{\text{org}} , \tag{13.14}$$

$$p_i^{\text{aq}} = P_i^{\text{S}} x_i^{\text{aq}} \gamma_i^{\text{aq}} . \tag{13.15}$$

At equilibrium, the chemical potentials in each phase are equal, then

$$P_i^{\text{S}} x_i^{\text{org}} \gamma_i^{\text{org}} = P_i^{\text{S}} x_i^{\text{aq}} \gamma_i^{\text{aq}} . \tag{13.16}$$

The partition coefficient P_i of the liquid-liquid component i expressed as a molar fraction is given by the following equation

$$P_i = \frac{x_i^{\text{org}}}{x_i^{\text{aq}}} = \frac{\gamma_i^{\text{aq}}}{\gamma_i^{\text{org}}} . \tag{13.17}$$

The partition coefficient P_i is defined for the same molecule in the two phases. The liquid-liquid partition coefficient P_i', expressed in concentration terms, is given by

$$P_i' = \frac{C_{\text{org}}}{C_{\text{aq}}} , \tag{13.18}$$

where C_{org} is the solute concentration (mol/L) in the organic phase at equilibrium, and C_{aq} is the solute concentration (mol/L) in the aqueous phase at equilibrium.

In the case of two partially miscible phases, a portion of each liquid phase dissolves in the other phase, the partition coefficient is then apparent because it takes into account the liquid-liquid partition of the solute in each phase. At infinite dilution, the coefficient of liquid-

liquid partition of the component i is constant in this range of concentration. Solute-solute interactions are then negligible and the nature of the solvent-solute interactions does not change.

13.5.2 Mass Transfer

The dynamic aspect of the release of aroma compounds is not considered in the partition study at equilibrium. Aroma compounds are distributed between the matrix and the gas phase: measurement of the transport phenomena is a central preoccupation because flavor is one of the key factors determining food quality and acceptance [13.217]. The distribution of compounds in the food requires their diffusion in the different phases and their transfer from one phase to another. Transfers of small molecules (water, aroma compounds) can occur between homogeneous or heterogeneous (in composition or in physical state) phases. The measurements of diffusion and transfer are not always easy [13.218].

Diffusion

In macroscopically immobile media, the matter migrates due to the propagation of the molecular agitation [13.219]. Molecular diffusion is defined as a transfer matter within a stationary system. It is due to a chemical potential gradient, pressure gradient or temperature gradient.

In a steady state, the Fick's law expresses the amount of diffusing matter m_i of component i through the surface section S, in a direction normal to the surface, for a time t and a distance dx

$$J_i = \frac{\mathrm{d}m_i}{\mathrm{d}t} = -SD_i\frac{\mathrm{d}C_i}{\mathrm{d}x}\,, \tag{13.19}$$

where J_i is the flux of component i (mol/s), D_i is the diffusion coefficient (m^2/s) and dC_i/dx the concentration gradient of component i in the distance x.

The diffusion coefficient D_i of a component i in a given system depends on the mass, on the shape and on the molar volume of the component, on the viscosity of the solution and on the temperature of the system [13.33].

If the conditions, at a given point, vary upon the time or in a unidirectional way, the applied Fick's law in the case of a steady state is as follows

$$\frac{\mathrm{d}C_i}{\mathrm{d}t} = D_i\frac{\mathrm{d}^2C_i}{\mathrm{d}x^2}\,. \tag{13.20}$$

There are many solutions to this equation given by *Crank* [13.220] upon the initial conditions and the limits.

Transfers Between Different Phases

A transfer between two phases through a planar interface can occur in a multiphase system:

- From the vapor phase to the liquid phase (or solid)
- From the liquid phase to the liquid phase (or solid).

For example, in the case of a transfer of aroma compound through the vapor-matrix interface between the matrix and the vapor phase, the global mass transfer coefficient k (m/s) can be determined by

$$k = \frac{J_i}{A\left(C_{\mathrm{matrix}} - C_{\mathrm{vapor}}\right)}\,, \tag{13.21}$$

where J_i is the flow of component i (mol/s), C_{matrix} and C_{vapor} the concentration of aroma compounds at a given time (mol/m^3) in the matrix and in the vapor phase, respectively, and A is the interfacial area between the vapor and matrix phases (m^2).

The aroma compounds are predominantly lipophilic. According to *McNulty* and *Karel* [13.192], the transfer of these compounds towards the vapor phase is performed in two steps: first the aroma compounds must cross the lipid phase – aqueous phase interface and after the aqueous phase – vapor interface. The calculation of transfer rates between the two corresponding phases allows quantifying the transfer of compounds at the interfaces. Transfer rates are determined by following the evolution of the concentration of the compound in one or in the two phases over time.

These transfer rates depend on the nature of the aromatized phase and on the aroma compound. The transfer rate of the linear alcohols from C_3 to C_8 of sunflower oil towards the water increases with the length of the carbon chain but decreases if tristearin is used [13.192]. *Castelain* et al. (1994) [13.221] showed that the transfer of hydrophobic compounds is faster from water to oil than from oil to water. *Salvador* et al. [13.159] determined that the transfer of the hydrophilic compound, diacetyl, is faster from oil towards the vapor phase than from water towards the vapor phase.

This thermodynamic and kinetic knowledge is useful to the study of physico-chemical interactions between aroma compounds and constituents of food matrices and release phenomena.

13.6 Preservation of Food Quality and Perspectives

The objective is to use these physico-chemical parameters (saturation vapor pressure, water solubility, hydrophobicity) to predict the behavior of aroma compounds in a food matrix. It is therefore useful to try to link the results of sensory evaluation to vapor partition coefficients matrix of aroma compounds P_i and to mass transfer coefficients k. These physico-chemical parameters determine not only the potential amount of aroma compounds available in the gaseous state to be perceived by the receptors of the olfactory epithelium but also the rate to obtain the thermodynamic equilibrium.

The distribution of an aroma compound in food depends on its affinity for the different phases, and its ability to be released into the vapor phase [13.222]. This distribution, responsible for the availability of aroma compounds, will modify sensory perception at sniffing or during consumption.

A food is a very complex matrix containing mostly lipids, proteins, carbohydrates and emulsifiers from lipid or protein types, thickeners and water. The use of these components can modify the structure of the food, which will eventually induce a difference in sensory perception. The release of aroma compounds may also be reduced by the ability of certain food components to delay the mobility of the molecules towards the surface, which results from a high viscosity or a barrier due to the structure (gel with a three-dimensional (3-D) network).

For example, the impact of the size of fat globules on the sensory perception of model cheeses containing sodium caseinate as emulsifier (11−22%) was highlighted by *Dubois* et al. [13.223]. The intensity of the note due to garlic diallyl sulfide decreases as the size of fat cells decreases, this decrease is correlated to a reduction of this compound in the vapor phase. Molecules used to stabilize emulsions such as proteins or polysaccharides could also bind to aroma compounds and influence their distribution within the emulsion (within the droplets, continuous phase and oil-interface water), which can affect the availability of flavor molecules [13.141, 224]. *Charles* et al. [13.162] also showed an effect of the size of the oil droplets on the perception of volatile compounds in a salad dressing. The release of aroma compounds, and therefore, their perceived intensity, are more important for the more hydrophilic compounds (acids, alcohols, acetoin, diacetyl) in the presence of large droplets. Because of a decrease of the viscosity of the salad dressing with the droplet size increase, the release of the compounds is then facilitated. *Miettinen* et al. [13.163] conducted sensory evaluation by sniffing on emulsions based on 5 and 50% rapeseed oil. They observed that an effect of droplet size on the perception of linalool is more important for small droplet sizes, obtained by increasing the pressure during homogenization. But, for the same concentration of fat, the type of emulsifier does not affect sensory perception.

The stability of aroma compounds plays an important role in food quality, but it is not easy to control. A way to preserve the sensory perception, and thus to retain aroma compounds inside the food, is encapsulation. Encapsulation is often a relatively effective method to limit the degradation of aromas during processes and storage of the product. Encapsulation also allows to limit or prevent undesirable events such as the aroma-aroma interactions and reactions induced by light and/or oxygen [13.225]. The method of encapsulation of sensitive substances consists of two steps: the first is the production of an emulsion composed of the couple *aroma-lipid compound* in a solution of a dense material that forms the *wall* such as polysaccharides or proteins. The second step is the drying or cooling of the emulsion to stabilize the capsule [13.226]. The stability of the encapsulated flavor compound depends on the nature of the *core*, the nature of the *wall*, the encapsulation method, the interactions and the storage conditions. The encapsulation size can vary from a few millimeters to less than a micrometer, which gives it the name of *microencapsulation*. Microencapsulation is a technique that is increasingly being developed and widely used in the pharmaceutical, cosmetic and food industries [13.227]. Microencapsulation comprises an active substance coating with a uniform continuous or composite layer. There are several microencapsulation techniques: chemical (coacervation, co-crystallization, molecular inclusion) and/or mechanical (spray drying, freeze drying, extrusion). Coatings, especially emulsified coatings, can be used as microencapsulation agents for aroma compounds, this gives them the name of *active* packaging [13.228].

This microencapsulation in edible films prevents the release of aromas and protects them from oxidation [13.227]. There are a few studies on this topic, *Kim* et al. [13.229] studied the encapsulation of orange essential oil in films based on sodium caseinate, whey and soy proteins. They found that soy protein was more efficient to retain the orange essential oil with 87.7% retention, followed by sodium caseinate with 81.5% retention and ultimately whey protein being the least efficient with 72.7% retention. The retention of aroma model in maltodextrins, gum acacia, corn syrup, modified starch, soy and whey proteins was proposed by *Dronen* [13.230]. Similarly, the retention of several aroma compounds in various starch matrices

was studied by *Boutboul* et al. [13.87]. More recently *Rodrigues* and *Grosso* [13.231] compared microencapsulation with Cashew gum and arabic gums to protect the aroma of coffee extracts.

Homogeneous films consisting of only one substance had good barrier properties and good mechanical properties, but rarely both simultaneously. Emulsified films for which the lipids are dispersed in a continuous matrix of hydrocolloids have the advantage of simplifying the manufacturing and application processes [13.232]. That is why the desired properties are often reached by using the combination of different materials. Thus, hydrocolloids form interchain interactions to create a network responsible for the mechanical strength and lipids have a water barrier role or a carrier role to encapsulate the hydrophobic volatile compounds.

Lately, *Ciriminna* and *Pagliaro* [13.233] opened the route to sustainable fragrances and aromas using the sol-gel microencapsulation of odorants and flavors: sol-gel encapsulation technology is a promising method to encapsulate fragrance and aroma chemicals. It allows an effective control of biomolecules, drugs or essential oils released. The sol-gel entrapment of aroma in the inner pores of amorphous sol-gel SiO_2 allows the practical utilization of chemically unstable essentials oils.

14. Models of the Oral Cavity for the Investigation of Olfaction

Christian Salles, Ofir Benjamin

In this chapter, we will briefly describe the complexity of the main mechanical, biochemical and physicochemical phenomena that occur in the mouth during food consumption using examples. To better understand the reactions occurring in the mouth during food consumption, in vitro systems called model mouths were developed to simulate food consumption and thus answer some of the more fundamental questions regarding olfactory perception. This chapter provides examples of the applications of the model mouth in performing oral functions, such as mastication, saliva production and airflow, as well as swallowing, while the released volatile compounds are measured. The recent model mouth designs represent the actual occurrence of food consumption under oral conditions in a more accurate way. We believe that this type of methodology will be even more commonly applied in the future to improve the knowledge in this field.

14.1 Oral Food Processing and the Effect on Olfaction

During food consumption, various oral processing steps are followed. Initially, the solid food is ingested, then masticated, and mixed with saliva to form a bolus. The food particles are transferred into different locations in the mouth, until they are ready to be swallowed [14.1, 2]. During the complex process of oral food consumption, the physical properties of food are modified and, as a consequence of these diverse steps as a whole, the perception of flavor and texture are affected. Therefore, the release of flavor compounds from the food and their delivery to receptors are key factors leading to flavor perception.

In the last twenty years, several devices have been proposed to simulate the various steps and parameters involved in this process [14.3, 4]. These simulators were developed to study the breakdown of food and/or the release of volatile compounds from food products of various textures. Due to the vast complexity of the mouth's functionalities, the development of mouth model had to be focused on a limited number of factors to simulate a specific process for the study under consideration.

14.1.1 Main Oral Functions

The major in-mouth phenomena that occur after the ingestion of solid food are mastication, salivation, the formation of the bolus, the transport of particles into different locations in the mouth and swallowing [14.1, 2]. Mastication is the action of breaking down food and preparing a food bolus for swallowing. During this step of oral food processing, the physical properties of the food are modified and the perception of flavor and texture are affected. The release of aroma and taste compounds from the food and their delivery to receptors are key factors leading to flavor perception. The breakdown of food into particles, associated with the effect of temperature, increases the surface area of the food that is exposed to saliva and air. This facilitates the dissolution of taste compounds within saliva and

the release of volatile compounds into the gas phase of the *mouth space*, leading to flavor sensations. During this process, variations in the texture of the food and the bolus are constantly perceived and the chewing pattern is consequently adjusted according to the peripheral feedback. In addition, the masticatory pattern and the characteristics of saliva may vary considerably between individuals [14.2].

Food oral processing is divided into the three following phases: I) ingestion, II) rhythmic sequences of mastication and, III) swallowing and clearance. The properties of food (flavor and texture) are perceived during these three consecutive stages. The temporal perception of flavor and texture are important determinants in the acceptability and choice of food by the consumer, with direct consequences for his nutritional status. The breakdown patterns are specific to the food under consideration. Whereas solids must be fragmented by the teeth and be softened by and mixed with saliva to form a cohesive bolus [14.5], liquids are nearly ready to be swallowed [14.6]. Furthermore, the type and extent of oral forces change throughout the process according to the physical state of the bolus that is perceived by mechanoreceptors. Subsequent motor actions are then adapted through feedback-control mechanisms. In the case of brittle solids, the first transformation that occurs in the mouth consists of the fragmentation of the food into smaller particles. The breakage function depends mainly on the anatomical characteristics of the subjects [14.7]. The breakage function also depends on the resistance of the food to be broken [14.8]. Saliva also plays a role in the formation of a bolus from brittle food because it allows the particles to cohere due to its viscosity. Cohesive foods, such as meat and some cheeses, do not break into separate particles; instead, they are softened by chewing [14.9]. In particular, cheeses with a low lipid-to-protein ratio result in harder boli than those with a high ratio. For this type of food, the salivary intake into the food matrix is an important factor in determining the texture of the bolus: the higher the salivary intake, the softer the bolus. In the case of semisolids, the main change in food properties that occurs is the reduction of viscosity due to shearing forces, the temperature change, dilution, or chemical degradation induced by saliva.

Texture, which is dependent on the physical properties of food, is perceived through mechanoreceptors that are distributed in the oral cavity. The masticatory process can be considered as a combination of compressive and shearing activities. Studies of the mechanical properties of food have indicated that chewing and the mandibular movements occurring during the breakdown of solid food are strongly affected by the food's texture [14.10]. Thus, the hardness of the food has an effect on the number of chewing strokes necessary to trigger a swallow. The harder the food, the more chewing strokes are needed. Increasing the hardness of the food also increases the extent of the masticatory motions, thereby increasing the forces applied to the food matrix [14.11]. Compression has been shown to be dominant during the early stages of biscuit breakdown, and shearing was found to be dominant during the subsequent stages of mastication [14.12]. Food texture also affects the salivary flow rate because the chewing forces developed during mastication and the salivary flow rate, particularly the parotid gland secretion, are linked. The hardness of solid foods is therefore positively correlated with the parotid gland flow rate.

In addition to the initial hardness of the food, the progressive comminution and softening of food during mastication also affects oral physiological parameters [14.13]. Generally, the force generated by jaw muscles decreases during bolus formation due to sensory feedback between the intraoral mechanoreceptors and the muscles involved in mastication. Oral physiology and textural perception are tightly linked due to the sensory feedback between the chewing behavior and the food texture during food consumption. Moreover, tongue movements, temperature and the salivary composition are also important for textural perception because these oral parameters can modify the matrix structure of the food during in-mouth processing and consequently the sensory evaluation of texture.

In the case of brittle food (biscuits and chips), its texture is determined by the ability of the matrix to form particles, the rate of particle size reduction and the resulting particle size distribution. The level of lubrication of the particles, provided by salivation, is of obvious importance in forming a cohesive bolus prior to the swallowing step [14.5]. For nonbrittle foods, such as meat and meat products, different correlations between the oral physiological parameters and texture perception were found [14.14]. For example, the work and efficiency of chewing were found to be relevant parameters in predicting textural perception. Subjects with low efficiencies presented shorter chewing time and reached the maximal intensity of tenderness earlier. However, other works have shown that subjects presenting a lower chewing efficiency required a longer chewing time to form a bolus [14.15].

14.1.2 Release and Perception of Flavor in Oral Processing

Flavor perception during food consumption is determined by the nature and amount of volatile and non-

volatile compounds and the availability of these compounds to the sensory system as a function of time. The extent and rate of the release of flavor compounds and their subsequent transport to the receptors depend on the process of breaking down the food matrix through mastication. The progressive breakdown of the food matrix, the salivary volume and the swallowing process are important factors in the release of both nonvolatile and volatile compounds, but differences between the two compound categories can be observed.

In general, the quantity of nonvolatile compounds in saliva increases at the beginning of the chewing process, reaches a maximum, and then decreases more or less rapidly until the end of mastication. For example, the salivary concentration of nonvolatile compounds that were released from a piece of chewing gum peaked within the first minute of mastication [14.16]. The kinetics of the release of nonvolatile compounds from a model cheese were related to various chewing parameters, such as the rate, duration, and efficiency of mastication, which were closely linked to each other and to the salivary flow rate [14.17–19]. The release of sodium from the salt in model cheeses was highly affected by textural and compositional factors, and the oral physiology of individuals. For example, rapid sodium release was linked to increased bite force and slower sodium release was linked to a prolonged chewing sequence, whereas a faster perception of saltiness was related to the masticatory performance and bite force. As the area of surface contact increases during chewing, more taste papillae are stimulated and the perceived intensity increases. The compositional factors of the model cheese matrices, particularly the fat and water contents, had strong impacts on both the release of sodium in the mouth and the perception of saltiness. Increasing the fat content and reducing the water content were both found to be related to a global decrease in the release of sodium and an increase in the perceived saltiness. This result suggests that the water content affects the initial release of sodium, whereas the effect of the fat content is more pronounced in the perception of saltiness during the chewing process. However, the effect of each compositional parameter on the release of sodium differs according to the duration of chewing, and globally some of the oral parameters that affect the release of sodium are different from the parameters that affect the perception of saltiness. Thus, the significant distinction between the time of sodium release and the time of the perception of saltiness can be explained by the differential effects of both the oral and matrix parameters.

Mastication also plays a key role in the temporal pattern of the release of volatile organic compounds (VOCs), whereas processes such as swallowing and the flow of nasal air determine their subsequent delivery to receptors located in the nose. The process of mastication involves the gas-phase transfer of VOCs from the mouth to the pharynx, where they are swept through the upper airways to the nose by the air that is expired from the lungs. As is the case for nonvolatile compounds, the release of VOCs in the mouth depends on both the food characteristics and the oral parameters. For example, for cheese products, an increase in the masticatory rate increases the overall aroma release. The level of the effect of the masticatory rate differs for compounds depending on their varying mass-transfer coefficients. Most of the chewing parameters are positively correlated with a high concentration of volatiles in the nose, mainly due to the increase in the surface area due to the sample breakdown [14.20, 21]. Volatile compound release was also shown to depend on the interaction between the food matrix composition and the chewing behavior. The seal between the mouth and the pharynx opens intermittently during mastication according to the air movement in and out of the mouth [14.22]. During jaw closure, the volume of the mouth decreases, which may push some air out of the mouth into the pharynx [14.23]. However, oral behaviors vary highly according to the subject, leading to interindividual differences in the patterns of volatile compound release. For example, during the consumption of a sweet mint tablet, swallowing events were the main contributors to menthone release. The tongue and jaw movements did not induce menthone release in all of the subjects, indicating that the interindividual differences in terms of the quantity of menthone released arose from the percentage of degradation of the sweet mint tablet [14.24].

In the case of chewable products such as cheeses, it was shown that subjects differentially adapted their chewing behaviors in forming a swallowable bolus [14.25] and that this phenomenon was an important source of interindividual variability. Food texture affects both oral behavior and flavor release. An increase in firmness induced an increase in the chewing duration and the amount of saliva that was incorporated into the food bolus, which led to an increase in the total amount of released VOCs. The release rate of the volatile compounds differed according to their physiochemical properties. A higher fat content led to a larger amount of product remaining in the mouth after swallowing, resulting in the release of a smaller amount of volatile compounds and a prolonged persistence of aroma in the breath. The polarity of the volatile compound affects its release rate. A larger amount of a more polar compound, ethyl propanoate, was released during the masticatory step, whereas more nonan-2-one

was released during the post-swallowing step and it was more persistent in the mouth, due to its higher hydrophobicity [14.26].

The release and perception of flavor are also affected by the composition of the food and the quantity of saliva, which vary greatly among individuals. Saliva is a complex viscous aqueous medium containing minerals and a wide variety of organic molecules, including proteins with various properties, such as enzymatic conversion, binding, and transport. Saliva plays an important role in the in-mouth breakdown process, mainly due to its hydrating, lubricating and hydrolytic capacities. Moreover, saliva dilutes the food in the mouth, thus decreasing the amount of volatile compounds that are released to the air. Saliva actively contributes to the formation of a bolus that can be swallowed and to the release of active compounds, including taste and aroma compounds, during chewing and swallowing [14.2]. Thus, saliva plays a major role in flavor perception [14.27]. Volatile compounds can interact differentially with the components of saliva [14.28]. Three types of behavior were reported based on the physicochemical properties of the volatile components: The partition coefficient of a group of compounds is not affected by mucin; mucin decreases the partition coefficient of the second group, mainly through hydrophobic interactions between saliva proteins and VOCs; and mucin decreases the partition coefficient of the last group but that process is affected by the presence of salt and sugar. Different salivary enzymatic activities are suspected to have a nonnegligible effect on taste and aroma perception. Regarding volatile compounds, their flavor can be altered by the salivary enzymatic activities [14.29, 30]. For example, ester hydrolysis by salivary extracts was found to alter flavor in model systems. The addition of human saliva to white wine led to significant changes in the volatile compound profiles. In particular, the levels of esters and fused alcohols were reduced by 32% and 80%, respectively, whereas in contrast, the levels of 2-phenyl ethanol and furfural were increased by 27% and 155%, respectively [14.31]. Regarding nonvolatile compounds, the in-mouth amylase activity, which hydrolyses bonds within amylose and amylopectin, can quickly lower the viscosity of starch in starch-thickened foods [14.32]. This enzymatic activity can reduce the perception of saltiness in starch-thickened foods as the structure of the product is changed during the enzymatic process. Thus, a direct relation was found between the level of α-amylase activity in saliva and the perception of saltiness in starchy matrices [14.33]. As another example, human salivary lipase is suspected to affect the perception of fat but this conclusion is subject to controversy. However, recent studies showed that human salivary lipase plays a significant role in the perception of fat [14.34, 35].

14.2 Simulation of Oral Processing

As described previously, human olfaction is a complex process that involves a wide array of factors that interact to affect the final perception of flavor. The main factors include mastication and the mixing of the bolus by the teeth and tongue, temperature and hydration, salivary enzymatic reactions, and airflow. Simulating in vivo oral functions using model mouth devices poses a challenge and in some cases, the actual behavior cannot be fully reproduced. However, the large deviations in the masticatory and swallowing patterns among individuals and the differences in the flow pattern and composition of saliva created the need to apply model mouths in investigations. The main advantage of these models is the ability to isolate a single parameter and study its effect on food breakdown and volatile compound release. This chapter describes the development of oral processing models in the field of volatile compound release, from the early simple devices to the recent ones. Moreover, the model-simulated oral functions and the research applications of the model mouth in food science are mentioned.

14.2.1 History of Model Mouth Designs

More than twenty years have passed since the development of the early models to simulate oral food processing and the release of VOCs. The models incorporated the following functions:

- Mastication and food breakdown
- Salivary mixing
- Airflow
- Body temperature
- VOC sampling.

The aim of each model is to determine the complexity of the model's features. The earliest models focused on sampling the VOCs that had been released into the headspace at certain intervals. A 21 flask containing a 50 ml sample and 10 ml of artificial saliva was used

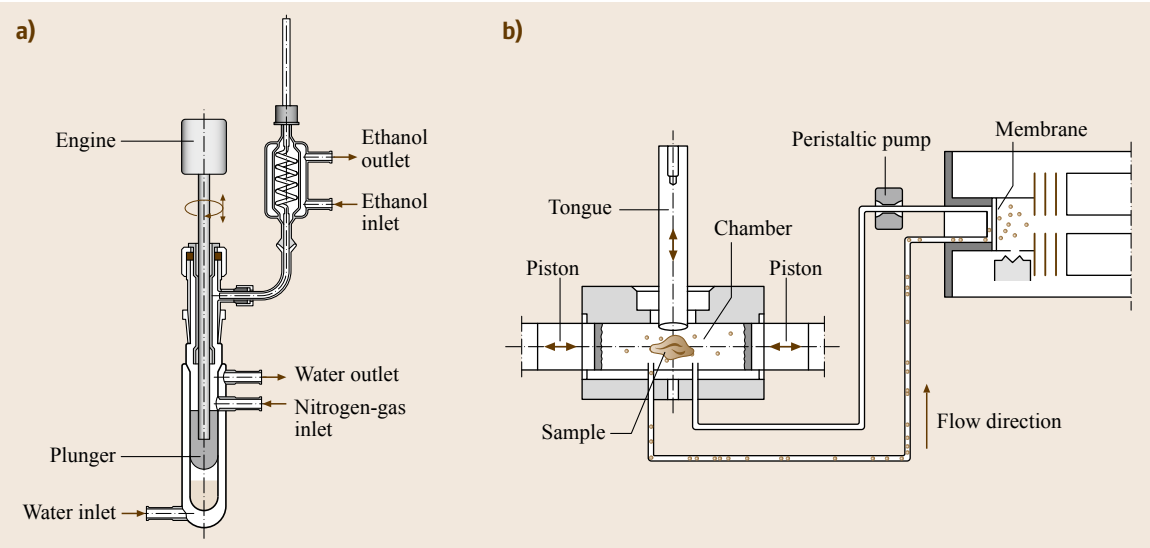

Fig. 14.1 Examples of model mouth designs to simulate oral food processing and VOC release **(a)** after [14.36], **(b)** after [14.37]

to study the release of VOCs from alcoholic beverages (old malt whiskey) [14.38]. Oral mastication in this model was mimicked by shaking a flask containing glass beads. The headspace was sampled after equilibrium was reached, at 45 min. Another device was developed [14.39] and was later used in the investigation of flavor release from dressings [14.40]; this device consisted of a temperature-controlled sample flask (70 ml) and an oscillating plunger moving vertically (4 cycles/min) to evaluate the effect of mastication on the release of VOCs from food samples (Fig. 14.1a). The samples were mixed with artificial saliva that was prepared using the major minerals and proteins that exist in human saliva. Certain VOCs were inserted into solid food (rehydrated diced bell peppers) or liquid food matrices (cream dressings or sunflower oil). The VOCs released from the food samples were trapped in a Tenax trap with a nitrogen gas flush and were later analyzed using gas chromatography with flame-ionization detection (GC-FID).

The first model mouth used to perform dynamic headspace analysis of VOC release was the so-called *retronasal aroma simulator* (RAS) [14.41]. Its design was based on a modified blender; nitrogen was purged over the sample in this blender while the temperature was held at 37 °C. The headspace was sampled at certain time points, which allowed the authors to plot the temporal release curves of several VOCs and to calculate the volatility rate constants ($k \times 10^{-5}\,\mathrm{min}^{-1}$). However, this model mouth lacked the proper dimensions and chewing geometry of the human mouth. Artificial saliva was incorporated into the device immediately before the sample was introduced, unlike in the more advanced apparatus [14.42] in which artificial saliva was pumped continuously into the glass reactor. Inside was a stirrer made of a six-star impeller, which mixed the liquid food. This model was the first to use a computer-controlled system to regulate the flow rates of the air and salivary inlets and the sample outlet. This system yielded VOC release data with a highly satisfactory level of reproducibility. The problem with this model was the nonproportionality of the conditions relative to those of a human mouth. For example, the stirrer speed of 450 rpm and the salivary flow rate of 175 ml/min deviated strongly from the real-life parameters. Later, the accuracy of the masticatory compressive and the shearing strengths was increased by using two horizontal pistons with wavy surfaces to simulate the irregularity of teeth shape and by applying one vertical piston to mimic the tongue's actions [14.37]. Together, the pistons chewed solid food (chewing gum) under the control and direction of the user via compressed air. Another unique feature of this model was the ability to measure the released VOCs online using a membrane-inlet mass spectrometer (MIMS) to simulate monitoring of their release during eating.

Despite the progress made in the development of model mouth systems, there were challenges to overcome to obtain a better resemblance to a real human mouth. The main problems with the models described above were the limited number of oral functions that could be represented simultaneously and the fact that the dimensions used were quite different from those of an actual oral environment.

Table 14.1 Comparison of functionalities between model mouth devices

Model mouth device	*Van Ruth* and *Roozen* [14.36]	*Roberts* and *Acree* [14.41]	*Woda* et al. [14.43]	*Arvisenet* et al. [14.44]	*Salles* et al. [14.45]	*Benjamin* et al. [14.46]	*Ishihara* et al. [14.47]
Airflow	Nitrogen 20 ml/min	Air or nitrogen 1200 ml/min	–	Helium not indicated	Air 30–50 ml/min	Air 1000 ml/min	–
Salivation	Constant volume	Constant volume	Small spurts	Constant volume	Constant flow rate	Constant flow rate	Constant flow rate

Food texture range	Soft–medium	All	Medium–hard	Medium–hard	All	Soft	All

14.2.2 Recent Developments in Model Mouth Devices

To address the previously mentioned limitations of the model mouth, more sophisticated and functional devices have recently been developed. This section describes several models that were designed to simulate the mastication of solid food through teeth and jaw movements and the mixing of liquid food through the pre-swallowing tongue pressure while monitoring the release of volatile compounds. A comparison of the functionalities of some model mouth devices is presented in Table 14.1.

The ability of the model to perform proper masticatory actions is well correlated with the exposure of the surface area of the bolus particles and their proper mixing with saliva. Both processes have a significant impact on VOC release [14.48]. The masticatory function of the model can be evaluated by comparing the sizes of the food particles generated with those generated by the human mouth using image analysis. The artificial mouth presented in [14.44] was developed to study the VOC release from apples crushed at different frequencies of compressive movements, speeds of rotational movement and periods of mastication. The apparatus was composed of a sample container (600 ml) and a notched plunger that rotated vertically and horizontally according to controlled motors (Fig. 14.2a). The apple samples were mixed with artificial saliva and the VOCs were extracted using solid-phase microextraction (SPME) fibers before analysis using gas chromatography (GC). The authors found that both the duration of mastication and the speed of rotational movement affected the intensity of the released aromas due to the different sizes of tissue obtained. Hence, any oxidative and enzymatic reactions that occurred accordingly affected VOC release. The same device was used to compare the aroma extract obtained from bread mastication to the aroma perceived in the human mouth [14.19]. It was found that saliva and water differentially affected the way the bread was commuted into small particles. Due to the presence of salivary proteins, saliva played a significant role in the release of VOCs according to their physicochemical properties.

A novel chewing simulator that integrated most of the main functions of the human mouth has recently been developed (Fig. 14.2b) [14.45]. This device includes a fixed upper jaw and a mobile lower jaw with teeth that reproduce the molar motif and can generate shearing forces of up to 250 N. The compressive and shearing movements are controlled in angular and vertical planes by a computer. Another unique feature of this model is that an inert material called polyetheretherketone (PEEK) was used to build the apparatus to avoid

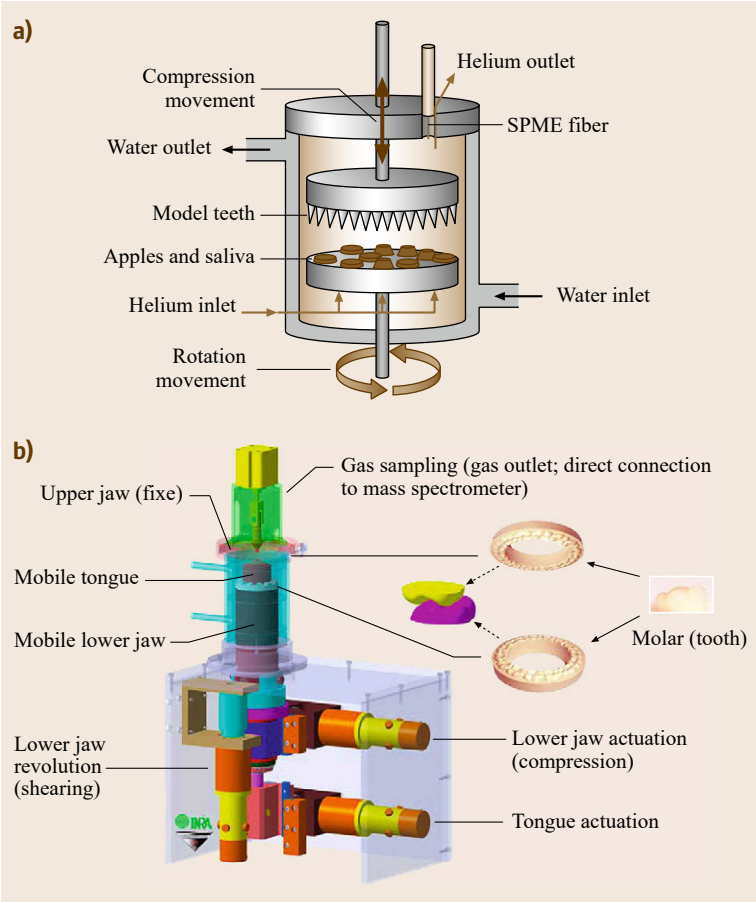

Fig. 14.2 Examples of recent model mouth designs to simulate solid food mastication and VOC release (**a**) after [14.44], (**b**) after [14.45]

the loss of VOCs through adsorption to the material. The operational volume resembles that of the oral cavity (100 ml), and artificial saliva is pumped into the chewing cell using a controlled flow system to mimic the salivary flow rate in the mouth under nonstimulated and stimulated conditions (0–5 ml/min). The masticatory capability of the simulator was tested using peanuts under oral environmental conditions. The results indicated that the course of natural food breakdown could be reproduced if the appropriate shearing forces and angles were applied as a function of the mechanical properties of the food sample. This chewing simulator was used to study the brittle behavior of cereal food products under masticatory conditions. The study reported that food fragmentation is followed by significant agglomeration after less than ten chewing cycles. Both phenomena were correlated with the magnitude of force applied and the evolution of the force. Moreover, through artificial mastication of the products, the chewing simulator was also able to discriminate products under dry masticatory conditions. The results showed a qualitative agreement with human mastication and textural properties of naturally chewed food [14.49].

The release of VOCs into the headspace is monitored in real time through a direct connection to an atmospheric pressure-ionization mass spectrometry device (API-MS) [14.50]. In particular, the temporal pattern of volatile compound release was found to change according to the oral parameters and the physico-chemical properties of the compounds.

Other devices were more dedicated to the study of food-bolus formation and the changes that occur during the chewing process. The artificial masticatory advanced machine (AM2) was developed to mimic the process of bolus formation in the mouth [14.43]. The main aim was to simulate the preparation of a food bolus in the model that had properties similar to those produced by natural mastication. The masticatory chamber is a cylindrical cavity. The two ends of the chamber are formed by the stationary *maxillary disk* and the moving *mandibular disk*. The mandibular disk can move back and forth along and rotate around the central axis of the cylinder. The authors obtained a good level of consis-

tency between the in vivo and in vitro results for the breakdown of peanuts and carrots using different chewing cycles, with good repeatability. The in vitro and in vivo boluses displayed the same median particle size distributions for each food. The in vitro and in vivo boluses obtained at different times during the chewing process were also similar when the in vitro mechanical parameters were adjusted [14.51].

The simulation of liquid and semisolid food processing in the mouth has not progressed much, nor has the simulation of the tongue's role in volatile compound release. A mouth simulator has been specifically developed for semisolid foods, for which the oral processing is dominated by the effects of tongue movements [14.52]. The system, which is equipped with an electric motor to rotate the sample using a mixing vane, as well as a video camera, laser, optical sensor and temperature probe, is able to measure changes in viscosity due to temperature, shear, dilution and structural breakdown and to mimic the mixing pattern of semisolids and saliva in the mouth. Changes due to mixing were analyzed using a reflectance sensor (online) and image processing (offline). This study showed that enzyme-induced structural breakdown has a dramatic effect on the viscosity of starch-based semisolid products in time scales that are relevant to those of in-mouth processing.

A simpler mouth model was developed to quantify the salt release from food structures, such as biopolymer gels, after they were compressed [14.53]. The model consists of a jacketed vessel fitted with an impeller and a conductivity probe. To measure the results of diffusion, the sample is caged in the liquid phase and subjected to low shear, whereas to measure the results of compression, the sample was subjected to cyclic compressions using a texture-analyzer probe. The authors observed that salt release was affected by both the type of gelling agent used and the temperature. In particular, the compression of the gel only affected salt release when fractures occurred, which was interpreted as being a consequence of the increased surface area. A mechanical simulator was developed to mimic the action of the human jaw in the presence or absence of artificial saliva for both soft and harder foods [14.47]. The simulator consists of a cylindrical chamber composed of acrylic resin and a flat plunger with a 50 mm diameter for simulating compression and shearing simultaneously. This device was used to prepare a model bolus from various gel samples and to subject them to dynamic viscoelasticity measurements to investigate the rheological properties regarding the gel composition and the level of added saliva. As an example of its application, a model bolus prepared from a binary gel (mixture of gellan gum and psyllium seed gum) using this device showed weak-gel rheological behavior and had greater structural homogeneity than that derived from gellan gum gel. Moreover, the dynamic viscoelasticity parameters of the binary gel were less dependent on the level of saliva. The authors also reported that the greater structural homogeneity of the model bolus formed from composite gels with various physical properties were related to their greater miscibility with saliva [14.54].

Another artificial mouth has been developed to study the in-mouth processing of soft foods [14.55]. The system is composed of a 150 ml closed double-jacketed vessel with a usable volume of 100 ml. The shear rate applied to the studied mixture can be modulated using a marine propeller driven by a viscosimeter. The temperature is controlled at 35 °C and the redox potential and sodium concentration of the saliva are continuously recorded during processing by the artificial mouth. For example, one application was studying the effect of the saliva/cheese ratio and the cheese composition on salt release using pooled raw human saliva previously collected from different people, and following the changes in the composition of the saliva using different types of sensors. Regarding salt release during cheese digestion in the artificial mouth, good correlations with the sodium concentration were observed using a single sodium sensor and an array system that combined chloride and sodium detectors. By comparing domestically prepared soft cheese samples treated with deionised water and pooled human saliva in the artificial mouth system, it was found that a larger amount of sodium was released from the water-treated samples, whereas in general, a smaller amount of sodium was released from the saliva-treated cheeses. This slower release was attributed to the partial absorption of sodium by the saliva during the initial stages of digestion.

Recently, an innovative and dynamic model mouth has been developed to investigate whether the intraoral pressures produced by the tongue affect the release of VOCs [14.46]. The tongue is known to play an important role in manipulating and transporting the bolus within the mouth and lubricating it with saliva while applying pressure against the hard palate [14.2]. This model mouth incorporates some of the main human oral features to allow a better understanding of the pattern of VOC release in the mouth.

The model includes several parts that function simultaneously. The volume of the main chamber replicates that of the oral and nasal cavities in which the VOCs are released from a food bolus. Within the chamber, an artificial tongue composed of glass and silicone rubber masticates the sample. Various materials for constructing the tongue were considered to find materials

with the viscoelastic properties of human muscle and inertness against the absorption of VOCs. Finally, glass material was chosen for the experiments on the release of volatile compounds, because it responds well to the pressures exerted by the elastic silicone rubber. The forces and pressures generated by the tongue are measured using two sensors: a compression load cell to assess force and a pressure transducer. The tongue movements are controlled by a computer-driven actuator and follow different mathematical movement patterns (sine wave, pulse and ramp). Figure 14.3 illustrates the pressure patterns generated by the artificial tongue made of glass and silicone rubber compared to the human tongue. The patterns for both materials follow similar curves with an average maximal pressure and duration of 20–30 kPa and 0.4–0.8 s, respectively. These values correspond to real values measured in participants while they swallowed liquids [14.56, 57]. The chamber has temperature-control circulation using a jacketed cylinder and the artificial saliva flows into the bottom and is mixed with the food. At the same time, a flow of air carries the VOCs from the headspace to the PTR-MS instrument for online detection. Thus, this model mouth can simulate a very rapid process, such as the consumption of liquid food. In the next sections, several applications of the model will be discussed.

The oral food processing is not complete without considering the swallowing phase and the intense VOC release that appears after. It was found that the majority of the VOCs are present in the thin layer coating the throat after swallowing and are carried into the nasal cavity by the exhaled air [14.58, 59]. To simulate the dynamic conditions of VOC release from liquid foods after swallowing, a model artificial throat was designed [14.60]. The system consists of vertical glass tubing that splits into the two following parts: the upper part into which the sample, artificial saliva and the cleaning solution are poured; and the bottom part from which the liquids are drained (Fig. 14.4). In the middle, there is a piece of Viton rubber that can be opened or closed using a clamp to mimic the swallowing behavior and the closure of the pharynx by the velum. A thin layer of liquid remains on the rubber surface and is responsible for the continuous release of volatile compounds. The VOCs are monitored online using an atmospheric pressure chemical ionization gas-phase analyzer (APCI-GPA). Testing the hypothesis that the release of the majority of VOCs is enhanced after swallowing yielded comparable results in the artificial throat and in humans. Compared with the results obtained using static headspace analysis or a model mouth, the relative amounts of VOCs released were much lower for the artificial throat due to the short measurement time, and closer to human values. However, the model system cannot fully simulate the events that occur in the human throat. One of the main differences between the two systems is the force that drives the swallowing, which is gravity in the artificial throat and pharyngeal peristalsis in the human throat. Therefore, the intensity of VOC release cannot be expected to be the same. In the future, the artificial throat model will undergo some modification, such as the addition of tidal airflow to simulate breathing patterns, control of the temperature and humidity of the air and the choice of material for the tube.

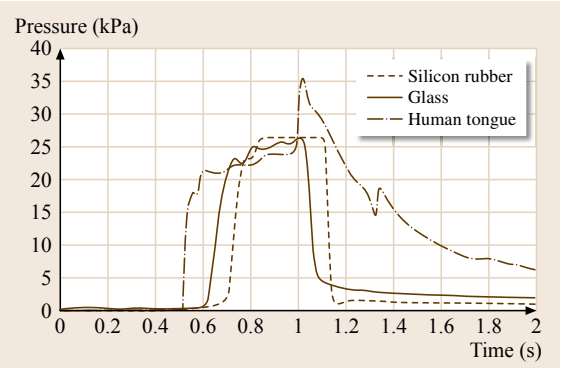

Fig. 14.3 Pressure pattern comparisons between the model mouth and human swallowing (after [14.46])

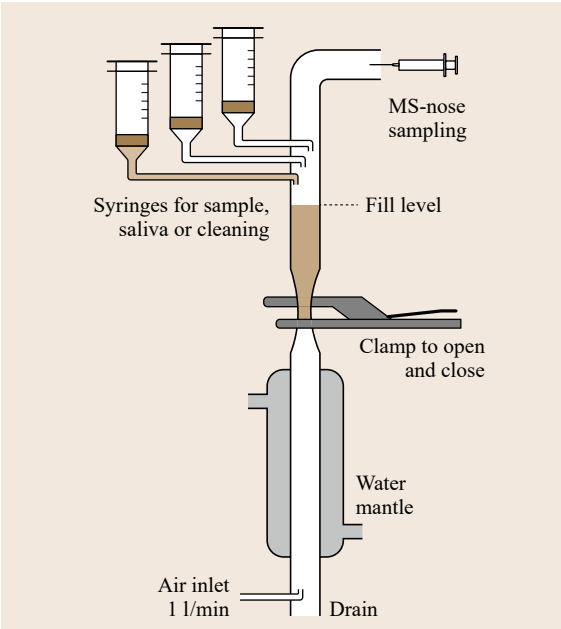

Fig. 14.4 Schematic overview of the artificial throat (after [14.60])

14.2.3 Simulation of the Oral Conditions and Oral Processing

In the section concerning the main oral functions, the high level of complexity within the mouth during oral food processing was explained. Understanding the role of each factor within the mouth and its effect on the release of flavor compounds is nearly impossible. However, a model mouth system has the clear advantage of allowing the analysis of a single parameter. The following oral functions and conditions are discussed in this section: mastication, mixing with saliva, temperature and airflow.

The mastication of solid and liquid food using the teeth and tongue has been investigated using several model mouths. One of the earlier models of *van Ruth* and *Buhr* [14.61] was applied to masticating rehydrated diced bell peppers using a plunger to make up and down screw-like movements. The intensity of the VOCs in the headspace was higher after mastication compared to that of nonmasticated material, which emphasizes the effect of the exposure of new surface areas and the efficacy of mixing food with saliva. The increased release of VOCs after mastication was also strongly perceived by assessors in terms of the odor intensity. The role of mastication for different types of foods was demonstrated using a more advanced mouth model [14.62]. The chewing efficiency of this device greatly resembled that of the panelists according to the size distribution of peanut particles that were produced at different force intensities and masticatory frequencies. The combined effect of similar mandibular, tongue and teeth shearing forces, shear angles and oral dimensions were found to be the key elements for a suitable model to simulate solid-food mastication. The structure and composition of the food affect the pattern of VOC release. This effect was clearly observed using the model mouth system. Using this device, significant differences in the release of VOCs from chewing gum compared to olives were reported.

The effect of mastication on liquid foods was studied using different mouth models [14.61, 63]. Similar to the case with solid foods, mastication generally enhances the release of volatile compounds from liquids. The turbulence from mixing and the changes in the extent of the interfacial surface area facilitate the diffusion of the VOCs into the headspace. The gas–liquid interface was increased two-fold by increasing the stirring rate from 100 to 400 rpm, which corresponded to a three-fold increase in the released VOCs [14.42]. The effects of tongue pressure and mastication on the release of VOCs in the mouth are very difficult to evaluate. However, a recently developed model mouth with an artificial tongue provides useful knowledge on the possible effects of the human tongue [14.46]. The authors applied a range of actual tongue intraoral pressures for various periods while monitoring the released VOCs online using a proton transfer reaction mass spectrometer. The findings validated the results regarding the enhanced VOC release after the mastication of solid and liquid foods. The tongue was found to create more turbulence in the liquid and more changes to the interfacial surface area when it remained in the liquid longer. The effect of the tongue on VOC release was observed as a clear peak after each masticatory cycle, following a different pattern according to the physicochemical properties of the VOC (Fig. 14.5). The location of the tongue in relation to the liquid and its direction of movement also affected the release of volatile compounds due to possible changes in the diffusion of VOCs from the liquid to the interface and then into the headspace (Fig. 14.6). The tongue is covered by a thin layer of liquid after mastication, which supports the release of more VOCs.

Finding that the composition and flow of saliva affected the release of volatiles in the mouth raised questions as to the extent of the impacts and the underlying mechanisms. Once again, the model mouth can be a suitable system in which to isolate the saliva parameter in food processing. Most of the model mouth systems use artificial saliva containing the major minerals (sodium, chloride, calcium, potassium and phosphate), proteins (mucin) and enzymes (e.g., amylase and lipase). The final composition should be close to that of human saliva and should have similar physical properties, such as the viscosity, pH and ionic strength.

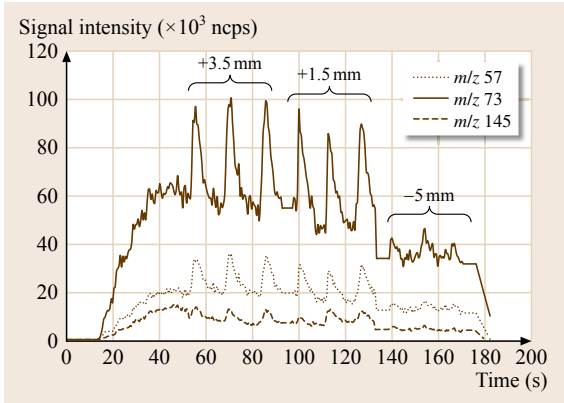

Fig. 14.5 Release curves for three volatile organic compounds (1-butanol (m/z 57), ethyl butyrate (m/z 89) and ethyl hexanoate (m/z 145)) masticated by the tongue in downward direction and different initial tongue positions from the aqueous solution surface (plus position relates to above the surface and minus position to below the surface) (after [14.64])

Among the effects of saliva on VOC release that are found in the model mouth are the dilution effect, interactions with salivary proteins and enzymes and to some extent, the possibility of *salting-out* [14.40, 65, 66]. For example, the effect of the amylase in saliva on VOC release is demonstrated by the higher odor intensity when the food contains starch. The degradation of starch by amylase leads to the release of volatile compounds that were trapped in the food complex, regardless of whether the amylase is human or porcine. VOCs are not equally affected by the presence of saliva; the effect depends on the polarity of the compound. Hydrophobic VOCs can be retained by interactions with proteins and hydrophilic VOCs can be retained by being diluted in a liquid system. An interesting finding was obtained when artificial saliva was compared to human saliva using the dynamic model mouth system with a flavored liquid sample [14.64]. These two types of saliva showed similar VOC release patterns, which supported the usage of artificial saliva as a proper alternative to human saliva. However, when saliva was replaced with water or artificial saliva lacking mucin, the extent of VOC release was higher. The authors attributed the increase in the extent of VOC release to the lower viscosities of the mixtures lacking the mucin that was present in the other types of saliva. The more viscous samples tended to adhere better to the tongue and the glass of the chamber, forming new surfaces that were exposed to the headspace. The salivary flow rate into the model chamber can be controlled at various rates to simulate a large variety of flows due to individual differences and the types of food. Consequently, the change in the flow rate corresponds mainly to the dilution effect of the sample.

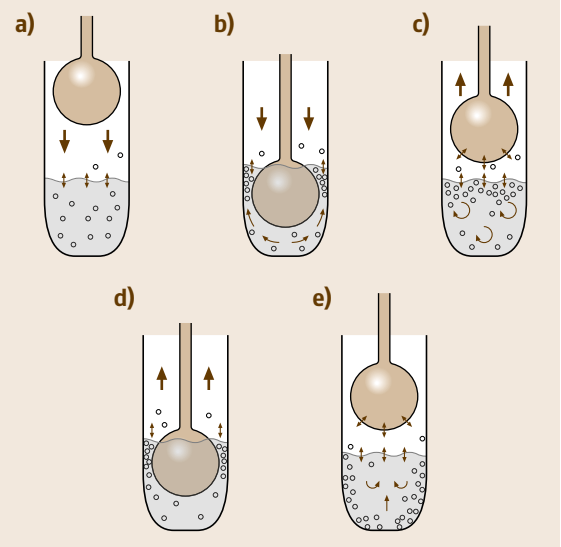

Fig. 14.6 Schematic illustrations of the artificial tongue masticating the sample at forward **(a–c)** and backward **(d–e)** movement directions (after [14.64])

The transfer of VOCs from the food to the oral and nasal cavities also depends on the respiratory rate of the lungs and the timing of the opening of the velum. To mimic the real situation of airflow, the model mouth design should consider the displacement of the volume of air in the headspace with a new supplement of air after each swallowing event, or in the case of solid food, with small volumes of air during the masticatory process. Most models used a continuous flow rate to simplify the experiment while ignoring the high level of complexity in oral physiology concerning the airflow. The model mouth designed by *Rabe* and collaborators [14.42] is most likely the one that most closely simulated the normal airflow patterns. In this model, the airflow is controlled by valves that introduce air at certain time points in correlation with the stirring and saliva-flow activities. Increasing the rate of airflow resulted in a higher flavor intensity due to the enrichment of the VOC content in the headspace. The effect of the airflow is highly dependent on the headspace volume. In the case of a large headspace volume, the enrichment process is slow when the air exchange occurs too rapidly relative to the rate of the mass transfer of VOCs.

The oral temperature is another important parameter that affects the release of VOCs. The rapid change in the temperature of a food sample once it was introduced into the mouth was measured in a model mouth system using a thermocouple sensor that was within the chamber [14.64]. In less than 70 and 100 s, oil- and water-based samples, respectively, reached body temperature (Fig. 14.7). The relationship between the temperature (T) and the partition coefficient (K) of VOCs can be described by the following equation

$$\frac{\mathrm{d}\ln K}{\mathrm{d}T} = \frac{\Delta H^\circ}{RT^2}\,, \tag{14.1}$$

where ΔH° (kJ/mol) is the enthalpy of vaporisation of the VOCs and R is the universal gas constant. The higher the temperature becomes, the more volatile compounds are released into the headspace due to the lower ΔH°. The change in the temperature of the sample that occurs during oral processing also affects the solubility of the VOCs. Large hydrophobic VOCs were found to be less soluble at cool temperatures than were hydrophilic compounds that interacted with water through hydrogen bonds [14.64]. Moreover, the viscosity of the medium is temperature-dependent, which is more pronounced in oily systems. The viscosity of oil decreases five-fold from 60 to 4 °C, which affects the molecular and eddy diffusion of the VOCs.

Another oral phenomenon that is difficult to mimic in in vitro devices is the mucosa covering the oral surface. The artificial devices reported to date are composed of metal, glass or chemical polymers that do not confer the same mechanical, biochemical and physicochemical properties as the human mucosa. The dissimilarities have many consequences at different levels. The structure of the oral mucosa in different regions of the mouth varies considerably and consequently, the water-absorptive capacity varies according to the mouth region. The thickness of the salivary film varies in different regions of the mouth, depending on the proximity of the minor and major salivary glands. The salivary pellicle is a film that coats the oral surfaces and functions as a moisture retainer, a protective barrier, a lubricant and a determinant for microbial colonization. The pellicle is a multilayered film that is initially formed by the selective adsorption of salivary molecules to oral surfaces, followed by homo- or heterotypic complexing of these molecules with other molecules in the ambient saliva. The salivary components that adsorb to the oral mucosal epithelial cells comprise the mucosal pellicle. The forces that mediate the interactions between the salivary molecules and the epithelial cell surface most likely include noncovalent interactions involving electrostatic and hydrophobic forces. The oral mucosal pellicle that is formed by the selective adsorption of saliva to the epithelial cell plasma membrane cannot be closely reproduced in the in vitro surfaces but has many effects on the partitioning of the volatile and nonvolatile stimulatory compounds within different phases of the residence within the oral cavity and on the food-breakdown mechanisms involved in oral processing, such as tribological factors, resistance to breakdown and the deformation of the bolus. Therefore, the artificial saliva formulation is important in properly reproducing the oral phenomena through in vitro processes.

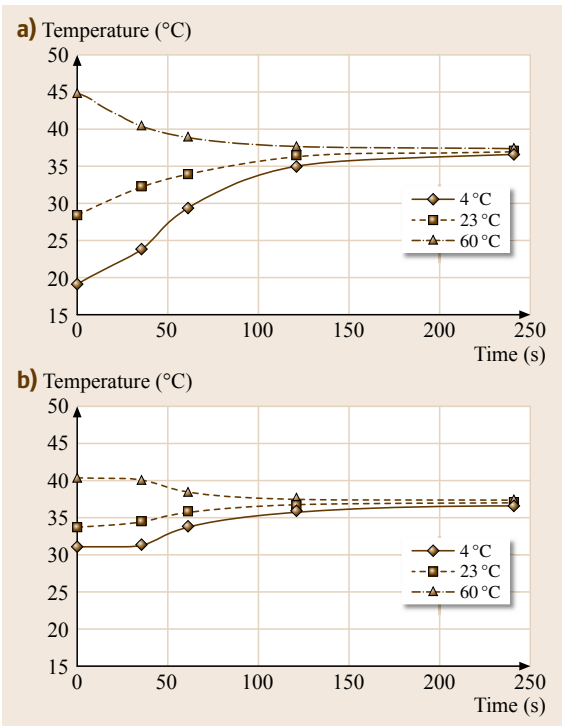

Fig. 14.7 Temperature curves in the model mouth of **(a)** aqueous solution and **(b)** oil samples versus mastication time period. The sample temperature was 4, 23 and 60 °C (after [14.64])

However, exactly reproducing human saliva is particularly difficult because of the high level of complexity of this biological fluid, its unstable character, its interindividual variability and the high cost of human salivary ingredients. The previous observations showed the importance of the physical properties of saliva in oral processes. The properties and composition of saliva are subject to significant subject variability, which is difficult to mimic using artificial solutions. Artificial saliva formulations that satisfy the viscosity requirement for the use in a masticator apparatus designed to prepare food boluses have been proposed [14.67]. The properties and composition of saliva also affect the in-mouth release of volatile compounds, which is another reason that a relevant formulation of artificial saliva is important. This statement is supported by various examples. The significant differences in the volatility of compounds that occurred when artificial saliva or water was added indicated that the saliva replacement was inadequate for studies of volatile compound release [14.68]. The salivary components differentially interact with the volatile compounds according to their physicochemical properties, leading to changes in their volatility [14.28]. The enzymatic activities of saliva can modify the composition of the released volatile compounds [14.29–31].

The human sensory system can be mimicked by electronic systems that are coupled to the mouth simulator for the detection and quantification of the released compounds. A connection to an API-MS or PTR-MS device allows the online recording of the real-time release of volatile compounds during the artificial chewing of food [14.61, 69]. However, the limitation of such detection systems is the level of sensitivity because the human olfactory system is much more sensitive and detects active odorants at concentrations at which no electronic system can detect them. There are very few reports concerning the in vitro detection of the release of nonvolatile taste compounds during oral processing. Simple sensor systems, such as pH, conductivity

and sodium probes, or more complex sensor systems, such as electronic tongues, can be implemented in artificial mouth devices. Electronic tongues [14.70], which are considered artificial gustatory sensors, consist of sensor arrays and pattern-recognition systems. These systems generally aim to discriminate and analyze food and beverages [14.71, 72], but they generally need a large volume of liquid sample, are limited in sensitivity and the obtained results are poorly correlated with the taste attributes described and rated by a sensory panel because they consist only of the simultaneous measurements of chemical components by sensor-array systems. More recently, cell-based sensors have been developed, which have some advantages, such as fast response, excellent selectivity, high sensitivity [14.48], and the ability to respond specifically to compounds of a given basic taste. The use of such sensors coupled with a mouth-simulator device appears to be a promising way to mimic taste perception.

14.2.4 Model Mouth Applications

Model mouth systems have a wide range of applications in the fields of food science, nutrition, pharmacology and medicine. The following are a few examples of their applications in completed studies and future possibilities for their use:

1. Characterizing the release of VOCs from food samples according to composition. For example, the strong retention of hydrophobic VOCs in emulsions and oil-based systems was easily discerned using the model mouth [14.64].
2. Differentiating between food products as a function of the pattern of flavor release in the mouth. The release of aromas from red and white wines was compared under oral conditions using artificial saliva and a model mouth system [14.31].
3. Performing release-pattern assessments of different VOCs from food matrices during oral processing using a model mouth system.
4. Investigating oral food-processing behavior of food systems such as emulsions. Its ability to apply several oral parameters simultaneously while monitoring the release of flavor makes the model mouth a powerful research tool. For example, the model mouth can be used to gain more knowledge on the food-structure/flavor-release relationship [14.73]. This relationship was examined in two types of emulsion systems: primary and multilayered emulsions. The stability of the primary emulsion was more affected by changes in pH and saliva composition (e.g., the content of mucin) than was that of the multilayered emulsion, which also exhibited enhanced VOC release (Fig. 14.8). A multilayered emulsion consisting of two layers of pectin and β-lactoglobulin tended to better resist oil-droplet flocculation during consumption.
5. Comparing flavor release in in vitro experiments using the model mouth and in in vivo trials using participants. The results of such research can be used to evaluate the accuracy of the model mouth and to improve the elements that differ significantly [14.74].
6. The model mouth can be utilised in applications other than flavor release, such as taste analysis, salt-diffusion measurements and food-texture optimisation.
7. The model mouth can be used as a predictive tool. The oral parameters can be decoupled because each parameter is individually controlled. The model mouth could also be useful in testing mathematical models based on in vivo-acquired data.

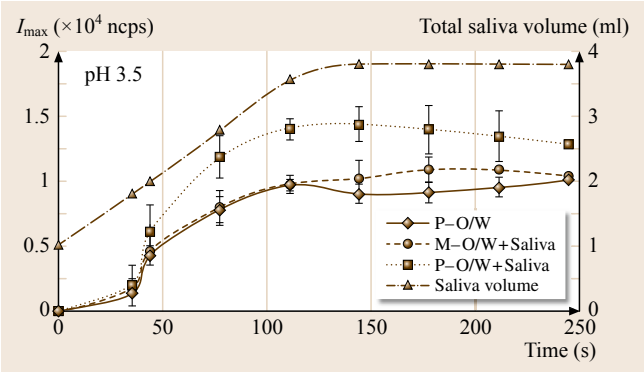

Fig. 14.8 The maximum signal intensity after mastication (I_{max}) of ethyl hexanoate from multilayer oil-in-water (M-O/W) emulsions at pH 3.5 as a function of saliva addition (after [14.73])

14.3 Conclusions

This chapter described an important tool for investigations of the oral processing of food. Using a model mouth system provides the researcher with control over different parameters that affect this complex process while investigating their impact on olfactory perception. The chapter includes a short background on the main oral functions and their influence on the release of VOCs. The history of model mouth devices and the

recent improvements are considered in the chapter, together with details on certain oral functions that can be simulated by these models. Lastly, the applications of the model mouth in the field of food science are mentioned. Without doubt, research will be conducted in the future using such systems to improve the fundamental understanding of olfactory perception, the development of food products and quality assurance.

15. Regulatory Oversight and Safety Assessment of Flavorings

Karl-Heinz Engel

This chapter serves as an example of governmental regulatory oversight and safety assessment of flavorings. In the European Union (EU), the regulatory framework for the use of flavorings in and on foods is provided by Regulation (EC) No 1334/2008. The Regulation provides for three basic regulatory tools: (i) a Union list of flavorings and source materials approved for use in and on foods, (ii) conditions of use of flavorings and food ingredients with flavoring properties in and on foods, and (iii) rules on the labeling of flavorings. The safety evaluation of flavoring substances has been performed using a group-based approach. The procedure is based on a decision tree that considers information on structure–activity relationships, metabolism, intake, and toxicity.

15.1 Regulatory Framework

In the European Union (EU), the regulatory framework for the use of flavorings in and on foods is provided by Regulation (EC) No 1334/2008 of the European Parliament and of the Council of December 16th, 2008 [15.1]. This Regulation repealed Council Directive 88/388/EEC of 22 June 1988 on the approximation of the laws of the Member States relating to flavorings for use in foodstuffs and to source materials for their production [15.2] and Commission Directive 91/71/EEC of 16 January 1991 laying down rules for labeling of flavorings [15.3]. The Regulation applies to flavorings, food ingredients with flavoring properties, to food-containing flavorings and/or food ingredients with flavoring properties, and to source materials for flavorings and/or source materials for food ingredients with flavoring properties.

A flavoring or any food in which such a flavoring and/or food ingredients with flavoring properties are present, must not be placed on the market if their use does not comply with this Regulation. Flavorings or food ingredients with flavoring properties to be used in or on food must meet the following general conditions: (i) They do not, on the basis of the available scientific evidence, pose a safety risk to the health of the consumer, and (ii) their use does not mislead the consumer.

The Regulation provides for three basic regulatory tools:

- A Union list of flavorings and source materials approved for use in and on foods.
- Conditions of use of flavorings and food ingredients with flavoring properties in and on foods.
- Rules on the labeling of flavorings.

15.1.1 Categories of Flavorings

Flavorings are products not intended to be consumed as such, which are added to food in order to impart or

modify odor and/or taste; they comprise the following categories:

- Flavoring substances: defined chemical substances with flavoring properties
- Flavoring preparations: products, other than flavoring substances, obtained from food by appropriate physical, enzymatic or microbiological processes either in the raw state of the material or after processing for human consumption by one or more of the traditional food preparation processes listed in Annex II of Regulation (EC) No 1334/2008 [15.1] and/or obtained from material of vegetable, animal, or microbiological origin, other than food, by appropriate physical, enzymatic, or microbiological processes, the material being taken as such or prepared by one or more of the traditional food preparation processes listed in Annex II of Regulation (EC) No 1334/2008 [15.1].
- Thermal process flavorings: products obtained after heat treatment from a mixture of ingredients not necessarily having flavoring properties themselves, of which at least one contains nitrogen (amino) and another is a reducing sugar; the ingredients for the production of thermal process flavorings may be food and/or source material other than food.
- Smoke flavorings: products obtained by fractionation and purification of a condensed smoke yielding primary smoke condensates, primary tar fractions, and/or derived smoke flavorings as defined in Regulation (EC) No 2056/2003 [15.4].
- Flavor precursors: products, not necessarily having flavor properties themselves, intentionally added to food for the sole purpose of producing flavor by breaking down or reacting with other components during food processing; they may be obtained from food and/or source material other than food.
- Other flavorings: flavorings that do not fall under one of the abovementioned definitions; an example is the so-called *rum ether*.

15.1.2 Establishment of a Union list

One of the basic differences between Regulation (EC) No 1334/2008 [15.1] and the former Directive Council Directive 88/388/EEC [15.2] is the fact that flavoring substances may only be placed on the market and used in or on foods if they are included in the so-called Union list; a list of flavoring substances that are authorized to the exclusion of all others. The procedure to establish such a list had been laid down in Regulation (EC) No 2232/96 of the European Parliament and of the Council of October 28, 1996 [15.5]. Member States were requested to notify to the Commission a list of flavoring substances which at that time were legally accepted on their territory. The resulting register of about 2800 substances notified by the Member States was adopted by Commission Decision (1999/217/EC) of February 23, 1999 [15.6]. The measures for the evaluation program were laid down by Commission Regulation (EC) No 1565/2000 of 18 July 2000 [15.7]. In the light of the large number of substances in the register, it was decided to make use of already existing safety assessments. Flavoring substances that had been considered as being safe at the current levels of intake either by the Scientific Committee on Food of the European Commission (SCF), the Experts on Flavoring Substances of the Council of Europe (CEFS) or by the Joint FAO/WHO Expert Committee on Food Additives (JECFA) before 2000 did not need to be re-evaluated. Flavoring substances classified after 2000 by JECFA as presenting no safety concern at the current level of intake had to be considered by the SCF (subsequently replaced by the European Food Safety Authority (EFSA)); on the basis of these considerations it was decided whether the outcome of the performed safety evaluations was acceptable or whether further evaluation is necessary. The remaining flavoring substances had to be evaluated by the SCF or the EFSA; the principles underlying the employed safety assessment procedure are outlined in detail in Sect. 15.2. The Union list of flavoring substances has finally been adopted by Commission Implementing Regulation (EU) No 872/2012 of October 1, 2012 [15.8] and introduced in Annex I of Regulation (EC) no 1334/2008 [15.1].

15.1.3 Specific Conditions of Use for Flavorings and Food Ingredients with Flavoring Properties

In addition to a *positive list* containing flavoring substances authorized to the exclusion of all others, the Regulation 1334/2008 [15.1] also provides for *negative lists*. These contain flavoring substances or flavoring source materials which shall not be used as such or set specific conditions for the use of flavorings and food ingredients with flavoring properties.

The CEFS has evaluated flavoring source materials since 1970 and identified a number of substances occurring naturally in flavorings and food ingredients with flavoring properties that may raise safety concerns [15.9]. Since 1999, the SCF and later the EFSA have expressed opinions on these substances. Substances for which the toxicological concern raised by the CEFS was confirmed are regarded as undesirable substances. These substances shall not be added as such

Table 15.1 Substances that shall not be added as such to food (after [15.1])

Agaric acid	Menthofuran
Aloin	4-Allyl-1,2-dimethoxybenzene (methyleugenol)
Capsaicin	Pulegone
1,2-Benzopyrone (coumarin)	Quassin
Hypericine	1-Allyl-3,4-methylene dioxy benzene (safrole)
β-Asarone	Teucrin A
1-Allyl-4-methoxybenzene (estragol)	Thujone (alpha and beta)
Hydrocyanic acid	

Table 15.2 Examples of maximum levels of undesirable substances in certain foods

Name of the substance	Compound food in which the presence of the substance is restricted	Maximum level (mg/kg)
Estragol[a]	Dairy products	50
	Processed fruits, vegetables, nuts, seeds	50
	Fish products	50
	Nonalcoholic beverages	10
Methyleugenol[a]	Dairy products	20
	Meat preparations and meat products	15
	Fish preparations and fish products	10
	Soups and sauces	60
	Ready-to-eat savories	20
	Nonalcoholic beverages	1
Pulegone	Mint/peppermint-containing confectionery	250
	Micro breath freshening confectionery	2500
	Chewing gum	350
	Beverages:	
	Mint/peppermint-containing nonalcoholic	20
	Mint/peppermint-containing alcoholic	100
Coumarin	Traditional and/or seasonal bakery ware containing a reference to cinnamon in the labeling	50
	Breakfast cereals including muesli	20
	Fine bakery ware, with the exception of traditional and/or seasonal bakery ware containing a reference to cinnamon in the labeling	15
	Desserts	5

[a] The maximum levels shall not apply where a compound food contains no added flavorings and the only food ingredients with flavoring properties which have been added are fresh, dried, or frozen herbs and spices. After consultation with the Member States and the Authority, based on data made available by the Member States and on the newest scientific information, and taking into account the use of herbs and spices and natural flavoring preparations, the Commission, if appropriate, proposes amendments to this derogation.

to food and are listed in Annex III, Part A of Regulation 1334/2008 [15.1] (Table 15.1).

Undesirable substances may be present in flavoring preparations and food ingredients with flavoring properties, which are traditionally used as foods or food ingredients. Maximum levels have been established for the presence of these undesirable substances in those foods, which contribute most to the human intake of these substances. They are listed in Annex III, Part B of Regulation 1334/2008 [15.1]. Table 15.2 shows examples in terms of the compound foods in which the presence of the substance is restricted and the respective maximum levels.

Source materials that shall not be used for the production of flavorings and food ingredients with flavoring properties are listed in Annex IV, Part A of Regulation 1334/2008 [15.1]. At present, only one source material is listed: tetraploid form of *Acorus calamus* L.

For flavorings and food ingredients with flavoring properties produced from certain source materials, conditions of use have been established in Annex IV, Part B of Regulation 1334/2008 [15.1]. For example, flavorings and food ingredients with flavoring properties produced from St. John's wort (*Hypericum perforatum* L.) may only be used for the production of alcoholic beverages.

15.1.4 Rules on the Labeling of Flavorings

Regulation 1334/2008 [15.1] does not differentiate between *nature-identical* flavoring substances (i. e., those obtained by chemical synthesis or isolated by chemical processes and chemically identical to a substance naturally present in material of vegetable or animal origin) and *artificial* flavoring substances (those obtained by chemical synthesis but not chemically identical to a substance naturally present in material of vegetable or animal origin) as previously defined in Council Directive 88/388/EEC [15.2].

There are, however, specific requirements for the use of the term *natural*:

- *Natural flavoring substance* means a flavoring substance obtained by appropriate physical, enzymatic, or microbiological processes from material of vegetable, animal, or microbiological origin either in the raw state or after processing for human consumption by one or more of the traditional food preparation processes listed in Annex II of the Regulation (Table 15.3). Natural flavoring substances correspond to substances that are naturally present and have been identified in nature.
- The term *natural* for the description of a flavoring may only be used if the flavoring component comprises only flavoring preparations and/or natural flavoring substances.
- The term *natural flavoring substance(s)* may only be used for flavorings in which the flavoring component contains exclusively natural flavoring substances.
- The term *natural* may only be used in combination with a reference to a food, food category, or a vegetable or animal flavoring source if the flavoring component has been obtained exclusively or by at least 95% by w/w from the source material referred to.
- The term *natural* food(s) or food category or source(s) *flavoring with other natural flavorings* may only be used if the flavoring component is partially derived from the source material referred to, the flavor of which can be easily recognized.
- The term *natural flavoring* may only be used if the flavoring component is derived from different source materials and where a reference to the source materials would not reflect their flavor or taste.

Table 15.3 List of traditional food preparation processes (after [15.1])

Baking	Grinding
Chopping	Heating
Coating	Infusion
Cooking	Maceration
Cooling	Microbiological processes
Cutting	Mixing
Distillation/Rectification	Peeling
Drying	Percolation
Emulsification	Pressing
Evaporation	Pressure cooking[c]
Extraction[a]	Refrigeration/Freezing
Fermentation	Roasting/Grilling
Filtration	Squeezing
Frying[b]	Steeping

[a] Including solvent extraction in accordance with Directive 88/344/EEC
[b] Up to 240 °C at atmospheric pressure
[c] Up to 120 °C

15.2 Safety Assessment Procedures

15.2.1 Evaluation of Flavoring Substances Included in the Union List

The measures for the adoption of an evaluation program were laid down in Commission Regulation No 1565/2000 [15.7]. In order to make the evaluation process as efficient as possible, a group-based approach should be followed. The flavoring substances contained in the register were divided into 34 structurally related chemical groups; substances within a group are considered to have some common metabolic and biological behaviors. The following information had to be provided:

- Purity and chemical specification
- Natural occurrence in foods
- Total amount of the substance that is added to foods in the EU
- Normal and maximum use levels of the substance in defined food categories, if available
- All relevant toxicological and metabolic studies on the substance or closely related substances.

The principles of the evaluation were based on an opinion expressed by the SCF on December 2, 1999 [15.10]. The SCF considered a procedure developed by JECFA at the 44th meeting [15.11] and

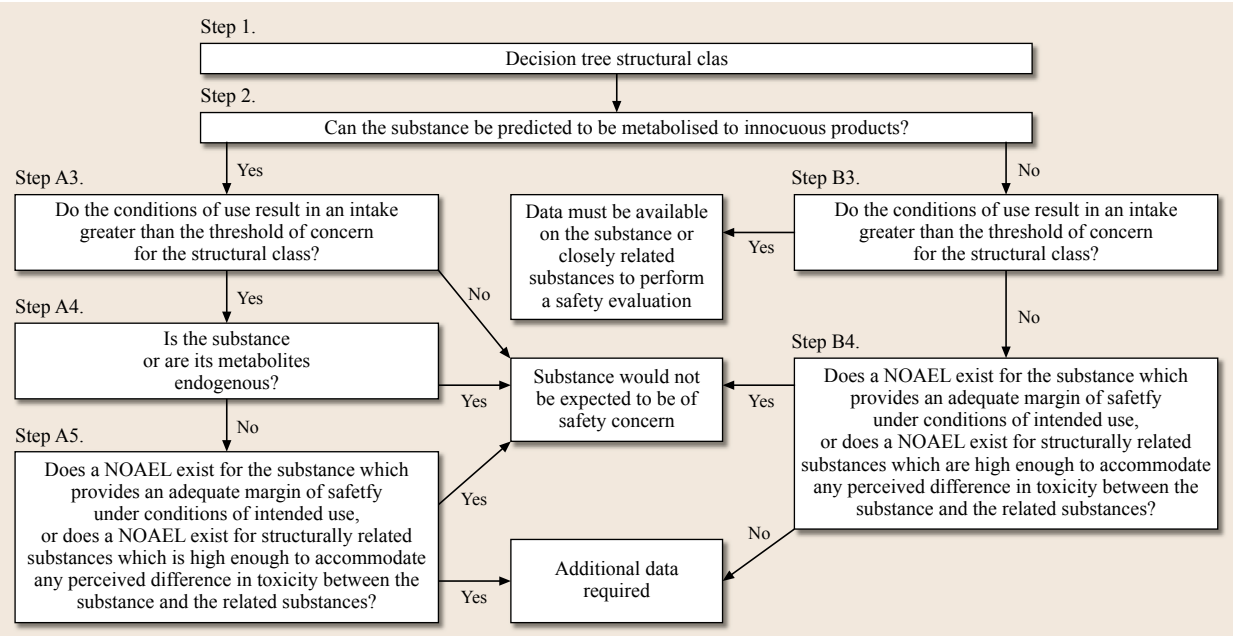

Fig. 15.1 Procedure for safety evaluation of chemically defined flavoring substances (NOAEL: no observed adverse effect level)

subsequently applied in an adjusted version to the evaluation of a large group of chemically defined flavoring substances [15.12–14] as the most updated and systematic approach. The procedure is based on a stepwise decision-tree approach that considers information on structure–activity relationships, metabolism, intake, and toxicity (Fig. 15.1).

The first step is the assignment of a flavoring substance to one of three classes (I, II, III) for which thresholds of concern (human exposure thresholds) have been specified. Class I contains flavoring substances that have simple chemical structures and efficient modes of metabolism, which would suggest a low order of oral toxicity. Class II contains substances with structural features that are less innocuous, but are not suggestive of toxicity. Class III includes flavoring substances with structural features that permit no strong initial presumption of safety, or may even suggest significant toxicity [15.15]. The thresholds of concern for these structural classes (1800, 540, and 90 $\mu g/(person\,day)$, respectively) are derived from a large dataset derived from subchronic and chronic animal studies. They were calculated using a 100-fold safety factor from the 5-th centile of either the no-observed-effect-levels (NOELs) from chronic studies or of one-third of the NOELs from subchronic studies [15.12, 16].

The next steps in the decision tree address the following questions:

- Can the flavoring substance be predicted to be metabolized to innocuous products?
- Do the conditions of use result in an intake greater than the threshold of toxicological concern for the structural class?
- Is the flavoring substance or are its metabolites endogenous?
- Does a no-observed-adverse-effect level (NOAEL) exist for the flavoring substance or structurally related substances, which provides an adequate margin of safety under the conditions of intended use?

The decision tree shown in Fig. 15.1 corresponds to the decision tree as applied by JECFA [15.12–14], except that the option to accept flavoring substances with the only argument that their estimated intake is lower than the threshold of concern of 1.5 $\mu g/(person\,day)$ was not adopted by the SCF [15.10]. In addition, the SCF also emphasized that flavoring substances should be examined for structural alerts of potential genotoxicity.

The intake assessment plays an important role in the application of the Procedure. As a default, the so-called *maximized survey-derived daily intake* (MSDI) approach, which is based on annual production volumes, was used [15.17]. However, when the EFSA Panel examined the information provided by the European Flavor Industry on the use levels of flavoring substances in various food categories, it became ob-

vious that the MSDI approach in a number of cases would grossly underestimate the intake by regular consumers of products flavored at the use levels reported by the Industry. Therefore, the intakes were also estimated using the *modified theoretical added maximum daily intake* (mTAMDI) approach, which is based on normal use levels reported by Industry and consumption data for certain food categories [15.17]. The mTAMDI value was not considered in the Procedure but was only used as tool to prioritize the flavoring substances according to the need for a refined intake screen and the request for more precise data.

The flavoring substances have been assessed in so-called flavoring group evaluations (FGE). The following types of conclusions can be found:

- Based on the default MSDI approach, the candidate substance, which was evaluated through the Procedure, would not give rise to safety concern at the estimated level of intake arising from the use as flavoring substance.
- Based on the mTAMDI approach, the estimated intake of a flavoring substance is above the threshold of concern for the respective structural class. In this case, more reliable exposure data are required. On the basis of such additional data, the flavoring substance should be re-evaluated using the Procedure; subsequently, additional toxicological data might become necessary.
- Additional toxicological data are required.
- Additional specification data, for example, regarding geometrical and/or optical isomers, are required.

Substances shown to be genotoxic in vitro and in vivo are toxicologically not acceptable and were deleted from the register; an example is pentane-2,4-dione [15.18, 19]. For substances shown to be genotoxic in vitro, further in vivo genotoxicity data are required.

The α,β-unsaturated aldehyde and ketone structures are considered as structural alerts for genotoxicity. The EFSA Panel noted that there were limited genotoxicity data on these flavoring substances but that positive genotoxicity studies were identified for some substances in the group. Flavoring Group Evaluation 19 (FGE.19) contains 360 flavorings substances from the EU register being α,β-unsaturated aldehydes or ketones and precursors, which could give rise to such carbonyl substances via hydrolysis and/or oxidation [15.20]. These substances were divided into structurally related subgroups, representative substances were selected, and the Flavoring Industry has to provide additional genotoxicity data. If on the basis of these data, a genotoxic potential can be ruled out, the substances are merged with structurally related substances in other FGEs and evaluated using the Procedure.

Guidance documents, such as a scientific opinion on genotoxicity testing strategies applicable to food and feed safety assessment [15.21] and genotoxicity test strategies for substances belonging to FGE.19 [15.22], and a scientific report regarding minimum criteria for the acceptance of in vivo alkaline Comet Assay reports [15.23] are available.

15.2.2 Evaluation of Newly Submitted Flavoring Substances

The established Union list is open-ended and capable of being amended in the light of scientific and technical developments. The European Commission has requested EFSA to elaborate a guidance document for the risk assessment of flavorings newly submitted after the adoption of the Union list [15.24]. The EFSA Panel considered that the data required for the risk assessment of new flavorings should build upon the experience gained in the course of the evaluation of flavoring substances included in the Union list. Therefore, a general principle of this guidance is that flavorings which can be assigned to one of the existing flavoring group evaluations (FGEs) on the basis of structural and metabolic similarities should be evaluated according to the scientific principles and to the group-based approach underlying the former evaluation program (Fig. 15.2).

In addition, the guidance provides a procedure for the evaluation of flavoring substances that cannot be assigned to one of the existing FGEs. The scheme outlined in Fig. 15.3 shows that the type of data required depends on the following:

- Whether there are experimental data available for the substance to demonstrate that the metabolites can be considered innocuous, and

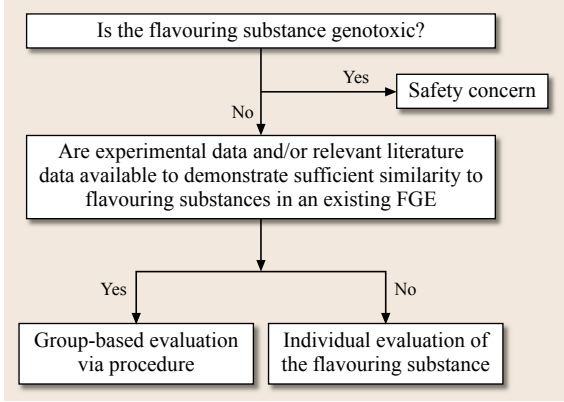

Fig. 15.2 Overall strategy for the risk assessment of flavoring substances

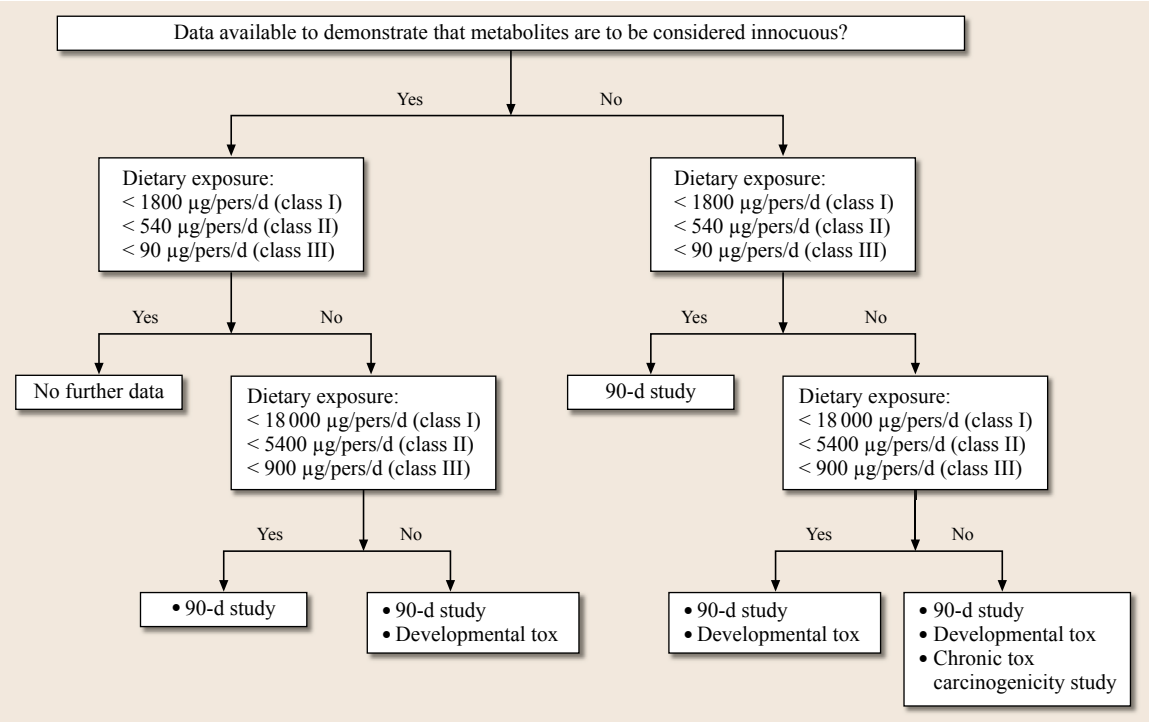

Fig. 15.3 Individual evaluation of the flavoring substance

- Whether the chronic dietary exposure, based on added use levels, is below or above the threshold of concern of the structural class to which the flavoring substance belongs.

The dietary exposure assessment plays an important role in the guidance document. The applicant needs to provide:

- Normal and maximum occurrence levels as added flavoring substance
- Normal and maximum occurrence levels of the substance from other sources, e.g., as natural constituent, as substance developed through the processing of foods, as carry-over originating from their use in animal feed or as residues of packagings
- Normal and maximum combined occurrence levels of the substance, taking into account all sources.

In addition, the applicant needs to indicate the non-food uses of the flavoring substance.

For the assessment of dietary exposure, a new approach called *added portions exposure technique* (APET) has been introduced [15.24]. The APET is calculated based on the occurrence levels provided by the applicant in a list of food categories and subcategories corresponding to the CODEX General Standard for Food Additives [15.25] used by JECFA to develop the SPET technique [15.26]. The APET is calculated by summing the highest potential dietary exposure within each of the two groups (*Beverages* and *Solid foods*). Such an estimate, based on daily consumption of one single standard portion of beverage and one single portion of solid food, is likely to provide a conservative assessment of long-term average dietary exposure for consumers of flavored products. The APET is expressed in mg/kg bw per day. For an adult, a body weight of 60 kg is considered and the portions are those established by the JECFA when developing the SPET technique (FAO/WHO, 2008). A case study on the use of the APET technique to estimate total dietary exposure to flavoring substances has been provided [15.27].

15.3 Flavorings Other than Flavoring Substances

In addition to flavoring substances, Article 9 of Regulation (EC) No 1334/2008 of the European Parliament specifies the following categories of flavorings for which an evaluation and approval are required:

- Flavoring preparations obtained from material of vegetable, animal, or microbiological origin, other than food.
- Thermal process flavorings for which ingredients for their production are source materials other than food and/or for which the conditions of their production and/or the maximum levels of undesirable substances set out in Annex V of Regulation 1334/2008 [15.1] are not met. These conditions are as follows:

  1. The temperature of the products during processing shall not exceed 180 °C.
  2. The duration of the thermal processing shall not exceed 15 min at 180 °C with correspondingly longer times at lower temperatures, i. e., a doubling of the heating time for each decrease of temperature by 10 °C, up to a maximum of 12 h.
  3. The pH during processing should not exceed the value of 8.0.

  The maximum levels for 2-amino-3,4,8-trimethylimidazo [4,5-f] quinoxaline and 2-amino-1-methyl-6-phenylimidazol [4,5-b] pyridine are 50 µg/kg.
- Flavor precursors obtained from source material other than food.
- Other flavorings.

For these categories of flavorings, the respective information that has to be supplied with an application for authorization is described in the EFSA guidance document [15.24].

15.3.1 Smoke Flavorings

For smoke flavorings as defined in Regulation (EC) No 2056/2003 [15.4], also a Union list has been established which contains authorized smoke-flavoring primary products for use as such in or on foods and/or for the production of derived smoke flavorings [15.28]. The specific requirements for the evaluation of smoke flavoring primary products have been compiled in an EFSA guidance document. They comprise data on the manufacturing process, the identity of the primary product, and toxicological data [15.29]. Quality criteria for validated analytical methods for sampling, identification, and characterization of primary smoke products have been laid down in Commission Regulation (EC) No 627/2006 of April 21, 2006 [15.30]. For assessment of the dietary exposure to smoke flavoring primary products specific methods have been developed [15.31]. The safety assessments of eleven smoke-flavoring primary products evaluated by EFSA have been summarized in an overview [15.32].

15.4 Outlook

The implementation of the Union list constitutes a basic change in paradigm regarding the use of flavoring substances in foods in the EU. On the one hand, a list of authorized substances will be helpful because it may increase consumers' confidence and may serve as a reliable platform for the involved stakeholders. On the other hand, it remains to be seen how far innovations and research will be hampered by this new economically relevant hurdle. It will also be interesting to follow which role the regulatory oversight implemented in the EU will play in the light of other internationally applied approaches and whether it will serve as model for regions in which the respective regulatory tools are being developed.

16. Odors in Paper and Cardboard Packaging

Michael Czerny

Packaging materials based on paper are often used for packing foods, for example, flour, spices, rice, noodles and frozen products. Like all materials used for packing, cardboards and papers have to fulfill legal requirements in order to avoid the transfer of undesirable and harmful packaging constituents to foods. These legislations also cover the deterioration in the organoleptic properties of the packed food. Thus, methods and standards have been established in order to evaluate the sensory impact of packaging on foods.

This chapter reviews several human-sensory tests that are often applied for the evaluation of the organoleptic – in particular olfactory – quality of cardboards and papers. The standards enable a fast and reliable detection and characterization of packaging odors, but sources of odors are difficult to identify. Therefore, instrumental–analytical methods like gas chromatography in combination with mass spectrometry (GC/MS) and/or olfactometry (GC/O) are helpful tools for the identification of undesirable odorants. Based on the chemical structures, pathways and precursors, contamination sources can be detected and strategies for reduction or elimination of packaging odor can be developed.

16.1 Paper

16.1.1 History

The native papyrus plant was the first raw material used for manufacturing paper-like sheets by the Egyptians already in 4th century BC. Thin strips of pith from the plant stems were laid crosswise over each other and were then hammered and pressed together. The starch-containing sap that came out of the pith helped to strengthen the structure [16.1]. Paper akin to the paper we know today was first manufactured more than 2000 years ago. The Chinese court official and inventor of this paper was Ts'ai Lun who developed the manufacturing process in 105 AD. He used waste textiles, tree bark, and fishing nets and processed these into a thin, smooth sheet. Up to the middle of the 8th century, this valuable paper manufacturing process was kept secret. Then, a lost Chinese military campaign resulted in the secret passing to the Arab world. Subsequently, other Arab campaigns saw paper-making spread from the East to the West.

In the 13th century, the technology arrived in Europe. The first paper mill in Europe is recorded as being in Valencia (Spain) and the first mill in Germany was built in Nuremberg in 1390 [16.2, 3]. The invention of the paper machine in 1799 allowed the rapidly growing demand for paper to be met and the first paper manufacturers were established [16.1]. Paper is nowadays manufactured from plant fibers by a process of felt formation and gluing. By varying a wide range of parameters during the manufacture, more than 3000 different types of paper can be distinguished. The worldwide production of paper and cardboard amounted to 400 million metric tons in 2012 [16.4]; the regional distribution is displayed in Fig. 16.1.

16.1.2 Industrial Paper Manufacture

Paper manufacturinginvolves several steps and types of mechanical and chemical treatment of wood, the main raw material source. In the chemical process, wood chips are boiled in a solution of sulfur-containing acid or alkali [16.1]. The lignin almost completely dissolves and the fibers readily separate. The result is brown chemical pulp that is used, among other things, for making corrugated board. For paper and cardboard manufacture, the pulp must then be bleached (the second manufacturing step) in order to meet optical requirements (degree of whiteness).

In the mechanical process, mechanical pulp is recovered. The pulping process weakens the lignin and the fibers readily separate [16.1]. The mechanical pulp and chemical pulp are also called primary fibers. Secondary fibers can be recovered from waste paper. This pulp is suspended, purified, and milled. Depending on the type of paper, various amounts of raw materials (primary and secondary fibers) and additives are combined to give the paper improved quality and stability [16.5].

The porridge-like feed has a water content of 99% and is passed to the paper machine where the fiber suspension is drained through a moving screen and forms a layer. This removes a large amount of the water. The resulting paper web has low strength and a residual moisture content of about 80% and is transferred onto an absorbent mat. Press rolls remove water under pressure and the residual moisture is decreased to 60–65%. The paper web is dried in a labyrinth-type, steam-heated drying cylinder. The strength increases and the residual moisture content decreases to 5–8%. If no further finishing is required to improve the surface quality for printing, the paper is smoothed using steel rollers. Finally the paper is rolled up ready for forwarding to industry. Coating with compounds or polymers is applied if a high printing quality of papers is required [16.5].

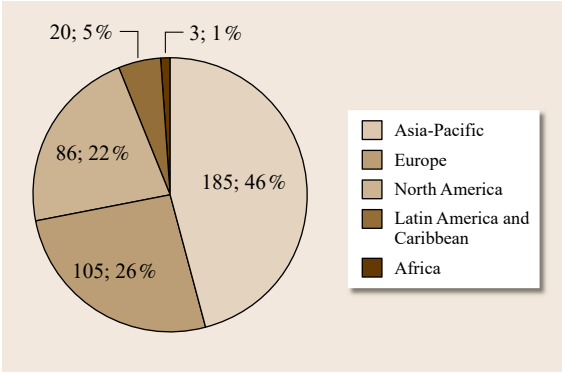

Fig. 16.1 Regional distribution of paper and cardboard production (in million metric tons and percent) in 2012 (after [16.4])

16.1.3 Classification of Paper and Cardboard

Paper is often used as a general term for paper, board and cardboard. Paper and board can be distinguished by their mass per unit area. According to DIN 6730 [16.6], paper has a grammage of $7\,g/m^2$ up to $225\,g/m^2$. Above this value, the material is called board. The term cardboard is not officially defined. However, Ref. [16.7] states that cardboard has a mass per unit area between that of paper and board (Table 16.1). The manufacturing processes for these three materials are, however, essentially based on the same principle [16.5].

Cardboard is widely used as a packaging material. It has considerably greater weight than paper and this gives it greater stiffness and strength. These are key properties when selecting a suitable packaging material.

Cardboard has a multilayer structure but consists of the same materials as paper. The different raw materials (mechanical and chemical pulp) give rise to different types of cardboard designated by letter/number coding as described in DIN 19303 (Table 16.2). The codes have three letters/numbers. The first letter designates the surface coating, the second letter designates the pulp used and the digit at the end designates the color of the reverse side [16.8].

Table 16.1 Classification of paper, cardboard and board according to [16.7]

	Grammage (g/m^2)
Paper	8–150
Cardboard	150–450
Board	> 450

Table 16.2 Codes of cardboard categories (after [16.8])

	Code	Explanation
1. Coating	A	Cast-coated
	G	Pigment-coated
	U	Uncoated
2. Materials	Z	Chemical pulp treatment, bleached
	N	Chemical pulp treatment, unbleached
	C	Mechanical pulp treatment
	T	Cardboard with recycled paper
	D	Cardboard with recycled paper, grey middle, and bottom layer
3. Colour	1	White
	2	Cream-colored
	3	Brown

A typical example of cardboard used by the food industry is GC1 which is a pigment-coated cardboard made of mechanical pulp with a white reverse side. The sole difference between GC1 and GC2 cardboard is the application of color on the reverse side (Table 16.2).

16.2 Legal Basics: Food Legislation

Many different dry foods (e.g., flour, spices, sweets, rice, noodles, and sugar) as well as foods with high fat content (e.g., chocolate, frozen products) are packed in paper or cardboard. These packaging materials might contain compounds which can migrate into the packed food resulting in a contamination of foods with negative effects for the food itself and the human health. In order to protect both foods and consumers from negative impacts, the legislative authorities of several countries established statutory requirements for packaging, paper, and cardboard.

16.2.1 Legislation in Europe

In Europe, there is no legislation specifically covering the use of paper, board, and cardboard. Merely the general suitability of packaging for food is described in Regulation (EC) No 1935/2004 [16.9]. Article 1, Paragraph 2 of this regulation defines materials and objects as materials and objects (. . .) that are finished products, which:

- Are intended to be brought into contact with food or
- Are already in contact with food and were intended for that purpose or
- Can reasonably be expected to be brought into contact with food or transfer their constituents to food under normal or foreseeable conditions of use.

General requirements and interactions between the packaging and food are specified in Article 3, Paragraph 1. Accordingly, materials and objects must be manufactured in compliance with good manufacturing practice such that, under the normal or foreseeable conditions of use, they do not transfer their constituents to foods in quantities which could:

- Endanger human health or
- Bring about an unacceptable change in the composition of food or
- Bring about deterioration in the organoleptic characteristics thereof.

Beside this legislation, Regulation No 10/2011 [16.10], which is a specific measure of Regulation (EC) 1935/2004 [16.9], contains a positive list of monomers and additives which can be used in manufacturing of food packaging.

Even though food legislation in Europe is in the process of being harmonized, it is still necessary to have valid legislation at a national level. Taken Germany as an example for a member country of the EU, the German Food and Feed Code (Lebensmittel- und Futtermittelgesetzbuch, LFGB) covers all stages of food manufacturing processes and focuses on food safety [16.11]. Just like at a European level, German food legislation contains no specific regulations for cardboard packaging for foods. The German Food and Feed Code (Article 30, Paragraph 1) prohibits consumer products to be manufactured or treated in such a way that when used as intended or foreseen, they are harmful to health due to their material composition and in particular due to toxicologically active substances or due to contaminants. Article 31 contains regulations for the migration of substances into foods covering the health risk, the quantity of compound transfer, and the avoidance of negative impact on aroma, taste, and appearance of food resulting from packaging including paper and cardboard. Both Articles are adopted from Regulation (EC) No 1935/2004 (Articles 2 and 3) [16.9].

For materials that are not regulated by Regulations (EC) No 1935/2004 and No 10/2011 there are no statutory regulations in Germany but rather recommendations of the German Institute for Risk Assessment (Bundesinstitut für Risikobewertung, BfR). Recommendation XXXVI covers papers, cardboards, and boards and lists all raw materials for paper production, auxiliary materials and finishing materials that may be used for the manufacture which are not regulated by EU legislation [16.12].

16.2.2 Legislation in US

The Food and Drug Administration (FDA) is responsible for the approval and monitoring of foods in the USA. The FDA regulations on paper and cardboard are given in the Code of Federal Regulations, Title 21 (Food and Drugs) [16.13]. Only general requirements are given in part 174.5 of the title such as good manufacturing practice or the organoleptic inertness of a packaging material.

16.3 Analytical Methods

The legal basics described in Sect. 16.2 demand that paper-based packaging is manufactured such that emitting compounds do not negatively impact – besides health risks – the packed food. In order to evaluate the presence of sensorial-active compounds in paper and cardboards and their transfer to foods, several test methods have been established. In general, two approaches are applied for the detection and description of the organoleptic food characteristics:

i. Human-sensory tests with sensory panels consisting of usually trained assessors which evaluate packaging or packed foods by use of their senses (in particular smell and taste) and
ii. Instrumental–analytical tests that focus on the identification of packaging compounds by means of chromatographic and detection tools.

All reported compounds responsible for negative sensory sensations in paper and cardboard are volatile and – in case of a transfer – the odor of foods is affected. Tastants seem to play a limited or no role in deterioration because much higher amounts of tastants in comparison to odorants are necessary in order to influence the sensory food quality. Regarding hexanal – a typical autoxidation product of unsaturated carbon acids – and sucrose as examples, the thresholds (10 and 8200 µg/l water, respectively) differ by the factor 820 [16.14, 15]. Therefore, instrumental-analytical methods aim at the elucidation of the volatile fraction by gas chromatography/mass spectrometry (GC-MS).

The following sections describe, in particular, the sensory methods which have been established in the EU and United States. The procedures are very similar and easy to apply in most cases for testing the sensory quality of paper and cardboard as well as their potential for odor transfer to foods. Instrumental-analytical methods and isolation techniques aiming at the identification of odorants are reported subsequently.

16.3.1 Sensory Methods

According to DIN EN ISO 5492:2009, sensory analysis is defined as *the science involved with the assessment of the organoleptic attributes of a product by the senses* meaning that the sensory characteristics are evaluated by sight, smell, taste, touch, and sound [16.16]. Chemical and physical stimuli emitted from foods or materials are incorporated and detected by receptors in the relevant sensory organs, converted into stimulus patterns and transmitted to the central nervous system. Regarding smell as an example, volatile and odor-active compounds evaporate from paper or cardboard into the air which is inhaled by a human. The volatiles reach the olfactory receptors located in the nose and a signal pattern is sent to the brain, which is perceived as an odor (Chap. 27).

Sensory analysis allows the characterization of a product and – in consequence – the determination of its sensory quality. Standards with defined procedures for the characterization of the sensory quality of paper and cardboard by a sensory panel have been established. Requirements for test facilities, test execution and training and selection of assessors have been defined in additional standards in order to objectify the results of sensory tests. Table 16.3 lists several standards which have particular relevance to the sensory evaluation of paper and cardboard packaging.

DIN EN 1230

DIN EN 1230 is split into two parts. The first part (DIN EN 1230-1) concerns the perception of the intrinsic odor of paper and cardboard when these materials are

Table 16.3 Standards applied in sensory tests for the evaluation of paper and cardboards

Standard	Title
DIN EN 1230-1:2010	Paper and board intended to come into contact with foodstuffs – Sensory analysis – Part 1: Odour
DIN EN 1230-2:2010	Paper and board intended to come into contact with foodstuffs – Sensory analysis – Part 2: Off-flavor (taint)
ISO 13302:2003	Sensory analysis – Methods for assessing modifications to the flavors of foodstuffs due to packaging
ASTM E619-09	Standard practice for evaluating foreign odors in paper packaging
DIN EN ISO 8586:2012	Sensory analysis – General guidelines for the selection, training, and monitoring of selected assessors and expert sensory assessors
ISO 8589:2007	Sensory analysis – General guidance for the design of test rooms
DIN EN ISO 4120:2007	Sensory analysis – Methodology – Triangle test
DIN EN ISO 5495:2007	Sensory analysis – Methodology – Paired comparison test
DIN EN ISO 10399:2010	Sensory analysis – Methodology – Duo-trio test
DIN ISO 8587:2010	Sensory analysis – Methodology – Ranking
DIN EN ISO 13299:2010	Sensory analysis – Methodology – General guidance for establishing a sensory profile

used for food packaging [16.17]. The second part of this standard (DIN EN 1230-2) describes a procedure for testing the transfer of flavors from paper and cardboard to foods [16.18]. Both standards can only be applied to paper and cardboards packaging. Sensory panels trained according to standard DIN EN ISO 8586 [16.19] and test rooms according to ISO 8589 [16.20] are again required for the tests.

DIN EN 1230-1. This standard is applicable to all types of papers and cardboards including coated and/or printed materials which are intended to come into contact directly or indirectly with food. The test procedure describes the sampling of defined paper or cardboard size (6 dm^2). The samples are inserted into glass jars (volume: 500 ml), closed with lids and stored at a temperature of 23 °C (±2 °C) for 20–24 h in the dark. The odor of the samples and a blank sample (glass jar without sample) is finally evaluated by a sensory panel which consists of at least eight trained assessors. They have to open the lid of the jar, sniff the samples, and score the intensity of the overall odor on a five-point scale (Table 16.4).

The description of the odor using attributes can be indicated from score 2 onward. The arithmetic mean is calculated from the single evaluations and rounded to 0.5 score units.

DIN EN 1230-2. In contrast to DIN EN 1230-1, the transfer of paper and cardboard constituents which migrate via the gas phase into foods is tested by DIN EN 1230-2 [16.18]. All types of papers and cardboards including coated and/or printed materials, which are intended to come into contact with food are investigated.

The standard requires a food that has to be tested in addition to paper and cardboard. If feasible, the same kind of food intended for packaging with the test paper or cardboard should be used as test sample. If this is not possible, a suitable food model (test sample) which exhibits low odor intensity should be selected. Some recommendations for food models are specified in the standard, for example, butter or margarine (simulating meat and cheese), cookies (dry and nonfat foods), and water (milk products and other beverages).

The food (or test sample) and the packaging are inserted into a glass jar by avoiding any direct contact. Figure 16.2 displays an example of such a setup which separates food from packaging: saturated magnesium nitrate or sodium chloride solutions are added to the glass jar in order to adjust humidity to 53 or 75%, respectively. A Petri dish containing the test sample is placed above the solution. A grid is inserted above the dish and the packaging sample is placed on the grid.

In parallel, a blank sample is prepared using the setup but without any food or test sample. The glass jars are stored at 23 °C (±2 °C) for 44–48 h in darkness. Differences in both the test and the blank samples are evaluated by a sensory panel using a triangle test according to DIN EN ISO 4120 [16.21]. A triangle series consists of three test vessels, one vessel with sample A (e.g., test sample) and two vessels with sample B (blank sample) (Fig. 16.3).

The assessors have to taste the samples and to detect the sample which is differing in the overall sensory sensation from the other. Based on the number of assessors and correct answers, significant differences of both samples and consequently a transfer of packaging odor to foods can be determined.

ISO 13302

Standard ISO 13302 [16.22] covers in contrast to DIN EN ISO 4120-1 and 4120-2 besides paper and card-

Table 16.4 Five-point scale used for the evaluation of odor intensity of paper and cardboard according to DIN EN 1230-1 (after [16.17])

Score	Intensity
0	No perceptible odor
1	Just perceptible odor
2	Moderate odor
3	Moderate to strong odor
4	Strong odor

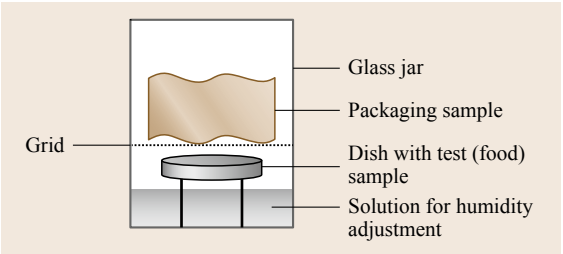

Fig. 16.2 Example of an experimental setup for testing odor transfer of paper and cardboard into foods according to DIN EN 1230-2 (after [16.18])

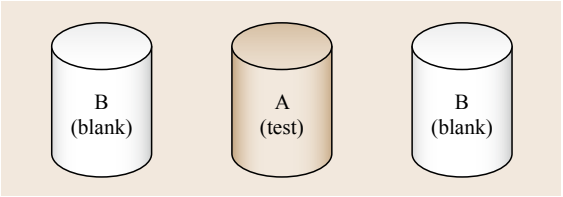

Fig. 16.3 Experimental setup of a triangle test according to DIN EN ISO 4120 (after [16.21])

board all materials for packaging foodstuffs including, for example, plastics, foils, kitchen utensils, etc. The procedures of the standards is however similar. Sensory panels trained according to standard DIN EN ISO 8586 are again required for the tests [16.19]. The actual food should be used for testing but storage (temperature, contact time, etc.) should comply with the conditions which are applicable for a food-packaging system. Although Annex C of the standard provides more information regarding food models and specifications on storage temperature, the storage conditions of the relevant foods packed in paper-based materials are identical with DIN EN ISO 4120-2.

The inherent odor of a packaging or the effect of odor transfer to a food can be evaluated based on the overall odor intensity using, for example, the scale listed in Table 16.4. In addition to a triangle test (DIN EN ISO 4120) [16.21], further sensory tests can be applied in order to determine modifications in the flavor of foods:

- Paired comparison test (DIN EN ISO 5495) [16.23]: the test compares one test and one blank sample by asking the assessors: *Which sample is tainted*?
- Duo trio test with constant reference (DIN EN ISO 10399) [16.24]: the test consists of a blank sample which is known to the assessors (reference) and additionally of another blank sample and the test sample (both not known to assessors). The assessors have to detect the sample deviating from the reference among both unknown samples.
- Ranking test (DIN ISO 8587) [16.25]: the test is applied if three or more samples are compared and the taint is known. Several samples – blank sample may be included – are ranked according to the intensity of the off-flavor.

Affected foods are then determined by application of statistical methods.

ASTM E619 – 09

The American standard ASTM E619 covers a wider range of paper products including [16.26]:

> *. . . all paper packaging products and . . . auxiliary components, such as coatings, inks, and adhesives, as well as plastic materials used in conjunction with paper.*

Several preparation methods (direct examination of packaging (with/without confinement), moistening methods, test of odor transfer) are described in detail and suggested for use in dependence on the material. A sensory panel with trained assessors is used and requirements for test rooms are specified. The odor intensity of the samples (paper, auxiliary components, test food used for transfer experiments) should be scored on five-point scales (Table 16.5).

The arithmetic mean of the individual scorings is calculated. After intensity scoring, the assessors should characterize the perceived off-odor.

DIN EN ISO 13299:2010

The sensory test methods described in Sect. 16.3.1, *DIN EN 1230–ASTM E619 – 09* are easy to perform and provide results within a short period (usually one day). However, more detailed information on taints is sometimes helpful regarding odor characteristics and their intensities, for example, by establishing a sensory profile according to DIN EN ISO 13299:2010 [16.27]. This approach might be used, for example, during development and optimization of (new) packaging materials.

The conventional profile is among the four different types of profiles, which is applied most frequently. Training of the panel assessors according to DIN EN ISO 8586 [16.19] is a prerequisite for performing the test. The odor attributes of packaging are identified by the panel in a first session. An already existing terminology or a packaging-specific terminology which is later on applied to the material is used for the evaluation of the characteristic descriptors. An appropriate intensity scale like an ordinal scale (series of numbers related to intensity) or an interval scale (unstructured lines) is selected in a second step. Finally, the intensities of each characteristic descriptor is evaluated on the selected scale. The arithmetic mean is calculated and the result can be displayed as a spiderweb diagram as displayed in Fig. 16.4.

16.3.2 Instrumental–Analytical Methods

Sensory methods enable a fast and reliable detection and characterization of packaging odors. However, sources of packaging odor are difficult to identify via sensory approaches because no information on the nature of the odorants responsible for a smell is determined. Knowledge on chemical structures of odorants would allow the identification of pathways, precursors

Table 16.5 Five-point scales used for the evaluation of odor intensity of paper and cardboard according to ASTM E619-09 (after [16.26])

Intensity	Score of scale	
	A	B
None	1	0
Very slight	2	0.5
Slight	3	1
Moderate	4	2
Strong	5	3

and contamination sources and finally the development of strategies for reduction or elimination of packaging odor. Several research groups aimed therefore at the elucidation of the composition of the volatile fraction in particular by gas chromatography in combination with MS.

Isolation of Volatile Compounds

A prerequisite for the analysis of volatile compounds by GC is their isolation from paper and cardboard packaging. In general, two isolation principles are applied: (i) extraction from the headspace and (ii) extraction by solvents.

Several of these methods have been established successfully within the last decades. The methods described subsequently are isolation techniques which have been applied to paper and cardboard.

Solid-Phase Micro Extraction. Solid phase micro extraction (SPME) is a headspace preparation technique [16.29]. Although a direct extraction from liquids (including nonvolatiles) is also possible, the headspace approach is applied most frequently. The basic principle of SPME is the ad- or absorption of headspace volatiles to polymers or sorbents coated onto fused silica. The fiber is connected to a steel needle and both, fiber and steel needle, are inserted into a septum-piercing needle. By connection to a needle holder, the fiber at the tip of the steel needle can be moved through the piercing needle and exposed to the gas phase above a sample that should be analyzed.

To achieve this aim the sample to be analyzed is placed into a vial, sealed with a cap with a septum and volatiles are allowed to evaporate until equilibrium. The piercing needle is subsequently penetrated through the septum of the cap, the fiber is exposed to the sample headspace and the volatiles are ad-/absorb to the coating. After extraction, the fiber is removed into the piercing needle and the piercing needle is also removed from the septum. Then, the needle is introduced, for example, into a heated split/splitless injector, the fiber is exposed, and the volatiles are thermo-desorbed and analyzed by GC.

SPME is a rapid isolation technique that requires no solvents. The fiber can be used up to 100 times depending on the ab-/adsorbent and the chosen desorption conditions. However, volatiles with lower volatility are discriminated when using this approach.

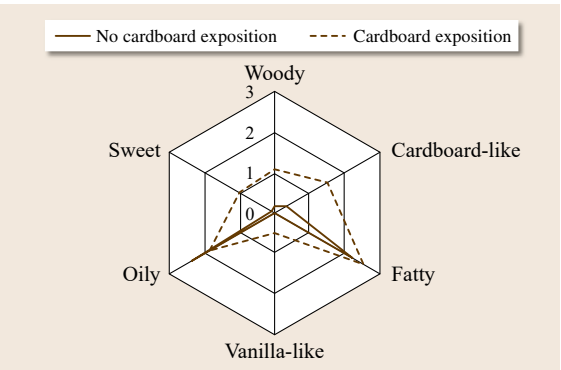

Fig. 16.4 Conventional profile of sunflower oil with and without cardboard exposition (test conditions according to DIN EN 1230-2 (after [16.21])) (figure adapted from [16.28])

Simultaneous Distillation–Extraction. Extracts containing the volatile fraction can also be obtained by extracting them from paper and cardboard with a solvent. Solvents with a low boiling point (e.g., *n*-pentane, diethyl ether, dichloromethane) are usually chosen due to the fact that the extract has to be concentrated for GC analysis by distilling off the solvent; accordingly, volatiles with a boiling point lower than the solvent are lost. However, nonvolatiles like fat are also extracted and a separation of the nonvolatiles that would cause problems during GC is required.

In 1964, *Likens* and *Nickerson* developed an isolation technique that allows the extraction exclusively of the volatile fraction [16.30]. This simultaneous distillation–extraction (SDE) technique uses a special glass tool. A sample is added to a flask which contains water and this flask is then connected to the device. After boiling, the mixture of water vapor and evaporated volatiles is led into a mixing chamber. In another flask, which is also connected to the glass tool, an organic solvent immiscible with water is evaporated by boiling and transferred into the mixing chamber. The vapors are condensed and the volatiles are extracted from the aqueous into the organic phase. Due to their differing density, water and organic solvent are returned in the course of the respective distillation processes to the corresponding flask. The organic extract is subsequently concentrated and used for GC analysis.

SDE allows a relatively fast isolation of volatiles but thermal treatment of the samples during boiling may adulterate the composition of the volatile fraction due to generation of compounds from precursors or degradation of volatiles by chemical reactions that are thermally enhanced.

Solvent-Assisted Flavor Evaporation. The solvent-assisted flavor evaporation (SAFE) technique is a method for the isolation of volatiles from a solvent extract by mild distillation in high vacuum [16.31]. Low boiling solvents are commonly chosen and solid materials can be extracted by, for example, stirring prior to

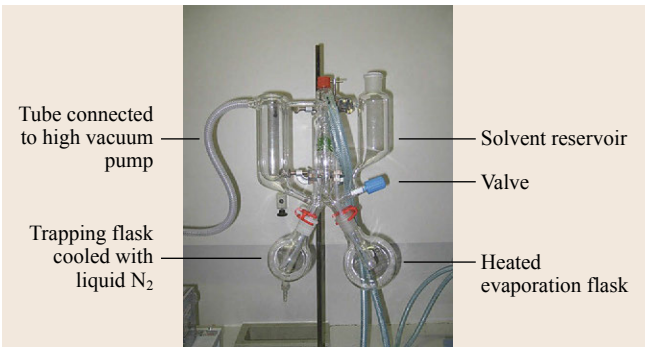

Fig. 16.5 Photograph of glass device used for solvent-assisted flavor evaporation (SAFE) technique according to [16.31]

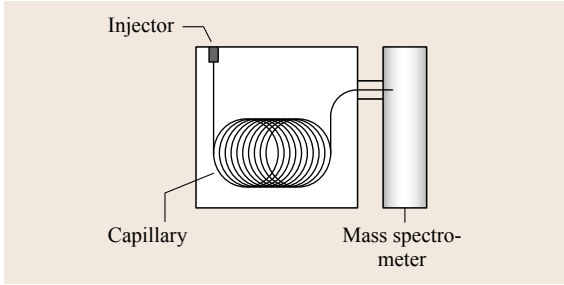

Fig. 16.6 Schematic setup of a gas chromatograph with mass spectrometer

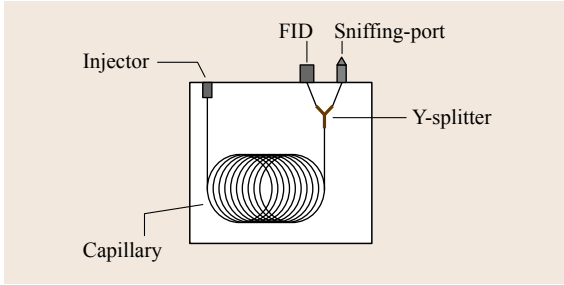

Fig. 16.7 Schematic setup of a gas chromatography/olfactometry system

distillation. In several cases, liquids (e.g., juices, beer) can be distilled directly without any additional pretreatment.

The glass device used for distillation is displayed in Fig 16.5. It is set to a vacuum of about 10^{-1}–10^{-2} Pa by a high-vacuum pump. The left trapping flask is cooled with liquid nitrogen and the right evaporation flask is heated to 40–50 °C depending on the solvent used for extraction. The organic extract is filled into the reservoir and dropped via the valve into the evaporation flask. Solvent and volatiles evaporate and they are transferred into the trapping flask where they are condensed and frozen. The flask is removed, the frozen distillate is thawed and finally concentrated.

The SAFE technique is a very gentle isolation method because the thermal impact is low. Disadvantages are the at times relatively high time required for the distillation process, the loss of volatiles with a boiling point lower than that of the solvent during concentration of the distillate, and the discrimination of higher boiling compounds [16.31, 32].

Gas Chromatography/Mass Spectrometry

GC/MS is a standard method for the separation of a volatile mixture and the identification of volatile compounds. A GC/MS system (Fig. 16.6) consists of an injector (e.g., split/splitless, on-column) into which a solvent extract from, for example, paper and cardboard is injected or an SPME fiber with ab-/adsorbed volatiles is inserted (Sect. 16.3.2, *Isolation of Volatile Compounds*). The injector is coupled to a capillary column [16.33].

By applying a carrier gas flow (e.g., helium) to the injector and in consequence to the capillary column, the volatiles are transferred onto the capillary column and are separated by the chromatographic process (whereby a temperature program is required). The end of the capillary column is installed into a mass spectrometer in which the separated volatiles are transferred. In the electron impact mode (MS-EI) the compounds are ionized and fragmented by an electron beam. The ions are recorded by a detector resulting in characteristic mass spectra (fragmentation patterns) of each volatile [16.34]. Commonly, a comparison of the mass spectrum and the retention time with the properties of the supposed reference compound confirms the structure of the volatile.

GC/MS analysis can be performed with extracts of the cardboard material and by using SPME.

Gas Chromatography/Olfactometry (GC/O)

Analysis of volatiles by GC/MS reveals the chemical structures of compounds. Volatiles vary however in their odor activity by a magnitude of at least 10^9 [16.18] and no information on odor activity of a single compound can be obtained. Therefore, the human sense of smell was introduced to analysis and gas chromatography/olfactometry (GC/O) was established in the 1980s.

In GC/O analysis, a regular gas chromatograph with injector and capillary column is used. In contrast to, for example, GC/MS, the compounds eluting at the end of the capillary column are commonly split by a Y-splitter into two capillaries leading to a detector (flame ionization detector (FID), MS) and a heated sniffing-port [16.33] (Fig. 16.7). An experienced assessor sniffs the compounds of an extract separated by GC at the sniffing port and records the perception of odor-active

compounds in the gas chromatogram or by a voice-recording system. In order to estimate the relative contribution of each detected odorant, aroma extract dilution analysis (AEDA) can be performed [16.33]. The extract is diluted stepwise in a defined ratio (usually 1 : 2, v/v) with the extraction solvent, and GC/O analysis is repeated with each dilution until no odor is perceived. Flavour dilution (FD) factors of the odorants which are defined as the highest dilution in which a compound is still perceived can be determined and the relative impact of the odor-active substance to the odor can be assessed.

Two-Dimensional Gas Chromatography/ Mass Spectrometry/Olfactometry

Identification of some odorants can be achieved by GC/O in combination with a mass spectrometer. However, many odorants are trace compounds with odor thresholds within or below the ppb range [16.18] and identification by GC/O/MS often fails because mass spectra of co-eluting nonodor-active compounds are obtained. A purification and separation of odorants is therefore required prior to identification experiments. Fractionation of the extract by, for example, column chromatography on silica gel can be applied but it is time- and material consuming. Two-dimensional gas chromatography in combination with mass spectrometry and olfactometry (2D-GC/MS/O) is an analytical alternative [16.35]. For an extensive description of the methodology please refer to Chaps. 19 and 17 in this book. Here the main features are only briefly depicted in the following:

The system consists of two gas chromatographs which are connected via a cryo trap (Fig. 16.8). The first GC oven is equipped with an injector and a capillary column. The end of the capillary is split into a sniffing port and a detector (flame ionization detector). The compounds of an extract are analyzed by GC and odor-active compounds, which are detected in a first GC run, are transferred in a second run via the transfer unit onto the cyro trap. After trapping and thermodesorption, the compounds are analyzed after separation on the capillary column of the second GC oven. This column differs from the column of the first GC in polarity. Column combinations of a polar (FFAP, first GC) and nonpolar column (DB-5, second GC) are often chosen. Thereby, further separation of the transferred compounds is achieved. Again, the analyzed compounds are split at the end of the column and led to a mass spectrometer and a sniffing port at which odorants are detected by sniffing. The detection of odor-active compounds by sniffing and recording of mass spectra in parallel provides the desired information on the chemical structure of odorants. Analyses of reference compounds under the same GC conditions finally confirm the results.

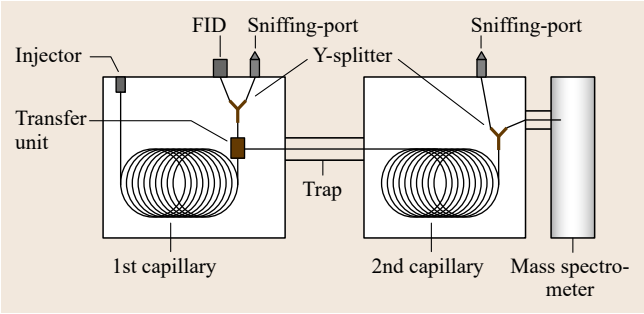

Fig. 16.8 Schematic setup of a 2-D gas chromatography-mass spectrometry/olfactometry system

16.4 Off-Odorants in Paper and Cardboard Packaging

The volatile composition of paper and cardboard is very complex. *Donetzhuber* et al. [16.36] identified more than 200 compounds in commercial samples from European manufacturers and further investigations increased the number of volatiles reported until today to a total of 291 volatiles [16.28, 36–46]. These volatiles belong to different substance classes, in particular aromatic compounds, aldehydes, alcohols, ketones, esters and aliphatic hydrocarbons (Table 16.6).

However, only some publications are available focussing on the elucidation of odor-active compounds in paper and cardboard by GC/O approaches or considering volatile concentration in relation to odor threshold.

Fresh cardboard is usually not odorless and exhibits a weak odor. It is therefore not surprising that various volatile compounds have been identified [16.41]. In particular unsaturated aldehydes like (*E*)-non-2-enal, (*E*, *E*)-nona-2,4-dienal, (*E*, *E*)-deca-2,4-dienal, and oct-1-en-3-ol with fatty and mushroom-like notes were considered as contributors to cardboard odor due to their determined concentrations in relation to their known high odor activities. Thereby, unsaturated fatty acids from wood resins were assumed as precursors of the odorants, which are generated by autoxidation.

Analysis of commercial cardboard by GC/O after SPME extraction demonstrated that additional saturated and unsaturated aldehydes with a (*E*)-2 configuration (C_4–C_9) can be odor-active constituents [16.42]. Application of SAFE for volatile extraction and AEDA further revealed vanillin (vanilla-

like), γ-nonalactone, δ-decalactone, γ-dodecalactone (coconut-like), 2-methoxyphenol (smoky, vanilla-like), 3-propylphenol (leather-like, ink-like), 4-methyl-, and 4-ethylphenol (horsestable-like, faecal) as odorants with high intensities [16.28].

Coating of papers with latex can cause an odor which is not defined precisely but described as characteristic and unique for latex [16.43]. Analysis of such papers coated with styrene-butadiene latex in comparison with off-odor-free papers by GC/FID and GC/MS evaluated 4-phenyl cyclohex-1-ene as the constituent solely present in the papers affected with *latex odor*. The compound was proposed as a product of a side-chain reaction during latex manufacturing (Diels–Alder condensation of styrene and buta-1,3-diene, Fig. 16.9). An interesting GC/O approach was applied in this study in order to clarify the odor impact of the compound: a flame ionization detector (FID) of the GC/FID system was used as sniffing port after extinguishing the flame. 4-Phenyl cyclohex-1-ene was the only compound which exhibited the typical *latex odor* during sniffing. Quantification of the odorant in several raw latices revealed concentrations of 35–331 mg/kg which were far above the determined odor threshold of 4-phenyl cyclohex-1-ene (10 µg/kg water, 5.2 mg/kg latex coated paper). The odorant was confirmed in another investigation as the key odorant of latex coated and unprinted paper by GC/O analysis using extracts obtained by SDE [16.46]. Optimization and control of paper coating with latex is required in order to minimize or reduce the formation of the off-odorant.

Off-set printing was reported as another source of cardboard odor [16.44]. GC/O analysis clearly confirmed the presence of several odor-active unsaturated aldehydes and ketones (e.g., oct-1-en-3-one, (*E*, *E*)-nona-2,4-dienal, (*E*, *E*)-deca-2,4-dienal). Autoxidation of unsaturated fatty acids at the cardboard surface during off-set ink drying was elucidated as the crucial step in odor formation. Adaption of the drying process (temperature, time) can be a strategy in order to minimize or to avoid autoxidation and consequently odor.

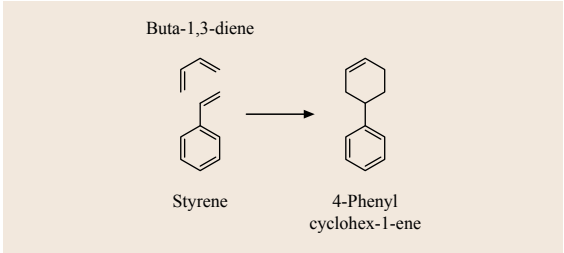

Fig. 16.9 Diels–Alder condensation of buta-1,3-diene and styrene leading to 4-phenyl cyclohex-1-ene

Cardboard produced by using recycled paper-based materials can be affected with chemical, musty and sour odor [16.45]. Oct-1-en-3-one (mushroom-like), oct-1-en-3-ol (mushroom-like), benzaldehyde (bitter almond-like), an unspecified 2-nonenal isomer (leaf-like, fatty), acetophenone (sweet, honey-like), 3-methylbutanoic acid (musty, sewer-like, sweaty, pungent) and an unspecified methylguaiacol isomer (phenolic) were identified by GC/O analysis in such cardboard with high odor intensities. It was concluded that off-odor of recycled cardboard can be correlated with aromatic odorants (benzaldehyde, acetophenone, methylguaiacol) in combination with lipid autoxidation products (oct-1-en-3-one, oct-1-en-3-ol, 2-nonenal).

Microorganisms are another potential source for off-odors in unprinted paper and cardboard. In particular, the introduction of closed water circuits in paper mills caused odor problems by a massive growth of anaerobic bacteria (*Bacillus* and *Clostridium* ssp.) [16.46]. They are able to metabolize cellulose and starch into short-chain fatty acids like butanoic acid, 2-/3-methylbutanoic acid and pentanoic acid with cheesy and sweaty odor notes causing off-odors. Biocides and slime control agents were successfully applied in order to reduce the germ count and to eliminate these unpleasant notes [16.47].

16.5 Summary

Paper and cardboard used as food packaging must be manufactured such that the organoleptic properties of foods are not negatively affected. Several sensory tests have been developed in order to detect and to characterize paper and cardboard odor on an objective basis. These methods are rapid and easy to apply but it is often difficult to obtain information on odor sources. In contrast, gas chromatography/olfactometry offers this possibility. By detection and identification of the odor-active compounds, the odor of paper and cardboard is characterized on a molecular level, odorant pathways and sources can be elucidated and measures can be taken for odor reduction and control.

Sources and odorant pathways causing paper and cardboard odor have been elucidated using GC/O. They are summarized as follows together with possible avoidance strategies (given in brackets):

- Formation of 4-phenyl cyclohex-1-ene in a chemical side-reaction of styrene and buta-1,3-diene during paper coating (optimization of latex coating resulting in 4-phenyl cyclohex-1-ene concentrations which are not relevant for odor).
- Autoxidation of unsaturated fatty acids to yield highly odor-active unsaturated aldehydes and ketones during off-set printing (replacement of unsaturated fatty acids with another agent, oxygen reduction, temperature control).
- Introduction of recycled paper odorants during paper processing (pre-selection of contaminated recycled paper).
- Microorganisms bio-converting cellulose and starch into odor-active short-chain fatty acids (use of biocides).

Part C Analytics

Part C Analytics, Sensor Technology and Human-Sensory Evaluation

The previous sections provide detailed information about the broad importance of odorants in diverse aspects of human life. Commonly, numerous volatiles can be detected in our environment, from the air we breathe to the food we consume, and beyond. However, when it comes to odorants, the analytical scientist often faces the problem that the target substances are present at only low concentrations amongst countless odorless volatiles. In the early days of odorant analysis, this problem was partly addressed by recovering the molecules from large sample sets, e.g., by distilling or extracting liters of a sample and then tediously separating the respective molecules into their single constituents, thereby applying extremely laborious and time-consuming methodologies. A major problem in these analyses was to establish which molecule or fraction should be focused on and to determine how to avoid degrading target substances or generating artifacts during the diverse recovery, enrichment, and separation steps. With the advent of novel analytical techniques, primarily gas chromatography (GC) and mass spectrometry (MS), but also fast and gentle techniques capable of handling minimal sample quantities but still generating meaningful structural information, a new era in odorant analytics dawned. In this respect, especially the idea of combining human olfactory skills with instrumental methodologies led to a veritable revolution in resolving such molecules. Nowadays, modern odorant analytics is capable of tracing odorous contaminants, elucidating odorous constituents in complex odor mixtures or amongst an abundance of non-odorous molecules, assigning stereo-chemical characteristics within the course of a GC separation, or monitoring compounds while they are generated, released, exhaled, or captured, in several cases even in real time. This knowledge is then implementable in testing tools and protocols that link human smell perception with the data recorded by the analytical device, to elaborate the real sensory meaning and impact of what is measured by machines.

Humans do not function like machines, and their sensing does not follow the same relationships, such as a linear behavior, which are the basic principles of instrumental detectors. However, even if we are not yet at the stage of having developed a universal artificial nose that can sniff out what is important in our lives with the same speed and accuracy as the human organ, the analytics that can be achieved today is still highly impressive, as will become apparent in the following section.

17. Gas Chromatography–Mass Spectrometry in Odorant Analysis

Sung-Tong Chin, Graham T. Eyres, Philip J. Marriott

Precise odorant analysis by gas chromatography (GC) with olfactometry (O) methods, especially for complex sample mixtures, relies firstly upon achieving the best possible chemical separation of the volatile components. Odorants are often sampled from the headspace into the GC, since this is where our perception of the product is usually conducted, but the total sample or a liquid extract (e.g., from a wine sample) may also be introduced into the GC. Multidimensional GC (MDGC) methods achieve higher resolution than single column GC. For complex mixtures heart-cut MDGC, where discrete subsamples of eluate are transferred from the first column separation for analysis on a second column, significantly improve resolution of the components in the heart-cut fraction. Alternatively, comprehensive two-dimensional GC (GC × GC) improves resolution for all components in the injected material, but here the second column must complete analysis of each fraction very quickly e.g., within 5 s. Both approaches have been widely studied for aroma extracts and essential oils. Integrating simultaneous olfactometry – providing sensory assessment of a compound – and mass spectrometry (MS) – providing identification of the compound – in the MDGC experiment is important. At the end of the second column, split flow of effluent to O and MS allows effective dual detection of the resolved components. This is best conducted by the heart-cut MDGC approach. Novel methods usually based on MDGC can also be used to re-combine different odor-eliciting compounds, to study synergistic effects.

Understanding flavor perception firstly requires identification of the volatile compounds responsible for the characteristic aroma properties of the food or beverage sample. Amongst these compounds are those that impart specific aroma identified with specific products. These are commonly known as character-impact odorants. Odorant analysis has traditionally relied on gas chromatography (GC) as the separation tool of choice for the analysis of volatile compounds. GC incorporates high-resolution gas phase separation of analytes using an appropriate stationary phase coated capillary column and elution in a carrier gas stream to a detector. Sample introduction may be achieved by liquid injection of a sample or by analysis of a headspace gas above a sample of interest via split, splitless or thermal desorption. Detectors may have a universal response to all compounds, such as the flame ionization detector (FID), or they may be selective, where a given element provides a specific mode of response. For example, selective detection is found for halogens (electron capture detector), sulfur (flame photometric detector), nitrogen (nitrogen-phosphorus detector), amongst others. For analysis of odorants, the two key detectors are (i) the mass spectrometer that provides identification of compounds through mass spectrum interpretation (usually MS database matching with database of reference spectra), and (ii) sensory evaluation of eluted peaks by human assessors via olfactometry.

Hyphenating a high-resolution GC separation with detection of human assessors, known as GC-olfacto-

metry (GC-O), has been an indispensable tool to identify the odorants in sample mixtures [17.1, 2]. In this technique, the human assessor provides the most sensitive and selective detector for the chemical property of interest – odor activity. Various GC-O protocols such as odor intensity, dilution-to-threshold, or detection frequency, may be applied in assigning the relative importance to odor-active compounds eluting individually from a GC separation [17.1, 3–8].

A common limitation in odorant analysis is the incidence of overlapping chromatographic peaks arising due to insufficient resolution in complex samples. This presents considerable challenges in determining the chemical compounds responsible for a perceived odor activity. Multidimensional gas chromatography (MDGC) has evolved in the past few decades, involving the incorporation of multiple separation dimensions (more than one GC column) to enhance the resolving power of the analysis. This chapter describes the advent of various MDGC approaches for odorant analysis and their applications.

17.1 Rationale for Multidimensional GC

Overlapping of chromatographic peaks is mainly due to insufficient resolution power in a given separation method; this is increasingly important for a complex sample. The power of mass spectrometry (MS) is often unable to provide an unambiguous mass spectrum for each compound present in grossly co-eluted peaks [17.9], even by utilizing spectral deconvolution algorithms. In this circumstance it is very challenging to precisely assign a chemical compound to the odor perception, particularly when a trace odor-active compound co-elutes with a matrix background of an abundant odor-inactive peak. The technology of achieving individual component separation and odor assessment still plays an important role in odor analysis. Combining olfactory detection with simultaneous mass spectrometry and retention index estimation is a powerful identification strategy for the characterization of an unknown odor.

To simplify the complexity of an odor extract, various sample preparation and fractionation procedures are commonly applied prior to GC-O analysis. These are typically low resolution methods such as acid/base chemical isolation [17.10, 11], flash sorbent/agar fractionation [17.12–16], and normal or reversed-phase liquid chromatography (LC) [17.16–18]. Multiple fractions are generated from the original aroma extract corresponding to the process condition (pH, polarity, ion exchange ligand), which then require further analysis. Such methods have been reviewed elsewhere [17.19–21], and often exhibit the possibilities of analyte losses or artifact formation caused by hydrolysis and oxidation of analytes during the fractionation process [17.2, 21]. These techniques are also incompatible with headspace aroma extraction techniques, as the isolated odorants are normally thermally desorbed from the sorbent medium directly into the GC inlet. The pre-fractionation processes to simplify the aroma extract do not suit analysis by solid phase microextraction (SPME), which is widely used in odor analysis.

An alternative approach is to improve resolution using MDGC. The essence of MDGC is the incorporation of multiple gas phase separations by using more than one GC column organized in a sequential arrangement. The two columns typically have orthogonal separation mechanisms (different column selectivities) which are referred to as *dimensions* of separation. A transfer process between the analytical columns serves to effectively decouple individual retentions and transfer target analytes from the first dimension to the second dimension. This results in greater resolving power, and significantly higher peak capacity without artifact generation. Development of MDGC has undergone a recent resurgence through development of precision devices such as microfluidic switches, better gas flow control and improved fast responding detection methods [17.22].

Essentially, the two main approaches for online MDGC involve (a) subjecting a target portion(s) of chromatographic effluent from a first dimensional column to a secondary column separation (conventional heart-cut MDGC), or (b) applying the two-column separation advantage to the entire sample via a fast, continuous modulation process (comprehensive two-dimensional GC; GC × GC).

17.2 Offline MDGC-O

Offline two-dimensional (2-D) GC involves separation using two columns in two discrete analytical systems. In principle, offline MDGC uses high resolution GC as a preparative primary separation dimension to isolate and simplify the complexity of a target fraction, in contrast to other pre-fractionation tools described

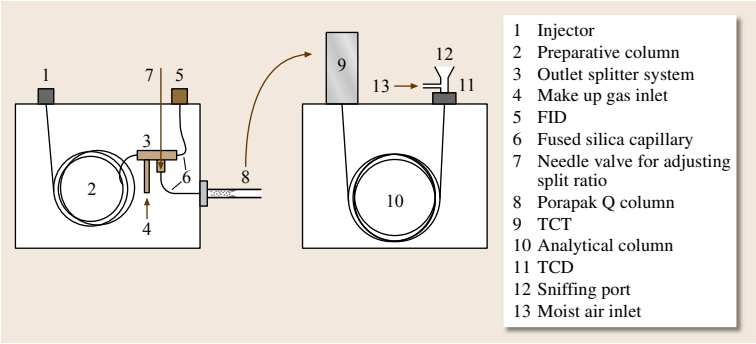

Fig. 17.1 Schematic diagram of an offline MDGC system (after [17.23])

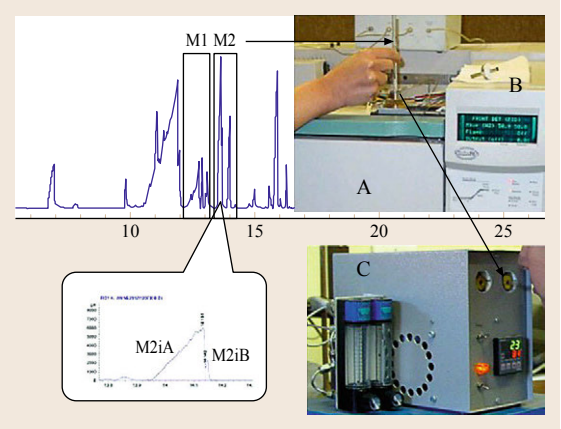

Fig. 17.2 Heart-cutting and offline olfactometry for identifying the fraction of a chromatogram responsible for a coffee odor. Sections of the chromatogram are captured from the GC effluent on a MCT (*A*). The trap rests on the flame tip of an inactive FID during collection. The FID ion collector is removed prior to heart-cutting (*B*). The odor is thermally desorbed from the trap with 20 ml/min nitrogen gas flow in an offline olfactometer (after [17.24])

above. An additional sorbent trapping medium is commonly required to perform a *heart-cut* operation by trapping the target region(s) eluting from the first dimensional (^{1}D) GC separation. Subsequently, trapped analytes are either solvent eluted or thermally desorbed from the absorbent medium for introduction into the second dimensional (^{2}D) GC separation. Although manual operation may be implemented in some cases, this method offers the convenience of subjecting the trapped region(s) to another individual chromatography and/or detection system when a flow switching ancillary device is unavailable and/or online hyphenating configuration is unachievable, such as in the case of nuclear magnetic resonance (NMR) spectroscopy. Nevertheless, losses of target analytes during the trapping procedure cannot be neglected, whilst contamination of the trapping medium also needs to be considered to ensure the sample has the highest possible purity.

Miranda et al. [17.25] reported the identification of odor-active compounds from the headspace of banana passa using offline MDGC-O/MS analysis. An open-tubular capillary (1 m × 0.33 mm id) coated with DB-210 phase with a CO_2/acetone cold trap was applied as the trapping medium at the olfactory outlet of a ^{1}D separation. After five analyses collecting the most potent aroma chromatographic regions, the most odor-active compound, 4-hydroxy-2,5-dimethyl-3(2*H*)-furanone (sweet, caramel), was identified through its MS library matching. Similarly, *Rogerson* et al. [17.26] proposed a GC fractionation approach to investigate the sweet aroma descriptors in Portuguese wines from the Douro region. The target odor region from the ^{1}D separation was collected by the condensation of sniffing port effluent into a 2 ml vial filled with 10 µl of diethyl ether at −20 °C. A norisoprenoid compound identified as 2,6,6-trimethylcyclohex-2-ene-1,4-dione with a sweet, honey aroma character was determined to be the key contributor to Port wine aroma.

Figure 17.1 illustrates the configuration of an offline MDGC arrangement reported by *Nishimura* [17.23], which included the application of a Porapak Q column (6 mm O.D. glass tube) as the trapping medium and a thermal desorption cold trap injector (TCT) for analyte desorption to ^{2}D analysis. The oxygenated hydrocarbon fraction of the extract from Japanese fresh ginger rhizomes was analyzed for the chiral composition of characteristic odorants in fresh ginger samples. After ^{1}D separation in a Wax megabore column, each enantiomer of linalool, 4-terpineol, isoborneol and borneol was successfully trapped and resolved in the chiral CP-Cyclodextrin-2,3,6-M-19 column. The odor character of each enantiomer was confirmed in ^{2}D analysis with simultaneous thermal conductivity detection (TCD) and olfactory assessment.

Recently, a multichannel open tubular silicone rubber trap (MCT) was described for its trapping capability under room temperature conditions for headspace sam-

pling of milk and wine volatiles (Fig. 17.2) [17.24, 27]. Discrete portions of the chromatographic profile, either individual peak(s), region(s) or combinations of both can be recaptured with a second MCT during a subsequent run that can be further thermally desorbed for direct aroma evaluation or into GC–MS with simultaneous olfactometry for odorant identification. An aroma region of several minutes allows sniffing of each aroma fraction by six panelists. Olfactory results suggested that a synergistic combination of 2-heptanone and 2-nonanone could be responsible for a pungent cheese, sour milk-like aroma [17.27]. The manual method should be suitable for automation with appropriate MDGC method development. This approach was also applied to the investigation of the compounds responsible for coffee aroma character in *Pinotage* wine from several South African wine cellars [17.24]. Synergistic aroma effects were evaluated utilizing the recaptured fractions, released in a controlled manner for offline olfactory evaluation, and for qualitative analysis using GC × GC–TOFMS for compound separation and identification. This approach permitted correlation of odor activity with specific identified compounds. Combined furfural and 2-furanmethanol resulted in a synergistic effect for the occurrence of coffee odor in *Pinotage* wine, which is a desired effect that is deliberately obtained from toasted oak wood. It was demonstrated that neither of the individual compounds in isolation was responsible for the characteristic aroma.

17.3 Online MDGC-O

Most modern MDGC techniques involve online transfer of heart cut regions using a valve or flow-switching device, such as a Deans-switch system. Microfluidic flow technology offers better operational inertness and precision in the flow switching and solute modulation processes [17.22, 28–32]. Figure 17.3 illustrates a schematic configuration of an online MDGC system mounted with a Deans-switch interface (DS) and a cryogenic trap (CT). The peak broadening due to solute dispersion as a consequence from ^{1}D chromatography can be minimized by cryofocusing at the ^{2}D inlet, giving the best performance of multidimensional analysis with automated control. In addition, fast oven programming can be offered by a dual-oven low-thermal mass (LTM) GC system with greater flexibility of independent temperature control implemented in both separating dimensions [17.33, 34]. The emergence of integrated MDGC-O/MS further extends the analytical efficiency with operational flexibility, which is effective for rapidly characterizing the aroma compounds and identifying taints for odor quality issues [17.9, 35].

For odorant analysts, MDGC-O/MS remains the method of choice to detect odor-active compounds in aroma extracts, supported by retention indices, and structural or element-specific information with other detectors. Based on the Siemens SiCHROMAT-2 double-oven GC and a Deans switch MDGC arrangement, *Nitz* et al. [17.36] described a system equipped with different injection modes, a micropreparative (μ-prep) module, a sniffing port and MS detection. Applications described by these authors are representative of many key aspects of flavor work, such as trace-level flavor compounds (methoxypyrazines and geosmin) as potential off-flavor compounds in various samples, and isolation of a terpene compound from parsley via μ-prep sampling after MDGC [17.37]. *Ragunathan* et al. [17.38, 39] demonstrated an MDGC system operating with valve-based effluent switching but configured with multiple parallel cryogenic traps that enabled multistage separation and Fourier transform infra-red (FTIR) and MS detection.

In the case of chiral flavor compounds, enantio-MDGC-MS provides a new approach for flavor-authenticity control [17.40–42]. Further, the combination of enantio-MDGC with isotope ratio MS (IRMS) [17.43, 44] allows evaluation of the origin of particular flavor compounds on not only the basis of their enantiomeric distribution but also consideration of the natural variation in isotope distribution for characterizing sample provenance. Constant-flow MDGC combustion/pyrolysis-IRMS was applied to the authenticity assessment of (*E*)-α(β)-ionone from six different

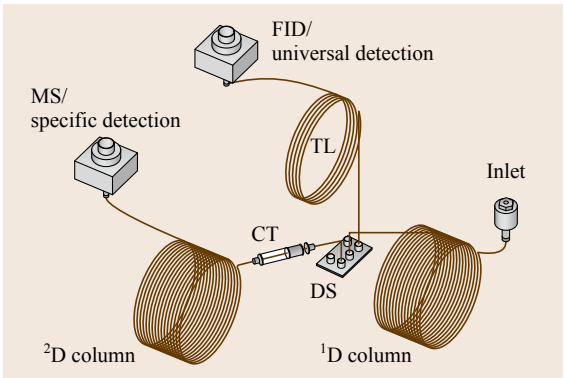

Fig. 17.3 Schematic diagram of heart-cut MDGC system

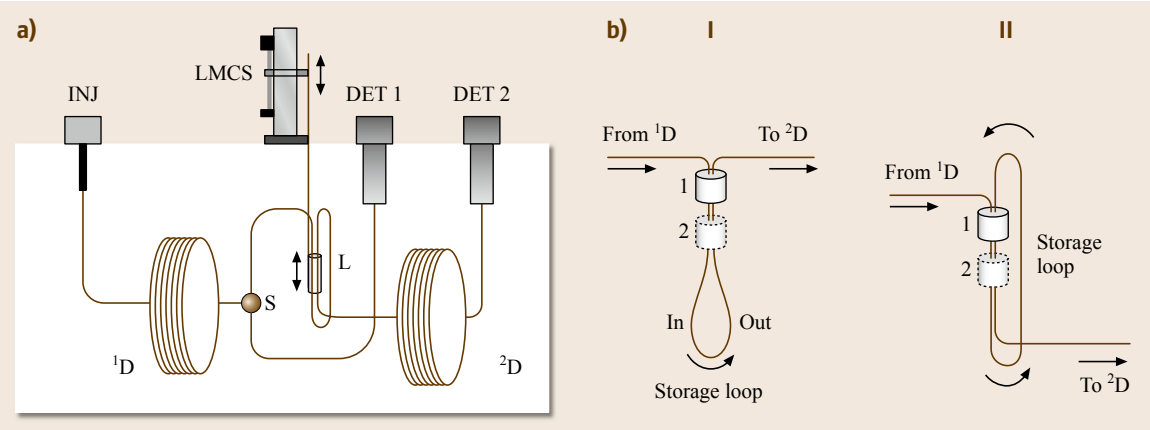

Fig. 17.4a,b Schematic diagram of **(a)** MDGC-DCSI-O system incorporating a looped column (L) through a LMCS. Target regions are selected, sampled, and passed to the second dimension (^{2}D) by action of the LMCS cryotrap. The splitter union (S) allows a small flow to pass to the first detector (DET 1) to allow precise selection of the target region. **(b)** Two different arrangements for the looped column modulator (after [17.9])

raspberry cultivars [17.45]. Characteristic authenticity ranges were accomplished by correlation of both $\partial^2 H_{V\text{-}SMOW}$ and $\partial^{13} C_{V\text{-}PDB}$ values.

An alternative online transfer mechanism incorporating MDGC was proposed by *Begnaud* et al. [17.46, 47] utilizing a double cool-strand interface (DCSI) arrangement incorporating the longitudinally modulated cryogenic system (LMCS) device, which required no additional pneumatic flow control (Fig. 17.4). This design was demonstrated to be useful in separation of chiral volatiles in malodor analysis with coupling to olfactory detection [17.46, 47]. An alternative loop arrangement (Fig. 17.4b) and the distinction between the two approaches is described in *Eyres* et al. [17.48] and *Ruhle* et al. [17.49]. *Eyres* et al. [17.48, 50] introduced a μ-prep technique based upon capillary MDGC utilizing the modified loop modulator interface as the transfer device to the ^{2}D separation, with a Deans switch to divert the flow to an external trapping assembly (xTA) at the outlet of the ^{2}D column, where the single analyte compound was collected with multiple injections until the desired amount was accumulated. It was demonstrated that sufficient quantities of the isolated analyte could be obtained to perform offline 2-D NMR analysis. This approach can be applied to resolve, isolate and identify pure volatile components from a complex sample matrix. This μ-prep system was also applied with x-ray analysis of isomeric products from catalysis reactions of phenyl acetylene with *para*-substituted aryl iodides [17.51].

17.4 Novel Approaches in Olfactometry

The most effective use of olfactometry in odorant analysis comes from a good understanding of the human assessor as the specific detector. Applying sound principles of sensory science to olfactometry experiments has the potential to provide the greatest understanding of odor perception [17.1]. In olfactometry experiments, a panel of multiple assessors is typically required, which can make a comprehensive investigation very time consuming. In an attempt to alleviate this limitation, a multisniffing system incorporating three olfactory ports with simultaneous MS detection was presented by *Debonneville* et al. [17.3]. A computer-controlled eight-way GC-O system was also developed that allows for an aromagram computed from eight panelists to be obtained simultaneously in a single GC analysis [17.52].

Sample representativeness is also an important issue to ensure any sample extract for analysis matches the original sample and that the sample preparation method does not result in artifact formation. A direct GC-O (D-GC-O) system using an uncoated deactivated fused silica column with no separation of analytes was proposed to evaluate the representativeness of an SPME extract desorbed into the GC injector [17.53].

Typical odorant analysis aims to achieve complete resolution of odor active compounds and with indi-

vidual olfactory assessment. However, the overall odor perception of a sample is the result of a complex combination of many interacting odorants and their proportional release from the original sample matrix [17.1]. It is also difficult to determine the recombined odor simply from individual separated compound(s), due to complex interactions and physiological effects [17.54]. Best practice in odorant analysis involves validation of the importance of the identified compounds by recombination studies to assess that the simulated model sample of the top odorants is similar to the original sample [17.55]. The contribution of individual compounds in the mixture may then be evaluated using omission experiments. A novel system for characterization of aroma mixtures in an online system was developed by *Johnson* et al. [17.56], termed GC recomposition-olfactometry (GC-RO). This system utilizes microfluidic flow-switching to heart-cut selected peaks and recombines them using a cryotrap prior to olfactory detection. The system was demonstrated by evaluation of an SPME extract of lavender flowers. Another system to investigate odor mixture interactions was presented by *Williams* et al. [17.57] where odorants from a GC separation were presented into an air stream with a constant background odorant, termed a GC-pedestal olfactometer (GC-PO). The advantage of these techniques is that interaction studies can be performed even when the odorants have not been identified.

17.5 GC × GC Approaches for Global Volatile Screening

Comprehensive flavor characterization studies often require a combination of analytical techniques utilizing an olfactory detector and chemical detectors in order to obtain the most precise interpretation. Comprehensive two-dimensional GC (GC × GC) is increasingly applied to odorant analysis in conjunction with dual detection devices (olfactometry and MS detection) to provide more accurate identification and improved sensitivity. *Breme* et al. [17.52] combined GC × GC coupled to time-of-flight mass spectrometry (GC × GC-TOFMS) analyses with the eight-way GC-O system for the identification of trace odorant constituents in an Indian cress sample. *Rochat* et al. [17.58] applied GC × GC-TOFMS for analysis of sulfur-containing compounds in roasted beef as key aroma components. Correlated with GC-SNIF (GC-surface of nasal impact frequency olfactometry), a number of sulfur compounds in the top note were confirmed, with some compounds identified for the first time.

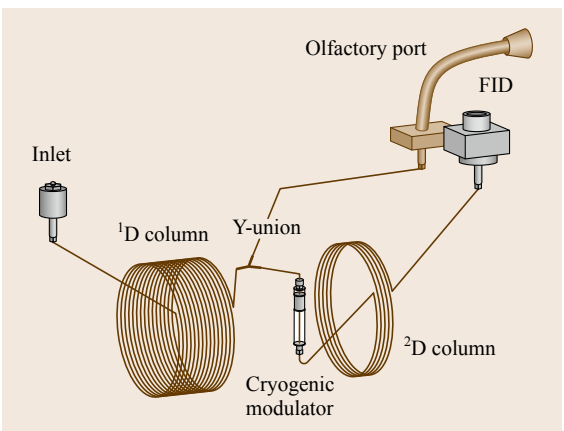

Fig. 17.5 Schematic diagram of GC × GC-FID/GC-O system

d'Acampora Zellner et al. [17.59] attempted to overcome imprecise interpretation of co-eluting peaks in the odor-active region from GC-O by coupling a sniff port with GC × GC. However, this technique is technically demanding, due to a number of very narrow modulated peaks (0.1–0.4 s peak width) which are too narrow for the typical breathing cycle of a human (3–4 s) [17.9]. Therefore, the application of H/C MDGC for the study of aroma-impact regions with olfactory detection remains important. *Eyres* et al. [17.60] studied the spicy character of hop essential oil by comparing data from GC-O with GC × GC-TOFMS to locate the odor-active regions. The co-eluting cluster of compounds responsible for a spicy odor could be resolved by H/C MDGC on ^{2}D, and generated discrete broader peaks (3–6 s) appropriate for olfactory assessment. Volatile constituents in wine and brewed coffee were analyzed using three different systems, the first incorporating both GC-O and GC × GC-FID as illustrated in Fig. 17.5, a GC × GC-TOFMS and a dual detection GC × GC–FID/FPD design [17.61]. Impact odorants were tentatively identified through data correlation of GC × GC contour plots across the results obtained using either TOFMS, or with flame photometric detection (FPD) for sulfur speciation (S_2^* emission). Interpolating the GC × GC data with those obtained from olfactory detection presents a great challenge in terms of method accuracy, robustness and simplicity. This highlights the requirement for an integrated MDGC-olfactometry arrangement.

17.6 Integrated MDGC-O Arrangement

Recently, a selectable 1-D/2-D GC–O/MS system was developed using multiple microfluidic Deans switches and LTM-GC [17.33, 34, 62–64]. The developed system offers the simplicity and flexible implementation of fast programmable 1-D or 2-D GC–MS operation, simultaneously with MS and olfactometry and element-specific detections such as nitrogen chemoluminescence detector (NCD), nitrogen phosphorus detector (NPD), pulsed flame photometric detector (PFPD) and sulfur chemiluminescence detector (SCD) to assure selection of a heart-cut region and correct identification of compounds of interest. Preparative fraction collection (PFC) was coupled to this system outlet for analysis of ultra-trace amounts of odor compounds [17.33]. The selectable system was applied for the assessment of sulfur compounds in whiskey samples by simultaneous heart-cuts of 16 fractions to the ^{2}D column in conjunction with retention time locking and sulfur specific detection and MS [17.63]. Such an approach was also validated and tested for its reproducibility and quantitative analysis of fragrance [17.62].

A dual switchable GC × GC/targeted MDGC analysis was proposed for study of aroma-impact compounds where GC × GC can be incorporated with MDGC to permit precise identification of aroma active compounds [17.66]. An integrated switchable MDGC system that allows targeted MDGC and GC × GC analysis to be performed in a single run with simultaneous MS and olfactory detection was developed as shown in Fig. 17.6 [17.65]. The system also utilized the techniques of online enrichment of target compounds by in-oven trapping [17.67] as well as cumulative solid phase microextraction sampling [17.68] to amplify the signal for improved sensitivity and identification. Utilizing the developed integrated system, olfactory data from 1-D GC-O was readily matched to MDGC-O/MS identification, with complementary GC × GC-FID analysis giving an overview of the sample's complexity. Any desired co-eluted regions from the ^{1}D column can be selected to permit targeted MDGC separation on a longer ^{2}D column than that employed for GC × GC operation. This workflow strategy is shown in Fig. 17.6b. This system results in better resolution and was proposed to be suitable for coupling with olfactometry or other detection methods that require slow acquisition rates, such as Fourier transform ion cyclotron resonance mass spectrometer (FT-ICR-MS). Analysis of several potent odor regions for wine and coffee samples as a complex problem was demonstrated as example applications [17.61]. Isomer identification is also feasible through verification by simultaneous matching of acquired mass spectral data, supported by both primary and secondary dimension retention indices data.

A variety of multicolumn methods have been developed to suit current volatile chemical analysis, with hybrid systems incorporating facets of both conventional H/C MDGC and GC × GC technologies. *Mitrevski* and *Marriott* [17.69] recently reported a hybrid (sequential) GC × GC-MDGC method for complex sample manipulation. This method was applied to separation

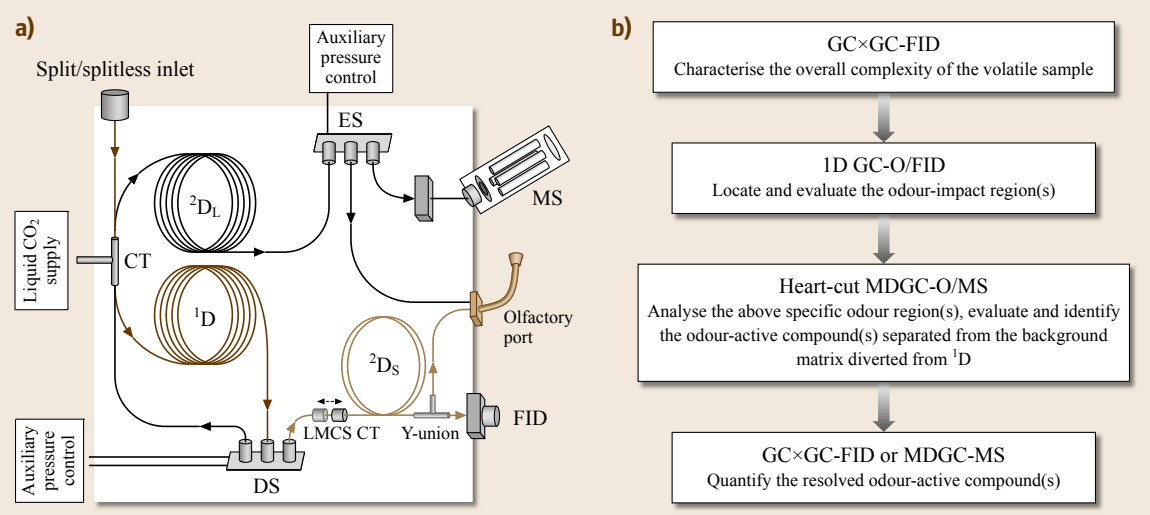

Fig. 17.6 Schematic diagram of **(a)** integrated MDGC/GC × GC-O/MS system; **(b)** Flow diagram of the strategy for odor-impact analysis in a complex sample using the integrated system (after [17.65])

and quantitative analysis of oxygenates in a thermally-stressed algae-derived biofuel oil without any pre-fractionation procedure. Profile reproducibility before and after heart-cut operations was demonstrated by extracting single components from a complex coffee volatile sample.

17.7 Current Challenges and Future Perspectives

Although current MDGC technology has greatly enhanced the reliability of compound identification owing to improved separation from the dominating background in analyzed samples, general acceptance of MDGC technologies is mostly restricted to the academic research sector, and is less commonly applied by industry to identify taints related to flavor and general profiling of aroma products. Through recent advances in development of standardized systems and approaches in online coupled systems, MDGC is a ready-for-adoption technology for widespread use in the industrial laboratory. Thus, a range of approaches should be validated as simpler automatic and less expensive solutions for odor analysis compared with more complex mass spectrometry methods that do not target complete component separation. MDGC methods can be conveniently adapted for rapid determination of aroma-related sensory problems in the industry.

Online interaction studies through recombination of odorant mixtures rather than evaluation of individual compounds is critically important in order to assess overall perception and to validate GC-O findings. This approach verifies significant perceptual interactions of volatiles which exist below their putative sensory threshold, representing an under-explored and promising research area in odorant analysis. Combining MDGC recomposition olfactometry methodology with other bioassays would generate useful information on the relationship between stimulus and perceived flavor response, or the pathway between these two parameters involving genetics, receptor binding, transduction and translation to cortical neurons.

17.8 Concluding Remarks

The resurgence of multidimensional gas chromatography techniques in conjunction with olfactory analysis provides a powerful approach to identify odorants in complex food and fragrance samples. There is great potential of MDGC approaches to enhance understanding of flavor perception through high-resolution odorant analysis utilizing innovations in advanced separation and detection systems. Improved separations in association with flavor/aroma analysis is especially bright, and continued innovation in this space assures that not only useful studies on fundamental human odor perceptions, but also contributions to chemical ecology research of other organisms with olfactory systems similar to that of humans will be enhanced.

18. Odorant Detection by On-line Chemical Ionization Mass Spectrometry

Jonathan Beauchamp, Erika Zardin

The nasal olfactory receptors allow us, as human beings, to detect and perceive odors almost instantaneously upon exposure and over a broad range of concentrations down to ultratrace levels. Translating this rapid and sensitive detection of odorant molecules to the analytical laboratory is a challenging, nontrivial endeavor that remains unachieved to date. On-line mass spectrometry based on chemical ionization (CIMS) comprises sophisticated analytical techniques that meet several of the key requirements in odorant detection, namely fast response times and direct analyses, trace level limits of detection, and a high sensitivity to a suite of odors or, more specifically, odorants. This chapter discusses on-line CIMS and its application in odorant detection in selected fields. The prominent CIMS techniques of selected ion flow tube mass spectrometry (SIFT-MS), proton transfer reaction MS (PTR-MS) and atmospheric pressure chemical ionization MS (APCI-MS) are considered, commencing with a brief introduction to their historical developments and a discussion of their operational features and suitability for odorant detection, followed by a review of their widespread applications in odorant measurements in diverse fields of study.

Chemical ionization mass spectrometry (CIMS) refers to mass spectrometric techniques that utilize specific reagent ions for the chemical ionization of neutral analyte molecules in the gas phase. Although chemical ionization is also employed in other systems such as gas chromatography MS (GC-MS) – in addition to the more frequently used electron ionization (EI) – CIMS in the context of this chapter refers to specific MS techniques that allow the ionization and detection of gas-phase volatile organic compounds (VOCs) directly and in a continuous manner, i. e., in real-time without the need of sample pretreatments such as enrichment, dehydration, or chromatographic separation.

It is noteworthy that none of the major on-line CIMS techniques discussed in this chapter were invented to specifically measure odor-active molecules, and their initial exploits were mostly in fields with only loose association per se to aroma or odor analysis. Their implementation for the specific purpose of odorant detection has been a by-product of their efficient and sensitive response to volatile compounds, regardless of the odor activity of the target molecules. The recognition of this application by researchers working in odor-related fields steered their early and successive development and increasing deployment for odorant detection in diverse areas of research.

This chapter commences with a retrospective of the development of CIMS and discusses the current predominant analytical CIMS tools that are in use for on-line odorant detection in different disciplines, focusing on their development and basic operating principles. The ensuing discussion moves on to the varying applications of these on-line CIMS techniques in individual fields of odor detection. Due to the nature of CIMS, whereby an extensive range of VOCs are detectable whether they are odorous or not, part of the discussion inevitably alludes to the detection of nonodorous molecules. Further, there are many studies that report on

the detection of odoriferous molecules without consideration of their odor-active properties. For the purposes of this chapter, which focuses on the detection of odorous molecules, these are broadly taken as being any compound that elicits an odor impression in the human nose at the typical concentrations encountered in the respective environment or application. This latter aspect is particularly important, since many molecules manifest odorous attributes only above a certain concentration threshold that might not be often reached in everyday scenarios.

Given the long history of CIMS and the rapid growth of related real-time tools over the last few decades, particularly in recent years, this chapter is by no means authoritative but aims to provide a broad overview of major past and present endeavors of diverse on-line CIMS techniques in the detection of odorants, and hints at prospective applications. It should be noted that the odorants treated in this chapter are discussed in terms of their detection by CIMS, but not at length on their (bio)chemical origins – or where necessary, only superficially – since this is the focus of other chapters of this book. Furthermore, since applications and best practices in the fields covered in this chapter are constantly being updated and novel developments are continually being introduced at a fast rate, the reader is advised to refer to the most recent scientific literature for the latest information on specific methods and topics.

Mass spectrometry, by definition, is the analytical procedure by which ionized target atoms or molecules are detected on the basis of the ratio of their mass to charge (m/z). In other words, the signal response elicited by an ion reaching the detector within the system is dependent on the m/z-related settings of the mass spectrometer. The ionized molecule that corresponds to this m/z signal – or spectrum thereof – is then identified according to known ionization pathways and fragmentation patterns, either from theoretical models or via analogous analysis of the pure compound. The abbreviation m/z appearing throughout this chapter represents the dimensionless quantity used almost universally as the independent variable in a mass spectrum. Odorant concentrations are presented in parts-per-unit-volume notation, typically parts per million (10^{-6}), parts per billion (10^{-9}), and parts per trillion (10^{-12}) by volume, or ppm_v, ppb_v and ppt_v, respectively. Although this unit of measure represents a volume mixing ratio (VMR) and, strictly speaking, is not a concentration, it is deemed most appropriate for all intents and purposes of the discussion on odor abundance and threshold/detection levels and is interchangeably referred to as *concentration*.

18.1 Techniques

Before discussing applications in odorant detection, the major on-line CIMS techniques currently in use for the detection of volatile (odorous) compounds are introduced, commencing with a brief history and subsequent outline of the operating principles of each technique, as well as presenting a discourse on the analytical advantages and shortcomings for odorant detection.

18.1.1 A Brief History of CIMS

Chemical ionization mass spectrometry was conceived half a century ago by the experimental work of *Burnaby Munson*, *Frank Field* and colleagues at the Humble Oil and Refining Co. in Baytown, TX, USA with their discovery of a technique in mass spectrometry that was *based on the formation of the ions of an unknown material by chemical reactions in the gas phase* [18.1]. The formation of product ions via chemical reactions inspired them to name this new technique *chemical ionization* [18.2]. In their seminal paper that introduced this new ionization method, *Munson* and *Field* showed that operating their mass spectrometer at high pressures of 1 torr ($\approx$ 133.3 Pa, or 1.33 mbar) and adding a reaction gas into the ionization chamber – in their experiments, methane – with a small amount of additives, or target compounds, led to the production of stable primary ions (CH_5^+ and $C_2H_5^+$) that did not react further with methane but did react by proton or hydride transfer with the organic additives to produce relatively clean and stable spectra of the latter, including appreciable amounts of quasi-molecular ions [18.1]. In comparison to the conventional method of electron (impact) ionization (EI), which yielded complex mass spectra due to extensive fragmentation upon ionization of the neutral target, this new technique was anticipated to be of especial relevance for both qualitative and quantitative compound analysis. This was the inception of chemical ionization mass spectrometry and the basis for the development of the on-line CIMS techniques of today. A thorough chronology of the initial experiments that led to the discovery of CIMS and its subsequent development is provided in the reminiscent article by *Field* [18.2]; further details of the ion chemistry observed in these early studies are recounted in a historic overview paper by *Munson* [18.3].

The subsequent developments that led to the invention of the derivative techniques at the focus of this chapter then diverged. In Boulder, CO, USA, experi-

ments carried out by *Eldon Ferguson*, *Fred Fehsenfeld* and *Art Schmeltekopf* at the Upper Atmosphere and Space Physics Division of the National Bureau of Standards – later to become the National Oceanic and Atmospheric Administration (NOAA) – in the mid-1960s led to the development of a technique known as *flowing afterglow* (FA) that was applied to investigate ion-molecule reactions in the Earth's upper atmosphere [18.4, 5]. The system comprised of a microwave discharge source to produce helium ions that were channeled via a nozzle into a flow tube in which neutral reactant gas could be added for subsequent ionization by He^+ ions [18.4]. The afterglow from which the name was derived referred to photoemissions that resulted from electron-ion recombination in the downstream plasma, which accordingly indicated the presence of ions in the flow tube [18.6]. A quadrupole MS coupled to the system allowed for mass spectrometric selection and subsequent detection of ions emerging from the flow tube and paved the way for studies on ion-molecule reactions under defined conditions. For further reading, a retrospective by *Ferguson* on the early development of FA and the first experiments on ion-molecule chemistry is available in the scientific literature [18.6].

Subsequent work by *McFarland*, *Albritton* and the aforementioned researchers at the Aeronomy Laboratory at NOAA in the early 1970s produced the flow drift tube (FDT) that was incorporated into the FA system [18.7]. This was a key feature of the new technique because it enabled the relative ion-neutral kinetic energy in the reaction region to be increased from thermal conditions to several electron-volts (eV) kinetic energy and allowed for precise control of the conditions within the chamber [18.6].

At the time of the experiments leading to the introduction of the FDT, concurrent studies by *Adams* and *Smith* at the University of Birmingham, UK made use of a quadrupole mass filter that was coupled to a FA system, being placed between the low pressure ion source and the FA region to allow single reagent ions to be preselected and injected via an aspirator into the flow tube [18.8]. In particular, the technique allowed these selected species – primarily either H_3O^+, O_2^+ or NO^+ – to be injected into the flow tube at sufficiently low energy to reduce fragmentation from ion collisions. Based on this feature of reagent ion preselection, *Adams* and *Smith* named their technique the selected ion flow tube (SIFT) and its initial exploits were in the investigation and characterization of ion-neutral reactions in the terrestrial upper atmosphere and in interstellar clouds [18.9].

This notion of selecting reagent ions prior to introduction into the flow tube reaction chamber was adopted in the FDT system of the NOAA group to create a selected ion flow drift tube (SIFDT) [18.10]. This combined system offered the advantage of providing a pure reagent ion beam, which was injected into the reaction chamber via a Venturi inlet aperture, with the versatility of the drift tube that employed an electric field to allow the ions to be accelerated to several eV kinetic energy [18.7, 10]. As with the SIFT-MS instrument, the selected ion flow drift tube mass spectrometer (SIFDT-MS) was operated extensively for studying ion-molecule reactions, rather than being used as an analytical detection system per se.

It was not until the mid-1990s that these CIMS techniques shifted in their use from basic research tools to applied analytical instruments for compound detection. Two decades after the SIFT-MS technique was introduced its use in the detection of the volatile constituents in exhaled breath was demonstrated, a research field that at the time was in its infancy and was certainly a niche discipline for the SIFT-MS device [18.11]; similar studies were performed using the SIFDT-MS instrument [18.12]. Around the same time, Werner Lindinger, Armin Hansel, Alfons Jordan and colleagues at the Institute of Ion Physics at the University of Innsbruck, Austria, replaced the preselection quadrupole mass filter of their SIFDT-MS system with a hollow cathode discharge ion source to generate hydronium – or more correctly, oxonium or hydroxonium – ions, H_3O^+, as reagent ions at a purity of $\geq 99.5\%$ that were channeled via a Venturi inlet into the downstream FDT; the high purity reagent ion production in the hollow cathode obviated the need for a preselection mass filter and its associated bulky vacuum pumping system, thus making for a more compact instrument. Because the chemical ionization within the FDT reaction chamber proceeded exclusively via proton transfer reaction (PTR) from the hydronium reagent ions to the neutral target analytes, the name proton transfer reaction MS (PTR-MS) was adopted for this new system [18.13]. Unlike the SIFT-MS instrument, the PTR-MS system was developed with the specific intention of use as an analytical detection system for VOCs, rather than for ion-molecule reaction kinetics studies. As such, key fields of application for this tool were identified and explored upon its conception [18.13–15].

The early developments of techniques leading to atmospheric pressure ionization (API) took place at a number of independent research laboratories, each with its own apparatus and specific mode of ionization, and proceeded independently from the advancements on the FA and FDT systems. Although experiments that made use of reaction chambers at atmospheric pressure were reported in the 1960s, the acronym API first appeared in the early 1970s in the studies reported by

Horning, *Carroll* and coworkers [18.16, 17]. In their system, a ^{63}Ni radiation source was used to ionize N_2 and reference compounds being injected directly into a pure nitrogen carrier gas flow. This system was deemed to be particularly suited as an ultrasensitive detector for gas or liquid chromatography systems [18.18, 19]. An alternative device with a corona discharge ionization source made use of a curtain gas to promote declustering of ions before they entered the mass spectrometer, which critically allowed humid air to be sampled and ionized directly [18.18–20]. It might be noted that inclusion of the term *chemical* in API, i. e., atmospheric pressure chemical ionization (APCI) was generally adopted to better distinguish between CI systems operating at very high pressures and other high pressure ion sources such as plasma discharges [18.20].

The developments and diverse applications of APCI-MS are reported in a number of comprehensive review articles [18.20–24]. For the purposes of this chapter, however, a critical development in conceptualizing direct sample injection for APCI-MS, as required for on-line analysis, was made in the late 1970s by *Lovett* and coworkers, who interfaced a mouthpiece sampler to a commercial APCI-MS system – the Trace Atmospheric Gas Analyzer (TAGA (Sciex Inc., Toronto, Ontario, Canada)) – for the real-time analysis of volatiles in exhaled breath [18.25]. Their breath analysis dilution inlet system comprised of a mouthpiece through which breath gas was exhaled and mixed via a tapered glass pipette into a carrier gas flow from a pressurised zero-grade air source for subsequent introduction into the TAGA instrument. Using this system it was possible to perform direct analyses of breath ammonia, as well as other metabolites and endogenous compounds such as acetone, within seconds, which was a major breakthrough compared to the several hours required in conventional breath analysis involving sample workup, derivatization, column separation, etc. Further developments of this direct sample injection system were reported by *Benoit* and colleagues, who constructed a breath inlet system that consisted of filters, valves and a chamber to mix breath gas with the carrier gas before sample introduction into the ion chamber of the atmospheric pressure ionization mass spectrometer (API-MS) [18.26]. The major progress introduced by this development was that the interface eliminated the high ammonia and its associated interferences that had been observed in the earlier system devised by Lovett and colleagues, yet achieved sufficient sensitivity to detect other species such as methanol and ethanol in exhaled breath.

Alternative samplers using either a membrane [18.27] or fiber [18.28] to improve the interface for breath analysis applications of APCI-MS – specifically for food-flavor applications – were also reported, both showing promising results for novel real-time assessment of aroma compounds during food mastication. A further critical development in APCI-MS and its application in the detection of odorants occurred in the mid-1990s when *Robert Linforth* and *Andrew Taylor* at the University of Nottingham, UK constructed a new sampling interface for the direct analysis of breath, which they named MS-Nose, that overcame the shortcomings of previous attempts by offering a minimal dead volume and fast linear flow rates for sampling [18.29, 30]. Their system comprised of a short length of deactivated fused silica capillary sheathed in a tube carrying a flow of nitrogen such that breath gas was transferred via a Venturi into the corona discharge ionization source. The advantage of this system was that it enabled continuous distal sampling of breath at a constant rate and in real-time, without the need to regulate the exhaled breath flow, as was demonstrated by in vivo analyses of the release of volatile flavor compounds in food applications [18.30]. Subsequently, alternative interfaces for direct injection of APCI-MS for optimized sampling have emerged, similarly showing excellent functionality for food-flavor release studies [18.31].

It is perhaps worthy of note that all three techniques emerged as on-line tools for the dedicated application of detecting volatiles in gas samples (rather than their use to study ion-molecule reaction kinetics) at approximately the same time, partly owing to the great degree of interaction and exchange of ideas between the pioneers of these techniques.

18.1.2 Sampling and Measurement

On-line CIMS techniques are unique in their ability to sensitively detect a wide range of compound classes over concentrations spanning several orders of magnitude and down to ultratrace levels in real-time. The general aspects of sampling and measurement that are specific to on-line CIMS techniques are briefly discussed here.

Chemical Ionization

The International Union of Pure and Applied Chemistry (IUPAC) defines chemical ionization as *the process whereby new ionized species are formed when gaseous molecules interact with ions* and *may involve transfer of an electron, proton or other charged species between the reactants* [18.32]. Although chemical ionization (CI) can proceed via both positive and negative ionization, in general the term CI refers to positive-ion CI, whereas negative-ion CI is specifically stated as such, i. e., NICI. This chapter considers only appli-

cations of positive-ion CI, as applied in the three main on-line CIMS techniques discussed herein. (It might be noted that NICI is also routinely employed in APCI-MS, albeit not extensively in on-line APCI-MS for odorant-related applications.)

In CI, rather than ionizing neutral target molecules via the bombardment of energetic electrons as in EI, by photons as in photoionization, or through a high-potential electrode as in field ionization, the process of ion-molecule reactions are utilized, which take place at lower energies and thereby cause less fragmentation of the target molecules upon charge acquisition [18.18]. The ionization energies encountered in CI generally range from thermal energies to only a few eV; by comparison, the conventional EI in commercial GC-MS systems typically occurs at energies of $\approx 70\,\mathrm{eV}$. As such, CI is referred to as a *soft ionization* method to indicate the less energetic nature of ionization. A direct outcome of this soft ionization process, as opposed to the wide range of molecular fragments known to be produced by EI, is that it frequently produces the molecular – or quasi-molecular – ion in quantifiable abundance and, as indicated above, the characteristic mass spectra of target analytes obtained by CI are generally stable, with limited interferences and high reproducibility.

Ionization of neutral molecules by CI can occur in one of four modes:

1. Proton transfer
2. Charge exchange (or transfer)
3. Anion abstraction, and
4. Electrophilic addition [18.18, 33].

The three main on-line CIMS techniques discussed in this chapter make use of proton transfer and charge exchange reactions, therefore types 3 and 4 will not be dealt with further here.

Reagent Ions and Proton Affinity

A common feature of all of the three on-line CIMS systems discussed here is their predominant use of proton transfer reactions for the ionization of neutral target molecules, more specifically their use of H_3O^+ as the reagent ion species. It is therefore pertinent here to briefly introduce and discuss the concept of proton affinity (PA). The IUPAC defines proton affinity (for a species M) to be *the negative of the enthalpy change in the gas-phase reaction … between a proton (more appropriately hydron) and the chemical species concerned …* [18.32], i. e., in the reaction $M + H^+ \rightarrow [M + H]^+$ *at a specified temperature, usually* 298 K [18.34]. Alternatively, it can be considered as the energy required to separate a proton, H^+, from a species, M, in the reaction $MH^+ \rightarrow M + H^+$. Broadly speaking, if a neutral molecule, M, encounters a protonated reagent, RH^+, the proton will be transferred to the neutral, i. e., $RH^+ + M \rightarrow MH^+ + R$ on the condition that the proton affinity of M is greater than that of R. A great benefit of employing proton transfer is that the reactions are exothermic, proceeding rapidly and with similar reaction rates that are close to the collisional rate of several $10^{-9}\,\mathrm{cm^3/s}$ [18.3, 35]. Moreover, these reactions generate singly charged product ions that are stable and rarely undergo further decomposition. By comparison, endothermic reactions are comparatively slow and less suitable for on-line applications.

The use of hydronium as the reagent ion species in proton transfer reactions is particularly propitious for the detection of VOCs in air because the proton affinities of the major constituents of air, i. e., N_2, O_2, CO_2, Ar, etc., are less than that of water and as such these neutral molecules do not undergo ionization upon collision with H_3O^+. Conversely, the proton affinities of most VOCs are greater than the PA of water – as summarized in Fig. 18.1 and compiled in the literature [18.36, 37] – and are thus ionized upon every collision. This fortuitously means that air (or pure N_2) can be used as the sample carrier gas without the need for prior dilution or filtering. Moreover, the high water vapor content in humid gas samples – such as exhaled breath – does not pose a problem in the analysis and can be accounted for by careful control and reduction of the amount of water entering the source [18.30], knowledge on the proton transfer and ligand switching reactions involving hydrated hydronium ions [18.38], or adequate calibration of the instrumentation [18.39, 40].

As indicated above, SIFT-MS, as well as an adapted PTR-MS system employing the selected (switchable) reagent ion (SRI) feature [18.43], make use of reactions from NO^+ or O_2^+ precursor ions. Whereas the reactions involving O_2^+ reagent ions proceed exclusively via charge exchange, several additional reaction processes can occur with NO^+, namely hydride, hydroxide or alkoxide ion transfer, or ion-molecule association reactions [18.44]. Charge transfer reactions from O_2^+ are highly energetic and produce multiple fragments of neutral analytes, making their use less suitable for general VOC analysis. However, the benefit of CI via O_2^+ – particularly with reference to odorant detection – is in their ability to ionize small molecules such as ammonia, NH_3, and carbon disulfide, CS_2, which are otherwise not detectable via PTR using hydronium ions. Additionally, charge exchange reactions from O_2^+ allow for the detection of some alkanes such as methane and pentane [18.44]. Ionization via NO^+ precursor ions results in the generation of unique fragmentation patterns for certain isobaric species, thereby aiding compound iden-

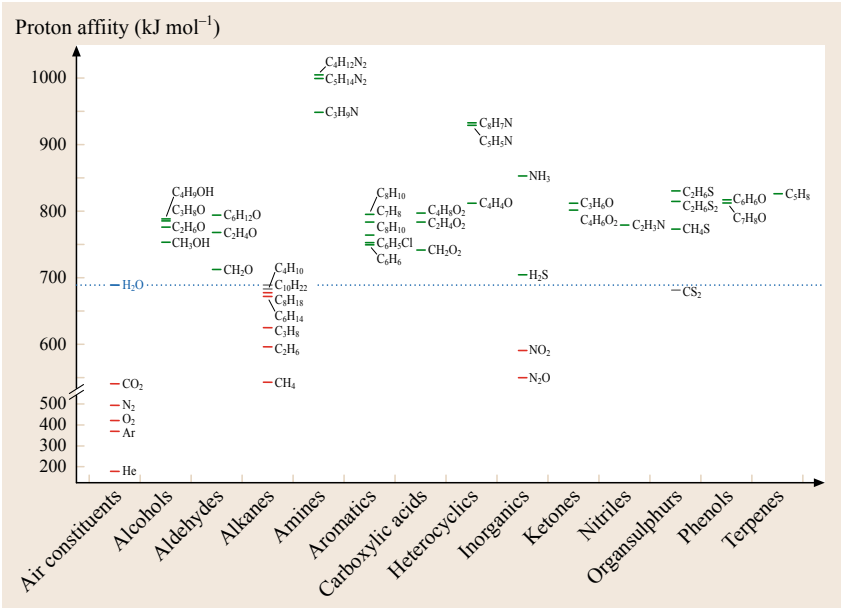

Fig. 18.1 Proton affinity (PA) scale indicating the position of water amongst the major constituents of air and selected (odorant) volatile organic classes (Fraunhofer IVV). Values taken from [18.37], [18.41] (alkanes), [18.42] ($C_6H_{12}O$, hexanal), and [18.38] (C_4H_4O, furan; C_7H_8O, *p*-cresol)

tification when used in combination with CI via H_3O^+ and O_2^+. Further discussion on the ion chemistry of the reactions involving O_2^+ or NO^+ with neutral molecules will not be included here but can be found in the literature [18.9, 43, 44]. Importantly, however, the combined use of these three precursors for the ionization of neutrals extends the analytical range and can improve compound identification, since techniques that use single reagent ions cannot discriminate between isobaric or isomeric analytes. Due to their limited and rather specific use, chemical ionization via other reagent ions such as Kr^+ or Li^+ will not be treated here, but can be found in the corresponding literature [18.45, 46].

Gas Sampling

By definition, on-line CIMS techniques allow for the real-time detection of volatile compounds present at trace levels in a gas matrix such as air. Correspondingly, air or other gases can be sampled directly without the prior need for dehydration or enrichment. This warrants an inlet sampling system that allows for a continuous delivery of the sample gas into the ionization or reaction chamber, which is commonly achieved by use of a small-diameter sampling line capillary – with inner diameter on the order of 0.25–1.5 mm – typically made of an inert material such as Teflon (perfluoroalkoxy (PFA) or polytetrafluoroethylene (PTFE)), polyether ether ketone (PEEK), or passivated stainless steel such as Silcosteel. The inlet line is generally heated to above-ambient conditions, ranging from around 40 to up to 150 °C to avoid condensation or compound adsorption within the sampling tubes. This offers the advantage that thermally labile compounds reach the ionization chamber intact, although compounds with low vapor pressure might adhere to the inner surfaces of the inlet system even at such elevated temperatures; these are typically oxygenated species such as large terpenoids and sesquiterpenes, furans, and carboxylic acids, amongst others. The flow of sample gas through the inlet system is usually variable, ranging from several tens of milliliters to a few liters per minute. The choice of sample gas flow depends on the measurement application: typically, slow flows are used to limit the perturbations of the sample equilibrium at source whereas fast flows might be employed in the assessment of rapid processes to minimize the residence time of a sample within the inlet system and effectively increase the detection response time.

The evaluation of odorant emissions from physical samples is generally achieved by sampling the headspace gas – that is, the gas immediately above and surrounding the sample – and analyzing its constituent odor compounds. In *static headspace* analysis the sample under investigation is placed within a closed container such as a glass vial under defined conditions and, after a period of equilibration, sample gas is withdrawn and analyzed accordingly. Although this mode of analysis provides relevant information by *fingerprinting* constituent odorants and quantifying relative abundances, it offers limited insights into the dynamics of emissions processes. The dynamic profiles of odorants released from specific sample matrices is of interest in many disciplines, for instance in flavor research for the aroma release from food, or in indoor air quality for the

emissions of odorants from building materials, as well as in several other applications described in this chapter. Although direct-injection GC-MS exists in the form of portable instruments, the standard benchtop GC-MS approach for such analyses is to perform intermittent gas sampling of the headspace gas of a solid or liquid sample, for example via purge-and-trap onto adsorbents or into vessels, or by adsorption onto fibers as in solid-phase microextraction (SPME). A further desorption step is subsequently required to release the analytes into the carrier gas and the chromatographic column, thereby creating an inherently discontinuous depiction of the dynamic release. In *dynamic headspace* analysis using on-line CIMS the headspace gas of a sample is measured continuously under defined conditions to generate a more detailed picture of the release kinetics. This uninterrupted sampling and the lack of the chromatographic step thus affords the dynamic analysis of a sample in a highly time-resolved fashion that is not attainable with GC-MS.

Measurement Principles and Modes

The majority of on-line CIMS instruments are equipped with a quadrupole mass spectrometer (QMS) which operates by means of establishing a defined electromagnetic field along the axis of the filter rods that allow specific ions – or rather, ions of specific m/z – to pass through to the detector. Accordingly, only single m/z per setting are transmitted through the mass spectrometer. This imposes a limitation on the detection speed, since the individual setting for each m/z and corresponding product ion must be cycled through sequentially, each for a minimal detection time on the order of a few tens of milliseconds, depending on the system and the abundance of the target compound. This is commonly referred to as the duty cycle of the QMS. These quadrupole-based systems can be operated in one of two modes, namely on an individual ion detection basis referred to as selected ion detection (SID), selected ion monitoring (SIM) or multiple ion detection (MID) mode (subsequently referred to as SID mode), or by a full scan of individual m/z over a predefined m/z range, known as *scan* mode. Each mode of analysis is suited to specific applications.

SID mode is generally used when the compounds are known a priori and allows for targeted dynamic profiling of single or multiple analytes. This analysis mode offers the benefit of a reduced sampling time, since only selected analytes are targeted. In addition, if only a few analytes are selected then the instrumental detection limit can effectively be reduced by extending the integration or dwell time of the MS, without compromising the detection time to any great extent. The integration time is the period for which the quadrupole filter is set to select a specific m/z value: extending this period increases the signal-to-noise ratio by allowing more time for trace analytes to reach the detector and correspondingly reduces the statistical noise of the signal at that particular m/z. Although a longer dwell time can be imposed in measurements made in scan mode, this introduces an extended analysis period due to the accumulation of the individual dwell times over the entire scan period.

Scan mode is typically employed when analyzing gas samples with unknown constituents. In this mode, the entire mass spectrum within a defined m/z range is measured, usually repeatedly, to provide clues to constituent compounds. Scans can be made continuously for monitoring purposes, albeit with a slower time resolution of measurements compared to SID mode, depending on the dwell time and m/z range selected. Generally, mass scan measurements are useful for full mass spectral fingerprinting of samples and are often accompanied by the subsequent application of data-mining tools to identify distinctive MS patterns that specifically relate to the sample properties of interest. This application is discussed in more detail in Sect. 18.2.1.

Replacement of the QMS with a time-of-flight (TOF) mass spectrometer has been tested for APCI-MS [18.30] and is available as a standard configuration in PTR-MS, i. e., PTR-TOF-MS [18.47]. TOF mass spectrometers rely on injecting an ion swarm into an electromagnetic field-free region under high vacuum. The ions enter the flight chamber with equal initial kinetic energy but become separated in space and time as they traverse the chamber due to their different velocities. This phenomenon allows the ions to be counted at the detector on the basis of their arrival time, that is, by their time of flight. The inherent difference between TOF-MS and QMS is that in TOF-MS only the *scan* mode of measurement exists per se, in that there is generally no filter for preselecting individual ions. Instead, all ions are pulsed into the flight chamber and it is a matter of the settings of the pulse-counting electronics as to which defined m/z range is included in the data acquisition and subsequent processing. This offers the distinct advantage that all product ion signals within the measurement range are registered without the need for their selection a priori, as is required in QMS. The rapid pulsing and flight times result in scan times of fractions of a second, thus entire mass spectra are gathered much more rapidly than in QMS [18.48]. Furthermore, the highly accurate registration of flight times afford a greater mass-resolving power that enables many isobaric compounds – that is, compounds with the same nominal mass but different chemical composition – to be separated [18.49, 50].

A third, alternative option to the use of QMS or TOF-MS is an ion trap MS. IT-MS-based systems offer distinct advantages over QMS, primarily related to the extended analytical range of several hundred m/z almost simultaneously, as well as the possibility to initiate collision-induced dissociation (CID) reactions that enhance the resolution by generating characteristic fragmentation patterns and thereby allow for isobaric compound separation in many cases. The details of IT-MS will not be discussed here and the reader is referred to several review papers on the topic [18.51–54], but it should be noted that IT-MS has been employed in some of the on-line CIMS techniques discussed here, from prototype to commercial instrumentation, notably APCI-ITMS [18.31] and PTR-ITMS [18.55–57].

18.1.3 On-line CIMS Techniques

Chemical ionization is exploited in a diverse number of on-line analytical instruments that utilize mass spectrometry, but in terms of prevalence three systems in particular have been at the forefront of scientific research over the past two decades, namely SIFT-MS, PTR-MS and APCI-MS, and are thus at the focus of this chapter. Schematic representations of each instrument are presented in Fig. 18.2.

Although these three techniques have found use in most of the branches of odor detection outlined in this chapter, historically each can be considered to dominate a specific field: SIFT-MS in breath gas analysis for medical purposes, PTR-MS in the environmental sciences and varied niche applications, and APCI-MS for food and flavor-related studies. This will become apparent in the weighting of citations to related studies throughout this chapter. Nevertheless, in recent years each of these CIMS techniques has diversified and proliferated in these major sectors, as well as other niche areas, as is evident in the ensuing discussion. Since the focus of this chapter is on the application of on-line CIMS to odorant detection, technical details of their operation is kept to a minimal here and the reader is referred to the cited literature for more detailed information.

A comparative review of the performances of APCI, SIFT, PTR-MS for the rapid monitoring and quantitation of biogenic VOCs of interest in food, medical and environmental sciences has been published [18.58], summarizing the key technological differences and providing examples of applications to these fields. Table 18.1, adapted from the above, provides a useful overview of the main technological features and differences between the three on-line CIMS techniques reviewed in this chapter.

Selected Ion Flow Tube Mass Spectrometry, SIFT-MS

Selected ion flow tube MS, SIFT-MS, combines the use of proton transfer reactions from H_3O^+ and charge exchange reactions from NO^+ and O_2^+ for the detection of gas-phase organic compounds in diverse applications. Unlike proton transfer reactions, charge transfer involved in the reactions of neutrals with NO^+ or O_2^+ are more energetic and generally incur a greater degree of fragmentation of the target molecule. However, this is a desirable effect that is exploited in SIFT-MS to separate isomeric species and improve compound identification in the mass spectra of unknown gas mixtures based on known fragmentation pathways. Generation of the three main precursor ions is achieved in an external ion source – typically a microwave resonator – from which the reagent ions are selectively transferred into a flow tube via a preselection QMS (Fig. 18.2a) [18.11]. At the exit of this mass filter these primary ions are injected into a fast-flowing inert carrier gas – usually pure He at ≈ 100 Pa (or ≈ 1 Torr) – via a Venturi-type orifice and travel as a thermalised ion swarm along the length of the flow tube. Sample gas containing the neutral target compounds is added to the downstream flow and these constituents interact and react with the reagent ions to form positive products that allow for subsequent mass filtering and detection via a channeltron multiplier/pulse counting system [18.38]. The early use of SIFT-MS to study the ion chemistry of ion-neutral reactions has generated a database containing kinetic data on thousands of ion-molecule reactions, which is of great value in understanding the mass spectra produced when detecting trace gas constituents and offers a means for broad quantitation of these compounds from a theoretical approach, without the imperative need for calibration.

The literature contains a wealth of information on the operational aspects and ion-neutral kinetics taking place in SIFT-MS and the interested reader is referred to these for more detailed reading material [18.11, 38, 44].

Proton Transfer Reaction Mass Spectrometry, PTR-MS

Proton transfer reaction MS, PTR-MS, traditionally makes use of proton transfer reactions from hydronium reagent ions to neutral target molecules [18.13], although the recent introduction of the selective (or switchable) reagent ion (SRI) feature of the commercial instruments has broadened the ionization regime to alternatively utilize charge exchange reactions via NO^+ or O_2^+ (as in SIFT-MS) and other reagents such as Kr^+ [18.43, 45, 61]. The PTR-MS instrument comprises a separate front-end ion source to gener-

ate the necessary reagent ions that are subsequently transferred to a flow drift tube (FDT) region wherein they encounter the neutral analytes of the sample gas (Fig. 18.2b). Reagent ion generation is typically achieved to a high degree of purity ($\geq$ 99.5%) using a hollow cathode discharge ion source [18.13], although direct current discharge [18.59] and ^{241}Am radioactive ion sources also exist [18.60].

Sample gas containing the volatile targets at trace concentrations is added to and flows through the FDT of the PTR system whereupon it encounters the reagent ions emerging from the ion source that drift along the tube by means of the applied electric field, typically at 40–60 V/cm. Proton transfer reactions occur upon every collision of a hydronium ion and neutral analyte within the sample gas and the ionized target molecule is subsequently subjected to the electric field and drifts with the precursor ions axially along the reaction chamber. Ions reaching the end of the drift tube are channeled by means of ion transfer lenses into the

Table 18.1 Comparative overview of the main features of SIFT-MS, PTR-MS and APCI-MS (after [18.58])

Feature	SIFT-MS	PTR-MS		APCI-MS
		PTR-QMS	PTR-TOF-MS	
Ion source	Corona discharge	Hollow cathode discharge[a]		Microwave discharge
Reagent ion[b]	H_3O^+, NO^+, O_2^+	H_3O^+ (NO^+, O_2^+)[c]		$(H_2O)_nH^+$
Buffer gas	He	Air (sample matrix)		N_2 (dry)
Sample dilution	Yes	No		Yes
Reaction region	Fast flow tube	Flow drift tube		None
Mass analyzer	Quadrupole	Quadrupole	Time of flight	Quadrupole, QqQ
Detector[d]	SEM	SEM, MCP[e]	MCP	SEM

[a] Direct current discharge [18.59] or radioactive α-particles [18.60] have also been reported.
[b] Refers only to positive ionization mode: negative ionization is available in both SIFT-MS and APCI-MS.
[c] NO^+ and O_2^+ modes are available through use of a selectable reagent ion (SRI) interface [18.43].
[d] SEM, secondary electron multiplier; MCP, microchannel plate; QqQ, triple-quadrupole
[e] Most PTR-QMS instruments use an SEM, but some are equipped with an MCP.

mass spectrometer, where they are separated according to their m/z and transferred to a detection system. The conventional PTR-MS systems operate a quadrupole mass filter – and are thus sometimes also referred to as PTR-QMS – but recent adaptations have included coupling the PTR reaction chamber with a time-of-flight (TOF) mass spectrometer to create a PTR-TOF-MS [18.47, 62]. This development offers the distinct advantages of TOF mass spectrometry to the PTR technique, namely a high mass resolving power – at least three orders of magnitude greater than the conventional PTR-QMS system – and the rapid (instantaneous) analysis of a complete mass spectrum. The detection of ions passing through the mass filter is achieved via a secondary electron multiplier (SEM), in PTR-QMS or a microchannel plate (MCP) in PTR-TOF-MS. It is also worthy of note that the combination of PTR with ion trap mass spectrometers has been investigated, but since no broad application to odorant detection has been made it will not be further discussed here: the interested reader is referred to the literature reports on these developments [18.55–57, 63, 64].

The use of a drift tube, i. e., the application of an electric field to the flow tube, allows the ionization energy to be controlled to some degree, with typical ion kinetic energies of 1−2 eV. The reaction rates for proton transfer reactions are generally well known from literature reports or from theoretical calculations based on the polarizability and permanent dipole moment of the neutral targets. This enables quantitation of the neutral analytes via calculation, although the accuracy can be greatly improved to between ±15−30% by calibration of the system [18.35, 65]. In this context, it should be noted that the primary gas composition of the sample being analyzed can affect the ion energetics within the FDT reaction chamber due to altered ion mobility. Unlike SIFT-MS or APCI-MS, which employ high flows of separate buffer gas comprising He or N_2, respectively, in PTR-MS the sample gas itself acts as the buffer gas. As such, the choice of sample gas composition is of importance. To give an example, exhaled breath or the exhaust gas from a fermentation tank contain elevated levels of carbon dioxide and water vapor, typically several per cent, both of which are known to affect the ionization processes and lead to clustering within the drift tube [18.66]. Although this is a critical issue, such changes can easily be accounted and corrected for by appropriate normalization of the signal response at the detector [18.67, 68] or by calibration of the instrument using the same primary gas matrix composition [18.39].

Further details on the operating principles of PTR-MS and the varied applications of this technique can be found in review articles [18.35, 69] and in a recently published comprehensive textbook on PTR-MS [18.70].

Atmospheric Pressure Chemical Ionization Mass Spectrometry, APCI-MS

Atmospheric pressure chemical ionization MS, APCI-MS, in the context of this chapter, is a technique that employs proton transfer reactions from protonated water reagents for the chemical ionization and subsequent detection of VOCs. In APCI the ions undergo thermalization by soft collisions that effectively offer a channel drain for the excess energy in the exothermal protonation reaction [18.33]. As such, APCI is typically a softer ionization process than in conventional CI and is especially sensitive for the detection of basic compounds (referring to gas-phase basicity), or those with low ionization energies; conversely, APCI is insensitive to many nonbasic compounds and these are often not detectable [18.3]. Although different manifestations of APCI-MS have found widespread use as detectors in liquid and gas chromatography (LC and

GC, respectively), the on-line APCI-MS technique that is discussed here is a system that enables the direct, continuous and real-time analysis of gas-phase volatiles.

Unlike SIFT-MS and PTR-MS, APCI-MS does not include a separate ion source but rather the process of precursor ion formation, charge exchange and clustering proceeds in one small region [18.71]. Sample gas is introduced into the reaction chamber via a Venturi nitrogen flow that ensures adequate dilution and control of humidity in the sample gas (Fig. 18.2c). The mixing ratio of this flow is approximately 5–50 ml/min sample gas into 10 l/min nitrogen flow [18.30]. The reagent ion plasma within the reaction region is generated and maintained by a corona discharge between a corona pin and the chamber that serves as the counter electrode, which is typically held at 4 kV [18.33]. Precursor ions are formed in this discharge region by the ionization of the sample air constituents to predominantly form hydronium ion water clusters, $H_3O^+(H_2O)_n$ [18.72], which subsequently protonate neutral organic target analytes present in the sample gas according to the conditions imposed by their proton affinities, as discussed earlier. Reagent and product ions are then transferred into the detection system via a mass filter, usually a QMS, although tests with TOF-MS and IT-MS have also been performed [18.30, 73]. Improvements in sensitivity for the detection of compounds in humid gas samples – specifically in relation to food aroma compounds measured in exhaled breath (i. e., nosespace analysis; Sect. 18.2.1) – have been achieved by humidifying both the sheath and auxiliary gases (relative humidity 88–98%) [18.74]; compared to dry conditions, where strong fragmentation of the target molecules is observed, humidification results in the production of the protonated parent ion in the majority of compounds tested.

Technical details of the construction of on-line APCI-MS and the processes of ionization and detection, as well as its applications, can be found in the literature [18.30, 31] and in patent documents [18.29].

Other On-line CIMS Techniques

Ion molecule reaction MS, IMR-MS, is an on-line CIMS technique that closely reflects the operating principles of SIFT and PTR. Unlike those methods, however, IMR-MS utilities primary ions generated from inert gas – either Hg, Xe or Kr – via EI for subsequent ion-molecule reactions with neutral analytes [18.75, 76]. A preselection mass filter downstream of the ion source, similar to SIFT-MS, is used to channel a high-purity ion beam into the IMR chamber. The technique was developed at the University of Innsbruck, Austria and, like PTR-MS, was derived from the SIFDT-MS studies on ion-molecule reactions undertaken in the Institute of Ion Physics laboratories in the early 1990s. IMR-MS has achieved good commercial success as a trace gas analyzer, particularly in the automotive engineering industry for exhaust gas emissions measurements and in the beverage industry as a rapid quality-control tool for monitoring impurities in recycled bottles, to name but a few. The direct application of IMR-MS in the detection of odorous compounds per se is limited to date, thus this CIMS-based method will not be discussed further in this chapter.

Ion mobility spectrometry, IMS, is a method for characterizing chemical substances according to their gas-phase ion mobility [18.77]. Chemical ionization is induced by collisions of the analyte with ionized carrier gas molecules (N_2 or air), mainly produced by radioactive β-radiation sources. Strictly speaking, IMS is not a mass spectrometric system in the classical sense in that it does not involve the discrete separation of charged molecules by a mass filter, but rather utilizes the combined properties of the mobility and m/z of analyte ions. The analysis is achieved by subjecting the analyte ions – generated in a front-end ion source – to a drift tube of fixed length and defined electric field strength at ambient pressure and determining their drift time, which is proportional to the inverse of their mobility. An ion swarm drifting under such conditions experiences a separation process that is based, amongst other instrumental parameters, on the dimension, structure and ion mobility constant of the individual ions, dictating their drift velocities. The ions are then detected upon impaction on a terminating Faraday plate. Because of the structural dependencies it is possible to separate isomeric (but not enantiomeric) ions, thus the resulting ion mobility spectrum contains information on the nature of the different trace compounds present in the sample gas. Due to the occurrence of ion-molecule reactions and the relatively poor resolution of the species formed, IMS is generally not used to identify unknown compounds, but it is being increasingly applied to cases where the volatiles investigated are known. It has been used extensively in the detection of various species, including odorants, in diverse fields of application, as is indicated in the relevant sections of this chapter, and is in widespread use for safety and security applications [18.78]. For more details on the IMS technique the interested reader is referred to the review articles available in the literature [18.79, 80].

Ion attachment mass spectrometry, IAMS, is a less prevalent CIMS technique that utilizes lithium ion (Li^+) attachment to produce mass spectra consisting solely of quasi-molecular ions [18.46, 81]. The method was originally developed by adapting a commercial APCI-MS system to include a lithium ion source to produce Li^+ for subsequent use in the chemical ioniza-

tion reaction chamber [18.81, 82]. Li^+ IAMS has been successfully demonstrated to detect organic compounds at trace concentrations in air, including the detection of aroma compounds from strawberries [18.83], as is briefly discussed in Sect. 18.2.1.

Hybrid Techniques

A major drawback of the on-line CIMS techniques is the inherent difficulty in compound identification within the mass spectrum of complex gas matrices such as food headspace, exhaled breath or environmental odor plumes, i. e., gas mixtures in which the constituent volatiles are not known a priori. This is chiefly due to the limited amount of chemical-structural information inferable from the m/z values of quasi-molecular ions or their isotopic distribution patterns, but is also a consequence of the low (nominal) mass resolution of the QMS fitted in most CIMS instruments, causing a certain degree of signal overlap from individual isobaric compounds or fragments. Furthermore, the lack of a chromatographic separation step prevents the elucidation of stereoisomeric odor-active compounds, since enantiomeric VOCs cannot be resolved by CIMS.

Although compound identification can be aided by the use of different precursor ions, for example as in SIFT-MS [18.84] and in PTR-MS operating with the SRI feature for the discrimination of isomeric compounds [18.60], or by the implementation of high resolution MS systems as in PTR-TOF-MS for the separation of isobars [18.47], the unequivocal identification of many (or most) compounds within complex VOC mixtures is seldom achievable by CIMS alone. The developments of hybrid techniques that interface GC systems to CIMS instruments have addressed this issue, although this is invariably achieved at the cost of the fast time resolution and real-time detection. A brief report on these developments is given, but will not be discussed at length in view of their limited reported use in odorant detection to date.

Gas chromatography (GC) is the analytical gold standard for odorant detection. The technique is discussed in detail in another chapter of this book (Chap. 17), but its key features are briefly recapitulated here. In GC, constituent gas-phase molecules in a sample become separated as they are purged through a chromatographic column. This flow contains intermittently eluting compounds that are continuously transferred to an MS in which individual compounds undergo EI (or CI, depending on the application and analytical intention) to produce characteristic mass spectra that are matched with well-defined elution times. The combined knowledge of this time, referred to as the *retention time* – or in combination with reference compounds, the *retention index* – and the fragmentation pattern allows for compound identification to a high degree of reliability. The characteristic EI mass spectra of thousands of VOCs are well known and available in diverse libraries, as are the retention indices of numerous compounds within defined chromatographic columns. An additional feature for odorant detection is GC-olfactometry (GC-O) in which the flow exiting the column is split in parallel to the detector (an MS or a flame ionization detector (FID)) and to an odor detection port that allows olfactometric detection of the eluting odorant by the human nose, thereby providing an additional dimension in characterizing each compound in terms of the odor impression it elicits.

The advantages offered by GC-MS make this technique an obvious choice for coupling with on-line CIMS techniques. This combination has been made for SIFT-MS [18.85], PTR-MS [18.86–88] and APCI-MS [18.89] with good success, but the downside of these systems in the past was the inherent loss of the real-time detection feature. An alternative hyphenated system that was recently developed coupled a short GC column to a PTR-TOF-MS instrument and allowed for inline switching between direct and GC analysis, with chromatographic separation possible within 90 s due to the resistive heating capability of the column at a rate of 30 °C/s [18.90]. This *fastGC* approach offers a promising compromise between obtaining real-time data and achieving compound identification. In the aforementioned study, the system was used to analyze volatiles present in the headspace of wine, with GC separation indicating that several groups of isomeric (aroma) compounds were present in the wine headspace. Furthermore, channeling the sample via the fastGC interface offered the additional advantage of 'removing' ethanol – which commonly causes a problem in PTR-MS analyses of alcoholic beverages when present in high amounts due to sequestration of reagent ions [18.91, 92]; see Sect. 18.2.1 – due to its early elution from the column, thus allowing for the subsequent unhindered detection of trace aroma compounds. This fastGC-PTR-TOF-MS system has also been demonstrated to be suitable for the headspace analysis of other beverages, as discussed in a recent review article [18.93]. Another alternative GC-type interface approach is the use of a multicapillary column (MCC), analogous to that used in IMS [18.94]. The MCC is constructed of approximately 1000 single, tightly packed capillaries for parallel separation of volatiles in a gaseous sample. This construction allows sufficient gas flow for directly interfacing with PTR-MS without the need for an additional carrier gas flow and offers a complete analysis every 5–10 min. The coupled MCC-PTR-TOF-MS system has been successfully demonstrated in a number of applications, including the

unambiguous detection of individual aldehydes within a mixture, as well as the separation of ketone isomers [18.94].

18.1.4 Instrumental Performances

The capability and suitability of a given analytical method for its intended task is typically expressed in terms of its performance parameters. For the purpose of this chapter this is defined as the ability of an instrument to detect a substance of interest at a given concentration level and within the dynamic range of measurement. The most important performance parameters for the on-line CIMS techniques reviewed here are defined in the following.

Definitions

Sensitivity is a measure of the intensity of the signal response to a given stimulus. For the on-line CIMS techniques discussed here the stimulus is a VOC at a specified concentration and the signal response relates to the counting unit of the detection system, typically given as a current, for example milliampere (mA), or converted to a response frequency in counts per second (cps) or Hertz (Hz). The sensitivity is then expressed as the response per unit concentration, thus is typically reported as cps ppb_v^{-1} or similar; in this notation the sensitivity represents the signal intensity in cps for the detection of a 1 ppb_v stimulus of the target compound. Sensitivities are compound-dependent and can be determined via calibration of the system using certified gas standards containing the compounds of interest [18.39].

Limits of detection and *quantitation* (LOD and LOQ, respectively) give a measure of the lowest analyte concentration that can be reliably detected and quantified. The LOD of on-line CIMS instruments is generally defined as the minimum gas-phase concentration at which a compound elicits an instrumental signal that can be significantly distinguished from instrumental noise, the latter being the signal in the absence of a stimulus. Typically, this is determined by measuring blank gas matrices containing no VOC analytes, and the resulting instrumental signal is referred to as the noise level; the LOD is generally given as three standard deviations above the noise, i. e., a signal-to-noise ratio of 3. By comparison, the LOQ is defined as the minimum analyte concentration that can be reported with a defined confidence level, commonly 95%. LOQ is typically stated as 3.3 × LOD, or 10 times the standard deviation of the blank. For the on-line CIMS described here, LOD and LOQ are VOC-dependent but are mostly in the ppt_v to ppb_v range.

Dynamic range (of measurement) is the concentration range of a given analyte that is linearly proportional to the instrumental signal response: for the on-line CIMS techniques considered here it spans from the LOD (ppt_v or ppb_v) to a few tens of ppm_v, above which the ion-molecule reactions that underlie these methods might deviate from the prescribed kinetics and yield compromised results.

Mass resolving power is a parameter of the mass spectrometer, indicating the ability to distinguish between ions of different exact mass. The commonly adopted definition of mass resolving power R is based on the full-width at half maximum (FWHM) of the mass spectral peak and is given by

$$R = \frac{m_{\text{nominal}}}{\Delta m_{\text{FWHM}}} \,. \tag{18.1}$$

For two ions with nominal peak centers at m_{nominal}, the term m_{FWHM} represents the minimum separation of peak centers at FWHM that allows the two ions to be clearly discriminated. Note that R is mass-dependent and thus varies with the compound measured. Since the on-line CIMS systems reviewed here are commonly fitted with quadrupole mass filters (with the exception of PTR-TOF-MS, PTR-ITMS and APCI-ITMS), the achieved mass resolving power is limited to unity, that is, only integer m/z are measured and thus nominally isobaric compounds cannot be resolved. An exception is offered by PTR-TOF-MS, whereby the TOF-MS affords a mass resolving power of several thousand (> 5000–10 000, depending on the system [18.95]); thus, provided the separation between the FWHM of two neighboring peaks is sufficiently large, the center of the peaks yields the measured mass with an accuracy sufficient for determining the chemical composition of many volatile (odor) compounds [18.49, 50]. Likewise IT-MS-based systems such as APCI-ITMS allow for greater resolution due to the MS^n capabilities [18.31, 74, 96].

Specificity relates to the ability of a technique to accurately (unambiguously) detect a specific compound. This poses problems in PTR-QMS and APCI-MS due to their employment of a quadrupole mass filter, which imposes limitations in the ability to separate isobaric and isomeric species (cf., *mass resolving power*). Although SIFT-MS also incorporates a QMS, separation of such species is achieved to a reasonable degree of success by the interchangeable use of NO^+ and O_2^+ (together with H_3O^+) reagent ions for charge exchange reactions of analytes, which typically produce varying and distinguishable fragmentation products. PTR-SRI-MS makes similar use of these alternative reagent ions to the same effect. PTR-TOF-MS offers separation of isobaric species due to its high mass resolving power. A combined PTR-SRI-TOF-MS system thereby makes the unambiguous detection of many isomeric and isobaric

Table 18.2 Compound classes of volatiles that are generally detectable by SIFT-MS, PTR-MS and APCI-MS, including example compounds and their descriptive characteristic odor attributes

Compound class	Subgroup	Example compound[a]	Typical odor attribute
Inorganic		Ammonia[b]	Ammonia, pungent
		Hydrogen sulfide	Rotten eggs
Alcohols		Methanol, ethanol, butanol	Ethanolic, alcohol
Aliphatic hydrocarbons[b]	Alkanes	Methane, ethane, propane, butane, pentane, hexane	odorless, gasoline
Amines		Trimethylamine, putrescine, cadaverine	Fishy, putrid
Aromatic hydrocarbons	Single-ring	Benzene, toluene, xylene	Gasoline
	Chlorinated	Chlorobenzene, tricholoroethene	Chlorine, solvent
Carbonyls	Aldehydes	Formaldehyde[b], acetaldehyde, hexanal, octanal, 2-methylbutanal	Green/grassy, soapy/citric, malty
	Ketones	Acetone, 2,3-butanedione	Solvent, butter, sweet
Carboxylic acids		Formic, acetic, butanoic acid	Acidic, vinegar, rancid
Esters		Butyl acetate, butyl formate	Fruity, flowery
Heterocyclic hydrocarbons	Aromatics	Pyridine, indole, skatole	Fecal
Nitrogen oxide[c]		NO_2, N_2O	Pungent, irritating, sweet
Phenols		Phenol, *p*-cresol	Ink, fecal
Organosulfur	Reduced sulfur	Carbon disulfide	Rotten eggs
	Disulfides	Dimethyl sulfide, disulfide, trisulfide	Decaying cabbage, garlic
	Thiols	Methanethiol	Rotten, sulfuric
Terpenes, terpenoids		Isoprene	
	Monoterpenes	α-Pinene, (R)-/(S)-limonene, 3-carene	Woody, citric, sharp-pungent, musty
	Sesquiterpenes	Caryophyllene, farnesene	Carrot, parsley, earthy

[a] Common compound names are given.
[b] Compounds not detectable by proton transfer from H_3O^+ due to their lower/similar proton affinities to water. This includes alkanes of chain length $< C_8$, alkenes, cycloalkanes of chain length $< C_5$, ammonia, formaldehyde, amongst others. Such compounds may be detectable via charge exchange using O_2^+ and/or NO^+ (i. e., in SIFT-MS and PTR-SRI-MS)
[c] Not detectable.

species possible, in principle; an addition of the fastGC system extends this ability further. APCI-ITMS makes use of the MS^n feature of the ion trap for fragmentation under well-defined conditions, with many odorants demonstrating unique fragmentation, thus making their unambiguous detection possible [18.97].

Accuracy reflects the proximity of a reported measured value to the estimated *true* value. This is generally assessed by means of a calibration of the system. Calibrations of on-line CIMS are typically performed by repeated measurements of VOC standards carrying certified purity and concentrations, which are sequentially diluted with a VOC-free carrier gas to produce well-defined concentrations of the analyte [18.39]. The latter procedure is also adopted for establishing the quantitative performance, or sensitivity, of an instrument, i. e., to assess the instrumental response to a given VOC stimulus concentration. For the on-line CIMS techniques included here, the quantitative accuracy of known and unknown analytes ranges from approximately ± 10 to $\pm 50\%$ depending on the technique and whether or not an external calibration is performed by means of certified VOC standards. In this sense, an accuracy of $\pm 10\%$ indicates that the reported concentration measured is within 10% of the true concentration.

Precision is a measure of the agreement among replicate measurements of a reference sample under prescribed and repeatable analytical conditions. Alternatively, it is the degree of deviation from a continuous stimulus at a constant concentration, for example by fluctuations in the stability of the signal. Since VOC measurements by on-line CIMS systems typically do not entail sample workup steps, the precision is mainly affected by the sampling mode, for example dynamic versus static headspace. A precision of, say, 2% indicates that the signal for a given constant stimulus fluctuates by only 2%.

Response time is defined as the time required for the system to respond to or detect a change in the stimulus after this change has physically occurred. This parameter is dominated by the gas flows of the inlet system and the corresponding residence time of sample gas in the inlet before reaching the detection region. For the techniques reviewed here, this is typically in the range of fractions of a second, for example 85 ms reported for PTR-QMS [18.98].

Classes of Odorants Detectable by On-line CIMS

Many important odors – or rather, odorants – can be suitably investigated by using the sensitive, real-time CIMS techniques described here. The soft ionization via diverse precursor ions imparts selectivity and produces relatively simple (*clean*) spectral patterns. Mass spectral interpretation and chemical identification is often possible for experienced users without recourse to dedicated MS software, as is generally required for EI spectra interpretation in MS, and this knowledge of reaction schemes and kinetic parameters allows for absolute quantitation in real-time, often with acceptable accuracy. As with all analytical systems, each technique offers its own advantages and disadvantages over the other. An overview of the classes of volatiles generally detectable by the three on-line CIMS techniques of SIFT-MS, PTR-MS and APCI-MS, with examples of common odorants falling in these classes, is given in Table 18.2.

18.2 Applications

The diverse on-line CIMS techniques discussed in the present chapter have varied fields of application. Their implementation for the detection of nonodorous VOCs inevitably is more extensive than their use for odor-active compounds owing to the fact that they are sensitive to most volatiles regardless of the odor activity of the compound. This section focuses on selected applications of on-line CIMS that are primarily relevant to the detection of odor-active compounds, although some nonodorous applications are included for completeness. Studies include the measurement of atmospheric or biogenic VOCs relevant to the environment and climate, security applications such as the detection of illicit drugs or chemical warfare agents, and medical research by investigation of breath-borne volatiles, amongst many others.

18.2.1 Food and Flavor

The most common, frequent and regular exposure of human beings to odorous molecules is from food-related odors, more appropriately aroma compounds. A western diet traditionally involves three meals per day, which equates to over one thousand regular and distinct annual encounters with a suite of odorants, notwithstanding meals being interspersed with flavorful snacks or beverages. As such, food consumption is one of our primary and most important interactions with odorous molecules, particularly in view of its mostly positive associations. The reader is referred to other chapters in this book for more in-depth accounts of food flavors and their physiological and psychological effects on us as consumers.

Research on food-related aromas has been a prominent area of on-line CIMS research over the last two decades. The real-time detection capabilities of these techniques make them essential tools for investigating dynamic changes associated with aroma release from foods. Unlike GC-MS that requires samples to be pretreated via extraction, enrichment and water removal, which greatly limits the sampling frequency to several minutes at best, on-line CIMS techniques enable samples to be analyzed without preconditioning, resulting in sampling frequencies of several hertz (Hz), as outlined above.

Due to the very nature of the food and flavor research applications of on-line CIMS necessarily detecting odor-active (aroma) compounds, and the growing prevalence of these techniques in this field, it is impossible to provide a comprehensive treatment of all published food-flavor studies in the confines of this subsection, which would be a chapter in itself. As such, an overview will be given here based on representative studies and highlights of recent years.

Food and flavor studies using on-line CIMS can be essentially placed in two categories: in vivo or nosespace analysis, and in vitro or headspace analysis. The former allows for the degree of aroma release during food consumption to be studied, relating the dynamics to the properties of the food matrix, consumption behavior and sensory impressions experienced by the consumer; the latter offers the opportunity to study retention and release of aroma compounds for different formulations, to examine degradative processes such as oxidation and microbial spoilage during storage or, when used in combination with multivariate analysis, allows a screening of products to potentially categorize their type, place of origin, or authenticity. These main investigative aspects will be discussed in the individual subsections here. The rapid measurement capabilities of on-line CIMS are essential for both types of studies. In in vivo studies, the release of aroma molecules from a food matrix is detected during the mastication of the food and thus requires fast detection. Equally, the on-line capabilities allow for flavor release of model systems to be assessed via headspace analysis, for instance during storage under different conditions, or to evaluate the aroma compounds experienced by consumers prior to consumption (e.g., the bouquet of a wine or the aroma of a freshly brewed coffee).

The development of the MS-nose interface for APCI-MS in the mid-1990s had the specific intention of enabling the technique to be used for flavor release studies (Sect. 18.1.1); similarly, one of the key areas of application of the PTR-MS in the same period was food-flavor release. By comparison, SIFT-MS has seen its application to flavor studies only relatively recently, but is equally rapidly becoming a recognized tool for flavor release studies. Nevertheless, APCI-MS and PTR-MS dominate the subdiscipline of real-time flavor release, as is evident from the related studies cited here.

In general, APCI-MS and PTR-MS have been well characterized for their detection of individual aroma compounds. (It might be noted that there are extensive SIFT-MS studies on its detection of VOCs reported in the scientific literature, but these mostly are not specifically on odorants.) There are many papers in the scientific literature that report on characteristic mass spectra (fragmentation patterns) of individual aroma compounds at different instrumental operating conditions, as well as with regard to signal response linearity and limits of detection [18.30, 99–103]. Some researchers have performed direct comparisons between APCI-MS and PTR-MS: one such study indicated similar performances of both techniques for volatile aroma compound detection [18.104], whereas another study claimed APCI-MS to have a 10-fold lower LOD and 10-times broader dynamic range than PTR-MS [18.105]. The author of the latter study attributed the poorer performance of the PTR-MS to a high degree of fragmentation, but noted that the settings could be optimized for aroma compound detection: it might be noted here that the PTR-MS operating settings used in the latter study were indeed not those typically used for food-flavor studies, and this offers a note of caution in that the settings of any of the on-line CIMS techniques discussed in this chapter must be optimized for the specific area of application. Studies have also compared individual on-line CIMS techniques with other tools such as GC-MS, e.g., in relation to the detection of volatiles from meat and meat products using SIFT-MS and SPME-GC-MS [18.106], during dry fermented sausage processing [18.107], and for the aroma analysis of dried red bell peppers [18.108], whereby PTR-MS in the latter study was found to produce data that was more comparable to GC-MS and GC coupled with flame ionization detection (FID) than APCI-MS.

Food Headspace Analysis

A key driver of aroma release from food systems is the hydrophobicity and lipophilicity of the odorant in question. Food matrices – both solid and liquid – have high diversity in terms of their nonvolatile composition and rheology, which dictates the degree of release of specific aroma compounds during production, storage, preparation and consumption. As such, the potential for on-line CIMS to study flavor release in model and real systems, both in vitro and in vivo, is seemingly endless. Indeed such studies reported in the scientific literature already number in the hundreds, thus cannot be covered fully here, but rather just a selection of typical applications is presented.

In vitro analysis of foods by on-line CIMS is used to either monitor individual, targeted compounds over time, for example, in view of aroma development or as quality markers (e.g., to indicate spoilage; see related section on food spoilage), or is applied to analyze the entire suite of volatiles in the headspace of the food, typically with subsequent multivariate data-mining analysis to discriminate samples. These two modes of application will be treated briefly here, after first discussing basic studies on flavor release.

Flavor Composition and Release. In headspace analysis one of the key parameters that determines the detection of aroma compounds is the degree of partitioning from the solid or liquid phase of the food matrix to the gas-phase in the headspace. This phenomenon is driven by many factors that include the physicochemical properties of the volatile compound in question and the formulation of the food matrix from which it is released; for the latter, the phase (liquid, solid, foam, gel), pH, relative composition of nonvolatiles such as sugars, proteins, fats, amongst other factors, is decisive (Chap. 13). Conveniently, the rapid analytical capabilities offered by on-line CIMS allow for partitioning to be purposely studied in relation to these factors. In liquid systems, dedicated analyses using stripping cells in both model [18.109] and real systems (coffee) [18.110] provide invaluable information on Henry's law constants that can support explanations for the mechanisms involved in flavor release and perception. The influence of the food matrix composition on aroma release and the resulting partitioning coefficients have been studied for numerous model formulations, including in gelatine, starch and pectin gels with a correlation to their sugar composition [18.111], textural properties such as strength [18.112] and elasticity [18.113, 114], and mechanical treatment [18.115], for oil-in-water emulsions [18.116, 117], low and high viscosity aqueous solutions with different sugar and bulking agent compositions [18.118, 119], in carbohydrate model systems and the influence of buffer and temperature [18.106], and in hydrating powders, focusing on the impact of protein, lipid and carbohydrate composition [18.120]. The extent of aroma release in relation to the degree of carbonation in liquid systems has also been studied, for

instance in PTR-MS measurements that followed the release of six aroma compounds from an artificial throat model, whereby it was demonstrated that increased carbonation typically promoted aroma release, the extent of which was dominated by the physicochemical properties of the compound [18.121].

Many studies use a model mouth or artificial throat to simulate in vivo conditions and monitor flavor release using on-line CIMS. The model mouth developed for the aforementioned studies on oil-in-water emulsions [18.122] was also used to investigate the role that tongue pressure and oral conditions have on volatile release [18.123]. In particular, the release of several flavor compounds, including 1-butanol, ethyl butanoate and ethyl hexanoate, was monitored under different mastication conditions, with upward and downward tongue mastication assessed for different initial positions at constant tongue pressure and mastication duration. The real-time data provided by PTR-MS revealed an initial flavor *burst* after every tongue stroke (Fig. 18.3). Other model mouth systems have been developed and used to study the influence of mastication rate and saliva on aroma release [18.124–126]. A comprehensive treatment of the use of model mouths to simulate and study flavor release is provided in a review article [18.127] and in another chapter of this book (Chap. 14).

Besides investigating the influence of diverse parameters on the aroma release in model systems, on-line CIMS has been used extensively to characterize the general volatile composition from different foods. The details of these numerous studies will not be discussed here, but rather a selection is listed to give an indication of the diversity of such research. PTR-MS has been used for the headspace volatile analysis, amongst others, of red kidney beans [18.128], juice and custard [18.129], to evaluate different treatments (heat versus pressure) of red orange juice [18.130], diverse cheeses [18.131–133], berry fruits [18.134, 135], apples [18.136], bread [18.137], cereal bars [18.138], coffee [18.139–142] and red bell peppers [18.143]. SIFT-MS has been increasingly used in recent years to perform such analyses, for instance in olive oil [18.144], to establish the kinetics of VOC emissions during yeast fermentations [18.145], in dry fermented sausages [18.146], Atlantic cod [18.147], and Parmesan cheeses [18.148]. Diverse fruits and vegetables have undergone SIFT-MS headspace studies on their constituent volatiles, as also reviewed and reported in the scientific literature [18.149], including the investigation of volatiles formed by lipoxygenase (LOX) activity in strawberries during storage, different cultivars of strawberries or at different levels of ripeness [18.150], sliced carrots during air drying [18.151], tomatoes and tomato puree [18.152, 153], and bell and jalepeño peppers during frozen storage and thawing or the effects of enzyme activity [18.154, 155]. Furthermore, nuts, seeds and grains have been studied using SIFT-MS, with roasting being at the focus of study for some targets, for instance, looking at volatiles of cocoa during roasting or at different pH levels [18.156, 157], or investigation into the effects of roasting sweet almonds, peanuts and pumpkin seeds [18.158–161]. Such applications can be extended to processed foods; one example here is the use of headspace analysis by SIFT-MS to investigate the character-impact odorants associated with basil and pesto, primarily the terpenoids methyl cinnamate, eucalyptol, linalool and estragole using NO^+ as a precursor ion to minimize compound interferences [18.162]. APCI-MS has been used to study many foods as diverse as kiwi fruit [18.163], milk [18.164], tea [18.165] and sausages [18.166], amongst others. Although not in widespread use, Li^+ IAMS has been used – in a demonstration of its practical application – to detect aroma compounds present in the headspace of strawberry [18.83]. Although the identification of

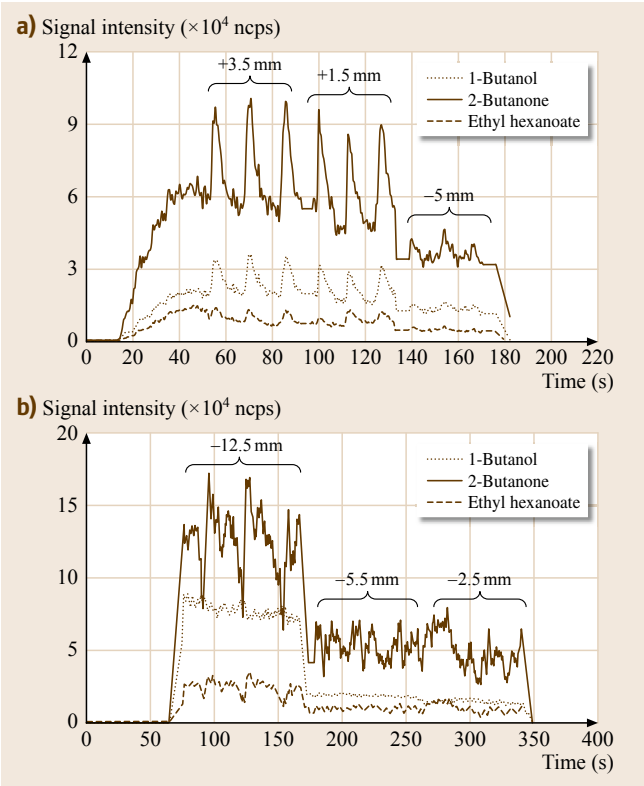

Fig. 18.3a,b Flavor release of 1-butanol, ethyl butanoate and ethyl hexanoate during **(a)** downward and **(b)** upward tongue mastication in a model mouth at constant pressure (25 kPa) and duration (0.4 s). Distance labels (in mm) refer to initial positions of the tongue (plus is above-surface; minus is below-surface) (after [18.123])

the mass spectral peaks was based principally on mass number, thereby carrying a degree of uncertainty, several compounds were detected and tentatively identified, including methanol, acetaldehyde, ethanol, acetone, propanol, methyl propanol, methyl butanol, demonstrating that this technology – like APCI-MS, PTR-MS and SIFT-MS – has potential use for aroma compound assessment from foods.

The headspace analysis of volatile aroma compounds in alcoholic beverages presents a particular challenge for on-line CIMS because of varying ethanol concentrations and interferences from protonated ethanol products. This issue has been addressed in several studies. The ability of APCI-MS to measure such beverages was assessed using an ethanolic model system and by adding ethanol into the source via the sweep gas [18.167]. The system developed was used to measure the partitioning of selected volatiles and was shown to deliver consistent and quantitative ionization provided the ethanol concentration in the source was above a certain threshold, with the ethanolic solutions found to reduce the partition coefficient of most of the aroma compounds tested. Subsequent APCI-MS studies on ethanolic systems under dynamic conditions have explored the influence of ethanol content, temperature and gas flow rate on the release of aroma compounds [18.168, 169]. Similar attempts at utilizing protonated ethanol as reagent ions for subsequent protonation reactions with target volatiles have been made using PTR-MS. In one study the sample headspace was diluted into an ethanol-saturated nitrogen carrier gas flow via a stripping cell to achieve a steady ethanol concentration and to promote conversion of H_3O^+ primary ions into protonated ethanol and ethanol cluster ions, such that subsequent protonation reactions of target volatiles were achieved with ethanol as a primary ion [18.92]. The technique was used successfully for mass spectral fingerprinting of different wine varieties but suffered from complex mass spectra, making individual compound identification difficult. To circumvent this problem, an alternative approach was proposed, whereby the sample headspace was diluted by a factor of 1:40 with nitrogen, and target aromas were ionized in the standard manner via H_3O^+ [18.91]. Here it was demonstrated that the ethanol concentration in the headspace had no influence on the wine headspace composition and the method was deemed better suited for routine applications than the previous approach.

Mass Spectral Fingerprinting. Volatile headspace profiling, or mass spectral fingerprinting, by on-line CIMS has been used successfully to discriminate between food products. In such studies, the entire spectrum of volatiles in the headspace of the samples are rapidly recorded and the resulting data are subjected to multivariate analysis such as partial least squares discriminant analysis (PLS-DA), principal components analysis (PCA), or analysis of variance (ANOVA), amongst others. These powerful statistical tools allow for correlations between large datasets, for instance providing indications of the degree of similarities or differences. By these means, it has been possible to categorize samples based on their headspace volatile profiles for diverse goals, including distinguishing different geographic origins or products with protected designation of origin (PDO) status, predicting sensory impressions, or distinguishing between varieties or

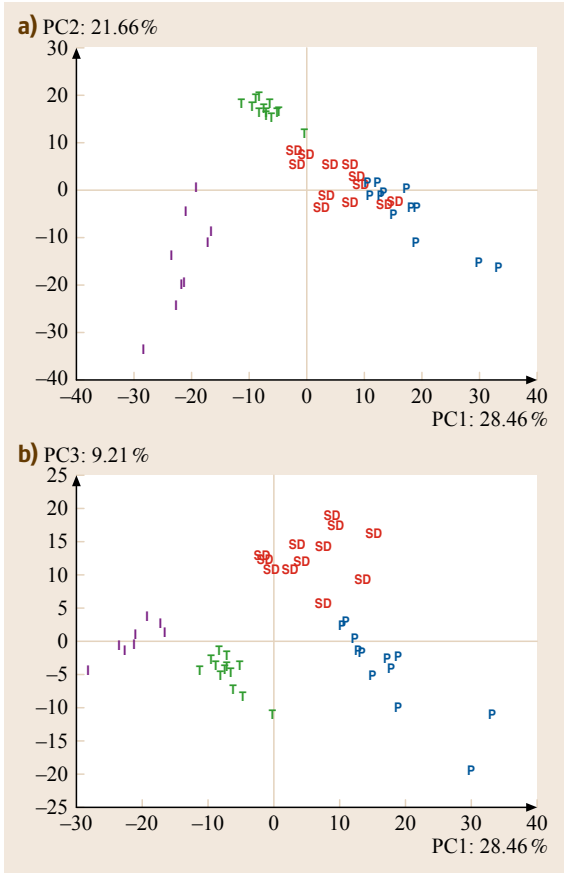

Fig. 18.4a,b Principal component analysis (PCA) score plots based on PTR-TOF-MS mass spectra of four types of ham, namely Iberian (I), Parma (P), San Daniele (SD) and Toscana (T), representing **(a)** the first vs. second and **(b)** first vs. third principal components. The headspace analyses of three replicates of 46 ham samples yielded more than 700 mass spectral peaks; PCA could discriminate between samples with a good degree of success (after [18.170])

types of particular foodstuffs. Examples of each of these applications are given here.

The practice of discriminating products according to their geographic origin is based on the premise that the volatile profiles of these foods will be affected to a lesser or greater extent by many factors during their growth and rearing or production. For plant-based foods these include soil conditions and growth climate, plant or fruit genotype, and ripening conditions. For animal products other factors can additionally play a role, including breed, feeding regime (which also depends on the feed and the factors affecting its production), and rearing procedures. The volatile profiles of both plant-based and animal-based foods are further affected by subsequent processing, thus clearly many factors come into play. On-line CIMS techniques have proven that mass spectral profiling with chemometric data processing can be successfully applied to foods to discriminate between different geographic origin, which has potential use as a rapid, nondestructive tool for food authenticity assessment relating to PDO status or fraudulent production. Such analyses have been demonstrated, for example, for cashew nuts [18.171], honey [18.172, 173] Iberian ham [18.174] (SIFT-MS), olive oil [18.175], dry cured ham [18.170], coffee [18.140, 176], wine [18.91] (PTR-MS), Stilton and cheddar cheeses [18.177, 178] and apples [18.179] (APCI-MS), to name but a few. As an example, the aforementioned study on dry cured ham involved performing rapid PTR-TOF-MS headspace analysis on 138 samples comprising triplicates of 46 hams sourced from four types (Iberian, Parma, San Daniele, and Toscana) [18.170]. The spectral fingerprints comprised over 700 peaks, and these were subjected to PCA, as well as random forest and discriminant PLS, with the resulting score plots indicating reasonably good separation of the samples (Fig. 18.4). Such studies demonstrate the utility of mass spectral fingerprinting to potentially screen foods for PDO status.

The use of mass spectral fingerprinting to predict sensory profiles is a powerful technique and a key area of potential application of on-line CIMS, since it potentially allows manufacturers to quickly assess product quality based on its volatile (aroma) headspace profile. Such assessments are traditionally performed by highly trained sensory assessors, but the use of on-line analytical instrumentation is desired by the industry to monitor sensory quality during production (e.g., during coffee roasting), or as a screening tool for rapid sample throughput to flag problematic samples along the production line (e.g., compromised flavor due to oxidation). It might also be used in more basic studies to ascertain general aroma compositions of related products.

Sensory profiling by on-line CIMS headspace analysis has been reported in several cases. In one study on mozzarella cheese, multivariate statistical data analysis indicated that both the CIMS method and the trained sensory panel delivered comparable sample descriptions [18.133]. Sensory profiles of espresso coffee were predicted by PTR-MS headspace data and were shown to reflect the flavors reported by the skilled sensory panel to a high degree [18.139]. APCI-MS has been used for similar purposes on beer, with a discrimination of samples based on key aroma compounds [18.180], or in Swiss cheeses, distinguishing between cheeses based their VOC profiles and related odor activity values (OAVs) [18.181]. SIFT-MS headspace analysis has been similarly applied, for example, to investigate the flavor interactions for sodium-reduced cheese sauce in wholegrain macaroni, whereby the volatiles detected by SIFT-MS were compared to taste attributes for the pasta with and without sauce [18.182].

In terms of screening approaches, SIFT-MS has been used to discriminate honeys produced from different flowers [18.183]. PTR-MS has been investigated as a potential tool to rapidly assess the oxidative alteration of olive oil via headspace analysis of the volatiles, whereby multivariate analysis of the mass spectral data generated models that could reliably classify oils as extra virgin or defective, with many peaks in the mass spectra – predominantly aldehydes – correlating with the peroxide values of the oils, as were determined independently, thereby suggesting that this was an appropriate nondestructive tool for peroxide determination [18.184]. The ripening of Swiss cheese was similarly studied based on volatiles – primarily sulfur compounds, but also carboxylic acids – released into the headspace, whereby it was found that the formation of propionic acid during curing of the cheese coincided with the production of key flavor impact sulfur compounds such as dimethyl sulfide and methyl mercaptan [18.185].

Food Spoilage. The unpleasant odor that food develops when it spoils is often the first indicator to consumers that the food is no longer fit for consumption. These odorants are by-products of the breakdown and metabolism of food substrates from microbial, enzymatic, oxidative or other degradative activity. Like other applications, on-line CIMS techniques are particularly suited to investigating food spoilage as they allow for continuous, nondestructive analysis, thus enabling the development of such volatile odorous spoilage metabolites to be monitored over time. Despite its suitability, however, there are only few studies that report on the use of on-line CIMS for meat spoilage measurements, and these only involve either PTR-MS or SIFT-MS; no reports of the use of APCI-MS for the detection of volatile spoilage metabolites could be found in the sci-

entific literature. The primary focus of such research is to identify prospective volatile spoilage markers that could be used for quick assessment of food quality and ultimately lead to the development of intelligent food freshness indicators (FFIs) based on emissions from specific compounds that signal when a food has reached its end of shelf-life and should no longer be consumed.

Investigations on the spoilage of meat by PTR-MS appeared soon after the development of the technique, with a series of studies on different meats in relation to packaging conditions and in correlation with bacterial species and colony growth. The first PTR-MS publication on this topic involved measuring the VOC emission profile of beef, pork and poultry under aerobic or anaerobic (vacuum-packed) conditions over a 13-day storage period [18.186]. The headspace of individual samples was analyzed on successive days to create VOC profiles of the different meats and storage conditions. The paper only names a handful of compounds – although apparently more were detected than reported – including 2-butenal and C4-esters, all showing an increase with storage, as would be expected. Differences in the generation of individual compounds were also observed between air-packed and vacuum-packed samples. A follow-up study further looked at the specific microbial species growing on the meat during spoilage [18.187]. Again, a number of VOCs were found to be generated and increase in concentration during spoilage, corresponding to an increase in bacterial numbers. Odorous compounds detected included the sulfurous compounds methanethiol, dimethyl sulfide, thioacetic acid methyl ester, dimethyl disulfide, and 2,3-dimethyl trisulfide. Of these compounds, dimethyl sulfide was found to have the highest correlation with bacterial spoilage. In a complementary study, the same researchers investigated whether ozone treatment of pork meat affects microbial growth, with dimethyl sulfide used as a proxy to determine the latter [18.188]. Although this compound was observed to be at much lower concentrations in the headspace of pork that had been exposed to ozone (compared to oxygen or untreated samples), bacterial numbers were high regardless of treatment. Another study associated with food spoilage looked at the volatile emissions from different bacterial cultures that degrade meat, namely *Escherichia coli*, *Shigella flexneri*, *Salmonella enterica* and *Candida tropicalis* [18.189]. The study made use of PTR-MS to monitor each of the four samples in repeated succession via an on-line sampling setup. The overall mass spectral profiles, as well as the temporal dynamics of individual VOCs were found to vary greatly according to microbial species; another finding, however, was that bacterial numbers generally did not correlate with VOC abundance, principally owing to the highly variable concentrations over time and making a case for the need for real-time as opposed to offline measurements in any such studies.

Milk spoilage has been investigated by PTR-MS from diverse angles. In one study, the microbially induced spoilage of fresh cow milk was followed over a 17-day period, comparing samples treated with sodium azide (to inhibit bacterial growth) with untreated samples [18.190]. Based on the suite of VOCs that increased in concentration in the headspace of the milk samples over the storage period in comparison with bacterial numbers, it was reported that the milk showed signs of spoilage only after a certain threshold abundance of microbial activity was achieved, which has potential utility for the development of FFIs. In another study, photooxidative spoilage of milk was monitored on-line by PTR-MS, with several compounds showing a distinct increase during light exposure of the milk compared to unexposed samples [18.191]. The latter pilot study makes a case for using PTR-MS (or any of the on-line CIMS techniques) to investigate the kinetics of such reactions in far more detail than achievable with offline analytical methods. PTR-TOF-MS has similarly been applied to dynamic headspace analysis of milk, albeit not for spoilage but to study lactic acid fermentation [18.192]. The headspace measurements were made by discontinuous sampling (i. e., not constant monitoring), but nevertheless provided semi-dynamic data with a time resolution of ≈ 20 min. Many key flavor or off-flavor compounds were observed to develop during the fermentation, including diacetyl, methanethiol, dimethyl sulfide and furfural.

Recent studies have demonstrated the applicability of SIFT-MS for food spoilage monitoring based on the strengths of its on-line sampling capabilities. Beef packaged under modified atmosphere was the focus of one such trial, whereby SIFT-MS was used to monitor VOCs produced during lipid oxidation [18.193]. The notable outcome of these trials was that SIFT-MS was able to detect differences in meat samples at an earlier stage than complementary SPME-GC-MS analyses, highlighting its potential suitability for lipid oxidation monitoring. In a different study on the lactic acid bacterial spoilage of sweet bell peppers, SIFT-MS was used to monitor the VOC composition in the headspace of samples packed under different atmospheres [18.194]. The clear advantage of using SIFT-MS over other conventional methods for such analyses was the convenience of not needing to open packaging for the analysis – which might alter the concentrations of volatiles – but additionally that the analysis simulated the sensory impressions experienced by consumers upon opening the packaging.

The microbiological spoilage of fish and crustaceans has been studied using SIFT-MS, notably iridescent shark fillets [18.195], cod fillets [18.196], and brown shrimp [18.197]. In the former, a SIFT-MS method was developed to monitor the growth and metabolic production of bacteria on packaged fillets, either under air, vacuum-packed, or modified atmosphere packaging (MAP) with complementary VOC analyses performed with SPME-GC-MS [18.195]. Several volatiles – including odor-active candidates – were observed to increase during spoilage, notably ethanol, 2,3-butanediol, diacetyl, acetoin, ethyl acetate, acetic acid and sulfur compounds. In the latter aforementioned study on brown shrimp, a selection of 17 volatiles, including alcohols, acids, ketones, amines and sulfur compounds in the headspace of samples inoculated with specific bacterial strains were monitored by SIFT-MS on a daily basis [18.197], whereby VOC concentrations and colony forming units of the bacteria were found to show similar increases. SIFT-MS has also been explored as a potential tool to monitor and establish the oxidative status in oils in comparison with sensory rancidity [18.198], or to determine antioxidants [18.199].

Food Nosespace Analysis

When food is consumed, constituent aroma compounds are released from the food matrix during mastication and swallowing. Their subsequent velopharyngeal transfer through the nasal cavity during exhalation elicits a response in the olfactory epithelium, when the latter is exposed to these odor-active volatile compounds. This simplified explanation does not consider the intricacies of this complex process, such as the physicochemical properties of the individual aroma compounds [18.200], variabilities in mastication processes, the composition of saliva, the anatomy of the oral and nasal cavities [18.127], or potential biotransformation of compounds en route through the nose [18.201]; these phenomena are discussed in detail elsewhere in this handbook. For the purposes of the present chapter, in flavor research it is assumed that the exhaled nasal breath during food consumption generally reflects the composition and quantities of volatile aroma compounds that reach the olfactory cleft and elicit a flavor impression in the consumer. A concept that was made possible by on-line CIMS tools is that of *nosespace* analysis, whereby nosespace refers to the gas directly exiting the nostrils and is assumed to be representative of retronasal aroma perception. This method has a large caveat in that concentrations of odorants detected in the nosespace do not necessarily reflect odor intensity impressions, which is dictated by odor thresholds and potencies of the odorants in combination with the mostly non-linear or

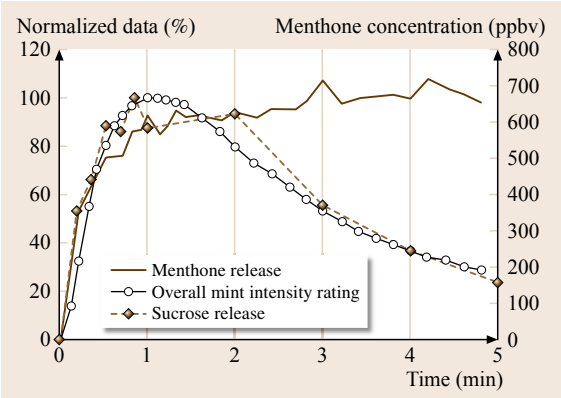

Fig. 18.5 APCI-MS nosespace analysis of menthone release during mastication of a chewing gum, whereby perceived mint intensity followed the sucrose release curve, despite menthone intensity remaining high (after [18.202])

cumulative integration of multiple sensory stimuli by the brain; indeed it was the application of APCI-MS for nosespace analysis that provided unequivocal evidence of the perceptual interaction between nonvolatile and volatile flavor compounds whereby the flavor perception of a mint-flavored chewing gum was shown to be dictated by the temporal profile of sucrose levels in the saliva and not the concentration of menthone in exhaled nasal breath, which remained steady whilst sucrose and flavor perception levels dropped concordantly (Fig. 18.5) [18.202]. Similar studies have been performed on other food matrices, for instance strawberry-flavored yogurt of different formulations, whereby the aroma release of the fruity compounds ethyl butanoate, (*Z*)-hex-3-enol and ethyl 3-methylbutanoate – as measured by PTR-MS – was found to be suppressed by sweeteners [18.203].

Several independent developments to APCI-MS have made it particularly suited to measuring retronasal flavor release. The early construction of an interface for direct injection of breath gas into the APCI-MS ionization chamber that was discussed earlier [18.25, 26] (Sect. 18.1.1) paved the way for later developments by *Taylor*, *Linforth* and colleagues [18.30] to allow for the measurement of flavor release via nosespace analysis. Other APCI-MS developments for optimized flavor release characterization via breath have also been made, including the use of IT-MS with a novel sample gas injection system [18.31], and the development of a mathematical model for characterizing release based on APCI-MS time-resolved data [18.96].

The persistence of several volatile aroma compounds in the breath from a six-person panel after ingestion of aqueous solutions was investigated using the aforementioned APCI-MS system [18.204]. The

extent of persistence was found to be similar for all panelists, whereby hydrophobicity and vapor pressure were key factors influencing the in vivo behavior of aroma compounds. The degree of interindividual variability was also investigated by conducting nosespace analysis of menthone released from a mint sweet using APCI-MS [18.205]. The release of menthone in 68 subjects that were tested according to a strict protocol for mouth movements was dominated by swallowing actions and the degree of degradation of the sweet in the mouth, which was suggested to relate to proteins, particularly the content of enzymes, in the saliva; by comparison, tongue and jaw movements were found to not have an influence on flavor release. Other attempts at modeling the kinetics of flavor release using APCI-MS nosespace analysis have also been made [18.206], whereby the interindividual variability was found to be very high, which was attributed mainly to differing swallowing and breathing patterns between subjects, thereby requiring nosespace data to be corrected for airflow rate in order be comparable. The study concluded that flavor molecules detected in the nosespace were primarily from liquid left in the throat after swallowing. Similar studies using APCI-MS to characterize flavor release similarly concluded that the main flavor impression resulted from a swallow breath from the throat, rather than from the mouth, with flavor-enriched air being delivered to the nose via exhalation immediately after the swallowing event [18.207]. APCI-MS has been used to investigate taste-aroma interactions in citrus-flavored model beverages by following aroma release profiles in combination with sensory analyses by a trained panel on models with altered acid and sugar types [18.208]. The study highlighted a difference in flavor perception due to sugar type, rather than physical factors, suggesting different receptors or receptor mechanisms involved in the perception process.

The interindividual variability and effects of food matrix composition on retronasal aroma release was investigated using APCI-MS [18.209]. The results of the study, which was performed using a panel of 30 subjects consuming nine different food products, suggested that the degree of retronasal aroma release is specific to an individual and relatively independent of the type of food consumed, with subjects who exhibited a high retronasal aroma release profile displaying these regardless of whether the food was semiliquid or solid. It was suggested, however, that foods could nevertheless be tailored to increase retronasal aroma stimulation with a view to potentially enhancing satiety and thereby reducing intake, which is of relevance in the current epidemic of obesity in the western world [18.210].

PTR-MS has been used extensively to investigate in-mouth aroma release and retronasal perception. Two such studies assessed how texture (of flavored whey protein gels) affected aroma release and perception [18.211, 212]. Another study compared trigeminal, taste and aroma perceptions by way of example on mint-flavored carbonated beverages, whereby the addition of CO_2 to the beverage was found to induce physicochemical modifications and sensory interactions with taste and aroma perceptions [18.213, 214].

Model custards that were flavored with strawberry aroma were used to study aroma release in relation to the interactions of oral processing and food texture via nosespace analysis using PTR-MS [18.215]. In particular, the consumption behavior of the panelists undergoing a free-chewing protocol could be separated into groups according to swallowing time, whereby subjects that swallowed relatively quickly displayed higher aroma release from the firmer custard than from the softer custard, whereas the latter matrix exhibited higher flavor release in the group that swallowed later, further highlighting interindividual variability. Similarly, the breath-by-breath aroma release from banana was investigated using PTR-MS, comparing ripe with unripe bananas [18.216]. In particular, two characteristic flavor impact compounds of ripe banana, namely isopentyl and isobutyl acetate, and two character impact compounds of unripe banana, 2-E-hexenal and hexanal, were monitored and compared.

The popularity and rich aroma complexity of coffee has made this beverage a key foodstuff for investigation by on-line CIMS, both in vivo and in vitro. A study that combined in vivo nosespace analysis by PTR-TOF-MS with the measure temporal dominance of sensation (TDS) investigated the roasting degree and sugar addition on aroma release and perception in espresso coffee [18.217]. The degree of roasting was found to have a higher impact on both aroma release and perception, whereas the addition of sugar had no effect on the former, despite influencing the perceived flavor of the coffee, thus highlighting sensory congruency effects. Similar comparisons of nosespace aroma release measurement data with sensory data were made in a PTR-MS study comparing PTR-MS data with time intensity perceptual measurements of flavor release using a strict breathing and consumption protocol [18.218].

Despite the only relatively recent deployment of SIFT-MS to food and flavor release monitoring, the technique has been shown to be suitable for nosespace analysis, such as for the case of aroma release from tomatillo and different varieties of tomato (and in comparison to headspace aroma release) [18.219] or strawberries after processing [18.150].

18.2.2 Environmental Odors

Odors have a range of physiological and psychological impacts on humans, spanning the whole spectrum from pleasantness and relaxation to symptoms of irritation and negative health effects. It is generally recognized that prolonged exposure to negatively rated environmental odors can cause reactions ranging from emotional stress such as states of anxiety, unease or depression, to physical symptoms, such as headache, eye and airways irritation, respiratory problems, or nausea [18.220]. Environmental malodors can diminish quality of life of those affected, raise intolerance and trigger complaints from workers and residents, thus requiring mitigating actions from facilities managements and regulatory acts from the local authorities [18.221, 222] (Chap. 25). Yet odor mitigating actions are hampered by difficulties in assessing the characteristics of community and individual odor exposures, and the variable odor perception thresholds of the odorants. It has been reported that the psychophysiological association between odor annoyance and air contaminants – whether these are odorants or not – is complex, involving several factors including sex, age, health status, social, geographic and environmental context [18.223]. Negative health effects often cannot be reconciled with the chemical constitution of environmental odorants, their chemical composition or concentration [18.224], since a multifaceted relationship exists between odor properties, exposure, sensitivity and individual responses such as annoyance or sensory irritation [18.225]. In general, a dose-response gradient is found to relate reported annoyance with the concentration of air pollutants [18.226], but such relationships are complex and critically dependent upon the olfactory quality assessed and the hedonic tone such as liking or disliking [18.227], while frequency and intensity of episodes contribute to the overall odor impact assessment. Since odors can be smelt at much lower concentrations than those eliciting upper respiratory tract irritation, in exposed workers or communities there is confusion between odor perception and irritation: this factor, coupled with individual variability in odor sensitivity and response, complicates the evaluation of adverse effects or annoyance [18.225].

An environmental odor can be composed of many tens of nonodoriferous substances and only a few compounds with low odor threshold, while in both categories their concentrations are typically at trace levels (i. e., gas volume mixing ratios in the range from ppm_v down to ppt_v or lower). Outdoor and indoor chemoanalytical odor monitoring is commonly conducted by discontinuous active or passive sampling, followed by offline analysis in the laboratory. This is typically achieved with techniques such as thermal desorption (TD) coupled to GC separation and MS detection (TD-GC-MS) in combination with olfactory detection ports as in GC-MS/O (Chap. 17). For this purpose, discrete ambient air samples bearing odors are collected onto VOC adsorbent materials, either actively – by means of a portable pump purging sample gas through tubes packed with adsorbent resin such as Tenax TA or activated carbon (Carbotrap/Carbopack) [18.228] – or passively onto porous materials or fibers, such as in the case of a Radiello diffusive sampler [18.229] or headspace SPME fibers [18.230]. These methods provide a time-averaged quantitation of the odorant VOC over a period of several minutes to several days; however, it is often desirable to instantaneously capture the gas sample at times of short-term or acute malodor events. A common alternative for instantaneous odor sampling consists of capturing, or *grabbing*, defined volumes of sample gas into an evacuated inert gas canister (e.g., SUMMA or Silcocan canisters with a passivated inner-surface coating), or into polymer material bags commonly made of polyvinyl fluoride (Tedlar bags) or polyterephthalic ester copolymer (Nalophan NA). Useful comparisons on the relative efficiencies of these sampling methods with regards to odorant recovery, sample stability and artifact issues have been reported [18.231–233]. The most widely used VOC sample collection and offline analysis protocols are those of the United States Environmental Protection Agency (EPA) Compendium of Methods for the Determination of Toxic Organic Compounds in Ambient Air (TO methods), commonly known as the US EPA TO suite of methods [18.234]. These custom analysis protocols have been central to the understanding of environmental and indoor odors, owing to the power of GC-MS techniques to separate and chemically identify and quantify complex mixtures, despite being somewhat limited in the suite of target VOC classes validated for each TO method [18.235]. It has become evident, however, that these methodologies are prone to significant sampling artifacts and analytical interferences and that many of the more active odorants (especially acids and carbonyl compounds) might not be stable enough to endure sampling, handling and thermal desorption without undergoing chemical transformation before they reach the analyzer. Generally, losses during storage and stability issues limit VOC recoveries in all of the aforementioned sampling methods [18.236]. Moreover, being rather work-intensive and discontinuous in nature, these methods are not suitable for long-term, highly time-resolved and directional monitoring of VOC sources in the field or indoors, as is generally desirable to address issues of

odor complaints. The shortcomings of the discontinuous headspace, purge-and-trap or sample-grab methods have been partly overcome by the development of rapid and field-deployable devices such as handheld GC-MS systems [18.237]. Nevertheless, the application of this tool to complex environmental odor issues is somewhat restricted, being less sensitive than laboratory GC-MS and constrained in the suite of VOCs that can be monitored at trace levels, owing to the limitations of the built-in GC column. Some form of sample preconcentration is required for increasing the sensitivity, while chemical identification and accurate quantitation are limited to the compounds for which reference standards are run.

In perspective, the discontinuous sampling and offline analysis methods outlined in the US EPA TO suite of methods do not offer sufficient time resolutions to allow the capture of the real-time fluctuations of odorant compounds in the ambient air and are subject to analytical artifacts. Although these shortcomings have been partly overcome by field-portable GC-MS and open path-Fourier transform infrared (OP-FTIR) spectroscopy, optimum performance is only achieved when the odor nuisance compound is known a priori and the instruments can thereby be used as source-monitoring tools. On-line CIMS techniques have the advantage of giving instantaneous snapshots of the ambient air composition, regardless of whether or not the compounds of interest are known a priori. Given the lack of sample handling required, the high time resolution and enhanced sensitivity, and the wide range of nonspecific VOCs detectable, on-line CIMS techniques offer a highly time-resolved record of the unidentified compound mixture in the sample air at times of complaints and can thus be used as fast screening tools. The VOC concentration datasets generated can then be post-analyzed focusing on selecting specific ions for VOC fingerprinting. Nevertheless, the reviewed techniques are principally tools for fast monitoring and for gas-phase fingerprinting, rather than for chemical-structural elucidation of unknown compounds. Although these can provide molecular mass information on the target analytes, the capability of separating isobars and isomers (or specific odorant stereoisomers) and to unambiguously ascertain the chemical identity of unknown analytes remains a strongpoint of the slower and specific GC-MS techniques.

In this section the status of on-line CIMS as research tools for the instantaneous monitoring of complex air pollutant mixtures – both indoor and outdoor – is discussed. The scope here is to describe the applications of CIMS to environmental odors arising from VOCs, or for which VOCs are markers, therefore the measurement of inorganic odorants – commonly conducted by means of highly specific monitors or sensors – will be omitted. A treatise on environmental odor detection would, however, not be complete without mentioning the relative standing of CIMS techniques to those of the electronic noses (e-noses), which are semispecific gas sensor arrays that are sensitive to a wide range of odorants and employ complex algorithms for pattern recognition; the operating principles and performances of this technology are outlined at length in another chapter of this book (Chap. 21).

While on-line CIMS instruments stand as research tools capable of revealing molecular and structural chemical information on the sampled air irrespective of the odor attribute of the constituent VOCs, e-noses are fast and semispecific screening tools aimed at the detection of selected VOCs whose odor characteristics are known from the outset [18.238]. The on-line CIMS techniques discussed in this chapter are unspecific, thus are ideal analytical tools for complex mixtures of unknown odorants. Moreover, the underlying soft ionization processes produce little to no fragmentation of the parent ions, making it easier to deconvolute the resulting mass spectra and to extract the chemical information. The spectra produced by these techniques represent essentially the gas-phase fingerprints of the target molecules or mixture, irrespective of its odor activity. For completeness it has to be noted that, when a specific odorant or a limited range of VOCs is known a priori to be emitted in ambient air in certain areas but their source apportionments are unknown, the closest approach to on-line and continuous trace level monitoring is achieved by applying OP-FTIR. This optical spectroscopic technique has recently been successfully applied to monitor VOCs continuously along different optical paths for identifying multiple odor sources by targeting a limited suite of odorants or a nonodorous plume tracer such as methane [18.239–241].

Indoor Odors

Odors within the indoor environment can generate sensory irritation and annoyance that can result in psychological effects, including a distraction from work and a consequential loss in productivity [18.242]. Indoor odor is discussed in depth in another chapter of this book (Chap. 26) and will not be treated in detail here, but rather the application of on-line CIMS techniques to monitor such odors.

People assess the quality of the air indoors primarily on the basis of its odor and on their perception of associated health risk. The major contributors to indoor odorants are human occupant odors (i. e., body odor), environmental tobacco smoke, volatile building materials, bio-odorants (particularly mold, human and animal-derived materials), air fresheners, perfumes and

residues of cleaning products. These are mostly present as complex mixtures, thereby complicating the assessment of the total odorant problem [18.243].

It is important to note that many of the VOCs that are primarily emitted from indoor sources such as building materials, air conditioners, furniture, flooring and carpeting materials, cleaning products, printers, etc. are not odor-active [18.244]. Thus, although they might be the cause of general discomfort, often it is the perceived odor that is presumed to be the culprit. Furthermore, even if the concentrations of certain odor-active VOCs inside buildings are far below their reported odor thresholds, compounded effects at sub-detection threshold levels might cause the exacerbation of symptoms that lead to a complaint [18.245, 246]. Moreover, chemical reactions between VOCs and oxidants, such as ozone, nitrogen oxide and electromagnetic radiation, can produce oxygenated VOCs [18.247] and secondary organic aerosols (SOA) [18.248] that might be responsible for the reported symptoms, while the overall impact of toxic compounds adsorbed onto particles or forming SOA has not been clarified to date [18.249].

Keeping in mind the aforementioned remarks, indoor environmental odor or associated irritant VOCs have been investigated by on-line CIMS in a number of recent studies. The CIMS techniques can provide a snapshot of the air composition at the time of complaint, but for the unambiguous identification and characterization of active odorants these must be used in combination with offline techniques, typically TD-GC-MS/O, for detailed chemical identification and quantitation of the compounds measured within the mass spectrum, and to resolve isomeric or isobaric compounds that are indistinguishable by the on-line CIMS system.

Among odor-active compounds as specific markers of indoor air pollution, formaldehyde is a well-documented indoor irritant [18.250] with a characteristic pungent odor [18.251]. Formaldehyde can be measured by all of the described CIMS techniques, although in some cases its detection is hindered by interferences, humidity effects and low sensitivity when using hydronium for proton transfer reactions due to the similar proton affinities of the reagent and analyte (see Fig. 18.1 and Table 18.2). This is the case for PTR-MS [18.252], although an optimized mode of operation can significantly enhance its performance for on-line formaldehyde detection at low absolute humidity [18.253].

Common terpenes such as limonene, α-pinene, citronellal, geraniol and linalool are the main odorous ingredients of virtually any cleaning agent or ambient air fresheners. They readily react with ozone, and the resulting oxidation products have a high irritation potential [18.250, 254], partly due to the formation of formaldehyde, and can equally be odor-active [18.255]. Ozone-initiated terpene reaction products may therefore be of concern in ozone-rich environments ($\geq 0.1\,\mathrm{mg/m^3}$) with elevated limonene concentrations, such as office environments [18.256]. Gas-phase oxidation products of several terpenes (monoterpenes, sesquiterpenes and oxygenated terpenes) arising from the reaction with ozone have been measured by PTR-MS in environmental simulation chambers such as Teflon chambers and fluoroplastic bags [18.257, 258]. The temporal evolution of the concentrations of products such as formaldehyde, acetaldehyde, formic acid, acetone, acetic acid, and nopinone (tentatively identified by their m/z) were followed although no discussion on the potentially odorous and irritant characteristics of these volatiles was presented, since the rationale of these studies was on the kinetics of outdoor and indoor atmospheric chemistry and aerosol formation. Similarly, APCI-MS was used in a chamber study to follow the kinetics of terpene oxidation processes at different ozone ratios [18.259] with focus on the kinetics of formation of gas-phase tracers relevant to aerosol formation and subsequent modeling. A background study on the ion-molecule reaction of H_3O^+, NO^+ and O_2^+ with various monoterpenes by SIFT-MS has been reported [18.260], investigating the feasibility of using these ions as primary reagents for the detection of monoterpenes by SIFT-MS. The reaction of individual monoterpenes with each reagent ion was found to proceed at the collisional rate, although in a mixture of the studied monoterpenes the concentration of each constituent could only be approximated from the SIFT-MS spectra by assuming averaged rate constant and product distribution.

Many building materials are persistently perceived as odorous, although the concentrations of the detected organic compounds are close to or below their reported odor thresholds [18.261]. Any of the on-line CIMS techniques outlined in this chapter can be effective tools for establishing VOC emission signatures of building materials, although PTR-MS is a prominent technique in this field of application [18.262]. A direct measurement of building material emissions has been reported by PTR-MS [18.263], with the results correlating well with measures of odor acceptability by humans that allow for fingerprinting and chemometric analysis on the material release patterns. A series of emissions tests on building products and characterizations of the release of paint additives was successfully carried out using both PTR-QMS and PTR-TOF-MS [18.264]. Owing to its enhanced sensitivity and specificity compared to PTR-QMS, the

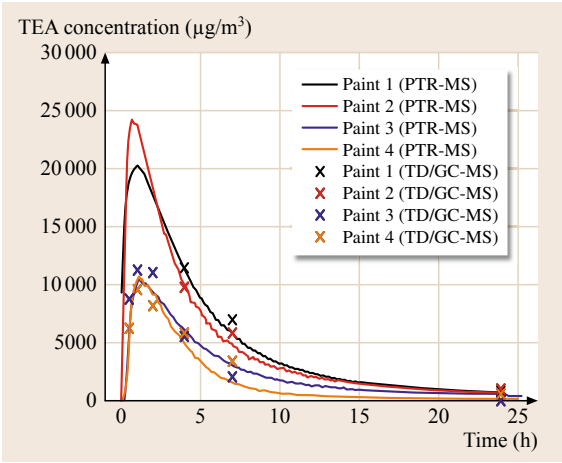

Fig. 18.6 Comparison of PTR-MS and TD-GC-MS analysis of the release of trimethylamine (TEA) from four freshly applied paints (after [18.264])

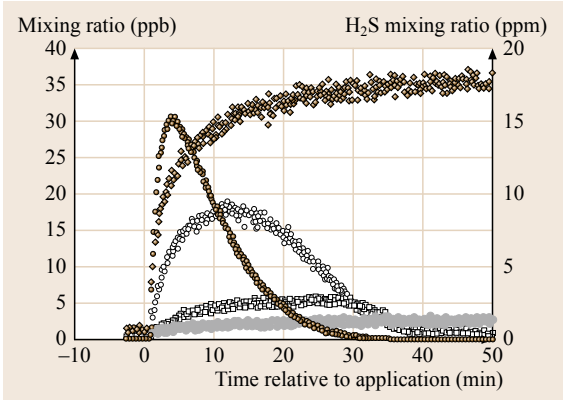

Fig. 18.7 Presence of hydrogen sulfide (*closed black circles*), methaniethiole (*open circles*), dimethyl sulfide (*open squares*), 4-methylphenol (*open diamonds*) and 3-ethylphenol (*closed grey circles*) within a static emission chamber after application of a pig manure, as measured by PTR-MS (after [18.267])

PTR-TOF-MS instrument was deemed a more suitable tool for the task of generating VOC datasets that can undergo multivariate analysis to disentangle the complex patterns of indoor VOCs, or for predicting parameters that cannot be directly measured. Further, the real-time detection offered by PTR-MS was demonstrated to reveal the kinetics of release in far greater detail than TD-GC-MS, as shown in the emission of trimethylamine from freshly applied paints [18.264] (Fig. 18.6).

Another selected, but not exhaustive, example of applications in this field is the assessment of emission characteristics of odorous VOCs from incense and scented candle burning by PTR-MS [18.265], in which the concentration profiles from the onset of burning and the emission rates of tens of VOCs were revealed along with other indoor air pollutants such as NO_x and particulates (the latter measured by dedicated techniques). The on-line detection capabilities of APCI-MS have also been put to use in detecting VOCs in cigarette smoke via use of a smoking machine, whereby puff-by-puff analyses of VOCs including acrylonitrile, crotonaldehyde, benzene and toluene demonstrated the applicability of this on-line method [18.266].

Generally, research in these fields using on-line CIMS techniques has revealed the presence of compounds previously overlooked in surveys of indoor pollutants, reflecting the limitations of the analytical methods routinely used for such monitoring purposes. Moreover, the application of uni- and multivariate statistical modeling to the complex chemical data matrix obtained by on-line CIMS allows for the prediction of parameters that cannot be directly measured, such as odor impact in relation to VOC concentration.

Outdoor Odors

The topic of environmental odor monitoring is the subject of another chapter of this book (Chap. 25), thus only an overview of its main challenges and of the potential of on-line CIMS techniques to contribute analytical solutions is given here. When monitoring outdoor environmental odors, a particular analytical challenge lies in the highly transient nature of the odorant abundances, which is affected by meteorology and local dispersion conditions. Furthermore, it is necessary to discern the odorant signal from the background ambient air, which is often made of a complex combination from mixed sources such as urban, agricultural, landfill or industrial [18.268]. Odor complaints are associated with a wide variety of industries and operations including agriculture and livestock, sewage treatment plants, paints, plastics, resins and chemical manufacturers, refining operations, rendering plants, pulp mills and landfills, to name the most prevalent. A range of inorganic and organic compounds are responsible for industrial and environmental odors, depending on the source. Commonly encountered inorganic substances with powerful odorants properties are ammonia (NH_3) from agriculture and animal farming, inorganic amines (e.g., chloramines, NH_2Cl) from chlorine disinfection in drinking water and swimming pools, inorganic sulfur compounds including hydrogen sulfide (H_2S) from petrochemical, paper milling and photographic industries, and sulfur dioxide (SO_2) and carbon disulfide (CS_2) emitted by sewage pipes and aerobic sewage water treatments [18.269]. Nevertheless, organic volatiles are by far the most commonly encountered causes of environmental odor complaints.

Table 18.3 Chemical groups of odorous compounds associated with industrial processes

Industrial process	Chemical group
Petroleum refining	Carboxylic acids, aldehydes, thiols, organic sulfides, phenols
Vehicles (incomplete fuel combustion)	Aliphatic and aromatic hydrocarbons, nitrogen oxides
Pulp/paper processing	Alcohols, aldehydes, ketones, thiols, reduced sulfur compounds, organic sulfides, terpenes and sesquiterpenes
Pharmaceutical production	Organic amines, reduced sulfur compounds
Agriculture (fertilizers, pesticides, animal rearing)	Alcohols, aldehydes, amines, carboxylic acids, chlorinated compounds, esters, ketones, thiols, phenols, reduced sulfur compounds
Chemical manufacture (paints, solvents, plastics, rubbers)	Carboxylic acids, alcohols, aldehydes, amines, chlorinated aromatics, esters, ketones, thiols, phenols
Metallurgy	Carboxylic acids, aldehydes, aromatic and aliphatic hydrocarbons
Sewage/municipal wastewater treatment	Carboxylic acids, aldehydes, ammonia, aliphatic and aromatic hydrocarbons, hydrogen sulfide, organic sulfides, terpenes
Bio-waste composting	Carboxylic acids, alcohols, aldehydes, esters, furans, ketones, organic sulfides, terpenes
Waste management (landfill, incineration, composting, sorting)	Carboxylic acids, esters, ketones, terpenes
Rendering plants	Aldehydes, esters, ketones, aromatic hydrocarbons, halogenated hydrocarbons, organic sulfides

The VOCs commonly investigated in studies on environmental odor complaints include the classes listed in Table 18.3.

An example amongst the processes listed in Table 18.3 is the application of on-line CIMS to monitor odorous emissions from animal production facilities, in particular swine rearing operations, which has been recently reviewed [18.270] (and references therein). Pig farms are a source of a complex mixture of VOCs over a wide range of molecular weights and with diverse physicochemical properties, with the VOCs emitted being preferentially bound to smaller-size dust particles inside and outside swine barns. The major VOC sources investigated include air inside barns, in the headspace of manure storages or composts, or in the open atmosphere above wastewater and surrounding swine farms. Some studies have also included liquid swine manure due to its use as a fertilizer in agricultural land. The most abundant VOCs that were quantified in at least two independent studies included acetic, butanoic, isovaleric, valeric and propionic acid, dimethyl sulfide and disulfide, p-cresol, skatole and trimethylamine in air, although the majority of the studies used a range of discontinuous sampling, preparation and analysis methods based on GC and LC with different detectors. Only two studies were reported on continuous and real-time odorous VOC monitoring in air samples, both deploying PTR-MS. More recently, PTR-MS has been applied for studies on animal agriculture, mainly for swine [18.267, 271–274] (Fig. 18.7), but also for monitoring emissions from cattle [18.275, 276]. Additionally, an application of on-line CIMS to measure the headspace above pig feces and urine in a laboratory setting was conducted by SIFT-MS [18.277].

The coupling of on-line CIMS with olfactometric assessment tools is highly desirable for the purpose of producing accurate yet real-time determination of ambient odor concentration. This approach has been tested, for instance, by measuring odor emissions and abatement efficiency of biofilters in composting plants [18.278, 279], a common source of odor nuisance complaints. In that study, the approach of correlating PTR-MS instrumental signal response to olfactometric assessment by means of multivariate calibration yielded a good estimate of odor concentration. Another application of on-line CIMS in ambient air monitoring is to measure instances of odor nuisance and determine its source by comparison of volatile profiles with library data, for instance, by the unique volatile emissions profiles from pig or chicken livestock [18.280, 281].

The application of on-line CIMS has led to unprecedented advancements in both atmospheric environmental studies and in plant physiology, by allowing the detailed measurement of localized or diffuse atmospheric and biogenic VOC emissions. Besides being inherently odorous to the human nose, these compounds are relevant to the environment and climate. Pivotal studies on the emissions of biogenic VOCs such as isoprene, terpenes and terpenoids (amongst which are the odorous α-pinene and limonene, among tens of others) from vegetation have been conducted by PTR-MS [18.282] and by SIFT-MS [18.283]. Another potential area of application for on-line CIMS in environmental gas monitoring is in the detection of hydrocarbon seeps from oil or gas extraction, whereby SIFT-MS has been demonstrated to meet the conditions for detecting the small linear hydrocarbons with high precision [18.284].

In conclusion, the chemical composition of a gas mixture – either indoor or outdoor air – does not represent the odor perception, which is a subjective impression in human olfaction. Nonetheless, on-line CIMS monitoring of small organic compounds is extremely useful for the purpose of investigating indoor and outdoor air quality and associated odor issues, both in the field or under simulated conditions such as in gas and smog chamber studies. It is, however, crucial to apply these techniques with a deep knowledge of their limitations, interferences, and of the uncertainties associated with the measured data. The chemical composition and concentration information obtained by CIMS has then to be critically linked with the characteristics of community and individual odor exposures, whilst accounting for the subjective odor perception thresholds of odorants. With the caveat that complementary human sensory assessments is indispensable to identify the odor impression, indoor and outdoor VOC monitoring by on-line CIMS is generating unprecedented data with high temporal resolution and chemical information. Materials emission factors and flux measurements can thus be measured, which undoubtedly represents the future of research in this area.

18.2.3 Human Odor Emissions

The human body is a continuous source of odor to its immediate surroundings. Odor emanations from the body are primarily from breath, typically in the form of oral malodor, and sweat (Chaps. 48 and 49), or more specifically from the bacterial breakdown of food particles in the mouth or sweat constituents after secretion. Further, odorants are present in most other bodily fluids, even if these do not contribute to the exterior *odor-print* of an individual. Blood, urine, feces, human milk, semen and vaginal secretions all contain distinct constituent volatile molecules (including odorants) that can be affected by health state and diet, amongst other things; the totality of the volatile constituents of these bodily fluids – comprising at least 1840 VOCs – has been termed the *human volatilome* [18.285, 286].

The detection of odorants from bodily media by on-line CIMS has been limited to date, primarily because of the lack of a need for rapid detection of samples that are intrinsically slow or infrequent to acquire. The physiological and psychological role of such odorants has been treated elsewhere in this handbook. This section details the role that on-line CIMS has played in detecting such emanations.

Breath Analysis and Oral Malodor

Breath gas analysis has seen high activity in recent years with the emergence of new technologies that enable fast and comprehensive analysis of breath gas constituents. Primarily, breath analysis focuses on the search for volatile or nonvolatile constituents of exhaled breath gas, aerosols or condensate that represent unique biomarkers as indicators of state of health or specific diseases. The major advantages of analyzing breath for disease biomarkers over other bodily fluids such as blood or urine is that breath is inexhaustible, allows for noninvasive sampling, and can provide point-of-care results. In the context of this chapter, the emphasis on odorous molecules in breath restricts the discussion to predominantly oral malodor, whereas the majority of breath gas studies focus on end-tidal breath, i. e., gas from the deep lungs. The interested reader is referred to review articles that deal with breath analysis and biomarkers in general and not selectively odor-active compounds [18.287, 288]. Further, a recent comprehensive compendium of VOCs reported to be found in diverse bodily fluids highlights the complexity of the human volatilome and provides further indications of human endogenous odorous molecules [18.285, 286].

Of the on-line CIMS techniques outlined in this chapter, two stand out as the prevailing technologies in the analysis of exhaled breath volatiles in terms of their cumulative implementation in breath analysis, namely SIFT-MS and PTR-MS [18.44]. As is evident from Sect. 18.2.1, APCI-MS has been used extensively in the analysis of aroma compounds exhaled during food consumption, i. e., in nosespace analysis, to characterize in vivo aroma release. By comparison, its implementation in the analysis of endogenous breath constituents or oral malodor has been very limited, despite this technique being the first of the on-line CIMS tools to be used for analyzing breath. Indeed, as reported in the introduction, the development of a direct breath sampling interface for an APCI-MS in the late 1970s and early 1980s was a catalyst for establishing methods for the direct injection CIMS techniques of today [18.25, 26]. These initial studies reported on the detection of the most predominant volatiles in breath, namely ammonia, acetone, methanol and ethanol. More recent breath studies using APCI-MS include the analysis of fatty acid vapors in breath [18.289], and the detection of volatiles – including pyridine, isoprene and hydrogen sulfide – in a simulated breath atmosphere in view of its use to monitor exposure or disease biomarkers [18.290, 291]. Medically related breath analysis by APCI-MS, however, remains a niche area of application.

As indicated above, SIFT-MS and PTR-MS have been used more extensively in breath research, and both techniques were identified early on in their development as tools that are ideally suited to detecting VOCs in breath. Like APCI-MS, they fulfill the key requirements for the favorable aspects of breath analysis, i. e., rapid

and direct detection with immediate results. Moreover, unlike offline analytical methods such as GC-MS that are typically selective for specific compound classes, the on-line CIMS techniques offer nonselective detection of VOCs, thus the targeted molecules must not necessarily be known a priori. Further, the high humidity of exhaled breath is not a hindrance to the analysis when appropriately accounted for, thus samples must not undergo dehydration prior to their analysis [18.44].

There is a wealth of studies that have investigated the volatiles present in exhaled breath in view of discovering disease-specific biomarkers. As mentioned earlier, these typically do not focus on odorous compounds, but a brief summary is given here as a matter of course. The majority of studies on potential disease biomarkers have used a *discovery* approach, detecting a suite of VOCs in breath and performing statistical analyses on the data to find significant correlations. Alternatively, *targeted* studies investigate known VOCs and examine their correlations with specific diseases. In terms of general breath gas analysis, SIFT-MS has been employed for studies on endogenous volatiles such as methanol [18.292], isoprene [18.293], ethanol and acetaldehyde [18.294], C3-C10 aldehydes [18.295] and carbon dioxide [18.296], for disease-specific biomarker discovery, such as pentane as a marker for bowel disease [18.297], or for exposure monitoring, for instance in a study on xylene and trimethylbenzene levels in breath and blood after exposure [18.298] or for pollution exposure monitoring in breath [18.299]. The use of PTR-MS in breath analysis is similarly widespread, ranging from studies on the kinetics of endogenous compounds such as isoprene and acetone during exercise or sleep [18.300–303], detection of specific compounds in smokers' breath [18.304–306], the pharmacokinetics of compounds such as 1,8-cineole after ingestion of a pharmaceutical preparation [18.307], or investigating medical conditions such as renal transplantation [18.308], liver cirrhosis [18.309, 310], coeliac disease [18.311], or gestational diabetes mellitus [18.312], to name but a few. Other breath-related studies using on-line CIMS have investigated procedures in breath sampling and storage, and how these can influence constituent volatiles detected [18.233, 313–317], or a comparison between exhaled breath volatiles and those present in exhaled breath condensate (EBC) [18.318]. An overview of further breath-related studies using SIFT-MS and PTR-MS are available in review papers [18.44] or in recent journal special issues dedicated to these techniques [18.319, 320].

Let us now return to the focus of this chapter, namely odorant detection, in relation to breath. Halitosis (or bad breath) is caused by the presence of a range of odoriferous VOCs in exhaled breath. The offending odors are principally generated directly in the oral cavity, but in some cases halitosis is associated with episodes of eructation of food-related volatiles present in the gut or is related to the pulmonary excretion of systemic volatiles, such as in the case of ketosis or in conditions such as trimethylaminuria. The key candidate volatiles that cause oral malodor are volatile sulfur compounds (VSCs), typically hydrogen sulfide, methanethiol, dimethyl sulfide and other sulfides, but also short-chain fatty acids such as propionic, butanoic, pentanoic and 4-methylpentanoic acids, polyamines such as cadaverine and putrescine, phenolic compounds such as indole, skatole and pyridine, and nitrogen-containing compounds such as urea and ammonia can all contribute, depending on the specific medical condition [18.321]. Unfortunately for halitosis sufferers, these compounds are not only characterized by their unpleasant odor, but they typically have very low odor thresholds, such that they exhibit a potent odor even at ultratrace concentrations. For deeper insights into halitosis and its organoleptic assessment, the reader is referred to review articles on the topic [18.321, 322].

The very low detection limits offered by the on-line CIMS techniques, in combination with the direct sampling capabilities that reduce the potential losses of these labile substances, make these ideal tools to investigate oral malodor. Despite this, studies on oral malodor using on-line CIMS techniques are far sparser than general breath analysis studies; indeed to date only SIFT-MS has been used for oral malodor-related studies. A case study on oral malodor used SIFT-MS to characterize the ion-molecule reactions occurring with different reagent ions on the malodorous compounds indole and 3-methylindole (skatole), with results demonstrating a higher concentration of these compounds in oral air of subjects with clinically significant oral malodors compared to healthy controls [18.323]. SIFT-MS has also been demonstrated to detect the polyamines cadaverine and putrescine, which can be present in oral air [18.324]. Another study used an in vitro matrix biofilm perfusion model to test the efficacy of treatment with putative antimicrobial or anti-malodor actives based on the concentration of H_2S and other VSCs detected by SIFT-MS, as well as using SIFT-MS to validate microbial fuel cell-based H_2S sensing electrodes [18.325]. The study revealed higher levels of VOCs in the post-treatment placebo and negative treatment samples, and reduced levels after treatment with the active agents.

Ammonia in breath has been the subject of analysis by SIFT-MS, whereby it has been shown that this compound is primarily generated in the oral cavity, rather than arising from the systemic circulation, which of-

fers a note of caution on general breath analysis that contributions of volatiles from the oral cavity can be significant [18.326] and present a potential source of confounders. Sulfur compounds have been investigated in a similar fashion using SIFT-MS, comparing concentrations in mouth- and nose-exhaled breath and in the oral cavity. It was found that the concentrations of hydrogen sulfide, methanethiol, dimethyl sulfide and dimethyl disulfide were higher in the closed mouth than in nose-exhaled breath, suggesting that they are largely produced in the oral cavity [18.327].

In a diet-related malodor study, SIFT-MS has been employed to investigate the effect of drinking milk on suppressing or eliminating breath malodor in relation to garlic consumption. It was demonstrated that milk was effective in reducing the major odor compounds of garlic in breath, namely diallyl disulfide, allyl methyl disulfide, allyl mercaptan, allyl methyl sulfide and methyl mercaptan, with whole milk producing a greater reduction effect than fat-free milk [18.328], although other treatments were investigated in a follow-up [18.329]. PTR-MS has similarly been employed to investigate the compounds arising after garlic consumption. In the study, the VSC constituents of garlic were monitored in exhaled breath for up to 30 h after ingestion of raw garlic [18.330]. Allyl methyl sulfide and disulfide, diallyl sulfide, disulfide and trisulfide, and dimethyl sulfide were all detected in exhaled breath, whereby most of the compounds followed a transient increase and decrease over a 2–4 h period with the exception of dimethyl sulfide, which was still elevated in exhaled breath 30 h after ingestion of the garlic.

Body Odor

Human body odor is primarily related to the microbial breakdown of sweat excretions, which generates and releases odor-active compounds. Diet can influence the overall odor emanations from the body, whereby aroma compounds consumed with food can be excreted through the sweat glands, either in unaltered form or after being metabolized and converted into derivative forms. The use of on-line CIMS to investigate body odor or skin emanations has been limited to date. In terms of direct analyses with human subjects, one PTR-MS study investigated the presence of carboxylic acids in the axilla of volunteers, comparing use of a deodorant with use of an antiperspirant for one week [18.331]. The measurements, which utilized a specially designed sampling unit that cupped the axilla of the volunteer for direct measurement of odorants at the armpit, found acetic, propanoic, butanoic, pentanoic and hexanoic acids at high concentrations. Although the data represented only a single subject, an inverse effect of antiperspirant use and concentrations of selected fatty acids was evident, which was confirmed by the subjective impressions of a sensory assessor. This study has potentially high commercial value, as it allows sensory assessments of axillary odor following use of underarm deodorant or antiperspirant to be validated from a chemo-analytical approach.

An alternative method to investigate axillary odor is to use worn clothing as a surrogate, as was performed in a PTR-MS study that aimed to differentiate between different types of fabrics [18.332]. Short-chain carboxylic acids were at the focus of the investigation, where it was found that worn polyester fabric had significantly higher levels of odorous compounds compared to wool or cotton, as was confirmed in sensory assessments. The degree of adsorption of body odor compounds on three different textiles was similarly studied by PTR-MS, whereby specific textiles were found to adsorb compounds less or more efficiently, with decanal and cyclohexanone adsorbing more to wool, and ethylbenzene and butanoic acid methyl ester more to polyester, with all three textiles, including cotton, showing high adsorption of phenol [18.333]. Another study that used worn clothing as a proxy for skin emanations investigated the effects of ozone exposure on skin at ozone concentrations relevant to typical altitudes of air travel. Participants were asked to wear t-shirts overnight and subsequently place these in a simulated aircraft cabin, which was then flushed with ozone and the cabin air monitored by PTR-MS [18.65]. The presence of ozone led to a production in saturated and unsaturated aldehydes, and carboxylic acids, which reflected anecdotal observations of a higher odor in the cabin after ozone exposure compared to before. The theme of ozone-initiated lipid oxidation was followed further by direct PTR-MS measurements of skin emanations after ozone exposure [18.334]. In particular, the investigation revealed oxidation products such as dicarbonyls that may be respiratory irritants. Volatile lipid peroxidation products were similarly investigated in one study that exposed skin to ultraviolet (UV) light. PTR-MS was used to monitor reaction products during and after exposure, whereby compounds such as acetaldehyde and propanal, as well as some unidentified product ions, showed dramatic increases in concentrations above the skin during UV exposure [18.335].

One example of a SIFT-MS application loosely related to body odor is experiments performed on skin emanations after ingestion of glucose in the fasting state, with corresponding analyses of exhaled breath [18.336]. The results did not produce directly correlative responses in breath and skin in terms of their temporal developments, but demonstrated that most

compounds were present in both, with ammonia flagged by the authors to be of particular value in future applications, for instance to monitor the efficacy of haemodialysis treatment. Acetone emissions showed the highest correlation with blood glucose in breath and skin emanations, equally holding promise for potential future clinical use. APCI-MS has been used to investigate fatty acids from skin by use of secondary electrospray ionization (SESI) and subsequent detection via APCI-MS, whereby lactic acid and a complete series of saturated and singly unsaturated fatty acids were observed, as well as other metabolites such as ketomonocarboxylic and hydroxymonocarboxylic acids [18.337].

Bodily Fluids

In addition to bad breath and body odor discussed above, on-line CIMS techniques have been employed to characterize the volatiles present in other bodily fluids such as blood, urine and feces. As with breath analysis, most on-line CIMS studies of these bodily media focus on characterizing the overall volatile emissions, rather than purposely looking at the odorants, with the aim of identifying disease-specific volatile biomarkers. However, since odor-active volatiles are inevitably measured in these fluids, a brief review of research in this area is included here for completeness.

On-line CIMS analysis of the constituent volatiles in blood or urine is typically performed via direct headspace analysis, i. e., by sampling the gas immediately above the liquid sample. SIFT-MS has been used, for instance, to assess the correlation between breath and blood concentrations of ethanol after alcohol consumption. A comparison between breath ethanol levels – analyzed both directly and via sampling bags – with the ethanol levels in the headspace of blood measured by SIFT-MS, as well as data from a routine clinical determination of ethanol levels in blood, showed a high correlation and revealed that ethanol in the exhaled breath is in equilibrium with the ethanol in the blood, which is the main premise for alcohol *breathalyzers* used in law enforcement for drunk driving [18.298]. Other studies have similarly compared the concentrations of VOCs, primarily endogenous compounds, in breath and blood. PTR-MS, for instance, was used to investigate the potential of exhaled breath to be used as a surrogate for blood in detecting such compounds, although in those studies only the breath and not the blood was analyzed using PTR-MS [18.338, 339].

Urine headspace has been analyzed by SIFT-MS for several compounds, including acetonitrile [18.340], acetone, butanone, pentanone, hexanone and heptanone [18.341], and 3-hydroxybutanoic acid and other ketones [18.342], or to investigate potential volatile metabolites for profiling gastro-esophageal cancer [18.343]. Acetonitrile in urine was similarly investigated by PTR-MS in a study to correlate urinary levels with smoking habits wherein significantly higher concentrations were found in the urine of heavy smokers compared to nonsmoking controls [18.344]. The headspace of urine was also analyzed recently to ascertain changes in its composition after strenuous walking, whereby acetic acid, amongst other metabolites, was identified as a significant marker for exercise effects [18.345].

Decomposition Odor and Entrapment Odor

Postmortem decomposition odor and entrapped human odor are of interest in forensic science and search and rescue endeavors. Most studies investigating human odor emission are conducted offline by use of hyphenated GC techniques [18.346] and GC-MS has indisputably been pivotal in acquiring a good understanding of human odor, ranging from breath gas, blood, and urine to tissue decomposition [18.346–352].

Law enforcement and rescue agencies have long made use of the highly sensitive canine sense of smell to locate human remains or survivors after natural or manmade disasters [18.353]. Despite the exceptional abilities of trained dogs in this task, their usage has certain shortcomings such as a high cost for training, a rapid onset of fatigue leading to limited working hours (typically only 20 min before they require several hours of rest to recuperate) and only 6–8 years average working lifetimes. The development of field-portable analytical instruments that mimic the canine ability of locating live humans or remains is thus highly desirable.

The on-line CIMS techniques covered in this chapter have a range of potential applications in the field: the equipment can operate continuously and reproducibly with sufficiently low LODs that are necessary for the detection of human odor emanations, and their fast time resolution could allow for monitoring the intermittent nature of human odor emissions in real-time at the point of interest. Although these techniques cannot yet achieve the sensitivity of the canine nose, these could be used as a complementary tool in the field, for instance for the purpose of preliminary screening of large sites.

To increase the recovery rate of surface and subsurface human survivors or cadavers, the artificial decomposition (or bodily fluid) odor surrogates used for canine training and instrumental calibration should closely mimic the composition and time-intensity release curves encountered under realistic scenarios. Perhaps the greatest barrier to wider applications of on-line CIMS applications in these fields is the lack of complete characterization of the odor signature (chemical fingerprint) of human decomposition odors and the

large spectrum of VOCs emitted by bodily fluids – i. e., the human volatilome [18.286] – which consequently limits the availability of comprehensive synthetic odor surrogates, for example those used as canine training aids [18.354, 355]. Such synthetic odorant mixtures should also be used to calibrate the on-line CIMS signal responses and to improve spectral identification, while their accuracy and appropriateness as training and instrumental calibration aids should be thoroughly evaluated by applying procedures similar to those used for assessing food flavoring compositions and odorant delivery systems described elsewhere in this chapter.

Despite the great potential for successful applications in the field of forensics and search-and-rescue, the technical literature is currently devoid of reports on the implementation of on-line CIMS. Near-real-time applications have been reported only for multicapillary column ion mobility spectrometry (MCC-IMS). Specifically, these relate to the fingerprinting of urine odorants [18.356] that can be used for purposes of subject location under ruins, VOCs emitted from humans entrapped in confined spaces [18.357] and general fingerprinting of skin odorants [18.358]. Recent advancements in the sensitive and quantitative detection of skin-borne volatile biomarkers of entrapped humans have been achieved by PTR-SRI-TOF-MS [18.359].

Despite the fact that the chemical identification capabilities of on-line CIMS do not yet reach those of GC-MS, and although complex patterns of odor mixtures are not immediately discernible as with e-noses or sensors arrays (the latter have nonetheless limited applications in these fields [18.360]), the techniques reviewed in this chapter have distinct advantages that could contribute to in situ applications for survivor or cadaver localization. They offer highly sensitive measurements of specific target VOCs and require no sample separation, thereby enabling fast screening purposes based on molecular masses, in addition to being deployable in the field and offering a relatively low cost and high throughput for sample analysis when compared to multiple steps and handling required for the offline GC methods. As such, once the chemical fingerprinting of body fluids and decomposition odors has been narrowed down to a core set of tracer VOCs, it is anticipated that the application of CIMS to these types of investigation will proliferate in the near future.

18.2.4 Olfaction

The field of olfactology, i. e., the study of the sense of smell, has been discussed extensively in several chapters of this book. On-line CIMS techniques are of utility in certain aspects of this field of research, but have been far from exploited to date. As with in vivo aroma release or exhaled breath odor studies, specific olfactology-related investigations can greatly benefit from the real-time analytical capabilities of on-line CIMS. Applications of on-line CIMS in olfactology-related studies can be broadly categorized into two branches: validation of tools used in olfactology, and the study of human physiology and olfaction. These are treated briefly below.

Validating Tools Used in Studies on Olfaction

The assessment of olfaction in terms of the sensitivity and function (or dysfunction) of the human sense of smell is typically made by presenting the subject with a specific odorant or series of individual odorants at defined concentrations. In terms of olfactory ability, this might involve identifying or naming a specific smell within a selection of different smells. For sensitivity, the odor and perception thresholds can be determined by ascertaining the presented odor concentration below which the person no longer detects or perceives it. Similar methods are employed for dysfunction in relation to varying forms of anosmia, whereby odors must be named or their perception must be indicated during presentation of specific odorants at varying concentrations.

Most olfaction-related tools used by otorhinolaryngologists in determining olfactory ability have undergone rigorous evaluation from a clinical perspective, but few have been the subject of chemo-analytical validation. In other words, they have been demonstrated to be reliable tests for their intended purposes, but – especially for olfactory sensitivity testing, whereby the presented odorant concentration is a key feature of the test – the odorants in use in such tests are rarely accurately quantified analytically, but rather are presumed based on their methods of preparation.

There are diverse tools that are in routine use for assessing olfaction, the most prominent being the University of Pennsylvania Smell Identification Test (UPSIT) [18.361], the Connecticut Chemosensory Clinical Research Center Test (CCCRC) [18.362], and the combined odor identification, discrimination and threshold assessment using Sniffin' Sticks [18.363]. Human olfactory function assessment methods are treated in more detail elsewhere in this book (Chap. 23). As with the other applications outlined in this chapter, the benefits of using on-line CIMS for such investigations are the wide range of detectable compounds, the broad dynamic range of measurable concentrations, and the real-time capabilities.

Sniffin' Sticks have found widespread use in testing olfactory sensitivity and acuity [18.363], and the threshold test comprises a set of odorant pens covering a range of concentrations of *n*-butanol that are used to determine the threshold of human subjects to this

particular odorant, and by inference approximate the keenness of their sense of smell. This test battery has been validated from a clinical approach [18.364, 365], but previously not to any great extent from a chemo-analytical perspective, with only one study reporting on the release of *n*-butanol from the tips of individual pens, as measured by GC-MS [18.366]. PTR-MS was recently used to provide a comprehensive validation assessment of the gas-phase concentrations of *n*-butanol released from the tips of the Sniffin' Sticks olfactory threshold test set in terms of concentration linearity and stability over time [18.367]. Pens were presented to the PTR-MS via a custom-made analytical setup according to the same protocol used for testing human subjects. By continuously monitoring the *n*-butanol signal, the gas-phase concentration linearity across the pens could be determined; for these specific investigations it could be shown that gas-phase *n*-butanol released from the tips of the pens was linear over the full concentration range, as had been previously only assumed. Furthermore, assessments of older pens indicated good odorant (concentration) stability provided the pens were stored correctly. This one example highlights the power of on-line CIMS for validating such tools in a quick and reliable fashion.

An air-dilution olfactometer is a device that generates odorant pulses at predefined concentrations and for predetermined pulse durations [18.368, 369]. It can be used for odorant delivery with simultaneous measurement of olfactory event-related potentials via electroencephalography (EEG) in assessments of neurological activity in response to odorant exposure. As with the tools outlined above, the odorant concentrations presented to the subjects undergoing examination are typically only calculated. In this case, calculations are made based on the specific conditions of the system, i. e., the set mixing ratios of the (presumed) saturated odorant gas and the air dilution flow. Past attempts at validation have used sensors such as a photoionization detection (PID) system to measure the temporal resolution of odorant pulses, but typically rely on GC-MS analyses for quantitation [18.369]. On-line CIMS techniques offer both a high temporal resolution and accurate quantitation and are thus highly appropriate tools for validating such tools. PTR-MS was recently used to characterize the odorant pulses generated by one such air-dilution olfactometer [18.370]. Focusing on the odorous compounds hydrogen sulfide, ethyl butanoate, ethyl hexanoate, and 2,3-butanedione, the PTR-MS analyses revealed a dependence of the delivered odorant concentration on the pulse duration. In particular, the briefest pulse of 50 ms produced a H_2S concentration that was less than half that of the longest pulse of 3.2 s. Furthermore, the relative odorant concentrations set at the olfactometer were not necessarily reflected at its delivery port and depletion in concentration was observed for odorants that were delivered by the olfactometer from aqueous solutions. These results indicated that such gas-dilution olfactometer systems should not be operated with the assumption that the set concentrations are accurately delivered by the system, but nevertheless the device was deemed suitable for the settings typically encountered in its clinical use [18.370]. Two commercial field olfactomters were also recently validated by SIFT-MS with respect to their ability to generate accurate dilutions, specifically for the compounds acetic acid, propanoic acid, *n*-butanol, dimethyl sulfide and dimethyl disulfide [18.371]. One of the two systems showed a good performance, albeit with a breakthrough of the compounds through the activated carbon filter at the highest concentrations; the other system was found to produce linear concentrations, although these were higher than expected theoretically.

APCI-MS (MS-Nose) was used to measure the in vivo flavor release of the compound ethyl butanoate from milk (whole and skim milk samples) and to replicate this via defined odorant pulses from a gas-dilution olfactometer [18.372]. The latter were then verified using the same APCI-MS, where it was shown that the areas under the flavor release curves were consistent in most cases. This study further demonstrates how odorant delivery tools such as the gas-dilution olfactometer can be calibrated using on-line CIMS techniques. APCI-MS was also recently used to assess the variability in odor delivery of several simple systems commonly used for human sensory testing, namely from squeezable wash bottles, hinged-lidded plastic sniff pots, cosmetic cotton buds placed in a tube, and a dynamic system of purging air through the odor solution via a fine sinter [18.373]. An odor mixture containing eight compounds of different physicochemical properties in water was used to study odor delivery from these systems during typical procedures of use, for example squeezing the wash bottle for 10 s for sampling, followed by a 30 s pause in a repetitive manner. The assessments via on-line APCI-MS detection demonstrated the rapid decrease in headspace concentrations from the initial values to subsequent squeezes, lid-openings, and purge time for the different systems for most of the compounds, whereby 3-methylbutanol and diacetyl showed the least change for the latter two systems. Following this initial concentration drop, however, the levels stabilized to produce fairly consistent concentrations. Although the systems tested are primarily used for determining odor attributes rather than for threshold assessments, whereby fluctuations in the absolute concentration might not be too critical, this study nevertheless demonstrates the need for validating

such methods to ensure consistency. Furthermore, the authors attributed some losses in compound concentrations from the squeezable wash bottle to interactions of individual compounds with the plastic material of the bottle, further highlighting the importance of choosing appropriate materials when working with volatile odor compounds.

Human Olfaction

The rapid and sensitive detection capabilities of on-line CIMS techniques have long been exploited in food-flavor research for aroma detection in relation to flavor release from foods, in particular in the form of correlative determinations of exhaled *nosespace* aroma compound concentrations with perceived sensory impressions, as reported and discussed in Sect. 18.2.1. Despite the wealth of information gained from such studies, critics have often voiced their concerns that the odor concentrations detected in the exhaled breath exiting the nostrils do not necessarily represent those that reach the nasal epithelium in the olfactory cleft, located at the upper apex of the nasal cavity, and interact with the epithelial cells to elicit an odor impression in the brain. The basis of these arguments is that the physicochemical properties of individual odorants and their affinity to the nasal mucosa will determine the extent to which they can successfully traverse the nasal cavity; odorants released in the oral cavity have a different route to the olfactory cleft (retronasal perception) than through the nares (orthonasal perception). As such, in the field of human olfaction it is desirable to determine odorant concentrations directly at their site of physiological detection, i. e., at the nasal epithelium. Despite this, on-line CIMS has been largely overlooked in this niche area of research, but has recently been used in several investigations for probative assessments of specific odorants at different positions within the nose.

Very few studies in the past have made progress in this direction by conducting in vivo detection of odorants within the nasal cavity. Amongst these, the trigeminal sensation associated with exposure to carbon dioxide (CO_2) by its directed stimulation has been investigated at different locations within the nose by simultaneous intranasal detection of this compound [18.374]. In that study, however, the temporal attribute of the stimulus, which is a critical parameter for perception, was not considered, but rather the intranasal concentrations of CO_2 were determined only once these had stabilized. Another study used an e-nose sensor with a sampling rate of 8.3 Hz to detect and quantify H_2S at the olfactory cleft at two stimulus concentrations (2 and 10 ppm_v) and comparatively for orthonasal and retronasal odor administration routes [18.375]. This investigation successfully demonstrated that odorants can be measured intranasally with a high temporal resolution, with indications that there was no difference in concentration observed at the olfactory cleft from orthonasal or retronasal administration; it should be noted here that other odorants might be expected to perform differently to this specific compound.

Based on the initial success in detecting a single odorant intranasally using a sensor system, trials of multiple-aroma detection in relation to perception and administration routes were conducted using PTR-MS by measuring the concentrations and temporal profiles of stimuli of specific aroma compounds released from model food custards [18.376]. In particular, the chosen aroma compounds were measured at four positions within the nasal cavity, namely in the nostril, in front of the middle turbinate, in the area of the olfactory cleft, and in the nasopharynx, as released via the oral cavity during mastication of two custards of different viscosity; a liquid and a solid custard. The highly time-resolved measurements showed clear differences in release, both between compounds and between custard viscosities for individual compounds. Moreover, the concentration maxima of all compounds were observed to be highest at the nasopharynx and lowest at the olfactory cleft, with the different positions also showing varying latencies of compound arrival.

In a similar study, PTR-MS was used to detect individual odorants exiting the nostrils in relation to modes of presentation, either an orthonasal or a retronasal stimulus of discrete odorant pulses generated by a gas-dilution olfactometer [18.377]. In particular, a comparison was made between ipsilateral and contralateral orthonasal and retronasal stimulus presentations, i. e., between odorant concentrations at the nostril coming from pulses presented either on the same side or on the opposite side of the nasal cavity as the sampling position. Here it was shown that, as intuitively expected, the odorant concentrations exiting the nostril from retronasal stimulus presentation were similar for ipsilateral and contralateral sampling, since the air containing the odorant essentially flows equally between the two chambers of the nose. By comparison, orthonasal stimulus presentation elicited much lower concentrations at the nostril during contralateral (compared to ipsilateral) detection, since the odorant was required to flow in through one nostril and out through the other. An interesting finding of this study was the large discrepancy in the concentration of the odorant detected directly as emitted from the olfactometer compared to its intranasal detection. The authors explained this phenomenon to be a culmination of the distribution of the odorant within the nasal cavity and adsorption of the odorant to the mucosal lining, the degree of which depends on gas flows, the nasal anatomy and the

physicochemical properties of the compounds in question [18.200]. In addition to the evaluation of cortical olfactory processing – detailed below – the visualization of swallowing processes during food consumption provides additional insights into olfaction in this context. The aforementioned study used videofluoroscopy of the oral and pharyngeal processes [18.378] in combination with PTR-MS nosespace analyses to identify consumption behavior responsible for retronasal aroma release. In one example using model food gels of different hardness, videofluoroscopy showed that panelists tended to press the gel against the frontal region of the hard palate using their tongue, without direct chewing action [18.377]. It was found that individual consumption patterns greatly affected flavor release, whereby the velum-tongue border remained closed in nonchewers until the sample was swallowed, which was then followed by a higher intensity swallow breath compared to panelists that chewed their sample.

Subsequent studies have employed on-line CIMS to assess how the mode of sniffing can affect intranasal concentrations of individual odorants. One study investigated how the odorant 2,3-butanedione (diacetyl) was delivered to the region of the olfactory cleft in relation to the sniffing behavior of subjects, with a comparison between normal inspiration, rapid sniffs and a single, forced sniff [18.379]. The normal sniff was observed to elicit the maximum concentrations at the olfactory cleft, which anecdotally reflected the highest intensities subjectively perceived. In a further study the concentrations of *n*-butanol at the olfactory cleft, as detected by PTR-MS, were compared to the odor thresholds of individual subjects that were ascertained by means of odorant pens (Sniffin' Sticks). Comparison of intranasal concentration and odor threshold indicated an overall alignment of *n*-butanol concentrations at the olfactory cleft with the corresponding odor threshold and the reports from subjects that they did or did not perceive the odor (false/correct perception responses) [18.380]. Additionally, concentrations in the pens generally correlated positively with concentrations at the cleft, which provides evidence of the pen performance – as similarly demonstrated in a separate study [18.367] – as well as demonstrating the validity of such intranasal sampling methods to perform corresponding subjective threshold and odorant delivery tests.

Moving to ex vivo studies, a series of measurements using APCI-MS was made to study the dynamics of odorant uptake by odorant-binding protein (OBP) [18.381, 382]. The dynamic biomimetric odorant-binding system (DyBOBS) developed for these studies featured a capillary tube with its inner surface coated in a thin aqueous film of recombinant rate OBP, through which known concentrations of odorants were passed and their uptake and release monitored by on-line APCI-MS. The system showed time-dependent changes and remarkably high reproducibility, offering a promising technique for investigating odorant mass transfer from the gas-phase to the liquid-phase of OBPs. On-line APCI-MS has also been used to validate a system for retronasal olfactory stimulation that combines an automated odorant stimulus delivery system with functional magnetic resonance imaging (fMRI) acquisition of brain activity to complement basic sensory research in terms of cortical olfactory processing [18.383] (see also Chap. 38).

This handful of studies demonstrates the utility of on-line CIMS techniques for investigations in the field of olfaction and highlights the benefits for scientists working in the field of chemosensation to increasingly embrace these tools in years to come.

18.2.5 Miscellaneous Applications

This final applications section reports on niche areas in which on-line CIMS techniques have been deployed, with only loose association to odorant detection. It is included here for completeness to provide the reader with some insights into other areas of use for these on-line CIMS tools. Inevitably there are some further minor areas of application that are not well documented in the scientific literature and are therefore not reported here.

Chemical Warfare Agents and Toxic Industrial Compounds

Chemical warfare agents (CWAs) and highly toxic industrial compounds (TICs) are briefly considered under the umbrella of detecting volatile *odoriferous* compounds using on-line CIMS techniques for scenarios such as real-time, in situ threat monitoring, for example first responders to war or terrorist attacks, or in the protection of workers operating at chemical facilities or on location at environmental contamination sites. TICs are also potentially dispersed as attack or contaminant agents and thus fall in the same category as CWAs. It might be noted that such situations typically involve CWAs or TICs at trace levels that are below human odor perception or detection thresholds.

CWAs are synthetic compounds with low molecular weight that are characterized as fast acting and potentially lethal for humans at very low levels. Typical compounds in this group include the nerve gases sarin (GB) and tabun (GA), or the blister agents mustard gas (HD) and lewisite 1 (L1), to name but a few. A compilation of chemical structures, volatility at 25 °C, and inhalation toxicity data of CWAs is given in the literature [18.384]. Most of these substances exist as stable liquids or solids with low volatility at room tempera-

ture; these sometimes exhibit characteristic odors (e.g., mustard gas smells like garlic, onion or mustard), although the human sense of smell is generally numbed rapidly after exposure, typically after only a few inhalations. Common chemicals that are widely produced, transported, and stored can also be classified as TICs, i. e., having high toxicity and being easily vaporized. These are especially noxious when released at elevated concentrations, and can include compounds such as ammonia, formaldehyde, sulfur dioxide, phosgene, chloroacetone, chloroacetophenone, and many others compiled and ranked into health-hazard lists.

CWAs and TICs are usually released as vapor or aerosols and enter the body mainly via inhalation or dermal exposure, hence the need for detection in the gas and/or particulate phase. Due to their often rapid action and high lethality there is a necessary demand for rapid and reliable methods for the early detection and identification of CWAs and TICs and their degradation products at the point of interest (hence portability is also a requirement for these methods), typically within a few seconds to less than a minute, and a high detection specificity to avoid false alarms [18.385]. Because of the acute toxicity at low concentration levels the required detection limits are in the range of ppb_v down to ppt_v levels. For example, the detection requirements for sarin are gas-phase concentrations of $150\,\mu g/m^3$ (ca. 25 ppb_v) [18.384], which is necessarily well below the toxicity level (LCt50 within 1 min) and often at subodor thresholds for humans. Interfering environmental signals from emissions, for example by exhaust gases or smoke resulting from burning materials at the site of an attack or accident, as well as the influence of variable sample gas humidity, pose significant issues for the reliable detection and quantitation of these agents.

The recommendation for analytical field inspections of CWAs under the Chemical Weapons Convention include GC-MS and IMS for on-site screening [18.386]. Application requirements are fast analysis times (< 30 s), high sensitivity, high selectivity towards the specific agents, and good precision with a wide dynamic range and suitable accuracy. Although commercially available portable GC and GC-MS can provide highly sensitive and specific detection of CWAs in air, often the required real-time detection is not achievable. IMS has found widespread use for screening CWAs [18.387–391], yet the technique is affected by a low sensitivity and specificity (the latter leading to frequent false alarms) and by relatively long response and recovery times due to strong adsorption of CWAs on the internal surfaces of the device [18.384, 392]. Auxiliary reagent gases (e.g., ammonia) affect ionization processes and are quite common in IMS-based CWA detectors for suppressing fragmentation effectively and thereby allow for the implementation of algorithms for automated agent identification in field applications.

APCI-MS has long been reported as a detector capable of real-time detection of CWAs down to ppt_v-levels, both in positive and negative ionization modes [18.393–395]. Lately, an improved method for sensitively and selectively detecting CWAs was developed by using counterflow introduction APCI-MS. This latest technique relies on corona discharge to form reactant ions that are then driven by an electric field in an opposite direction to the airflow, thus eliminating the interfering neutral molecules ozone and nitrogen oxide and resulting in a more efficient ionization of the target compounds, particularly in the negative ionization mode [18.396].

SIFT-MS has also been trialled for CWA detection, with a paper reporting on the rate coefficients and branching ratios of the reaction of fifteen CWA precursors and surrogates with hydronium, NO^+ and O_2^+ reagent ions, thus enabling quantitative detection [18.397]. For most of the investigated compounds the real-time LODs were in the ppb_v to ppt_v range at a detection time of 10 s. Despite its promise, no further work on SIFT-MS applications for CWA detection has emerged in the literature since the aforementioned paper.

PTR-MS shows promise as a suitable technique for the sensitive, selective and fast detection of CWAs and TICs, particularly with the higher accuracy spectral resolution afforded by the PTR-TOF-MS instrument configurations [18.398], but also in the simpler and compact PTR-QMS model. Both systems have been trialled using hydronium as the main reagent to detect CWAs and TICs [18.399]. Additionally, ammonia has been used as a reagent ion in combination with a reduced drift voltage to effectively suppress the fragmentation of product ions of the nerve agents sarin, soman, cyclosarin and tabun [18.400], which is necessary in order to generate and implement algorithms for automated agent identification in field applications. On the other hand, appearance of particular fragments might deliver additional information. Making use of these effects allows switching between fragment and molecular ion peak spectra; thus targeted fragmentation can be used to confirm identification based on molecular peak detection.

In conclusion, all of the on-line CIMS techniques deliver the necessary requirements for both immediate detection and continuous on-site monitoring of CWAs and TICs. Currently, limits of detection for commercial and research grade on-line CIMS instruments are estimated in the ppt_v to ppq_v levels, and the range of detectable CWAs and TICs agents in on-line CIMS

is being constantly expanded by advancements in theoretical studies and measurements of ion chemistry properties [18.401].

Process Analysis

The processing industry as a whole, including chemical, pharmaceutical, biochemical, cosmetic and food processing sectors, strive for simultaneous analysis and continuous process control. The information for the task is provided by integrating a variety of analyzers encompassing near-infrared spectroscopy, electrochemical probes and multiarray gas sensors to generate thousands of different real-time signals from chemical or biological processes. Providing on-line/in-line/at-line and in situ measurements has to meet specific requirements, for example warrant aseptic conditions and detect a high number of analytes simultaneously and without disrupting the process. On-line mass spectrometry equipped with carefully designed inlet interfaces, in some instances CIMS techniques, are well established in several fields of industrial and bioindustrial processing [18.402] where their capability for real-time sample analysis and high analytical throughput yields insights into the dynamics of chemical or biochemical reactions and kinetics, also for labile intermediates or metabolites [18.403]. Although such VOCs do not strictly belong to the odorants category, a selection of on-line CIMS applications in the field of industrial process monitoring is provided in the following for completeness.

PTR-MS has been deployed in the biopharmaceutical industry to support the understanding and control of production processes and to monitor these in view of increasing the product yield, an application demonstrated by the measurement of the headspace gas from within a bioreactor [18.404]. Constituent VOCs in the headspace of the reactor used for fermentation of *Escherichia coli* were monitored in real-time and compared with biomass dry matter weight and recombinant protein production rate. Twenty VOCs that correlated with these bioprocess parameters were identified and proposed to be of potential use as indicators for on-line monitoring of fermentation progress. Moreover, advanced on-line monitoring of cell culture off-gas has also been achieved by deploying PTR-MS [18.405, 406]. PTR-MS has also found application in biogas-producing facilities to monitor odorous trace impurities such as H_2S, which presents an operational and environmental challenge, along with monitoring of marker VOCs as quality indicators of the biogas product [18.407]. On the chemical processing side, PTR-MS was used for the analysis of syngas in an industrial Fischer-Tropsch process to detect a variety of volatile organic and inorganic compounds, such as HCN, H_2S, RSH, carbonyls, acids, alcohols and others, potentially odorous VOCs [18.407].

18.3 Conclusion and Outlook

On-line chemical ionization mass spectrometry, CIMS, has developed over the past two decades to become a powerful tool in the real-time detection of VOCs, including odor compounds. The use of such systems in the detection of odorants has evolved from a handful of niche and classical areas of study to a wide range of fields of application that cover food aromas, environmental and indoor odors, studies related to olfaction, detection of chemical warfare agents, forensics and many more. This chapter has introduced and discussed the three current major on-line CIMS techniques of selected ion flow tube MS (SIFT-MS), proton transfer reaction MS (PTR-MS) and atmospheric pressure chemical ionization MS (APCI-MS), and their implementation for the detection of odorous compounds in diverse disciplines. The less common techniques such as ion-molecule reaction MS (IMR-MS), ion mobility spectrometry (IMS) and ion attachment MS (IAMS), are also introduced, with references to specific odor-related applications given, where appropriate. The chapter provides an up-to-date compilation of the state of research using these powerful CIMS tools.

The on-line CIMS techniques reviewed in this chapter have their primary strength in providing very fast and highly sensitive analysis of VOCs, including odorous compounds, whilst practically eliminating analytical artifacts and sample losses arising from pretreatment, sample storage and thermal desorption steps that are mandatory for routine analytical methods. The use of fast, on-line CIMS techniques overcomes the need of discontinuous purge-and-trap or preseparation or preconcentration steps customarily required by the GC-MS methods, thus allowing for real-time detection of odorous VOCs down to ultratrace levels in diverse areas of application. As such, the CIMS techniques greatly increase the number of samples analyzed on-site, thus significantly reducing data uncertainty and improving time resolution for determining fast odorant emission or release processes. Furthermore, the method of analyzing solid or liquid samples is nondestructive since measurements proceed only in the

gas-phase from the sample headspace, thus samples can be analyzed repeatedly, as appropriate, as is the case for monitoring food spoilage or aroma development.

Despite the applicability of the on-line CIMS techniques in the fields addressed in this chapter, it is crucial to apply them with knowledge of their strengths and limitations, bearing in mind that these are principally tools for real-time measurement, gas-phase fingerprinting, and nontargeted screening of VOCs, rather than for exhaustive chemical-structural elucidation of known and unknown analytes. Although on-line CIMS can provide some chemical-structural information on the target analytes, the capability to thoroughly separate and identify isobars, isomers and, in many cases, specific odorant stereoisomers, remains a strongpoint of the slower and specific GC-MS techniques. For certain applications, accurate concentration assessment of selected odorants can only be achieved by the GC-MS techniques, especially by the hyphenated (GC-GC) systems, for which customary quantitation procedures (such as internal standard additions or stable isotope dilution assays) provide unsurpassed accuracy and precision in quantitation, although there is evidence indicating that on-line CIMS techniques perform better for some applications [18.58, 408, 409]. Further, in terms of quantitation, a particular strength of on-line CIMS techniques is the opportunity to make relative comparisons of dynamic changes, which is made possible by the mostly linear response to analytes over a wider range of gas-phase concentrations.

The generation of large, chemically detailed and highly time-resolved concentration datasets afforded by on-line CIMS opens the path to the application of powerful multivariate statistical methods, encompassing chemometrics, data-mining and statistical modeling techniques. These can be applied to solve problems of fingerprinting, classification or calibration across virtually all the fields of applications described in this chapter. Successful examples have been described for applications with SIFT-MS [18.148], APCI-MS [18.179], PTR-MS [18.131] and PTR-TOF-MS [18.282]. The continuing endeavors to increase detection sensitivities, reduce the limits of detection, and expand the range of detectable compounds by improved compound discrimination are welcome developments that will broaden the appeal of on-line CIMS techniques for odorant detection. As the mass spectrometric detectors (QMS, TOF-MS) and the CI method described in this chapter have reached a steady state of development, the latest technological progress heads toward better collimation and preselection of the analyte ions before these proceed to the detector. Some of these developments have already been implemented in research or commercial instruments and have been demonstrated to further increase the detection sensitivity, expand the detection range and to increase mass resolution and enhance selectivity. In the case of APCI-ITMS, for instance, the ion trap enhances the detection sensitivity of polychlorinated biphenyls and allows for the monitoring in ambient air [18.410].

A dual-purpose drift tube/ion funnel can be coupled to various types of mass spectrometers to increase the detection sensitivity, which has been reported in terms of a radio frequency ion funnel in PTR-MS [18.411]. Alternatively, in PTR-QiTOF-MS a quadrupole ion guide (Qi) preselects the ions entering the TOF-MS area, to enhance the mass resolution [18.95]. The implementation of a fastGC add-on to PTR-MS instruments offers fast gas chromatographic performances by separating the neutral analyte molecules before these undergo proton attachment, which in turn enhances discrimination and allows identification of isomers. This has readily found application in food and flavor research, for example in wine aroma analysis or in medical application such as breath gas research [18.90, 94], as well as in biogenic emissions [18.412]. The recent launch of a commercial SIFT-MS instrument with negative reagent ions, namely O^-, O_2^-, OH^- and NO_2^-, extends the analytical range of detectable compound classes – albeit not focused on odorants – to include acidic gases (HCl, HF, SO_2), greenhouse gases (CO_2, CH_3, NO_2, H_2O), photochemical smog precursors (NO_x, ozone, PAN), and tracer gases (e.g., sulfur hexafluoride SF_6). Pending developments in this field also include the planned launch of a commercial APCI-MS tailored for the sensitive, on-line detection of VOCs.

Although on-line CIMS have an analytical range beyond only odorous substances, their implementation for odorant detection is highly valid, as is evident from the diverse range of applications reviewed in this chapter. To date their main dedicated use to detect odorous molecules has been in aroma research, but many niche fields can profit from the analytical capabilities of the on-line CIMS techniques of SIFT-MS, PTR-MS, and APCI-MS, most notably due to their real-time detection capabilities, wide dynamic range, and low limits of detection. Certainly this technology will be increasingly deployed in such fields once its potential is fully realized.

Acknowledgments. The authors would like to thank the following people for supplying material on the main techniques discussed within this chapter, namely Murray McEwan and Vaughan Langford of Syft Technologies Ltd., Christchurch, New Zealand (SIFT-MS), Jens Herbig and Lukas Märk of IONICON Analytik GmbH,

Innsbruck, Austria (PTR-MS), Jean-Luc Le Quéré at INRA, Dijon, France, Andy Taylor of Mars Petcare, Waltham on the Wolds, Leicestershire, UK, Robert Linforth at University of Nottingham, Nottingham, UK and Ed Sprake at Waters Corporation, Wilmslow, UK (APCI-MS).

19. Enantioselective Gas Chromatography with Cyclodextrin in Odorant Analysis

Cecilia Cagliero, Barbara Sgorbini, Chiara Cordero, Erica Liberto, Patrizia Rubiolo, Carlo Bicchi

This chapter concerns enantioselective gas-chromatography (Es-GC) with cyclodextrin derivatives as chiral stationary phases for chiral recognition of volatile odorants in the flavor and fragrance field. The text is divided into two main parts. The first one is more general and deals with enantiomers and odor and need for chiral recognition, evolution of chiral stationary phases for Es-GC since its beginning, followed by the history of cyclodextrins and their applications to enantioselective GC. It also includes some theoretical aspects of enantiomer separation with cyclodextrin derivatives and their influence on routine chiral recognition.

The second part concerns the strategy of chiral recognition in routine analysis with cyclodextrin derivatives as chiral stationary phases illustrated by examples with real natural product samples. This part describes enantiomer automatic identification or their excess or ratio determination in complex mixtures by enantioselective GC combined with mass spectrometry; in particular it deals with the potential of multidimensional techniques and of fast GC in chiral recognition and the role played by mass spectrometry. The last paragraph concerns the use of total analysis systems in chiral recognition.

Metabolite formation in a biological matrix (plant or animal) is almost always stereoguided, and the resulting components are very often chiral and present an enantiomeric excess. Enantiomer recognition and enantiomeric excess (ee) and/or ratio (er) determinations of a chiral compound are therefore important parameters to characterize the matrix and its biological activity, in particular in the fields of food, flavor, and fragrance. Enantiomeric recognition is therefore very important:

1. To correlate chemical composition and organoleptic properties
2. To determine the biosynthetic pathway of a compound
3. To classify a sample
4. To determine the geographic origin of a *natural* sample
5. To implement quality control and detect frauds or adulteration of *natural* samples: enantiomeric composition can reveal the addition to *natural* products of cheap synthetic materials or volatiles from other sources, mainly to reduce costs.

The interaction of a molecule with olfactory receptors is usually stereoselective, meaning that the

Table 19.1 Examples of different odor characteristics of enantiomers of chiral molecules [19.1]

Compound	Enantiomer	Characteristics
Nootkatone	(5*R*, 6*S*, 8*R*)-(+)	Grapefruit
	(5*S*, 6*R*, 8*S*)-(−)	Woody-spicy
2-Methylbutanoic acid	(*R*)-(−)	Penetrating, reminiscent of cheese and sweet
	(*S*)-(+)	Pleasant, sweet, elegant, fruity note
Ethyl 2-methylbutanoate	(*R*)-(−)	First medical, phenolic note, later sweet, fruity
	(*S*)-(+)	Ether-like, sweet, after dilution pleasant apple note
2-Ethylhexanoic acid	(*R*)-(−)	Herbaceus, earthy
	(*S*)-(+)	Sweet, herbaceus, faint musty
1-Octen-3-ol	(*R*)-(−)	Intensive mushroom note, fruity, soft
	(*S*)-(+)	Herbaceus, green, musty
Linalool	(*S*)-(+)	Flower-fresh, reminiscent of lily of the valley
	(*S*)-(+)	Differs slightly in odor
(*E*)-Nerolidol	(*R*)-(−)	Pleasant, woody, warm, musty
	(*S*)-(+)	Slightly sweet, mild, soft, flowery different to (*Z*), less intensive
(*Z*)-Nerolidol	(*R*)-(−)	Intensive, flowery, sweet, fresh
	(*S*)-(+)	Woody, green, fresh bark
Limonene	(*R*)-(+)	Fresh, pleasant, orange-like
	(*S*)-(−)	Faint mint note, turpentine note
α-Ionone	(*R*)-(+)	Fine violet-like, fruity, flowery, raspberry-like
	(*S*)-(−)	Strong woody aspects, raspberry-like
α-Terpineol	(*R*)-(+)	Strong, flowery sweet, lilac
	(*S*)-(−)	Tarry, reminiscent of colp pipe
Carvone	(*R*)-(−)	Herbaceus odor, reminiscent of dill seeds
	(*S*)-(+)	Herbaceus odor, reminiscent of spearmint
α-Phellandrene	(*R*)-(−)	Citrus odor, slight peppery note
	(*S*)-(+)	Weed-like, dill-like
Menthol	(1*R*, 3*R*, 4*S*)-(−)	Refreshing, mint note, cool
	(1*S*, 3*S*, 4*R*)-(+)	Mint, phenolic note, medical note, camphor-like, not refreshing
Whiskey lactone	(3*R*, 4*S*)-(−)	Strong coconut note, reminiscent of celery
	(3*S*, 4*R*)-(+)	Piquant celery note, faint coconut note, green walnut note
	(3*R*, 4*R*)(+)	Sweet woody, bright fresh coconut note
	(3*S*, 4*S*)-(−)	Faint coconut note, faint musty, earthy, reminiscent of hay
δ-Decalactone	(*R*)-(+)	Sweet, fruity, milk note
	(*S*)-(−)	Sweet, fruity, peach note, fatty, butter-like
Theaspirane	(2*R*, 5*S*)-(−)	Highly attractive intense fresh-fruity
	(2*S*, 5*R*)-(+)	Naphtalene-like
	(2*R*, 5*R*)-(+)	Weak camphoraceus note
	(2*S*, 5*S*)-(−)	Fresh camphoraceus note
2-Methyl-4-propyl-1,3-oxathiane	(2*R*, 4*S*)-(−)	Sulfurous, herbaceous-green, roasty, linseed oil-like, onion
	(2*S*, 4*R*)-(+)	Sulfurous, fatty, fruity-green- tropical fruit, grapefruits
	(2*R*, 4*R*)-(−)	Green grass soot, earthy, red radish note
	(2*S*, 4*S*)-(+)	Sulfurous, slight bloomy-sweet
γ-Pentalactone	(*R*)	Faint, sweet
	(*S*)	Nearly odorless
γ-Hexalactone	(*R*)	Faint, sweet coconut with a fatty-herbaceous hay note
	(*S*)	Sweet, creamy coconut with some woody aspects
γ-Heptalactone	(*R*)	Sweet, spicy, herbaceous hay note, reminiscent of coumarin
	(*S*)	Fatty, coconut note with fruity-sweet aspects, less intense than the opposite enantiomer
γ-Octalactone	(*R*)	Spicy-green, coconut note, with almond notes
	(*S*)	Fatty, coconut note, less intense than the opposite enantiomer
γ-Nonalactone	(*R*)	Strong, sweet, soft coconut with fatty-milky aspects
	(*S*)	Fatty, mouldy, weak coconut less intense than the opposite enantiomer
γ-Decalactone	(*R*)	Strong, fatty-sweet fruity note, some reminiscence to coconut, caramel
	(*S*)	Soft, sweet coconut note with fruity-fatty aspects

Table 19.1 (continued)

Compound	Enantiomer	Characteristics
γ-Undecalactone	(*R*)	Strong, fatty-sweet, reminiscent of peach, with some bloomy aspects
	(*S*)	Fatty-sweet aldehyde note, less intense than the opposite enantiomer
γ-Dodecalactone	(*R*)	Strong, fatty-sweet, bloomy note with aldehyde and woody aspects
	(*S*)	Fatty-fruity, milky notes, less intense than the opposite enantiomer
2-Pentanol	(*R*)	Light, seedy, sharp
	(*S*)	Heavy, wild berry, ripe, dusty, astringent
2-Hexanol	(*R*)	Mushroom, dusty, oily
	(*S*)	Mushroom, green, ripe, berry, astringent, metallic
2-Heptanol	(*R*)	Fruity, sweet, oily, fatty
	(*S*)	Mushroom, oily, fatty, blue cheese, mouldy
2-Octanol	(*R*)	Creamy, cucumber, fatty, sour
	(*S*)	Mushroom, oily, fatty, creamy, grape
2-Pentyl acetate	(*R*)	Fruity, muscat, green, metallic, chemical
	(*S*)	Fruity, apple, plum, metallic
2-Hexyl acetate	(*R*)	Sour, fruity, cherry, plum, strawberry
	(*S*)	Sweaty, sour, fruity, plum, nectarine
2-Heptyl acetate	(*R*)	Green, fatty, banana, methyl ketone
	(*S*)	Mushroom, earthy, wild berry
2-Octyl acetate	(*R*)	Fatty burnt, boiled vegetable
	(*S*)	Fruity, plum, dusty

organoleptic properties of the enantiomers of a chiral molecule can be different and may elicit different odor sensations or intensities. The earliest evidence of this different perception of chiral odorants was found by *Rienacker* and *Ohloff* [19.2]; it concerned β-citronellol, whose (+)-β-enantiomer was described as having a typical citronella odor, while that of the (−)-β-enantiomer was rated as a geranium type smell. Since then the different odor responses of a very large number of enantiomeric chiral odorants have been investigated [19.1, 3]; Table 19.1 reports some examples of chiral compounds whose enantiomers present different odors.

19.1 Chiral Recognition and Enantioselective Gas-Chromatography (Es-GC)

Gas chromatography (GC), in particular, in combination with mass spectrometry (MS), is the most widely used and powerful technique to define the composition of the volatile fraction of natural product samples. However, GC with conventional stationary phases fails with er because separation is based on physicochemical properties, whose values are the same for both enantiomers of the chiral molecule. Stationary phases with a chiral selector in their structure that interacts differently with each enantiomer of the chiral compound(s) must therefore be used to achieve enantiomer separation. The first stationary phase for chiral separation of enantiomers by GC was introduced by *Gil-Av* et al. of the Weizmann Institute of Science, Israel [19.4–6]. They separated racemic amino acid alkyl esters on glass capillary columns coated with N-trifluoroacetyl-L-isoleucine lauryl ester.

Several chiral selectors have since been proposed, which operate on different principles. Three of these, distinguishable for the mode of selector–selectand interaction, have been successfully applied to routine analysis [19.7–9]:

- Separation of enantiomers on chiral amino acids via hydrogen bonding [19.4–6, 10–14]
- Separation of enantiomers on chiral metal coordination compounds via complexation [19.15, 16]
- Separation of enantiomers on cyclodextrin derivatives via inclusion (inter alia) [19.17, 18].

Cyclodextrin (CD) derivatives are the chiral stationary phases (CSP) most widely used in the flavor and fragrance field today, because of their wide range of application and high enantioselectivity, which offer the possibility to separate the underivatized enantiomers of a large number of chiral molecules with different structures and organic functions. The development of stationary phases based on different separation approaches has, however, made available appropriate CSPs for almost all enantiomer separations.

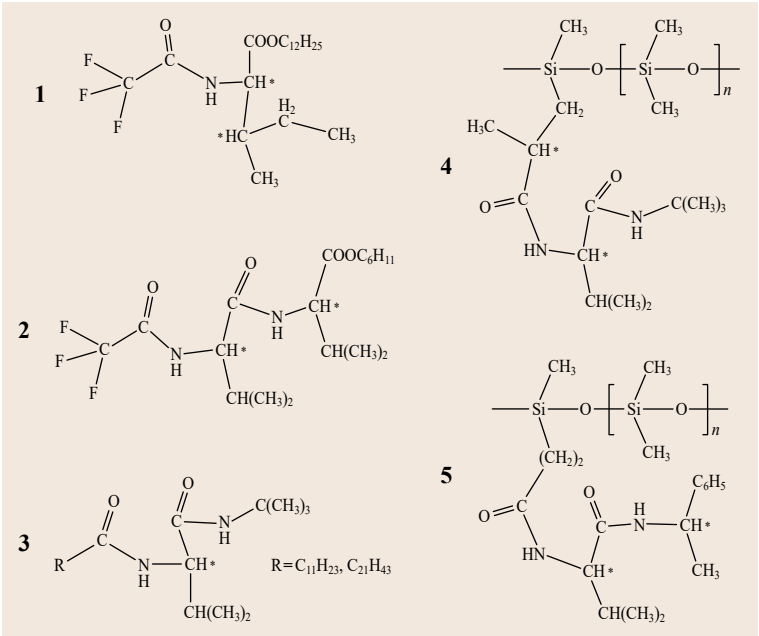

Fig. 19.1 Hydrogen-bonding type CSPs (1) *N*-trifluoroacetyl-L-isoleucine lauryl ester; (2) *N*-trifluoroacetyl-L-valyl-L-valine cyclohexyl ester; (3) *N*-Lauroyl-L-valyl-tert-butylamide; (4) L-valine-*t*-butylamide coupled to a copolymer of dimethylsiloxane; (5) L-valine-*t*-butylamide grafted on to modified polycyanopropylmethyl phenylmethyl silicone (OV-225)

The next paragraphs will briefly discuss the characteristics and chiral separation mechanisms of CSPs operating via hydrogen bonding, complexation with chiral metal coordination compounds, and CD, this last in greater detail because of the importance CDs now have in the flavor and fragrance field.

19.1.1 Chiral Stationary Phases Based on Hydrogen Bonding

The first CSP available were those based on hydrogen bonding. They are usually enantiomerically pure amino acid derived selectors, mostly applied to separate racemic amino acid derivatives, although they can also be used to separate other chiral molecules.

As already mentioned, separation of the enantiomers of *N*-trifluoroacetyl amino acid alkyl esters was first achieved in 1966, on *N*-trifluoroacetyl-L-isoleucine lauryl ester (**1**) (Fig. 19.1) using a glass capillary column [19.6] and then, in 1967, on *N*-trifluoroacetyl-L-valyl-L-valine cyclohexyl ester (**2**) (Fig. 19.1) using a packed column [19.5], in both cases by *Gil-Av*'s group. It was later shown that an additional amide function was fundamental to provide additional hydrogen bondings. The C-terminal amino acid was therefore replaced by an amine derived from valine, yielding the diamide (**3**) [19.19], and then coupled to a copolymer of dimethylsiloxane via the amino function, to yield Chirasil-Val (**4**) in both enantiomeric forms [19.11, 12]. Epimeric CSPs (L,*R* and L,*S*) (**5**) [19.20], containing two chiral centers, were also introduced, although they can either enhance (matched-case) or compensate for (mismatched-case) enantioselectivity. *Koppenhoefer* et al. modified the chiral backbone in Chirasil-Val (**4**) by varying loading and polarity, and by introducing rigid spacers [19.21–23]. Calixarene derivatives (Chirasil-Calix) [19.24] were also tested, but failed to markedly improve enantioselectivity.

Enantiomer separation by hydrogen-bonding CSPs usually requires the analyte (generally an amino acid) to be derivatized, to increase its volatility, and/or to introduce functions suitable for additional hydrogen-bonding association [19.13].

19.1.2 Chiral Stationary Phases Based on Metal Coordination

Complexation GC was introduced by *Schurig*; he applied a chiral metal coordination compound (dicar-

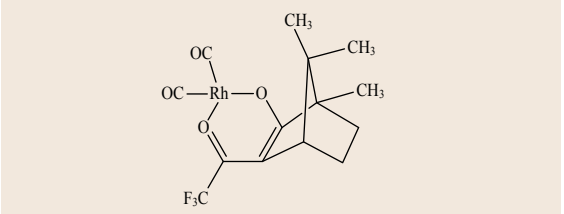

Fig. 19.2 Coordination-type stationary phases: dicarbonyl rhodium(I)-3-trifluoroacetyl-(*1R*)-camphorate

bonyl rhodium(I)-3-trifluoroacetyl-(1*R*)-camphorate) (Fig. 19.2) dissolved in squalane to separate the enantiomers of the chiral olefin 3-methylcyclopentene [19.25].

The chiral recognition effectiveness of these CSPs was confirmed by the enantiomer peak inversion when both enantiomeric selectors obtained from (*1R*)- and (*1S*)-camphor were applied, and by peak coalescence with the racemic selector [19.26]. Complexation GC was later extended to chiral oxygen-, nitrogen-, and sulfur-containing compounds, using various chiral 1,3-diketonate bis chelates of manganese(II), cobalt(II) and nickel(II) derived from perfluoroacylated terpene-ketones. The main limit of these CSPs was the low operative temperature range (25–120 °C); their thermostability was increased when the immobilised polymeric CSPs (*Chirasil-Nichel*) were introduced [19.27]. Before the advent of modified CD, complexation GC was successfully applied to chiral analysis of volatile nonhydrogen-bonding compounds such as pheromones [19.28], flavors and fragrances [19.28, 29], and products of enzymatic reactions, such as oxiranes [19.30]. Enantioselective complexation GC has also been used extensively to study the principles of chiral recognition.

19.1.3 Chiral Stationary Phases Based on (Inter Alia) Inclusion

The separation of enantiomers based on inclusion, using CD derivatives as chiral selector, is probably now the most widely adopted approach for Es-GC analysis, in particular in the flavor and fragrance field.

Cyclodextrin Derivatives as Chiral Selectors

The first reference to a substance that later proved to be a CD was published by *Villiers*; he isolated a crystalline substance from starch digested from *Bacillus amylobacter* [19.31, 32]. Twelve years later, *Schardinger* found that small amounts of two different crystalline products were formed when starch was digested by that microorganism [19.32]. Then, in the 1930s, *Pringsheim* and his group described the inclusion properties of crystalline dextrins and their acetates [19.33] and discovered their ability to form complexes with organic compounds having different structures. An important contribution to the elucidation of the crystalline structure of Schardinger's dextrin was given by *Freudenberg* and coworkers who, later in that decade, hypothesized that CD consisted of maltose units linked through α-1,4-glycosidic linkages. In 1936, they postulated the cyclic structure [19.34]. In the 1950s several groups, in particular those of *French* [19.35] and *Cramer* [19.36], studied in depth the chemical and physical properties of CDs, at the same time clarifying their enzymatic production. By the late 1960s, these studies led to the full elucidation of CDs' structures and physical properties, and their ability to form inclusion complexes was demonstrated; methods for their laboratory-scale preparation were also now developed. The three major CDs are crystalline, homogeneous, nonhygroscopic compounds consisting of torus-like macro-rings built up of 6–8 glucopyranose units (Fig. 19.3), the α-CDs, β-CDs, and γ-CDs, respectively. The CD ring is a conical cylinder in which the primary hydroxyl groups (position 6) are situated on one of the two edges of the ring and the secondary groups (positions 2 and 3) are placed on the other edge. For a general overview of CD chemistry refer to [19.37].

Several thousands of publications have discussed possible applications of CDs: a large proportion (nearly 25%) is in the pharmaceutical field, while about 20% concern applications to analytical chemistry and diagnostic preparations. The analytical applications of CDs mainly refer to their use in GC, high performance liquid chromatography (HPLC), capillary zone electrophoresis, and, to a lesser extent, thin layer chromatography (TLC), and to enhance of ultraviolet–visible (UV–Vis) absorption and luminescence/phosphorescence.

Chiral Stationary Phases Based on Cyclodextrin Derivatives for Es-GC. The first chiral separation in GC with CD as stationary phases was due to *Koscielski* and *Sibilska* [19.38]; they separated the enantiomers of α- and β-pinene, Δ-3-carene, and hydrogenated derivatives, on columns packed with a mixture of native α-cyclodextrin in formamide. Despite their high separation factor α, these columns had a limited lifetime and low efficiency. CDs were applied to capillary GC almost contemporarily, by *Juvancz* et al. [19.39] and *Schurig* et al. [19.16]. In other pioneering studies, *Alexander* et al. [19.40] and, shortly afterward, *Venema* and *Tolsma* [19.41], demonstrated that undiluted permethylated β-cyclodextrin could be employed in capillary columns for high-resolution separation of enantiomers at high temperatures. Subsequently, two different approaches were introduced to overcome the problems associated with the high melting point of permethylated CD:

(a) *Konig* and coworkers proposed using per-*n*-pentylated CD, which are liquid at room temperature. These CD derivatives can thus be used as such to separate enantiomers belonging to several classes of compounds [19.42–45].

(b) At about the same time, *Schurig* and *Nowotny* introduced permethylated-β-cyclodextrin dissolved in

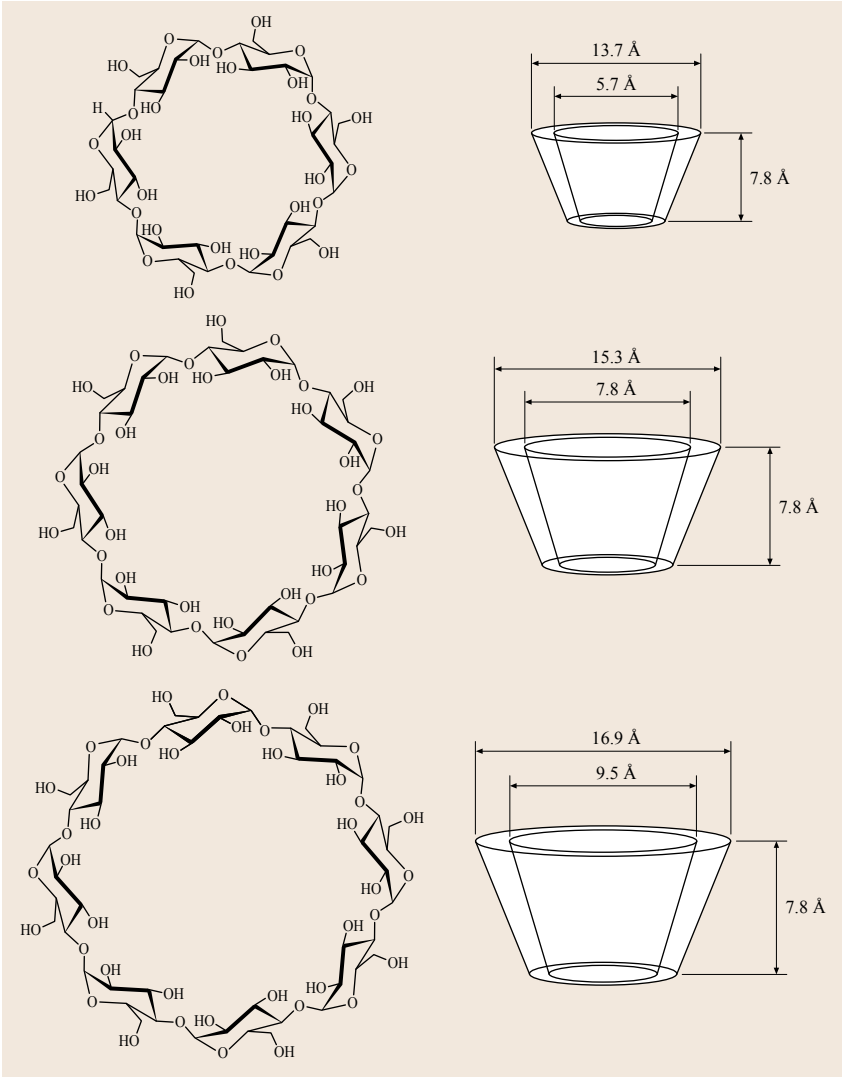

Fig. 19.3 Structure of α-, β-, and γ-cyclodextrins

moderately polar polysiloxanes (OV-1701) [19.16, 46]. This approach combined the high enantioselectivity of the modified CD with the very good gas chromatographic characteristics of polysiloxanes.

Dilution in polysiloxane is now almost the only approach in routine use. A number of in-depth investigations [19.47, 48] have, in fact, made it possible to obtain chiral columns with chromatographic properties, efficiency, and reliability comparable to those of conventional columns, which can operate successfully over an extended range of temperatures (0–240 °C).

Chemistry of Cyclodextrin Derivatives for Es-GC. The presence of three hydroxyl groups that can be regioselectively alkylated and acylated offers an enormous number of possible α-, β-, γ-cyclodextrin derivatives. Numerous derivatives have been described, mainly based on β-cyclodextrin derivatives, although no universally applicable derivative has yet been found. A fundamental improvement was the introduction of bulky substituents, the *tert*-butyldimethylsilyl (TBDMS) or *tert*-hexyldimethylsilyl- (THDMS) groups [19.49, 50] at the primary C6-hydroxy groups, first introduced by *Blum* and *Aichholz* [19.49, 51], but mainly developed by *Mosandl*'s group [19.51]. The bulky substituent conditions the CD conformation and inhibits entrance to the cavity at the smaller rim, thus orienting the analyte/CD interaction toward the wider rim, with the substituents at the C2- and C3-secondary hydroxy groups responsible for enantioselectivity.

The development of new CD derivatives is still necessary to extend the operative range and to embrace new applications such as multidimensional or fast Es-GC, as well as to increase enantioselectivity in comparison to existing ones. Unfortunately, the number of new CD derivatives with higher, wider, or *new* enantioselectivity that have been introduced over the last 10 years is very small. The authors have quite recently introduced *fully asymmetrically substituted derivatives* [19.52]. The already existing CD derivatives present the same *small* substituents (mainly acetyl, methyl, or ethyl groups) in the C2- and C3- secondary hydroxy groups, and bulky substituents (*t*-butyldimethylsilyl-, TBDMS) in the C6-primary hydroxyl groups, and at the same time provide good enantioselectivity and columns with good chromatographic properties. However, their enantioselectivities are very often complementary; therefore CD derivatives with a *mixed* substitution pattern in positions 2 and 3 of the wide rim may provide the desired synergy in enantioselectivity (the term *asymmetric* is here used to indicate the different nature of the substituents in positions 2, 3, and 6). The asymmetrically substituted methyl–ethyl derivatives (6^{I-VII}-*O*-TBDMS-3^{I-VII}-*O*-ethyl-2^{I-VII}-*O*-methyl/3^{I-VII}-*O*-methyl-2^{I-VII}-*O*-ethyl-β-cyclodextrin) were the most successful, since they were found to be more effective, in terms of both the number of chiral compounds separated into their enantiomers, and the resolution values, than the corresponding symmetrical CDs (6^{I-VII}-*O*-TBDMS-3^{I-VII}-*O*-methyl-2^{I-VII}-*O*-methyl/3^{I-VII}-*O*-ethyl-2^{I-VII}-*O*-ethyl-β-cyclodextrin), proving to be very useful in routine analysis for control of samples containing several chiral markers in a single run.

Several other approaches to improve enantioselectivity and chromatographic results have been attempted: (a) applying two or more chiral selectors in a single column, for example, (1) mixing two CDs [19.53–56] although the synergy in terms of enantioselectivity was not as high as expected; similar unsatisfactory results were obtained when two CD units were condensed; and (2) mixing two structurally different chiral selectors, amino acid derivatives, and CD derivatives; these were grafted simultaneously [19.57], linked to polysiloxane [19.58] or covalently linked to amino acid derivatives/CDs [19.59, 60]. These binary phases retained the enantioselective properties of each component, thus extending the range of enantioseparation achievable. (b) CD selector(s) chemically and permanently linked to a polysiloxane backbone [19.61–63] (Chirasil-Dex) as a way of advancing the dilution approach.

However, in the authors' opinion great efforts must yet be made to develop a further generation of CD derivatives with extended enantioselectivity and better chromatographic properties.

Mechanism of Chiral Recognition. It is difficult to rationalize chiral recognition involving modified CDs, since almost all classes of chiral compounds, ranging from apolar to highly polar, are susceptible to being separated into their enantiomers on the appropriate CD-derived CSP; there is often no logical dependence on molecular shape, size, or functionalities of either selectand or selector. This is because the recognition process is multimodal and may, inter alia, involve inclusion, hydrogen-bonding, dispersion forces, dipole–dipole interactions, electrostatic interactions, and hydrophobic interactions [19.9, 64–66]. The separation of enantiomers is due to the differences between the diastereomeric CD selector–selectand (enantiomer) association equilibria; although this is a low-energy interaction, separation is achieved, partly thanks to the high efficiency of capillary GC columns [19.13]. *Lipkowitz* et al. [19.67–69] made an important contribution to the molecular modeling of enantiomer separation with CDs, demonstrating the dichotomy that exists between the location of the preferred binding site of a selectand within the cavity, and that of the optimum chiral discrimination domain, which may, a priori, be different; they also discussed the importance of short-range dispersion forces as intermolecular forces. Another significant contribution, from Schurig's group, showed that inclusion of a molecule within the CD cavity may not be a prerequisite for a successful chiral recognition; they reported enantiomer separations obtained with per-*n*-pentylated amylose [19.70] and with modified linear dextrins [19.71, 72].

All these considerations combine to demonstrate that a strong molecular association is not always a prerequisite to efficient chiral discrimination [19.64] and that a weak selectand–selector interaction can often lead to successful chiral recognition. These results also explain possible changes of elution order of enantiomers from members of homologous series [19.73] and the unreliability of correlating absolute configuration with elution order.

Thermodynamics of Enantioseparation by Gas Chromatography. *Schurig* and coworkers introduced a thermodynamic model to describe enantiomer separation with CD derivatives [19.18, 74]. The model is based on two equilibria that condition the elution of a volatile solute, B eluting from a column containing a solution of a CD derivative, A in an achiral solvent, S, as stationary phase; K_L^0 is the partition coefficient of

B between the gas (g) and the liquid (l) phases, and K is the thermodynamic stability constant of the complex AB in the achiral solvent:

1. $B_{(g)} \overset{K_L^0}{\longleftrightarrow} B_{(l)}$
2. $B_{(l)} + A \overset{K}{\longleftrightarrow} AB.$

K_L^0 in the two equilibria can be defined through the activities (a) of the reagents in the solvent, that is,

$$K_L^0 = \frac{a_{B_{(l)}}}{a_{B_{(g)}}} \text{ for equilibrium (1)} \tag{19.1}$$

and

$$K_L^0 = \frac{a_{AB}}{a_A a_{B_{(l)}}} \text{ for equilibrium (2)} . \tag{19.2}$$

Since the total amount of solute B in the liquid phase is $a_{B_{(l)}} + a_{AB}$, the apparent partition coefficient K_L is

$$K_L = \frac{a_{B_{(l)}} + a_{AB}}{a_{B_{(g)}}}, \tag{19.3}$$

that, from (19.1) and (19.2), can be rewritten as [19.75, 76]

$$K_L = K_L^0(1 + Ka_A) . \tag{19.4}$$

On the basis of the fundamental equation of chromatography

$$t' = \frac{K_L}{\beta} t'_m, \tag{19.5}$$

where t'_m is the dead time, t' the net retention time, K_L the partition coefficient between mobile and stationary phase, and β the phase ratio; an analogous equation can be obtained for the net retention time

$$t' = t'_0(1 + Ka_A) , \tag{19.6}$$

where t_0 is the net retention time on an identical reference column, containing only the solvent S as stationary phase.

Equation (19.6) affords a definition of the retention increase (or retention increment) R' [19.77] as

$$R' = Ka_A , \tag{19.7}$$

as the quantitative measure of the increase in the retention of B due to the CD derivative, A diluted into the achiral solvent, S.

Equation (19.6) must be rewritten in terms of relative retention data to obtain an equation that is independent of column length, diameter, and film thickness, since experimentally it is impossible to obtain truly identical columns to determine t' and t'_0 [19.77]

$$r' = r_0(1 + R') \tag{19.8a}$$

or

$$R' = \frac{r'}{r_0} - 1 , \tag{19.8b}$$

where r' is the relative retention of solute B calculated versus an inert reference standard B*

$$r = \frac{t'}{t'^*} \quad \text{[chiral column (A in S)]} \tag{19.9}$$

$$r_0 = \frac{t'_0}{t'^*_0} \quad \text{[achiral reference column (only S)]}. \tag{19.10}$$

If solute B is a racemic mixture of the enantiomers B_R and B_S, and R arbitrarily represents the last-eluted enantiomer, since $K^0_{LR} = K^0_{LS}$, enantiomer separation of B_R and B_S must be due to different values of K_R and K_S. The chiral separation factor is therefore given by

$$\alpha = \frac{K_{LR}}{K_{LS}} = \frac{t'_R}{t'_S} = \frac{r_R}{r_S} . \tag{19.11}$$

Equation (19.11) can be modified on the basis of (19.4) and (19.7)

$$\alpha = \frac{K_R a_A + 1}{K_S a_A + 1} = \frac{R'_R + 1}{R'_S + 1} . \tag{19.12}$$

From the thermodynamic relationship of free enthalpy

$$\Delta G = -RT \ln K, \tag{19.13}$$

and the ratio of the thermodynamic stability constants

$$\frac{K_R}{K_S} = \frac{R'_R}{R'_S} = \frac{r_R - r_0}{r_S - r_0} , \tag{19.14}$$

it is possible to determine the difference in the free enthalpies of formation of the diastereomeric associates

$$\begin{aligned} \Delta_{R,S}(\Delta G) &= \Delta G_R - \Delta G_S \\ &= -RT \ln \frac{K_R}{K_S} = -RT \ln \frac{R'_R}{R'_S} , \end{aligned} \tag{19.15}$$

and the enthalpic and entropic contributions to $\Delta_{R,S}(\Delta G)$, from the *Gibbs–Helmholtz* equation

$$\Delta_{R,S}(\Delta G) = \Delta_{R,S}(\Delta H) - T\Delta_{R,S}(\Delta S) . \tag{19.16}$$

This equation also indicates that, for a 1 : 1 molecular association, the quantities $\Delta_{R,S}(\Delta S)$ and $\Delta_{R,S}(\Delta H)$

display an opposite effect $\Delta_{R,S}(\Delta G)$. At the isoenantioselective temperature T_{iso}

$$T_{iso} = \frac{\Delta_{R,S}(\Delta H)}{\Delta_{R,S}(\Delta S)} , \tag{19.17}$$

a peak coalescence occurs ($-\Delta_{R,S}(\Delta G) = 0$, $K_R = K_S$, no separation of enantiomers). Above T_{iso}, the enantioselectivity ($\Delta_{R,S}(\Delta G)$) changes and is governed by $\Delta_{R,S}(\Delta S)$, while below T_{iso}, it depends on $\Delta_{R,S}(\Delta H)$.

The most important impact of these results on routine Es-GC is that, in most cases, even at high temperatures, enantioselectivity is dominated by enthalpy-control, with an increase in the separation factor α with decreasing temperature. As a consequence, the lowest possible temperature for Es-GC separation of enantiomers must be applied, not least because the separation of enantiomers by GC with CD derivatives as chiral selector is based on fast kinetics and is thermodynamically driven [19.78].

19.2 Measurement of the Enantiomeric Distribution

The main aim of the GC separation of enantiomers is to precisely determine the enantiomer distribution of one (or more) marker components in a matrix, in order to characterize it. This aim is further stimulated by the legislation on chiral compounds, which is becoming increasingly stringent, thus requiring that reliable methods for enantiomer composition determination be developed.

Enantiomeric distribution is usually expressed in terms of *enantiomeric excess* (ee), *enantiomeric composition* (ec), or *enantiomeric ratio* (er) [19.79]. *Enantiomeric excess* expresses the superabundance of one enantiomer over the other, and is defined as

$$\text{ee} = \frac{E_1 - E_2}{E_1 + E_2} , \tag{19.18}$$

where E_1 and E_2 are the areas of the enantiomers, E_1 being the major enantiomer; ee ranges from 0 for racemic mixture to 1 for pure E_1. In routine practice, ee is often expressed as a percentage

$$\%\text{ee} = \frac{E_1 - E_2}{E_1 + E_2} \cdot 100 = \%E_1 - \%E_2 . \tag{19.19}$$

Enantiomeric purity has also been used as a synonym for ee.

Enantiomeric composition (ec) is defined as the molar fraction of the major enantiomer x_{E_1} in a mixture

$$\text{ec} = x_{E_1} = \frac{E_1}{E_1 + E_2} . \tag{19.20}$$

In this case too, in routine, ec is in general expressed as a percentage

$$\text{ec}\% = x_{E_1} = \frac{E_1}{E_1 + E_2} \cdot 100 . \tag{19.21}$$

Lastly, the *enantiomeric ratio*, er, is defined as

$$\text{er} = \frac{E_1}{E_2} , \tag{19.22}$$

where E_1 is the major enantiomer; er extends from ee = 1, for a racemic mixture, to ee $= \infty$, for pure E_1. The terms er and ee are correlated as follows

$$\text{ee} = \frac{(\text{er} - 1)}{(\text{er} + 1)} \tag{19.23}$$

and

$$\text{er} = \frac{(1 + \text{ee})}{(1 - \text{ee})} . \tag{19.24}$$

In routine analysis, correct measurement of the above parameters requires that the peaks of the two enantiomers be baseline separated, that their resolution is

$$R_S \geq 1.5 .$$

The separation factor α cannot therefore be used routinely in the flavor and fragrance field, because it does not consider peak widths, and must be determined isothermally.

19.3 Enantioselective GC Analysis with Cyclodextrins in the Flavor and Fragrance Field

Enantiomer separation by Es-GC with columns coated with modified CDs as chiral selector has been successfully applied to several fields of contemporary research, such as checking essential oil authenticity [19.80], flavors and fragrances and alcoholic beverages [19.81, 82], and clinical chemistry [19.82]. Terpenoids [19.83], enzymatic reactions [19.84], organochlorine pesticides [19.85, 86], alkyl nitrates as atmospheric constituents [19.87], and volatile pharmaceutical compounds can also be investigated [19.64].

The second part of this chapter will be devoted entirely to chiral recognition strategies in the flavor and fragrance field by Es-GC, with CD derivatives as stationary phase; it is based on the authors' day-to-day experience in this field.

CD derivatives are the most widely used chiral selectors in Es-GC of chiral components in the flavor and fragrance field, most probably because their physicochemical characteristics (polarity, reactivity, and volatility) are highly *compatible* with the enantiomer discriminative interactions provided by CDs.

As is the case of all stationary phases, CDs have advantages and disadvantages, both absolutely and in comparison to the other CSPs described above. Their main advantages are as follows:

- They can separate underivatized enantiomers, thereby enabling real natural product samples to be directly analyzed without any manipulation.
- They can separate almost all classes of volatile chiral compounds, thanks to the wide range of selectivity covered by the large number of available CD derivatives.
- They possess good chromatographic properties (efficiency and inertness) and a wide range of operative temperatures of columns prepared with CDs, thanks to their dilution in moderately polar polysiloxanes.

However, CDs also present some disadvantages, limiting not only their popularity but also the routine use of Es-GC, because they tend erroneously to be considered complex:

- Absence of a *universal* CD derivative separating most chiral compounds; this means that a laboratory must be provided with a number columns to extend the range of analyzable chiral compounds.
- Difficulty of identifying enantiomers and measuring ee and/or er in real-world complex samples with mono-dimensional Es-GC, because of the increased probability of interferences due to the doubling of the number of chiral analyte peaks; this limit is extremely frequent in the flavor and fragrance field.
- Long analysis time, due to the use of long columns and low temperature rates, because of the CD mechanism of separation.

Partly in view of the above three points, the next paragraphs will examine the optimization of strategies for the chiral recognition of odorous markers by Es-GC and Es-GC-MS, with CD as chiral selectors in complex mixtures in the flavor and fragrance field, based mainly on the authors' experience.

19.4 Testing Column Efficiency and Enantioselectivity

A short paragraph must first be dedicated to a critical and often-neglected point: column efficiency and enantioselectivity. Conventional GC columns in general, but even more so Es-GC columns, must be tested periodically for their efficiency and enantioselectivity, in order to obtain reliable results. This evaluation requires the use of dedicated test mixtures, such as the Grob test, to evaluate chromatographic performance of a column over time, and a chiral test for enantioselectivity. In the authors' laboratory, a test mixture containing racemates with different volatilities, structures, and polarities has been designed to check column enantioselectivity; it is used continually [19.47] (its composition is reported in the caption of Fig. 19.4). Figure 19.4 reports the chiral test profiles carried out on the four columns used to build the chiral library (Sect. 19.5.1).

19.5 Analysis of Enantiomers in Complex Samples

Reliable chiral recognition of marker compounds in complex real-world samples generally requires a two-dimensional approach, in order to avoid erroneous identifications due to peak overlapping; this is a particular risk because of the doubling of the number of peaks of chiral analytes when separated by Es-GC. Two complementary but distinct approaches are therefore available (Sect. 19.5.1): the first is to adopt *a second dimension in separation* (by conventional heart-cut GC-GC or comprehensive GC), while the second approach implies using a *second dimension in detection*, by coupling GC with MS. The latter method applies a strategy that is the converse of the conventional one: the enantiomer(s) is(are) located in the chromatogram by their MS spectrum and identified by GC data (Kovats retention indices (I_s) [19.88], or linear retention indices (I_s^T)) [19.89, 90]. This is because, as is known, MS is not a chiral probe so that the mass spectra of two enantiomers cannot be distinguished. This makes it impossible to determine which enantiomer is present in a sample. Conversely, chromatographic data (and in particular linear retention indices) are the most reliable and effective parameters for enantiomer identification, being characteristic for each analyte (enantiomer), since they depend on its chromatographic interaction with the adopted stationary phase; similar considerations can be made with locked retention times, which were introduced by *Giarrocco* et al. and by *Blumberg* and *Klee* [19.91, 92].

19.5.1 Location and Identification of Enantiomers in Complex Samples

The basic concepts of *multidimensional* gas-chromatography are described in Chap. 17 of this book, and will therefore not be discussed here. Two techniques commonly known as multidimensional GC are at present used in chiral recognition:

1. Heart-cut GC–GC is as yet the most widely used approach for ee and er determination of chiral compounds in complex mixtures, in particular for applications in which a small number of chiral components (or fractions) (possibly eluting at relatively different temperatures) are to be submitted to chiral recognition. With this technique, *the selected chiral components* (peaks) eluting from the first, achiral, column (first dimension – ^{1}D) coated with a conventional stationary phase are on-line and automatically transferred to the second, chiral, column (second dimension – ^{2}D), through a dedicated time-programmable interface, for a programmed time fraction of the whole chromatographic

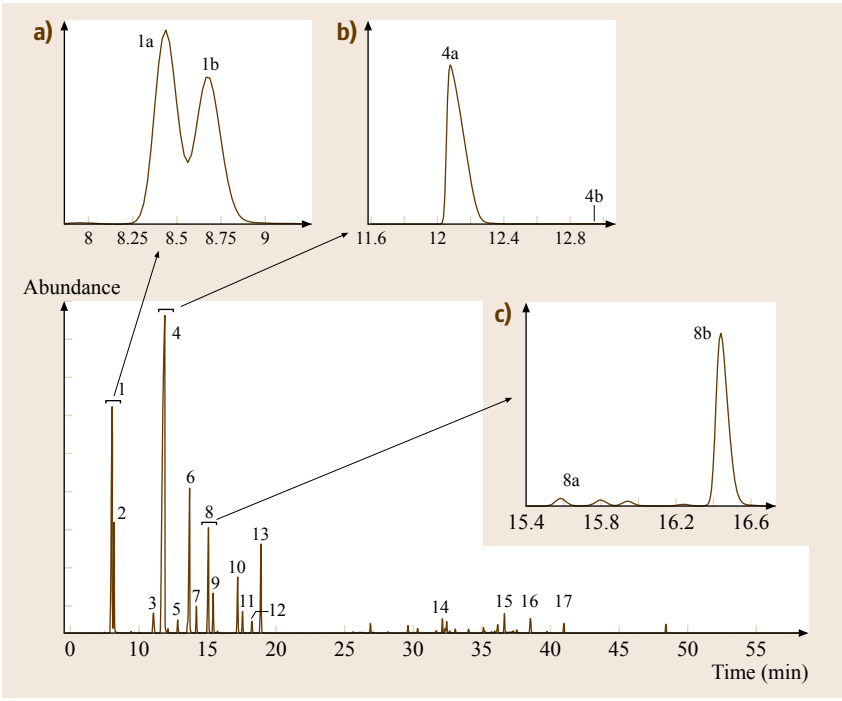

Fig. 19.5 HS-SPME heart-cut GC-GC analysis of the volatile fraction of a juniper (*Juniperus communis* L.) twig sample from Norway *HS-SPME sampling*: fiber: 2 cm Stableflex 50/30 µm divinylbenzene (DVB)-Carboxen-PDMS (Supelco, Bellafonte, USA); sample amount: 20 mg, vial volume: 20 ml; sampling time: 10 min, temperature: 50 °C. *Peak identification* 1. α-pinene 2. α-thujene, 3. β-pinene 4. sabinene, 5. δ-3-carene, 6. α-phellandrene+myrcene, 7. α-phellandrene, 8. limonene, 9. β-phellandrene, 10. γ-terpinene, 11. β-ocimene, 12. p-cymene, 13. α-terpinolene, 14. terpinen-4-ol acetate, 15. γ-muurolene, 16. germacrene B, 17. myrtenyl acetate. run [19.93–95]. Figure 19.5 reports the HS-SPME heart-cut GC-GC profile of the volatile fraction of a juniper (*Juniperus communis* L.) twig sample from Norway *HS-SPME* with an HP-5 (25 m × 0.25 mm d_c × 0.25 mm d_f) as first column and 30% 6^{I-VII}-*O*-TBDMS-2^{I-VII}-3^{I-VII}-*O*-ethyl-β-CD in PS086 (25 m × 0.25 mm d_c × 0.25 mm d_f mm) as second column; for analysis conditions and peak identification.

2. Two-dimensional comprehensive GC (GC × GC) is suitable for highly complex mixtures, in which several components are to be submitted to chiral recognition. In GC × GC, *each component* eluting from the first column is on-line and automatically trapped, refocused, and reinjected into the second column, in a fixed time (4–8 s) by a thermal or valve-based focusing device (modulator) [19.96]. Unlike heart-cut GC-GC, the GC × GC system for chiral recognition consists of a chiral column of conventional i.d. and length (^{1}D) connected to a very short narrow-bore (NB) column (^{2}D) coated with a conventional stationary phase, to enable fast analyses to be run during the time of one modulation. The chiral column must be in the first dimension because of the high efficiency required for effective enantiomer separation [19.97, 98]. Figure 19.6 reports the GC × GC contour plots of lavender essential oil.

As already mentioned, enantiomers have indistinguishable mass spectra, making chromatographic data indispensable for their reliable identification in chiral recognition. The most widely used and reliable methods to identify sample components through gas chromatographic data are based on retention indices (I_s^T) or, alternatively, on the retention time locking (RTL) approach. Either of these systems makes identification more reliable than the simpler retention time or relative retention time approaches, since they overcome most of their limits, in terms of precision and repeatability. However, correct identification of an analyte in a sample, through chromatographic data, always implies the availability of pure reference standards; this is particularly significant in the case of Es-GC in which, to establish the correct order of elution of each enantiomer within a pair, it is indispensable to have a single enantiomer standard, or one or more real-world samples in which one precisely identified member of the pair is present as such, or in a well-known enantiomeric excess.

Retention indices were first introduced by *Kováts* [19.88] for isothermal analysis (I_s); their use was later extended to temperature-programmed analysis (linear retention indices (I_s^T)) by *Van den Dool* et al. [19.89, 90]. I^T is a number that expresses the entity of the analyte/stationary phase interaction relative to a reference standard mixture (homologous series of hydrocarbons or fatty acid methyl or ethyl esters) and provides its unequivocal position in the chromatogram, provided that rigorously standardized analysis conditions are applied. In agreement with the authors' experience, I_s^T with the same stationary phases are indispensable in Es-GC to identify an enantiomer in a sample. This approach implies that the enantiomer is located in the chromatogram through its mass spectrum, and then identified through its I^T by comparison to that of the reference standard determined on the same column. I_s^T in essential oil analysis were reviewed by *d'Acampora Zellner* et al. [19.99] and their importance in plant volatile fraction discussed by *Rubiolo* et al. [19.100].

In general, the identification potential of GC is somewhat neglected because of the power of MS when used as detector for GC. Few GC-MS software packages, therefore, include I_s^T information to help component identification, while some of them only report I_s^T values in the library as *blind* or *inactive* data, making them only useful for additional confirmation [19.101–107]. On the contrary, the *interactive* use of I_s^T values (their use as an active identification parameter) can actually be highly effective, since it provides a second

orthogonal tool to identify a compound, operating in parallel to MS spectra.

An MS library specific for the identification of enantiomer components in the flavor and fragrance field was developed by the authors, using I_s^T values *interactively* in parallel to MS spectra [19.108]. The library was built at an interlaboratory level with the collaboration of two research groups, to increase result reliability. It is based on the interactive I^T/mass spectrum system [19.103] developed by *Costa* et al. [19.109] for the flavor and fragrance field, where I_s^T are automatically calculated and incorporated as an active part of the matching criteria together with mass spectra. The correct identification of an analyte is assured by the range within which its I^T must fall (retention index allowance (RIA) see below), which must be determined preliminarily.

The library consists of 134 racemates whose I^T values were determined on four CD coated with different CD chiral selectors. Table 19.2 reports the list of racemates included in the first version of the library.

Four cyclodextrin derivatives diluted at 30% in PS-086 had to be used to obtain the separation of most of the racemates usually analyzed in the flavor and fragrance field, in particular:

- 6^{I-VII}-*O*-methyl-3^{I-VII}-*O*-pentyl-2^{I-VII}-*O*-methyl-β-cyclodextrin (2,6DM3PEN-β-CD) [19.110, 111]
- 6^{I-VII}-*O*-TBDMS-3^{I-VII}-*O*-methyl-2^{I-VII}-*O*-methyl-β-cyclodextrin (2,3DM6TBDMS-β-CD) [19.112]
- 6^{I-VII}-O-TBDMS-3^{I-VII}-O-ethyl-2^{I-VII}-O-ethyl-β-cyclodextrin (2,3DE6TBDMS-β-CD) [19.113]
- 6^{I-VII}-O-TBDMS-3^{I-VII}-O-acetyl-2^{I-VII}-O-acetyl-β-cyclodextrin (2,3DA6TBDMS-β-CD) [19.112]

The determination of the RIA window, the range within which the I^T of an analyte has to fall to be correctly identified, is a key point for univocal identification. An effectively operating library should be based on a single RIA window to be applied automatically to all enantiomers analyzed on all columns investigated. The ideal RIA should be *narrow* enough to include only one of the two enantiomers, but at the same time *wide* enough to avoid the I^T of a given analyte falling outside the range because of retention variation. A reliable RIA therefore requires baseline enantiomer separation and highly stable I^T values, the latter being obtainable, among others, by highly standardized analysis, constantly tested inert columns, and corrected injection volumes.

The single RIA for this library was obtained from the average RIA of each class of compounds, in its turn determined from the individual RIA of each of the enantiomers of the 134 racemates investigated, analyzed on the four enantioselective columns adopted. A single average RIA value of -1 and $+2$ for all analytes analyzed on all the columns investigated was adopted.

Automatic mass spectral deconvolution (AMDIS) [19.101] is another software package, developed by the National Institute of Standards and Technology (USA), that actively uses I_s^T, often in combination with NIST Mass Spectral Libraries.

Retention time locking (RTL) [19.91, 92] is a different approach for reliably identifying an analyte from its GC retention data in programmed temperature analysis. The principle underlying RTL involves determining

the adjustment of inlet pressure necessary to achieve the desired match in retention time(s) of an analyte(s) with similarly configured GC systems.

19.5.2 Mass Spectrometry and Reliability of Chiral Recognition

Clearly, the recent advances in MS can dramatically increase the diagnostic power of GC-MS, thanks to the routine use of tandem mass spectrometry or MS/MS (mass spectrometry/mass spectrometry or MS^n). These systems consist not only of the last generation of well-established triple quadrupole (QqQ – tandem-in-space) and ion trap (IT-MS – tandem-in-time) MS/MS analyzers, but also include the most recent hybrid mass spectrometers that are based on high-resolution time of flight (TOF)-MS analyzers, as such or as a second MS unit in combination with a quadrupole or an ion-trap analyzer (Q-TOF or IT-TOF, respectively). The resulting hybrid system, in combination with soft ionization ion sources, thus combines the advantages of tandem MS with those of high-resolution analyzers; these advantages include, for instance, the determination of the exact mass of molecular ions and/or fragments, at an accuracy below 5 ppm. However, Es-GC alone is sometimes not sufficient to detect the authenticity of a sample, in particular when racemates naturally occur, or when they derive from processing and/or storage or, especially, from adulteration with a synthetic enantiomer. A decisive step toward achieving a unequivocal definition of sample authenticity is combining Es-GC (or even better Es-GC-GC) with isotope ratio mass spectrometry (IRMS). The effectiveness of Es-GC-IRMS is based on the consideration that the ratio between stable isotopes of enantiomers from the same natural source may be expected to be the same (δ-C^{13}) even when a partial enantiomer racemization has occurred, since both enantiomers are generally formed through the same biosynthetic pathway in the same natural organism. In a GC-IRMS system, analytes eluting from the GC column are on-line combusted to CO_2 in a dedicated oven, from where the combusted product is directly introduced into an IRMS system. The abundances of 44 ($^{12}C^{16}O_2$), 45 ($^{13}C^{16}O_2$, $^{12}C^{16}O^{17}O_2$), and 46 ($^{12}C^{16}O^{18}O$) ions in the nmole range are then simultaneously measured with high precision (≤ 0.3 ‰), and the peak areas ratio of the two isotopic peaks compared to a standard reference value. A detailed discussion of this technique is outside the scope of this chapter [19.114].

19.6 Fast Enantioselective GC Analysis

A further important limit often conditioning the routine use of Es-GC is the long analysis time, due to the small difference in the energy of association between each selectand (enantiomer) and the CD chiral selectors; this means that very high chromatographic efficiency is required to obtain enantiomer separation. As shown in the above paragraphs, Es-GC separation of enantiomers with CDs as chiral selectors is based on fast kinetics, and is entirely governed by thermodynamics; as a consequence, it closely depends on temperature. Long analysis times are therefore to be expected, since long columns and low temperature rates must in general be applied.

Routine applications require the development of fast Es-GC methods, in order to satisfy the large number of control analyses required. Routine fast-GC can in general be obtained by acting on column length, inner diameter, and/or flow-rate, and has resulted in the adoption of NB columns [19.115]. In fast-Es-GC, NB columns not only increase analysis speed and analyte detectability, because of peak sharpening [19.116], but also reduce the enantiomer elution temperature; this results in a gain of enantioselectivity that compensates (in full or in part) for the loss of efficiency (N) due to column shortening. Enantiomer separations with CDs with short columns were already under study in the early 1990s; they afford separation even in a few seconds [19.117–119]. *Schurig* and *Czesla* [19.120] studied the basis for speeding up ES-GC in depth, and concluded that short, conventional 0.25 –mm d_c columns would have to be used for fast Es-GC, because of their good loadability, integration characteristics, use of conventional instrumentation, and lower consumption of carrier gas. However, conventional d_c short columns can only be used successfully for monodimensional fast Es-GC when chiral compounds have to be recognized in low-complexity samples and/or when a limited number of enantiomers are to be analyzed simultaneously. With medium-to-high complexity samples, as is often the case in the flavor and fragrance field, a highly efficient separation system combined with single- or multiple-ion monitoring-MS detection (SIM-MS or MIM-MS) is necessary to determine ee and/or er correctly (see Sect. 20.3). This paragraph critically discusses the two complementary methods developed and adopted in the authors' laboratory to speed up routine Es-GC analyses [19.121, 122]. The two methods will now be briefly described and illustrated through the analysis of a lavender essential oil. Lavender essential oil is used as an example for both

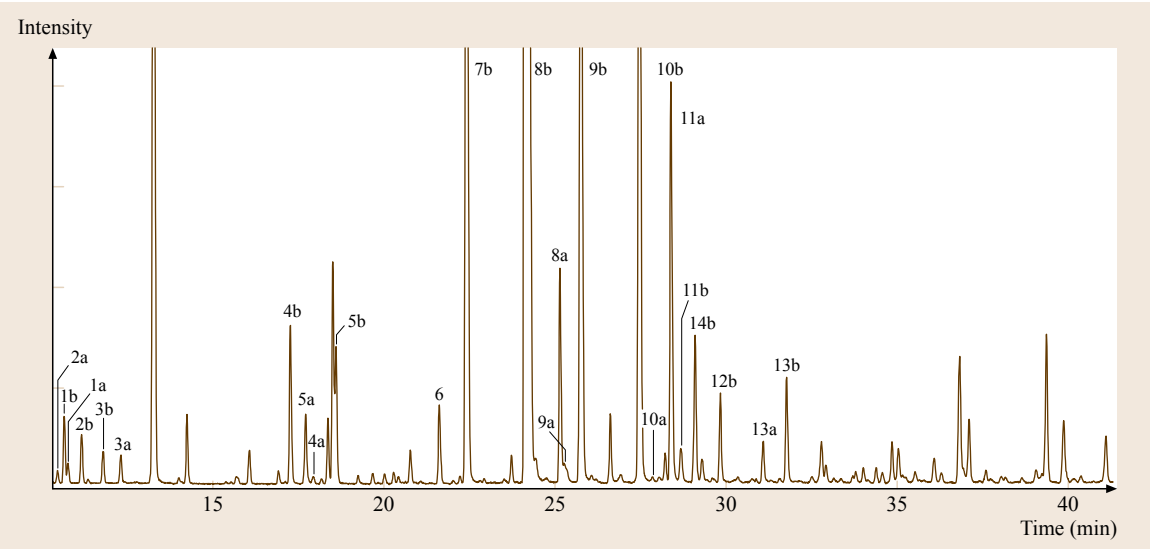

Fig. 19.7 The Es-GC-MS profiles of the lavender essential oil analyzed with the reference column, 30% $6^{I–VII}$-*O*-TBDMS-$2^{I–VII}$-$3^{I–VII}$-*O*-ethyl-β-CD in PS086 (25 m × 25*mm* d_c, 25*mm* d_f). For analysis conditions see Table 19.3. Peak identification: 1: α-pinene, 2: camphene, 3: β-pinene, 4: β-phellandrene, 5: limonene, 6: 1-octen-3-ol, 7: camphor, 8: linalool, 9: borneol, 10: linalyl acetate, 11: 4-terpineol, 12: lavandulol, 13: α-terpineol, 14: lavandulyl acetate; a: (*R*) enantiomer, b: (*S*) enantiomer, 6: not separated; 7a, 12a and 14a: not detected [19.122]

approaches, because it is characterized by several chiral markers whose enantiomeric composition is reliably described in the literature [19.123, 124]. Lavender essential oil contains several optically active components: α- and β-pinene, camphene, β-phellandrene, limonene, 1-octen-3-ol, camphor, linalool, borneol, linalyl acetate, terpinen-4-ol, lavandulol, α-terpineol, and lavandulyl acetate.

MS plays a crucial role in the first approach [19.122]. This consists of searching for the best trade-off between speed of analysis and loss of resolution of chiral compounds, even at the expenses of separating the other sample components. This is valid since the separated enantiomers can be highlighted by operating in extract-ion, SIM- or MIM-MS modes. Analysis time can therefore be reduced by exploiting the excess of resolution that columns coated with the last generation of CD derivatives can provide for several chiral compounds, by acting on column dimension, flow rate, and temperature rate. The essential prerequisite is to maintain baseline separation of the enantiomers of the chiral compound(s) investigated, so as to afford correct ee or er determination. With this approach, co-elution of the chiral components with other sample components, due to column shortening and increased heating rates, is to be expected but should not interfere with enantiomeric recognition of the chiral marker(s), because MS as a second dimension in detection, in extract-ion mode (or SIM- or MIM-MS) with diagnostic and specific ions, reliably discriminates them from other co-eluting peaks.

Figure 19.7 reports the Es-GC-MS profiles of the lavender essential oil analysed with the reference conventional column, together with the identification of peaks of chiral components.

Table 19.3 compares enantiomer resolutions of chiral components, analysis time, and % analysis time reduction, when lavender essential oil was analysed with the reference conventional column, and with the 10, 5 and 2 m narrow bore columns. Column length and analysis conditions were considered adoptable for routine analysis only when enantiomer resolutions of all chiral compounds were above 1.5.

The results (Fig. 19.8) show that:

1. The 10 m NB column can only be used at 2 °C/min, because at higher rates terpinen-4-ol, linalyl acetate and borneol are not baselxine separated.
2. The highest temperature rate for the 5 m NB column was 5 °C/min, because at 10 °C/min resolution of terpinen-4-ol was only 1.2, as is clear from its ion profiles at m/z 71, 111, 154.
3. Similar considerations can be made for 2 m NB columns.

Under these conditions, the analysis time was reduced from about 40 min with the reference column to about 14 min with the 5 m NB column. Figure 19.8

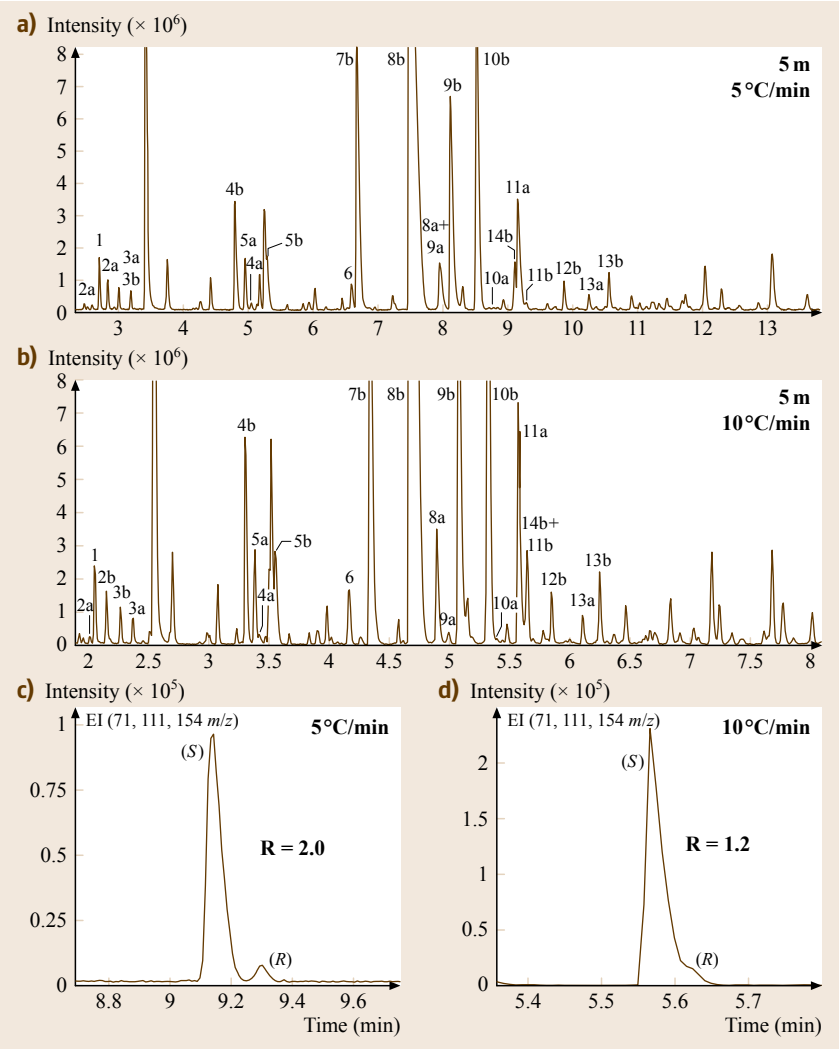

Fig. 19.8a–d The Es-GC-MS profiles of the lavender essential oil analyzed with the 5 m NB column at 5 **(a)** and 10 °C/min **(b)**. Extract ion profiles of terpinen-4-ol (71, 111, 154 m/z) at 5 **(c)** and 10 °C/min **(d)**. For analysis conditions see Table 19.3. For peak identification, see caption to Fig. 19.7 [19.122]

reports the Es-GC-MS profiles of the lavender essential oil analyzed with the 5 m NB column at 5 (A) and 10 °C/min (B) and the extract ion profiles of terpinen-4-ol (71, 111, 154 m/z) at 5 (C) and 10 °C/min (D).

The second approach [19.121] is based on the opposite strategy – shortening analysis time by seeking the maximum separation efficiency of the chromatographic system, by optimizing analysis conditions. The routine analyses of a large number of different samples in a single field (aromas from different matrices) are in general carried out under the same standardized GC conditions, partly because of the possibility of automatically identifying peaks from chromatographic data (relative retention times, linear retention indices, RTL, etc.). Usually, satisfactory separations are obtained under nonspecific routine conditions, thanks to much-higher-than-required efficiency of the chromatographic system, to the detriment of analysis times. Optimization of analysis conditions for a specific sample, that is, tuning a dedicated method for each matrix, can successfully and dramatically speed up routine GC analyses. *Blumberg* and coworkers [19.125–129] investigated in depth the most important theoretical concepts required to optimize capillary GC methods and to obtain the best speed–separation trade-off, while preserving separation and peak elution order.

These studies resulted in the well-known GC method translation [19.130], a short description of which will now be given. This approach implies optimizing the chromatographic conditions to give the best speed–separation trade-off with a conventional d_c column, and then transferring the optimized method to a shorter NB column. The parameters influencing a GC analysis are divided into two main groups: *translatable*

(column dimension (d_c and length), outlet pressure (1 atm for flame ionization detector (FID), vacuum for MS, etc.), carrier gas and flow rate) and *nontranslatable* (stationary phase type and phase ratio). The crucial operative parameter is hold-up time, which is taken as time unit to express all time-related parameters (duration of temperature plateau(s) and heating rate(s)) and to determine the normalized temperature program. Two methods are translatable only when nontranslatable parameters and normalized temperature programs are identical. The method-translation principles applied to a given temperature-programmed analysis enable either the flow rate to be optimized, producing the highest efficiency (i. e., the plate number) of a given column (efficiency-optimized flow, EOF), or a combination of flow rate, column dimensions, and carrier gas to be determined that corresponds to the shortest analysis time for a given required plate number (speed-optimized flow, SOF [19.127]). Method translation software can be downloaded for free from the Internet [19.130].

Optimization of Es-GC analysis conditions of lavender essential oil with a conventional 25 m × 0.25 mm column consisted of three main steps:

1. Choice of initial conditions to be optimized
2. Determination of optimal multirate temperature program for a predetermined fixed column pressure
3. Determination of optimal pressure (i. e., flow-rate) for the normalized optimal multirate temperature program.

The lavender essential oil was first analyzed with the conventional d_c column, under the temperature and flow conditions applied to routine analyses, that is, helium flow rate 1 ml/min and 2 °C/min heating rate. Under these conditions, the chiral markers were well separated in an analysis time of 35.2 min. Table 19.4 reports order of elution, retention times (t_R), and resolutions (R_S) of the enantiomers of the chiral markers investigated. Figure 19.9a reports the Es-GC pattern of the lavender essential oil investigated, analyzed un-

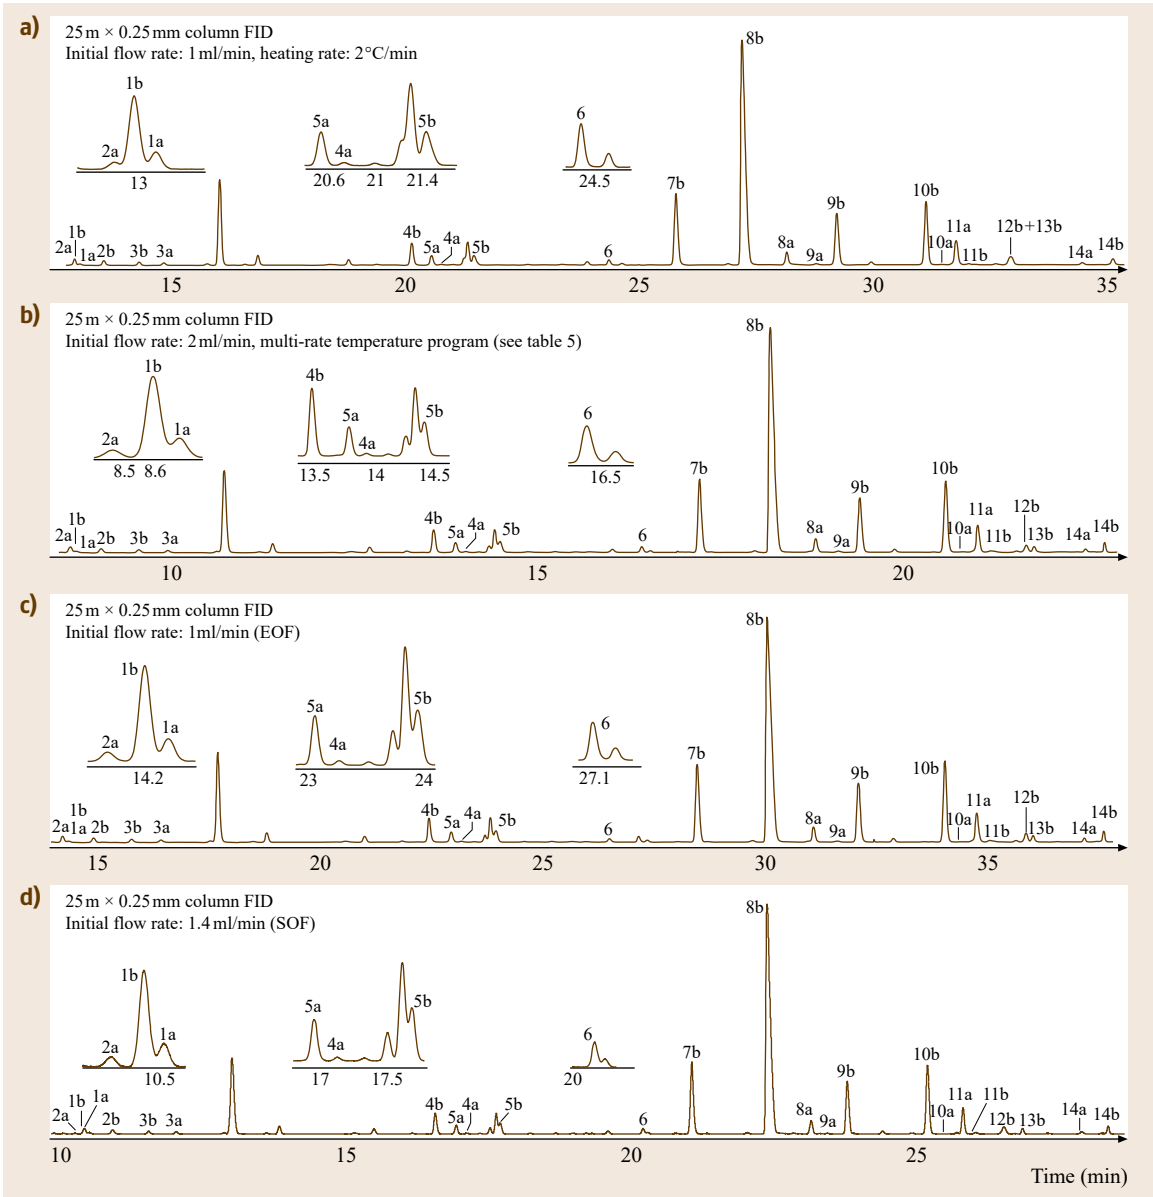

Fig. 19.9a–d Es-GC-MS profile of the lavender essential oil analyzed under different conditions with a conventional d_c column. For analysis conditions see text and Table 19.3. For peak identification, see caption to Fig. 19.7 [19.121]

der routine analysis conditions. This CD column and these conditions produced baseline separation of all chiral compounds, with the exception of α-pinene (1) enantiomers (R_S around 1) and of 1-octen-3-ol (6) enantiomers (not separated at all), while the (*S*)-enantiomers of camphor (7), lavandulol (13), and lavandulyl acetate (12) were not detectable, and (*R*)-lavandulol (13b) and (*R*)-lavandulyl acetate (12b) coeluted. As the starting point for method optimization, the initial flow rate was doubled to 2 ml/min (4) to reduce the time needed for method development, because this choice did not affect the final optimal conditions.

The optimal multirate temperature program at a fixed initial flow rate was obtained by applying a set of different single-ramp heating rates, namely 2.6, 3.3, and 5 °C/min (°C/t_m) (Table 19.4). The most satisfactory separation was obtained at 2.6 °C/min rate, which resulted in an analysis time of about 25.5 min. These experiments showed that, besides the separation of the enantiomers of chiral markers, lavender essential

oil presented three critical pairs of components: α-pinene (1)/camphene (2), 1-octen-3ol (6)/γ-terpinene, and (*R*)-lavandulol (13b)/(*R*)-lavandulyl acetate (12b), that are separated at different heating rates (2.6, 3.3, and 2.6 °C/min, respectively). A multiramp temperature program was therefore applied to obtain the best resolution of critical pairs in the shortest time; in particular, from 50 to 74 °C (elution temperature of (*R*)-α-pinene (1b), retention time 8.62 min) at 2.6 °C/min, then to 115 °C (elution temperature of (*R*)-lavandulol

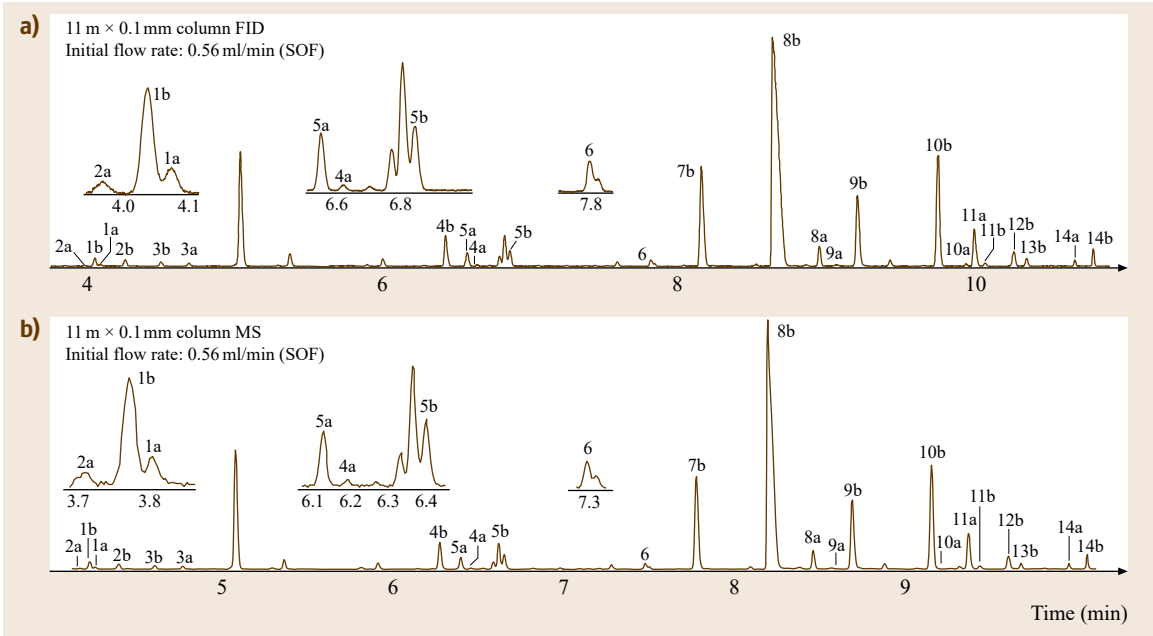

Fig. 19.10a,b Es-GC-MS profiles of the lavender essential oil analyzed under SOF conditions with the NB column. For analysis conditions, see text and Table 19.5. For peak identification, see caption to Fig. 19.7 [19.121]

(13b), retention time 21.79) at 3.3 °C/min, then to 220 °C at 15 °C/min to clear the column. Figure 19.9b reports the Es-GC pattern of the lavender essential oil analyzed under the optimized multirate temperature program.

The next step was to optimize the flow rate by determining the initial EOF (initial flow that maximizes column efficiency and peak resolution) and calculating the initial SOF (initial flow that minimizes analysis time at fixed efficiency) [19.125]. A reasonable compromise to optimize the flow rate is to apply the initial value that is optimal for the most critical pair (or the most important pair, in this case α-pinene). This can be EOF, which causes the highest column efficiency for a given solute pair and, as a result, its highest resolution (see below), but it can also be the initial SOF, which causes the shortest analysis time for a given resolution of the critical pair. Ten different pressures were applied to the column, resulting in different initial flow rates. The GC method translator was used to translate the temperature program for each pressure, in order to maintain the same normalized temperature program in all cases. Table 19.5 reports the initial flow rates, the corresponding translated temperature programs, and the resulting analysis times. SOF can be calculated from EOF as SOF $= \sqrt{2}$ EOF [19.127], that is, in this study, the initial EOF was 1 ml/min so that the initial SOF was 1.4 ml/min, and the corresponding first two heating rates were 2.02 and 2.57 °C/min (Table 19.5). Under these conditions, the analysis time was 29.3 min.

Table 19.6 reports retention times, enantiomer resolution, and σ values of chiral markers of the lavender essential oil analyzed, under the optimal conditions determined. The lavender essential oil profiles at EOF and SOF are shown in Fig. 19.9c,d respectively.

The optimized SOF method with a conventional (25 m × 0.25 mm × 0.25 µm) column was then translated to the corresponding NB column (11.13 m × 0.1 mm × 0.1 µm). Parameters of the translated method are shown in Table 19.5, and the essential oil profile in Fig. 19.10a. The flow rate was reduced in proportion with the column d_c, from 1.4 to 0.56 ml/min, thus assuring SOF operation of the NB column. Under these conditions, and because both columns had very similar length/d_c ratio, translation did not affect resolution of any peak pair (Table. 19.6), but analysis time was reduced to about a third (29.50 versus 10.78 min), without loss of peak resolution.

The SOF analysis conditions with ES-GC-FID were then translated to the Es-GC-MS for the same lavender essential oil analysis. Translation from conventional column at SOF to the MS method with NB column at SOF reduced analysis time overall to about a third (retention time of the last peak was reduced from 29.28 to 10.09 min).

19.7 Total Analysis Systems and Real-World Sample Analysis

The above paragraphs show that Es-GC is very successful as a technique for chiral odor recognition in the flavor and fragrance field, in particular when considered within the modern strategies of analysis based on fully automatic systems, better known as *Total Analysis Systems* (TASs); these are systems in which the three main steps of the analytical process (sample preparation, analysis, and data processing) are on-line integrated into a single step [19.131, 132]. The success of TAS systems is one of the factors that has greatly contributed to the radical change of strategies that began in the early 1990s in analysing volatiles in the flavor and fragrance fields [19.133].

The adoption of these systems in general, and in particular in chiral recognition, has been made possible by the parallel improvements achieved not only in Es-GC but also in sample preparation and mass spectrometry as detector (Sect. 19.5.2). In spite of the number of effective distillation and extraction techniques introduced into sample preparation over this period, the volatile nature of most odorants in the flavor and fragrance field makes headspace sampling, when applicable, the technique of choice for these analyses [19.100, 134, 135]. HS techniques have the advantages of being solvent-free, fast, simple, reliable, and, above all, easy to automate; they can also be combined on-line to GC-MS systems. These considerations include both conventional (static (S-HS) or dynamic (D-HS)) modes, and high concentration capacity headspace techniques (HCC-HS) [19.134–136]. HCC-HS are recently developed techniques that act as a *bridge* between S-HS and D-HS techniques: volatiles are statically or dynamically accumulated on polymers, operating in sorption and/or adsorption modes or, less frequently, on solvents (headspace solid-phase microextraction (HS-SPME), headspace sorptive extraction (HSSE), headspace sorptive tape extraction (HS-STE), headspace liquid-phase microextraction (HS-LPME), etc.). The development of these techniques was favoured by the success of polydimethylsiloxane (PDMS) as an accumulation material for volatiles [19.137].

Figure 19.11 reports an example of a TAS where the genuineness of a peach juice is determined by a one-step analysis by HS-SPME-Fast-GC-MS and (SIM-MS) [19.81].

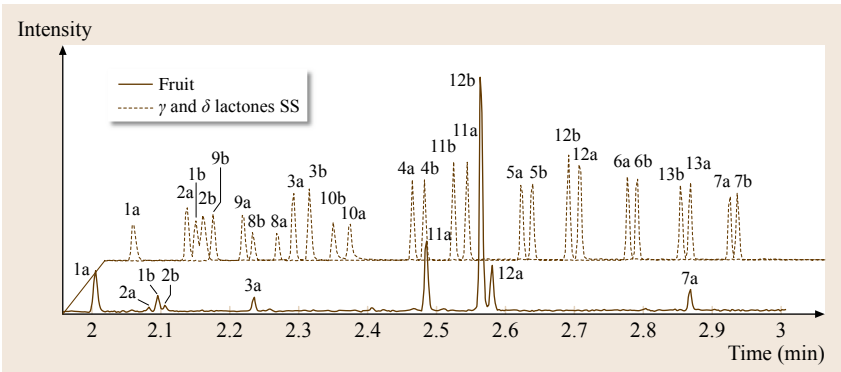

Fig. 19.11 HS-SPME-Fast-Es-GC-SIM-MS profiles of peach juice HS and γ-C6-C12 and δ-C6-C12 (—) standard solutions on a 30% 6^{I-VII}-*O*-TBDMS-$2^{I-VII-}3^{I-VII}$-*O*-acetyl-β-CD in PS086 (5 m, d_c: 0.10 mm, d_f: 0.10 mm) Sampling conditions: fiber: 2 cm Stableflex 50/30 µm DVB-Carboxen-PDMS (Supelco, Bellefonte, PA, USA); sample amount: 20 mg; vial volume: 20 ml; sampling time: 20 min, temperature: 60 °C. Analysis conditions: injection mode: split; split ratio: 1 : 50. Inj. temperature: 230 °C, transfer line: 250 °C; ion source: 200 °C; ionization mode: EI at 70 eV. Scan range: 35–350 m/z. Temperature program, 90 °C/24.0/140 °C/60.0/220 °C. Peak identification: 1: γ-hexalactone, 2: γ-heptalactone, 3: γ-octalactone, 4: γ-nonalactone, 5: γ-decalactone, 6: γ-undecalactone, 7:γ-dodecalactone, 8: δ-hexalactone; 9: δ-octalactone, 10: δ-nonalactone, 11: δ-decalactone, 12: δ-undecalactone, 13: δ-dodecalactone; (a) *(R)*-enantiomer, (b) *(S)*-enantiomer

19.8 Conclusions

Cyclodextrin derivatives are nowadays the most effective chiral stationary phases available for Es-GC in the flavor and fragrance field. This consideration is not only justified by the number of CD derivatives with high enantioselectivity and good chromatographic properties offering the possibility to separate most enantiomer pairs without derivatization to the corresponding diastereoisomers, but also to the performance of the resulting GC columns, also thanks to the dilution in moderately polar polysiloxanes, in particular:

- High stability and separation repeatability maintained for hundredth of injections.
- Efficiency and analysis times comparable to those of conventional columns.
- High inertness with classes of compounds, within a relatively wide range of polarity.
- Extended operative temperature range (20–250°). As a result, very few enantiomer pairs in this field cannot be separated with these chiral selectors provided that a suitable derivative is adopted.

However, in view of an ever increasing demand of chiral recognition, a lot of work has still to be done, mainly on two complementary directions: a) the first one concerning an ever better understanding of the mechanisms that are the basis of enantiomer recognition with CD derivatives in vapour phase thus allowing the operator to design a separation and avoiding to proceed by trial and error, as it is often the case with new enantiomer pairs, and b) the latter implying introduction of a new generation of CD derivatives with a more universal enantioselectivity enabling to extend their use to the separation of highly polar chiral compounds.

20. Stable Isotope Ratio Analysis for Authenticity Control

Norbert Christoph, Antje Schellenberg, Wiebke Zander, Gerhard Krammer

This chapter summarizes terms, definitions, and reference materials used for stable isotope ratio analysis (SIRA) of the bioelements hydrogen, carbon, and oxygen. The principles of biotic and abiotic fractionation in biomolecules like flavor compounds are explained. A short review of the common methods for the determination of isotope ratios $^{2}H/^{1}H$, $^{13}C/^{12}C$, and $^{18}O/^{16}O$, using isotope ratio mass spectrometry (IRMS) and nuclear magnetic resonance spectrometry (NMR) of hydrogen and carbon (^{2}H- and ^{13}C-NMR) are introduced. Further the focus is set on selected applications of authentication control of flavor compound and flavorings using isotope ratio analysis. Examples of benzaldehyde, vanillin, vanilla flavorings and vanilla extracts, butanoic acid, isoprenoids, and essential oils as well as fruity flavor compounds like γ- and δ-lactones are presented. Potentials and limitations of SIRA are discussed taking the analytical requirements into consideration, as well as representative databases and suitable guidelines for authenticity assessment.

Authenticity of a single flavoring substance, a flavoring, or an essential oil can be defined as the genuineness of the described purity and source of origin. The regulation of *the European Parliament and Council* on flavorings lays down the criteria for the use and labeling of flavorings and certain food ingredients with flavoring properties for intended food use. Flavorings should, in particular, not be used in a way as to mislead the consumer about issues related to the nature, quality of ingredients used, genuineness, or the production processes. The *International Organization of the Flavor Industry (IOFI)* has established the *IOFI Code of Practice* corresponding to official regulations, which describes best practices and finds full acknowledgment by all member associations and member companies. Thus the proof of authenticity of flavorings represents an important task regarding consumer protection against fraud and also regarding the legitimate interest of quality assurance departments in the flavor and fragrance as well as the food industry. In combination

with the correct labeling of products, the confirmation of a justifiable cost-to-benefit ratio reflects the commercial basis of fair trade in many industries besides the food industry like the pharmaceutical industry or animal nutrition industry.

Many commercially important flavoring substances can be produced via different routes like chemical synthesis, traditional food preparation methods, and enzymatic or microbiological processes from various sources. Due to the high demand for natural flavorings analytical methods have to be constantly optimized in order to detect sophisticated adulterations. The detection of adulterations or the proof of authenticity of flavorings involves the following three main analytical focus points according to EU legislation [20.1]:

- Is the flavoring substance or flavoring exclusively originating from the natural source or material referred to?
- Is the indication of the geographic origin and botanical variety of the source of the flavoring appropriate?
- Are flavoring substances derived from microbiological, enzymatic, or physical processes from natural and approved raw materials or are they synthesized by chemical processing?

Gas chromatography combined with mass spectrometry (GC-MS) is a standard analytical method not only for the determination of the qualitative and quantitative composition of a complex flavoring, often containing more than 100 flavor substances, but also for the proof of the purity of a single flavoring substance. The application of GC-MS methods usually provides a first qualitative and quantitative overview as well as a first insight regarding the potential source of a flavoring mixture including suspicious findings [20.2–4]. Enantioselective gas chromatography on chiral phases to determine the enantiomeric distribution may only help to prove the natural character of a few chiral flavor substances [20.5]. In consequence, a significant proof of authenticity, which also provides sufficient evidence in court, is not always possible with these methods only.

Since more than 30 years, the stable isotope ratio analysis (SIRA) of the bioelements hydrogen, carbon, and oxygen is used in laboratories of the flavor industry, but also in laboratories responsible for official consumer protection, for a more significant authenticity control of flavor compounds and flavorings [20.6–10]. Currently, the various possibilities of SIRA using IRMS, also coupled on-line with multidimensional gas chromatography [20.11] and enantioselective analysis [20.5], as well as nuclear magnetic resonance spectroscopy (NMR) are mainly focused on a significant assessment of authenticity of a flavor compound [20.12, 13].

20.1 Fundamentals

Each element is defined by the composition of its atomic nucleus, which contains a specific number of protons and neutrons. The number of protons is identical with the number in the periodic system of an element and defines the name of the element (1 for hydrogen, 6 for carbon, or 8 for oxygen). The sum of the protons and neutrons is responsible for the relative isotopic mass or the atomic mass.

Isotopes are variants of a particular chemical element which only differ in their number of neutrons. An additional neutron of an element defines an additional isotope of this element. For example, the predominant percentage of carbon ($\approx 99\%$) has 6 protons and 6 neutrons and is reported as ^{12}C to define its atomic mass. However, about 1.1% of the carbon in the Earth's biosphere has 6 protons and 7 neutrons and is the heavier stable isotope reported as ^{13}C. *Stable isotopes* do not decay into other elements. In contrast, *radioactive isotopes* (e.g., ^{14}C) are unstable and will decay into other elements [20.14, 15].

The stable isotope ratios of the bioelements carbon ($^{13}C/^{12}C$), hydrogen ($^{2}H/^{1}H$), and oxygen ($^{18}O/^{16}O$) are usually expressed in the so-called *delta notation* ($\delta^{13}C$, $\delta^{2}H$, $\delta^{18}O$). For the hydrogen isotope ^{2}H also the term *deuterium* with its abbreviation *D* is used. In case of isotope ratio of *isotopomers* the term (D/H) is used.

Isotopomers or *isotopic isomers* have the same number of each isotopic atom but have different positions of the heavier isotope in the molecule. For example, ethanol is composed of three isotopomers with deuterium occurring in the three positions (CH_2DCH_2-OH, CH_3CHDOH, and CH_3CH_2OD) [20.16]. *Isotopologues* are molecules that differ only in their isotopic composition. Water, the best known example, can be differentiated between *light water* (HOH), *semi-heavy water* with the deuterium isotope in equal proportion to the proton (HDO), and *heavy water* with two deuterium isotopes of hydrogen per molecule (D_2O or $^{2}H_2O$). Oxygen-related isotopologs of water include the heavy-oxygen

water ($H_2^{18}O$) and the more difficult to separate version with the ^{17}O-isotope.

20.1.1 Terms and Definitions

In order to establish an isotopic profile or signature for a material, the ratios of the stable isotopes of elements, such as $^2H/^1H$, $^{18}O/^{16}O$, $^{13}C/^{12}C$, $^{15}N/^{14}N$, and $^{34}S/^{32}S$ can be measured. Variations in the natural abundance of stable isotopes are expressed using the delta (δ) notation ($\delta^{13}C$) as shown in Eq. (20.1). δ-values are commonly expressed in parts per thousand (per mil or ‰). Isotope ratios are measured relative to international standards that define the measurement scale for particular isotopes (Table 20.1). The *International Atomic Energy Agency* (IAEA) has defined these scales by reference to natural or virtual materials identified by the V prefix:

$$\delta^{13}C[‰]_{V\text{-}PDB} = \left(\frac{R_{Sample}}{R_{Standard}} - 1\right) \cdot 1000\,, \qquad (20.1)$$

where R_{Sample} is a ratio ($[^{13}C]/[^{12}C]$) of the sample, $R_{Standard}$ is a ratio ($[^{13}C]/[^{12}C]$) of the international standard.

20.1.2 International Standards

The calibration and intercomparison materials typically consist of natural minerals and compounds commonly studied in isotope geochemistry, having the desired characteristics of isotopic composition, homogeneity, chemical purity, and stability. The IAEA distributes calibration and intercomparison materials for the interlaboratory calibration of measurements of stable isotope ratio variations in natural compounds. A comprehensive review of stable isotope scales and reference materials is the *IAEA-TECDOC-825*, available from the IAEA in Vienna [20.18]. Standards, calibration, and intercomparison materials can be grouped in primary reference standards, calibration materials, and intercomparison materials.

The primary reference standards used to express natural variations of isotopic composition of hydrogen, oxygen, carbon, nitrogen, and sulfur are SMOW, PDB, Air, and CDT. SMOW (*standard mean ocean water*) was used since it was defined by Craig in 1961 as reference to express the relative variations of $^2H/^1H$- and $^{18}O/^{16}O$-ratios in natural waters [20.19]. The definition of SMOW was based on a water standard of the *National Bureau of Standards* (NBS-1). PDB (*Peedee Belemnite*) consisted of calcium carbonate from the rostrum of a Cretaceous belemnite, *Belemnitella americana*, from the Peedee formation of South Carolina. The CO_2 evolved from PDB, by treatment with phosphoric acid, was adopted as the zero point for oxygen and carbon isotopic measurements. AIR (atmospheric nitrogen), with a very homogeneous isotopic composition all around the world [20.20], is the primary reference standard for nitrogen stable isotope variations. Atmosphere is the largest terrestrial reservoir of nitrogen, and it is also the main pool of this element taking part in natural and industrial processes (production of fertilizers). CDT (*Canyon Diablo Troilite*) consisted of FeS (Troilite) present in the iron meteorite of Canyon Diablo, Arizona. Meteoritic sulfur was taken as reference standard because its $^{34}S/^{32}S$ isotopic ratio exhibits only small variations and corresponds quite well to the average isotopic ratio of terrestrial sulfur [20.21]. CDT has a $^{32}S/^{34}S$-ratio of 22.22 $‰_{V\text{-}CDT}$ [20.22], and is considerably depleted in ^{34}S (about +20 $‰_{V\text{-}CDT}$) with respect to marine sulfate, which is isotopically the most homogeneous sulfur reservoir on the earth crust. From these primary reference standards SMOW, was selected as a theoretical calibration standard while PDB and CDT were used as such for long time.

The IAEA distributes these materials to laboratories around the world. All reference materials are carefully calibrated versus the primary reference standards based on internationally agreed and adopted calibration values. Both water reference materials V-SMOW (*Vienna Standard Mean Ocean Water*) and SLAP (*Standard Light Antarctic Precipitation*) are distributed for the calibration of the $^2H/^1H$, $^{18}O/^{16}O$, and $^{17}O/^{16}O$ variation measurements. V-SMOW was prepared by blending distilled ocean water with small amounts of other waters to produce an isotopic composition close to the

Table 20.1 International isotope ratio scales (after [20.17])

Element	International scale	Isotope ratio	Accepted ratio[a]
Hydrogen	Vienna Standard Mean Ocean Water (V-SMOW)	$^2H/^1H$	0.00015575
Oxygen	Vienna Standard Mean Ocean Water (V-SMOW)	$^{18}O/^{16}O$	0.0020052
Carbon	Vienna PeeDee Belemnite (V-PDB)	$^{13}C/^{12}C$	0.0111802
Nitrogen	AIR	$^{15}N/^{14}N$	0.0036782
Sulfur	Vienna Canyon Diablo Troilite (V-CDT)	$^{34}S/^{32}S$	0.0441509

[a] [Heavy isotope]/[light isotope]

Table 20.2 Reference materials

Name	Nature	Isotope	δ ‰ (±SD)[a]
GISP	Water	^{2}H	-189.5 ± 1.2
		^{18}O	-24.76 ± 0.09
IAEA-CH-7	Polyethylene	^{2}H	-100.3 ± 2.0
		^{13}C	-32.151 ± 0.050
IAEA-N-1	Ammonium sulfate	^{15}N	$+0.4 \pm 0.2$
NBS-18	Calcite	^{18}O	-23.2 ± 0.1
		^{13}C	-5.014 ± 0.035
IAEA-CH-6	Sucrose	^{13}C	-10.449 ± 0.033
NBS-127	Barium sulfate	^{34}S	$+20.3 \pm 0.4$
		^{18}O	$+9.3 \pm 0.4$

[a] The isotopic ratio data are reported in per mil (‰) deviation from the international isotope standards V-SMOW for oxygen and hydrogen, V-PDB for carbon, Air for nitrogen, and V-CDT for sulfur. The δ-values and SD are those reported by IAEA (compiled 2013) under: http://nucleus.iaea.org/rpst/ReferenceProducts/ReferenceMaterials/Stable_Isotopes/index.htm

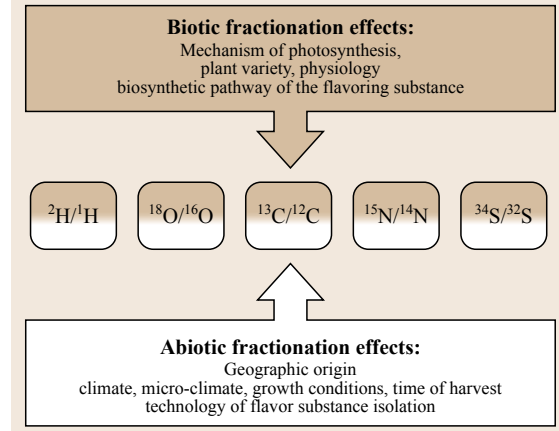

Fig. 20.1 Parameters, influencing biotic and abiotic stable isotope fractionation of bioelements in flavorings from plant sources

definition of SMOW. V-SMOW has an isotopic composition practically identical to the SMOW defined by Craig, while SLAP, which was prepared from South Pole firn, is considerably depleted in heavy isotopes with respect to V-SMOW. Now V-SMOW has been superseded by V-SMOW2 which was prepared at the IAEA Isotope Hydrology Laboratory in 2006 to replace the V-SMOW material [20.23]. PDB has isotopic ratios close to those of limestone of marine origin, and is considerably enriched in ^{13}C with respect to organic carbon compounds. Therefore, NBS-19 (or TS-Limestone) was distributed for the calibration of the $^{13}C/^{12}C$ and $^{18}O/^{16}O$ variation determinations. NBS-19 has been indirectly calibrated versus PDB. By international agreement, the isotopic composition of NBS-19 versus a hypothetical V-PDB (Vienna-PDB), supposed identical to PDB, has been fixed to $\delta^{13}C = +1.95\,‰_{\text{V-PDB}}$ and $\delta^{18}O = -2.20\,‰_{\text{V-SMOW}}$ [20.24]. The absolute isotopic ratios of NBS-19 have not been determined. Improved measurement precision has revealed that CDT was not isotopically homogeneous to be continued as the primary reference material and [20.25], as a consequence, the CDT scale has been replaced with V-CDT. V-CDT is defined by assigning a $\delta^{34}S$-value of $-0.3\,‰$ to IAEA-S-1 (silver sulfide) [20.26].

Intercomparison materials are natural and synthetic compounds, which provide the means for laboratories to periodically check the overall quality of the measurements performed, including the long-term reproducibility of sample preparation from a variety of materials, in comparison with those obtained by other laboratories. The δ-values of these materials (distributed by IAEA) are agreed and adopted internationally but, in contrast to the primary reference standards, have uncertainty associated with the δ-values (Table 20.2).

20.1.3 Principles of Stable Isotope Discrimination and Fractionation of Bioelements

Many studies on the inter- and intramolecular nonstatistical distribution of heavy stable isotopes of the bioelements ^{13}C, ^{2}H, ^{18}O, ^{15}N, and ^{34}S in plant material ingredients have proved that their distribution is controlled by physical and chemical principles, which result in a characteristic pattern and intrinsic correlation of stable isotope ratios. In plant materials, this pattern is mainly assigned by different biochemical mechanisms in different plant varieties and different physicochemical effects induced by the geographic locations and conditions of growth, harvest, or processing [20.14, 15, 27].

The so-called *stable isotope discrimination or fractionation* can be divided into *biotic* and *abiotic* processes, which both have main influences on the stable isotope distribution of hydrogen, carbon, oxygen, and nitrogen in an organic molecule like a flavoring substance. In addition, isotope fractionation effects, which may occur due to environmental influences (*anthropogenic fractionation*) as well as *geological fractionation* are affecting the composition of the soil where, for example, a plant was grown [20.14, 15]. This influence is prominent for sulfur and nitrogen but less relevant for the main bioelements hydrogen, carbon, and oxygen of flavor substances. The final isotopic pattern of components from a plant material integrates both biotic and abiotic factors.

Thus, the knowledge of the characteristic patterns and the mechanisms responsible is a powerful tool for authentication of individual flavoring substances.

Figure 20.1 shows the main influences on biotic and abiotic stable isotope fractionation.

20.1.4 Biotic Fractionation (Kinetic Fractionation Effects)

The best known and important biotic fractionation effect is the carbon-isotope discrimination, which is a result of the different primary *CO_2-fixation processes* by photosynthesis in terrestrial plants and which shows different ^{13}C-isotope fractionation, in the so-called *C_3-*, *C_4-plants*, and *CAM-plants* [20.28, 29]. The C_3-*plants* – the name is derived from the number of carbon atoms of phosphoglyceric acid, the first photosynthetic product – have a larger isotope effect on the ribulose-bisphosphate-carboxylase reaction, with the result of a depletion of the ^{13}C-isotopes and δ^{13}C-values between -37 and $-24\,‰_{\text{V-PDB}}$. C_3-plants represent the most abundant group of plants and comprise vegetable flavoring sources like pomaceous fruits, stone fruits, berry fruits, grapes, wheat, grain, or sugar beet [20.30].

C_4-plants – the name is derived from the four C-atoms of the oxalacetate, the photosynthetic product of the phosphoenolpyruvate-carboxylase reaction. Due to a smaller isotope effect, more ^{13}C is accumulated resulting in δ^{13}C-values between -16 and $-10\,‰_{\text{V-PDB}}$. The best known C_4-plants used in agricultural industry are sugar cane, corn, or millet.

Products from *CAM-plants* (crassulacean acid metabolism), which are characteristic for some succulents, orchids, and tropical grasses, have both CO_2-fixing reactions. Therefore the δ^{13}C-values range in between these areas of the C_3- and C_4-plants. Products of CAM-plants also show a higher enrichment of deuterium in carbohydrates and in some substances of their secondary metabolism, like aromatic compounds. CAM-plants with important flavorings are pineapple, vanilla, or agave [20.12, 14].

Fractionation of hydrogen and deuterium is also influenced by photosynthetic processes. Thus also deuterium is depleted in C_3-plants and accumulated in C_4-plants. Deuterium is also fractionated during alcoholic fermentation of sugar by yeasts. The corresponding biotic intramolecular fractionation effects induced by different kinetic and enzymatic mechanisms during biosynthesis and metabolism can also be used for authenticity assessment of a flavor substance. Due to the complex biosynthetic correlations in the formation and the extremely complicated analytical demands of the analysis of ^{13}C-patterns, only ^{2}H- and ^{18}O-patterns are of practical importance with regard to the following general rules [20.12]:

^{2}H-patterns:

- Natural aromatic compounds descending from the shikimic acid pathway show relative positional ^{2}H-abundances in the sequence $p > o \geq m$; when the *p*-position is hydroxylated, the sequence is inverted into $m > o$.
- Isoprenoids from the mevalonate pathway show in general a ^{2}H-depletion of the methylene groups relative to the methyl and vinyl positions, while those from the desoxyxylulose-phosphate pathway are characterised by a distinct relative ^{2}H-depletion of the vinyl groups.
- Chains of fatty acids and descendants or acetogenins show an alternating ^{2}H-abundance with relative ^{2}H-depletions in the odd (C = O-deriving) positions.

^{18}O-patterns:

- In natural compounds, the δ^{18}O-values of hydroxyl groups originating from monooxygenase reactions (most phenolic OH-groups, some OH-groups in isoprenoids) range between $+3$ and $+7\,‰_{\text{V-SMOW}}$.
- Oxygen functions introduced from water by a lyase reaction must be ^{18}O-depleted relative to this water, with water isotopically equilibrated carbonyl or carboxyl groups are relatively ^{18}O-enriched by about $+28$ and $\approx +19\,‰_{\text{V-SMOW}}$, respectively.
- Natural but also certain nature identical esters are characterized by an extreme ^{18}O-enrichment (up to $+40$ to $+60\,‰_{\text{V-SMOW}}$) of the carbonyl-O and a modest ^{18}O-content of the ether-O ($< +10\,‰_{\text{V-SMOW}}$).

20.1.5 Abiotic Fractionation (Thermodynamic Fractionation)

Abiotic fractionation processes are mainly induced by thermodynamic isotope effects during water evaporation and condensation, and the isotope equilibration between water and CO_2. There is a predictable linear relationship between ^{2}H and ^{18}O in water, which is referred to as *meteoric water line* and allows an approximation of ^{2}H based on measurements of ^{18}O and vice versa [20.19, 31, 32]. The following general rules have to be taken into consideration with regard to enrichment or depletion of heavier stable isotopes ^{2}H and ^{18}O in precipitation water:

- *Altitude effect*: the δ^{18}O- and δ^{2}H-values of precipitation decrease with increasing altitude. Typical

gradients are $-0.5\,‰_{\text{V-SMOW}}$ to $-0.5\,‰_{\text{V-SMOW}}$ per 100 m for ^{18}O, and $-1.5\,‰_{\text{V-SMOW}}$ to $-4\,‰_{\text{V-SMOW}}$ per 100 m for ^{2}H.

- *Latitude effect*: the $\delta^{18}O$- and $\delta^{2}H$-values decrease with increasing latitude because of the increasing degree of *rain-out* [20.33].
- *Continental effect*: Isotopic ratios decrease inland from the coast.
- *Amount effect*: The greater the amount of rainfall, the lower the $\delta^{18}O$- and $\delta^{2}H$-values of the rainfall.

Subsequently physical fractionation of water in a plant or in a fruit is the fractionation of plant or leaf water. Evaporation through the stomata or through the skin of a fruit or a vegetable enriches both ^{18}O and ^{2}H in fruit or leaf water. The extent of the enrichment depends on factors like microclimatic influences, location, water sustenance, but also physiological parameters like type of plant and finally agricultural conditions like period maturation of a fruit involving its different annual meteorological conditions and the date of harvest.

20.2 Methods for the Determination of Isotope Ratios

The ratio of stable isotopes of the bioelements H, C, O, S, and N in biomolecules like flavoring substances can be determined with IRMS. In analysis of volatile compounds like flavor substances or complex mixture of flavorings IRMS combined with gas chromatography is the method of choice.

Hydrogen or carbon isotope ratios of isotopomers of different positions or a functional group of a molecule can be determined either with ^{2}H-NMR or ^{13}C-NMR or using IRMS after specific degradation of a molecule.

20.2.1 Isotope Ratio Mass Spectrometry

Isotope ratio mass spectrometers are specifically designed to measure precisely small differences in the abundances of isotopes, such as $^{2}H/^{1}H$, $^{18}O/^{16}O$, and $^{13}C/^{12}C$, $^{15}N/^{14}N$, and $^{34}S/^{32}S$.

There are two common instrument configurations used – continuous flow IRMS (CF-IRMS) and dual-inlet IRMS (DI-IRMS). In dual inlet systems, the gases are generated off-line, and admitted into the sample bellows of the system. A second bellow contains the reference gas, and sample and reference are alternatively admitted into the ion source. In continuous-flow instruments, the dual inlet system is replaced by a carrier gas flow, commonly helium. This type of design is particularly suitable for the use of on-line preparation systems, such as elemental analyzers, gas chromatographs, or equilibrium devices. For isotope ratio measurement, the analyte must be converted into a simple gas (H_2, CO, CO_2, N_2, and SO_2) before entering the ion source of an isotope ratio mass spectrometer. The isotope ratio mass spectrometer measures the ratio of ions that correspond to these gases. For example, in the analysis of carbon isotope ratios, the mass spectrometer monitors ions with mass to charge ratios (m/z) of 44, 45, and 46, which correspond to the ions produced from CO_2 molecules containing ^{12}C, ^{13}C, ^{16}O, ^{17}O, and ^{18}O in various combinations. Ionization of the analyte gases is achieved using electron ionization (EI). The ionized gases are separated in a single magnetic sector analyzer by virtue of their momentum and are detected by an array of Faraday cups the output from which is used to calculate the final stable isotope ratio. This is calculated relative to a standard of known isotopic composition and expressed using the δ-notation.

The sample gas is produced in a range of automated preparation systems that can lead to *bulk* (BSIA) or *compound-specific* (CSIA) isotopic analysis.

An elemental analyzer coupled to an isotope ratio mass spectrometer (EA-IRMS) gives the bulk isotopic composition of the sample. Depending on the specific set up, it is possible to measure isotopic ratios of H, C, N, O and S in a range of solid and liquid matrices. At first the continuous flow elemental analyzer technique was suitable for the measurement of ^{13}C- and ^{15}N-isotopes in organic samples [20.34], and some years later for ^{34}S-isotopes in organic samples [20.35]. In combustion mode, C-, N-, and S-containing materials are converted into the measuring gases carbon dioxide, nitrogen, and sulfur dioxide for on-line isotopic analysis. The high-temperature conversion (*pyrolysis*) mode is employed for the analysis of isotope ratio of hydrogen and oxygen. Samples are loaded into silver capsules and dropped into a ceramic reactor lined by a glassy carbon tube (filled with glassy carbon) in the inside, where the sample is pyrolyzed [20.36–39]

On-line, high-precision CSIA was first demonstrated in 1978 by *Matthews* and *Hayes* [20.40–42], using a single-collector high-precision isotope ratio instrument. The compounds eluted from the chromatography column are carried by the helium flow; combusted in the interface, and carried into the source of the mass spectrometer. Initially, only ^{13}C could be determined [20.43]. Later modifications were made that allow measurement of N, O, and H isotope ratios [20.44, 45]. Carbon and nitrogen compounds eluting from the

chromatographic column then pass through a combustion reactor (an alumina tube containing Cu, Ni and, Pt wires maintained at 940 °C) where they are oxidatively combusted. This is followed by a reduction reactor (an alumina tube containing three Cu wires maintained at 600 °C) to reduce any nitrogen oxides to nitrogen [20.46]. For hydrogen and oxygen, a high-temperature thermal conversion reactor is required [20.47]. Following GC separation, the hydrogen bound in organic compounds must be quantitatively converted into H_2-gas prior to analysis in the IRMS. Quantitative conversion is achieved by high-temperature conversion (TC) at temperatures > 1400 °C [20.45].

The premise for gas chromatography isotope ratio mass spectrometry (GC-IRMS) is that the compounds constituting the sample mixture are amenable to GC, that is, they are suitably volatile and thermally stable. Polar compounds may require further chemical modification (derivatization) and in such cases the relative stable isotope ratio of the derivatization agent must also be determined. Coupling a liquid chromatograph to the IRMS (LC-IRMS) may overcome some of these problems [20.48]. However, LC-IRMS requires the elimination of the mobile phase either before or after oxidation of the sample of interest. The technique is useful to analyze high molecular weight compounds not well suited for GC-IRMS, such as sugars, amino acids, or active components of pharmaceuticals and drugs.

20.2.2 Nuclear Magnetic Resonance

Nuclear magnetic resonance spectroscopy (NMR) is a powerful analytical technique for determining the structure or purity of organic compounds and it is more and more frequently used in food analysis [20.32, 49, 50]. NMR is based on the fact that many nuclei, such as for example ^{1}H, ^{2}H and ^{13}C, possess a nuclear spin and thus have a nuclear magnetic moment. When placed in a magnetic field, the sample's nuclear magnetic moments align along the magnetic field's axis, resulting in a macroscopic magnetization, whose magnitude is proportional to the number of spins. By applying a pulsed magnetic field, oscillating at the observed isotope's specific resonance frequency, the magnetization can be rotated into the plane perpendicular to the magnetic field. There, it will precess around the field's axis, inducing an electrical current in the receiver coil, where it is picked up as the NMR-signal, the so-called *free induction decay* (FID). The distribution of frequencies contributing to the FID can be analyzed by Fourier-transformation. The normalized frequency (*chemical shift*) is characteristic of the chemical environment of the nucleus, as for example the protons of a methyl group possess a chemical shift of about 1 ppm.

The main disadvantages of NMR analysis for flavorings are on one hand a significantly lower sensitivity compared to mass spectrometry and on the other hand the lack of on-line separation techniques for volatile organic compounds. Whereas ^{1}H-spectra with signal-to-noise ratios of > 150 can be achieved within a few minutes, i. e. less than 50 scans for pure substances, more than 2000 scans are necessary to provide corresponding ^{2}H-NMR spectra, since the relative low natural abundance of ^{2}H with only 0.0145% of the hydrogen atoms has to be taken into account. In consequence, analytical applications with NMR stable isotope analysis are restricted to ^{2}H- and ^{13}C-NMR of single flavoring substances or pre-separated, concentrated and purified extracts of flavorings or flavored products only. The main advantage of NMR is that this technique is non-destructive [20.49].

20.2.3 ^{2}H–Nuclear Magnetic Resonance

^{2}H-Nuclear magnetic resonance was initially applied to the detection and official control of grape must and wine chaptalization with beet sugar via the nonstatistical distribution of deuterium in different sites of ethanol. The *site specific isotope fractionation NMR* (SNIF-NMR) is an official analytical method of wine control since 1990 [20.16, 50, 51].

Activities to use ^{2}H-NMR for characterizing the origin and authenticity of other biomolecules were soon focussed on single flavor substances [20.10, 51]. However, quantitative ^{2}H-NMR is limited to the application of pure or purified flavor substances. As for instance in case of vanilla flavoring or vanilla flavored products, ^{2}H-NMR analysis is only possible after extraction, purification and recrystallization of vanillin and a rather long measurement period of several hours with more than 3000 scans [20.52].

Besides vanillin, specific ^{2}H-NMR analytical protocols and spectral data are actually available for flavor substances like anethol, benzaldehyde, estragol, thymol, different lactones, monoterpenes, and terpenoid substances as well as essential oils esters [20.12, 53].

20.2.4 ^{13}C–Nuclear Magnetic Resonance

Due to the fact that the relative sensitivity of NMR for ^{13}C is theoretically higher by two orders of magnitude as compared to deuterium, a quantitative evaluation for this nucleus actually has only been performed in scientific studies [20.54–56]. The results have shown that carbon isotope effects are much smaller than hydrogen isotope effects, and in consequence that the relative differences between given positions are expected to be lower. Furthermore, in contrast to ^{2}H-NMR, ^{13}C-NMR

requires longer relaxation delays and measuring time for quantitative analysis. Nevertheless, the main feasibility of site-specific quantitative ^{13}C-NMR has been shown and characteristic ^{13}C-distributions in natural and synthetic vanillin originating from different sources have been obtained [20.54, 55].

20.3 Selected Applications of Authentication of Odorants

Isotope ratio analysis is the key method in the authentication of genuine flavorings as well as individual flavoring substances in quality control and assurance in food industries as well as for consumer protection purposes. In this chapter, a selected number of important applications in food industry is presented.

20.3.1 Benzaldehyde

The essential oils of bitter almond are important flavors used in the food and beverage industry. Bitter almond oil, which contains high amounts of benzaldehyde, is most relevant in numerous fruit and beverage applications [20.57]. The essential oil of bitter almond is obtained by water steam distillation of bitter almonds, apricots or other prunus seeds and contains up to 90% benzaldehyde. In order to distinguish between the different sources of benzaldehyd, for example, obtained by the oxidation of toluene, the alkaline hydrolysis of benzal chloride or from cinnamomum cassia different isotope ratio analyses are conducted.

For example, the δ^{13}C-values for benzaldehyde of botanical extracts (-27.9 ± 0.4 ‰$_{\text{V-PDB}}$) and natural oils (-28.6 ± 0.7 ‰$_{\text{V-PDB}}$) fall within a narrower range, this suggests a similar process or the generation from a botanical precursor. The δ^{13}C-values for benzaldehyde obtained from chemical synthesis (via benzalchloride) are depleted in ^{13}C relative to the natural samples (-29.2 ± 0.8 ‰$_{\text{V-PDB}}$), whereas synthesized material (via toluene oxidation) is enriched in ^{13}C by nearly 2‰ with respect to the natural extracts (-26.1 ± 0.6 ‰$_{\text{V-PDB}}$) [20.58]. The carbon isotope abundances are obviously not indicative for the origin of benzaldehyde, but the hydrogen isotope abundances seem to be more typical. Benzaldehyde from natural sources shows a mean δ^2H-value of -125 ± 14 ‰$_{\text{V-SMOW}}$. δ^2H-values of synthetic benzaldehyde depend on the manufacturing process. Products synthesized from benzal chloride have δ^2H-mean values of -40 ± 21 ‰$_{\text{V-SMOW}}$ and those derived from catalytic oxidation of toluene $+777 \pm 20$ ‰$_{\text{V-SMOW}}$ [20.59].

An important natural source of benzaldehyde is cassia oil. At the moment, it is impossible to differentiate the product derived from cassia oil from natural benzaldehyde by means of δ^2H-values [20.12, 62].

These examples show that in order to differentiate benzaldehyde from different origin via GC-IRMS multielement analysis is required. Table 20.3 indicates the ranges of δ^2H-, δ^{18}O-, and δ^{13}C-values of benzaldehyde and Fig. 20.2a,b illustrates examples of a multiele-

ment IRMS analysis of benzaldehyde, exhibiting that ex toluene can be distinguished from the remaining sources. The combination of δ^2H- and δ^{18}O-values presented in Table 20.3 provides further indication of the origin [20.12, 60].

For the unambiguous assignment of the origin of benzaldehyde the complementary use of quantitative ^{2}H-NMR data is essential, which is also known as SNIF-NMR in specific applications. Benzaldehyde is synthesized via the biosynthetic shikimic acid pathway, which leads to a different relative abundance of ^{2}H at the *ortho–meta–para* position at the aromatic ring [20.30]. The ^{2}H-NMR provides a practical means of determining the site-specific distribution of deuterium in benzaldehyde as well as differentiating petrochemical, cassia, and bitter almond oil benzaldehydes [20.63]. Figure 20.3 presents quantitative ^{2}H-NMR spectra of different benzaldehyde sources and Table 20.4 gives the relative abundances of ^{2}H at different positions of benzaldehyde depending on the origin in natural and nature identical benzaldehyde [20.30]. The repeatability of the ^{2}H-NMR measurements of benzaldehyde and the capability for both providing and quantifying adulterations have been estimated [20.64]. An unambiguous assignment of the benzaldehyde source by quantitative deuterium NMR data seem to be feasible as the examples in the 3-D plot in Fig. 20.4 show.

20.3.2 Vanillin, Vanilla Flavorings, Vanilla Extracts

Vanilla is an important natural flavor ingredient with major business relevance in the food and beverage industry [20.66, 67]. The worldwide production of natural vanilla extracts, commonly from vanilla beans of the species *Vanilla planifolia* and *Vanilla tahitensis* or *Vanilla pompona*, ranges at around 2000 metric tons per year while the consumption of vanillin (mainly in its synthetic form), the main flavoring ingredient in vanilla extracts, amounts to more than 12 000 metric tons per year. Due to the high demand and the relatively scarce availability, consumers' preferences for natural products and the dependence on the harvest of the natural crop, vanilla extracts command a high price that can vary considerably from season to season. Hence the differentiation of authentic vanillin from vanilla beans versus the inexpensive synthetic vanillin or other alternative natural sources converted into vanillin by biotransformation of lignin or ferulic acid is of high importance [20.65, 68]. For this reason, considerable effort has been directed toward the development of reliable methods for the detection of such adulteration. Among these efforts, the analysis of marker compounds and analysis of stable ratios of vanillin using isotopic ratio mass spectrometry or site specific natural isotopic

fractionation by nuclear magnetic resonance or techniques play an important role [20.65].

Table 20.5 gives an overview over IRMS δ^{2}H-, δ^{18}O-, and δ^{13}C-values of vanillin from different origins. Hoffman and Salb have published δ^{13}C-values of vanillin from most of the major growing areas and of vanillin from all three other sources (Table 20.6) [20.69]. Most vanillin qualities from other sources yield δ^{13}C-values more negative than −27.0 ‰$_{V\text{-}PDB}$. As a result of their experience, Hoffman and Salb set a limit of −21.0 ‰$_{V\text{-}PDB}$ as a standard of identity for natural vanillin. Any vanillin that gives a δ^{13}C-value more negative than −21.0 ‰$_{V\text{-}PDB}$ must be considered to contain vanillin from a source other than vanilla beans. Figure 20.5 shows the multielement analysis of numerous samples of vanillin from different sources and gives a good impression of how potent the IRMS analysis for the authentication of vanillin is representing different range of values depending on the origin of vanillin.

Another powerful tool for the authentication of vanillin is the quantitative ^{2}H-NMR spectroscopy. A results of a collaborative study performed with pure vanillin showed that the method allows a satisfactory discrimination between different vanillin

Table 20.7 Relative ^{2}H-abundances in vanillin (after [20.61])

sources [20.71]. The relative ^{2}H-abundances in vanillin at different positions are presented in Table 20.7, while Fig. 20.6 shows quantitative deuterium NMR spectra from different vanillin sources. Vanillin from ex guaiacol sources are easy to distinguish from natural and other source vanillin due to the high relative ^{2}H-abundance of the aldehyde as the overview of several quantitative deuterium NMR experiments in Fig. 20.7 illustrate. But also the clustering of different vanillin sources in the 3-D plot in Fig. 20.8 indicates a potential differentiation of the remaining origins.

Table 20.8 Range of δ^2H- and δ^{13}C-IRMS values of butanoic acid (after [20.72])

Butanoic acid	Origin	δ^2H ‰$_{V\text{-}SMOW}$	δ^{13}C ‰$_{V\text{-}PDB}$
	Other source butanoic acid	+63	−22.9
	Natural butanoic acid	−232	−14.5

20.3.3 Butanoic Acid

Butanoic acid is found in numerous milk products and especially the triglyceride of butanoic acid is used in many food and feed applications. The hydrolysis of the triglyceride and the release of butanoic acid itself are responsible for the unpleasant odor of rancid butter for example. Butanoic acid as educt for the production of various butyrate esters is manufactured for industries by fermentation of sugar or starch as natural sources or by synthesis.

Table 20.8 shows the δ^2H- and δ^{13}C-values of butanoic acid as it was found in the research of the Isotopic Studies Committee [20.72]. Emad Ehtesham just recently showed that the δ^2H- and δ^{13}C-values of four fatty acids (C4:0, C14:0, C16:0, C18:1) and bulk milk powder were found to be correlated with the regional production area of milk powder in New Zealand. In

this study, the δ^{13}C-value of butanoic acid was found to cover a wide range of −31.0 to −42.5 ‰$_{V\text{-}PDB}$, while the δ^2H-values showed a range between −130 and −170 ‰$_{V\text{-}SMOW}$ [20.75].

20.3.4 Isoprenoids and Essential Oils

Isoprenoids are widely spread in nature and comprise commercially important compound classes like mono, sesqui-, di- and triterpenes, iridoides, carotinoides, and steroides. There are numerous reviews citing important criteria for the quality control of isoprenoid compounds in essential oils [20.12, 76, 77].

Respectively, isoprenoids are produced in different compartments of cells and bacteria via the precursors mevalonic acid and deoxyxylulosephosphate [20.27]. For these reasons, the expected global δ^{13}C- and δ^2H-values show significant differences depending on the corresponding biosynthetic pathway [20.30, 78, 79]. In this chapter, the analysis of origanum oil and the main ingredient carvacrol is discussed based on Multicomponent-/Multielement-IRMS data. The enantiomeric distribution of the chiral minor compounds of the essential oil like pinene, limonene, and terpinen-4-ol can be achieved via chiral gas chromatography [20.73, 80]. The enantiomeric distribution of the minor compounds provides a first insight. A potential adulteration of the essential oil, based on the addition of the main value adding ingredient carvacrol is highly relevant.

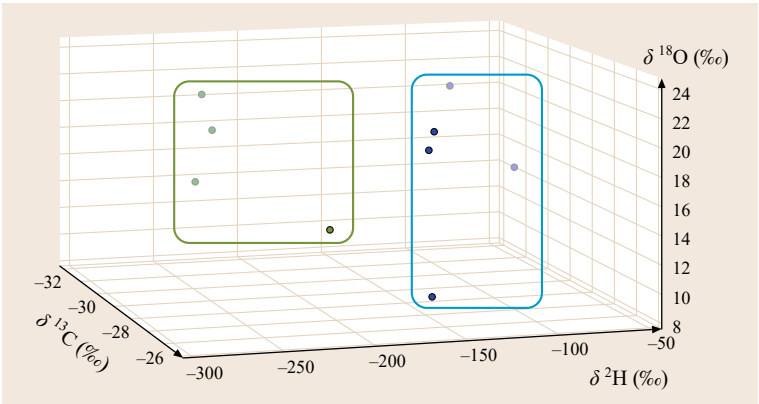

Fig. 20.10 Multi-element IRMS analysis of different sources of δ-decalactone (*green*: natural source, *blue*: other source; unpublished data Symrise AG)

Table 20.9 presents the ranges of δ^2H-, δ^{18}O-, and δ^{13}C-values of the aromatic monoterpene alcohol carvacrol in origanum oils [20.73]. This example illustrates that 3-D multielement IRMS analysis does not provide a complete resolution of all commercially relevant sources in this specific case.

20.3.5 Fruit Flavors (γ- and δ-Decalactones)

A prominent example for the authenticity control of natural flavorings in food products is the application of IRMS analysis of γ- and δ-decalactones. Chiral γ- and δ-decalactones are flavoring substances with high sensory importance for various fruit flavors with strawberry, raspberry, peach, apricot, mango, passion fruit, plum, and coconut profile [20.81]. The authenticity of the natural sources of γ- and δ-decalactones can be accessed by their enantiomeric composition [20.82]. Several synthesis and biosynthesis routes have been established to create these flavoring substances [20.83–87].

In the study of *Tamura* et al., γ- and δ-decalactones were analyzed in fruits of *Prunus* species, for example, peach, apricot, and nectarine from different geographical origin [20.74]. The results of the study and the data shown in Fig. 20.9 illustrate that a differentiation between the different species cannot be achieved using δ^2H and δ^{13}C IRMS data. On the other side, samples from natural and other sources show significant differences (Table 20.10). *Tamura* et al. also reported IRMS data for γ- and δ-decalactones from biosynthetic origin [20.74]. The presented data for γ-decalactones (Fig. 20.9) show within the given scope of natural variation a differentiation of other source material (purple box) from the samples produced via biosynthetic route. The distinction between natural and biosynthetic origin (green box), however, seems not to be possible in this case. δ-Decalactones from other source origin (blue box) and natural sources (green box) can be distinguished as shown in Fig. 20.10.

20.4 Requirements and Guidelines for Authentication

Stable isotope ratio analysis is the method with high relevance for the quality control in flavor industry. In official food control laboratories, SIRA is mostly used in specific cases, if suspicious facts are evident or suspicious findings have to be confirmed. The application of SIRA for authentication of flavorings in official food control finds its limitations in the fact that primarily flavored products have to be analyzed in food, which always requires rather elaborate sample clean-up techniques for the final characterization of flavor substances via SIRA. In both responsibilities, the check for purity of a single flavor substance or the qualitative and quantitative composition of a complex flavoring is determined using GC, GC-MS, and high pressure liquid chromatography (HPLC) at the beginning of a flavor analysis. For the investigation of the natural status of a flavoring substance, additional methods like enantioselective analysis of chiral flavor compounds are used. However, in order to get a definite proof of authenticity, SIRA is the only method of choice.

The use of stable isotope data for assessment of authenticity of flavor substances and flavorings has to meet the same requirements as for the conventional

analytical data of ingredients of natural materials. Validated analytical techniques, reliable and representative reference samples and validated data are the basis for the assessment as well as mathematical, statistical, and multivariate methodologies for calculation and evaluation of the relevant analytical parameters with regard to a final significant result and assessment of authenticity. Examples for corresponding statistical and multivariate procedures are discussed by example of authentication of wines using stable isotope data or elements [20.88–90].

20.4.1 Analytical Requirements

The sophisticated methods of SIRA require high efforts in isolation and analytical instrumentation thus the following essentials are important for acquisition of reliable and comparable stable isotope data:

- Stable isotope fractionation and discrimination has to be avoided during isolation, concentration, and measurement of a flavor substance.
- Validated procedures of SIRA for the target flavor compound with defined analytical data of uncertainty and reproducibility must be available.
- Participation in ring tests or proficiency tests including the isolation from the representative matrix is indispensable.

20.4.2 Requirements of Representative Reference Data

Isotope patterns of a natural flavoring source and its flavor substances are characterized by the natural variations due to the biotic and abiotic fractionation, and biosynthetic effects. Further effects are different processing and isolation techniques of flavorings or single flavorings from the source materials, especially if physical, enzymatic, or fermentative processes are involved. Since the evaluation of analytical data from natural sources is almost based on reference data, the following aspects have to be taken into consideration:

- Stable isotope data of the flavor compound originating from authentic reference samples must be available.
- The meta data of the sample to be analyzed and reference sample(s) like source, botanical cultivar or variety, geographic origin, year, or even perhaps the time of harvest need to be available as accurate as possible.
- The significance of the assessment depends on the question whether sufficient representative and validated data are available, preferably in a validated data bank.

20.4.3 Guidelines for Interpretation and Evaluation of Isotope Data

The authentication of a flavor substance or a flavoring by SIRA has to provide convincing evidence in a court case and therefore should be based on the following guidelines for interpretation and evaluation:

In case of a single stable isotope ratio of a single flavoring substance, it has to be evaluated for its genuineness and first of all be checked, whether the isotope value or ratio is within the known and expected range of reference samples or data published in literature. If the value outranges the expected natural range, the value can be assessed as a so-called *cut-off value* for which no extensive reference material is necessary. As an example, a δ^{13}C-value of $-35\,‰_{\text{V-PDB}}$ for vanillin can be assessed as a cut-off value for genuine vanillin from vanilla bean, since the minimum δ^{13}C-value is $-23\,‰_{\text{V-PDB}}$ (taking into account uncertainty of measurement and preparation). If the value is near the authentic range the variation of the natural distribution should be investigated. The confidence interval of the reference value depends on the number and standard deviation of the data available. In addition, uncertainty of the measurement has to be taken into consideration as well.

Using the multielement approach, typical correlations can be used for authentication of a single flavor substance. The combination of gas chromatography-combustion-isotope ratio mass spectrometry (GC-C-IRMS) and gas chromatography-pyrolysis-isotope ratio mass spectrometry (GC-P-IRMS) is applied to the authenticity assessment of flavor compounds from various sources. The combination of on-line capillary GC-C-IRMS and GC-P-IRMS to determine δ^{13}C- and δ^{18}O-values of estragole and methyl eugenol showed that the δ^{18}O-values enabled differentiation even if δ^{13}C-values of products from natural and synthetic origin are rather similar [20.91]. By correlation of the δ^{2}H- and δ^{13}C-values of cinnamaldehyde, characteristic authenticity ranges were defined for Ceylon, cassia, and wood cinnamon [20.92]. An important substance in raspberry flavor is α-ionone which is available as natural, natural-identical, and biotechnologically produced compound. The δ^{13}C-value of natural α-ionone is -29.0 to $-35.1\,‰_{\text{V-PDB}}$, of the natural-identical -24.3 to $-27.1\,‰_{\text{V-PDB}}$ and of the biotechnologically produced -10.2 to $-31.7\,‰_{\text{V-PDB}}$. The δ^{2}H-values of natural (-190 to $-214\,‰_{\text{V-SMOW}}$) and biotechnological (-205 to $-296\,‰_{\text{V-SMOW}}$) α-ionone are more negative than the

δ^2H-values of the natural-identical α-ionone [20.93]. A combination of δ^2H- and δ^{13}C-values allows a secure proof of the origin of α-ionone.

Using δ^{13}C-, δ^{18}O-, and δ^2H-data of the multielement analysis as well as enantioselective multidimensional GC-MS of linalool and linalyl acetate, a differentiation of the synthetic and natural compound is possible as well as an authenticity assessment of lavender oil [20.94].

The isotope ratio analysis provides multielement as well as multicomponent data, which provides information about the authenticity of a flavoring with much more higher significance, even with a limited number of reference samples available.

20.5 Conclusion

The authenticity control of natural flavoring substances, natural flavoring preparations and in particular essential oils must be focused on two main areas. The authentication of the source material and the verification of the application of legally permitted production methods.

In both areas, the pattern of stable isotopes like ^{13}C-, ^{2}H-, and ^{18}O-values of the source materials allow in many cases the assignment to source specific multielement data clusters, which provide a more detailed differentiation than the assignment to the pool of C_3-, C_4-, and CAM-plants only. In this context, the availability of authentic reference compounds is of utmost importance and will require additional studies in the next years in order to capture the full spectrum of potential source materials.

The second focus area of process-specific indicators requires also high efforts, since natural flavor compounds may be produced either by extraction and isolation of natural sources, by microbiological and enzymatic (biosynthetic) procedures, or by appropriate physical and traditional food preparation processes. Thus it is necessary to fully understand all process-derived isotope shifts and subsequent modifications of the stable isotopes patterns. In order to achieve these aims, a close scientific cooperation between academia, industry, and government authorities will be required.

21. Machine Olfaction

Brian Guthrie

It has been a longstanding goal of many research groups to replicate human olfactory sense with instruments. Sensor technology aims not only to replace the traditional analytic methods that are mostly focused on individual chemical identification and quantitation, but also to predict the human perceptions of smell, odor recognition and odor hedonics, thus replacing human sensory evaluation. Sensors have progressed from early gas sensors, to e-noses and e-tongues to biosensors and bio-e-noses that utilize elements from natural signal transduction to gain better sensitivity and selectivity. There has recently been a rapid increase in research and development of advanced sensor technologies and enabling technologies such as nanotechnology, cellular biology, wireless communication, and neural computing methods that have helped overcome the sensitivity, selectivity, portability and recognition problems of early sensor systems. Much of this development comes in response to global bioterrorism and other security threats. The activities in the various areas enabled by machine olfaction are poised to impact many industries not only as potential enablers of competitive advantage, but also through international standards development and enforcement. However, while machine olfaction instruments and sensors systems have been under development for more than 30 years, they still cannot completely replace the human senses for sensitivity, selectivity, and speed. While complete replacement of human sensory perception is not yet possible, certain sensor arrays provide fast, cheap, portable, networkable, low-expertise alternatives in some applications where simple detection is required. Nevertheless, current machine olfaction devices can provide a low-sample preparation approach that significantly reduces the amount of human sensory and advanced chemical testing needed.

Machine olfaction is the instrumental replication of the human olfactory sense. Many research groups have worked in this area since the applications for machine olfaction are extremely broad. The instruments, sensors and approaches for machine olfaction, or artificial olfaction, have been reviewed by *Sankaran* et al. [21.1] and *Bartlett* et al. [21.2]. Many of these will be discussed below with a particular focus on agriculture and the food industry.

There are many types of sensors, each with individual strengths and weaknesses. In general, compared to the traditional analytical methods or human sensory

testing, they can be faster, lower cost (instrument, sample preparation), require lower expertise, and can be portable and networkable. The emergence of biosensor technology has significantly increased the selectivity and sensitivity of electronic sensors. The technologies that enable these devices are still improving.

There is evidence that the leaders in the food industry and other industries have begun to incorporate instruments for machine olfaction into normal operations and research and development efforts. For example, industrial researchers reported e-nose applications in spices and flavorings [21.3], clinical diagnosis [21.4], food quality control (QC) [21.5], body odor sensors for personal care applications [21.6], bad breath sensors [21.7], as well as gas sensors and ambient mass spectrometer-based sensor systems, across several applications, such as milk analysis, vitamin analysis, process monitoring, rapid analytics, packaging analysis, and sensory testing replacement [21.8]. They report the use of proton transfer reaction and laser mass spectrometer (MS) e-nose systems for the detection of oxidation in infant formula [21.9], for process monitoring in coffee roasting [21.10, 11], milk quality assessment [21.12], detection of contaminants [21.13, 14], volatile release [21.15], off flavor and packaging taint analysis and quality assessment of cocoa liquor to name a few [21.16–19]. The needs in many broad application areas will surely continue to drive the development of sensor technology and data analytics that enable machine olfaction.

21.1 Chemical Senses

The chemical sense of taste (gustation) and smell (olfaction) and their interaction (flavor) are highly evolved and extremely sensitive. Humans use these senses to find acceptable food, to recognize mating partnerships, to detect disease and many other things that are vital to survival. These senses are especially important in industries related to food and food quality. *Sankan* et al. [21.1] and *Dymerski* et al. [21.20] reviewed the cell biology of olfaction and gustation.

21.1.1 Olfaction

Several reviews of biological olfactory processes can be found in the literature [21.21–24].

If one were to break the cell biology of olfaction down and express the various subprocesses in terms of instrumental counterparts, the following elements would be represented:

- Two sampling points (*ortho*- and *retro*-nasal olfaction, with *retro*-nasal olfaction providing dynamic, repeated sampling during eating)
- A preconcentration/absorbent system (olfactory binding proteins)
- Rapid clearing, broadly tuned sensor array (mucus, olfactory receptor proteins, olfactory neurons)
- A self-calibrating signal processor and pattern recognition system [21.25].

These elements are often targets for instrumental reproduction as elements in the electronic sensor systems.

21.1.2 Gustation

Recently, large advances have been made in the understanding of gustatory processes from the identification of receptors at the periphery to the integration of gustatory signals with other signals in the cortex and other regions of the brain. These have been extensively reviewed [21.26–30].

The processes of gustation are similar in the most part to olfaction. Gustatory information is however more closely associated with information from oral processing and trigeminal information. Also, gustatory sensation is compiled with much more information, such as nutritional status, than olfactory information before it reaches the cognitive processing centers of the brain. These elements, that are unique to gustation, are difficult to imitate with artificial taste sensors.

21.1.3 Sensory Perceptual and Cognitive Processing

After many years of research, the mechanisms involved in olfactory perception and cognition are still not well known. The rules that govern the perception of chemical mixtures are even less understood. Brain activation studies are only recently starting to reveal some of the information processing and connections that occur in the brain [21.31, 32]. While rapid advances in the understanding of these processes are expected, it is currently not completely possible to build biomimetic data processing models directly for artificial olfaction and gustation.

21.1.4 Instrumental Surrogates for Human Chemical Senses

Information Goals

Analytics and sensor systems strive to reproduce portions of, or complete, human olfactory systems. It is

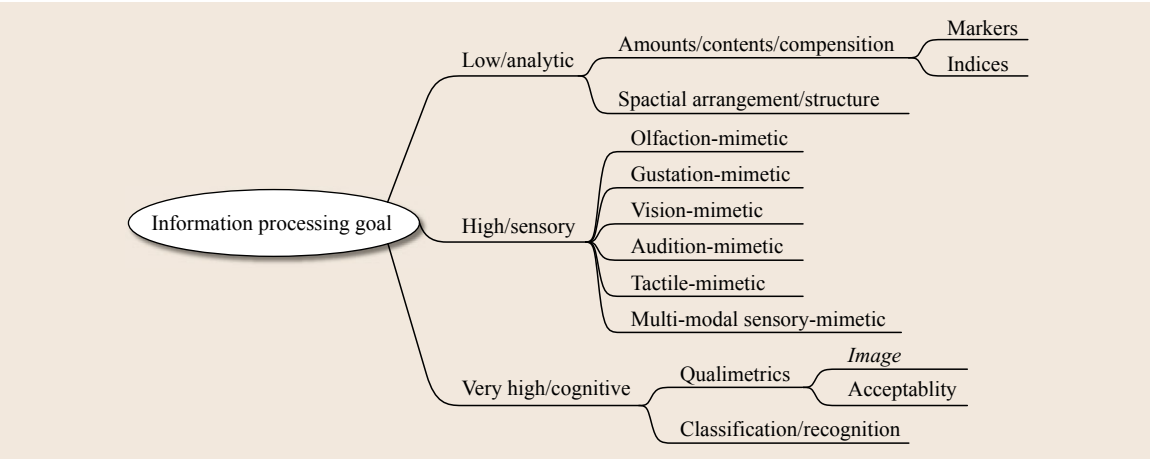

Fig. 21.1 Proposed information processing scheme of analytical and sensor systems

helpful to understand the information generated by each. The information processing goals of these methods are outlined below in Fig. 21.1.

Many analytical methods that are used for quality control and trade specifications are focused on the determination of the amounts of certain chemicals, marker chemicals, compositions, or some indices of quality that are well known. These assays can also be focused on the determination of the chemical structure of target compounds or other spatial information. These methods are considered to have somewhat low information goals relative to human perception of quality and class. They have been validated where single compounds or sets of compounds have shown a good correlation with human sensory perception. For example, hexanal is often used as an analytical marker for the human perception of rancidity, or low quality (nontypical sensory impressions). However, satisfactory simple analytical level predictors of human perception are rare.

A generation of sensor systems have attempted to serve as instrumental replacements for individual senses, called here *sense-mimetic*. These were the early e-nose and e-tongue instruments focused at reproducing the selectivity and sensitivity of human olfaction and gustation respectively. However, this high sensory information goal was rarely met. This is not surprising given that the transduction of information in the human systems is only poorly understood today and human senses do not act in isolation.

Researchers next attempted to develop systems with the very high information goals of replacing human perception and cognition, representing an even more challenging task. Pattern recognition procedures were first attached to the early within-mode sensors and sensor arrays. The next step to achieve a high level of information processing followed discoveries in human psychophysics with a greater array of sensors being mixed with even more types of signal processing, pattern recognition and information theoretics being applied. These systems often included e-nose sensor arrays plus e-tongue sensor arrays and other sensor types to mirror the data and thought processes used by humans to make determinations such as *quality*, *class*, and *acceptability*.

One could argue whether it is rational to attempt such a high information goal with instruments since the principles of human sensory perception and recognition of mixed chemical stimuli are not well understood [21.33–36] thus tuning of these systems cannot proceed from first principles but must be generated from data-driven empirical observations with the usual data analytic problems of overfitting, low generalization of results to other systems or species, etc. Only recently have *odor spaces*, or a comprehensive understanding of the multidimensional *tuning* of odor quality, intensity and duration, been explored for lower organisms such as flies [21.37]. In this work, researchers used Drosophila antenna responses to 100 odorants to establish an *odor space* for this organism. Such an understanding of the human odor space, along with the added understanding of human cognitive processing of chemical stimulants, would be required to develop machine olfaction systems with high-level information processing capabilities such as the prediction of food quality.

The ideal system for the replacement of the human chemical senses would include the following items listed below. Some artificial systems are more successful than others. The ideal sensor system would:

- Handle sampling and sample preparation and/or concentration

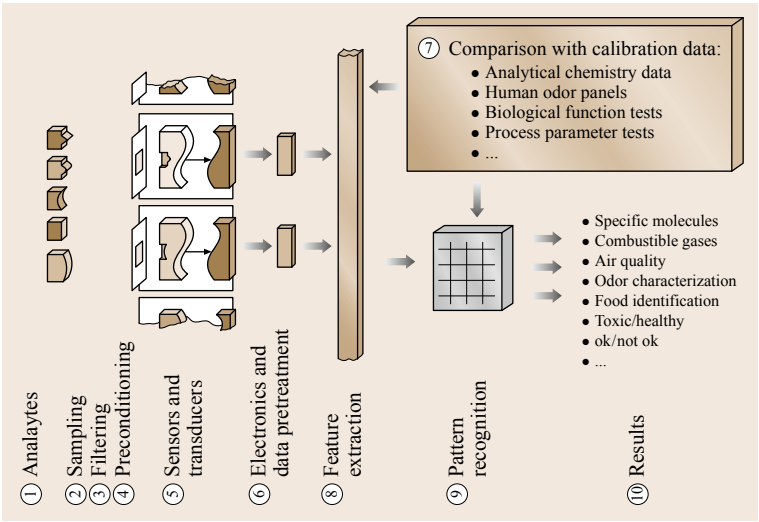

Fig. 21.2 Typical sensor system setup (after [21.38])

- Have fast responses or data acquisition and data processing response times
- Have rapid pattern recognition and classification capabilities
- Have sensors that are rapidly reset with little drift and not be troubled by high levels of interfering compounds
- Would be portable with low energy consumption and networkable
- Would be of low cost, but achieve long life.

Systems with characteristics relating to each of these features are discussed further below.

21.1.5 Machine Olfaction

Many research groups have worked to replicate human olfaction. The sensors and approaches for machine olfaction, or artificial olfaction, have been reviewed by *Sankaran* et al. [21.1] and *Bartlett* et al. [21.2]. Typical sensor arrangements, whether for e-nose or e-tongue, are shown below in Fig. 21.2 [21.38].

Most systems begin with elements for sample introduction, often with preconcentration or filtering. Analytes then interact with sensors or arrays of sensors. There are a large number of possible sensors and combinations. These will be discussed further below. The sensors transduce the interactions of the chemicals into electric signals that are usually pretreated before further signal processing. Data systems, after extensive calibration, will extract the important features of the signals and then, with the use of pattern recognition algorithms, attempt to interpret the sensor response. The interpretation that is desired is captured by training a pattern recognition system using either supervised classification (*good* versus *bad*, location 1 versus location 2, age 1 versus age 2, etc.), unsupervised classification (sample groupings) or detection (below a certain level) approaches.

It should be noted that the calibrations require large numbers of samples and must include all known interferences or contaminants. Initial calibrations can take a lot of effort to establish, and they take a long period of maintenance and adjustment until all noise can be tuned out of the calibrations.

However, researchers have found that machine olfaction can only work, considering the current sensor technology, for a limited set of conditions. *Rock* et al. [21.38] developed a scheme shown below to capture this (Fig. 21.3).

According to this scheme, the ideal case for reliable measurement is when the volatiles responsible for the odor of interest are in high concentration while the odorless or interfering volatiles are not (case 1). If the odorless or interfering volatiles are correlated with the odorous volatiles, then a limited odor measurement is possible (case 2). Otherwise, odorless volatiles can mask the target volatiles (case 3) and no odor measurement is possible. If odorless volatiles can be masked (case 4), then odor measurements are possible. For trace levels of odor volatiles, a limited odor measurement capability is possible if they are correlated with odorless volatiles (case 5), if not (case 6), odor measurement is not possible. Much of the work, when establishing a sensor-based method, is to determine the situation for the case under development. However, it is well known that key food volatiles are usually present in only trace amounts. Therefore, the research is usually focused on the extent of correlation to odorless volatiles (e.g., case 6 or case 5) and the extent of the odor

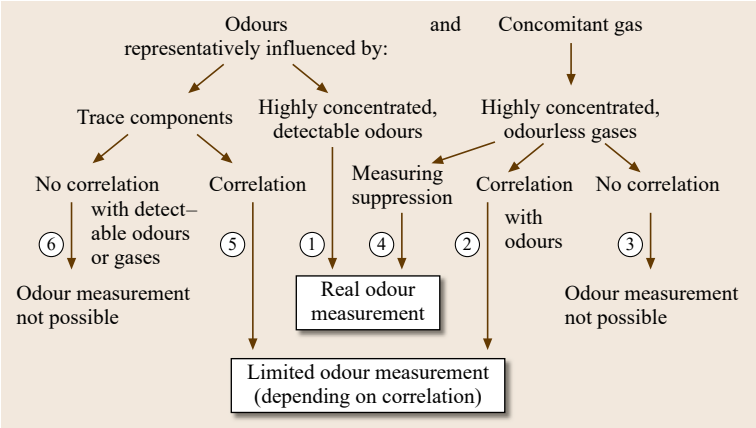

Fig. 21.3 Scheme showing possible conditions for reliable odor measurements (after [21.38])

measurement possible given the trace levels of target analytes.

Quantitative odor–structure relationships have been found [21.39]. Human odor spaces and primary odor dimensions have been hypothesized. However, these have not led to the development of better machine olfaction systems. Odor perception has been found to be more of a function of perceptual processing rather than receptor events at the periphery of the nervous system.

21.1.6 Chemical Senses Perception–Cognition Coding

The neurobiology involved with the transduction and coding of the chemical senses is critical in the development of instrumental sensor systems that reproduce the highest information capabilities of the human chemical senses. *Hoare* et al. [21.40] hypothesized that flies use fuzzy coding in olfaction. Fuzzy methods are being used today as a part of the data analytics used with several sensor systems discussed below. *Haddad* [21.41] reviewed the information processing involved in the neurobiology of human olfaction where the physical space of odorant molecules is transformed through a neural space of information processing, and then into a perceptual space of smell. They reported that odor measurement metrics significantly hinder an expanded understanding of human olfactory coding.

While the exact information processes are not known, many data analytic methods attempt to imitate the neural processing found in the human chemical senses to replicate perceptual and cognitive processes in humans.

21.2 Sensor Types

21.2.1 Overview

The different sensors used in machine olfaction and gustation and rapid food analysis are described below. The different types can include simple gas sensors that have either single or multiple reactivity (*cross-reactivity*) to detect single or multiple gases and vapors. These consist of high temperature sensors with reactive surfaces and low temperature polymeric sensors that can have adsorptive coatings for increased selectivity. Optical gas and vapor sensors consist of probes coated with arrays of different dyes that produce colored response patterns that are linked with wave guides or optical fibers to detectors where patterns can be recorded and converted to a response. Gas and vapor sensors can also utilize ionization with mass separation and detection as a type of sensor array.

Liquid sensors exist that include various types of electrodes and spectrophotometric devices. More recently, a large number of biosensors have been developed for liquid samples that consist of combining binding elements found in nature (DNA, RNA, enzyme, immunoglobulins, antibodies, proteins, etc.), giving high selectivity, with a micro- or nanoscale optical or electronic transduction system that provides high sensitivity.

It is important to note that, like the chemical senses, the goal of sensor systems is to generate a pattern or fingerprint that can be recognized, rather than traditional analytic chemistry that is to quantitate individual chemical species. To that end, sensor systems have evolved using arrays of single or multiple types of sensors as a way to capture the most diverse pattern possible to increase the chances of successful recognition in data

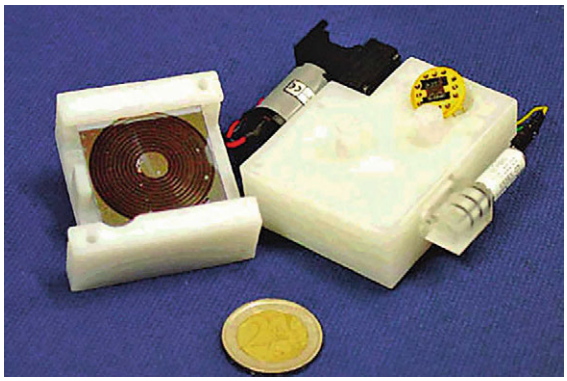

Fig. 21.4 Example of a portable hybrid microsystem GC sensor system: zero grade air unit, GC column, MOX sensor (after [21.42], Copyright 2005 Elsevier)

analysis. Thus, many sensor systems today contain mixtures of different types of sensors arranged as arrays.

Early and significant problem areas for sensor systems involved sample concentration and miniaturization and portability. In response to these problems, more recent sensor system designs commonly combine sensors and arrays with sample introduction systems for collection and concentration, such as microfluidic devices, with sensors and sensor arrays in a microsystem format. One manufacturer has designed a complete gas chromatography system with a metal oxide (MOX) detection system that fits in one hand and can run on batteries [21.42] (Fig. 21.4).

Each of these sensor types will be discussed in further detail below.

In addition to sensor-based systems, methods for nondestructive food testing have been developed and are frequently reported in the literature. These tend to utilize spectral detection in combination with pattern recognition. High selectivity was reported using methods such as nuclear magnetic resonance (NMR) imaging, near-infrared spectroscopy (NIR), mid-infrared spectroscopy (Mid-IR) and fluorescence. One example of such an approach was reported by *Lin* et al. [21.43] who used NIR and support vector machines (SVM) to determine the freshness of eggs. These methods are outside the scope of this review and will only briefly be discussed further below.

21.2.2 Chemical Sensors

The early chemical sensors were designed for detection of single gas vapors or for single components of liquid systems and not initially for pattern recognition. Many of these are found in the literature. *Nanto* [21.44] reviewed the various types of chemical sensors. These were the original types of sensors used in first generation e-nose instruments [21.45]. A summary of the types and chemical sensors is shown below in Table 21.1.

Cross-reactive gas sensors were developed to generate complex patterns for better selectivity of materials with complex odors from mixtures of volatile chemicals. *Albert* et al. [21.46] reviewed cross-reactive gas sensors. These sensors are designed to react differently when exposed to different odorants. A common design for sensing volatiles involves the use of arrays of thin-film cross-reactive chemoresistive vapor sensors. One type is called a carbon-black polymer composite (CBPC) sensor. The group of Nathan Lewis from Caltech has been very active in the development of these types of sensors. These commonly utilize different types of polymers in the sensor array, such as poly-(ethylene-vinyl acetate) (PEVA), each with carbon black additives for conductivity. The conductivity of each polymer changes differently as it absorbs vapors and swells. Arrays with different polymer components allow the generation of a spatiotemporal conductivity pattern [21.47]. These have been designed for specific sensing applications such as fatty acid sensing [21.48] and many other applications. Arrays have been compared to human olfaction [21.49]. The CyranNose e-nose system was developed using arrays based on these sensors with chemometric pattern recognition analysis [21.50].

21.2.3 E-Nose

Electronic nose (e-nose) technology has been under development for close to 30 years. Several families of sensors have been developed and then arrays of different sensors have been assembled to better approximate the sensitivity and selectivity of human olfaction. Recently, e-nose technology has been reviewed for safety and quality determinations in food, and pharmaceuticals [21.20, 51–58], applications in agriculture and forestry [21.59, 60], developments in sensor and instrument technology [21.61–68], and advances in data processing and analysis [21.69].

Many different e-nose platform technologies have evolved over the last 30 years of development. Most evolutions and platforms were attempts to make improvements from the previous technology. Inexpensive electrical sensors, such as gas metal oxide semiconductor (MOS) and metal oxide semiconductor field effect transistors (MOSFET), and gravimetrical sensors, such as surface acoustic wave, bulk acoustic wave and microcantilever systems, were used in the first e-nose instruments. The electrical sensors required high temperatures and had significant drift. Their performance was also significantly impacted by vapor interferences

Table 21.1 Overview of Chemosensors (after [21.44]). Classification of chemosensors that have been exploited so far. Metal oxide semiconductor (MOS), MOS field effect transistor (MOSFET); quartz crystal microbalance (QCM), surface acoustic wave (SAW), surface plasmon resonance (SPR)

Principle	Measurand	Sensor type		Fabrication methods	Availability/ sensitivity	Advantages	Disadvantages
Conducto-metric	Conductance	Chemo-resistor	MOS	Microfabricated, Sputtering	Commercial, many types, 5−500 ppm	Inexpensive, microfabricated	Operates at high temperature
			Conducting polymer	Microfabricated, electroplating, plasma CVD, screen printing, spin coating	Commercial, many types, 0.1−100 ppm	Operates at room temperature, microfabricated	Very sensitive to humidity
Capacitive	Capacitance	Chemo-capacitor	Polymer	Microfabricated, Spin coating	Research	Applicable to CMOS-based chemosensor	Very sensitive to humidity
Potentio-metric	Volt-age/e.m.f.	Chemdiode	Schottky Diode	Microfabricated	Research	Integrated, Applicable to CMOS-based chemosensor	Needs Pd, Pt, Au, Ir (expensive)
	I-V/C-V	Chemotran-sistor	MOSFET	Microfabricated	Commercial, special order only, ppm	Integrated, Applicable to CMOS-based chemosensor	Odorant reac-tionproduct must penetrate gate
Calorimetric	Temperature	Thermal chemosensor	Thertmister (pyroolec-tric)	Microfabricated, Ceramic fab.	Research	Low cost	Slow response
			Pellistor	Microfabricated	Research	Low cost	Slow response
			Thermocou-ple	Microfabricated	Research	Low cost	Slow response
Gravimetric	Piezoelec-tricity	Mass-sensitive chemosensor	QCM	Microfabricated, Screen printing, Dip coating, Spin coating	Commercial, several types, 1.0 ng mass change	Well understood technology	MEMs fabrication interface electron-ics?
			SAW	Microfabricated, Screen printing, Dip coating, Spin coating	Commercial, several types, 1.0 ng mass change	Differential devices can be quite sensitive	Interface electron-ics?
Optical	Refractive index	Resonant-type chemosensor	SPR	Microfabricated, Screen printing, Dip coating, Spin coating	Research	High electrical noise immunity	Expensive
	Interisity/ spectrum	Fiber-optic chemosensor	Fluores-cence, chemolu-minescence	Dip coating	Research	High electrical noise immunity	Restricted avail-ability of light sources
Amperometry	current	Toxic Gas Sensor	Electrocata-lyst	Composite Electrode	Commercial ppb-ppm	Low cost noRh interference	Size

such a water vapor, ethanol, and others. Lower temperature polymer sensors were developed to improve the drift and interference stability of e-nose instruments. Both these and the gas sensors lacked adequate selectivity for high information goals. Many different modifications such as coatings, molecular imprinting of polymers, and advanced pattern recognition methods were employed to overcome these problems. These resulted in improvements; however, they were still not able to provide acceptable results for many high information applications. As a result of this and due to the need for better sensitivity and selectivity and reproducibility, new technology platforms were developed.

As the next step in their evolution, e-nose systems based on mass spectrometry were developed to gain more selectivity. The mass-spectrometer-based e-noses

utilize various types of soft chemical ionization with mass separation. This creates virtual sensors at each measured mass-to-charge ratio. Optical e-nose systems based on dyes and color or fluorescence have also been developed in an effort to generate more diverse response patterns thus enabling more sensitivity and selectivity.

E-nose developers then looked to human physiology and incorporated biomimetic elements into their sensor design. For example, several researchers have attempted to increase the performance of e-nose systems by imitating the dynamic spatiotemporal separation of high vapor pressure and low vapor pressure volatiles that occurs in the turbinate regions of human sinuses during normal human *ortho*-nasal olfaction. *Woodka* et al. [21.70] reported such a biomimetic approach using a spatiotemporal sensor system containing a carbon black conducting polymer (CBCP) sensor array arranged spatially with the sample flow. *Gardner* et al. [21.71] also attempted to imitate the dynamics of odorant reception on the human nasal mucosa during olfaction, which they called *nasal chromatography*, where the olfactory mucosa and its absorptive properties in time and space are imitated using a planner chromatography system and sensors to collect responses from layers of volatiles as they pass broadly tuned sensors. Others have attempted to use a nasal flow pattern to increase the sensitivity of the sensor arrays [21.72].

In the latest biomimetic evolution of the e-nose, called bio e-noses, actual elements from nature, such as enzymes, proteins, antibodies and other elements are being developed to further enhance the capabilities of e-nose sensor systems. These will be discussed further below. The following sections review the different components used in various e-nose sensor systems.

E-nose sensor performance and applications are extremely broad. Many different types have been developed for different types of volatiles and different applications. The sensor types are discussed below. Many applications are also reviewed. A vast number of volatile chemicals have been targeted by these devices. This review focuses on the applications of the various systems and sensors rather than the volatile classes and detailed detection mechanisms that are described in the references.

Electrical Sensors

Electrical sensors can be classified into the following categories according to the circuitry used and measurement principle: conductance, potentiometry, capacitance, and amperometry.

Conductivity-Based Sensors. Metal oxide semiconductor (MOS) sensors are one of the common types of conductivity-based electric sensors. The food and e-nose applications of these have been reviewed by *Berna* [21.53]. These sensors have the advantage of being easy and inexpensive to make with many different types of metal oxides available. The film thickness can be varied to have a slow response time (thick film) or fast response time (thin film) depending on the application requirements. These sensors, however, lack sensitivity, require high operational temperatures and are extremely sensitive to inferences from water vapor and other volatiles.

There are two types of sensors based on the chemical reactions that occur at the surface. N-Type MOS sensors are sensitive to reducing gases such as H_2, CH_4, CO, H_2S, and C_2H_5. SnO_2 sensors were amongst the earliest and most common N-type MOS sensors used. Many modifications have been tried to increase the sensitivity of these sensors including surface modification [21.73], doping (Taguchi sensors, [21.74]) and the use of carbon nanotubes and nanowires [21.75–77]. ZnO sensors are often used to monitor ethanol and acetic acid in spoilage, industrial, and occupational monitoring. Improvements have also been developed for these such as the modification with porphyrins [21.78]. Other types of N-type MOS include those of the following oxides: TiO, TgO, gallium Ox, Fe(III)Ox, and WO_3. These sensors are in use and are effective in applications to monitor the gases mentioned. They have some use in modern e-nose systems, but they are usually combined with other types of sensors.

P-Type MOS sensors are sensitive to oxidizing gases such as O_2, NO_2, and Cl_2. Several common materials of construction are NiO, CoO, and CuO. P-Type MOS sensors have found use in the detection of specific volatiles of importance in food such as for monitoring trimethylamine to determine fish freshness [21.79].

These types of sensors are often combined with other types of sensors in arrays to overcome their inherent weaknesses such as drift, limited specificity, and interference from common volatiles. For example ZnO MOS sensors were combined with surface acoustic wave detector and polymer coatings for increased selectivity to classify wine [21.80, 81] and many other applications discussed further below.

Further development of these types of sensors continues today. Complementary MOS (CMOS) has become a common platform for chemical microsensor systems [21.82]. Advances in sensor substrate materials and methods, such as hydrogel technology and substrate patterning, look promising for improved performance [21.83].

Conducting polymer sensors are the next major type of conductivity-based electric sensors. Their use as sensors has been the subject of several reviews [21.84–87]. They operate at much lower temperatures than MOS

sensors. The conductivity of these sensors changes as they adsorb vapors. The two types are intrinsically conductive polymers (ICP) and composite conducting polymer sensors.

The ICPs are still very sensitive to water vapor and drift. They also have been known to oxidize with time and change their responses. The most common base polymer used for ICP sensors are lanthanide bis-phthalocyanines [21.88], which commonly contain modifiers to improve performance. The following materials have also been used in ICP sensors: metallophthalocyanines, phthalocyanines [21.89], and polymers of pyrrole, aniline, thiophene, acetylene, phenylvinylene, 3,4-ethylenedioxythiophene, N-vinylcarbazone, and ethinylenevinylene. Polymer materials are easily structured. Nanostructuring of thin film ICPs has been reported to improve their performance as sensors [21.90]. Sensors with large numbers of different polymers can be further generated using new approaches such as inkjet printing [21.91].

Composite conductive polymers (CP) are another class of material used in the construction of conductivity-based sensor design. The group of *Lewis* [21.49] has reported extensively on the development and application of carbon black polymer composite (CBCP) sensors and arrays. The base polymers can be varied to create arrays with different swelling properties. Polystyrene, acrylate, vinyl alcohol and others have been used in these sensors [21.92]. Composites with dopants such as zinc phthalocyanine have shown improved performance [21.93]. The polymeric nature of these sensors allows the fabrication of different physical forms. Conductive foams were also studied in an attempt to obtain a better conductive polymer sensor and to improve performance [21.94].

More recently, single walled carbon nanotubes (SWNT) have been used in the design of conductive polymer sensors. *Kong* et al. [21.95] report their use in the detection of NH_3 and NO_2.

Potentiometric Sensors. Potentiometric sensors measure the change in voltage. They were an attempt to achieve a lower operating temperature than MOS-based sensors. While they have lower operational temperatures than MOS sensors, they are still troubled by significant drift.

The most common type of potentiometric sensor is the metal oxide field effect transistor (MOSFET). These sensors use the same material as found in MOS sensors, but they are arranged on a chip in a manner to enable the measurement of voltage changes. New types of field effect transistors are beginning to be developed. Tunnel-field effect transistors [21.96] are reported to have greatly improved sensitivity.

Capacitance Sensors. Single walled carbon nanotubes (SWNT) have been used in capacitance circuits as chemical sensors that work well in the detection of polar analytes [21.97]. *Philip* et al. [21.98] developed composite thin films of polymethylmethacrylate (PMMA) with multiwalled carbon nanotubes (CNTs) and surface-modified multiwalled carbon nanotubes (f-CNTs) for solvent vapor-sensing applications. *Star* et al. [21.99] used chemical vapor deposition to apply metal nanoparticles to SWNT for toxic gas sensor applications.

CBCP have also been used in capacitance circuits as gas sensors. Amino-terminated dendrimer-carbon black composite sensors showed excellent sensitivity in the detection of butyl amine [21.48]. Organic acid vapor sensors have also been designed using poly-(ethylenimine)-carbon black composites [21.100, 101].

Amperometric Sensors. Amperometric gas sensors have been used for the detection of harmful gases such as CO, NOS, H_2S, and SO_2. Catalytic bead sensors, containing a catalytic pellistor, are another type of sensor arrangement for the detection of harmful and flammable gas vapors. RAE Sensor Company offers these as personal and lightweight flammable gas monitors for industrial applications.

Electrochemical/Voltammetry Sensors. Electrochemical sensors contain various types of electrodes, such as Ag-carbon electrodes, where a voltage can be applied and a response measured as the result of an oxidation or reduction reaction. The common electrodes are often coated to increase performance. Langmuir–Blodgett (LB) or the Langmuir–Schaefer (LS) films of conductive phthalocyanine have been used as voltammetric sensors for the determination of antioxidants [21.102], but have limited application as volatile sensors in machine olfaction.

Gravimetric Sensors

Gravimetric sensors monitor the absorption of chemical vapors by measuring the frequency changes of reference waves. These are also called piezoelectric or acoustic sensors. These types of sensors have been developed as gas sensors and are found in e-nose arrays. The technology used in acoustic wave-type sensors has been reviewed [21.103, 104]. Acoustic wave sensors operate to measure either waves in the bulk of the sensor material or surface oriented waves. These are described further below. These types of sensors rely on the absorption of target volatiles by single polymers or polymer arrays. As with other sensor types, this limits their selectivity since many volatiles can have similar absorption and solubility properties in polymers. The

adsorption and solubility is mainly based on polarity with volatiles of similar polarity adsorbing with similar patterns. These sensors are also limited in that volatiles can often take significant time to desorb from the polymers, making the response of the system slow and the duty cycle less than desirable.

Bulk Acoustic Wave (BAW) Sensors. Quartz crystal microbalances (QCM) are often used as BAW sensors. The QCM surfaces are often modified with an additional adsorbent such as chromatography packing material [21.105] or an adsorbent polymer coating [21.106] to enhance the sensitivity. Molecular imprinted polymers (MIP) have shown improved results when used with these sensors [21.107].

Surface Acoustic Wave (SAW) Sensors. SAW sensors have a resonating substrate, such as ZnO, $LiNbO_3$, $LiTaO_3$ quartz, or SiO_2, as their core. Various reference waves such as Rayleigh waves, surface transverse waves, Bleustein–Gulyaev waves, or Lamb and Love waves are established across these substrates. The changes in frequencies can be related to the amount of analyte that is absorbed. Several different coating strategies can be used to treat the surfaces of SAW sensors to make them more selective. Polymer coatings [21.108, 109], Langmuir–Blodgett films (LB) [21.110] and self-assembled monolayers (SAM) have been reported as methods to improve the performance of SAW sensors.

Microcantilever Devices. Microcantilever devices were evaluated by *Wachter* et al. [21.111] to determine the possibility of using them as sensors. The microcantilevers are first coated with an absorbent polymer film and the changes in resonance frequency are measured with exposure and absorption of analyte vapors [21.112, 113]. Different polymer films and coatings can be used to change the sensitivity and selectivity of these types of sensors [21.114].

Optical Sensors

Optical sensors have been developed in an effort to increase the complexity of the response pattern to increase the selectivity of the sensors. These systems include a radiation source. Many of these use addressable optical fiber bundles or wave guides. Typical optical detectors are used with these systems to record the response. These include photodiodes, charge coupled devices (CCD), or CMOS detectors. The detection modes include absorbance, fluorescence, polarization, optical layer thickness and color. Static or dynamics responses are recorded.

Colorimetric Optical Sensor. Colored patterns can be generated using a variety of dyes, such as pH sensitive dyes and solvatochromic pigments. Chemical vapor sensors have been developed that utilized these for vapor detection. For example, metalloporphyrin dyes with LED or photodetectors have been used to monitor VOCs, such as ethanol and acetic acid for meat spoilage detection [21.115, 116]. Photonic crystals arranged as Bragg stacks with Bragg diffraction peaks within visible wavelengths have also been used as colorimetric optical sensors to monitor amines in the headspace of bacterial cultures [21.117].

Sensor arrays have been fabricated using a large number of different dyes for VOC and odor detection [21.118–121]. Colorimetric dye arrays are also combined with other types of sensors to have cross reactivity [21.122, 123]. Nanoparticles have also been used to increase the sensitivity of these types of sensors [21.124].

Fluorescence-Based Optical Sensors. Fluorescence sensors are based on the polymer absorption of organic vapor and the fluorescence enhancement of immobilized fluorophores. Many use fiber optics, microbeads [21.125, 126], or other wave guides to form sensor arrays. The fluorophores are usually solvatochromic dyes. Exposure to organic vapors causes responses such as spectral shifts, intensity changes, spectral shape variations and temporal responses that are measured and recorded [21.122]. The ability to obtain different types of responses and patterns has led several to use such devices as a model for human olfaction [21.127, 128]. Arrays of these types of device can be portable and sensitive [21.129].

Mass Spectrometer-Based E-Nose-Type Systems

Mass spectrometers have found renewed interest as rapid, highly selective and sensitive sensors systems for e-nose types of applications. Their use and advantages, as compared to other gas or vapor sensors, have been reviewed [21.20, 130].

Virtually any existing mass spectrometer could be used like an e-nose with the proper pattern recognition analysis and sample introduction system. Headspace (HS) extraction is often coupled with MS without chromatographic separation to perform a rapid *mass chromatography* or *fingerprint MS*. For example, *Vera* et al. [21.131] and *Kojima* et al. [21.132] used HS-MS to classify beer samples. This has become a fairly widespread alternative to integrated e-nose instruments. However, these systems still require a high level of expertise to operate and they require the develop-

ment of pattern recognition models and calibration models.

Makers of e-nose equipment added mass detectors to their existing arrays of MOS sensors in order to achieve more selectivity. The early e-nose systems using mass spectrometers used the typical analytical instruments with vacuum and the typical types of ionization commonly available such as chemical and electron impact ionization with the usual types of mass separation including quadruple, time of flight, ion trap and others.
