The ability to perform ionization at atmospheric pressures (ambient MS) has led to the development of different systems that have greatly reduced sample introduction times while maintaining the selectivity and sensitivity of standard mass-spectrometry instruments [21.133, 134]. There are many different types of systems that are now capable of atmospheric ionization. They use a variety of ionization methods including chemical, laser, and photoionization. These systems are capable of sampling solids with the use of surface desorption where even large biomolecule measurement and surface mapping is possible [21.135, 136]. Several methods include: desorption atmospheric pressure photoionization (DAPPI), resonance-enhanced multiphoton ionization (REMPI), vacuum ultraviolet single-photon ionization (VUV-SPI), extractive electrospray ionization (EESI), electrospray-assisted laser desorption (ELDI), matrix-assisted laser desorption electrospray ionization (MALDI-ESI), laser-assisted electrospray ionization (LAESI), and atmospheric pressure laser ionization (APLI). Not all of these are available commercially as turnkey e-nose systems.

Atmospheric pressure chemical ionization (APCI) was one of the first ambient MS methods to be developed and then used for ambient mass-spectrometry e-nose types of applications. Selected ion flow tube (SIFT)-MS has been developed for e-nose applications [21.137]. This system allows different reagent gases to be used. Desorption electrospray ionization (DESI) can be used for rapid spot sampling of samples at atmospheric pressures. Proton-transfer reaction (PTR) ionization creates charged volatile water clusters as the ionization reagent. This ionizes analytes via proton transfer at ambient pressures. Direct analysis in real time (DART) [21.138] uses charged helium ions to ionize sample gases and vapors.

Ion Mobility spectrometry mass spectrometry (IMS-MS) has been found to be an excellent instrumental platform for rapid ambient mass-spectrometry-based detection such as e-nose types of applications. It has found broad use in security, military, antiterrorism applications, and food applications in quality and safety management tasks such as: the detection of metabolites from bacteria and mold for the identification and control of their growth; process control in food production and fermentation; quality control of raw materials or for the control of storage conditions; and the quality control of packaging materials [21.139]. High field asymmetric waveform IMS-MS (FAIMS) is one format that is especially useful and is a common platform for e-nose types of instruments [21.140–142]. The Owl-Stone Company [21.143] markets an ultraFAIMS for rapid sensing and e-nose applications.

Marsili [21.144] improved the performance of a mass-spectrometry e-nose system by using a solid phase microextraction (SPME) to concentrate aroma volatiles before introduction to the mass-spectrometry instrument.

Gas Chromatography–Based Systems

Many sensors and sensor arrays generate patterns using different polymers with dopants, coatings or absorbents; or, by separation of chemical fragments based on mass-to-charge ratios. The selectivity of these systems, while improved, was still a liability. Researchers then focused on using traditional analytical approaches, such as fast gas chromatography (GC), as a way to increase the dimensionality and diversity of patterns. Standard GC instruments have detectors that require gases, vacuum systems, and energy supplies. To overcome these problems, developers built integrated systems using GC technology to separate analytes and to create diverse patterns, but with nontraditional detectors that had fewer operational requirements [21.145]. A common combination was the integration of a fast-GC separator, often miniaturized, with a SAW detector [21.146–148]. The Znose [21.149] is a commercial version of this type of e-nose system.

Vibrational Spectroscopy–Based Systems

While not usually classified as e-nose technology, many researchers have evaluated different types of vibrational spectroscopy as rapid nondestructive ways to perform the same types of testing attempted by e-nose and e-tongue instruments, specifically replacing traditional analytical methods and human sensory and acceptability testing. Vibrational spectroscopy can provide results in less time with less expertise and sample preparation. Infrared spectroscopy (IR) methods, such as Fourier transform (FT)-IR, FT-mid range IR and vis-NIR, were the most commonly evaluated methods. These find much more utilization in biosensor systems that are discussed further below and will not be reviewed extensively here. However, a few examples of their use include monitoring nuisance odors from animal production using (FT)-IR [21.150], seafood freshness monitoring using (FT)-IR [21.151], FT-mid

range IR for beverages QC, and vis-NIR to discriminate wines [21.152]. Thermo Scientific offers a portable IR system, called MIRAN SapphIRe, using photoacoustic IR that is based on this type of approach.

Combined Technologies

Sensor researchers have started combining technologies in an effort to further improve the ability of these systems to respond like the human olfactory system, which is able to generate a huge number of patterns with extremely cross-reactive receptors. The developments in cross-reactive chemical sensors has been reviewed by *Albert* et al. [21.46]. Some e-nose developers looked at nature and attempted to develop bioinspired chemical sensors and e-noses. For example, *Al Yamani* et al. [21.153], used a bioinspired recognition approach with their design for the determination of VOCs.

Enhancing Technologies

Different technologies have been applied in an effort to improve the sensitivity and selectivity of sensors. The reduction of size and power requirements has also motivated the exploration of technologies to enhance the performance of sensors. Many of these are not simply focused on one type of sensor, but rather across sensors types. Several of these enhancing technologies are discussed below.

Coatings. Coating technology has the potential to make an impact across several different types of sensors. As an example, *Lima* et al. [21.154] reported a plasma treatment for thin polymer films that was able to preconcentrate VOCs for sensor applications.

Molecular Imprinted Polymers. Molecular imprinted polymer (MIP) technology has been used to build polymers that can be very selective in certain applications such as separation and purification. The use of MIP in sensor applications has been reviewed by *Shimizu* and *Stephenson* [21.155]. They report that this is a rapid and cheap way to increase the selectivity of polymer-based sensors and to decrease cross reactivity for improved pattern generation. MIPs have been especially helpful with gravimetric-based sensors. MIP and QCM technology has been used for high sensitivity detection of explosives [21.156], and VOCs [21.157]. *Dickert* et al. [21.158] reports that MIP-based *synthetic receptors* can provide very sensitive surfaces for the detection of small molecules and larger target analytes up to the length-scale of whole cells.

Nano-Enhancements. One of the central focuses of the nanotechnology revolution has been the development of advanced sensor technology. The nanotechnology-enabled toolkit allows the facile generation of sensor patterning, advanced wave-guide fabrication, high surface area nanoparticles, conducting carbon nanotubes, and other devices that are on track to deliver breakthroughs such as single molecule detection, extreme miniaturization and portability. The recent trend is to couple a nanotechnology-derived device with a biosensor system.

Sampling. Regardless of the sensor or sensor array used, one of the major weaknesses of e-nose systems is the sampling. Human olfaction has many orders of magnitude of differences in its sensitivities to certain key volatiles. For example, certain volatiles associated with tainted products can be detected in as low as parts per billion. Typical chemical analytical methods often require extensive isolation and concentration of volatiles before instrumental analysis. While sensor technology has made advances, the introduction of samples to detect trace amounts of volatiles, whether actively or passively, has been a problem, especially if there is an interfering vapor present. Sample concentration is laborious and manual. Traditional systems needed for sampling and sample concentration do not lend themselves to rapid sensitive analysis and eliminate many of the advantages of most e-nose systems. *Nakamoto* [21.159] reviewed the sampling methods used with e-nose systems.

21.2.4 Biosensors

E-noses and e-tongues have achieved some limited success in reproducing human sensory perception and replacing traditional analytical chemistry methods. Part of the problem was due to a trade-off between speed, low sample preparation and other advantageous features with the level of selectivity and sensitivity that was possible. Biosensors are the next evolutionary step towards the goal of replacing human sensory or traditional analytical methods. Biosensors combine a selective biological recognition element, such as enzymes, DNA, antibodies, receptors/proteins, membranes and even whole cells [21.160] and tissues, with a sensitive transducer. These biological recognition elements come directly from the cellular components involved with signal transduction, or they provide high detection selectivity for these components. They are versatile analytical tools applied more and more in different fields, such as medicine, food quality and safety control, environment pollution monitoring and many others [21.161]. They can provide very high levels of selectivity and sensitivity.

Their use in the replacement of traditional microbiological methods for the detection of pathogens have

been reviewed [21.162–168]. Several other areas of application, such as biomedical research [21.4], pollution monitoring [21.169] and food quality measurement and process control [21.170] have also been reviewed. *Velasco-Garcia* and *Mottram* [21.171] reviewed the use of biosensors in agriculture including detection of pollutants in crops and soils, detection and identification of infectious diseases in crops and livestock, online measurements of important food processing parameters, monitoring animal fertility and screening therapeutic drugs in veterinary testing. The biosensors most related to human olfaction are reviewed further below.

Modes of Action

As mentioned previously, biosensors are built around two main operational elements. They are constructed to contain an analyte recognition element, usually derived from a biological source. The recognition element is coupled to a transducer that is designed for extremely high sensitivity. These are discussed further below.

Recognition. The two general types of recognition elements are molecular-based and cell-based.

Antibodies are one of the most common molecular-based biosensor recognition elements used for immunoassays. *Skottrup* et al. [21.172] reviewed the use of surface immobilized antibodies for the detection of pathogens. Antibodies have been immobilized on a variety of other materials, such as magnetic beads in a magnetoresistive immunosensor for *E. coli* [21.173], quartz crystal microbalance for human immunoglobulin quantitation [21.174], and hydrogel particles in multiplex immunoassays [21.83]. These are usually employed as strategies to improve the transduction of the biosensors. These detect epitopes on target cells and thus are not usually included in e-nose systems focused on detection of olfactory-active volatiles.

Enzymes are another commonly used recognition element in biosensors. They are used in simple ethanol biosensors where immobilized alcohol oxidase generates hydrogen peroxide from ethanol vapors that can be detected with amperometric electrodes [21.175]. *Moyo* et al. [21.176] reviewed the different methods involving the polymer immobilization of enzymes for use in *enzyme electrodes* in biosensor applications.

Many other molecular-based recognition elements have been used in the design of biosensors. Biosensor recognition elements have been constructed using ion channels, nucleic acid/peptide nucleic acid (hybridization), genes, modified surfaces-SPR (biotin-silicon nanowires, streptavidin), immobilized olfactory receptors [21.177], ribozyme elements (Halfzyme, RiboReporters) and other biological themes of molecular interaction. For example, *Vidic* et al. [21.177] coexpressed a human olfactory receptor (OR) and G-proteins in Saccharomyces cerevisiae cells. The cells where used to prepare nanosomes and immobilized on a sensor chip. Using surface plasmon resonance they were able to quantitatively evaluate OR stimulation by an odorant, and G protein activation with discrimination between odorant ligands and unrelated odorants. There have been many recent developments using these types of approaches.

Biosensors have been designed with cell-based (cytosensor) recognition elements. Artificial cell membranes and tissues have been used. *Liu* et al. [21.178] used the olfactory tissue taken from a rat to make a biosensor for odors. They constructed this *neuron chip* by fixing the biological tissues onto the surface of a light-addressable potentiometric sensor (LAPS) [21.179]. They reported that the olfactory mucosa tissue of the rat was in a natural state with neuronal populations and functional receptor units of the cilia well preserved. The electrical properties of the tissue-semiconductor interface were analyzed by the volume conductor theory and the sheet conductor model. Then, the local field extracellular potentials of the receptor cells in the olfactory mucosa tissue were simulated and monitored. The results suggested that this tissue-semiconductor hybrid system was sensitive to odorants. They believed that the receptor cell-based biosensor technology is a valuable tool to record data with high information content with respect to odor stimulation in the intact cellular environment of the olfactory epithelium. While this approach had the advantages of intact epithelium, the preparation was complex and the durability of such a device is unknown. However, this could be a useful research tool when used with in vivo experiments.

Immobilized whole cells have also been studied as recognition elements in selective volatile sensors. Yeast clones (2,4-dinitrotoluene) [21.180], modified bacterial cells (napthlaene, salicylate, chlorophenols, cyanide) [21.181, 182], and GPCR-Hela/olfactory cells ((-)citronellal) [21.183, 184] have been reported to have benefits as recognition elements in biosensors. *Dickert* et al. [21.158] used biomolecular imprinting to make *synthetic* receptors that could be used with whole cell detection systems that where sensitive to coffee volatiles and others.

Bio-E-Nose

A class of biosensor attempts to closely mimic the human olfactory system. The researchers involved with this approach borrow different elements of the human olfactory system, such as receptors, tissue, or data processing as design elements. The area of the bio-e-nose

and the biomimetic approach to volatile sensing has been reviewed extensively [21.54, 185–190].

The construction of bio-e-nose devices has required the development of new materials. Sensitive coatings are formed using dip or drop coating, self-assembled monolayers (SAM) [21.191], Langmuir–Blodgett films [21.192], and others. Single walled carbon nanotube or PET polymers [21.193] and neural cell coated polymers [21.194] are some other examples. QCM and SPR are commonly used as detectors.

Odorants enter the human nasal cavity and are absorbed in the olfactory mucosa. These volatiles then are thought to interact with odor-binding proteins (OBP), however the exact details are somewhat controversial. Several bio-e-nose developers have used this initial binding event as the focus of their bio-e-nose designs. The efficacy of synthetic OBPs as sensor elements was explored using computer simulations of docking and scoring to calculate binding efficiencies [21.195, 196]. *Sankaran* et al. [21.197, 198] used synthetic odor-binding peptides in a bio-e-nose device to detect alcohols from Salmonella contamination. *Kruse* et al. [21.199] also used this technique to build an alcohol sensor. *Jaworski* et al. [21.200] used this approach to design a selective coating for the detection of volatiles associated with explosives. *McAlpine* et al. [21.201] attached odor-binding peptides to nanowires to increase their sensitivity.

After volatiles are bound to OBPs in the olfactory mucosa, they are thought to be transported to olfactory receptors where they start a cascade of enzymatic events that eventually lead to the generation of a series of nerve impulses. Many researchers have used cell-based approaches where olfactory receptor proteins (ORP) are either cloned or extracted and then expressed or implanted into heterologous cells that facilitate screening, or used directly. This has been reviewed by *Du* et al. [21.202]. The receptors can be extracted from animals such as rats, frogs, mice and humans. *Wu* [21.203] extracted bullfrog ORPs and used them directly in a piezoelectric biosensor. Several human cell lines are commonly used for cell-based screening with receptor clones. Human embryonic kidney 293 (HEK293) cells have been used with the expression of human ORPs [21.204], mouse olfactory receptor protein libraries [21.205], and with rat ORPs [21.206]. The human Xenopus laevis melanophore cell line has also been used to express an ORP sensitive to amines [21.207]. ORPs from *C. elegans* were expressed in *E. coli* [21.208]. *Minic* et al. [21.209] were able to express mammalian ORPs in yeast (*Saccharomyces cerevisiae*) for odor screening. *Vidic* et al. [21.177] expressed mammalian ORP in yeast (*Saccharomyces cerevisiae*) and then extracted them as membrane nanosomes to be attached to a sensor chip using SPR detection. These types of systems are still evolving. While potentially capable of very high specificity, the exact details about aspects such as detection limits, specificity, durability of these systems, especially for use as industrial sensors, are not reported.

Table 21.2 Examples of combined sensor platforms and applications

Sensor Combination	Application	References
E-nose/e-tongue	Tea	[21.210]
E-nose/e-tongue	Black tea	[21.211, 212]
E-nose/e-tongue	Beverages: water, orange juice and milks	[21.213]
E-nose/e-tongue	Port wine	[21.214]
E-nose/e-tongue	Wine	[21.215]
E-nose/e-tongue	Italian wine	[21.216]

E-nose/GC/UV-vis	Wine aging	[21.230]
E-nose/MS	Wine origin	[21.231]

Moving further from the periphery of the olfactory system, some researchers are using the neural apparatus, such as elements that contain olfactory receptor neurons (ORN) from the olfactory system. The rationale is that the native reception and transduction is in place and that the nervous impulse would be easier to understand from a pattern recognition point of view. Endogenous tissues or whole cells were often used as elements in these types of bio-e-nose sensors and arrays. *Liu* et al. [21.232] used intact olfactory tissue from a rat to make a microelectrode array to detect odor patterns. *Liu* et al. [21.184] also used cultured human olfactory neurons to create a light-addressable potentiometric sensor (*neuron chip*) that was sensitive to acetic

acid. These devices are just beginning to be developed. They are expected to ultimately be capable of sensing many volatiles.

Along these lines, several research groups evaluated the construction of bio-e-noses from complete organs that also contained the ORN systems. Insect antennae were popular in these as well as parts from other animals. The rationale is that the olfaction of certain insects is tuned to certain volatiles such as amines for decaying animals, plants with infections and others. One group used antennae and ORN from blowflies (*Calliphora vicina*), to make sensitive detectors for biogenic amines [21.233, 234]. *Schutz* et al. [21.235] used the antennae from the Colorado potato beetle (*Leptinotarsa decemlineata*) to make a biofield effect transistor bio-e-nose to detect damaged plant volatiles. *Mead* [21.236] used similar logic and looked at antennae from lobsters to detect toxic chemicals.

21.2.5 Combination Sensor Systems

The human sense of flavor emerges from a cognitive fusion of gustatory and *retro*-olfactory signals. With e-nose, e-tongue and biosensors all evolving, much research has been focused on combining the different sensor platforms to gain the advantage of generating even more complex patterns and to attempt to reproduce human flavor sensations. This idea was often extended to include an instrumental surrogate for human vision using either instrumental colorimetry or spectral methods, and even electromechanical sensors to model mouthfeel, to increase the data available for fusion and analysis. *Ruiz–Altisent* et al. [21.60] and *Winquist* et al. [21.237] discussed the use of combined sensor platforms and their applications. Several examples of multisensor systems are listed in the Table 21.2 below. Hybrid sensor systems continue to be developed.

21.3 Biomimetic Data Analytic Approaches

Human sensory evaluation (cognition) of olfactory signals involves considerable information processing. An approach to data analytics applied to electronic sensor signals utilizes a biomimetic framework that imitates elements from biological olfaction and gustation in an attempt to achieve the higher information goals discussed earlier [21.238, 239]. *Martinelli* et al. [21.240] discussed the weakness of artificial olfactory sensors in light of the natural processing of olfactory information in biological systems. They used optical sensors to study biological olfaction. *Perera* et al. [21.241] proposed a new method reportedly inspired by the early olfactory receptor processes. Using data from two metal oxide sensors driven by a sinusoidal temperature profile, they performed data feature extraction and selection based on the projection of sensor features in *class space* using an algorithm suitable for high-dimensional feature vectors with robustness where only a small number of samples are available as a training dataset. They reported improved results since the approach accounted for sensor variance.

Raman et al. [21.242] focused on the first two stages in the olfactory transduction pathway: distributed coding with olfactory receptor neurons and chemotopic convergence onto glomerular units. They called the coding of olfactory receptor inputs the *chemotropic code* or a monotonic concentration-response model that maps sensor array inputs into a distributed activation pattern, similar to patterns found in the activation of a large population of neuroreceptors. Projection onto glomerular units in the olfactory bulb was simulated with a self-organizing model of chemotopic convergence. The pattern recognition performance of the model was characterized using a database of odor patterns from an array of temperature modulated chemical sensors. The chemotopic code achieved by the proposed model was shown to improve the signal-to-noise ratio available at the sensor inputs while being consistent with results from neurobiology. The authors [21.243] extended their model to capture on-off surround lateral interactions associated with convergence of the signals and validated their model using chemical sensors thereby enhancing signal contrast and separating identity information from intensity information.

Pioggia et al. [21.244] built an artificial data analytic model inspired by the mammalian cortex for the fusion of e-nose and e-tongue data using *neural* computing methods that aspire to capture the same neural network processing that likely happens in nature. These data analytic methods use layers of artificial *perceptrons*, or cross-linked transfer functions, that allow the tuning of complex and nonlinear responses from complex inputs such as those found in biology, after sufficient training or learning has occurred. The authors called this particular rendition a cortical-based artificial neural network (CANN). They reported better performance using CANN than other artificial neural networks methods, such as a multilayer perceptron (MLP), Kohonen self-organizing map (KSOM) and fuzzy Kohonen self-organizing map (FKSOM). *Robertsson* et al. [21.245] suggested the use of a similar approach that mimicked a human perception model

for sensory information processing applied to e-tongue sensor data.

Human olfaction produces information that is temporally and spatially resolved. Nasal flow rates tend to spread out the volatile impact zone across the olfactory tissues. *Gopel* [21.246] reviewed these ideas plus those from hyperspectral analysis from chemical imaging and discussed their application to e-nose and bio-e-nose systems. Further development of spatially-resolved sensor arrays is expected.

21.4 Machine Olfaction Applications

There are an incredible number of e-nose applications in the literature. This review will focus mainly on those of potential importance to the food industry and associated areas. These include food, environmental monitoring, clinical diagnostics, agriculture and supply chain, and industrial applications. These will be discussed in further detail below.

21.4.1 Food and Beverage Applications

For food and beverages, e-noses have been used to determine quality and safety. Moreover, they have been used to monitor food processing and shelf life. Also, they have been used to replace the usual human sensory testing tasks used in product development, and tasks such as measuring maturing and determining authenticity and origin. E-nose sensor applications in these types of food areas have been reviewed in several publications [21.56, 130, 247].

Determination of Quality, Identity or Origin

The determination of quality is very important in food and ingredients. It is directly related to value but extremely hard to measure instrumentally. Human panels are usually needed, specifically if characterizing the sensory quality of foods. This is extremely difficult in most production settings. The costs in time and people can be very high. Also, there is often a need to determine product origin and adulteration. In fact, researchers from the IFSH (Institute for Food Safety and Health, a lab associated with the Food and Drug Agency, USA) recently gave a presentation on olive oil authentication favorably comparing an e-nose's ability to detect adulteration versus LCMS. As a result, there have been a large number of reports focused on the evaluation of e-nose systems in this area. A list of these reports is shown below in Table 21.3.

E-nose sensors have also been used to test ingredients. These tests focus on the determination of quality, authenticity, adulteration and other applications much like those e-nose applications found for finished foods. Several examples of e-nose testing of food ingredients are listed below in Table 21.4.

Food Safety Methods

Food safety is perhaps the major application of electronic sensor technology. There is a constant need to be able to determine toxins and pathogens with speed, accuracy and sensitivity from the farm to the fork. Several reviews of work in this area have been reported. *Casalinuovo* et al. [21.381] reviewed the use of e-noses for the detection of the volatiles associated with food spoilage organisms and pathogens. These systems provide extremely rapid responses compared to the standard methods that require culturing and identifying microbial contaminants or traditional analytical methods for toxins. Steady improvements have been made using the volatile metabolic markers from organisms to confirm microbial identities and quantities. Their ultimate utility will be directly linked to the sensitivity that can be achieved. Work on single-molecule detection systems should greatly enable these. It is likely that these will serve as rapid surveillance methods to trigger subsequent standard testing.

Rapid detection of grain spoilage is another major area of potential for the application of e-nose technology. Mold growth on wet grain and subsequent mycotoxin production is a perennial problem. *Magan* and *Evans* [21.382] reviewed the use of e-noses for early detection of volatiles associated with fungal growth in grain. *Sahgal* et al. [21.383] discussed the possibility of using e-noses to discriminate between mycotoxigenic and nontoxigenic molds. Rapid methods are needed to support efficient supply chain management. This requires rapid, field-ready systems. While current systems are limited in sensitivity, there is ongoing research to develop new sensors to detect these contaminants. Nanotechnology, such as nanoscale construction of waveguides and other devices, should greatly enable these improvements.

Reports on the use of e-nose sensors for a variety of food safety applications are listed below in Table 21.5. The major areas include natural and manmade toxin detection, and pathogen detection.

Human Sensory Replacement

Human sensory testing is considered by some to be laborious and therefore expensive, subjective and slow.

Table 21.3 Selected applications of e-nose technology in finished foods

Food category	Product or application	References
Quality, grading, classification or origin applications		
Confection	Chocolates	[21.248]
Meat	Handling	[21.249]
Meat	Raw and cooked	[21.250]
Meat	Modified atmosphere packaging (MAP) poultry	[21.251]

Also, a high degree of rigor is required to obtain consistent results. These make it difficult to perform in many locations where the access to isolated sensory laboratories, panelists and trained sensory scientists is limited. Researchers have attempted to develop electronic sensors that can replace some of the common human sensory testing methods to take the burden off of the other researchers [21.420]. Some of these studies are listed below in Table 21.6.

Food Process Monitoring

Process control systems utilize many types of sensors. Human sensory testing is only typically used after processing on finished food products. Researchers have found many potential opportunities to use e-nose sensors to control and direct processing, and in subsequent post-processing steps. A common area is the tracking of food fermentation and ripening processes. These can take years and it is very expensive to perform repeated sensory testing. Also, the storage costs of these types of processes can be high. Methods achieving early predictions of quality are of great interest. Also, many food products are processed using cooking and baking where the sensory quality of the food changes rapidly as the product moisture drops and as product temperature rises. E-noses have been studied as a way to control these processes to help the product stay in the desirable cook-level window. Several of these studies are listed below in Table 21.7.

Food Shelf Life and Storage Monitoring

Another significant application of e-nose sensor technology is to determine food shelf life, maturity or ripeness and shelf spoilage. Many fresh food products ripen, but then degrade and deteriorate chemically and microbiologically during storage. This can lead to health risks and economic loss. A significant amount of work has been done with the most sensitive foods to determine if e-nose sensors can replace human sensory testing and microbiological testing in the determination of the quality, maturity and safety of fresh food. *Casalinuovo* et al. [21.381] reviewed the use of e-noses in the detection of food spoilage. Additional studies are listed below in Table 21.8.

21.4.2 Environmental Monitoring

Human olfaction enables us to detect potentially harmful gases. For example, we have a reflective apnea response when we smell certain odors, such as ammonia, that provides protection for our airways. As global populations increase, monitoring of the environment is an increasing area of potential importance for many. There is a growing awareness of air quality, both indoor and outdoor, water quality, and other sources of potential contamination. Odors can warn about hazards, but can also cause significant nuisances.

E-nose sensors' cross-reactive abilities, to sense multiple chemicals simultaneously, have led to their increased use in environmental monitoring. *Romain* and *Nicolas* [21.515] reviewed the use of MOS e-noses for environmental monitoring. *Feng* et al. [21.516] evaluated a colorimetric sensor for the detection of toxic industrial gases. The quality of indoor air is increasingly becoming the focus of recent studies. Hospitals especially are concerned with indoor air quality and the use of e-noses to detect air-borne pathogens [21.517]. *Trevathan* et al. [21.518] reported a wireless sensor system for marine environmental monitoring called SEMAT. The use of e-nose sensors for air and water monitoring are discussed further below.

Air

Air quality has been a significant problem for agriculture. Many agricultural practices produce odor and VOCs that need to be controlled and are the subject of regulatory control. *Tsujita* et al. [21.519] reviewed the use of gas sensors for air pollution monitoring. Several different applications of e-nose sensors for the monitoring of air quality are listed below in Table 21.9.

Water

Water quality is related to lack of odor. Thus water with any detectable odor is considered of low quality. Future

fresh water supplies will become increasing pressured and quality is sure to suffer as supply becomes limited. There is an expectation that the need for water quality assessment will grow rapidly. Thus the need for rapid instrumental methods to replace human olfaction and sensory testing methods will also grow. Several reports of the use of e-noses to monitor water quality and waste water quality are listed below in Table 21.10.

21.4.3 Clinical Diagnostics

All animals, including humans, use their sense of smell to detect sickness, whether consciously or subconsciously. Animals such as dogs have been trained to detect illnesses, such as cancer, with a high degree of accuracy. Volatiles sensors have also been evaluated for this application. A brief review of e-nose technology used in clinical diagnostics is included below. The key applications are the detection and diagnosis of infectious diseases, such as respiratory and urinary tract infection, the detection of cancer and the replacement or support of standard clinical methods. Several researchers have reviewed the medical applications of e-nose technology [21.4, 552, 553].

Infectious Diseases

Turner and *Magan* [21.554] reviewed the use of e-noses in the diagnosis of infectious diseases. *Pavlou* et al. [21.555] reported the use of an e-nose to detect volatiles and odors associated with *Mycobacterium tuberculosis* (TB) in mixed culture with other bacteria. *Sahgal* et al. [21.556] used e-nose sensors to identify odors from fungal infections caused by *Trichophyton* species. *Pavlou* et al. [21.557] used an e-nose to differentiate odors from pathogen anaerobes from *Clostridium* species. And *Parry* et al. [21.558] used an e-nose to detect odors from hemolytic *Streptococcus* in leg ulcers.

Diagnosis of Diseases via the Upper Respiratory Tract Odors

Breath odor analysis has been particularly useful in the diagnosis of a diversity of upper respiratory diseases [21.559], and cancers [21.560]. In fact, breath odor markers also exist for other diseases such as diabetes and potentially many more. Several examples

Maturation/ripening	Fish, cod roe	[21.261]

of these are listed below in Table 21.11. Currently, it has not been clearly established that the underlying molecular principles can be attributed to odorous constituents. However, at least for the animal sniffer, such as dogs, this seems to be valid [21.561]. Greater interest in breath odor analytics is expected for clinical diagnostics. This should also drive the development of machine olfaction devices for this application.

Urinary and Renal Disease

Urinary volatiles and odors have been linked to certain types of disorders. E-noses have been used to determine if they can replace the traditional analytical methods. Several reports are shown in Table 21.12. This is another example of how future advancements in instrumental odor detection and recognition technology can be leveraged in nontraditional applications. However, it can be argued that certain mammals currently use urine and the odors of urine for a variety of common communication applications such as marking territories and others.

Digestion

Fermentation of undigested foods in the large bowel by its resident bacteria results in the creation of several chemicals including volatile gases that influence colonic and metabolic health. *Fermentonomics* describes the investigation and analysis of the fermentome by noninvasive means and may have a potentially wide application in medicine. Digestion disorders have seen significant focus by e-nose clinical researchers. One notable report was by *Arasaradnam* et al. [21.581] who used an e-nose to evaluate the VOCs associated with patients' *fermentome* to diagnose inflammatory bowel disease and diabetes.

Cancer

As mentioned above, certain odors have been found to be associated with certain diseases and these are being explored for diagnostic potential. Machine olfaction is useful since many of these odorants are below the detection thresholds of humans. While they are not below the detection thresholds of certain animals, machine olfaction devices are more convenient for regular use.

Renal dysfunction	Monitoring hemodialysis	[21.567]

E-noses have found increasing use in the detection of cancer, especially lung cancer [21.582]. For example, *Di Natale* et al. [21.583] collected breath samples from patients with lung cancer and analyzed them for alkanes and aromatic compounds using an electronic nose, composed by eight quartz microbalance (QMB) gas sensors, coated with different metalloporphyrins. These sensors show a good sensitivity towards those compounds previously indicated as possible lung cancer markers in breath. The application of a partial least squares-discriminant analysis (PLS-DA) with this system correctly classified 94% of the cancer patients. Other systems for the detection of cancer-related odors have used SPME preconcentration with a capillary column GC and pairs of SAW sensors, one coated with a thin polyisobutylene (PIB) film as detectors [21.582–585]. *Dragonieri* et al. [21.586] used an e-nose with breath analysis to detect pleural mesothelioma. Also, *Li* et al. [21.587] used breath analysis to detect breast cancer.

Rapid Clinical Testing

The use of odor analysis in clinical diagnosis has been expanding to areas outside of cancer diagnosis. E-noses, especially CBCP-type sensor arrays, have found use in replacing the standard clinical testing methods using odor analysis to diagnose bacterial eye infections [21.599], blood culture [21.600], asthma [21.601], cerebrospinal fluid assays [21.602], eye, ear, nose and throat infections [21.603], and poisoning from radon in water [21.604] as examples.

21.4.4 Agriculture and Supply Chain

Networking of wireless sensors has the potential to allow access to information never before available with potential impacts to supply chain management. While these are not used in agricultural supply chains yet, several reports have started to appear and they include machine olfaction [21.605]. *Ruiz-Garcia* et al. [21.606] reviewed their applications and trends for use in food and agriculture. They have been used to monitor vineyards [21.607], relative humidity sensing [21.608], environmental monitoring [21.609], and in precision horticulture [21.610].

Plant Pathology

Volatile analysis has been useful in the detection and diagnosis of plant diseases. E-noses have been studied for their efficacy in performing these studies faster with less expensive equipment that requires a lower level of expertise to operate. Several studies using e-nose sensors in plant health are listed below in Table 21.13.

Forest Products

E-noses have found extensive use in monitoring forest products. For example, *Baietto* et al. [21.611] used e-nose sensors to detect wood rot. *Wilson* et al. [21.612] reviewed the use of e-nose sensors for the identification of woody plants.

Stored Grain Quality Management

The quality of crops changes during storage. This has a direct impact on the quality and value of the grain.

Table 21.14 A selection of reports using e-nose sensors for stored grain and food quality management

Area	Focus	Product	References
Pest control	Insects	Wheat	[21.455, 613]
Pest control	Insects	Grain	[21.614]
Pest control	Stink bug	Cotton, soybean	[21.615]
Pest control	Insects	Rice	[21.616, 617]
Age monitoring		Wheat	[21.300, 456, 618]
Spoilage	Fungus detection	Grains	[21.382]
Spoilage	Microbial quality classification	Grains	[21.360]
Spoilage		Onions	[21.619]
Quality management	Quality classification	Rapeseed	[21.494]

This is an important area for global commodity businesses. E-noses and sensors have been used to determine the quality of grain and other food in order to effectively manage these supply chains for maximum value and safety [21.620]. Several of these studies involving the use of e-nose sensors for storage quality management are listed below in Table 21.14.

Supply Chain Monitoring

In addition to storage quality management, e-nose sensors have been used along the supply chain to ensure identity and traceability, quality and value. These types of applications are of growing interest with the continued globalization of food supply, especially in the maintenance of identity preservation systems. Radio frequency identification smart tags transmit sensor information for tracking and confirmation. For example, *Abad* et al. [21.621] used radio frequency identification (RFID) with different sensors to track fish logistic chains. *Amador* et al. [21.622] used RFID to track fresh pineapples and their temperatures during transit. *Ruiz-Garcia* et al. [21.623] discussed the use of wireless networks for real-time monitoring of fruit logistics. Also, *Jedermann* et al. [21.624] discussed a similar system for perishable food transport. While this technology mainly logs temperature and moisture data, it is highly likely that miniature e-nose sensors will soon be added to these systems.

Plant Physiology

There have been limited reports involving the use of e-nose sensors to monitor plant physiology and development; however, this could be an emerging area in the future. In one study in this area, *Komaraiah* et al. [21.625] used gas sensor arrays to determine plant cell culture growth.

Feed Quality

There are not many reports of rapid feed quality determination using machine olfaction instruments such as e-nose sensors. NIR methods have been well established. However, *Campagnoli* [21.626] reported on the potential application of e-noses in processed animal protein (PAP) detection in feed materials.

21.4.5 Further Industrial Applications

Machine olfaction is finding application in many more fields. Just a few examples of these are highlighted below. Many are reported as the cost, selectivity, portability and information processing capabilities continue to advance.

Occupational Health and Safety

E-nose technology has reportedly been used in health and safety to detect toxic gases. One example is given by *Gawas* et al. [21.539] who used an nanostructured ferrite e-nose sensor to detect ammonia gas. Others like this have already been mentioned above in the section on safety applications.

Cosmetics Formulation and Quality Control

E-nose sensors have found some use in the quality control of cosmetics. *Branca* et al. [21.627] used an e-nose to detect certain fragrance compounds. *Hanaki* et al. [21.628] developed a system to deformulate the components of blended fragrances.

Pharmaceutics Research

E-noses have been also used in screening methods used to develop pharmaceuticals. For example *Naraghi* et al. [21.629] used an e-nose to screen volatile fingerprints associated with the efficacy of candidate antifungal agents.

Bioindustrial Process Monitoring

As with food process monitoring, machine olfaction devices such as e-nose sensors have also been used in bioindustrial process monitoring where there is a need for rapid online process sensors. *Rudnitskaya* and *Legin* [21.630] reviewed this area and the potential for using e-noses and e-tongues for this purpose. *Cimander*

and *Mandenius* [21.631] reported the use of multivariate process control of bioprocesses using mixed sensors including an e-nose, mass spectrometers, NIR and standard bioreactor probes.

Rapid Microbiological Testing

Finally, machine olfaction device e-noses have found some use in general microbiological testing methods. For example, e-noses have been used to monitor mold growth in liquid media [21.632] and to discriminate bacteria [21.633, 634].

Rapid, In-field Explosives Detection

The use of e-noses for the detection of explosives, such as land mines has been reviewed by *Gardner* [21.635].

21.5 Conclusions

Current instruments available for machine olfaction are not without problems. Sensitivity, selectivity and reproducibility have always been problematic for electronic sensors. Even with the advancements produced by improved data analytics, biorecognition elements and nanoenabled transduction elements, these devices can require a very large number of samples to train the pattern recognition procedures, and then potentially years of calibration maintenance to tune out all types of interferences and noise associated with the samples of interest. Thus, the economics of these methods can suffer if they include estimates of the training and calibration efforts. Also, biosensors may have limits on their useful service lives. This could also change the economics of their use especially if high levels of expertise are required for their maintenance and use. Gas sensor arrays are inexpensive but can suffer from low selectivity and sensitivity. Mass-spectrometer-based sensors are fairly selective and sensitive with the appropriate sample preparation, but they are expensive and require a high level of expertise to maintain and operate. Also, while recent advances in sensor technology have been significant, it is the opinion of the author that no system currently available can completely produce data equivalent to human olfactory perception. However, this is likely to change as sensor technology and an understanding of human brain science and cognition advance.

22. High-Throughput Receptor Screening Assay

Alex Veithen, Magali Philippeau, Pierre Chatelain

The recent technical advances in functional expression of olfactory receptors (ORs) make full deorphanization of human OR repertoire a realistic objective. Such a global knowledge of the precise mechanisms of odorant/receptor pairings will represent a crucial step for the development of an accurate model of how human nose perceives its chemical environment. Beyond its interest for basic science, it will also lead to the development of industrial applications such as receptor-based odorant design, development of selective odor blockers or enhancers and represents therefore an interesting opportunity for players active in the field of flavors and fragrances. Here, we will describe and discuss a high-throughput screening approach that aims at the objective of human OR mass deorphanization. However, the completion of this ambitious task is not a prerequisite to the development of commercial applications. With the expanding number of deorphanized ORs, structure–activity relationship studies on OR responding to an odorant of interest has already started. Likewise, the use of the screening approach to identify either blockers for malodor-responding ORs or positive enhancers of fine fragrance-tuned ORs is underway. These different aspects will also be discussed. Finally, beyond the human ORs, other classes of human chemoreceptors for volatiles as well as animal chemoreceptors may also represent industrial opportunities that will be briefly reviewed.

22.1 Working with ORs

The discovery of olfactory receptors (ORs) by *Buck* and *Axel* [22.1] as well as the experimental confirmation of the combinatory theory of odor coding [22.2], initially proposed by *Polak* [22.3], have paved the way for an accurate understanding of the molecular mechanisms of olfaction. Beyond their fundamental interest, these pioneering researches have also led to consider industrial applications such as the design of antagonists that would selectively block the perception of a given malodor, the setup of positive allosteric modulators (PAMs), molecules with no or only weak intrinsic olfactory properties but that could boost the perception of other odorant, the identification or design of new molecules that would share the same odor characteristics than expensive compounds used in perfumery.

22.1.1 Interest of Massive Deorphanization of ORs

The proper achievement of these applications needs a deep and accurate comprehension of the odor coding, and deciphering this code will require an extensive knowledge of the interactions of each individual odorant with its ORs. The combinatory theory of olfaction predicts that the odor perception elicited by one molecule will rely on the activation of at least one, but most likely several different odorant receptors. Therefore, it is important to know different receptors that are implicated in the detection of the target odor prior to consider modifying the perception by acting on these receptors. So far there are few demonstrations of the involvement of a determined OR in the perception of a given odorant molecule. In a study combining in vitro characterization of the OR7D4 and genotype-phenotype analysis, *Keller* et al. [22.4] were able to demonstrate that this OR plays an important role in the perception of the male sweat malodor component androstenone. Likewise, the hypersensitivity to isovaleric acid has been linked to the presence of the functional haplotype of the segregating pseudogene OR11H7P [22.9]. Along the same line, the variation of detection threshold of *cis*-3-hexen-1-ol among the population can be explained by different sensitivities of the haplotypes of OR2J3 [22.15] while the sensitivities for β-ionone and guaiacol odor intensity are dependent on the presence of the functional allele of OR5A1 [22.17] and OR10G4 [22.5], respectively. These studies have often been benefited by previous reports on the relatively high frequency of specific anosmia, hyposmia, or hyperosmia that have allowed making the link between the perception phenotype of the considered odorants and the genetic defect in the corresponding receptor. Although the identification and frequency reports of anosmia or hyposmia have been performed for several odorants (for example [22.22, 23]), these data are far from being able to cover all the odorants of interest. Moreover, to be of use, the frequency of the phenotype must be relatively high in the population in order to get a sufficient occurrence in a reasonably sized cohort of tested volunteers. This may not be the case for many odorants.

A complementary approach for deciphering the olfactory code consists in a systematic deorphanization of the ORs of the species of interest (human, in our case). It took several years between the first identification of mammalian ORs and the demonstration of the activation of a mouse OR by an odorant. Now, more than 20 years later, the number of OR deorphanizations remains low. Based on a compilation of published results, it appears that one or more ligands have been identified for at least 55 human ORs (Table 22.1). Knowing that the human genome encompasses about 400 sequences that encode a complete and potentially functional OR protein [22.26, 27], it can be considered that about 14% of the human OR repertoire is deorphanized. This per-

centage could even be re-evaluated taking into account that a significant portion (32%) of the human OR genes could be functional pseudogenes, despite their complete coding sequence [22.28].

Notwithstanding this rather optimistic view on the progress of human OR deorphanization, a huge effort remains to be done in order to complete the general human olfactory map. This implies a systematic testing of a diversified odorant molecule library, covering an as large as possible diversity of chemical structures and organoleptic properties, on the human orphan ORs. Regarding the number of chemicals that can effectively be recognized by the human nose, which is far over 10 000, it is impossible to cover the whole range of odorants by a single screening campaign. Owing to the large number of (human) ORs, the even higher number of odorant molecules and the combinatorial nature of olfaction coupled to technical difficulties, deciphering the olfactory code and developing applications seem to be long-term goals. Nevertheless, clear progresses have been made in recent years; they will be further presented in this chapter.

22.1.2 Brief Overview on Different Approaches Used to Deorphanize ORs

To get a grip on OR deorphanization, one needs to make use of a robust system that allows to record the activation of an OR by its ligand. Different experimental systems have been successfully used to demonstrate such interactions and have already been reviewed [22.29–31].

Briefly, a first category of systems consists in working directly on a living animal or on ex-vivo samples where the ORs are expressed. For example, using an adenovirus to overexpress the I7 receptor in rat olfactory epithelium, *Zhao* et al. [22.32] were able to identify octanal as an activator of this OR using electro-olfactogram records on prepared olfactory mucosa. The response of isolated olfactory neurons to odorants and the subsequent identification of the implicated receptor by single cell reverse transcription polymerase chain reaction (RT-PCR) also led to successful deorphanization of mouse ORs [22.2, 33]. However, these approaches can hardly be considered for mass deorphanization of human ORs.

The second category of systems refers to the in vitro expression of ORs in cultured cells. This approach has been widely used to deorphanize ORs. The cell type used can be directly derived from the olfactory epithelium [22.34–36], from heterologous mammalian cells such as human embryonic kidney 293 cell line (HEK293) (see among others [22.13, 16, 37–39]) or Hela [22.40]. Other models such as insect cells where the OR gene has been introduced via a baculovirus system [22.41, 42] or *Xenopus* oocytes injected with the complementary ribonucleic acid (cRNA) corresponding to the OR of interest [22.43] have also been described. Yeast cultures have also been considered for ORs expression [22.44–47]. In these systems, yeasts have been engineered in order either to couple the cell growth on deficient media with the activation of the studied OR or to induce the expression of a reporter gene. Finally, this cell model has also been used to develop microsensors based on the measurements of OR activity by microconductimetry or by surface plasmon resonance.

In this chapter, we will describe the screening platform dedicated to OR that has been set up at ChemCom. The application to antagonist and PAM research will also be presented and discussed.

22.2 How to Identify Ligands with in vitro Functional Assays

22.2.1 Deorphanization

Upon the initial discovery, it took several years before the reliable identification of ligands for ORs. The reason for such a delay is to find in the difficulty to express ORs in usual heterologous cell cultures that were shown suitable for identifying activators of nonolfactory G protein coupled receptors (GPCRs). It was observed that ORs expressed in these systems are not or only poorly targeted to the plasma membrane of the cultured cells [22.36, 48–50]. Different strategies have been followed to fix this problem. Some consist in adding the N-terminal sequence tag to the ORs in order to avoid their retention in the endoplasmic reticulum [22.16, 37, 51–53]. Although improving the targeting of several ORs, this approach was not found to be sufficient to allow the cell surface expression of any OR. Another approach has consisted in expressing, along with the

OR, ancillary elements such as the odorant response abnormal protein 4 (ODR-4) [22.36] or receptor transport proteins (RTP) 1 and 2 [22.39]. These chaperone proteins have been shown to enhance the targeting of ORs to the plasma membrane in cultured cell lines. Although their mode of action is not yet fully understood, the expression of the short version of RTP1, RTP1S, and RTP2 was found to be the most efficient system to allow a functional expression of human ORs in our hands. Therefore, we developed a HEK293T cell line that stably expresses both chaperones. This cell line has served as a major tool for deorphanizing of human ORs.

From this cell line, the activity of an OR can be shown using different functional assays (Fig. 22.1) that rely on the modification of a second messenger concentration occurring upon the triggering of the OR by its activator. Dose–response analyses performed on HEK293T cells stably express RTP1S and RTP2 that have been transiently transfected with OR2W1 along with $G_{\alpha 15olf47}$ (Fig. 22.1a), a modified version of cyclic-nucleotide gated chanel subunit 2 A (CNG2A) (Fig. 22.1b), no additional factor (Fig. 22.1c), cyclic adenosine monophosphate (cAMP) response element (CRE)-luciferase (Fig. 22.1d) or CRE-GFP (green fluorescente protein) (Fig. 22.1e). In the olfactory neuron, the activation of the receptor results in a stimulation of the $G_{\alpha olf}$ protein that in turn activates type III adenylate cyclase. The ensuing increase of cAMP concentration opens a cyclic nucleotide gated (CNG) channel that allows an entry of extracellular calcium in the cytoplasm of the cell (for recent reviews, see [22.54, 55]). Different functional assays have been developed based on the element of this olfactory cascade. At ChemCom, we implemented different assays that can be used to deorphanize ORs or that may serve as secondary confirmation assays.

Calcium Imaging-Based Functional Assays

Measurement of variations of cytoplasmic calcium concentration has been widely used to monitor the activity of GPCR and ion channels. It can be readily performed using fluorescent calcium-sensitive dies, such as Fura-2 or Fluo-4 [22.56]. Calcium imaging-based assays have been used to demonstrate the functionality of ORs (among others, see [22.33, 37, 40]). Actually, two types of calcium assays have been described. The first relies on the use of a type *q* G protein that couples the activation of the OR with the release of calcium from intracellular stores to the cytoplasm. The latter is based on the use of either the native form or a modified version of the olfactory CNG channel.

Some of the family I of GPCRs are able to activate a G_q protein that triggers the phospholipase C/inositol triphosphate (PLC/IP3) pathway, leading to a release of calcium from intracellular stores to the cytoplasm. The existence of such a transduction cascade has been suggested in olfactory neuron (reviewed in [22.57]) but, contrasting with the G_{olf}-cAMP-CNG cascade, it does

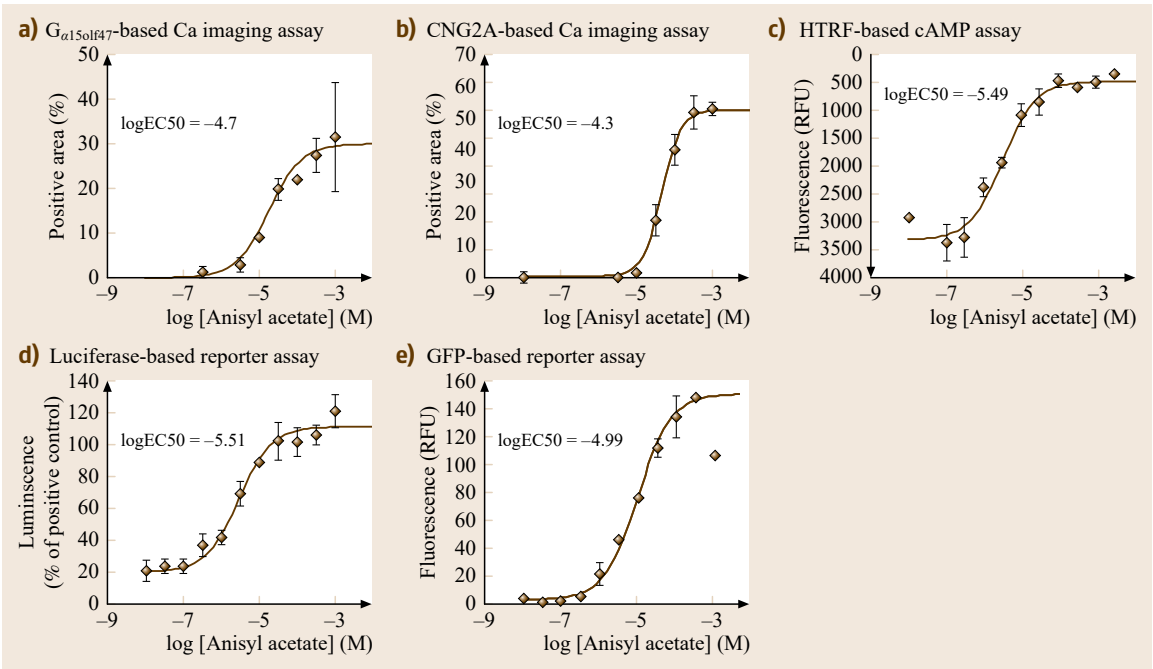

Fig. 22.1 Responses of OR2W1 to anisyl acetate measured with different functional assays

not seem to be mandatory for odor recognition and its physiological significance remains unclear. It has been reported in HEK293 cells that a calcium response occurs upon OR activation without the need of exogenous coupling G protein [22.11, 16]. However, we and others were not able to detect OR activation under this condition in our cell line. Other studies have shown that introduction of an promiscuous G protein such as $G_{\alpha 15}$ or $G_{\alpha 16}$ [22.13, 37, 38] or the chimeric $G_{\alpha qo}$ where the last 5 amino acids of $G_{\alpha q}$ were swapped for the corresponding residues of the $G_{\alpha o}$ [22.52] are required to allow the coupling with the PLC/IP3 pathway. In our hand, the chimeric $G_{\alpha 15olf47}$ was found to be the most efficient G protein for coupling the ORs to the intracellular calcium cascade.

In HEK293 cells that transiently express an OR along with a coupling type *q* G protein, an increase of fluorescence emission of the calcium-sensitive dye reflects the calcium burst that occurs upon activation of the receptor. This fluorescence increase can readily be monitored under a fluorescence microscope. An advantage of this experimental approach relies on its resolution at the cell level. Indeed, even if 1 or 2% of the studied cell population gives a recordable response to the stimulation by an odorant; they can be detected and an analysis can be performed. This may not be the case with conventional fluorometry that averages the response of the studied population. In this case, the response of a small percentage of cells will be too low to be interpreted as specific signal. It is probably the reason why quantification by calcium imaging under a microscope has been widely used to characterize the functional response of ORs. Experiments performed at ChemCom on several tens of receptors indicate that the percentage of responding cell determined by calcium imaging under a microscope upon transient transfection of the receptor may vary from 1% or less to about 50% of the cell population, depending on the OR tested.

The kinetic of calcium release in the cytoplasm of the cell, visualized by the increase of fluorescence emission (Fig. 22.2) can also be determined by microscopy-based calcium imaging. The burst of calcium is relatively rapid and occurs typically a few seconds upon injection of the OR activator. It recovers more slowly and a complete return to the basal level is observed within 2 min after injection (Fig. 22.2a). This characteristic time course of the calcium response has consequences when considering the G-protein-based calcium assay for screening purposes, as discussed in the following.

The time course of calcium response induced after a stimulation of OR2W1 with 1 mM anisyl acetate has

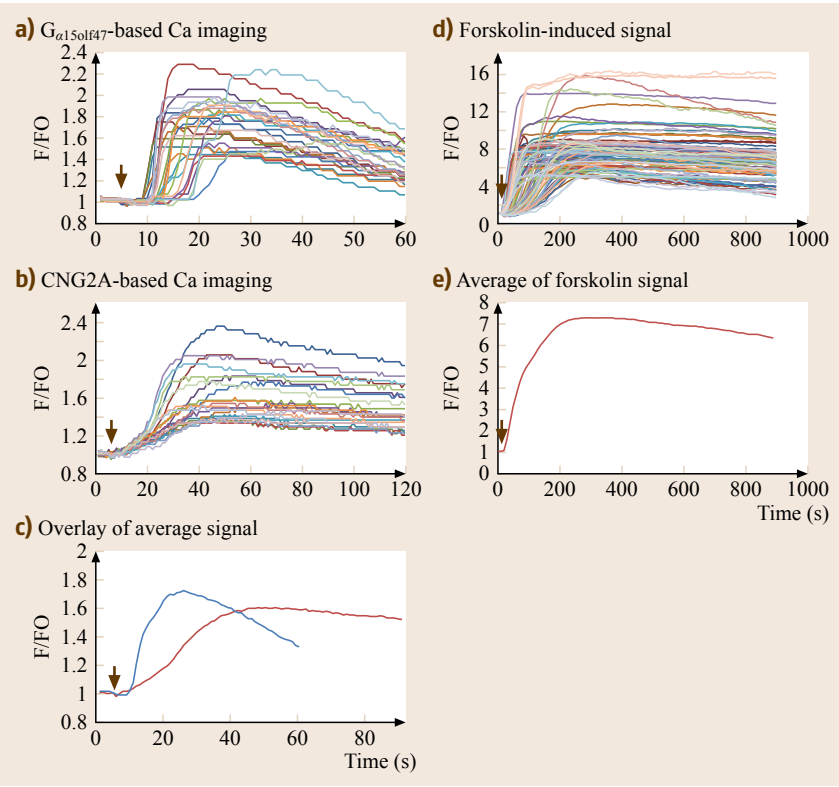

Fig. 22.2 Comparison of calcium responses relying on $G_{\alpha 15olf47}$ *or on CNG2A*

been determined using the $G_{\alpha 15olf47}$-based (Fig. 22.2a) or the CNG2A-based (Fig. 22.2b) calcium imaging assay. Each trace on the graphs in Fig. 22.2a,b represents the calcium fluctuation in a single cell. Arrows indicate the injection of the ligand. Note the difference of time scale between both graphs. The graph in Fig. 22.2c compares the average of traces from the graphs in Fig. 22.2a,b and clearly shows the difference in the response time courses.

The long-lasting signal observed with the CNG2A-based assay is further illustrated in graphs in Fig. 22.2d,e, where cells were stimulated with 10 μM (micromolar (μM)) forskolin in the presence of isobutyl methyl xanthine (IBMX). The signal is still close to its maximum 15 min after stimulation.

The use of CNG as an agent allowing a calcium response to OR stimulation in a heterologous expression system has also been described [22.40, 50]. Under these conditions, the calcium increase follows a slower kinetic. The firing of the cells begins more than 20–30 s after stimulation and a plateau is obtained after about 40 s (Fig. 22.2b). The recovery to the basal level can take several additional minutes (Fig. 22.2d,e). When the olfactory-specific guanosine triphosphate (GTP) exchange factor Ric8b [22.58] is co-expressed, it tends to reduce the latency, whereas the addition of the phosphodiesterase inhibitor IBMX slows down the return to the basal level.

From an experimental point of view, the rapidly fluctuating signal observed when using $G_{\alpha 15olf47}$ leads to take a picture every second during at least 1 min. Thus, the assay is slow and limits the throughput to 400–500 assay points per day. On the other hand, the long lasting and more stable signal observed when using CNG is compatible with the development of an assay based on end-point measurement. It consists in measuring the fluorescence just before the injection of the putative activator and executing one second measurements several minutes (5 min) after the injection. When working with multiwell supports, such as 96 well plates, a whole plate can be read within 5 min on a microscope equipped with a programmable automated stage and with a single injector. Thus, a throughput of 3000 assay points per day is a realistic estimate taking into account the handling of the plates and the setting up at the microscope. It needs, however, to be noted that the system works well for screening of a limited number of compounds to be injected because it limits the handling time. Therefore it is more tailored for the screening of one molecule of interest against a large array of receptors.

Direct Measurement of Cyclic AMP

The increase of intracellular cAMP has also been used to demonstrate the activation of ORs in a heterologous expression system [22.18, 58, 59]. Different cAMP assay kits are commercially available. At ChemCom, we have successfully used the homogenous time resolved fluorescence (HTRF)-based cAMP assay developed by Cisbio [22.60]. It consists in a competitive immunoassay between native cAMP produced by cells and the cAMP labeled with the dye d2. The tracer binding is visualized by a Mab anti-cAMP labeled with Cryptate. When excited by a 337 nm ultraviolet (UV) source, Cryptate normally re-emits a 620 nm wavelength light. Upon binding to labeled cAMP, the energy is transferred to the d2 dye and re-emitted at a 665 nm wavelength. The specific signal (energy transfer) is inversely proportional to the concentration of cAMP in the sample.

This type of assay is relatively simple to put in use and does not require additional elements such as coupling proteins. It can be set up for screening application. However, its cost can be deterrent for large scale screening campaigns and it is therefore better adapted as a secondary assay used for confirmation purposes.

Gene Reporter-Based Assays

Many recent OR deorphanizations have been performed using a reporter-based assay. It consists in introducing into cells, along with the OR of interest, a gene under the control of a cAMP sensitive reporter. Upon the stimulation of the OR and subsequent increase of cAMP, the reporter gene is transcribed and translated into a detectable protein. Several hours (typically, 4 h) after adding the stimulating agent, the reporter can be quantified. One of the advantages of this type of assay relies on its high sensitivity that is explained by the signal amplification that occurs at different steps between the triggering of the receptor and the synthesis of the reporter protein.

The most commonly used reporter corresponds to the firefly luciferase. The enzymatic activity of this protein can readily be quantified by a luminescence-based assay. The Dual-Glo assay provided by Promega allows a stable light emission that lasts during more than 30 min after addition of the reagent buffer. This characteristic is suitable when processing large series of plates and is convenient for high-throughput screening (HTS) purposes. The Dual-Glo assay also relies on the constitutive expression of a second enzyme, the *Renilla* luciferase, that serves for normalization of the expression. This normalization is not mandatory if the transfection of the receptor and the firefly luciferase is well standardized. Under these conditions, transfection of the *Renilla* luciferase gene can be omitted.

Alternatively to luciferase, other reporter genes under the control of cAMP sensitive promoter can be used. The gene of the secreted alkaline phosphatase (SEAP)

has been successfully used to demonstrate the activity of chemoreceptors [22.61–63].

The well-known green fluorescent protein can also serve as reporter [22.64]. It can be revealed by conventional fluorometry or under a fluorescent microscope. In our hands, it is less sensitive than the luciferase-based assay due to the fact that a fluorescence signal is less well detected and has a weaker signal-to-noise ratio than a luminescence-based signal. Therefore, a longer incubation period (8 h or more) is required to obtain a detectable signal with well-working receptors. On another hand, no particular treatment is required to reveal the fluorescence and the cells can be kept alive after measuring the fluorescence. This can allow some interesting applications, such as selection of responding cell populations by flow cytometry-based cell sorting or correlation studies of receptor expression (revealed by immunofluorescence) and functionality.

22.2.2 High-Throughput Screening for ORs

The importance of nonchemosensory GPCRs in physiological and physio-pathological processes has made them a target of choice for new drug discovery [22.65, 66]. In order to find new inhibitors as well as positive or negative modulators for these GPCRs or simply activators in the case of still orphan receptors, a strategy consisting of a systematic testing of large repositories of hundreds of thousands of small molecules was adopted by the drug industry and some large academic labs in the 1990s. This approach, known as HTS has led to some successes in identifying valuable activators for GPCRs.

Setting up the System

For ORs, an HTS approach appears as a pragmatic way to systematically deorphanize these but must be adapted to match its particularities. Contrasting with the random search of agonists among thousands of different chemical structures, libraries used for ORs deorphanization are composed of known odorants, increasing considerably the chances of success. On the other hand, it would not make a lot of sense to focus on the deorphanization of one single OR with an extended library of compounds, as it is done for GPCRs. At the very outset, all orphan ORs are of the same importance in the coding of odors. In fact, the OR-specific HTS must be seen as bi-dimensional by contrast with the classical, monodimensional HTS applied to pharma GPCRs. The first dimension corresponds to the molecules of the library to be tested (as in the case of HTS for pharma GPCRs) and the second dimension corresponds to the number of ORs considered. Therefore, the optimum strategy for the deorphanization of ORs consists in testing midsize libraries of odorants on a large array of ORs.

The construction of an expression library that contains all the purportedly functional human ORs constitutes a mandatory prerequisite to that kind of large-scale deorphanization screening. At ChemCom beginnings in 2000, we dedicated a significant effort in analyzing the weekly releases of the still in progress human genome sequencing project in order to constitute a database of human OR sequences. The same work was also done and published by other labs [22.67–71]. The collected information was used to clone the 388 unaltered human OR genes from genomic deoxyribonucleic acid (DNA) of different individuals into a mammalian cell expression vector.

The design of the odorant library may rely on different criteria. One of them might correspond to the organoleptic properties of the compounds. Ideally, the deorphanization library should contain representatives of all the category of odors. However, there is no general and accepted consensus for the description of odors and many different systems of odor classification have been proposed. Constituting the library on one particular classification might introduce a bias. A second criterion might correspond to the chemical structure of the compound. Although there is no obvious and systematic link between a given chemical function and a particular odor type, it can be assumed that a chemically well-diversified library will increase the chances to hit a large number of ORs. The availability of the compounds is also a nontrivial criterion. Unfortunately, there is no pre-made library dedicated to ORs research such as the chemical libraries that have been designed for the screening of GPCRs. Several hundreds of odor compounds coming from natural products or chemical synthesis are commercially available in flavor and fragrance (F&F) companies (e.g., Sigma Aldrich Fine Chemicals (SAFC) propose more than 1600 aroma raw materials in its catalog) and can be the primary source for deorphanization compounds. Finally, the construction of the screening library must rely on a compromise between these different criteria: the compounds will be chosen among known odorant catalogs and will cover different categories of odors. Since different classifications exist, one may consider compiling odor categories from different classification systems. Among different categories, attention will be paid to select the most diversified chemical structures.

Another important point when setting up a HTS concerns the choice of the functional assay. Again, it will have to fit different criteria that are mainly

1. The sensitivity of the assay
2. Its ability to be easily performed in large scale experiments
3. Its cost effectiveness.

A bunch of different functional assays have been used for HTS on nonsensory GPCRs (reviewed in [22.66]). For ORs, different assays that have been reported in the earlier section can be considered. The assays relying on a transient increase of intracellular calcium concentration imply that the measurement must be performed shortly after injection of the putative activator into the incubation buffer. Therefore the use of these assays for the screening of large libraries of compounds requires devices, such as the Fluorimetric Imaging Plate Reader (FLIPR) system from Molecular Devices or the Functional Drug Screening System (FDSS) from Hamamatsu Photonics, that are able to manage multiple injections and the recordings of several tens of conditions at a same time. Such kind of devices have been used to deorphanize ORs [22.40], but remains expensive. Assays based on the direct measurement of cyclic AMP, such as the HTRF-based cAMP assay, can also be considered for HTS. However, their cost can be deterrent for large-scale screening campaigns. At ChemCom, we have adopted the luciferase-based reporter gene assay as a primary screening assay. In addition to its sensitivity, it is relatively easy to achieve since it just requires a single step of reagent buffer addition prior to the reading. This assay can be fully automated, allowing a reasonable throughput of 5000–6000 measurements per working days, including controls. Typically, a large-scale deorphanization screening may involve a 400-compounds library and 300–400 different ORs that represents 432 000–576 000 measurements (each compound is tested at three different concentrations; control included).

Short Description of a HTS Run

The first step of screening consists in preparing screening libraries to be used during the entire screening campaign. Different compounds are diluted at a fixed concentration in a compatible solvent with the solubility of the compounds and the cellular assays. Usually, dimethyl sulfoxide (DMSO) is used as a solvent since it is relatively well tolerated by the cells and does not influence the functional response when used at a final concentration below 0.3% (v/v). For compounds that do not dissolve into DMSO, ethanol may be used as an alternative. The stock library is formatted in 96 well plates. Eighty wells are dedicated to screening compounds whereas the remaining 16 wells contain controls including blank (solvent alone), the positive activator forskolin that gives a maximum luminescence response and the ligand used to activate a reference OR. The stock library is stored at −20 °C and is used during the whole screening campaign. It is thawed at the day of the experiment to prepare three dilution plates, corresponding to the final concentrations to be tested in the μM range (in the incubation medium EMEM (Eagle's modified essential medium)). This dilution step is performed by the automated pipetting station Sciclone (Fig. 22.3).

The *Sciclone* (a) from Perkin Elmer corresponds to the compound management and liquid handling workstation with a *96 head*. It is linked to a *Twister* (b), a high capacity plate stacker. This stacker is a plug-and-play system offering flexibility. The *Twister* can manage three racks (c) that may each contain thirty 96-well plates. This station is also composed by a thermal plate sealer *PlateLoc* (d) from Velocity 11 that allows the sealing of the compounds plate after addition of argon gaz. This station is used to prepare the odorants plate at different concentrations, to carry out the serial dilutions, and to add the odorants on the assay plate for screening and/or validation experiments. The station is further equipped with a barcode reader (f). Each plate is labeled with a unique barcode in order to be tracked during the whole process. At this stage, the precise injection protocol is linked with the plate.

In a screening run or a validation experiment, after addition of ligands to the cells, the racks containing 96 well-culture plates are transferred to the incubation station corresponding to a CO_2 incubator (g) located close to the Sciclone pipetting station and exclusively dedicated to the incubation of the odorants during the assay.

The *Multidrop* station is composed by a liquid dispenser *Multidrop* (h) from Thermo scientific and a Twister plate stacker (i). This liquid handling device is used to add the lysis buffer at the end of the incubation.

The reading station is composed of the Spectramax M5 microplate reader (j) from Molecular Devices,

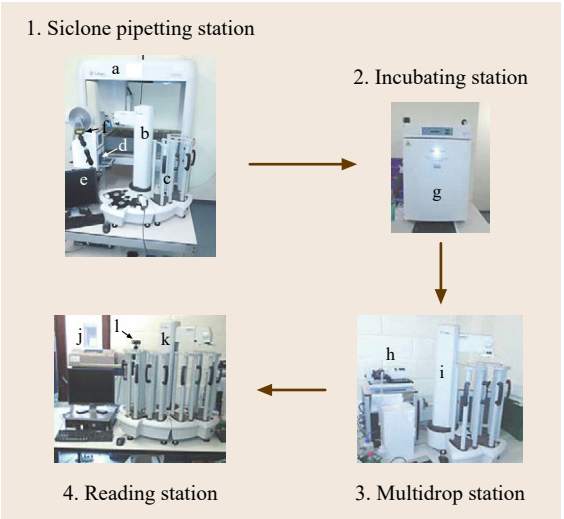

Fig. 22.3 The screening platform developed at ChemCom

a Twister plate stacker (k) and a barcode reader (l). After addition of the buffer, the plates are positioned on the twister, scanned and are red by the M5. The data are transferred along with the injection protocol to the screening database that performs the automated analysis for hit selection.

For each screening run, the cells are seeded in multiwell plates for which each well will represent a defined condition to be tested. Although different types of multiwell plates exist, ranging from 6 to 1536 wells per plate, we selected the 96-well type after a series of set up experiments. Higher formats of 384 or 1536 wells per plate required to be processed by robots for each pipetting operation, including cell seeding that requires to be performed in a sterile environment. The cell line used for screening is a HEK293T cell clone that stably expressed both RTP1S and RTP2 chaperone proteins [22.39, 72] and that was selected based on its ability to give the best functional response when expressing model ORs. For screening, the selected ORs are transfected along with the reporter gene using a standard lipofectant. This step is performed manually one day after the cell seeding. Sixteen hours after transfection, cells are incubated in the presence of the screening compounds. The addition of screening library to the cells is fully automated on the HTS platform (Fig. 22.3). After addition of compounds, the plates are stacked by a robotic arm on racks that can be put directly in a cell culture incubator for the 4 h incubation step. At the end of the incubation, the reaction buffer is added to the cells and after at least 30 min of incubation, the light emission due to the luciferase reaction is read on the Spectramax M5 luminometer. Again, these later steps, consisting of buffer addition and luminescence reading, are automated.

The main step of the screening relies on the determination of potential activators that are called *hits*. At ChemCom, we have developed a hit selection method based on a statistical analysis that is performed by plate. For each plate, the distribution of the responses is determined and the average value of the distribution is calculated. A well that shows a response higher than the value of average +2 standard deviations is considered as positive. The presence of outlier values (responses elicited by strong activators) can make the distribution of experimental data diverge from a normal distribution and can finally result in a skewing of the selection. Therefore, a Shapiro–Wilk test is first used to determine whether the distribution fits the Normal law (Fig. 22.4). If not, extreme points are removed and standard deviation is re-computed. To be granted as a hit, a compound must have produced a luminescence signal that exceeds the average +2 standard deviations value of the plate for at least two out of the three concentrations tested.

The hits are further validated by concentration–response analyses. Four independent tests of hit used at concentrations ranging from 10 nM to 316 µM are performed using the luciferase-based reporter assay. To be validated, the compound must produce a concentration-dependent increase of the luciferase signal that exceeds twice the value obtained for cells incubated with the buffer alone, in at least three out of the four tests. Additional experiments are performed to demonstrate that the activation is well receptor dependent by comparing concentration–response measurements performed in presence or in absence of the receptor. Confirmations

of the specific response of the hits on their respective ORs are also achieved using alternative functional assays, such as calcium imaging-based assays or direct measurement of cAMP, as described earlier.

22.2.3 High-Throughput Screening for Single Compounds

For molecules of interest, it can be worth considering an alternative screening approach that consists in screening the human OR library with the selected compound. This screening of ORs is performed in a similar way than the deorphanization screening with the notable difference of introducing 80 different ORs per 96 well plate. Each receptor is challenged with three different concentrations of the tested odorant (one plate per concentration). Hits are selected by applying the average +2 standard deviations method. However, we have observed that some of the receptors may present a basal activity that can be significant and may introduce a bias into the analysis. Therefore, an additional control, consisting in a plate containing the receptors that are incubated with buffer alone, is systematically introduced during the screening of ORs and serves to normalize the values of OR stimulated by the molecule of interest.

The validation process is achieved by concentration–response analysis as described earlier. Its extent is hardly predictable since it depends on the number of hits that may vary in function of the tested odorant. As an example, if hits are found for 50 ORs during the screening phase, a complete validation process can be performed within a week. Under these conditions, the screening of ORs has been proved to be, in our hands, a valuable and rapid approach to find matching receptors for odorants of interest.

22.3 Applications

22.3.1 Odorant-Receptor Characterization and Design

Once a first activator is identified for an OR, it is of interest to determine the range of selectivity of the receptor. According to the current odor coding theory, an OR may respond to more than one ligand and these activating compounds may present clearly different structures although sharing common points. The way to unravel the receptor selectivity consists in performing structure–activity relationship (SAR) studies that use the first identified activator as a starting reference [22.73]. One example of such SAR approach applied to OR has been provided by *Araneda* et al. [22.74] who showed that the rat I7 receptor was activated by aliphatic aldehydes having a length between ≈8 and ≈12 Å, with octanal as a reference agonist. The list of identified activators includes branched aldehydes such as (among others) 7-methyloctanal or 3,7-dimethyloctanal, and double bound-containing aldehydes such as *trans*-2-octenal or *trans*,*trans*-2,4-octadienal. It was further demonstrated by exploring the activating potential of different octanal analogs that, in addition to their aldehydic moiety, activators must have an optimal length exceeding 6.9 Å, as it is the case for octanal in its extended conformation [22.75]. Aldehydes of at least five carbons with a shorter length, below 6.5–6.9 Å, were found to bind but not to activate I7 and turned out, to be antagonist of the receptor. Another example of the SAR study was performed on the mouse mOREG receptor [22.38, 76, 77]. The 4-allyl-2-methoxyphenol, also known as eugenol, was found as the initial activator of this receptor. Series of molecules where one of the three functional groups linked to the benzene ring of eugenol was replaced by an alternative one were assessed. It allowed determining what kind of functional group can be tolerated in each position. For example, replacing the allyl group by an aldehyde (generating vanillin) or by a ketone does not affect the ability of the molecule to strongly activate mOREG. In contrast, a methyl or an ethyl moiety at this para position reduces the activating potential of the molecule whereas a carboxylic acid or an amine completely kills it. Likewise, the methoxy functionality in the ortho position can be substituted by an ethoxy or a methyl rest but not by a hydroxyl group. The swapping of the hydroxyl moiety of eugenol for an ethoxy or an acetate group results in a decrease of activity. It was later found that mOREG can also be activated by other classes of molecules nonrelated to eugenol, including other benzene-derivatives, polycyclic compounds, and cyclohexane-derivatives [22.63]. At ChemCom, the receptive range of OR51E1 was investigated by testing different series of carboxylic acids, starting with valeric acid as the reference ligand. It was found that the optimal structure, among the 60 different molecules tested, was the 5-norbornene-2-carboxylic acid. This compound possesses a 6-carbon ring where the carbons in positions 2 and 5 relatively to the carboxylic function are bridged by an additional $-CH_2$, conferring a rigid tri-dimensional shape with a calculated volume of 125 $Å^3$. The volume of the 5-norbornene-2-carboxylic acid must fit

the bulk of the receptor binding pocket since additional methylations of the bridged ring completely abolish the activating potential of the molecule.

Identification of the activators of a given OR associated with a 3-D modeling of this receptor can serve to predict the ligand binding pocket and its mechanism of interaction with the agonists. This type of in silico investigations have been performed on different human and murine ORs (see among others, [22.10, 43, 63, 74, 78, 79]; for a review see [22.80]). Based on this, modeling predictions of new activators can be executed and further confirmed experimentally. However, there are very few examples of a successful identification of new activators based on the in silico modeling of OR-agonist interactions and this approach still needs to be fed by experimental data. An alternative approach has also been proposed that exploits the results of large SAR studies to predict the suitable structure a compound must have and what it must avoid to be a bona fides activator of a selected OR [22.8, 81]. It consists in the identification of the chemical determinants that are shared by the identified activating compounds and in the computation of a 3-D model of a generic activator. New molecules that fit the model may be experimentally assessed as potential agonists. It needs to be noted that this data mining approach requires extensive SAR studies in order not to miss activating compounds that are only poorly or even not structurally related to the initial identified agonists. The aforementioned example of mOREG that was initially found to respond to eugenol-related compounds and more recently demonstrated to be activated by other unrelated families of agonists, is well illustrative of this necessity.

For some ORs, the receptive range appears so huge that the deduction of a generic agonist structure seems a hopeless task. Some examples of very broadly tuned receptors have been described [22.10, 82] but in our hand, OR2W1 is viewed as the archetypal example of that kind of OR. About 200 different activating molecules have been identified so far. This receptor also possesses the highest validated hit ratio of all the ORs we have deorphanized. In a screening performed with a chemically well-diversified library of 300 compounds, 9% of the molecules induced a validated activation of the OR. The agonist list includes aliphatic, monocyclic, or polycyclic alcohols, aldehydes, and carboxylic acids. Many aromatic compounds were also found among the activators. However, a more careful analysis of the potency of different agonists reveals some trends from this apparent lack of selectivity. For example, the optimal size of aliphatic activators corresponds to 7–8 carbon-containing chains. Considering other aliphatic chain-related molecules of the same length, *n*-alcohols are stronger agonists than aldehydes that are, in turn, stronger than acids. Likewise, saturated cyclic structures seem to be preferred over aromatic cycles as exemplified by the 1-cycohexylethanol that has a 10 time higher potency than its aromatic counterpart, the 1-phenylethanol. Interestingly, none of the molecule with a bulky moiety such as bridged cycles was found to activate OR2W1. Similarly, none of the tested molecules that contain primary amines are among the long list of agonists. At this stage, the tentative prediction about structural requirements for OR2W1 activators is that they must be more or less flat and must have both a hydrophobic and a hydrophilic moiety.

From different screening campaigns that have been performed at ChemCom, more than 100 ORs have been robustly deorphanized. Albeit not all of these ORs were submitted to extensive SAR studies, a global analysis of our data shows that receptors can be set in different categories regarding their agonist selectivity. Along with OR2W1, a series of ORs can be classified as broadly tuned since they respond to more than 20 different molecules among which obvious structural or organoleptic similarities are hard to identify. The OR1A1 that was previously reported to respond to a large series of activators [22.10] belong to this category. More surprisingly, OR1D4 that was found to respond to bourgeonal and to be expressed in both the olfactory epithelium and in sperm cells [22.11, 83] may also be labeled as broadly tuned. A second category encompasses ORs that respond to a structurally defined family of activators. For example, receptors activated exclusively by carboxylic acids have been identified. In addition to the earlier discussed OR51E1, other members of class 1 ORs present a similar selectivity for molecules with a carboxylic function. Receptors that are selective for agonists that contain a hydroxyl or an aldehyde group have also been discovered as well as ORs that only respond to cyclic nitrogen-containing aromatic substances such as pyrazines. The last category regroups receptors that are defined as narrowly tuned. In some cases, only a very small number of agonists is found for an OR, despite the effort invested in SAR exploration to identify alternative agonists. OR7D4 [22.4] is a good illustrative example of such narrowly tuned OR since it responds only to 5-α-androst-16-ene-3-one, androsta-4,16-dien-3-one, and with a very poor efficacy to androsta-4,16-dien-3β-ol. Likewise, OR8D1 is selectively activated by sotolone (3-hydroxy-4,5-dimethylfuran-2(5*H*)-one) and abhexone (3-hydroxy-4-methyl-5-ethylfuran-2(5*H*)-one), two structurally similar molecules that differ by the elongation of the methyl-function in position 5 of the cyclic lactone structure by one carbon moiety to yield an ethyl function in the latter. Recently, the range of selectivity of OR51E2

that shares a high degree of homology with OR51E1, was found to be restricted to two short chain carboxylic acids: propionic and acetic acids [22.84].

It is also worth exploring and comparing the receptive potential of closely related receptors. Indeed, some ORs corresponding to clearly differentiated genes in a genome may share a high degree of homology in their primary structures. A comparative analysis of the range of selectivity of these so-called paralogs may helps to understand the precise mechanism of interaction of the ORs with their agonists. The human OR subfamily 10G is an interesting example for such a multireceptor SAR study. Four of its members, OR10G3, OR10G4, OR10G7 and OR10G9 have been deorphanized by us (unpublished results) and by others [22.5, 6] with eugenol- and vanillin-related molecules. An SAR with a series of 28 analogous compounds with a structure derived from the 2-methoxyphenol (Fig. 22.5, compound 1) was performed on these four ORs. The trend that emerges from this study is that OR10G7 is more tolerant in term of selectivity, although it has a higher affinity for molecules with three carbon chain substitutions in the para position, relatively to the hydroxyl group on the benzene ring (Fig. 22.5, compounds 3, 4, 5, 14 and 23). OR10G3 showed a narrower selectivity, with a preference for compounds having a short hydrophobic substituent in the para position. OR10G4 and OR10G9, the very closely related paralogs of OR10G7 (the three ORs share up to 95% of homology in the transmembrane domains and loops), both responded to the same compounds. Their selectivity is also narrower than that of OR10G7 and more oriented to compounds with a short substituent in the para position. However, compared to OR10G3, they exclude different compounds from their agonist list. Interestingly, in a recent study [22.5], different haplotypes of OR10G4 were assessed in vitro and the data were correlated to the smelling performances of individuals bearing the different OR10G4 alleles. It turned out that OR10G4 can partly explain the intensity and valence perception of the 2-methoxyphenol (also known as guaiacol) but not of vanillin or ethylvanillin. Since we used a single haplotype of each receptor in our comparative SAR study on OR10G paralogs, it would be worth taking into account the allelic variation for the comparison of paralog's selectivity.

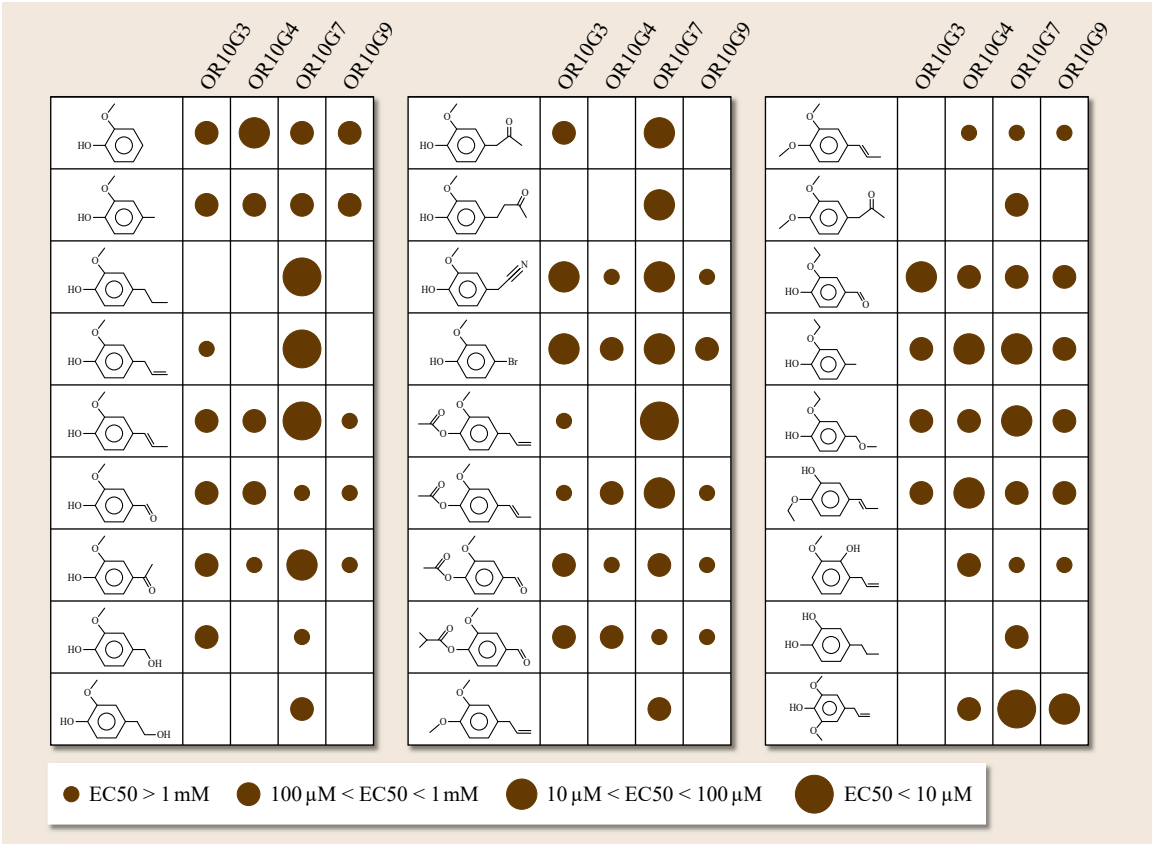

Fig. 22.5 Comparative structure–activity relationship study on OR10G receptors

From simple in vitro analysis based on heterologous expression systems, the interaction of a receptor with an odorant molecule can be considered as a clue but not as an evidence of the implication of this OR in the perception of the odor of its activator. The fact that many ORs are activated by several compounds with clearly different organoleptic properties reinforces the idea that the (cor)relations between the chemical structures and the odor families are not straightforward. However, some ORs are associated with molecules belonging only to well-defined odor families. In this case, dedicated SAR focusing on compounds that are known to possess a particular note may help to identify the corresponding ORs. Musk molecules, whatever their chemical structures: polycyclic, macrocyclic, nitro, and more recently alicyclic, are an example for which ChemCom has found very specific ORs. At ChemCom, different representatives of the musks families have been introduced in a screening library and several human ORs were found to respond to at least one musk molecule. After an extensive musk-oriented SAR, it turned out that some of the receptors are activated by representatives of the four chemical families that possess a musk note while others have a restricted profile of activation. This is reminiscent of mOREG and of the OR10G family described earlier. The association of ORs with different musk families is suggestive of their involvement in the perception of musky odors and makes them serious candidates for screening of additional libraries dedicated to the identification of new musk molecules. A similar example of association of human ORs with molecules sharing an amber note is also under investigation at ChemCom.

22.3.2 OR's Antagonists

Reducing the perception and the impact of bad smells represents an important challenge for the flavor and fragrance industry. Classical approaches for fighting malodors consist in overpowering the undesirable smell with a strong pleasant fragrance or in associating it with a weak but pleasant odor that makes the overall perception shift from unpleasantness to a more acceptable quality. Interfering with the perception of a malodor using an odorless agent that will specifically block the corresponding ORs appears as a new promising strategy. The recent advances in the expression and deorphanization of ORs has allowed to assess this concept experimentally. ChemCom has now evidences for the existence of odorless volatile blockers that counteract some malodors on human panels.

Identifying Antagonists

So far, there are some reports of molecules that were demonstrated to antagonize given ORs. They have been found either more or less serendipitously or by a more rational approach. For example, it was observed that undecanal inhibits the activation of the human OR1D4 by bourgeonal [22.11] and also reduces the perception of bourgeonal as shown by a psychophysiological study [22.83, 85]. In some cases, inhibitors were found among members of the same chemical family to which the agonist belong, as it is the case for methyl isoeugenol and isosafrol that antagonize mOREG [22.86, 87] or small aldehydes that antagonize the rat I7 receptor [22.75]. This makes sense since the mode of action of competitive antagonists consists in occupying the binding pocket and in stabilizing the receptor in an inactive conformation. If the antagonist has a stronger affinity for the receptor compared to the activator, the inhibitory effect is observed. It is therefore not surprising that molecules competing for the same binding site present strong structural similarities. A simple way to identify inhibitors for a receptor consists in checking the antagonist potential of structural analogs of its cognate agonist(s). Such an approach can also be coupled to 3-D-modeling of the receptor. A molecule that is predicted by a docking simulation to bind strongly to an OR but that did not activate the receptor when assayed experimentally has a good chance to be an antagonist. This is well exemplified by the study on the mouse receptor OR42-3 where undecanedioic and dodecanedioic acids were identified as antagonists by this way [22.43]. The data mining approach described by *Sanz* et al. [22.81] is a potential alternative to predict the antagonist nature of molecules. In this case, vanillin that was classified in a subgroup of molecules that contains other inhibitors of the human OR1G1 did well antagonize this OR in an in vitro assay.

It appears that this approach is not a definitive solution for identification of efficient antagonists of ORs. An OR may sometime share strong similarities with an agonist, ChemCom has discovered blockers that are completely different and hardly predictable based on the agonists' structure. As for activators, the systematic way to fish out these antagonists relies on an in vitro screening approach.

High-Throughput Screening of Antagonists

Although the principles that rule the design of an antagonist HTS are similar to those of HTS applied to OR deorphanization, some differences deserve to be pinpointed. First, the selection of the library of compounds relies on a quite different philosophy. Indeed, in contrast to deorphanization compounds that are preferably selected from known odorants, no organoleptic characteristic is predictive of an antagonist potential. Therefore, the paradigm for OR antagonist screening is the same as for other GPCRs: the larger and more chem-

ically diversified the library is, higher are the chances to find an antagonist. Already thinking to concrete applications, one might introduce some constrains such as selecting weak odorants or odorless compounds and molecules that are volatile. It may also be of interest to block pleasant odors. First from a basic view, it could allow the demonstration of the involvement of a given OR in the specific perception of a given odor. In other cases, it might allow the use of materials in applications where their strong bouquet could represent a limiting factor such as thymol for its bactericidal properties.

Contrasting with the deorphanization screening that is preferentially performed on a large array of ORs, the search of antagonists is restricted to OR that responds to malodors. On a technical point of view, an antagonist HTS run is very similar except that the agonist is added to the incubation medium along with the screened antagonist candidate. As usually done for screening of GPCR, the agonist is set at a concentration (efficacy concentration 80 (EC80)) that triggers 80% of the maximal response of the receptor [22.88]. It corresponds to a compromise between obtaining a well detectable signal and avoiding an over-saturation of the receptor that would hamper the identification of antagonists. This means that an accurate characterization of the OR interaction with its reference agonist by concentration–response analyses must have been performed prior to considering it for an antagonist HTS. When different activators of an OR are available, the most potent is often the best choice. As in the case of activator screenings, three concentrations of the putative antagonist are tested in order to limit the occurrence of either false positive or false negative results. The luciferase-based functional assay can also be used as primary assay for antagonist HTS and is performed as described earlier.

The hit selection process is also based on the same statistical method but, for antagonists, hits are defined as compounds that produce a response under the value of the mean minus 2 standard deviations. The selected hits are also validated by concentration–response experiments. A very important step in the validation process consists in assessing the specificity of the hit. Indeed, the tested chemicals might interact negatively with any of the components of the intracellular signal transduction cascade that is required to induce the luciferase synthesis or, more generally, they could produce a toxic effect that would result in a decrease of the measured signal. To identify these false positives, each hit is tested in concentration–response experiments on cells that do not express the receptor but are stimulated by forskolin, a direct activator of adenylate cyclase III that elicits a strong luciferase response. The hits that inhibit the forskolin-induced response and the OR agonist-induced response at the same concentrations are rejected.

Sensory Evaluation of Antagonists

Once confirmed, an OR-antagonist couple is the starting point for further characterization and investigation. When working on human ORs, the first question to answer is: Does the antagonist block or reduce the perception of given odors? This requires an accurate psychophysiological evaluation of the antagonist that must be performed on well-trained panelists able to score precisely the odor intensity in the presence or in the absence of the antagonist. Although there are several reports of antagonist identifications for murine or human ORs [22.11, 40, 43, 81, 86, 87], there is only one example, published so far, of an antagonist that has been found to inhibit a human receptor and that was further demonstrated to reduce the perception of the receptor's agonist [22.83]. The antagonist influence is even more difficult to demonstrate on mice, since animals cannot directly report on their perceptions. Therefore, humans remain the best models for studying OR antagonism. By analogy with drugs that antagonize GPCRs, the discovery of inhibitors for human ORs will provide tools for understanding the sense of smell in humans. OR antagonists will allow making the link between the activity of an odorant molecule on an OR (observed in vitro) and its result on the brain activity measured for example, in functional magnetic resonance imaging (fMRI)-based studies and finally on the perception assessed by a psychophysiological approach. It will be a way to demonstrate the involvement of a given OR in the perception of a given odor. Odorless blockers will be of high value in this respect. ChemCom identified several tens of antagonists of human ORs that are involved in the perception of pleasant odors or malodors such as sweat, bathroom, kitchen, mildew, urine and hair care products. Some were tested on human panels and have confirmed their in vitro activity in human noses.

Antagonist SAR Studies

Following the same philosophy as the one that prevails for activator, it can be worth investigating the structure–activity relationship of an OR-antagonist couple. That kind of studies can be motivated by different reasons such as identifying more appropriate inhibitors for specific applications or alternative blockers with more suitable physicochemical or organoleptic properties.

Exploring implies chemical synthesis which represents significant costs but will allow to identify new chemical structures leading to patent applications and the selection of the most appropriate compounds with respect to their use.

22.3.3 Modulators

The concept of allosteric modulation is emerging in the field of GPCR [22.89–91]. It is defined as the ability of a compound to interact with a region of a receptor that is different from the activator binding pocket and leads to a potentiation of the activation of the receptor by its cognate agonists that interact with the orthosteric binding region of the receptor (i. e., the binding pocket). A PAM may have no intrinsic ability to activate the receptor, although the case of allosteric agonism has been described. For GPCRs of pharmaceutical interest, PAMs represent a promising new approach since they can act more specifically and present reduced side effects.

Such modulators have first been identified for members of the family C GPCR that are characterized by the presence of a large extracellular domain. More recently, PAMs have been found for GPCRs of family A to which ORs belong. Although there is no example of PAMs described for ORs until now, this possibility remains to be investigated.

The screening of allosteric modulators is about the same than for antagonists. A particularity of the PAM screening is that the reference agonist is set at a concentration (efficacy concentration 20 (EC20)) that induces an activation corresponding to 20% of the maximal response of the receptor. The hit selection is performed as described for the agonist and hits are validated by concentration–response experiments where the reference agonist is set at its EC20. To discriminate between a true allosteric modulation and simple additional agonist effect, it is recommended to make a first preliminary agonist screening of the library on the selected OR. Such compounds must then be removed as they might also introduce a bias into the data analysis.

The ORs aimed at by this research are preferably selected within the OR responding to fragrances or flavors of interest. A PAM could boost the perception of a particular compound or even of a more complex bouquet. PAMs represent an important commercial value as some ingredients used in perfumery, such as hedione, have been empirically found to possess that sort of property. It is possible that they act as PAMs but their target receptors remain to be identified. On an economical point of view, PAMs could serve to lower the quantity of expensive odorants that are ingredients of commercial fragrances or that are rarely used because of their production costs. Likewise, reducing the concentration of certain ingredients that have raised concerns about their potential human or ecotoxicity could represent an interesting opportunity for PAMs. If it may be experimentally confirmed, the concept of olfactory PAM will certainly be promising in view of a great commercial success.

22.4 Other Chemosensory Receptors

22.4.1 Deorphanizing Other Receptors Involved in Olfaction

Two other types of chemosensory receptors have been described in the olfactory mucosa. The first one corresponds to trace amine associated receptors (TAARs; [22.61]) and the second to vomeronasal type I receptors (V1Rs ; [22.92]). In mouse, TAARs are expressed in the main olfactory epithelium and in the Grueneberg ganglion [22.93]. At least some of them respond to amine compounds that trigger stereotyped behavioral responses [22.94] or are involved in social interaction [22.95]. Very few is known about the olfactory role of TAARs in human. Of the six full gene sequences identified in the human genome, only TAAR1 and TAAR5 have been detected in the human nose [22.96, 97] and have been deorphanized [22.97–99]. TAAR1 responds to a large array of amine compounds whereas the TAAR5 receptive range is restricted so far to three compounds, among which trimethylamine is the most potent.

Although distantly related to ORs, TAARs trigger the same transduction cascade in the olfactory neuron. This means that functional assays that work with ORs can also be used for TAARs. At ChemCom, we consider TAARs as a putative additional class of odor receptors and we include them in our screening campaigns.

V1Rs refer to a family of putative pheromone receptors that are present in the vomeronasal organ of different species, including mouse and rat [22.100]. In human, the vomeronasal organ may still be observed but seems completely vestigial [22.101, 102]. Only five sequences of full gene remain in the human genome and the expression of four of them have been detected in the olfactory epithelium [22.103, 104]. The coupling cascade of the V1Rs is not yet clear but does not seem to stimulate adenylate cyclase. Only one publication reported the identification of aldehydes and alcohols as activators of human V1Rs using a heterologous expression system [22.105]. So far, only the activation of hV1R1 has been confirmed by an independent team using a purified receptor [22.106]. The role of human V1Rs in percep-

tion of odors or in perception of pheromones remains to be discovered. Nevertheless, it could be worth pursuing the research effort on human V1Rs since they might be involved in human pheromone perception, a concept that is still controversial.

22.4.2 Deorphanizing ORs in Animals

Vertebrates

Interacting with animal olfaction can be the basis of a series of applications, such as pest control, improvement of feeding of pets, or breeding animals. For many vertebrates of commercial interest, olfaction is the main sense used for food seeking, social interactions, or alarming to danger. In terms of mammal pest control, identifying receptors that mediate the alarm signals induced by a predator-emitted molecule may lead to the development of highly efficient repellents. In contrast, blocking the perception of molecules that play a role in mating can be a specific and environment friendly way to limit the proliferation of undesirable species in a particular area. Since the principles of odorant detection have been well conserved throughout the evolution of the vertebrates, consequently, the receptors that mediate olfaction are also concerned by this conservation. Therefore, the screening system set up for human ORs can be applied to deorphanize ORs of any species of interest belonging to this phylum. However, it is important to note that the number of ORs predicted to be functional vary from one species to the other but reach close to 1000 or more in mouse or dog. Therefore, the approach of OR screening, as described for human ORs seems a better option. It implies some knowledge of the physiological and behavioral aspects linked to the olfaction of the targeted animal and requires a prior identification of odorant (an individual molecule or a blend) of interest that can be either natural attractants or repellents. The receptor screening approach coupled to an SAR study may help in the design of new, more efficient or cheaper to produce compounds acting on the behavior. Seeking antagonists follows the same logic as described for human ORs. First, receptors for attracting molecules are sought in a receptor screening and, once identified, are submitted to an antagonist screening using a dedicated library of volatiles.

If nothing is known about the number of genomic sequences of the animal's ORs, the sequencing of its whole genome or its olfactory transcriptome may reasonably be considered. Various companies proposed an à la carte whole genome or transcriptome sequencing for an affordable price that does not exceed 10 000 dollars. Likewise, the physical obtaining and cloning of the OR open reading frames into expression vectors can be outsourced to specialized companies for about 400 dollars per sequence and requires 6 months. Assuming a target animal that would harbor 1000 ORs in its genome, a scale time of 1 year and budget of ≈400 000 dollars are realistic estimates for constituting a usable library of ORs.

Animal TAARs and vomeronasal receptors are targets of potential interest as they were demonstrated to play a role in avoidance behavior of mice [22.94] and at least one of the mouse TAARs (TAAR5) is involved in social interaction [22.95]. Similarly, vomeronasal receptors from type 1 and type 2 seem to play a role in rodent social interactions and are considered as pheromone receptors (reviewed in [22.107]). If the TAAR repertoire remains limited to less than 20 members in the studied mammal species and can be easily managed as additional ORs in screening, both vomeronasal receptor families own more than hundred members in rodents. They represent potentially interesting targets for pest control programs but robust screening systems allowing a systematic identification of V1R and V2R activators or inhibitors are still to be developed.

Insects

Some insects are well-known pests for agriculture or represent vectors for various infectious diseases that affect humans. The discovery of insect ORs [22.108–110] has paved the way for the elucidation of the molecular mechanisms of that chemical perception. Although the general functioning of the insect and vertebrate olfaction relies globally on the same principles, the receptors involved are different. In insects, ORs correspond to a heterodimeric complex where one of the subunits, known as OR83b or ORCO (olfactory receptor co-receptor), is common to all the ORs whereas the second subunit that is variable, defines the selectivity for the activator. Both subunits are related to the GPCR family but present an inverted membrane topology compared to classical GPCR members [22.111]. It has been shown that insect ORs behave as ion channels that promote entry of calcium in the olfactory neuron upon activation by its agonist. In addition to this fast ionotropic response, activation of the dimer also results in the production of cyclic AMP [22.112, 113].

Different functional expression systems have been assessed for insect ORs. The Xenopus oocyte-based expression system coupled to an electrophysiology-based assay has led to the deorphanization of multiple ORs [22.114–117]. Likewise, a calcium-based screening platform relying on HEK293 expressing mosquito ORs has been described and led to the identification of conventional *Aedes aegyptis* OR ligands and less conventional ORCO agonists [22.118]. Because of their higher throughput capacities, it is probable that these

heterologous cell-based systems will outperform the more conventional approach based on antennography or single sensillum recording, although these later techniques present the advantage of not requiring a prior identification and cloning of ORs for detecting olfactory active molecules.

Additional proteins such as odorant binding proteins (OBPs) or sensory neuron membrane proteins (SNMPs) have been proposed as possible partners in the activation of insect ORs (reviewed in [22.119, 120]). OBPs are present in the lymph that surrounds the neurons in the hairs of the sensory organs. They serve as solubilizer for odorant and pheromonal compounds. OBPs could also be involved in transporting the ligand to the receptor, although a direct interaction of OBPs with the ORs remains to be demonstrated. The fact that functional expression of insect ORs in heterologous systems does not require OBPs shows that these latter are not mandatory for the activation of the receptors. The number of OBP genes varies from one insect species to another, but can encompass several tens of members. This is suggestive of a ligand selectivity for OBPs that has been confirmed experimentally. Along with ORs, OBPs constitute potential targets for the identification of compounds that would interfere with the chemical perception of insect pests. Protocols that allow the in vitro quantification and monitoring of the binding of volatile compounds with insect OBPs have been described [22.121] and can be up-scaled to develop HTS for OBPs.

As noticed for mammals, the affordability of genome sequencing will certainly promote the extension of HTS to ORs and OBPs of insects. Despite the high variability from one species to another, the known insect olfactomes seem more limited than in mammals [22.122], a point that should certainly facilitate the screening effort. Regarding the number of pest-related issues and the growing need of ecologically safe alternatives to classical insecticides, the development of a new generation of species-specific attractants or repellants may represent a business opportunity for more than one industrial player. It is to bet that the first molecules of this type that will reach the market will represent the necessary proof of concept for fostering the interest for HTS approach in the programs aiming to manage insect populations.

22.5 Concluding Remarks

Progresses achieved in the functional expression of human ORs have paved the way for a systematic deorphanization of these chemoreceptors by an HTS approach. Owing the rapid progress in deorphanization in hORs and in their functional expression, it can be predicted that this project will be completed soon, leading to the constitution of a first olfactory map that will index the activators for all functional human ORs. With an increased number of deorphanized and characterized ORs, it will be easy to determine the profile of ORs responding to any single molecule and to more complex mixtures, in terms of OR activation and/or OR inhibition. This powerful tool will facilitate new applications such as identifying or designing new odorants or blends that will create new sensations or will mimic complex or expensive aromas or fragrances. The accumulation of data from the deorphanization project will also help the development of more accurate in silico modeling of OR-ligand interactions that could ultimately replace the cell-based experimental approach. As there are many more odorant materials (single compounds or blends) than ORs, an important challenge will consist in understanding the interaction of several molecules (including nonodorant compounds in the case of complex extracts) at the level of the receptor. Any compound could be either an agonist, an antagonist, or a positive or a negative modulator; several compounds could act at the receptor level leading to a degree of activation that cannot be anticipated in sensory studies. This might come out onto significant changes in the composition leading to costs saving in commercial formulations or replacement of harmful compounds.

The identification of specific antagonists for ORs activated by malodors that both inhibit the OR response in vitro and block or reduce the perception of the malodor by human, represents a key step towards commercial applications. Therefore HTS-based antagonist search will represent a major part of the industrial activity on human ORs. The concept of antagonists applied to ORs is likely to open new opportunities and additional values as antagonists will not induce habituation in contrast to well-known covering or masking formulae. Therefore, those blockers can be incorporated in consumer products (e.g., perfumes) allowing their users to profit themselves of a protection against external offensive odors.

Many ORs are expressed in nonolfactory tissues [22.123] where they may play a physiological role (reviewed in [22.124]) and in the following chapter of this book). Therefore, deorphanization of the ORs, establishing SAR for agonists and identifying antagonists may raise interest for the drug industry. In a recent re-

port that describes the implication of the mouse Olfr78 in blood pressure regulation, ectopically expressed ORs have been viewed as chemosensors [22.84]. Thus, deorphanization of the human ortholog, and identification of the natural endogenous activators for these ORs allows us to investigate its function. Likewise, antagonists of ectopically expressed ORs can constitute valuable tools to demonstrate the implication of these receptors in physiological processes. For example, two antagonists of OR51E2, the human ortholog of Olfr78, have been fished out from an antagonist screening performed at ChemCom and might be of interest to assess the involvement of this receptor in blood pressure regulation.

As this chapter intended to show, the HTS approach applied to human and animal ORs is one way for enhancing our detailed knowledge of the early stage of olfactory perception, but also represents an opportunity in the biotechnology sector, including the drug industry, for the development of original industrial applications.

23. Psychophysical Testing of Human Olfactory Function

Richard L. Doty

This chapter is an up-to-date review of psychophysical means for testing the human sense of smell. Strengths and weaknesses of major psychophysical paradigms are discussed, including ones associated with the measurement of odor detection, discrimination, identification, memory and both suprathreshold intensity and pleasantness assessment. Factors that influence olfactory test results are discussed in detail, including the influences of test parameters, such as test length, on test reliability. It is pointed out that non-forced-choice tests, unlike forced-choice tests, are incapable of discerning subject biases and malingering. Issues related to the comparison and interpretation of test results from nominally disparate tests that differ in sensitivity, reliability, operational demands, and other factors are discussed.

The goal of this chapter is to provide an overview and discussion of the major psychophysical methods available for assessing human smell perception. In general, psychophysical tests are those that quantify perception on the basis of verbal or other overt conscious responses on the part of a subject. Psychophysical measurement is historically rooted in concepts developed in the 19th century by such notables as *Weber* [23.1] and *Fechner* [23.2], and in the early to mid-20th century by *Thurstone* [23.3], *Stevens* [23.4], and others (*Peryam* [23.5]). Detailed information regarding the history, development, and mathematical foundations of psychophysical methods, including ones directly associated with olfaction, are available elsewhere [23.4, 6–18].

23.1 Stimulus Presentation Procedures

As illustrated in Fig. 23.1, numerous devices have been used to present odorants to humans for psychophysical testing. These include:

1. The draw tube olfactometer of *Zwaardemaker* [23.17, 19]
2. Glass sniff bottles and specialized cannisters [23.20–26]
3. Odorized glass rods, wooden sticks, felt-tipped pens, alcohol pads, plastics embedded with odorants, or strips of blotter or tissue paper [23.27–33]
4. Plastic squeeze bottles [23.34–38]
5. Bottles from which blasts of odorized air are presented [23.39, 40]
6. Microencapsulated *scratch and sniff* odorized strips [23.41–44]
7. Laboratory-based air-dilution olfactometers [23.23, 45–54]
8. Exposure chambers or hoods, including mobile units with analytical equipment and subject waiting rooms [23.46, 55, 56].

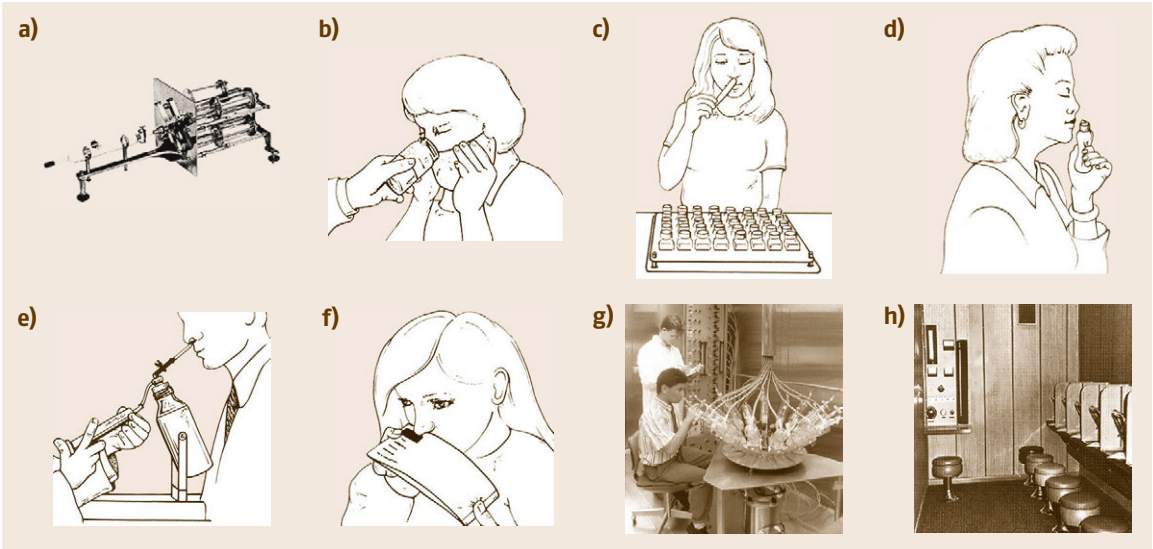

Fig. 23.1a–h Procedures for presenting odorants to subjects for assessment. **(a)** Early draw-tube olfactometer of Zwaardemaker. **(b)** Sniff bottle. **(c)** Perfumer's strip. **(d)** Squeeze bottle. **(e)** Blast injection device. **(f)** Microencapsulated *scratch and sniff* test. **(g)** Sniff ports on a rotating table connected to a dynamic air-dilution olfactometer. **(h)** Odor evaluation room of a mobile odor evaluation laboratory designed to evaluate responses of panel members to diesel exhaust (courtesy of Richard L. Doty, 2006)

For most clinical assessments, the only requirement for stimulus presentations is that they are reliable and that the stimuli reflect the involved odor qualities. For detailed structure-activity studies, air-dilution olfactometry is usually required. Regardless of the equipment involved in presenting odorants, the psychophysical paradigms are generally the same.

23.2 Measurement of Basal Olfactory Sensitivity

23.2.1 Detection and Recognition Thresholds

Paralleling to some extent the footsteps of the sensory evaluation of other sensory systems, most notably vision and hearing, the most popular modern procedures for quantifying olfactory function have included ones that assess the lowest level of stimulus that can be detected (detection threshold) or recognized (recognition threshold). The absolute or detection threshold is defined operationally as the lowest concentration where the presence of some type of subtle odor sensation that lacks a traditional odor quality is reliably detected, whereas the recognition threshold is defined as the lowest concentration where odor quality can be reliably discerned (e.g., *rose-like*). In most modern threshold tests, forced-choice procedures are employed; a subject must indicate, on a given trial, which of two or more stimuli (e.g., a low concentration odorant and one or more nonodorous blanks) is perceived as smelling stronger, rather than to simply report whether or not an odor is perceived. Such procedures minimize contamination by response biases (the conservatism or liberalism in reporting the presence of an odor under uncertain conditions) and typically provide lower and more reliable threshold values [23.57, 58].

Estimates of threshold values can be determined using numerous procedures, including:

1. The method of constant stimuli, where different concentrations of an odorant that span the threshold region are presented in random order to the subject
2. The method of limits procedure, where the stimuli are presented stepwise in either ascending or descending concentrations until the stimulus is reliably detected or recognized
3. The method of adjustment, where the subject adjusts, employing a specialized olfactometer, a stimulus to match another stimulus or to meet some criterion of perception, such as a perceived difference

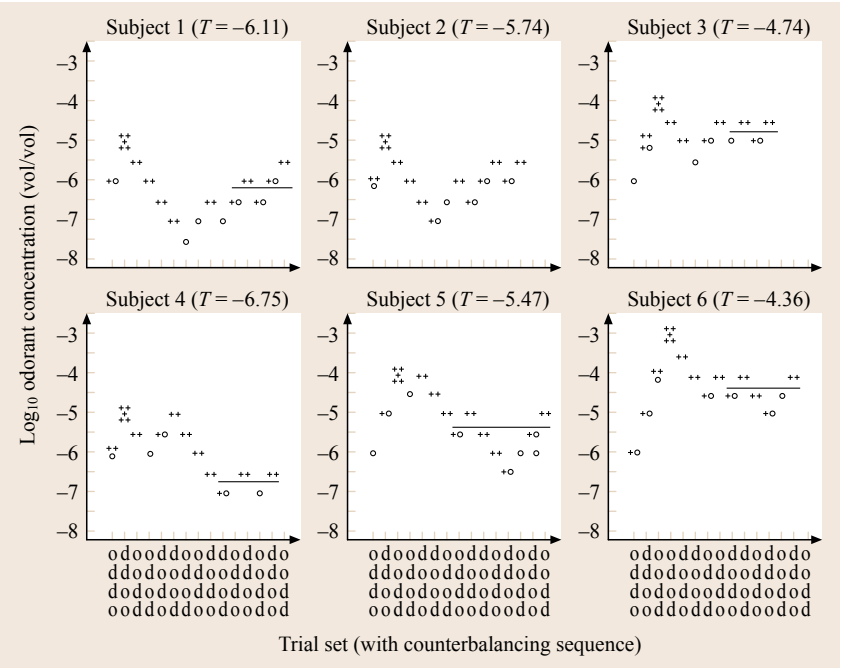

Fig. 23.2 Data illustrating single-staircase detection threshold determinations. Each plus (+) indicates a correct detection when an odorant versus a blank is presented. Each minus (−) indicates an incorrect report of an odorant. Threshold value (T; phenyl ethyl alcohol vol/vol in light USP grade mineral oil) is calculated as the mean of the last four of seven staircase reversals. The o's and d's on the abscissa indicate the counterbalancing order of the presentation sequences for each trial and are read downward (o: odorant presented first, then diluent; d: diluent presented first, then odorant)

4. Staircase procedures, in which the presented odorant concentration depends on the subject's performance on prior presentations or trials.

The staircase procedure, which was first used in the chemical senses in the mid-1970s [23.59], is a variant of the method of limits technique, but requires far fewer trials to obtain a reliable threshold [23.60]. In both the method of limits and staircase procedures, the direction of initial stimulus presentations is usually made from weak to strong in an effort to reduce adaptation effects of prior stimulation [23.61], although ascending and descending procedures generally provide similar detection threshold values [23.62].

Staircase procedures are most commonly employed in clinical situations, since they are reliable and economic of time. In the staircase procedure we developed for testing in the chemical senses [23.59], a trial consists of the presentation of two stimuli in rapid succession, one containing a concentration of odorant and one a blank comprising of either plain air or the material in which the odorant is dissolved. The subject's task is to report which of the two stimuli smells strongest. The employed concentration series extends below and above the perithreshold region of most persons in half-logarithmic dilution steps. Correct responses are required on five consecutive trials at a beginning concentration level before the next lower concentration is presented. If an incorrect response is made before five correct trials are attained, the process is repeated at one log concentration step higher. Once five consecutive correct trials occur at a given concentration level, the staircase is "reversed" and the next pair of trials is presented at a 0.5 log concentration step lower. From this point on, only one or two trials are presented at each step. If the first trial is missed, the staircase is moved to the next higher 0.5 log step concentration. When both trials are correctly performed, the next trial is given at one half-log unit concentration step lower. The threshold estimate is calculated as the mean of the last four of seven staircase reversal points. The general procedure is illustrated in Fig. 23.2, and is described in detail in a video [23.63].

As with all olfactory test measures, threshold values are relative and depend on such factors as the method of stimulus dilution, concentration step sizes, stimulus duration, species of molecule, type of psychophysical task, time between stimulus presentations, and the number of test trials [23.64, 65]. Some threshold measures, such as ones based on single ascending series presentations, exhibit considerable intra- and inter-subject variability [23.66–68]. Forced-choice paradigms and algorithms that incorporate more trials within the perithreshold region, such as staircase procedures, produce less variable measures and can be quite reliable. Within limits, reliability is systematically related to the number of trials within a test procedure [23.69]. For example, in the test procedure shown in Fig. 23.2, test–retest reliability is strongly related to the number of staircase reversals ($R^2 = 0.984$).

23.2.2 Difference Thresholds

In classical psychophysics, the smallest amount by which a stimulus must be changed to make it perceptibly stronger or weaker is considered a *just noticeable difference* or JND. This difference or differential threshold is, in effect, a measure of resolving power of the sensory system. In general, the size of the increment in odorant concentration (ΔI) required to produce a JND increases as the comparison concentration (I) increases, with the ratio approximating a constant (K); i. e., $\Delta I/I = K$ (Weber's law; [23.1]). The smaller the K value, the more sensitive the system is to fine changes in stimulation.

However, it is well known that K is not always a constant across the entire stimulus concentration continuum, being influenced at the extremes of the sensory continuum by the size of I [23.70]. Moreover, K can vary considerably among studies, depending on stimuli and test procedures. For example, using the Zwaardemaker olfactometer, *Gamble* [23.71] and *Hemandes* [23.72] found K values around 0.33 for a number of odorants. Using the same test procedure, *Zigler* and *Holoway* [23.73] reported, for the odor of Indian rubber, that K followed a hyperbolic function with a value of 0.17 at the upper end of the stimulus series and 0.99 at the lower end of the series. Using more modern procedures, *Wenzel* [23.54] found an average K of 0.15 for phenyl ethyl alcohol, whereas *Stone* and *Bolsey* [23.74] noted an average K of 0.28 for acetic and propionic acid. *Slotnick* and *Ptak* [23.75] reported an average K value of 0.32 for pentyl (amyl) acetate, whereas *Cain* [23.76, 77] found, in two subjects, K values for ethyl *n*-butyrate, *n*-amyl alcohol, *n*-butyl alcohol, and *n*-amyl butyrate of 0.30, 0.19, 0.07, and 0.09, respectively.

23.2.3 Signal Detection Measures

Signal detection theory (SDT) rejects the concept of a threshold as such and focuses on the roles of signal and noise as the milieu of the detection situation and subject factors, such as expectancies and rewards, in influencing the detection decision. SDT provides both a measure of sensory sensitivity and the subject's response criterion or bias [23.15]. The response criterion is the liberalism or conservatism of a subject in reporting a sensation under uncertain circumstances. For example, while two persons may experience the same subtle degree of sensation from a very weak stimulus, one may report that no sensation is perceived (e.g., because of lack of self-confidence) and the other may report that a sensation is clearly perceived. In this example, the stimulus was perceived to the same degree

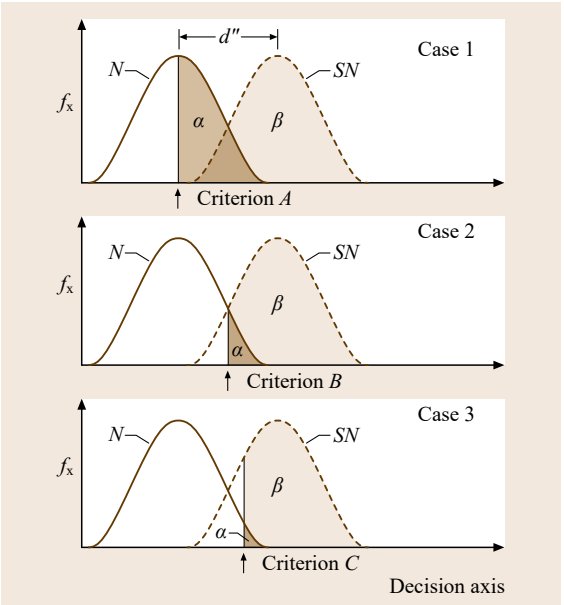

Fig. 23.3 Hypothetical distributions of signal plus noise (*SN*) and noise alone (*N*) plotted on the same axes (after [23.78], courtesy of *Doty*, Academic Press, 1976)

but the two subjects had different criteria for reporting its presence. In a classical non-forced-choice detection threshold paradigm, the investigator would conclude that these two subjects differed in sensitivity to the stimulus, when, in fact, they only differed in regards to their response biases.

In SDT, it is assumed that a stimulus is imbedded within a background of noise and that both can fluctuate over time. Noise can reflect a number of factors, such as variations in attention, stimulus fidelity, neural firing unrelated to the stimulus, and fluctuations in distracting physiological processes. When a signal is added to the *noise* (*N*) distribution, a *signal plus noise* (*SN*) distribution is in evidence. In most cases, the *N* and *SN* distributions are assumed to be normally distributed and can be represented on the same set of *z*-score axes, as shown in Fig. 23.3. The distance between the means of these distributions is the measure of the subject's sensitivity, d'.

The concept of the response criterion is also illustrated in Fig. 23.3. In this hypothetical example, d' (sensitivity) is held constant. The subject's task is to report whether or not an odor is perceived. Reports of *no* are represented by the areas under the *N* and *SN* curves to the left of the vertical line depicting the subject's response criterion, whereas reports of *yes* are indicated by the areas to the right of this line. In case 1, a very liberal criterion is depicted, with the subject reporting the presence of an odor on all of the SN trials (β) and

on half of the N trials (α). Thus, while correct detection of the odorant occurred all of the time (β), a large number of false alarms (α) occurred. This could reflect an instance where the subject was rewarded for reporting the detection of an odor and not admonished for making false alarms. In case 2, a less liberal response criterion is depicted, reflecting fewer correct detections (β) and fewer false alarms (α). In case 3, the observer had a very conservative response criterion, reflecting few false alarms but also somewhat fewer correct detections. This pattern of responses would result, for example, if a subject was penalized for making false positives and given few rewards for successfully detecting the odor. An important point is that, in all three of these hypothetical cases, sensitivity (d') was equivalent, as indicated by the same distance between the N and SN distributions.

In a typical SDT odor experiment, the subject is presented with a large number of odorant trials (*SN*) interspersed with nonodorant (*N*) trials. The odorant is usually a single concentration chosen to be detectable approximately half of the time [23.29, 79]. Commonly, an equal number of blank and odorant trials are presented. The proportion of the total odor trials (*SN*) on which a subject reports detecting an odor (the hit rate) is calculated, as is the proportion of blank trials (*N*) on which an odor is reported (the false alarm rate). When data meet the requirements for parametric statistics (normal distributed data with homogeneous variances), d' can be computed by converting these proportions to normal distribution standard deviation values (z-scores). d' equals the z-score for hits minus the z-score for false alarms [23.10]. The classical measure of response bias is the ratio, at the criterion point, of the ordinate of the SN distribution to that of the N distribution. Procedures for calculating d' for frequency distributions that are not normally distributed are available, including a number of nonparametric signal detection measures (see, [23.80–85]).

Although hundreds of trials are typically employed in signal detection studies, fewer trials have been used. *Potter* and *Butters* [23.86] and *Eichenbaum* et al. [23.87], for example, computed d' in olfactory studies using only 30 test trials. Such estimates are somewhat unstable, although *O'Mahony* et al. [23.88], in a taste study using sodium chloride, found that, after 40 trials, *Brown*'s nonparametric R index [23.80] fell within 5% of the values obtained after 200 trials in a little more than half the subjects tested. Ideally, however, all of the subjects should evidence such response stability, so as a general rule one should employ as many trials as practically possible.

23.3 Measurement of Suprathreshold Odor Perception

Numerous psychological attributes of odors can be quantified, including odor strength, hedonics (pleasantness/unpleasantness), and quality. These attributes change as a function of odorant concentration and species. Suprathreshold measures of intensity have been generally found to be less sensitive to olfactory dysfunction than a number of other measures. In a classic case, for example, a suprathreshold measure completely missed the marked influence of age on olfactory function [23.89]. Factor analysis studies suggest that suprathreshold measures may tap, at least to some extent, underling physiological processes that are distinct from those measured by threshold measures and some suprathreshold tests [23.90].

23.3.1 Rating Scales

Most persons in industrial cultures have used rating scales at one time or another. Such scales date back to antiquity [23.91]. For example, Galen employed a rudimentary hot–cold scale that was the basis for hot and cold body temperature scales used by physicians until thermometers were developed in the 19th century. In olfaction, rating scales of odor pleasantness/unpleasantness were used at least as early as 1923, when Young employed a 7-point scale ranging from −3 (very unpleasant) to +3 very pleasant to compare over time the consistency of hedonic responses [23.92].

In olfactory assessment, two types of scales are most popular today: category scales, where the relative amount of a sensation is signified by indicating which of a series of discrete categories best describes the sensation, such as was done by Young above, and line scales (also termed visual analog or graphic scales), where the subject or patient indicates the strength of the sensation by placing a mark along a line that has descriptors (termed anchors) located at its extremes (very weak–very strong). Because of the tendency of subjects to group responses at the extreme end of intensity scales, particularly for prothetic continua, a number of test developers have made an effort to incorporate ratio-like or logarithmic properties into the design of their scales to more closely mimic results obtained from magnitude estimation (Sect. 23.3.2) [23.93–96]. Responses on rating scales are influenced by a number of factors, including intent (trying to make the intervals on the scale equal in width), discrimination (use of categories narrows when discrimination is good and widens

when discrimination is poor), and expectation (ideas regarding the number of times each category should be used) [23.97]. For discussions of the general properties of rating scales, including the influences of category number on their psychometric properties, the reader is referred elsewhere [23.11, 97–100].

23.3.2 Magnitude Estimation and Matching Procedures

In magnitude matching, the relative magnitudes of members of a stimulus set are estimated on another continuum, with the goal of determining the ratio relations among the intensities (or other attributes) of the set. Unlike rating scales, the subject's responses are not confined to categories or a response line. In magnitude estimation (ME), the most common of such matching procedures, numbers are assigned to the relative magnitude of the sensations. For example, if the intensity of one stimulus is assigned the number of 100, a stimulus perceived half as strong would be given the number 50. If the intensity was perceived as four times as strong as the initial stimulus, then the number 400 would be assigned. In the *free-modulus* version of this procedure, the subject can choose any size or range of numbers he or she wishes, so long as they reflect the relative magnitudes of the perceived intensities. In the assigned modulus version of this test, a preassigned number is provided to the subject (often one from the middle stimulus of the series) in an effort to make his or her responses more reliable. The key element of interest in magnitude estimation is the relationships between the numbers, not their absolute values.

ME has been used to evaluate the relationship between odor and intensity for a number of compounds. In one procedure, negative numbers are used to denote unpleasant values and positive numbers pleasant values, with 0 signifying neutrality. As with other ME applications, the subject is instructed to denote the relative degrees of pleasantness and unpleasantness using ratio estimates. As shown in Fig. 23.4, while the intensity of an odor increases monotonically as a function of its concentration, this is not the case for hedonic responses which can be much more idiosynchratic [23.101].

Unlike the manner in which the data are presented in Fig. 23.3, ME intensity data are most commonly plotted on log–log coordinates (log odorant concentrations on the abscissa and log MEs on the ordinate) and the resulting functions are typically linear. Regression is used to determine the function, $\log P = n \log \Phi + \log k$, where P = perceived intensity, k = the Y intercept, Φ = stimulus concentration, and n = the slope. This function can be represented in its exponential form, $P = k\,\Phi^n$, where the exponent n is the slope of the function on the log–log plot. The Y intercept is frequently ignored, since it depends on the number system chosen by the subject or the experimenter. In olfaction, n varies in magnitude from odor to odor, but is generally less than 1, reflecting a negatively accelerated function on linear–linear coordinates. Some investigators have altered the power function equation in efforts to take into account such factors as differences in thresholds and vapor pressures [23.58, 103, 104].

Like most other sensory tasks, ME is influenced by procedural and subject factors [23.13, 58] and there is evidence that, for untrained or mathematically unsophisticated subjects, category scales and line scales may be superior to magnitude estimation when such factors as variability, reliability, and ease of use are considered [23.105, 106]. Since accurate responses to stimuli in an ME paradigm require a good memory for the prior stimulus, fidelity can be compromised if too much time lapses between stimulus presentations. On the other hand, if the trials occur too quickly, adaptation can distort the relationship. Some subjects fail to consistently provide ratio estimates of stimuli, and some fail to understand the concept of producing ratios [23.107, 108]. A contrast phenomenon can intervene; for example, a moderately intense odor is reported to be more intense when presented with weak comparison stimuli than with strong comparison stimuli, making it imperative that counterbalancing of stimulus presentations is made [23.109, 110]. The standard assigned to the subject, as well as units in which the stimulus concentration is expressed, can affect the exponent [23.111], and stimuli spanning a restricted range generally produce larger exponents than stimuli having a more expansive range [23.112]. Despite such influences – a number of which are shared by other psychophysical measures – such problems can be minimized by careful standardization and monitoring of the instructions, test procedures, and test stimuli.

Traditionally, only the slope (exponent) of the ME function has been used as the index of sensory function. The intercept or the distance of the function from the X-axis has been generally neglected, since its values are influenced by idiosyncratic differences in the use of numbers and by the type of ME paradigm employed (fixed versus free modulus). To gain information regarding the function's ordinate position, procedures have been developed that provide such information and, in addition, correct for differences among subjects in number usage and subject factors [23.113]. In one paradigm, judgments of the intensity of sensations from two modalities (broad band low frequency noise and smell) are made at the same time and placed on a common scale [23.114]. Under the assumption that subjects

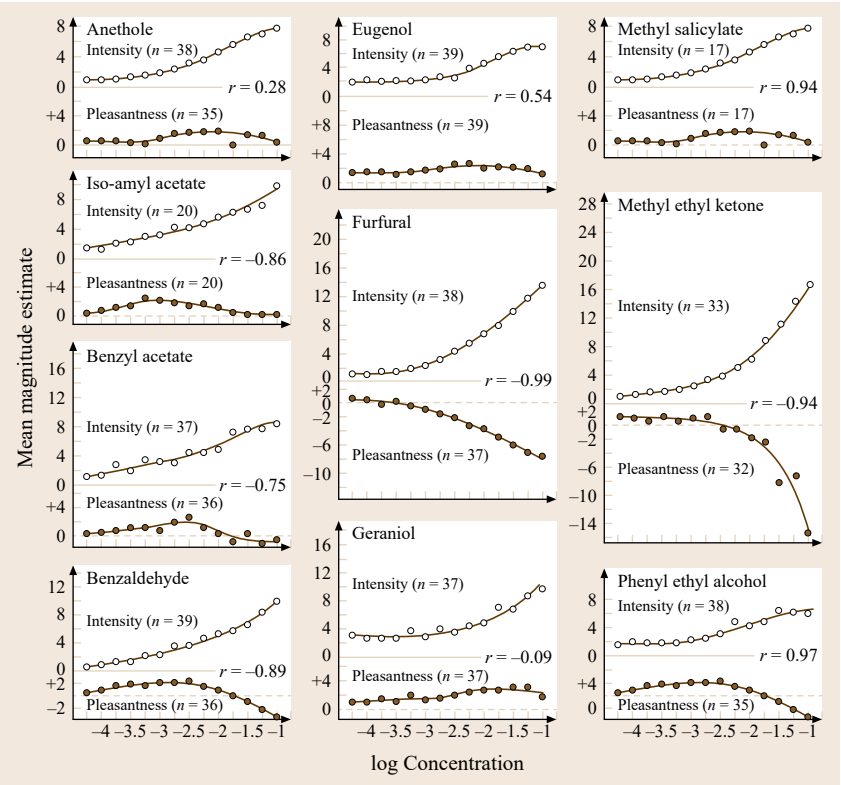

Fig. 23.4 Relationship of pleasantness and intensity magnitude estimates to odorant concentration in propylene glycol for 10 odorants (after [23.102] courtesy of *Doty*, The Psychonomic Society, 1975)

experience stimuli on the loudness continuum in the similar manner, differences among subjects' loudness ratings can be ascertained and the odor intensity continuum adjusted accordingly. Such normalization allows, theoretically, for a direct comparison of scale values across subjects. Thus, if the adjusted odor intensity magnitude value for one subject is 10 and for another subject is 20 at the same concentration level, the second subject is presumed to experience twice the odor intensity as the first subject.

Contrasts between the scaling parameters of ME procedures and rating scales have led to classification systems of the underlying sensory continua which may have some physiological merit. In 1957, *Stevens* and *Galanter* [23.97] classified perceptual continua that are related to stimulus magnitude by power functions, such as brightness and loudness, as *prothetic* (derived from the Greek prostithenai, which means *to add*). This was assumed to reflect their association with additive physiological processes such as the recruitment of more neurons and greater rates of firing in response to increases in stimulus intensity. When category ratings are plotted against magnitude estimates of the same stimuli, a downward curvilinear function is typically produced. Other continua, such as pitch, do not conform to a power function association and were classified by these authors as *metathetic*, which in Greek derives from a word meaning *to change or substitute*. According to Stevens and Galanter, metathetic continua exhibit uniformity of discrimination over the involved stimulus range and to a large extent are made of stimuli that reflect *what and where* rather than *how much*. When magnitude estimates and category scale values of metathetic stimuli are plotted against one another, linear or near-linear functions are found. The underlying changes across metathetic continua are assumed to reflect activation of more discrete physiological spatial elements as the magnitude of the stimulus property increases. For example, in the case of pitch, increases in frequency are associated with substantive recruitment of spatially distinct regions of the basilar membrane, rather than the additive recruitment of more neurons within the region.

The question arises as to whether the hedonic properties of equivalently intense and hedonically disparate odors reflect prothetic or metathetic continua. Using a procedure developed by *Eisler* [23.115] that expanded the prothetic/metathetic dichotomy into a continuous *protheticity* measure, *Doty* [23.116] addressed this issue. Power functions were fitted to the relationships between (a) magnitude estimation pleasantness values and (b) pleasantness values obtained from category

ratings and rank orderings of a diverse set of 20 relatively isointensive odorants. The functions relating the pleasantness of the diverse stimuli were nearly linear and only slightly prothetic, i. e., essentially metathetic (respective category scaling and rank order/magnitude estimation exponents = 0.60 and 0.63). Conceivably this could represent, as occurs with the case of pitch, recruitment of discrete sensory channels in a substitutive, rather than an additive, manner as pleasantness increases. In a second component of this study, analogous exponents were obtained from pleasantness data derived from quarter-log-step volume dilution series of two hedonically disparate odorants, the pleasant smelling odorant methyl salicylate and the unpleasant smelling odorant furfural. Methyl salicylate was found to scale in a more metathetic-like manner and furfural in a more prothetic-like manner (respective exponents = 0.68 and 0.20; respective rank order/magnitude exponents = 0.69 and 0.21. Thus, for olfaction, the degree of hedonic protheticity appears to depend upon the stimulus. It would be of interest to know whether, as odorant concentrations increase, metathetic-like odorants such as methyl salicylate recruit more spatially segregated elements of the olfactory receptor sheet than prothetic odorants like furfural, in a fashion analogous to pitch's association with the recruitment of substitutive activity from differing segments of the basilar membrane.

23.3.3 Odor Discrimination Tests

Odor discrimination tests seek to determine the degree to which a subject can tell the difference between odorants having different qualities (smells). The simplest of such tests are ones in which a subject is simply required to report whether two odorants smell differently. In one type of discrimination test, a series of same-odorant and different-odorant pairs is presented. The proportion of pairs that are correctly differentiated is taken as the measure of discrimination [23.82, 86, 88]. Numerous variations on this theme exist, including picking the *odd* stimulus from a set from which only the *odd* stimulus differs, either at a constant delay interval [23.32, 117] or at varying delay intervals [23.118]. The latter approach provides a measure of short-term memory as well as a measure of basic discrimination. Recently a discrimination test that employs a set of 15 stimuli representing pairs of different ratios of two odorants from a set of six odorants has been described [23.119].

Multidimensional scaling (MDS) is a very sophisticated means of establishing discrimination ability. In one MDS paradigm, subjects are asked to rate all possible pairs of a relatively large number of odorants on a visual analog scale depicting their similarity (e.g., a scale with anchors ranging from *completely different* to *exactly the same*). The correlations among these ratings are then subjected to an MDS algorithm that places the stimuli in two-dimensional (2-D) or three-dimensional (3-D) dimensional space relative to their perceived similarities [23.120]. Persons with poor discrimination tend to have spaces that have no distinct or reliable groupings, whereas those with good discrimination exhibit groups largely based on quality and pleasantness attributes. Although MDS clearly detects discrimination deficits, it is time consuming and statistical procedures for comparing one person's MDS space to normative data are not available. In persons with normal smell function, MDS stimulus spaces derived from the ratings of the names of odorants overlap with those derived from the actual smelling of odorants, signifying the presence of well-defined conceptual representations of odors [23.121, 122].

23.3.4 Odor Recognition Tests

Odor recognition tests are closely related to odor discrimination tests and, in some cases, overlap with them. Several types of quality recognition tests have been used. In the simplest type, a subject is asked whether each of a presented set of odorants is recognized. Identification is not required. This procedure is relatively crude, lacks normative referents, and is easy to malinger. A more quantitative odor recognition paradigm is the stimulus matching task. In one such test, a set of stimuli are provided and the subject is required to match the stimuli to those of a set of identical stimuli. An example of such a test is provided by *Abraham* and *Mathai* [23.123]. These investigators presented patients with eight vials that contained four odorants (two vials per odor). The patients were required to pair up the equivalent two-vial containers. The test score was the number of pairs that were correctly matched on each of two test administrations.

23.3.5 Odor Identification Tests

Tests that require a subject to identify an odorant are among the most popular procedures for assessing smell function. Such tests can be classified into three groups: naming tests, yes/no identification tests, and multiple-choice identification tests. The respective responses required, on a given trial, in these three types of tests are:

1. To name the stimulus
2. To report whether the stimulus smells like an object named by the examiner (does this smell like a rose?)

3. To identify the stimulus from a list of names or pictures.

Odor naming tests in which no response alternatives are provided are commonly used by neurologists to measure olfactory function [23.124, 125]. Unfortunately, like simple recognition tests, their value is limited since:

1. It is difficult even for most normal persons to name even familiar odors without cues
2. They lack normative referents
3. They are easy to malinger.

Yes/no identification tests are much more useful, since they require a patient to report whether or not each of a set of stimuli smells like a particular substance named by the experimenter and malingering can be detected when performance significantly falls below chance. Two trials with each stimulus are usually given, with the correct alternative provided on one trial and an incorrect one on the other (e.g., lemon odor is presented and the subject is asked on one trial whether the odor smells like lemon and on another trial whether the odor smells like smoke). Although yes/no identification tests require that the subject keeps the percept in memory long enough to compare it with the target word (which, of course, must also be recalled from memory), it has been argued that it is less influenced by cognitive demands than multiple-choice identification tests (see below). Since the chance performance of a yes/no identification test is 50% compared to 25% on a four-alternative multiple-choice identification test (see below), its range of discriminability is lower, and therefore more trials are needed to obtain equivalent statistical power.

A number of multiple-choice odor identification tests have been described in the clinical literature [23.22, 32, 33, 42, 125–130]. These tests are conceptually similar and, in the few cases that have been examined, strongly correlated with one another [23.90, 130, 131]. The most widely used odor identification test – the University of Pennsylvania Smell Identification Test (UPSIT) – became commercially available in the early 1980s [23.42]. This microencapsulated odor identification test has been administered to over a million persons worldwide and has been translated into over 20 different languages. On a given forced-choice trial, subjects are required to identify each odorant from a set of four descriptors [23.42, 43] (Fig. 23.1). The number of correct items serves as the test measure. Clinically, a patient's test score can be compared to norms and a percentile rank determined relative to one's age and sex [23.43].

Another odor identification test that has been used in some smell and taste clinics employs what is called a confusion matrix [23.12, 130]. In one version of this test, 10 suprathreshold stimuli are presented to a patient in counterbalanced order 10 times (100 total trials) [23.130]. The subject is required, on a given trial, to indicate which one of a set of 10 written response alternatives smells most like the odorant – response alternatives that actually reflect the stimuli that are presented, i. e., ammonia, chlorine bleach, licorice, mothballs, peppermint, roses, turpentine, vanilla, Vicks vapor rub, and vinegar. The subject must provide an answer even if no smell is perceived. The percentage of responses given to each alternative for each odorant is determined and displayed in a rectangular matrix (stimuli making up rows and response alternatives making up equivalently ordered columns). Responses along the negative diagonal represent correct responses, whereas those that fall away from the diagonal potentially represent *confusions*. The percentage of correct responses is used as the main test measure, although some of its proponents argue that the confusions (off-diagonal responses) may provide meaningful clinical information. The latter has yet to be clearly demonstrated. This test requires 45–60 min to administer, making it impractical in most clinical settings.

23.3.6 Odor Memory Tests

There are numerous means for assessing odor memory. For practical reasons, explicit, rather than implicit, memory tasks are most commonly performed – tasks where odors are presented which the subject must recall after various delay intervals. It is important to note, however, that odor memory itself is a complicated construct that is intimately interwoven with emotion, prior experiences, and semantic processes [23.132]. Moreover, deficits on a normal odor memory test could reflect problems with encoding (because of decreased sensory input), retrieval (inability to recognize the stimulus), or connections with higher brain centers associated with experiences with the odor (degree of familiarity). Despite attempts to minimize labeling of the inspection odor with a familiar word or item on the part of a subject, such labeling often occurs and, thus, the memory of the label, not the memory of the odor percept per se, which is often being measured across delay intervals. In other words, once an odor is recognized as that of an orange, for example, all that has to be remembered over time is the concept *orange*, not the specific smell of the orange. Later, when given stimuli from which to select the earlier perceived odor, the subject simply looks for the smell of an orange (which has been known and stored in long-term memory for much of his or her life). In effect, the odor is not what is being uniquely remembered over the retention interval,

only its name or concept and remembrance of having smelled the substance.

Although some investigators have attempted to employ novel, nondescript, and unfamiliar odorants in such tasks, it is difficult to find target odors that are not labeled by subjects as pleasant or unpleasant, fruity or non-fruity, medicine-like or nonmedicine-like, chemical-like or nonchemical-like, etc. although some odorants have been identified that are difficult to name [23.133]. Importantly, it is critical to recognize that performance across the delay intervals is what is classically assessing the *memory* component of the task, not necessarily the overall test score. As noted below, a number of odor memory tests are, in fact, essentially odor discrimination tests with varying inspection (delay) intervals. When scores on a (nominal) odor memory task differ between two groups (as evidenced by a main group effect in an analysis of variance), then a significant interaction term between the delay interval and the group would indicate an effect on memory, per se. Without an interaction with delay interval, the difference could simply reflect discrimination, not memory, although admittedly memory is a component of nearly all olfactory tasks, including those of detection, identification, and discrimination.

In one popular odor memory test paradigm, which can be labeled the *single-target match-to-sample test* (STT), a subject is required to smell a series of odorants, one at a time, and to select, after intervals that can range from less than a minute to a few hours, that odorant from an array of several odorants (distractor odors) [23.118, 134]. Alternatively, the recall period can consist of a single odor which the subject indicates is either the same or different from the target [23.135]. In clinical versions of the STT, repeated trials are typically performed at one or more retention intervals for each of several target stimuli [23.118]. A second popular test paradigm, the *multiple-target match-to-sample test* (MTT) [23.134] is similar to the ST except that initially a set of odorants is presented and one or more of the set of odorants is subsequently identified in either a yes/no paradigm or by selection from a larger set of stimuli into which they are embedded. A less common, but potentially useful, odor memory paradigm employs *single-probe serial position recall* [23.136]. In this task, several odors are presented in succession to a subject. After a brief period, one of the odors is presented again and the task of the subject is to recall the serial position of the previous presentation of the odor, for example whether it was the first, second, third, fourth, fifth, or sixth odor that had been presented in a series of six odor presentations. In addition to examining overall percent correct, the number of correct identifications at each serial position can be calculated. Thus, measures of primacy and recency can be assessed. Like findings using this paradigm with visual and auditory stimuli, erroneous responses for olfactory stimuli are more frequently attributed to serial positions adjacent to the probed position [23.136].

A number of examples of studies that have employed match-to-sample odor memory tests in clinical settings are available. *Jones* et al. [23.137] presented 20 pairs of odorants at 0 and 30 s delay intervals to 14 alcoholic Korsakoff psychosis patients, 14 alcoholic controls, and 14 nonalcoholic controls. The subject's task, on a given trial, was to indicate whether the second stimulus was the same or different from the first. At the 30 s delay interval, the subjects counted backward by threes in an effort to minimize semantic labelling. The Korsakoff psychosis patients performed more poorly than the controls at both the 0 and 30 s retention intervals. It is not clear, however, whether this effect was due to deficits in odor memory, discrimination, or both. Interestingly, acute alcohol intake has been shown to have similar adverse effects on a 12-item single target match-to-sample odor memory discrimination test in young nonalcoholic subjects [23.138]. In this double-blind study, ingestion of alcohol designed to reach the legal level of intoxication significantly depressed the test scores although, as with the Jones et al. study, no delay interval effects were observed at the short delay intervals employed (10, 30, and 60 s).

Jones–Gotman and Zatorre [23.139] reported that odor memory deficits were evident in patients who had undergone surgical cerebral extirpation for control of epilepsy. The memory task consisted of the presentation of eight target odors and eight new foils, and the yes–no recognition testing was performed twice after the initial testing – 20 m later and 24 h later. Relative to controls, impairment was noted in those patients who had received excision from the right temporal or the right orbitofrontal cortices.

Gregson and his colleagues have employed a single-probe serial position recall paradigm to demonstrate odor memory deficits in patients with schizophrenia [23.140], Kallmann's syndrome [23.125], and Korsakoff psychosis [23.141]. In their paradigm, three odorants are presented in a row to the patient. A fourth odorant, which is the same as one of the three odorants, is then presented and the patient's task is to report which of the three prior odors it represents. Seven three-odor combinations of 12 inspection stimuli were administered. Patients who had difficulty with this initial task were subsequently given two-odor combinations. The test score was the number of odors that were consistently recognized.

23.4 Issues in Olfactory Psychophysical Measurement

It is important to keep in mind that each approach to olfactory measurement has strengths and weaknesses, and that comparisons among the results obtained from nominally distinct test measures, such as those of odor identification, detection, discrimination, memory, and suprathreshold changes in odor intensity, can be problematic. This is because such measures typically differ on a range of both olfactory and nonolfactory factors that confound the comparisons and associated interpretations. Among such factors are odorant species, the time required for test administration, the number of trials involved, and abilities to perform nonolfactory elements of the testing. A key issue relates to differences in test reliabilities which, in turn, influence their relative sensitivities in detecting subject differences due to age, sex, personal habits, and disease. As shown in Fig. 23.5, the test–retest reliability of most olfactory tests is a function of the number of involved trials. However, very short tests (three items) may exhibit spuriously high reliability coefficients, since smell abilities are forced into a few broad categories. Spuriously high reliability coefficients also occur when reliabilities are based on samples that contain persons with smell dysfunction, since correlation coefficients are influenced by the range of values on which they are based. It should be pointed out that while a high reliability coefficient indicates that a group of individuals scored similarly *relative to one another* on a test from one test occasion to another, all of the individual's test scores still may be lower (or higher) on the second than on the first test occasion. In other words, systematic changes in the test values can occur for a number of reasons that are not necessarily reflected in the reliability coefficient.

An important consideration in olfactory testing is that despite differing names, most olfactory tests are not mutually exclusive and are usually correlated with one another [23.90]. This likely reflects the dependence upon common psychological and physiological mechanisms, not the least of which is the olfactory neuroepithelium that undergoes a considerable change with age and environmental exposures [23.142–145]. Functionally, a test of odor identification requires the ability to detect an odor, as well as to discriminate among odors and to remember them. A forced-choice threshold test requires a comparison of an odor or a weak sensation with alternatives, a task that again requires memory as well as discrimination. Differing degrees of semantic labeling may occur in odor discrimination tasks, just as occurs in odor identification tasks, again pointing to communalities among such procedures. To what degree different tests differentially tap higher brain structures or networks is debatable in light of the fact that such tests are not equated for reliability or discriminating power. This problem is not specific to olfaction, as it has long been apparent in psychological measures of cognition [23.146].

In an ideal world, olfactory tests would be matched on the basis of sensitivity, reliability, discriminability, and a range of nonolfactory controls (e.g., tests in another modality that require the same operational tasks) so as to eliminate, or at least understand, nonolfactory factors that may be contributing to the results. This is particularly true when mentation may be altered, as in dementia or head trauma. It is for this reason that we often employ the Picture Identification Test, a test essentially identical to the UPSIT but which uses pictures rather than odors as test stimuli [23.147]. If persons do well on this test, we know that the putative olfactory deficits are not due to lack of understanding the concepts involved in the test or to the operational procedures involved in taking the test.

From a practical clinical perspective, a number of basic issues arise that require notice. One common question is whether testing should be performed bilaterally (both sides of the nose at the same time) or unilaterally (i. e., each side of the nose separately). While most individuals with chemosensory dysfunction have bilateral dysfunction [23.131, 148, 149], unilateral dysfunction is not uncommon and often goes unnoticed [23.150]. As with hearing or vision, it is important to know whether one or the other side of the olfactory system is dysfunctional, and clinically unilateral testing can detect disorders that otherwise would go unrecognized (early stage tumors such as olfactory groove meningiomas). Interestingly, odor recognition memory is better under bilateral than unilateral test conditions [23.134] and, in the menopause, estrogen replacement therapy appears to influence the asymmetry noted on such memory tasks [23.151]. When performing unilateral testing, it is prudent to close the contralateral naris without distorting the septum by using a piece of Microfoam tape (3M Corporation, Minneapolis, MN) cut to fit tightly over the borders of the naris and have the patient exhale through the mouth after inhaling through the nose [23.43]. As in the case when both nares are blocked, this precaution decreases the likelihood for air to enter the blocked nasal chamber via the retronasal route.

Prior experience with odors, particularly that obtained on taste and smell organoleptic panels, needs to be taken into consideration in olfactory studies, as such experience can alter a range of olfactory test measures. For example, repeated testing within the perithreshold odorant concentration range results in decreased

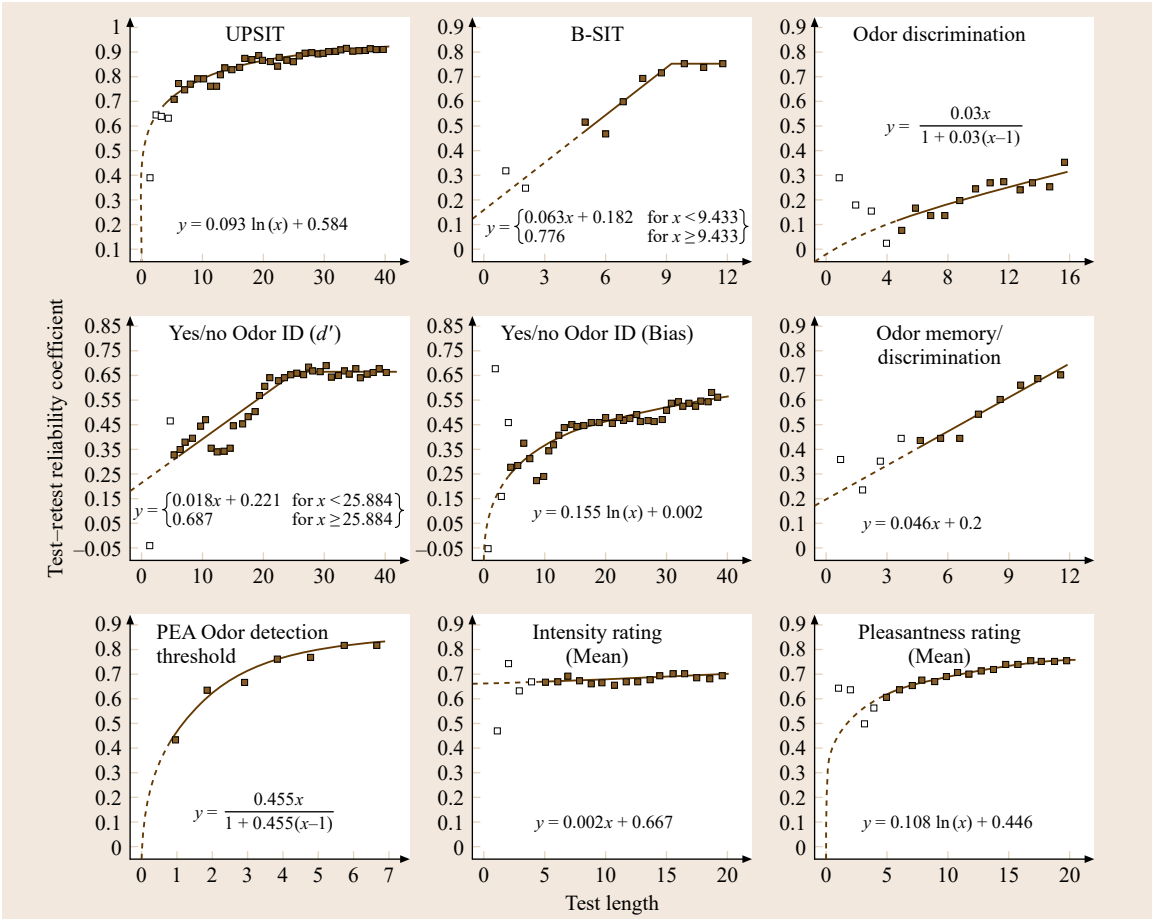

Fig. 23.5 Relationship of reliability to cumulative test length for test measures amenable to such an evaluation (after [23.69], courtesy of *Doty* et al., Oxford University, 1995)

thresholds or enhancement of signal detection sensitivity measures [23.79, 152–154]; practice with feedback influences the ability to name odors [23.155, 156]. Interestingly, the hedonic quality of odorants can be influenced by repeated exposure, making unpleasant odors less unpleasant and pleasant odors less pleasant [23.157]. Assuming that adaptation is not the primary basis for this phenomenon, affective components of odors appear to habituate somewhat independently of odor intensity.

One factor that is often overlooked in the administration of olfactory tests is the influence of adaptation or habituation on the olfactory test measure, a temporary decrease in smell function such as reflected, for example, by heightened detection threshold values or decreased intensity ratings (for a review, see [23.158]). Some chemicals produce a decrement in the perception of other chemicals (termed cross-adaptation). For these reasons, it is critical to use and maintain as optimal as possible inter-trial intervals that minimize confounding by such factors. The UPSIT, for example, was designed to minimize adaptation by:

1. Employing largely multicomponent "natural" odorants
2. Requiring minimal sampling of each odorant
3. Having verbal, rather than odorous, response alternatives
4. Ordering the presentation of odorants such that dissimilar odorants follow one another (thereby minimizing cross-adaptation)
5. Allowing adequate time between the smelling of each odorant item [23.42]

Another important issue relates to non-forced-choice tests that are susceptible to subject exaggeration and malingering. Recently, *Karnekull* et al. [23.159] demonstrated, in a nonclinical population, a positive

correlation between neuroticism and negative responses to both environmental odors and noise. Those highest on the measure of neuroticism rated odors as being more intense. Other work suggests that beliefs about odors can determine the amount of attention paid to them and how strongly they are rated. For example, when subjects are told they are being exposed to an unhealthy odor, their ratings of its intensity are greater, and the time required for adaptation is longer, than if they are told the odor is healthy [23.160–162]. However, forced-choice threshold tests do not detect threshold differences between persons who complain of chemical hypersensitivity to odors and those who do not [23.45, 163–165]. It is of interest that, unlike psychiatric malingerers, olfactory malingerers tend to downplay health problems that might influence the putative basis of their claimed disorder (smoking, dental problems, medication usage) [23.166]. On the other hand, they exaggerate symptoms congruent with their supposed problem, such as its severity, weight loss, appetite change, and interference with everyday activities.

23.5 Concluding Remarks

It is apparent from this chapter that a wide range of procedures are available for assessing olfactory function. However, much more work is needed to determine the relative value of such procedures in specific clinical and experimental settings. A challenge for the future is to determine the common and unique conceptual and physiological factors that are measured by such procedures.

Acknowledgments. The preparation of this chapter was supported, in part, by USAMRAA W81XWH-09-1-0467 from the Department of Defense.

24. Olfactometers According to EN 13725

Dietmar Mannebeck

In 1995 the technical committee TC264 air quality of the European Committee for Standardization convened the working group 2, which developed an odor testing standard. It was released in 2003 as EN 13725 air quality – measurement of odor concentration using dynamic olfactometry. As the methodology of dynamic olfactometry according this European Standard is approved among others in Australia as AS 4323.1 and in Chile as NCh 3190, the EN 13725 today is the most applied standard worldwide.

Other used methods for determination of odor thresholds are ASTM 679 as well as Japanese and Chinese standards. Compared with the EN 13725 these standards are working on a lower detail level concerning technical requirements and execution description.

In 2012 the TC264 took a resolution to review the standard. A revised draft standard is expected to become available in 2017.

The revised standard will contain comprehensive guidance on reference material, measurement uncertainty, health and safety issues, materials for olfactometry, sample storage and the sampling of different odor sources. Once the endpoint of the revision has been reached a release of an ISO standard based on EN 13725 is envisaged.

Like the measurement of noise, olfactometry is an effect-based measurement method to determine the effect of an odorant on perception in humans. The most common purpose of odor measurements in general is to estimate the degree of nuisance due to odor impact.

The sense of smell reacts extremely sensitively and differently to a large number of chemical substances. The odor threshold, i. e., the minimum gas-phase concentration of an odorant that triggers a perception response, is substance-specific and varies over an extensive range. The odor threshold for butanoic acid, for example, is around $6 \times 10^{-5}\,\mathrm{ppm_v}$ ($0.00016\,\mathrm{mg\,m^{-3}}$), while that of benzene is $300\,\mathrm{ppm_v}$ ($1000\,\mathrm{mg\,m^{-3}}$). The odor threshold detectable by humans is for many compounds below the analytical detection limit of the most sophisticated instrumentation. Unlike in olfaction, the detection and assessment of noise involves a straightforward measurement of primarily just a single variable (sound pressure) with its different frequencies using physical sensors. Odor measurement, on the other hand, often calls for the measurement of up to several hundred components through the analysis of the odor's constituents using technical sensors and subsequently the evaluation of their accumulated effect on odor perception. In other words, the effect of a mixture of odorants on odor perception cannot be commonly derived from the concentrations of its individual components. A universal technical solution to this enormous challenge is unlikely to be found in the foreseeable future.

At present, no general relationship has been established between the results of measurements using technical sensors and human odor perception. Moreover, current sensors are mostly too insensitive for

many applications, thus the human nose is indispensable as a sensor for olfactometry for the foreseeable future. Instruments that use technical sensors (electronic noses) therefore do not qualify as olfactometers, as specified according to the definitions of EN 13725 and discussed in the following.

24.1 General Characteristics

24.1.1 The Process for Determining Odor Concentration

According to the definition given in DIN EN 13725:2003, an olfactometer is a dilution system in which the odor sample, diluted or administered within a neutral carrier gas is presented to a panel for assessment. Presentation of the odor to the panelists can either start below the odor threshold and continue in an ascending sequence or take place in a random sequence below and above the threshold level.

The responses of the panel members can be gathered in two ways. In a *yes/no* inquiry, the panelist must choose between *yes, there is an odor* and *no, there is no odor* for each presentation of the smell. The alternative procedure is a forced choice inquiry. Here, the panel member must identify an odor sample among several simultaneously presented samples and choose from one of three different responses, namely *certain*, *inkling* or *guess*. Even if panelists are unable to detect a difference, they are forced to respond. The results are then evaluated by means of a so-called probit analysis or, as described in EN 13725, through an evaluation of the *certain* responses.

Since only the *certain* and *yes* responses are used in the calculation of the results, both methods yield comparable results and are accorded equal status in EN 13725. However, the more economical nature of the *yes/no* inquiry method in terms of the lower quantities of sample and dilution gas required, as well as its faster analysis time, make this method the most frequently used to date worldwide.

Figure 24.1 illustrates the general working principle of a computer-controlled olfactometer. The sample air from a sample bag is mixed with nonsmelling clean air in a dilution unit. To present the diluted sample air (purple) via a sniffing cone to the panelists (P 1–4), the dilution unit, a switch valve as well as the panel response are operated by a microcontroller.

Typically in odor assessments via olfactometry the device supplies the odor at a threshold concentration at which it is detected by just 50% of the population. This concentration is generally quantified in odor units (European) per volume, typically per cubic meter (ou_E/m^3), whereby the E suffix indicates that the value is measured according to EN 13725.

One ou_E/m^3 is defined as the quantity of an odorant distributed in $1\,m^3$ of odorless gas that just fulfills the condition of 50% prevalence of detection.

Features of the Measuring Method and Factors Affecting the Measurement Results

Many factors can affect the results of olfactometry measurements. The relevant parameters and their most important factors are as follows:

- *Dilution units* (olfactometer): Accuracy and stability of the dilution steps, flow rates, suitability of the materials used
- *Reference* (odor) *gases*: Traceability, stability during storage and transport
- *Panel members*: Mean value and standard deviation of the reference substance measurements
- *Assessment room*: Air quality, temperature, quietness.

In addition, the trueness of an olfactometric test in relation to the source depends decisively on sampling and sample handling.

24.1.2 Dilution Units (Olfactometer)

An olfactometer is an instrument used in the detection and measurement of an odor dilution. Olfactometers are

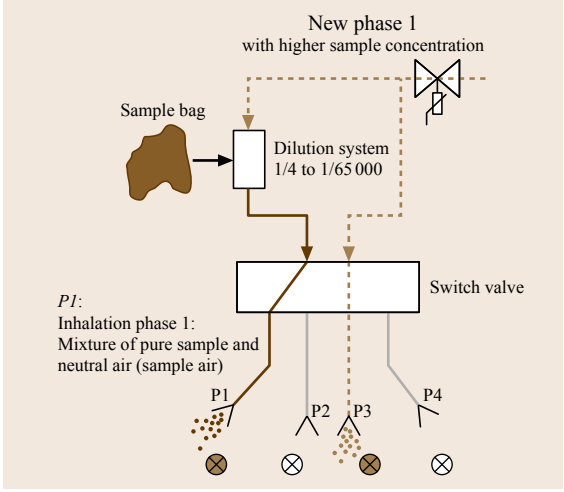

Fig. 24.1 Working principle of an olfactometer

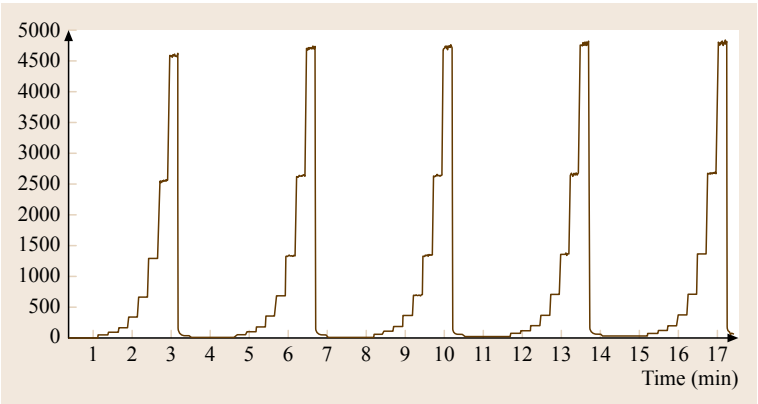

Fig. 24.2 Diagram of calibration with five repetitions per dilution step (example with propane tracer gas concentration in ppm)

used in conjunction with human subjects – more specifically, the human sense of smell – in laboratory settings to quantify and qualify human olfaction.

Requirements of an Olfactometer

The dilution apparatus of an olfactometer must satisfy a number of requirements and quality criteria. The use of inert (odorless) materials such as glass, stainless steel or polytetrafluoroethylene (PTFE) for all odorant-carrying parts of the olfactometer must be used in order to prevent corrosion, contamination and odor modification. It is known that a coating of stainless steel and glass such as silicone-carbon (SiC) improves the chemical resistance of an olfactometric dilution unit.

Furthermore, the device must meet certain standards of accuracy of dilution, repeatability and trueness. It should be noted here again that the odor perception of individual panelists is logarithmic, i. e., they are, depending on the concentration range of the respective odorant, only just about able to reliably distinguish a halving or doubling of the odor concentration. Such an extremely high accuracy of the dilution ratios is not absolutely necessary since the requirements on accuracy dictate that they must be in an appropriate ratio to other error sources, mainly the human as a sensor.

Requirements of a Dilution System Conforming to DIN EN 13725:2003.

- Dilution range from less than 2^7 to at least 2^{14}, with a range of at least 2^{13} between the maximum and minimum dilutions.
- Predilution is permitted and can be applied to reduce the concentration of a sample to within the measurement range of the instrument.
- The step factor between consecutive steps must be greater than 1.4 but less than 2.4.
- The evaluation process must enable panelists to sample easily without distraction throughout the assessment of the odor.
- The air flow delivering the odor to the panelist must be at least 20 l/min.
- The port must be shaped in such a way that the air velocity in the port is at least 0.2 m/s.

Calibration of an Olfactometer According to DIN EN 13725:2003.

- Each step should be run at least five times with the recording of at least 10 single values in each case (Fig. 24.2).
- A full calibration of the performance of the dilution unit must be made at least once per year.
- The accuracy A_d of a set dilution step must be $\leq \pm 20\%$ (Fig. 24.3).
- The instability I_d of a given stimulus must be greater than 5% (Fig. 24.3).
- The reference material (analysis gas) used must have an accuracy higher than $\pm$ 3%.

Fig. 24.3 Mobile measurement laboratory (odor room) in use on site

24.1.3 Panel Members

The results of an assessment using an olfactometer depend quite decisively on the individual panel members and in particular on their olfactory acuity, their ability to reproduce odor threshold detection, their mental concentration, and their tendency to guess.

Panel Selection and Recurrent Screening

Panel members are typically selected according to a set of criteria to ensure homogeneity in terms of their average sensitivity and a good reproducibility of odor threshold detection. The requirements that panel members must satisfy and their behavior during assessments is covered by a code of conduct in DIN EN 13725, which states among other things that:

- Panel members shall be at least 16 years of age and willing and able to follow instructions
- The panel member shall be motivated to carry out his/her job conscientiously
- The panel member shall be available for a complete measurement session; preferably for a sufficient period to build up and monitor a history of measurement
- From 30 min before and during olfactometric measurement, panel members shall not be allowed to smoke, eat, drink (except water) or use chewing gum or sweets
- Panel members shall take great care not to cause any interference with their own perception or that of others in the odor rooms by lack of personal hygiene or the use of perfumes, deodorants, body lotions or cosmetics
- Panel members suffering of a cold or any other ailment affecting their perception of smell (e.g., allergic fits, sinusitis) shall be excluded from participating in measurements
- Panel members shall be present in the odor room or in a room with comparable conditions 15 min before the measurements start in order to get adapted to the actual odor environment of the measuring room
- During measurements panel members shall not communicate with each other about the results of their choices. Informing them of the correctness of their choices after the measurement can enhance the motivation of the assessors during the measurements.

Example of the Selection of a New Panel Member

Although it is well known that the range of sensitivity to individual odorants is much wider than for many multisubstance mixtures, sensitivity is currently determined exclusively with *n*-butanol as the reference substance. For *n*-butanol, the odor threshold concentration requirements of a sample group is a mean of 0.040 µmol and within the limits of 0.020 and 0.080 µmol/mol, which corresponds to 63 to 246 $\mu g\,m^{-3}$, and the standard deviation of the individual threshold estimate (ITE) should be less than 2.3.

The measurements should take place on three nonconsecutive days with a total of at least 10 and at most 20 single threshold estimates per panel member. In general, gathering roughly 20 ITE on *n*-butanol per panel member on these three selection days has proven effective, as the associated improvement in statistical certainty has a positive effect and more panel members achieve compliance with the demanded values.

Above and beyond the criteria given in DIN EN 13725:2003 relating to the mean and standard deviation of reference substance measurement, the following points also have a large bearing on the quality of an olfactometric assessment:

- Panel member motivation (working atmosphere, payment)
- Identification with the work (main task as a panel member in a company)
- Information on the measurement (awareness of the importance of the test)
- Discipline (compliance with the code of conduct for panel members)
- Length of panel membership (experience of different odors)
- Frequency of panel member work (panel's state of training)
- Panel member stress (number of samples and breaks).

Limits to Panel Member Performance

Panel member performance is the limiting factor for the number of samples measurable by a panel in a single day. The work of a panel member demands a high degree of concentration and is therefore much more stressful than initially supposed. The methods therefore must be optimized so that panel members are exposed to as little stress as possible without the quality of assessments declining, thereby ensuring that as large a number of samples as possible can be processed in a day. The intervals between the dilution steps should not be smaller than necessary, with a step factor of two being considered optimal in most cases. Closer gradations expose panel members to more stress without achieving a significant improvement in results.

The method of limits with ascending odor concentration operates largely in the range below the threshold and with very low odor concentrations in the proximity

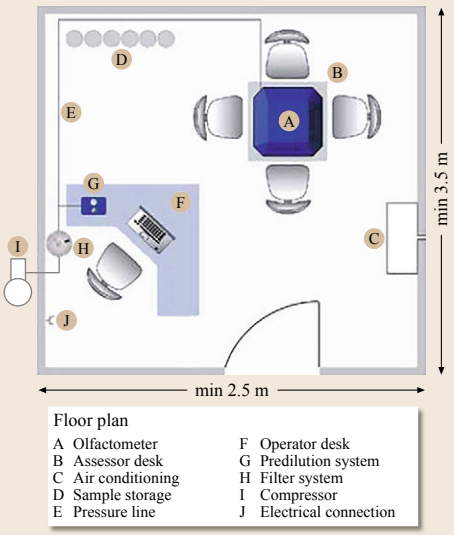

Fig. 24.4 Laboratory odor room, permanently installed

of the threshold concentration. The stressing of panel members via this method is much lower than with the method of constant stimuli.

If reference air and the diluted sample are presented alternately to panel members with each breath (inhalation), then adaptation is reliably prevented and panel members can compare each inhalatory breath with the next. The reproducibility of odor threshold identification is thus improved and the stressing of panel members is lower. Only given these preconditions can an average panel reliably measure about 16 samples per day if every four to six samples are followed by a break of at least 30 min. If a measurement project calls for a higher number of samples per day, several panels have to be employed.

24.1.4 Requirements of an Odor Room According to DIN EN 13725:2003

The European standard describes three types of possible odor rooms, each of which must be agreeable and odor-neutral:

- Stationary, permanent laboratory
- Mobile units, purpose built into a truck, van or container (Fig. 24.4)
- Specially adapted rooms.

Further requirements on the environment of the odor room are as follows:

- The room shall be kept well aired
- The maximum temperature in the room should be 25 °C
- Temperature fluctuations during the measuring process must not exceed ± 3 °C
- The room must not be exposed to direct sunlight
- No noise or light sources that can affect measurement are permitted
- The room must be hygienically clean
- It must be possible to force-ventilate the room via active carbon filters
- The CO_2 volume fraction in the room shall be less than 0.15%.

During prolonged sample transport to a permanently installed laboratory at the headquarters of the measurement institute, validation of storage stability is advisable. To this end, a single measurement should be performed on site after brief storage and an identical set of samples investigated again after a time equal to the planned storage time (maximum 30 h according to DIN EN 13725:2003). Only when storage stability has been confirmed should the maximum permissible storage time according to European standards be exploited in subsequent tests.

Sample preparation by dilution with nitrogen during sampling can improve a sample's storage properties. In all cases, temperature and exposure to sunlight during storage and transport must be controlled and documented to avoid thermal degradation or oxidation of the odorant molecules in the sample. One or more *reserve samples* for subsequent measurements should be planned if the samples are not to be immediately evaluated.

During measurements on site (at the location of the odor), the possibility of storing samples in an air-

Table 24.1 The table below lists the details that the assessment record or report must contain

Area	Required details
Olfactometer	Last calibration (with instability and accuracy)

Measurement room	Temperature Max. 25 °C Delta max. 3 °C
Panel	Abbreviation, position Number and position of responses and errors on blanks Reference values min. 10, max. 20 ITEs History of reference values
Laboratory	Reference values; 20 laboratory values Precision, accuracy (A and r) History of laboratory values
Project	Project name Operator Place of measurement
Measurement	Date, time Dilution range Number of rounds Subsequent panel selection delta Z; zero sample errors Remarks on measurement
Sample	Designation Date, starting time of sampling Sampling time Predilution for sampling

Example of a measurement record conforming to DIN EN 13725:2003

conditioned odor room ensures optimum storage conditions. Storage time should be kept as short as possible in all cases. During measurements on site, sampling and measurement time can be mutually adapted to permit greater flexibility, for instance during facility setup and optimization and in the event of changes in operational processes or disturbances to facility operation.

24.1.5 Ongoing Quality Control, Repeatability and Accuracy of the Laboratory

To ensure reproducible results and minimal measurement uncertainties of the olfactometric method, DIN EN 13725:2003 demands certain standards of repeatability and accuracy of laboratories. These refer to a reference concentration (EROM) of the standard reference material *n*-butanol at a concentration of 123 $\mu g/m^3$ or 0.040 $\mu mol/mol$.

As a result, over and above checks of the individual panel members, the overall olfactometric system comprising the odor room, olfactometer and panel are tested with the aid of *n*-butanol. DIN EN 13725 demands compliance with the following values in this scenario

$$\text{Required repeatability } r \leq 0.477\,,$$
$$\text{Required accuracy } A \leq 0.217\,.$$

These requirements are calculated with the aid of at least 10 and at most 20 values of the geometric mean of all panel members Z_{ITE}. When a sufficient number of threshold estimates is available, an evaluation based on 20 values is better, as the scatter is thus improved (lower).

Even if the requirements of laboratory values r and A are still satisfied, there is a risk of the demanded accuracy no longer being achieved in the event of constantly high or low laboratory values (sensitivity), as the systematic deviation from the EROM becomes too large. In practice, when selecting the panel for a measurement, it must be ensured that *sensitive* and *insensitive* panel members are uniformly distributed in a panel in accordance with EN provisions in order to keep the panel average as constant as possible.

The ongoing control of laboratory values against the standard reference material *n*-butanol must be repeated in accordance with DIN EN 13725:2003 after a maximum of 12 samples in each case. An assessment at the start of each measurement of the overall measurement system comprising panel members, olfactometer and odor room using *n*-butanol as the reference material has therefore become established practice in olfactometry laboratories.

24.1.6 Assessment Record or Report

Dynamic Olfactometry as the method to determine environmental odor concentration is standardized in Europe for more than 30 years.

State of the art today are fully automated olfactometers. Due to the fact that odors are always mixtures of several chemical components, standard industrial mass flow controllers, calibrated on single components as used for olfactometry for many years are not suitable for olfactometry. Modern olfactometers are based on the proven principle of combining gas jet pumps and fixed sapphire orifices. Today, dedicated laboratory information management systems (LIMS) for odor labs are used, allowing the laboratory to perform on a much higher quality level than in the past. This LIMS guides and assists the lab to qualify the sensory panel, keeping track of lab performance as well as managing reference gases and projects. All this information has to be recorded according to EN 13725:2003 (Table 24.1). The improvement of the

quality of the olfactometric method over the last 15 years has been demonstrated in several international lab comparison tests with more than 40 participating laboratories.

Although sensor technology has seen major achievements and breakthroughs in recent decades [24.1], the human panelist is still the sensor of choice when it comes to the question of ambient odor rating, and derived strategies related to controlling the quality of ambient air. Considering this fact, panelists play the central role in the quality of the olfactometrical results.

However, further developments and optimizations are required such as ergonomic design of olfactometers, thereby offering the panelists a distraction-free environment, as well as improvement of the materials used for the sample dilution to limit the distracting impact on olfactory perception to a minimum.

24.2 Evaluation and Presentation of Measurement Results

The calculation of olfactometric analyses starting with the presented dilutions via a panel member's ITE through to the measured value in ou_E/m^3 is described in the following.

A complete set of panel member responses consists of at least eight ITEs from at least four panel members. An ITE is counted as a panel member result if the latter gives a true, positive response for two successive dilution steps. The geometric mean from the last not-identified dilution step and the first correctly identified step forms the individual result (ITE). From the responses from all panel members, the mean value is calculated as the Z_{ITE}. Panel members whose individual sensitivity deviates by more than a factor of five ($\Delta ITE \geq 5$) from the mean value of all panel members are excluded from the calculation of the odor concentration. The same applies to panel members who supply more than 20% false responses to the presented neutral gas (presentations without odor). The software of most olfactometers excludes panel members automatically.

25. Assessment of Environmental Odor Impacts

Bettina Mannebeck, Heike Hauschildt

The field of environment odor assessment involves evaluating odors in ambient air, focussing primarily on offensive odors. Olfactometry is an indispensable tool used in this field to assess odors and establish their concentration at the source. This area of application incorporates regulated methods for sampling and measurement, and includes field inspections that aim to evaluate odors at or in close proximity to the problematic neighborhood. The human sense of smell is the primary tool for such analyses, representing an ideal proxy for the local population affected by the offending odor.

Various odor emissions are encountered in modern-day environments, many of which are increasingly relevant in terms of odor nuisance and are thus subject to legislations by local and national authorities. The past 20 years have seen a substantial increase in the number of regulations on environmental odors, both at the European Union (EU) level and at a national level by its member countries. This development has been concurrent with a growing common understanding and acceptance of annoyance and nuisance related to such odor emissions. Certainly, the effects of man-made environmental odors must be considered in the context of health and wellbeing, especially given the well-accepted holistic nature of health, which is defined by the World Health Organization as *not only the absence of disease, but also a state of complete physical, mental, and social well-being* [25.1].

However, the potential of odors to cause disease-like conditions is not fully understood, to date. Although symptoms of illness are often related to situations of extreme exposure, it is generally accepted that many somatic symptoms can be attributed to the exposure, rather than being caused by it per se. In other words, it appears that the psychological impact of odorant exposure has perhaps a more significant impact on wellbeing than the direct pharmacological or toxicological effects, at least in view of the low concentration levels often encountered, which potentially exhibit high odor potency and are thereby perceived as being at high levels. Further systematic studies would be required to comprehensively rule out the potential of actual physiological effects. Nevertheless, even if specific odorants are not of toxicological concern, the persistent exposure to unpleasant odors can dramatically reduce the quality of life of those affected. This might lead to source-directed, media-supported activities and/or lawsuits by the exposed community, resulting in an altered behavior by the perpetrator of the odor, by introducing abatement and/or avoidance strategies [25.1].

While odor regulations in the EU still vary greatly between its member states, methods for environmental odor assessment have been formalized at the EU level, with European standards as well as national, regional, and local guidelines available.

Given the fact that environmental odor is primarily concerned with its effects on human individuals or populations, it is reasonable that odor impact is evaluated by human assessors, both directly at the odor source and in the areas affected. To fulfill the required criteria for this important task, the assessors are carefully selected and tested using a defined routine to ensure that they can serve as a proxy for the broader population; in particular, this ensures that assessors

are not overly sensitive or conversely insensitive (or perhaps anosmic) to the target odorants. In addition to the requirements related to the olfactory sensitivity of individual assessors to specific reference materials, the necessary skills required by the panelists are also defined.

25.1 Odor Measurement at the Source

Olfactometry for investigating and evaluating odor emissions from sources is carried out according to the European standard EN 13725 [25.2]. Although this standard defines the method of odor assessment, there are currently no standardized practices for the method of sampling, neither at a national level nor from the EU. The annex of EN 13725 contains some details on sampling, with further details on measurement and sampling of stationary source emissions available in EN 15259 [25.3]. National guidelines in some instances, for example guidelines issued by Verein Deutscher Ingenieure (VDI), provide additional information on sampling and assessment.

25.1.1 Sampling

Planning and conducting sampling requires knowledge on the objectives of the measurement, the nature of the odor and its mass transport, and the targeted production processes that require monitoring. According to EN 13725, a sampling strategy should take into account the following aspects, which can be reviewed during a preliminary visit to the site [25.2]:

- Relevant odor-producing processes(s) to be identified
- Assessment of the toxicity and potential risk to the sampling team and the panel members of any emissions
- Location(s) of odor emission points
- Likely fluctuations in odor emissions with time (these can be estimated by using a continuous monitor like a flame ionization detector (FID))
- Odor sampling point locations
- Conditions affecting the odor emission:
  - Uncontrolled conditions, for example, the weather
  - Controlled or controllable conditions [25.2].

EN 15259 defines requirements for measurement sections and sites at waste gas ducts, and provides guidelines on the measurement objectives, plan and assessment report [25.3]. These considerations provide further steps towards gathering representative samples, conducting reliable assessments, and achieving comparable results.

Further questions that need to be addressed when setting up the sampling and measurement strategy relate to in situ assessment versus on-site sampling with off-site assessment, the storage period and conditions of samples for the latter scenario, and the sampling duration and the number of samples to be taken at each location. Some proposals for answering these questions are given in the following section.

Whether the analyses of samples are performed in situ or off-site after sampling depends on the specific goals of the measurement. In scenarios for which informative statements about emission behavior must be made available at short notice, for example as is necessary during the initial setup and optimization phase of an assessment task, in situ evaluation is helpful and often essential.

According to EN 13725 [25.2], the period between sampling and measurement, including sample transport, should not exceed 30 h. In Germany, VDI 3880 [25.4] dictates that for storage periods of longer than 6 h, proof must provided that the odor concentration in the samples has not changed from its original concentration at source. This check must be performed for each source and process condition, although a further examination may be omitted if the stability of odor samples has been proven at sources with identical waste gas compositions.

A frequently used sampling time is 30 min, as this is often required by law, in Germany by environmental laws. However, since a mean concentration value is often uninformative in cases of neighborhood nuisance caused by brief peak concentrations, shorter sampling times adapted to facility processes are advisable in some cases. This can be the case for sampled facilities with batch operation and/or discontinuous emission behavior.

A further sampling requirement is that the number of samples collected and analyzed must suit the task. To determine compliance with emission values, sampling is usually performed threefold. Facilities with consistent operating conditions that usually do not change over time require at least three single measurements with the highest odor flow rate during undisturbed continuous operation and at least one further measurement for each regularly occurring condition with fluctuating

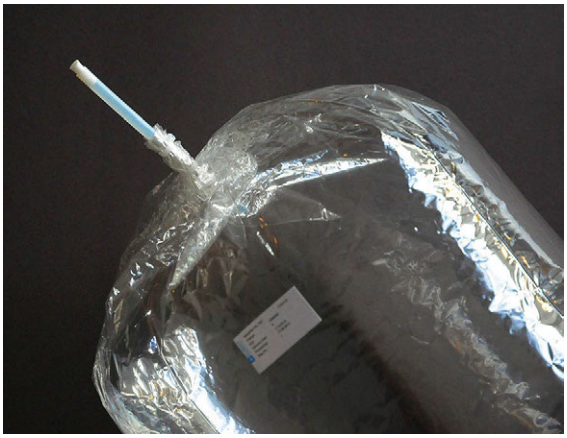

Fig. 25.1 Sample bag for odor samples made from Nalophan NA conform to EN 13725 (after [25.2])

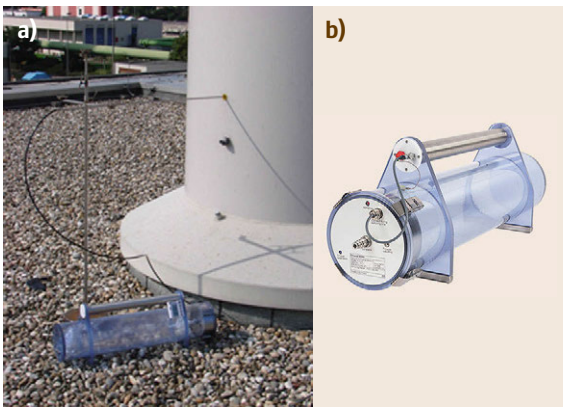

Fig. 25.2a,b Sample collection system consisting of a stainless steel probe, delivery pipe, and sampling device with sample bag at a duct source during sampling

emission behavior. Facilities with operating conditions that change over time require a higher number of measurements and at least six during the operating conditions that cause the highest emissions.

The demands on the material of all sampling materials (Fig. 25.1) are precisely defined in EN 13725 [25.2].

Different Types of Sources

Odor emission sources vary, and three different types of emission sources have been defined according to the shape of the emission source and to the presence of a volume flow. The three types of sources are: point sources, diffuse sources, and aerated diffuse sources.

Point Sources. Point sources or active duct sources, are waste gas ducts or ventilation outlets with a defined area and air flow rate. These sources are primarily industrial, controlled waste air sources such as stacks

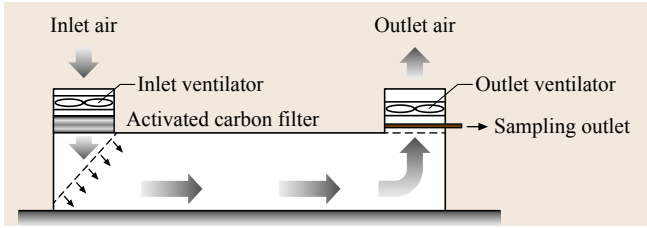

Fig. 25.3 Schematic diagram of an aerated sampling hood for diffuse or passive area sources: The inlet air is cleaned via the activated carbon filter and then directed over the open surface (liquid or solid) where it is loaded with the source-specific odor. The sampling outlet is used to collect the sample over an adequate period of time

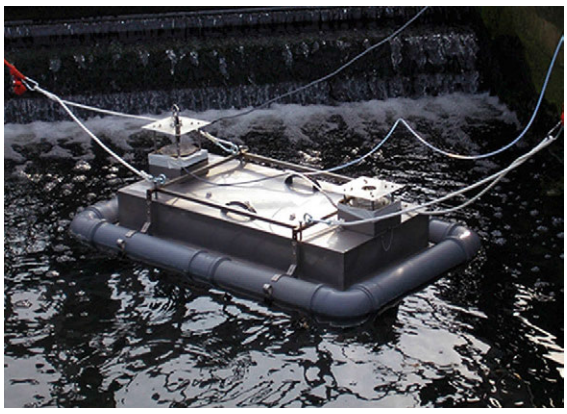

Fig. 25.4 An aerated sampling hood with floaters for liquid surfaces

and chimneys. In EN 15259 [25.3], these are termed stationary odor sources. A source is defined as active when the area-related waste air flow rate is greater than $30\,m^3/(m^2h)$ [25.4]. The complete measurement of active duct sources, in addition to sampling for olfactometry, includes the measurement of the waste air parameters such as flow rate, temperature, and humidity. The odor mass flow is calculated as the product of the measured odor concentration and the measured air flow rate. Indeed, a detailed knowledge of the facility at which the sample is taken, as well as its operating processes, is indispensable in allowing traceable statements that are representative of the state of the source to be made. Sampling at point sources can be done using a sampling chain consisting of a probe, a delivery pipe and a sample collection system [25.2], which usually consists of a sampling device and a sample bag. A typical sampling chain for duct sources is show in Fig. 25.2.

Diffuse Sources. Diffuse or passive sources are defined by convention to have a flow velocity of less than $30\,m\,h^{-1}$ based on the arithmetic mean over the entire surface [25.4]. Such sources are area sources (non-

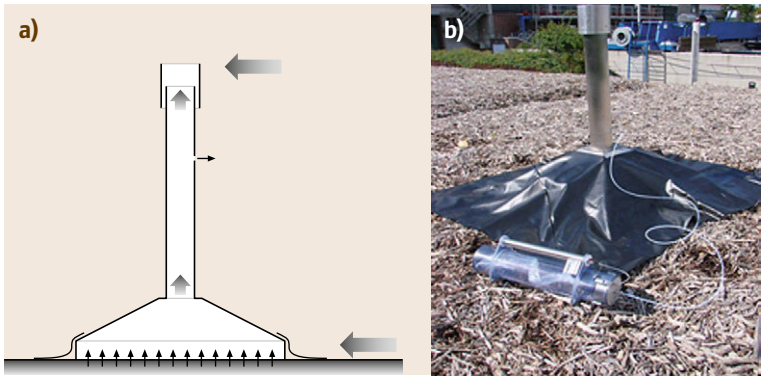

Fig. 25.5a,b Schematic diagram and picture of a sampling hood for active area sources. The sampling hood is placed on the surface of the aerated source. A sheeting (continuous apron) which overlaps the base of the sampling hood with a width of 0.2 m and a chimney collar prevents the dilution of the collected outlet gas by wind. The sampling/measurement orifice is used for sampling and concurrently for the corresponding velocity and temperature measurement. Schematic diagram **(a)** and picture **(b)** for active area sources.

aerated compost piles, waste dumps), passive liquid area sources (waste water tanks or basins), or volume sources (buildings with open windows or doors, leakages, ventilation through joints and windows, via wells or roof pipes). No standardized European regulations on sampling diffuse or passive sources are available at present. VDI guideline 3880 [25.4] describes a sampling strategy to ascertain the odor flow rate using specific measuring equipment, as shown in Figs. 25.3 and 25.4. As diffusion can be expected to have at least a noticeable effect on the overall emission flow, aerated sampling hoods are typically used. Calculation of the odor mass flow requires not only the odor concentration but also a corresponding volumetric flow rate per unit time. Thus the sampling methodology aims to extract a known quantity of air from a box covering a defined area of the source and to supply neutral gas to replace the extracted air with odor-free air. Sampling at diffuse sources can be done using a sampling chain consisting of an aerated sampling hood, a probe, a delivery pipe, and a sample collection system [25.2], which again typically consists of a sample bag and corresponding sampling device.

Aerated Diffuse Sources are diffuse sources with an air flow velocity of at least $30\,\mathrm{m\,h^{-1}}$. Such sources are usually area sources such as biofilters or aerated liquids. EN 13725 outlines two methods for sampling aerated diffuse sources:

- Via sampling hoods (Fig. 25.5)
- By covering the total source (or a large part of it) with foil to allow sampling of the mixed emission.

The flow rate of active area sources is measured in the crude gas ducts, with the sampling points defined according to EN 15259 [25.3]. Subsequent calculation of the clean gas flow rate requires the implementation of a humidity correction factor between the crude and clean gas [25.4] This approach relates to the fact that the measurement of the flow rate by means of a sampling hood placed over the surface of an active area source cannot be used directly for determining the waste air flow rate due to the influence of the wind and the pressure loss associated with mounting the sampling hood and leading to imprecise air flow rates. Still, the distribution of the air flow over the surface of the area source must be determined in addition to the flow rate, which is achieved by dividing the surface of the source into parts and measuring the individual air flows in each of these smaller areas. The amount of parts depends on the size of the source and is defined according to VDI guideline 3880. As long as the air flow rates of the parts differ by less than a factor of two, the source can be considered as homogenous [25.4]. Sampling at aerated diffuse sources can be done using a sampling chain consisting of a sampling hood, a probe, a delivery pipe and a sample collection system comprising the appropriate sampling bags and device [25.2].

25.1.2 Transport and Storage of Samples

Certain conditions must be met during transportation and storage of samples. On the one hand, the temperature should be controlled: the temperature in the sample bag should not exceed 25 °C and it should be kept above the dew point to prevent condensation in the sampling bag. On the other hand, exposure of the sample to sunlight must be avoided during storage and transportation to avoid photooxidation of odorants in the sample. Further, any damage or contamination of the bags, also from the ambient environment, must be prevented [25.2].

25.1.3 Measurement

Due to the nature of human olfaction in terms of its diversity in the perception of odor notes and the extensive dynamic range of sensitivity depending on the chemical structure of the odorant, there are currently no technical

sensors that offer an established relationship between the measurement detection and human odor perception, and most systems are too insensitive for many applications. As such, the human nose is indispensable in olfactometry.

Odor Concentration According to EN 13725

The determination of the odor concentration of a gaseous sample of odorants is determined by presenting a sample to a panel of selected and screened human subjects, varying the concentration by diluting with neutral gas, in order to determine the dilution factor at the 50% detection threshold.

More details concerning the determination of the odor concentration can be found in Chap. 24.

Descriptions of Environmental Odor

It is often helpful or even necessary to describe an odor in more detail than providing just its concentration. Especially in cases of odor annoyance, or when evaluating the efficacy of an odor mitigation technology, it is necessary to describe the odor in more detail.

Helpful parameters can be:

- Intensity – how strong do I perceive the odor?
- Hedonic tone – how pleasant do I perceive the odor?
- Odor character – how does it smell?
- Annoyance level – how disturbing is the odor?

These parameters are usually not part of a standardized evaluation under the current legislation. In some cases, however, for instance in Germany, the evaluation of the function of odor abatement technologies in which a comparison is made between the crude gas and clean gas is part of a license. In these cases, the license states that no crude gas character should be detectable in the clean gas.

Evaluating the intensity of an odor can be performed using an olfactometer according to VDI guideline 3882, sheet 1 [25.5], and likewise the evaluation of the hedonic odor tone can be performed according to sheet 2 of this guideline [25.6]; however, these are rare aspects of commercial projects involving odor measurements due to the required effort (and associated costs) and the absence of legal regulations.

Assessment of samples in a direct evaluation by a trained panel that takes into account the scales of the intensity or hedonic tone levels according to VDI guideline 3882 [25.5, 6] delivers useful additional information at manageable effort. Further, a direct evaluation can be used to gather information on verbal descriptions of the odor character or the annoyance level [25.7].

25.2 Measurement of Odor Impact by Field Measurement

The legislation of several European countries primarily focusses on protecting the population. In Germany, for example, the Federal Pollution Control Act (Bundes-Immissionsschutzgesetz – BImSchG) defines that harmful environmental effects must be avoided. It defines harmful environmental effects as those, which according to their nature, scale (concentration) or duration (persistence), are suited to bring about serious disadvantages or considerable nuisances for the public or neighborhood. In particular, the Act defines that an environmental odor is not a considerable nuisance as long as the human impact of an odor from production facilities is not more frequent than 10% of the yearly hours in inhabited areas or 15% of the yearly hours in commercial areas – provided the odor is not disgusting or nauseating.

The assessment of environmental odors in ambient air in several cases is only possible via the direct evaluation by a human panel. Dynamic olfactometry has a high detection limit, is generally only suitable for measuring odors of at least $10\,\mathrm{OU\,m^{-3}}$, and is thus not applicable for odors that can only just be perceived.

The draft of the European standard prEN 16841 [25.8, 9] presents methods that make direct use of the effects of odorants on the human sense of smell. This standard involves the use of qualified human panel members in the field to directly assess the presence of recognizable odors in ambient air according to a defined measurement plan and provides data that can be used to characterize odor exposure within a defined assessment area. So far the methods for field measurements are described in the guidelines VDI 3940 sheet 1 and 2 [25.10, 11].

The standard presents the following two key approaches:

- Part 1 describes a grid method that uses direct assessment of ambient air by panel members to characterize odor exposure within a defined assessment area.
- Part 2 describes a plume method for determining the extent of the downwind odor plume of a source.

The sensory methods described are only suitable for the assessment of odor in ambient air and are neither suitable for the occurrence of odor annoyance nor for the assessment of substances.

25.2.1 Grid Inspection (VDI 3940, Sheet 1)

Performing grid inspections to determine odor emissions in the vicinity of plants is covered by VDI Guideline 3940 Part 1 [25.10]. Trained odor inspectors are deployed to record odor detection at different monitoring points at different times of the day and night over a period of 10 min each. About 60 samples are recorded at each inspection point at 10 s intervals. The frequencies of the detected odors are then determined according to the concept of the *odor hour* and are statistically analyzed. A single measurement counts as an odor hour when the period for which an odor is present reaches or exceeds 10%. This implies that a recognizable type of odor is observed in at least 6 out of 60 observations, made at 10 s intervals within a 10 min measurement cycle.

The resulting odor hour frequency for each site is then plotted on a map as the number of positive assessments divided by the total number of single measurements, and are often color coded to indicate the severity of odor hours. Depending on the measurement task, this odor hour frequency map is generated for all installation-related odor types (to show the total odor impact) or for one or more specific installation or source odor types. The results of a grid inspection over half a year are shown in Fig. 25.6 for waste water related odors in the Rhine valley (cities of Mainz and Wiesbaden).

Grid inspections pose many challenges for the bodies responsible for monitoring odor emissions. Such inspections begin with a time-consuming and laborious phase of planning, made in coordination with the plant owners and the respective regulatory authorities before the project commences. In addition, a large amount of coordination and administrative work is required throughout the assessment period by the person responsible for the project (the project manager) to ensure that the inspections are performed in conformity with the guidelines.

The still widespread practice of paper inspection records for gathering the data has two serious inherent disadvantages. First, this method represents a high risk to the integrity of the data. Information from lost or incomplete records cannot be restored due to lack of redundancy, i. e., the absence of duplicate datasets. The second disadvantage relates to the fact that a considerable amount of time is lost between sending the records to the monitoring body and their corresponding non-availability of the information to the project manager. Consequently, this leads to a delay in the evaluation and delivery of informative results to the client.

In the current age of Internet applications and an increasing spread of powerful mobile terminal devices, the question perhaps arises as to why these grid inspections are still primarily carried out using paper records and why no satisfactory technical solution has been established, to date. To answer this question, it is necessary to take a closer look at the workflows involved in a grid inspection.

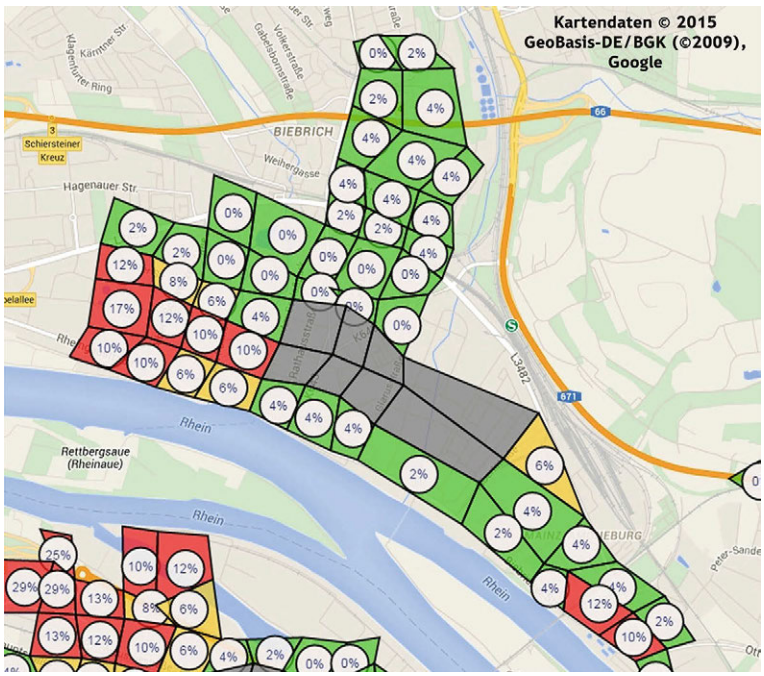

Fig. 25.6 An odor hour frequency map for installation-related waste water odors in the Rhine valley from 13/07/2011 to 27/01/2012. During this half-year, a total of 103 assessment squares (157 measurement points) were recorded. Each assessment square was measured 52 times, with 13 measurements for each measurement point (after [25.12])

Workflows for Grid Inspections

A grid inspection can be divided into three phases: planning, implementation, and evaluation. During the planning phase, site plans and map materials are used to define the inspection points and grid geometry for the evaluation area. The odor characters present in the evaluation area are determined with the help of an emissions register. The data collected during the grid inspection must be representative of the entire year, according to the requirements of VDI Guideline 3940 [25.10]. Attention must thereby be paid to the time and organizational planning to ensure a statistical spread of the scheduled sampling times during the day and night and on all weekdays. Before the project begins, the odor inspectors deployed for the project must be selected, trained, and familiarized with the work according to the requirements of EN 13725 [25.2]. The panel must comprise at least eight members (prEN 16841 [25.8]).

The implementation phase includes assigning and coordinating the odor inspectors and ensuring that the scheduled inspections are performed in conformity with the guidelines. As soon as the data collected during an inspection is passed on to the project manager, they must undergo a plausibility check to ensure that only validated data are incorporated in the evaluation.

The results are generally evaluated by transferring the data from the inspection records into prepared tables, where they can be analyzed and statistically evaluated. The results are usually delivered to the client in the form of a monitoring report that is sent after the end of the inspection period, although interim reports might be provided in some cases.

Optimization Potential of the Workflows

A large amount of work and time is required during the planning phase in order to collate the necessary data from various information sources and media for preparation of an appropriate schedule.

The deployment and organization of trained odor inspectors, most of whom do this work as a part-time side job, present additional challenges for the monitoring bodies. Inspections must be scheduled, adjusted and statistically spread uniformly among the odor inspectors for the entire project period. The monitoring body is also obliged to ensure that the inspectors perform their inspections properly by performing regular checks.

Therefore, organization and coordination of the inspections require fast and reliable communication between the monitoring body and the deployed inspectors. It must also be possible to respond at short notice to changes in inspection dates or times, or canceled or missed inspections, in order to minimize alterations in the inspection schedule. The organization of replacement personnel is an additional task for the project manager.

As is evident from the aforementioned issues, the administrative aspects of projects involve a large amount of work. Following an inspection by an odor inspector, the records must first be sent to the monitoring body, typically by post or e-mail. On arrival, the inspection records are then manually transferred into digital documents to enable a statistical evaluation. This human factor, especially where there are a large number of records, is an additional potential source of errors that can have negative effects on the quality of the results.

The digital documents form the basis for the preparation of interim and final reports, from which odor problems can be identified and possible measures can be derived. The time required for manual evaluation is therefore a decisive factor, which significantly limits the possibility of providing prompt results to the client.

Also the delivery of a final report to the client, from which the results of the inspection can be seen, always represents only a consideration of the past. In several cases an interim report is supplied in order to disseminate the findings on the initial odor emissions situation. According to this delayed availability of information (results from the field inspections) it is in generally not easy to directly trace odor emissions to emission-critical plant processes. Thus the plant owner is not enabled to quickly initiate corrective actions to improve the emissions situation. For a direct traceability, an immediate availability of information on the odor impact situation is indispensable.

The problems outlined above were identified early on in environmental odor emissions assessments and soon led to the development of rudimentary solutions.

The increasing spread of broadband Internet connectivity and efficient web applications in recent years has led to new options that are now available for dealing with these known problems. This development also benefits from the broad availability of powerful and cost-effective mobile terminal devices with Internet connectivity, which provide the basis for the development of comprehensive and efficient online systems that enable interaction between web and mobile applications.

State-of-the-Art Grid Inspection Tools

An online system for grid inspections is currently the most advanced method available for environmental odor emissions assessments. This online odor field inspection manager (OFIM) system combines the available Web 2.0 technologies to create a solution that

supports monitoring bodies from the initial planning steps through to delivery of the final results to the client. OFIM is based on a central online platform that is accessed by a web browser and enables users to log into the system from anywhere and to manage their own grid inspection projects. When new projects are created, the user can carry out all the necessary planning steps via this system, including creating and grouping various odor characters, defining inspection points and grid areas on the basis of digital map material, and defining inspection routes.

If grid points that are defined during the planning are not accessible for inspection, they can be relocated online within a very short time. Individual monitoring schedules that conform to VDI 3940 [25.10] can then be created automatically and the organization of personnel for the inspections can also be dealt with centrally via the online platform.

The inspectors can examine the planned inspection dates via Internet access to the system and can register for participation. Nevertheless, the final assignment of the inspection dates rests with the project manager to ensure the necessary statistical spread of the deployed inspectors.

The monitoring schedule includes information on the availability of inspectors, and with the assignment of an inspection date the system automatically sends a confirmation to the respective inspectors. This substantially reduces the administrative work required for assigning inspection dates and personnel coordination, which until now traditionally proceeded by phone calls and e-mails.

A mobile application for smart phones with the Google Android operating system is used by the odor inspectors to electronically record data during their inspections. Thanks to mobile Internet connections, smart phones using this system can be managed remotely, which is a major advantage compared to the earlier inspection system using pocket PCs. Moreover, this means that the mobile terminal devices can be kept by the inspectors for the entire inspection period, without the need for collection from and/or distribution to the inspectors before and after their use.

A user-friendly interface enables the inspectors to easily download the necessary project data on the day of the inspection, which is updated daily. GPS positioning is used during the inspection to ensure they are at the correct target coordinates. This is used by the monitoring body as an additional option for regular inspector control, as required in VDI 3940 [25.10]. The inspection results are subsequently transmitted to the online platform via the smart phone's Internet connection. This means that the results are imported into the system and are available to the project manager immediately after the inspection, allowing the results to be evaluated promptly. Further, the inspection results are evaluated fully automatically, thereby obviating the need for manual evaluation (and reducing potential human error) by the project manager. The system not only provides a detailed view of individual inspection results for the user, but also a comprehensive overview for a defined viewing period. With the selection of the required period, the results are made available to the users in various views, in tabular or graphical forms. The graphical representations of the results, for example, allow the emissions frequencies of the grid areas for the selected period to be examined at a glance. This allows the project manager to validate the results after a brief plausibility check.

An additional advantage of this online system is that access can also be made available to the client, which enables them to examine validated results for their project at any time. This might be of interest, for example, if certain plant processes are recorded at the same time, thereby making it possible to quickly draw conclusions regarding emission-critical processes and facilitate prompt initiation of measures to improve the emissions situation. If direct examination by the client is not required or not wanted by the authorities, the system can export the data for the preparation of reports.

25.3 Examples of the Evaluation of Odor and Emissions in Ambient Air

25.3.1 Case Studies

The application of grid inspections in real scenarios is explained in the following three case studies. The objectives and tasks in the application of grid inspection were different in each case, thereby illustrating the breadth of the system's use.

Case 1: Complex Plant Situation and Long-Term Inspection Monitoring

A waste treatment facility consisting of many individual plant parts caused marked complaints of odor nuisance among residents living downwind. The authorities deemed that the plant was suitable for approval. Despite the complaints, the plant owners planned to expand the facility.

Olfasense (former Odournet) was engaged to determine the overall emissions situation caused by the facility and its individual plant parts and to thereby participate in providing a solution to the problem in an advisory capacity. The assignment of the odors to specific parts of the plant and the measurement of the emissions of these individual parts were essential for achieving this. Assessment of the approved emissions of the individual plant parts showed that the limit values were exceeded in some locations and therefore the complaints of the residents were plausible. These inspections proceeded for over 4 years and were accepted by the plant operator and the residents as a control instrument.

Over a long monitoring period, it was possible to determine the emissions performance of the individual plant parts and to identify the critical processes. By optimizing the facility, the odor nuisance was reduced to below the limits defined by the authorities. The complaints situation has since been on a downward trend and continues to be monitored by means of inspections using the VDI 3940 method.

Case 2: Large-Scale Urban Area Inspections

Two adjacent German towns with diverse industrial areas and sewage treatment plants were subject to complaints of odors by the local populations. It was previously not possible to clearly assign these to individual plants. Olfasense (former Odournet) was therefore contracted by a governmental body to prepare extensive mapping of the odors in these urban areas.

The inspections were carried out over a 6-month period and included 170 inspection points. Inspections were carried out, recorded, and evaluated on a daily basis. Due to the transparency of the results and the determination of plausibility, it was possible to reliably assign the odors to the offending plants and thereby inform the plant owners of the critical odor situation of their plants.

Case 3: Correlating Grid Inspection Results in a Complaints Management System

A new waste treatment facility was set up with a complete complaint management system.

This grid inspection data system was integrated into an Internet communication platform that generated an online propagation modelling of the odor plume and a complaints recording tool and allowed for information to be transparently provided to the plant operator and local residents.

The system made it possible to integrate the grid inspection data into a complaints management system in order to compare the residents' complaints with objective data and to take appropriate action to control and improve the prevailing mood in the neighborhood. This precautionary measure is a good way of using open communication to prevent a tense neighborhood situation from developing.

25.4 Conclusion

This chapter presents a brief overview of the odor measurement methods used in the field of environmental odor assessment, either at the source or in affected areas. In the coming years, odor measurement will require the assignment of human assessors to capture the exposure-related effects on humans. It becomes clear that with the increasing demand for fast and transparent information state-of-the-art technologies will help to serve affected stakeholders in existing odor conflicts.

26. Material Odor Emissions and Indoor Air Quality

Andrea Burdack-Freitag, Anja Heinlein, Florian Mayer

Indoor air is a complex and dynamic mixture of a huge variety of volatiles and particulate matter. Some of the constituents are odorous and originate from various sources such as construction materials, furniture, cleaning products, inhabitants and many more. Therefore, every indoor environment has a unique chemical composition in its air space. Volatile organic compounds and odorants in indoor air may cause psychological and/or physiological discomfort in humans. To reduce unwanted indoor air pollutants, it is of great interest to evaluate their sources and chemical structures. This chapter will provide an overview of methods used to evaluate indoor air and material emissions as well as current knowledge of odorants emitted by selected and common sources of indoor odors and in addition human bio-effluents. Measures to avoid and reduce odors as well as health concerns associated with indoor odorants will be discussed. Importantly, this chapter focuses on odorous organic volatiles present in indoor environments – non-odorous volatile organic compounds that can also affect indoor air quality will be mentioned only in passing.

Nowadays, people spend large parts of their lives indoors. Next to noise level and thermal comfort, the quality of air is essential for wellbeing inside homes, offices, schools and other private and public buildings. Nonspecific complaints like eye and airway irritation, dry skin together with general symptoms of headache and lethargy that occur whilst people are sojourning in a specific room or building are attributed to the *sick building syndrome* [26.1]. The cause of the symptoms is not conclusively clarified, yet it is often attributed to the presence of volatile organic compounds (VOCs). In total, several hundred different compounds have been identified in indoor environments [26.2]. Since most indoor materials emit VOCs, efforts are continuously made to reduce the total amount of VOCs (TVOC), semivolatile organic compounds (SVOCs) and carcinogenic substances emitted from buildings, indoor materials and products by complying with maximum emission levels. A number of national and international guidelines and standards for the monitoring and minimization of emissions are available for building products, for example issued by the German Federal Environment Agency (Umweltbundesamt UBA), Committee for Health-Related Evaluation of Building Products (Ausschuss zur gesundheitlichen Bewertung von Bauprodukten AgBB), by DIBt (Deutsches Institut für Bautechnik, German Institute for Building Technology) or by the German Blue Angel Labeling System (Blauer Engel) [26.3–5]. It is nonetheless difficult to document if the use of low-emitting construction materials actually results in fewer complaints, since the symptoms are often complex [26.6]. Additionally, there is a possibility of confusion of odor with sensory irritation [26.6]. For this reason and the fact that consumers refuse products with a strong smell, manufacturers are challenged to reduce not only TVOC emissions but also emissions of odorants. Specialized methods for the evaluation of indoor odors, odorant analysis and identification of odor emission sources have to be employed to tackle these problems.

26.1 Effects on Indoor Air Quality

One aspect influencing indoor air quality is the presence of volatile organic compounds. As a subgroup of VOCs, odorants can affect the perceived air quality in particular when people are consciously aware of their presence. Numerous sources of indoor VOCs and odorants are known, such as construction materials, furniture, plants, air conditioning systems, electronic devices, cleaning agents and humans themselves. Thereby, most odors in indoor as well as outdoor environments are not perceived consciously, either because of their low intensity or because the odors match personal experiences and expectations and are therefore unconsciously integrated into an olfactory background. Through alignment of this background to a present situation the environment is usually perceived as odorless or neutral. The presence of an unusual or particularly intense odor leads to a deviation from the background and hence attracts attention. Thereby, one and the same odorant can affect people in different ways, depending on its origin. For example, a smoky odor in paint is considered offensive, whereas its origin from a fireplace might be acceptable [26.7], from a piece of cured ham even pleasing. Additionally, unpleasant odors are often associated with health risks, which may cause psychological stress as well as physiological symptoms such as respiratory problems, nausea and headache [26.8].

For a long time, efforts have been made to reduce TVOC emissions in construction materials and recommendations for maximum emission levels are available [26.3]. Yet with a reduction in total emissions, the problem of odorous annoyances is not simultaneously solved, since TVOC values and odor intensity are not directly correlated as could be shown for several materials [26.9–11]. Figure 26.1 shows the noncorrelation of TVOC emissions and the perceived odor intensity of an oriented strand board sample. Odorants with low odor thresholds often appear only in trace amounts and are not detectable in routine emission measurements, yet they may strongly affect the sensory impact of the source material.

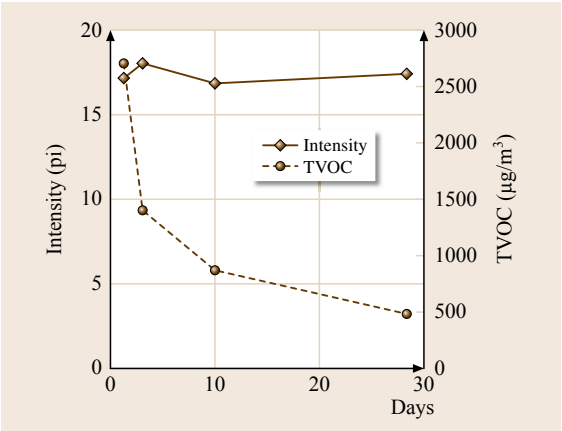

Fig. 26.1 Intensity and TVOC values of an oriented strand board sample (after [26.3])

26.2 Odor Evaluation Methods

Common techniques for odor analysis such as one- and multidimensional gas chromatography (GC) coupled with olfactometry (GC-O) and mass spectrometry (GC-MS), fractionation techniques and dilution methods such as aroma extract dilution analysis have been successfully applied to the analysis of indoor materials as well as air samples. Also, different sampling methods such as headspace and thermal desorption have proven suitable [26.8, 12, 13]. In recent years, online measurements based on mass-spectrometric (MS) detection, such as proton-transfer-reaction [time of flight] MS (PTR-[TOF]-MS), membrane inlet MS (MIMS) and selected ion flow tube MS (SIFT-MS) have been used for the assessment of environmental odorants [26.14]. As the methods mentioned are already well established in odor analysis and are thoroughly addressed in other chapters (Chaps. 17 and 18), they will not be enlarged upon in this chapter. Instead, panels, scales and methods used for the evaluation of indoor odors and odorous emissions from materials will be detailed.

26.2.1 Panels

A sensory panel should be considered as a true *measuring instrument*, and care should be taken in the recruitment of participants. Generally, it is possible to use either an untrained, naïve panel or a trained panel. Naïve panels should represent the average society regarding age, gender, social status and have a normal sense of smell. They should have no or little experience in olfactory testing and assess the presented odor unbiased. The rating of odor intensities and odor qualities by naïve panels should be interpreted with care since the perceptions are usually rather subjective. Yet hedonic tone such as pleasant/unpleasant or nauseous/appetizing from naïve panels are very valuable

since they represent the average perception of society. In untrained panels a number of 20–40 members is recommended to participate in the evaluation while in case of a trained panel 4–12 panelists are, depending on the specifications in various standards, considered as sufficient [26.13]. The members of trained panels have to be checked for olfactory dysfunctions and tested for their sensitivity to certain stimuli regularly. Guidelines for the selection, training and monitoring of panelists are available in ISO 8586:2012 and DIN EN 13725:2003 [26.15, 16]. Hence, trained assessors should be able to rate odors objectively and unbiased by personal preferences or aversions.

Next to the assessment of an odor in terms of its intensity, pleasantness or acceptability (see next sections), the odor quality can also be evaluated by descriptive sensory analysis. This should preferably be done by a trained panel with a well-developed flavor language. The application of standard lists or flavor wheels with fixed odor categories (e.g., fruity) subdivided by specific descriptors (e.g., apple, banana, strawberry and so on) can thereby facilitate the evaluation.

26.2.2 Scales

In order to evaluate different odor characteristics, diverse scales can be utilized, depending on the specific question and on the training status of the panel. Thereby, even for the same odor characteristic, such as its intensity, different designs of scales are in practice – for example category and comparative scales.

Odor Intensity

The odor intensity describes the relative strength of the odor above the recognition threshold (supra threshold). For the evaluation, many descriptive word category scales are in use, for example a seven-point scale with the descriptors *not perceptible, very weak, weak , distinct, strong, very strong* and *extremely strong* used by the German Guideline VDI 3882 Part 1 or a six-point scale with the descriptors *no odor, slight odor, moderate odor, strong odor, very strong odor* and *overwhelming odor* used by the Danish Society of Indoor Climate, based on the scale by *Yaglou* et al. (Fig. 26.2) [26.17–19].

Apart from that, comparative scales to assess odor intensity are widely used in order to measure the intensity more objectively and for a better interlaboratory comparability. Thereby, the intensity of the evaluated air is compared to the odor intensity of a series of concentrations of a reference compound in air. In the guideline DIN ISO 16000-28 [26.20] as well as German guideline VDI 4302, trained panelists rate the perceived intensity Π (PI) in comparison to ascending levels of acetone. The lowest reference point is 20 mg/m^3 (0 pi), where only 50% of the assessors can still perceive acetone (odor threshold), and is raised by another 20 mg/m^3 for each further reference point (e.g., 6 pi = 140 mg/m^3). Special equipment to present these different concentrations to the panelists is available [26.21–24] (Fig. 26.3). They consist of between one and eight funnels to present the different acetone concentrations including blank air. Systems with six to eight funnels present selected defined acetone concentrations while one- and two-funnel systems allow the individual adjustment of many different defined acetone concentrations. Similar to the perceived intensity scale, odor intensity referencing scales (OIRSs) used in the ASTM International Standard E544-99 and DIN EN

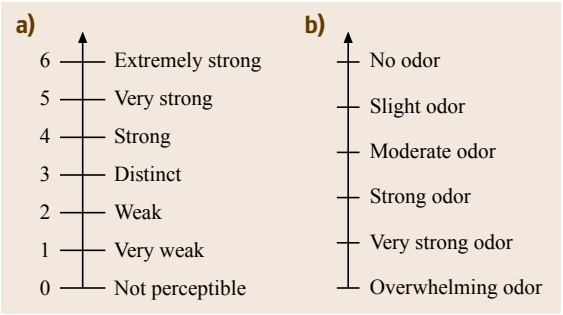

Fig. 26.2a,b Category scales for the evaluation of odor intensity according to **(a)** VDI 3882-1 (after [26.17]) and **(b)** Danish Society of Indoor Climate (after [26.18])

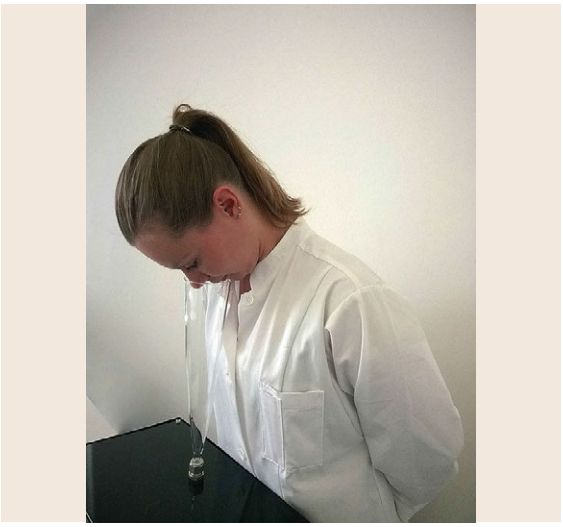

Fig. 26.3 A panelist is sniffing different concentrations of acetone in air that are being presented through special equipment with one sniffing funnel (Acetone Reference Standard ARS 2.0 developed by Fraunhofer IBP) (courtesy of Fraunhofer IBP)

13725:2003 employ a reference odorant, in this case n-butanol. Thereby, the reference odorant can either be presented in a static way using a set of bottles with fixed concentrations of the standard or dynamically using an olfactometer [26.16, 25].

Another approach to evaluating odor intensity is magnitude estimation, which puts the intensity of the assessed odor in relation to another odor. First, the assessor is asked to assign an arbitrary number to the intensity of a first odor (e.g., 50). The second odor is then rated in relation to the first (e.g., 25 if the odor is perceived as half as intense). This approach works best for similar odors [26.26].

Hedonic Odor Tone

Whilst odor intensity is a rather objective descriptor, the description of the hedonic odor tone is of a more subjective nature. It describes the subjective pleasantness or unpleasantness of an odor. Therefore, different category scales are in use, for example a nine-point scale ranging from extremely unpleasant (−4) to extremely pleasant (+4) (Fig. 26.4) or a 21-point scale ranging from unpleasant (−10) to pleasant (+10) [26.27, 28].

Acceptability

Like the hedonic odor tone, the rating of acceptability is of subjective nature. Acceptability or perceived air quality scales are widely used to measure the comfort in indoor environments [26.29]. Acceptability can be rated by a simple yes/no assessment or on a category scale. Panelists are thereby asked to imagine that they were exposed to the tested air for several hours daily. The scale can for example consist of two separate ranges, one reaching from *clearly not acceptable* (-1) to *just not acceptable* (0) and the other reaching from *just acceptable* (0) to *clearly acceptable* (+1) (Fig. 26.5) [26.10, 18, 30–33]. The discontinuity of this scale also forces the panelists to choose whether they perceive the air as generally acceptable or unacceptable. Acceptability votes are a combined impression of odor intensity and hedonic odor tone, as could be shown in experiments [26.29].

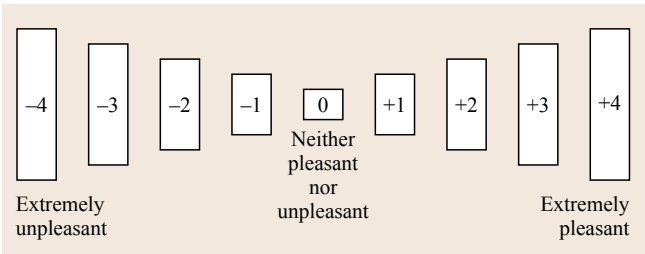

Fig. 26.4 Category scale for the evaluation of hedonic odor tone (VDI 3882-2, after [26.27])

26.2.3 Odor Evaluation of Indoor Air and Materials

The odor of a room or material can either be evaluated directly or after sampling. Different sampling techniques, depending on the type of source, and their subsequent analysis will be described in the following.

Evaluation and Sampling of Indoor Air

Ideally, the evaluation of indoor air should be performed directly on-site with a small trained or a huge untrained panel using intensity or acceptability scales as mentioned earlier [26.13]. Thereby, adaption effects have to be considered, which may vary between different odor sources. It could for example be shown that after a few minutes of exposure an adaption to human bioeffluents improves the acceptability of air considerably, adaption to tobacco smoke improves acceptability moderately and an adaption to emissions from construction materials improves acceptability only slightly [26.34]. To avoid adaption effects, dynamic sampling methods duct the air directly into a measurement device in close proximity to the odor source, either in situ or in a mobile laboratory, where the panelists can be exposed to the air in a more reproducible and timely controlled manner.

Due to cost and time constraints, these on-site evaluations are not always feasible. An alternative and widely used approach involves sampling, where an air sample of the investigated room is taken and transported to a test facility. The most crucial point in the course of this is to preserve the integrity of the sampled air. The quality of the sampling bag or container is essential in order to avoid contaminations or chemical-physical interactions between odorants and the sampling vessel such as adsorption processes and a permeation of compounds through the walls from the inside to the outside and vice versa. For this purpose, various gas sampling vessels such as polymer bags, glass bulbs or

stainless steel canisters are available that are considered to be impermeable, inert and odorless. Nonetheless, they should be checked for background emissions regularly [26.35, 36]. Additionally, condensation effects or further possible changes to the sampled air, for example due to degradation of compounds, must be avoided by temperature-controlled storage and transport or dilution of the sample. After transport to the lab, the air sample should be analyzed as quickly as possible, according to the European Standards EN 13725:2003 and ISO/DIN 16000-30 within 30 h from sampling, and according to German VDI 3880 within 6 h [26.16, 37, 38].

Another important and convenient approach to collecting an air sample is by sampling on adsorbent materials (Fig. 26.6). The most critical part of this approach is the choice of adsorbent, since discrimination processes are common. Three types of adsorbent materials are common: inorganic sorbents (e.g., silica gel), carbon-based porous materials (e.g., Carbotrap, charcoal) and porous organic polymers (e.g., Tenax). A combination of different adsorbent materials may help to recover a representative air sample. Hereby, it is important to ensure that no background odors are present on the adsorbent materials. Further ways to trap volatiles from air include liquid adsorbents, which often simultaneously function as derivatizing agents for specific target compounds, and cryo-trapping, which is often used in combination with solid sorbents. A subsequent desorption and analysis, by gas chromatography-mass spectrometry or elution and analysis, for example by high performance liquid chromatography, is then possible from adsorbent materials [26.2].

Sampling and Evaluation of Materials

To evaluate emissions from materials, several standardized methods are in use, ISO 16000-6/-9/-10/-11/-25 and ASTM D-5516/6670/7143 [26.39]. The tested materials are incubated in emission chambers with stainless steel or glass surfaces that are sealed gas-tight against the outdoor atmosphere, in which temperature, relative humidity, air exchange rate and air velocity can be controlled and adjusted to reflect realistic indoor conditions. Depending on the investigated material, several chamber sizes can be used, ranging from large walk-in test chambers with a volume of several cubic meters, through test chambers with 200–1000 l of volume (Fig. 26.7), CLIMPAQs (Chamber for Laboratory Investigations of Materials, Pollution and Air Quality) with 50 or 225 l of volume, to micro-chambers or Field and Laboratory Emission Cells (FLECs) with only few cubic centimeters of volume allowing quick tests or on-site measurements (Fig. 26.8). After incubation, volatiles can either be trapped on adsorbents for further analysis, the air can be directly evaluated at an outlet of a large emission chamber or whole air samples can be taken in sampling bags (Fig. 26.9), as described above.

Besides to emission chambers, passive flux samplers (PFSs) can also be used to trap emissions of flat surfaces. These are small, transportable devices that consist only of a small petri dish and an adsorption disc. Carbotrap B or a filter coated with 2,4-dinitrophenylhydrazine (DNPH) have been successfully used to trap emissions using passive flux samplers [26.40].

Evaluation of Air Samples

For a standardized presentation of the undiluted air in sampling bags to all panelists, direct sniffing sys-

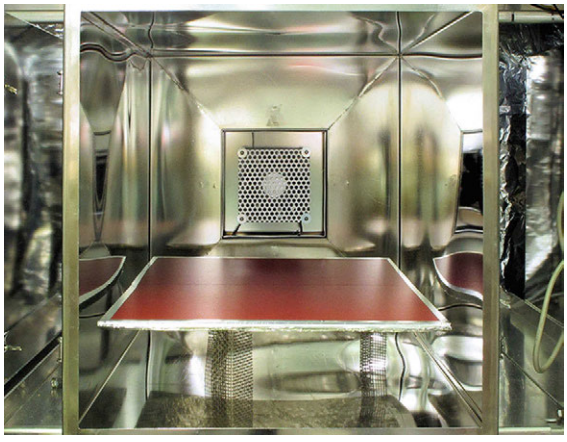

Fig. 26.7 Floor sample in a 200 l emission test chamber (courtesy of Fraunhofer IBP)

Fig. 26.8 Sampling of air using adsorbent material from a micro-chamber (courtesy of Fraunhofer IBP)

Fig. 26.9 Sampling of air from an emission test chamber into a sampling bag for subsequent odor evaluation (courtesy of Fraunhofer IBP)

tems are valuable. Thereby, the air sampling bags are introduced into the device, and the operator triggers a volume flow that causes the sampled air to stream through a funnel to the nose for odor evaluation (Fig. 26.10) [26.20]. Panelists can then rate odor characteristics as described above.

Another, widely used approach to evaluate air samples is dynamic olfactometry, using an olfactometer.

Fig. 26.10 A panelist evaluates an air sample provided by controlled deflation of an air sampling bag using a direct sniffing system (PureSniff) (courtesy of Fraunhofer IBP)

To assess the odor threshold, a diluted air sample can be presented to the panelists in ascending, randomized or descending concentration order. In ascending order the air sample is first diluted by a very large air volume, resulting in a sample with no perceptible odor. For subsequent samples, the volume of diluent is continuously decreased. The detection thresholds can then be determined through the first concentration in which each panelist has detected an odor and can be expressed as odor units per cubic meter (ou/m^3). In descending order, the air sample is continuously diluted with odor-free air by a factor of two. The minimum concentration perceived by 50% of the panel members results in the odor unit value per cubic meter. This method is only suitable for highly odorous samples since it does not allow small differences in the odor intensities of two weakly smelling odors to be distinguished [26.13]. Another disadvantage of the descending approach is that it could provoke adaption in the panelists as well as adsorption and carry-over effects. Similar problems could occur in a randomized order.

As an alternative to odor assessments by humans, *electronic noses* that mimic human olfaction have been developed (Chap. 21). They consist of an array of electrochemical sensors in conjunction with pattern recognition systems. The sensors need to possess partial sensitivity so that they do not only respond to a specific molecule but to a broad range or class of

volatiles [26.41]. In the field of indoor air quality control, specific electronic noses have been frequently used to monitor levels of harmful compounds such as formaldehyde, benzene, CO, NO_2 and toluene [26.42, 43], yet further applications to asses specific indoor odors are conceivable.

26.3 Indoor Odorants – Selected Sources

Some common indoor sources that have been investigated for odorous emissions will be discussed in the following. Table 26.1 gives an overview on potential odorants that have been identified as primary and secondary emissions from different materials. Interestingly, oxidized substance groups such as aldehydes, ketones and acids could be identified frequently and independently in several different sources.

26.3.1 Materials

Different types of construction materials possess their own specific emission patterns, depending on used raw materials, additives, coatings and processing methods. Amongst these emissions, several odor-active substances can impart a typical odor to a material or generate an unwanted off-odor. Secondary emissions, resulting from degradation processes of the materials such as oxidation and hydrolysis can thereby modify or generate odors over time (Fig. 26.11) [26.44].

Many studies use extraction techniques to isolate volatiles and odorants from materials, especially plastics, giving valuable information on material safety issues for example for food packaging or toys. These will not be mentioned here, since the liberation of odorants into air is considerably different than into fluids. Thereby, it should be kept in mind that the presence of a potential odorant in a given material does not necessarily cause the material to emit the typical odor. First of all, the liberation is dependent on physical factors such as humidity and temperature. Secondly, odor thresholds as well as synergistic effects among odorants have to be considered.

Plaster and Gypsum

Plaster is a very common and appreciated building product due to its flexible processing and wide field of application, for example as drywall, stucco or mortar for the coating of walls and ceilings. It consists of small-sized construction aggregate such as sand and binders such as lime. It is traded as solid powder and mixed with water to form a paste before use.

Plasters with organic binders have been investigated for their odor quality by means of gas chromatography-olfactometry/mass spectrometry. The odor of all plaster materials was mainly caused by organic acids such as acetic acid, pentanoic acid and hexanoic acid, which are responsible for acidic-sweaty and musty odor impressions. Furthermore, different samples emitted (*E*)-2-butenal, 2-ethylhexanol, 1-hexen-3-one and *p*-xylene, which are associated with plastic- and solvent-like odor impressions. In one sample with a fatty and rancid odor, (*Z*)-4-heptenal could be identified as key compound. Next to the compounds mentioned, further VOC emissions from plaster, such as further aldehydes, ketones, (cyclo)-alkanes/alkenes, alcohols, amines, amides, esters, glycols, heterocyclic compounds, organic acids, phenolic compounds, benzene derivatives, phthalates, silanes, siloxanes and terpenes, have been identified. Most of these substances are potentially odor active, yet due to concentrations below their odor thresholds they are unlikely to contribute to the odor impression of the investigated materials. It is furthermore important to notice that the odor impact compounds could not be identified by means of classical VOC analysis, but only by means of gas chromatography-olfactometry [26.45].

A special type of plaster is gypsum. It has a salt structure based on calcium sulfate ($CaSO_4$) and emits a typical odor described as gypsum-like, slightly milky and chalk-like [26.13]. Several aldehydes, ketones, acetic acid, 2-acetyl-1-pyrroline as well as traces of sulfur-containing odorants (sulfides, disulfides, trisulfides, thiols and aromatic sulfur compounds) have been detected as odorous emissions in gypsum samples using gas chromatography-olfactometry [26.7, 46, 47]. Depending on the raw material and processing

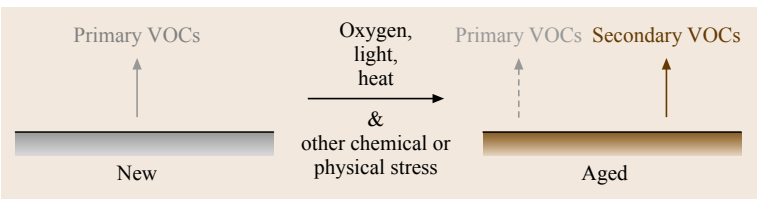

Fig. 26.11 Formation of secondary VOCs in materials

Table 26.1 Potential primary and secondary odorants emitted into indoor air by different sources

Odorant source	Primary VOCs potential odorants	Secondary VOCs condition	Potential odorants
Plaster/gypsum	Aliphatic aldehydes ((*E*)-2-butenal, (*Z*)-4-heptenal)	Oxidation	Increased benzaldehyde
	Aliphatic ketones (1-hexen-3-one)		
	Organic acids (acetic acid, pentanoic acid, hexanoic acid)		
	2-Ethyl-1-hexanol		
	p-Xylene		
	2-acetyl-1-pyrroline		
	Mono-/di-/trisulfides (dimethyltrisulfide)		
	Thiols (propanthiol)		
	Aromatic sulfur compounds		
Wood-based materials	Aliphatic aldehydes (pentanal, hexanal, heptanal, octanal, nonanal, (*Z*)-2-nonenal, (*E*)-2-nonenal, formaldehyde)	Oxidation	Increased aldehydes (several n-aldehydes, benzaldehyde, 2-nonenal, 4-nonenal, 6-nonenal)
	Terpenes (α-pinene, β-pinene, Δ3-carene, longifolene, β-phellandrene, camphene, myrcene, carvone, limonene, p-cymene, borneol, caryophyllene)	Microbiological degradation in combination with pentachloro phenol treatment	Chloro anisoles (2,3,4,6-tetrachloroanisole)
	Organic acids (acetic acid, butanoic acid)		
	Benzaldehyde		
	Acetophenone		
	1-Octen-3-one		
Linoleum	Aliphatic aldehydes (2-alkenals up to C_9)	Oxidation	Increased aldehydes
	Organic acids (up to C_6)		Increased organic acids (benzoic acid, propanoic acid)
	Ketones	Water	Increased organic acids (pentanoic acid)
	Toluene		Glycol ethers
	2-Pentylfuran		2-Decenal
Carpets	Esters (vinyl acetate)	Oxidation	Increased aldehydes (several n-aldehydes, 2-nonenal, acetaldehyde, methylbenzaldehyde)
	Alcohols (1,2-propandiole)		Ketones (2-butanone)
	Aliphatic aldehydes (up to C_{10})		Aliphatic acids
	Aromatic aldehydes (benzaldehyde, methylbenzaldehyde)	Heat	Benzothiazole
	Hydrocarbons (butylated hydroxytoluene, styrene, 4-phenylcyclohexene, 4-vinylcyclohexene)		
Polypropylene (PP)	Aliphatic ketones (C_6–C_9)	Oxidation	Increased ketones (C_6–C_9)
	Aliphatic aldehydes (C_6–C_9)		Increased aldehydes (C_6–C_9)
Polyethylene (PE)	Ketones (C_6–C_9)	Oxidation	Increased ketones (C_6–C_9)
	Aliphatic aldehydes (C_6–C_9, 8-nonenal)		Increased aldehydes (C_6–C_9)
	Sulfides	Thermal oxidation	Ketones (2,3-butanedione, 1-hexen-3-one, 1-hepten-3-one, 1-octen-3-one, 1-nonen-3-one)
	Thioles		Aldehydes (hexanal, octanal, nonanal, (*E*)-2-nonenal)
Thermoplastic polyolefin (TPO)	2-Acetyl-1-pyrroline		
	Ketones (2,3-butanedione, 1-hexen-3-one)		
	Aliphatic aldehydes (3-methylsulfanylpropanal, (*Z*)-2-nonenal, (*E*)-2-nonenal)		

Table 26.1 (continued)

Odorant source	Primary VOCs potential odorants	Secondary VOCs condition	Potential odorants
polystyrene (PS)	Hydrocarbons (styrene, α-methyl styrene)	Oxidation	Formaldehyde Benzaldehyde Benzoic acid
polyvinylchloride (PVC)	2-ethyl-1-hexanol	Water	Increased 2-ethyl-1-hexanol
	Phenol	Oxidation	2-Butanone
	1-Butanol		Increased aldehydes
polyurethane (PU)	Methylamines (trimethylamine)		
	Pyrazines (2-ethyl-3,5-dimethyl-pyrazine)		
polyphenylenoxide (PPO)	Phenols (guaiacols, cresols, xylenols)		
Rubber	Benzothiazole derivatives		
	Amines		
	Hydrocarbons (4-vinyl-cyclohexene, naphthalene, styrene)		
	Aliphatic aldehydes		
	Ketones		
	Esters (ethyl methylpropanoate, ethyl 2-methylbutanoate, ethyl pentanoate)		
	Phenols (*p*-/*m*-cresol)		
	Sulfides (hydrogen sulfide, carbon disulfide, dimethyl sulfide)		
	Benzaldehyde		
Electronics	Phenols (*p*-/*m*/*o*-cresol)		
Household and cleaning agents	Terpenes (citronellol, geraniol, linalool, α-terpineol, citronellal, geranial, neral, linalyl acetate, camphene, limonene, β-myrcene, α-phellandrene, α-pinene, β-pinene, α-terpinolene, α-terpinene)		
	Aliphatic aldehydes (octanal, nonanal, decanal)		
Human breath	Hydrocarbons (isoprene)		
	Aldehydes		
	Ketones (acetone)		
	Alcohols (ethanol, methanol)		
Human skin	Organic acids (3-methyl-2-hexanoic acid, 3-hydroxy-3-methylhexanoic acid)		
	Sulfanyl alcohols (3-sulfanylhexan-1-ol, 2-methyl-3-sulfanylbutan-1-ol, 3-sulfanylpentan-1-ol, 3-methyl-3-sulfanylhexan-1-ol)		
	16-androstenes (5α-androst-16-en-3-one)		
	Esters		
	Aldehydes (acetaldehyde, nonanal, decanal)		
	Hydrocarbons		
	Alcohols		
	Ketones (6-methyl-5-hepten-2-one, (*E*)-6,10-dimethyl-5,9-undecadien-2-one)		

methods, the concentration of sulfur-containing organic compounds can reach levels at which an unpleasant sulfurous off-odor is predominant [26.47]. After treatment with elevated ozone concentrations, a gypsum board sample showed increased secondary emissions of benzaldehyde, that could potentially lead to an off-odor [26.48].

Wood-Based Materials

Despite its wide use, the odor of wood itself has so far mainly been investigatedfor woods used for wine and spirits, where solvent extracts rather than emissions into air are used for analysis. Analysis of emissions from treated wood, wood products and furniture revealed mainly terpenes like α-pinene, β-pinene, Δ3-carene,

longifolene, β-phellandrene, camphene, myrcene, carvone, limonene, caryophyllene as well as saturated and unsaturated aldehydes, solvents and photo-initiator fragments such as benzaldehyde and acetophenone [26.13].

In parquet samples that were either oiled and waxed or varnished, the green-smelling short-chain aldehydes pentanal and hexanal, the wooden-smelling terpenes α- and β-pinene as well as 1-octen-3-one with a mushroom-like odor were identified as the most important odorants by means of GC-O and aroma dilution analysis. Important odorants that were specific for the used sealing were octanal, (*Z*)-2-nonenal and (*E*)-2-nonenal in oiled and waxed parquet and benzaldehyde and acetophenone in varnished parquet. Furthermore, not only differences in odor quality but also in intensity could be observed between the two samples. Since varnish prevents the release of odorants from the wooden parts to a higher extent than wax and oil, the overall odor of varnished parquet was less intense [26.49].

Wood-based panels, such as particle board, oriented strand board or medium density fiberboard are popular since they are less expensive, very versatile and still impart a nearly natural impression to furniture and construction materials. The panels are manufactured by binding small pieces of wood, often consisting of forest residues and sub-quality wood, with adhesives. Further additives such as wood preservatives, flame retardants, hardeners and hydrophobing agents might also be used. In these materials, formaldehyde and VOC emissions are of major concern [26.50]. Formaldehyde originates primarily from resins used to bind the wood particles, such as amino-formaldehyde, whereas other VOCs mainly originate from the wood itself [26.51]. Amongst other VOCs, further aldehydes (pentanal, hexanal, heptanal, octanal, nonanal) and terpenes (i. e., α- and β-pinene, camphene, 3-carene, p-cymene, limonene and borneol) originating directly from wood or from degradation of wood, have been detected and quantified in particleboard and medium density fiberboard products [26.52, 53]. Although these aldehydes and terpenes are well-known odorants, these studies did not assess the impact of these compounds on the overall odor of wood-based panels. Furthermore, organic acids like acetic acid and butanoic acid with a sweaty odor that originate from adhesives have been identified in oriented strand board samples [26.7].

Under the influence of ozone, it could be shown that terpene emissions decreased within 24 h while emissions of several aldehydes, such as *n*-aldehydes C_3 and C_5–C_{10}, benzaldehyde as well as 2-nonenal, 4-nonenal and 6-nonenal increased in different pine wood board samples [26.48].

In a case study, the use of unsuitably treated wood was identified as cause of a moldy off-odor in frame houses. The formerly used wood preservative pentachloro phenol can be degraded microbiologically to chloro anisoles, especially in damp areas with elevated microbiological activity. 2,3,4,6-tetrachloro anisole was identified as the main component in air samples taken from affected frame houses [26.54]. This substance has a very low odor threshold (0.01 ng/l air) and can therefore be the reason for the off-odor [26.55].

Linoleum

Linoleum is widely used as a flexible and durable floor covering. It is made of linoxyn (solidified linseed oil), natural resin, cork or wood particles, mineral fillers and pigments.

A gas chromatography-olfactometry investigation of linoleum samples revealed that mainly short-chain 2-alkenals (up to C_9) and fatty acids (up to C_6) with green, sour, citric and rancid odor attributes were responsible for the typical odor impression of linoleum [26.56]. As further odorous emissions from linoleum, saturated, branched and polyunsaturated aldehydes, ketones as well as toluene and 2-pentylfuran have been identified [26.13]. Oxidation of aldehydes to corresponding fatty acids has been observed in linoleum, which might cause a change in the odor impression of aged linoleum in comparison to new materials [26.44]. For example, increased emissions of benzoic acid and propanoic acid have been detected under the influence of ozone. Aldehyde emissions also increased whereas 1-penten-3-ol and 2-pentanone emissions were reduced [26.48]. Furthermore, the presence of water, either through wet cleaning or high water content in underlying concrete, has been shown to trigger secondary emissions of volatiles from linoleum, i. e., fatty acids, glycol ethers and 2-decenal. Especially pentanoic acid as well as 2-decenal with low odor thresholds (< 5 ng/l air [26.57–59]) can thereby generate an off-odor [26.60].

Carpets

For centuries, carpets have been valued as floor or wall coverings for their insulating and aesthetic properties. They consist of an upper layer of pile, made of natural or synthetic fiber, which is attached to an adhesive backing.

Odor emissions are mainly caused by the adhesive backing. For example, carpets with a polyvinylchloride (PVC) backing have been shown to emit primarily vinyl acetate and 1,2-propanediol whereas carpets with a polyurethane backing emit butylated hydroxytoluene [26.61]. Carpets with styrene-butadiene rubber latex backing have been shown to emit styrene, 4-phenyl cyclohexene and 4-vinyl cyclohexene [26.62].

Several n-aldehydes (up to C_{10}) as well as benzaldehyde and methylbenzaldehyde have been detected in carpets with rubber, textile, bitumen and PVC backings [26.48]. Under the influence of ozone, the total concentration of VOCs has been shown to increase in different carpets [26.62]. For example, emissions of saturated and unsaturated aldehydes (2-nonenal, acetaldehyde, methylbenzaldehyde) as well as branched and unbranched ketones (e.g., 2-butanone) and trace levels of aliphatic acids have been shown to increase in carpets that were incubated with ozone, depending on adhesives used as backing [26.48, 63]. Thereby, especially emissions of 2-nonenal can cause odor annoyances due to its persistence and very low odor threshold ($\leq$ 0.1 ng/l air for both (*E*)- and (*Z*)-isomer [26.64, 65]) [26.63]. Benzothiazole has been shown to be emitted in increasing amounts by a carpet with a styrene-butadiene rubber backing under the influence of heat [26.66]. While heat is of minor concern in building environments, temperatures up to 70 °C can be reached in parked cars, where textile floor coverings might then be a source of unwanted odorants.

Polymers

Plastics have become integral parts in many indoor environments. During the manufacturing of plastic materials from monomers using additives and accelerators, degradation or reaction products of raw materials can be generated, especially under the influence of heat, pressure, light or oxygen. Reaction products as well as the used raw materials themselves, especially in recycled products, may be odor active even in trace amounts.

Polypropylene PP. By means of GC-O, carbonyls with low odor thresholds, especially unsaturated C_6–C_9 ketones and aldehydes, were identified as major odor-active compounds emitted by polypropylene (PP). These are generated by oxidation processes from alkanes and alkenes and increase during aging of the material. Interestingly, commonly used stabilizers added during processing were unable to prevent the observed oxidation processes [26.67].

Polyethylene PE. Similar to polypropylene, unsaturated C_6–C_9 ketones and aldehydes were identified as the most important odor-active compounds emitted by polyethylene (PE), that are generated by oxidation independent of added antioxidants [26.67]. In another study, 8-nonenal has been identified as major contributor to the *plastic* off-odor in high density polyethylene (HDPE), although this study did not analyze air samples but used distillation to obtain volatiles [26.68]. Also, sulfurous smelling sulfides and thiols that originate from natural impurities in the mineral oil raw materials have been identified in PE samples [26.7]. Furthermore, the formation of secondary VOCs in PE after thermal oxidation has been studied. The treatment caused a strong waxy or burnt plastic off-odor. Using GC-O, several C_6–C_9 saturated or unsaturated aldehydes and ketones could be identified in the thermally oxidized samples. The most important were 2,3-butanedione, hexanal, 1-hepten-3-one, octanal, 1-octen-3-one, nonanal, 1-nonen-3-one and (*E*)-2-nonenal, whereof α-unsaturated aldehydes and ketones seem mainly responsible for the off-odor [26.69].

Further Polyolefines. In a thermoplastic polyolefin (TPO) sample, a strong roasty off-odor, rendering the product to be unacceptable for use, was identified as 2-acetyl-1-pyrroline, a nitrogen-containing molecule. Since none of the main ingredients of polyolefines contain nitrogen, the source of this off-odor has to be an additive. Due to the very low odor threshold of 2-acetyl-1-pyrroline (0.02 ng/l air [26.70]), even small amounts thereof can hence influence the sensory attributes of plastic materials [26.71]. Further important odor-active compounds identified in one TPO sample were 2,3-butanedione, 1-hexen-3-one, 3-methylsulfanylpropanal, (*Z*)-2-nonenal, (*E*)-2-nonenal and further unidentified compounds with roasty or geranium-like odors [26.72]. Other investigations of TPO materials showed that the odorant composition and overall odor perception is highly dependent on the formulation of raw materials, and on processing conditions, for example melt temperature and residence time during injection molding. The addition of a smell scavenger in TPO formulations has been shown to reduce amounts of acidic compounds, phenols and furanones, but not aldehydes [26.73]. Hence, the importance of elucidating the chemical structure of off-odors in order to find the right avoidance strategy becomes even more obvious.

Polystyrene (PS). Samples of polystyrene have been shown to emit the odor-active monomer styrene as well as α-methyl styrene that both cause acrid, solvent-like odor impressions [26.7]. After treatment with ozone for 24 h, styrene emissions decreased while emissions of formaldehyde, benzaldehyde and benzoic acid increased [26.48].

Polyvinylchloride PVC. A GC-O analysis of odorants emitted from polyvinylchloride (PVC) floorings revealed mainly 2-ethyl-1-hexanol (2E1H), phenol and 1-butanol as odor-active compounds. When in contact with wet construction materials, such as incompletely dried concrete with an alkaline pH, emissions of 2E1H increase sharply since this substance can be gener-

ated by hydrolysis of the ester di-2-ethylhexyl phthalate (DEHP), a plasticizer commonly used in PVC [26.74]. Contact with ozone led to secondary emissions of 2-butanone and increased emission of aldehydes in a PVC flooring sample [26.48].

Polyurethane PU. It could be shown that a polyurethane (PU)-specific odor is generated due to heat development during the manufacturing process. This odor arises from amine catalysts that are degraded to methylamines with low odor thresholds like trimethylamine, which can cause a fishy off-odor [26.75]. Furthermore, substituted pyrazines with extremely low odor thresholds (e.g., 2-ethyl-3,5-dimethyl-pyrazine; 7 pg/l air [26.76]) have been identified in PU samples causing earthy, nutty odor impressions [26.13, 71].

Polyphenylenoxide PPO. In Polyphenylenoxide (PPO), substituted phenols are used as raw materials and phenolic antioxidants are used as additives. Therefore, these phenols as well as degradation products thereof can be found to be emitted from the plastic material. For instance, odor-active guaiacols, cresols and xylenols have been identified by GC-O in emissions of PPO samples [26.71].

Rubber

The term rubber refers to polymers with elastic properties that can either be of natural or synthetic origin. To enhance the durability of these materials, they are often processed by vulcanization. During this process, the elastomers are cross-linked by addition of peroxides or sulfur together with nitrogen- and/or sulfur-containing accelerators like benzothiazole under heating. Therefore, benzothiazole derivatives as well as amines have been found to be emitted by rubber and seem responsible for the typical odor of rubber. Other compounds emitted by rubber are solvents, hydrocarbons like 4-vinyl-cyclohexene, aldehydes, ketones, esters like ethyl methylpropanoate, ethyl 2-methylbutanoate and ethyl pentanoate, phenolic compounds like *p*- and *m*-cresol, hydrogen sulfide, carbon disulfide, dimethyl sulfide as well as naphthalene, styrene and benzaldehyde [26.13].

Electronics

Electronics are active emission sources that develop heat during operation. Therefore, VOC emissions from electronic devices such as television sets, video recorders or computer monitors are especially high when switched on. A large number of VOCs from all kinds of substance classes, in total more than 350, have been shown to be emitted by electronics. Amongst them phenol-like compounds such as *m*-, *p*- and *o*-cresol, originating from printed circuit boards on phenolic resin basis, can be the source of odors [26.77, 78]. Additionally, it could be shown that the presence of operating personal computers can negatively affect perceived air quality and productivity in office environments. Since VOCs determined in this study could not sufficiently explain these adverse effects, the authors emphasize the inadequacy of analytical methods routinely used in indoor air quality investigations [26.79].

Household and Cleaning Agents

Cleaning agents, detergents and air fresheners are regularly used in indoor environments. These are usually scented to mask unwanted odors and to suggest cleanness and freshness. Odorants frequently used for this purpose are mainly terpenes like citronellol, geraniol, linalool, α-terpineol, citronellal, geranial, neral, linalyl acetate, camphene, limonene, β-myrcene, α-phellandrene, α-pinene, β-pinene, α-terpinolene and α-terpinene or aldehydes like octanal, nonanal and decanal [26.13, 80].

26.3.2 Human Emissions (Bio-effluents)

When entering a nonventilated, fully occupied room, the effect of human emissions on indoor air quality becomes obvious. In fact, humans continuously emit hundreds of VOCs through their breath and skin. Thereby, the composition of VOCs varies individually and is largely influenced by genetics, but also depends on age, health status, activity, personal hygiene and nutrition. Hence, human bio-effluents can also differ regionally and culturally. In an investigation of air samples collected in crowded rooms in Germany, indoor air contaminants that significantly correlate with human presence were identified. Those were ethanol, acetone and isoprene that originate from breath, nonanal and decanal that presumably originate from skin emissions as well as α-pinene, limonene and eucalyptol that are commonly used in personal care products. Although these substances are not willfully perceived by humans in the present concentrations since they do not exceed the odor thresholds, the combined presence of acetone, isoprene and limonene in elevated concentrations still correlates with the air quality being perceived as aversive [26.81].

Breath

Next to higher CO_2 levels in comparison to inhaled air, humans emit mainly isoprene, acetone, ethanol, methanol and other alcohols through their breath. Further compounds with molecular weights predominantly under 100 g/mol, including additional unsaturated as well as saturated hydrocarbons, aldehydes, ketones and

alcohols are emitted in minor quantities in human breath [26.82, 83]. While the major compounds are products of core metabolic processes and are similar in healthy humans, many minor compounds have exogenous sources such as food, medicine, skin care products or inhaled air and therefore underlie bigger qualitative and quantitative differences.

Skin

The axillary region is especially prone to the emission of human body odor (Chap. 49). The most important odor-active substances in human sweat are several carboxylic acids. Amongst them 3-methyl-2-hexenoic acid and 3-hydroxy-3-methylhexanoic acid are the most abundant ones, with very low odor thresholds in the range of 0.15–0.26 ng/l air [26.84–87]. Moreover, sulfanyl alcohols (3-sulfanylhexan-1-ol, 2-methyl-3-sulfanylbutan-1-ol, 3-sulfanylpentan-1-ol and 3-methyl-3-sulfanylhexan-1-ol) have been identified in trace amounts in human axilla secretions. Due to their extremely low odor thresholds in the range of 1–10 pg/l air, they are nonetheless likely to contribute to human body odor [26.88, 89]. Several volatile steroids of the 16-androstenes group with low odor thresholds (e.g., 5α-androst-16-en-3-one: 2.1 ng/l air [26.90]) have also been detected in human sweat [26.91–93].

Humans also emit various VOCs through non-axillary skin, amongst them several odorous compounds. As in breath, many of the emitted compounds are strongly dependent on individual factors, yet some are common to most humans. Studies that used headspace collection of volatiles emitted by skin surfaces found mainly carboxylic acids of various chain lengths, esters, aldehydes, alkanes, short chain alcohols and ketones. Thereby, 6-methyl-5-hepten-2-one, nonanal, decanal and (*E*)-6,10-dimethyl-5,9-undecadien-2-one (geranylacetone) have been frequently reported to be predominant in the volatile profile of human skin [26.94]. Furthermore, SPME (solid phase micro extraction)-measurements of skin emissions revealed acetone and acetaldehyde to be highly emitted next to the already mentioned 6-methyl-5-hepten-2-one [26.95].

26.4 Odor Avoidance and Reduction Measures

To minimize unwanted odorants in indoor air, basically two strategies can be followed. The most favorable is surely the avoidance of odorous emissions in the first place, by improving manufacturing processes or changing raw materials. The second strategy is the removal of odorous impact compounds from indoor air.

The ideal prerequisite for avoidance strategies is to know the nature of an unwanted off-odor in terms of its chemical structure, properties and concentration as well as to understand its generation pathway. Then, measures to eliminate the odor source from the material, for example by alterations in the production process, can be taken. Using this approach, an odor optimized PPO could be manufactured with improved values for odor intensity, hedonic odor tone and perceived air quality [26.71]. When recycled materials are used, the task of minimizing odorous emissions is especially challenging, since all kinds of odors might have been adsorbed to the raw materials during their previous use. The use of additives that bind specific odorants can help to minimize odors in the manufacturing of plastic materials. For example a combined zeolite called Abscents could effectively remove an off-odor in HDPE when added to raw materials during the manufacturing process [26.96].

A less cost-intensive and time-consuming strategy to control indoor odors is their removal from air. Therefore, mechanical filters that remove particles in combination with adsorbents that bind VOCs, such as activated carbon filters can be used. For example, mesophorous carbon materials such as activated CMK-3 and CMK-8 have been shown to remove indoor formaldehyde even at low concentrations [26.97, 98]. These filters need to be replaced from time to time when they have reached their capacity.

Other air purifiers use oxidation as a way to destruct VOCs and thereby allegedly remove pollutants from indoor air. For a long time, ozone-generating devices have been used, a strategy now severely criticized for potential health risks. For example, carboxylic acids, epoxides, organic peroxides, aldehydes and ketones have been shown to be formed by ozonolysis air purifiers [26.99]. Photocatalytic oxidation with active materials such as titanium dioxide (TiO_2) is also extensively used in order to destruct VOCs in indoor air [26.100]. Yet several studies have shown that this method does not always degrade the organic compounds completely to CO_2 and H_2O. Incomplete oxidation thereby generates aldehydes, ketones and organic acids, that might themselves be toxic, irritating or odorous, possibly even to greater extents than their precursors [26.101]. Plasma air cleaners as well as ionizer purifiers are suitable for particle removal, yet not for the removal of gas-phase pollutants. Plasma cleaners in combination with catalytic technologies have been shown to more efficiently remove VOCs [26.102].

26.5 Health Aspects and Sensory Irritations

Since this chapter is focused on odorants in indoor air, health concerns raised by other indoor VOCs such as benzene, carbon monoxide, formaldehyde, naphthalene, nitrogen dioxide, polycyclic aromatic hydrocarbons, trichloro ethylene or tetrachloro ethylene will not further be detailed, but are nonetheless of major concern. Information on this topic can be found elsewhere, for example from publications of the World Health Organization or other national authorities [26.103, 104]. Maximum levels of TVOCs, SVOCs (semivolatile organic compounds) and carcinogenic substances emitted from building products, as for example issued by the German Federal Environment Agency (Umweltbundesamt UBA), DIBt (Deutsches Institut für Bautechnik, German Institute for Building Technology) or the German Blue Angel Labeling System (Blauer Engel), as mentioned earlier, should generally be employed to minimize indoor air pollution [26.5].

When thinking about the specific health effects of odorants in indoor air, the main concern and most investigated effect is sensory irritation. Thereby, two important facts should be considered. First, it should be noted that an irritant is usually detected consciously in form of an odor – at least until the phenomenon of adaptation prevents awareness of the stimulus – since olfactory detection thresholds are generally one to four orders of magnitude lower than estimated thresholds for irritation effects of the upper airways [26.6, 105, 106]. A reason therefore is that sensory irritations in a person's ocular and nasal mucosae, also known as chemesthetic sensations, are transmitted through a different receptor system with different sensitivity than the olfactory system – the trigeminal nerve system [26.107] (Chap. 34). In several studies on sensory irritation of different vapors it could be shown that in homologous series the chemesthetic potency increases with chain length until a homolog is reached that fails to be detected (the cut-off homolog). For example, the cut-off homolog for a series of n-alcohols is 1-undecanol, for n-acetates decyl acetate, for *n*-butyrates hexyl butyrate, for 2-ketones 2-tridecanone, for *n*-alkylbenzenes heptyl benzene, for aldehydes dodecanal and for carboxylic acids heptanoic or octanoic acid, in ocular or nasal mucosa, respectively. Experiments suggest that these cut-off homologs exceed a critical molecular size that prevents them from interacting with the respective trigeminal receptors [26.108].

Second, it has to be noted that irritations may not originate from the odorant itself, but from reaction products being formed in indoor air, for example from reactions with ozone. Ozone present indoors may either be generated unwittingly from electronic devices such as photocopiers and laser printers or intentionally from air purifiers or it may simply infiltrate from outdoors [26.99, 109–111]. The reactions of ozone with some terpenes, such as d-limonene and α-pinene, that are common VOCs in indoor air originating for example from cleaning products and detergents, have been widely studied [26.111]. Due to C = C-bonds in their chemical structure, most terpenes easily react with ozone. In those reactions, several secondary pollutants such as various radicals, aldehydes (e.g., formaldehyde) and carboxylic acids as well as secondary organic aerosols (SOA), consisting of ultrafine ($< 0.1\,\mu m$) and lower fine ($0.1-2.5\,\mu m$) particle size ranges, are formed [26.112–117]. As opposed to their reactants, terpene/ozone oxidation products are associated with significantly higher sensory irritating effects [26.6, 118]. Thereby, the sensory irritating effect of formaldehyde is well documented in animal and human exposure studies [26.119–122]. Furthermore, it could be shown that terpene/ozone oxidation products of limonene, α-pinene and isoprene are causative of sensory irritations of the upper airways and airflow limitations in mice [26.105, 111, 123–127]. Although the ozone and terpene concentrations in these animal studies have been very high compared to realistic exposures of humans, derived human reference values for some common ozone initiated terpene reaction products indicated that 3-isopropenyl 6-oxo-heptanal, an oxidation product derived from limonene (Fig. 26.12), may contribute to sensory irritations in indoor environments [26.128, 129]. Further in vivo and in vitro studies of terpene oxidation products have observed health implications such as pulmonary inflammation, yet further data in order to substantiate these findings should be collected [26.111].

Overall, evidence for adverse health effects in rodents of terpene/ozone reaction products could be observed. Yet their impact on human health in an indoor setting depends on several factors such as concentrations of the reactants, relative humidity, reaction time (*fresh* or *aged* reaction products) and identity

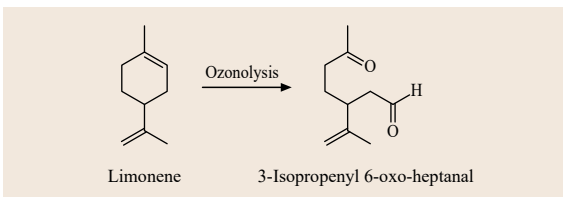

Fig. 26.12 Formation of the secondary pollutant 3-isoprenyl 6-oxo-heptanal from limonene through ozonolysis

of the terpene itself [26.111]. To fully understand the impact of ozone-initiated terpene chemistry on human health, multidisciplinary expertise from different scientific disciplines such as indoor and ambient air research, analytical and atmospheric chemistry as well as toxicology and medicine is required [26.111, 130].

As mentioned earlier, psychological stress as well as physiological symptoms such as respiratory problems, nausea and headache might also be caused by the simple association of unpleasant odors with negative health effects [26.8]. Notwithstanding, the presence of an unwanted odor in an indoor environment might also have a positive side-effect. For example the presence of earthy, moldy odors may be a hint for biological contaminations like mold with actual negative health implications, which would otherwise often remain undetected behind furniture or wallpapers.

Odorant S Part D

Part D Odorant Sensing and Physiological Effects

Instrumental sensing has been highlighted in the previous section, together with the need for cross-linking such analytical data with human olfaction. Human sensing, however, is a non-linear process, being based on complex mechanisms that are intertwined with each other and regulated via complex feedback mechanisms. Right at the periphery, volatile molecules can be modified by physiological steps; these may influence the release, the interaction with receptors, and may even potentially generate new odorous molecules or degrade others due to biotransformation processes. The human body not only detects molecules, but also reacts to these, and these reactions may again modulate the primary and subsequent detection processes. Accordingly, instrumental sensors mainly measure and interpret what is present, while human sensing involves adaptive physiological mechanisms and processing steps related to the potential meaning of the molecules that are present in the immediate environment. Human olfaction is targeted at recognizing patterns and eliminating information that is of no relevance, or rather, information that has been learned and developed not to be relevant in the course of evolutionary processes and in a specific environment. Thereby, it is interesting to note that human olfaction is by far not as inferior to animal olfaction as is commonly believed.

On the other hand, olfactory detection systems, i. e., olfactory receptors, are not the only physiological targets that can be activated or modulated by odorants. Odorous substances are commonly small, extremely mobile, and lipophilic with some contribution of hydrophilic moieties that allow them to traverse the body, often without relevant barriers, and make them potential agonists for different physiological targets. Moreover, one needs to keep in mind that odorants do not simply travel the human body, but that there might be further strong biotransformation processes, irrespective of the point of entry of the compound, i. e., via the airways or via the gastrointestinal tract. Depending on their composition and concentration they may, for example, activate ion channels that play a role in trigeminal sensing, as well as in a series of other physiological processes or diseases; they also might act on pathways and cascades involved in central nervous and inflammatory processes, or allergies. In complex feedback loops and integration steps, such different ways of chemosensation might even interact with each other, through suppressive, enhancing or additive mechanisms.

Odorants may additionally serve other physiological functions in the human body, such as cell-to-cell chemo-communication and chemotaxis. On the other hand, if sensing of such chemo-stimuli is so complex, the likelihood of deviations between individuals, or even failures of parts of the physiological detection system due to innate or acquired defects, is high. Accordingly, disrupted chemosensory perception is a topic that is also addressed in the following selection of chapters.

27. Odorant Sensing

Heinz Breer, Jörg Fleischer, Jörg Strotmann

Chemosensory perception is one of the most important systems for appraisal of the environment. In contrast to physical sensory modalities, whose stimuli nature is constant (light, sound), the ever-changing odorous environment requires that the chemosensory system can cope with varying situations. This is accomplished by a large number of odorant receptors, most of them with a broad recognition spectrum due to a plasticity of the binding cavity. This apparent fuzziness is mandatory for the combinatorial mode of odorant recognition that allows reception of an almost infinite number of odorants with an enormous discriminatory power. Odorant receptors are expressed in olfactory sensory neurons (OSNs) following the one-neuron one-receptor rule; only one from more than a thousand receptor genes is expressed, in fact either from the maternal or the paternal allele. Thus, the receptor type determines the molecular receptive range of a particular chemosensory neuron. The choice and continuous expression of a particular receptor gene is supposed to result from a hierarchy of regulatory processes, involving cis-regulatory deoxyribonucleic acid (DNA) elements, epigenetics and a negative feedback mechanism mediated by the receptor protein itself. The chemoelectrical transduction process in OSNs is mediated by an intracellular reaction cascade leading to the generation of action potentials that are conveyed to the brain. An individual OSN extends its axon directly into the olfactory bulb where it targets onto a distinct spherical neuropil – the olfactory glomerulus – that connects sensory input with output neurons and local modulatory interneurons. The connectivity is remarkably precise such that only axons from neurons with the same receptor type innervate a specific glomerulus. The molecular determinants that control the complex process of axonal pathfinding, segregation, and targeting that lead to a receptor-specific wiring of the olfactory system have been only partially unraveled.

27.1 Structure of the Olfactory System

The structural design of the nose directs the inspired air toward the olfactory epithelium located in the roof of the posterior nasal cavity. In rodents, the paired nasal passages are highly convoluted with up to four cartilaginous structures, the turbinates, protruding into the nasal lumen. These intricate structures not only increase the surface area covered by the chemosensory epithelium, but also affect the airflow in the nasal cavity [27.1]. The olfactory epithelium is a pseudostratified columnar epithelium that comprises different cell types including basal cells, supporting cells, and olfactory sensory neurons (OSNs) (Fig. 27.1). The basal cells are in fact

stem cells capable of constant generation of new OSNs, allowing the olfactory epithelium to be reconstituted every 2–4 weeks. Because of its regenerative capacity, damage to the olfactory epithelium, by inhalation of toxic fumes or physical injury, is often temporary and only in extreme cases permanent, leading to anosmia. The supporting cells appear to function, analogous to neural glial cells, as metabolic and physical support for the OSNs; they are tall columnar cells with apical microvilli.

27.2 Olfactory Sensory Neurons

The OSNs are bipolar neurons; their unmyelinated axons congregate to form the olfactory nerve (cranial nerve I), which crosses the cribriform plate and projects to the target domain in the brain, the olfactory bulb (OB). All OSNs project a solitary dendrite to the epithelial surface of the nasal cavity that is covered with mucus secreted from Bowman's glands located in the lamina propria. The dendrite terminates in a spherical swelling called *knob* with a diameter of 1–2 μm that is decorated with a number of long, nonmotile cilia protruding into the mucus layer, thus considerably increasing the surface area [27.3]. This is of immediate importance as the cilia are considered as specialized compartments of the cells, capable to interact with odorous molecules and to convert the chemical signal into an electrical response. This concept was initially based on the observation that deciliated OSNs no longer respond to odorants [27.4], and moreover that a large inward current is only elicited when the odor stimulus is directed at the cilia, whereas the same stimulus fails to induce any current when directed at the soma [27.5]. Later on, it has been found that cilia are endowed with odorant receptor (OR) proteins [27.6, 7] – and also contain a number of signaling elements, including the G protein alpha subunit G_{olf}, the adenylyl cyclase type III (ACIII), the phosphodiesterase PDE1C2, and cyclic nucleotide-gated (CNG) channels [27.6, 8–14].

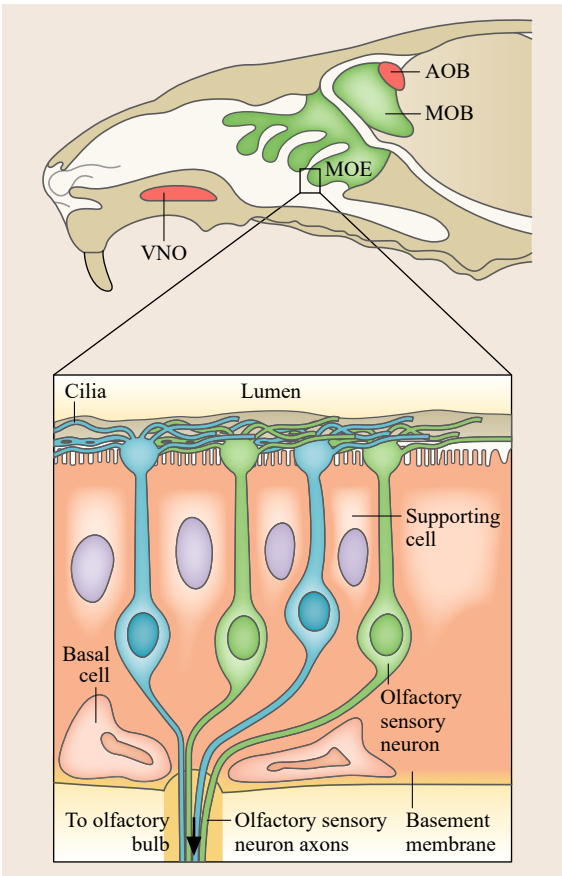

Fig. 27.1 Structure of the olfactory system: schematic sagittal representation of the head of a rodent. The main olfactory epithelium (MOE), the main olfactory bulb (MOB), the accessory olfactory system comprising the vomeronasal organ (VNO), and the accessory olfactory bulb (AOB) are highlighted (after [27.2])

27.2.1 Chemoelectrical Signal Transduction

In most cases, the process of odor sensing begins when the inhaled airstream containing scent molecules is flushed over the olfactory epithelium lining the nasal cavity. The odorous compounds then diffuse into the mucus, which is supposed to be facilitated by odorant binding proteins (OBPs). An interaction with appropriate chemosensory cilia triggers an intracellular reaction cascade converting the chemical stimulus into an electrical response.

The Canonical cAMP Cascade

The chemoelectrical transduction process is mediated via a transduction machinery that generates the second messenger cyclic adenosine monophosphate (cAMP), which in turn elicits a depolarization of the sensory cell [27.15] (Fig. 27.2).

First evidence for this so-called canonical cAMP pathway of olfactory signaling came from biochemical approaches demonstrating that odorants induce the synthesis of cAMP in olfactory cilia preparations [27.16, 17] and the accumulation of cAMP occurred within the

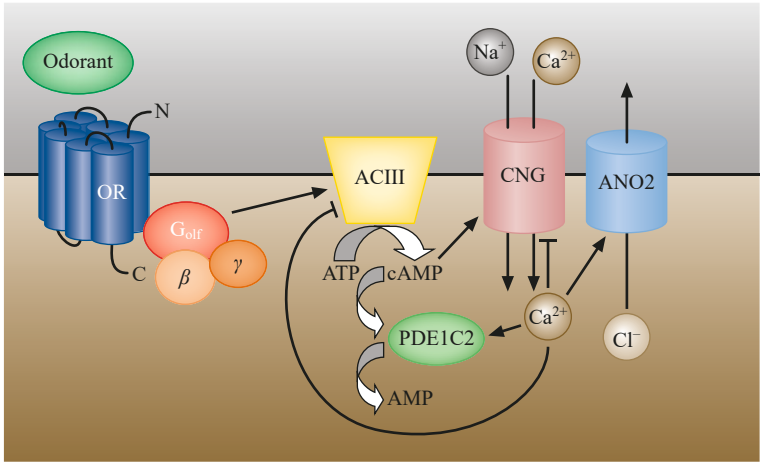

Fig. 27.2 Olfactory signaling cascade in OSNs

subsecond range [27.18]. This was in line with electrophysiological recordings demonstrating a latency of a few hundred milliseconds between odorant application and the electrical response [27.19]. The notion that the primary transduction process is based on a G-protein-coupled reaction cascade was substantiated by the findings that inhibition of G_{olf} by a specific antibody [27.20, 21] or deletion of the G_{olf} gene [27.9] led to a substantial reduction of odorant-evoked responses. G_{olf}, which is closely related to the G-protein G_s, is supposed to activate ACIII in the olfactory cilia [27.10], because a disruption of the ACIII gene in transgenic mice ablates odorant-evoked electrical responses [27.22]. As essential elements for converting elevated concentrations of cAMP into electrical currents of the sensory cells, CNG channels were identified in olfactory cilia [27.5, 23, 24]. The CNG channel of OSNs is a tetramer of three distinct subunits: two CNGA2, one CNGA4, and one CNGB1b [27.25–30]. Within the tetrameric complex, the two CNGA2 appear to be the principal channel subunits relevant for the activation by cAMP; the subunits CNGA4 and CNGB1b play a modulatory role contributing to the cAMP sensitivity, ion selectivity and permeability, as well as negative feedback control [27.27, 31, 32]. The olfactory CNG channel is permeable not only for K^+ and Na^+ ions but also for Ca^{2+} ions [27.4, 25, 33, 34]. The conductance of the channel was found to be relatively low ($\approx$ 0.5 pS), leading to a contribution of less than 0.05 pA of each individual channel [27.35]. Yet, conductance of Ca^{2+} by the CNG channel leads to an influx of Ca^{2+} ions from the mucus into the cilia, which evokes a rapid increase in the ciliary Ca^{2+} concentration [27.36, 37]. This is of particular importance since the ciliary membrane is endowed with Ca^{2+}-gated Cl^- channels that can be directly opened by an increase of cytoplasmic Ca^{2+} concentration [27.38]. Although diffusion of Ca^{2+} within the cilia appears to be limited [27.39] and Ca^{2+} ions are buffered by Ca^{2+}-binding proteins [27.40], the odorant-evoked Ca^{2+} influx via CNG channels clearly activates Ca^{2+}-dependent Cl^- channels in the ciliary membrane [27.41–43]. Under physiological conditions, opening of Ca^{2+}-activated Cl^- channels evokes a depolarizing inward current, an efflux of Cl^- ions. Such an efflux of Cl^- ions is based on an elevated intracellular Cl^- concentration in OSNs that is (at least) in a similar range as the Cl^- concentration of the mucus surrounding the cilia [27.44, 45]. This unusually high concentration of intracellular Cl^- of OSNs is believed to be mediated by the $Na^+K^+2Cl^-$ co-transporter Nkcc1 [27.46–48]. Two candidate proteins have been identified that may serve as Ca^{2+}-gated Cl^- channels in olfactory cilia; bestrophin-2 and transmembrane protein 16B (TMEM16B) (anoctamin-2 (AN02)) [27.49–51]. However, based on recent studies, a role of bestrophin-2 has been excluded [27.52]. Thus, currently, ANO2 seems to be the most promising candidate; in particular as a recent study has demonstrated that Ca^{2+}-activated Cl^- currents are absent in ANO2-deficient OSNs [27.53]. With a channel conductance of 0.5 pS [27.35] and a half-maximal activation at 5–20 µM Ca^{2+} [27.38, 54], ciliary Ca^{2+}-activated Cl^- channels are supposed to mediate up to 90% of the total odorant-induced current [27.46, 55]. In fact, more than 80% of the response was found to be blocked by the Cl^- channel inhibitor niflumic acid [27.56]. Therefore, it has been proposed that the Cl^- current provides a substantial amplification of the primary CNG-mediated cationic current [27.42] enabling a higher signal-to-noise ratio than the primary signal [27.35]. Yet, recent findings challenge the concept that Ca^{2+}-evoked Cl^- currents are essential for olfactory signaling: disruption of the ANO2 Cl^- channel reduced fluid-phase electro-olfactogram

responses by only ≈ 40%. Moreover, elimination of ANO2 did not affect air-phase electro-olfactograms and did not reduce performance in olfactory behavioural tasks [27.53]. Consequently, the authors of this study concluded that there may be no need for a boost by Cl^- channels.

Termination of Signaling Processes

For repeated stimulation and for encoding temporal information, it is essential that the odorant-induced cellular response in OSNs is terminated rapidly. The termination of the olfactory reaction cascade is primarily mediated by Ca^{2+}-dependent processes. At elevated Ca^{2+} concentrations, binding of Ca^{2+}/calmodulin inactivates CNG channels via channel closure. This is apparently due to the fact that binding of Ca^{2+}/calmodulin reduces the affinity of the channel for cAMP by up to 20-fold [27.57, 58]. Moreover, another Ca^{2+}/calmodulin-controlled protein – the Ca^{2+}/calmodulin-dependent protein kinase (CaM kinase II) – seems to play a role in signal termination. At increased Ca^{2+} concentrations, phosphorylation by CaM kinase II inactivates ACIII in olfactory cilia preparations [27.59, 60]; thus terminating ciliary cAMP generation. Also the calmodulin-dependent phosphodiesterase subtype PDE1C2 present in the cilia of OSNs may contribute to signal termination and/or adaptation to repeated stimulation [27.12, 61]. Since the ciliary concentration of Ca^{2+} is of central importance for olfactory signaling, a rapid removal of Ca^{2+} from the cilia is essential. This process seems to be mediated by the $Na^+/K^+/Ca^{2+}$-exchange protein 4 (NCKX4) (SLC24a4) [27.62]. In addition to Ca^{2+}-regulated processes, also phosphorylation of ORs by protein kinase A (PKA) and the G-protein-coupled receptor kinase 3 (GRK3) has been proposed to contribute to adaptation and/or signal termination in OSNs via receptor desensitization [27.63, 64]. Yet, further studies are required to unravel in more detail the relevance of receptor phosphorylation by different kinases for termination and adaptation of olfactory signaling.

27.3 Recognition of Odorants

The perception of smell is based on the highly sensitive recognition and precise discrimination of myriads of foreign molecules from the environment. This task is analogous to the recognition of diverse antigens by the immune system. The olfactory system, as well as the immune system, accomplishes this formidable challenge by means of many different receptors. In the immune system, the receptors are generated by a combinatorial arrangement of constant and variable immunoglobulin chains, whereas for the olfactory system more than a thousand genes are set aside to encode a repertoire of receptors that collectively can recognize and discriminate what seems to be an unlimited number of odorous compounds.

Table 27.1 Odorant receptors (OR) gene repertoire of selected vertebrate species

Species	Number of OR genes	Number of intact OR genes
Human	851	384
Chimpanzee	899	353
Dog	971	713
Mouse	1375	1194
Rat	1576	1284
Opossum	1516	899
Chicken	554	78
Pufferfish[a]	94	40
Zebrafish[a]	133	98

[a] After [27.65] and [27.66]

The notion that receptors for odorants may comprise a large family of seven-transmembrane-domain G-protein-coupled receptors (GPCRs) expressed in the olfactory epithelium has led to the discovery of the first few OR genes in rat [27.67]. This seminal finding opened the avenues for the identification of a whole family of OR genes that, on the basis of genomic library screenings, was predicted to comprise several hundred, may be more than a thousand members in mammals [27.68].

27.3.1 Diversity of Genes Encoding Odorant Receptors

More recently, detailed assessments of complete genome sequences revealed that the OR gene family accounts for about 1500 genes in mice. Thus, the multigene family that encodes the receptors for odorants represents the largest gene family in the mammalian genomes; collectively they represent up to 3% of all genes. The total length of the olfactory subgenome is estimated to be about 30 Mb and all OR genes occupy about 2% of the genomic DNA. As the genome sequences of additional species became available, a comparison of different olfactory subgenomes was possible. It turned out that the size of the OR repertoires (Table 27.1) varies considerably among different species; the reason for this remains elusive, as the number of OR genes often does not correlate with the apparent importance of olfaction. While humans and other primates,

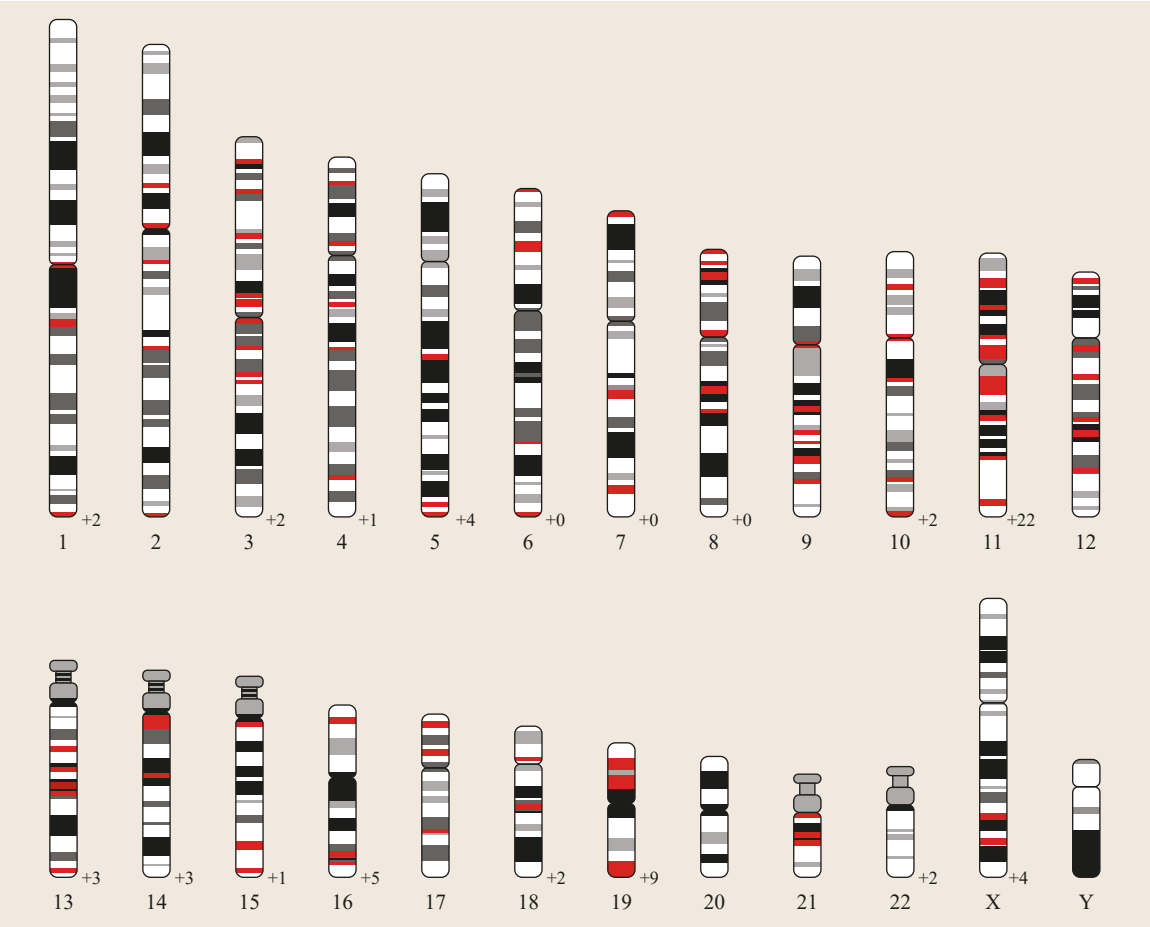

Fig. 27.3 Distribution of genes encoding ORs in the human genome. Genes for ORs are organized in clusters (labeled in *red*) with a bias for the pericentromeric and subtelomeric regions (after [27.69])

like chimpanzee, have about 800 OR genes [27.70, 71], the dog, being well-known for its excellent smelling capability has about 970 ORs [27.72]. The chicken's OR repertoire consists of 554 genes; only 78 among them are intact [27.73]. Lower vertebrates, such as fish have only a few dozens of OR genes, the Pufferfish has 40 ORs while the Zebrafish has 98 [27.65].

Genomic Organization

Each OR is expressed from a separate gene; the coding region is an intronless single exon of about 1 kb, as typical for many GPCRs [27.74]. There is a polyadenylation signal less than 1 kb downstream from the stop codon and a variable number of upstream exons [27.75]. The noncoding exons in the 5′ untranslated region may undergo alternate splicing leading to different isoforms of mRNAs [27.76]. Within the genome, the OR genes are distributed in multiple clusters, which are dispersed among various loci that contain anywhere from 1 to 100 genes [27.66]. In human, these clusters are found in more than 40 locations on almost all chromosomes, except chromosome 20 and the Y chromosome (Fig. 27.3). The largest clusters are localized on chromosomes 2 and 7, which harbor 344 and 267 OR genes, respectively. Within a cluster, spacing between adjacent OR-coding regions varies between 5 and 70 kb, and non-OR genes are usually excluded from OR gene clusters. While some chromosomes [27.1, 7, 10, 12, 15, 20] comprise many genes for ORs, chromosome 22 contains only a single OR-encoding gene.

Odorant Receptor Pseudogenes

A significant portion of the OR gene family has been pseudogenized. This is particularly striking in humans, where around 55% of the OR genes has degenerated to pseudogenes, leaving only about 350 apparently functional OR genes. Other primates, such as the chimpanzee, have a similar percentage of pseudo-

genes [27.77]. The proportion is much lower in rodents, where pseudogenes account for only about 15% of the OR genes [27.78]. These results imply that the mouse possesses over three times as many intact genes as human. In spite of the reduced number of OR subtypes, the human olfactory system retained the ability to recognize a broad spectrum of chemicals; however, it is probably less discriminating between closely related odorous compounds. The high proportion of pseudogenes [27.79] and the unusually high rate of single nucleotide polymorphisms (SNP) in human OR genes [27.80] indicate a variable repertoire of functional ORs in the human population. Interestingly, the decline of the OR gene family in some primates has been found to coincide with the acquisition of trichromatic vision, suggesting that better visual capability makes olfaction partially dispensable [27.81].

Odorant Receptor Gene Classes

Exploring candidate ORs in different species has led to the discovery of two unambiguous subdivisions of ORs, designated class I ORs that were first found in fish [27.82] and in the water-accessible nasal cavities of amphibia [27.83], and clearly distinguished from class II ORs typical for terrestrial vertebrates [27.84]. Genome database mining has subsequently shown that both classes do also exist in mammals. Based on sequence homology, 90% represent class II ORs and 10% are class I ORs. Interestingly, the more than 100 class I OR genes are assembled in a large cluster on human chromosome 11, as well as in the syntenic locus on mouse chromosome 7. Class I ORs in mammals were originally thought to be evolutionary relics; however, the relatively large number of intact class I OR genes in the mammalian genomes suggests an important role in mammalian olfaction [27.85]. This notion is supported by the finding that the percentage of pseudogenes among class I receptor genes is significantly lower compared to class II genes [27.86]. Class I genes are expressed exclusively in the most dorsal zone of the olfactory epithelium [27.87, 88] which has led to the speculation that they may be tuned to moderately hydrophobic odorants. Although the functional importance of class I ORs in mammals is still unclear, it is interesting to note that a recent study has demonstrated that dorsal-zone-depleted mutant mice lack the innate responses to aversive odorants [27.89].

The observation that class I ORs in mammals share the greatest sequence homology with fish ORs has raised the possibility that the class II ORs may be a more recent adaptation to terrestrial life. Consistent with this notion, class II ORs in mammals occurred at about the time during evolution as the common ancestor with amphibians. Moreover, it was found that in *Xenopus laevis*, class I ORs are exclusively expressed in the water-filled nasal diverticulum, whereas class II ORs are expressed in the air-filled diverticulum [27.83]. These observations suggest that when our ancestors began to occupy niches on land, much of the current diversity seen in the mammalian class II repertoires arose, and these more recently evolved ORs were adapted for the detection of airborne (or volatile) odorants.

Relationship to Invertebrate Odorant Receptors

ORs of invertebrates were identified first in the genomes of worms and flies. It turned out that both of them do not share any sequence homology to each other or to the vertebrate ORs; the fruit fly has about 60 and the mosquitos about 80 ORs [27.90, 91]. The repertoire of chemosensory receptors in *Caenorhabditis elegans* is quite large, more than around 800 functional OR genes that appear to have arisen independently from vertebrates and insects [27.92]. These findings emphasize that the absolute size of OR repertoires does not correlate with the complexity of the olfactory driven behavior. Moreover, the lack of homology between ORs from nematodes, insects and vertebrates implies that the evolutionary requirement for distinct olfactory abilities is met by recruiting novel gene families, rather than exploiting pre-existing gene families in the ancestral genomes.

27.3.2 Molecular Structure of Odorant Receptor Proteins

Sequence Motifs

The OR genes encode receptor proteins of 300–350 amino acids that are devoid of N-terminal signal peptides. They comprise all structural hallmarks typical for GPCRs, including seven hydrophobic transmembrane (TM) domains, a potential disulfide bond between conserved cysteines in the extracellular loops 1 and 2, a conserved glycosylation site in the N-terminal region, and potential phosphorylation sites in intracellular regions [27.94]. In addition, there are a few consensus motifs that allow to classify a vertebrate sequence as candidate OR, in particular MAYDRY at the end of TM3 that is considered as a sequence signature for the mammalian OR family [27.95, 96]. Moreover, motif FYVPAIFLSLTHRFGKHVPPLV on TM6 appears to be characteristic for class I ORs and the motifs MSPRVCVLLVAGSW (intracellular loop 2-TM4) and IFYGTAIFMY (TM6) are hallmarks for class II ORs [27.71] (Fig. 27.4). The TM domains 3, 4, and 5 are particularly variable and are considered as hypervariable regions and part of the ligand-binding pocket. The high variability of distinct positions within this do-

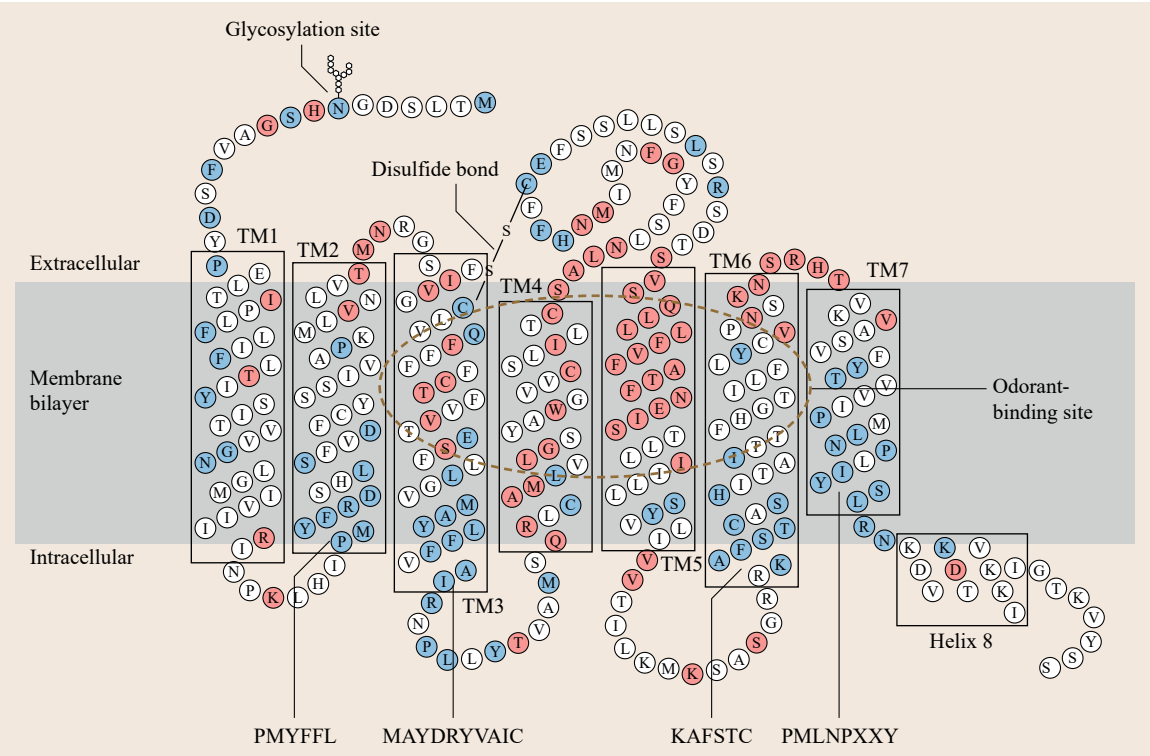

Fig. 27.4 Schematic representation of OR topology. The amino acid sequence of an exemplary OR, some conserved sequence motifs as well as the sites for glycosylation and disulfide bonds are depicted (after [27.93])

main may be the basis for the recognition of highly diverse ligands by a particular OR type [27.96].

Ligand–Binding Mechanisms

Exploring the intermolecular interactions between the odorous molecules and the receptor protein is essential not only for understanding the basis for the molecular recognition and discrimination, but also for deciphering the molecular basis for the receptor activation. This is a particularly intriguing task, because unlike most other GPCRs, ORs are activated by exogenous and mostly hydrophobic molecules. Moreover, individual receptor types are activated by many different odorants and the same odorant molecule can activate many different ORs [27.97]. Thus, the molecular features determining the specificity of an individual OR type for a distinct set of odorants are key parameters for the coding, and ultimately perception of odors. However, due to the lack of high-resolution structures of the OR proteins, it is still unknown how the protein structure determines its function, that is, which amino acid residues of the receptor protein interact with the odorous molecules, and how that determines the different ligand profiles of individual OR types. The highly variable residues in three of the seven TM domains (TM3-5) have led to the notion that these domains contribute to the binding pocket for a variety of odorants [27.98, 99]; however experimental proof for this concept is just emerging. Although a reliable structural basis for the ligand recognition of ORs is not available, the recent advances in computational power and bioinformatics methodology to perform molecular modelling approaches have opened new avenues for elucidating the molecular basis of odorant/receptor interaction. On the basis of known 3-D structures of other GPCRs, attempts have been made to get a first glimpse into the molecular interactions between receptor protein and odorous molecules [27.100, 101]. ORs belong to class A of the large GPCR superfamily and high-resolution structures of a few receptors in this class are currently available that have allowed to perform homology modelling studies using the high-resolution protein structure of rhodopsin or the $\beta 2$-adrenergic receptor [27.102] as a template to predict amino acid residues of the OR-binding pocket [27.101]. A combination of computational methods for the prediction of functionally important amino acids, together with site-directed mutagenesis and functional assessments, has allowed identifying 11 amino acid residues that seem to be part of the ligand-binding pocket and contribute to the inter-

action of a receptor protein with its cognate ligands. Based on the molecular models, 10 of these residues are located in the transmembrane helices TM3–TM6 and one in the extracellular loop between TM2 and TM3 [27.99, 101]. Moreover, docking studies have allowed some estimates for apparent affinities of an odorant toward the receptor. Subsequent studies have approached the question how the broadly tuned ORs can respond to chemical compounds with different structures. The results indicate that the recognition mode differs from those encountered in more specific systems, showing an opportunistic mode of binding. While receptors usually recognize their ligand through a network of oriented interactions, such as hydrogen bonds, the binding feature of broadly tuned ORs is dominated by hydrophobic contacts that favour multiple binding modes through opportunistic interactions [27.103]. Interestingly, a lack of an H-bonded interaction has also been observed in OBPs, where the odorous molecule is stabilized through a network of hydrophobic contacts within a solvent-occluded cavity [27.104, 105]. The domination of binding by nonpolar contacts provides an adaptability of the ORs such that they can bind several types of odorants with equivalent affinities, and nonetheless discriminate between very closely related odorants [27.103]. Molecular dynamics methodologies previously employed to study the opsins [27.106] and β2-adrenergic receptor [27.107] have recently been used to simulate the interaction of odorants with appropriate receptors [27.108]. This advanced technology has recently been extended allowing a so-called all-atom simulation at a nanosecond scale to simulate the molecular dynamics in a more realistic environment [27.108, 109]. These approaches may eventually lead to quantitative thermodynamic and kinetic constants for interactions between ORs and their cognate odorous ligands and their downstream signaling proteins.

27.4 Expression of Odorant Receptor Genes

The genes that encode ORs are expressed in OSNs that reside in the olfactory epithelium located on the so-called turbinates. A given OR gene is expressed in only a small fraction of the several million OSNs that are present in the epithelium; a population of neurons expressing the same OR gene typically comprises several thousand cells.

27.4.1 Spatial Expression Patterns

In the olfactory epithelium of mammals, each receptor-specific neuron population is restricted to an area that is called the expression zone for the corresponding OR gene, leading to a complex spatial pattern within the epithelium [27.110–112] (Fig. 27.5a). Expression zones are arranged as parallel stripes that run along the anterior–posterior axis of the nose. When viewed in both nasal cavities, the stripes are arrayed like a semicircular ring that is located at a distinct position along the dorsomedial to ventro-lateral axis of the nose. The zones are populated by OSNs with different OR types, and within a zone OSNs with the same OR are broadly and randomly distributed. The different zones are arranged like consecutive bands from dorsal to ventral, with adjoining zones overlapping to quite a degree [27.113, 114]. This spatial organization of OR gene expression results in a tessellate organization of the olfactory epithelium with OSN populations having distinct receptor types (Fig. 27.5b). There are, however, a few exceptions from this general principle: OSNs that express a member from the OR37 subfamily are restricted to a small patch in the center of the nasal turbinates [27.115, 116] (Fig. 27.5a). Here, these OSNs are concentrated in a small area at a much higher density than other receptor populations. In different mammalian species, the OSNs expressing OR37-type receptors are located at a similar central position, although the anatomical structures of the turbinates vary considerably [27.117]. The conservation of such a unique spatial organization across species supports the view that the locations of OSNs within the nasal epithelium are important for the proper function of the olfactory system.

Also the dorsomedial region of the nasal cavity is considered as unique regarding the expression of OR genes. Within this area, there is no zonal segregation; therefore the whole region is commonly referred to as the dorsal zone and distinguished from the ventral part. Moreover, the majority of sensory neurons within the dorsal zone express class I ORs that are evolutionary related to the ORs of fish.

The functional relevance of the spatial segregation of OSNs with distinct ORs is elusive. It has been speculated that such an arrangement may be important to position neurons with certain ORs at defined locations along the respiratory airflow. This may be important to match the proposed *chromatographic separation* of the volatile scent compounds according to their physicochemical properties, such as volatility and water solubility, along the air passage [27.118]; however, there is some controversy in the literature regarding this aspect [27.119]. Experimental evidence for a functional

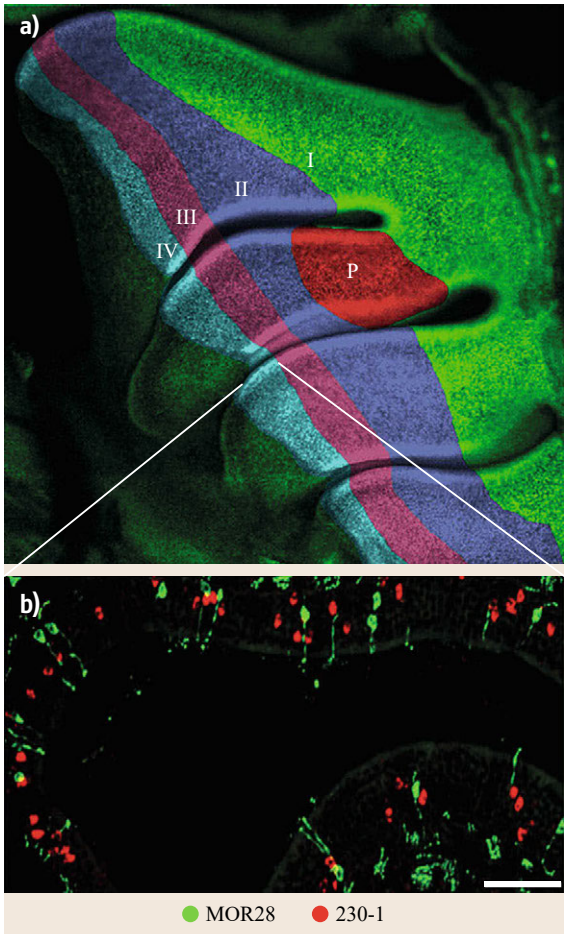

Fig. 27.5a,b Spatial expression patterns of ORs. **(a)** Neurons expressing the same receptor type are segregated in distinct zones, which are arranged from dorsal to ventral and extend along the anterior–posterior axis of the nose. In each zone, a distinct subset of receptor genes is expressed. *P* denotes the patch region, an exception from the otherwise elongated parallel organization of zones. **(b)** Within a given zone, neurons expressing a distinct receptor type are randomly distributed, as shown for MOR28 and MOR230-1 (after [27.120])

implication at this point only exists for the dorsal zone, where the ablation of all OSNs eliminates the innate avoidance behavior of mice to predator odors [27.89].

27.4.2 The One Neuron–One Receptor Rule

Although inherently difficult to prove, most of the available data currently favors the concept that each OSN expresses only a single OR gene from the huge repertoire [27.97, 121] (Fig. 27.6a); moreover, it is one allele of that gene, either the paternal or the maternal one that a cell selects [27.122]. Monoallelic expression is considered to prevent OSNs from having two ORs that are very similar in sequence, but still may differ in their odorant response profile. The mechanisms that enable an individual OSN to express only one OR gene are still at the beginning to be deciphered.

Control Mechanisms for Odorant Receptor Gene Expression

The fact that OSNs expressing the same OR gene are located within a defined zone of the olfactory epithelium, and this is the same across individuals, has led to the concept that this topography is genetically determined. This view implies that there are positional cues within the epithelium that operate in selecting the subset of OR genes suitable for expression within a given zone. Still, there is no evidence for such cue(s). However, in this context it is interesting to note that in some mouse lines an OR transgene is not expressed in its *receptor specific* zone, but in ectopic positions within the epithelium [27.124–127]. The reason for such aberrant spatial expression is unclear; it is hypothesized that the transgene integrated in the vicinity of an OR gene cluster and that the genomic locus exerted a significant influence on the transgene, thereby resulting in a corresponding spatial expression pattern [27.128]. The experiments indicate that the molecular machinery underlying the selection of a distinct OR gene for expression is not restricted to the zone in which the gene is typically expressed. Moreover, recent results suggest that OR genes may initially be chosen for expression in broader regions of the epithelium and only subsequently restricted to one defined region of the epithelium [27.129].

DNA-Regulatory Elements. One of the intriguing possibilities that DNA rearrangement may be responsible for the singular expression of an OR gene per OSN has been ruled out by cloning mice from nuclei of OSNs that already expressed a particular gene [27.130, 131]. In the cloned mice the expression pattern of ORs was normal, a result which strongly argues against the DNA rearrangement hypothesis.

Compared to most other genes, those encoding ORs are very compact units; they are comprised of only a single coding exon and a few short noncoding upstream exons (see above). The transcriptional start site (TSS) has been mapped to a few kilobases upstream, thus in very close proximity to the coding sequence [27.132, 133]. Bioinformatic analyses have revealed that the preceding promotor is frequently an adenin-thymin (AT)-rich region and that some promotors contain a canonical TATA-box which in most cases contains the core DNA sequence 5′-TATAAA-3′. The most prominent features of promotor regions for OR

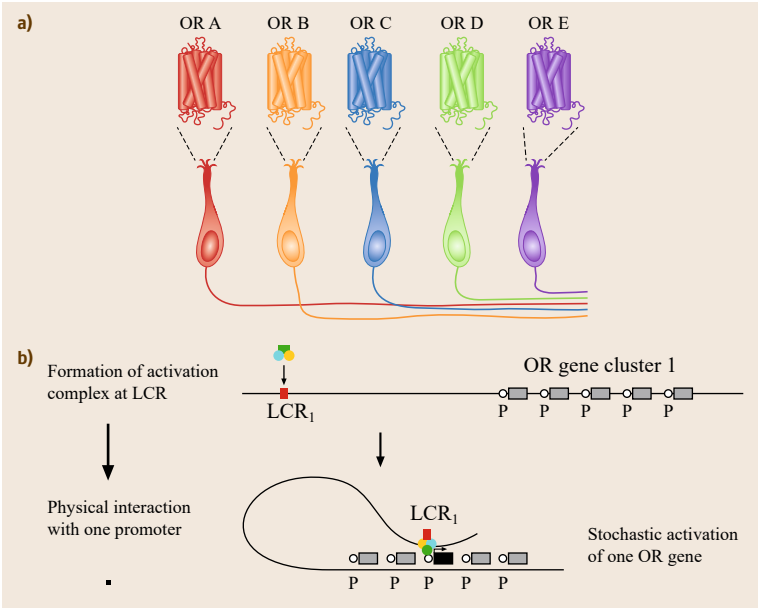

Fig. 27.6a,b Control of OR expression. **(a)** Each OSN expresses just one OR type, and only one allele of the more than 1000 receptor genes is expressed. **(b)** The process of a selective OR gene expression is assumed to be initiated by an interaction of the locus-control region (LCR) with the promotor region of a distinct OR gene within a gene cluster (after [27.123])

genes are the binding sites for homeodomain (HD) transcription factors and so-called O/E-(olf1/early B-cell factor) like sites. O/E-like sites are believed to be involved in determining the specific expression of OR genes in OSNs, because they are also found in promotors of other genes expressed in OSNs [27.134, 135]. Whether these elements are actually involved in the regulation of the spatial patterns is not yet clear; the unique organization of such elements in the putative promotors of genes with distinct expression patterns has been viewed in favor of this concept [27.136].

Experimental data concerning the mechanisms of OR gene regulation are still limited. Transgene technologies in mice have allowed to analyze a few fragments of OR gene loci for their capacity to reproduce the features of OR gene expression. Transgenes of around 10 kb are the smallest genomic fragments (minigenes) that closely reproduce the expression features of endogenous OR genes [27.125–127]. Very short DNA elements of about 150 base pairs upstream of the TSS turned out to be sufficient for eliciting the transgene expression. These elements contain the putative HD and an O/E-binding sites, and by site-directed mutagenesis they were shown to be important for in vivo expression of OR genes [27.125].

The finding that very short OR transgenes do not recapitulate all expression features of an intact gene implies that additional, more distantly located sequence elements are involved in controlling the expression of an OR gene. Indeed, such elements have been identified far more distant from the coding sequence than the typical promotor. One element (the *H-element*) is positioned in neighborhood to the MOR28 gene cluster on mouse chromosome 14 [27.137] and a second one (the *P-element*) within the cluster containing the P2 gene [27.138]. The deletion of these elements affects the expression of OR genes from the nearby cluster [27.139, 140]; therefore, they are considered as locus-control-regions (LCR), regulatory elements known for example, from the globin-gene cluster [27.141]. The finding that both, the *H-* and the *P-element*, share a conserved HD-binding site that is similar to the one in promotors of OR genes [27.132] led to the concept that the putative LCRs may physically interact with promotors of OR genes by looping onto these positions (Fig. 27.6b). When a multimerized HD-binding site from the *P-element* (19 bp) is added upstream of a minigene containing the MOR23-coding sequence, the transgene is expressed in a significantly higher number of neurons; elements with a mutant HD-binding site do not have this effect [27.142]. Based on these results, it was hypothesized that HD-binding sites in the *H-* and *P-elements* and in the OR promoters affect the probability of an OR gene to be chosen. In line with this idea, the frequency how often a gene from the MOR28 cluster is expressed correlates with its distance to the *H-region*. So far, only these two putative LCR elements have been identified in the vicinity of OR genes; thus it remains unclear whether they represent a general regulatory principle for controlling their expression.

Epigenetics. The results of very recent studies imply that also epigenetic mechanisms are involved in regulating the expression of OR genes. In olfactory progenitor

cells, all OR genes are associated with heterochromatin containing the repressive histone methylation mark H3K9me3 (tri-methylation of lysin at position 9 of histone 3) [27.143], suggesting that all OR genes are repressed prior to the onset of expression, and that the chosen OR gene is de-repressed by demethylation of H3K9 by the histone demethylase Lsd1 [27.144]. The downregulation of Lsd1 in mature OSNs apparently contributes to maintain the repressive histone methylation marks in chromatin associated with all other OR genes [27.144].

Odorant Receptor-Dependent Mechanisms. The results of several studies indicate that the receptor itself may play a role in maintaining the singularity of expression. A cell that expresses an OR pseudogene will switch to another OR gene [27.128, 137, 145]. Such a gene switch ensures that each mature OSN expresses a functional receptor protein. This model implies that a functional OR, once it is produced, contributes to silence the expression of all other OR genes, thus preventing the expression of additional ORs and ensuring the stable expression of a single receptor type in each neuron. This effect extends even to OR transgenes that are randomly inserted into other locations of the genome [27.146], implying that the sequence(s) involved in this control are within or very close to the transcribed regions of OR genes [27.147].

27.5 Odorant Receptor-Specific Wiring of Olfactory Sensory Neurons

Each OSN extends a single unbranched axon into the OB, the first relay station of olfactory information processing; thus, olfactory information is conveyed directly into the brain. Within the OB the axon terminal forms synapses with second order neurons in distinct anatomical structures, called glomeruli. A defined glomerulus harbors only the axons from OSNs that express the same OR [27.148], and a population of OSNs with the same OR typically projects to two distinct glomeruli, one is located in the medial and the other one in the lateral hemisphere of the OB [27.149]. An exception from this general dual-glomerular-projection rule are OSNs that express a member from the OR37 subfamily; these cells target only a single glomerulus that is located in the ventral domain of the bulb [27.116]. The location of a receptor-specific glomerulus within the OB is very similar among individuals; however, it is not entirely fixed; variations within an area of approximately 20–30 glomeruli have been observed. Also the location of glomeruli relative to each other can vary; these local permutations can result in different arrangements of glomeruli even in the two bulbs from one individual [27.116]. How this influences the processing of incoming information is not known.

Within the glomerulus, information conveyed by the OSNs is processed by a network of interneurons, before the projection neurons (mitral and tufted cells) relay it onto higher brain centers. The glomerulus-related circuitry is highly organized and the different cell types form a columnar structure with each glomerulus [27.150]. The neuronal networks beneath the two related glomeruli are interconnected through a set of intrabulbar projections mediated by tufted cells [27.151].

27.5.1 Organization of the Olfactory Sensory Map

The axonal projection pattern from the epithelium to the OB forms the anatomical basis of the olfactory sensory map. The formation of this complex projection pattern of OSNs along the axes of the OB has been intensively explored during recent years.

Glomerular Positioning Along the Bulbar Axes

OSNs located in the dorsal part of the olfactory epithelium send their axon to the dorsal domain of the OB, whereas neurons situated in the ventral region of the epithelium project to ventral aspects of the bulb; thus the receptor-related zonal organization of the olfactory epithelium is maintained in the dorsal-ventral topography of the OB; *zone-to-domain topography* [27.114, 153] (Fig. 27.7a). OSNs expressing a given receptor type are scattered within spatially defined but overlapping zones of the epithelium along the dorsal-ventral axis, and send their axon to a glomerulus at a corresponding position within the dorsal-ventral domains in the bulb. Each glomerulus is formed exclusively from neurons expressing the same receptor type. The topographic projection pattern along the dorsal-ventral axis is in part sculpted by complementary gradients of chemorepellent proteins and their receptors (Slits/Robo, Semaphorin/Neuropilin), indicated by the shaded bars. The notion that cues specific for the epithelial region in which an OSN is located may contribute to the process of axonal targeting was confirmed by the discovery of guidance factors that establish characteristic dorsal-ventral patterns [27.154–156]. It has been demonstrated that sets of repulsive ligand/receptor molecules, most notably Slit1/Robo2 and

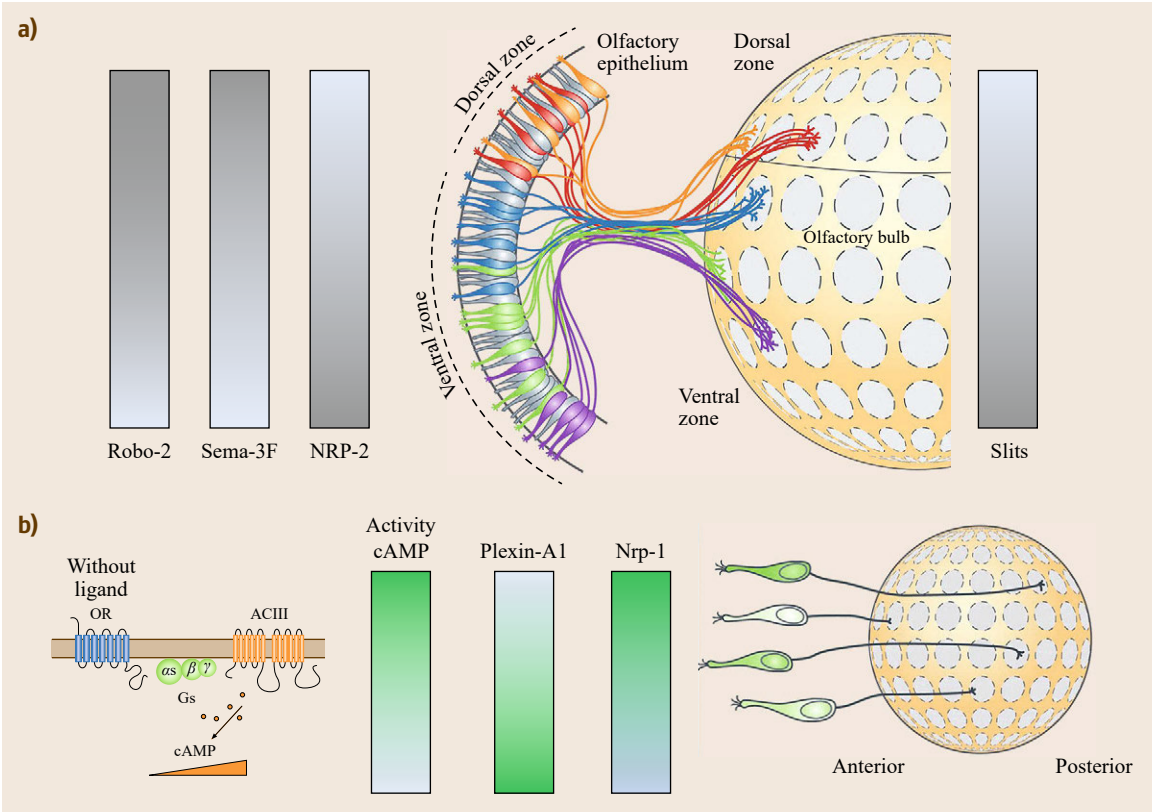

Fig. 27.7 Receptor-specific wiring in the olfactory system (after [27.152])

Neuropilin 2/Semaphorin3F, influence the projection of axons along the dorsal-ventral axis. For example, axons positive for Robo2 navigate to the dorsal domain of the bulb due to the repulsive effect of the Robo-ligands Slit1 and Slit3 present in the ventral domain of the bulb.

The second dimension of the axon guidance is the projection to either the medial side or to the lateral side of the bulb, where the glomeruli of the receptor-specific population are established (see above). Although this aspect of axon targeting is less well understood, it has been shown that the medial glomerulus is innervated by OSNs located in medial region in the olfactory epithelium, and the lateral glomerulus by OSNs located in the corresponding lateral region [27.157]. More recent studies suggest that the insulin-like growth factor (IGF1) plays a role in this process; in mouse mutants with a disrupted IGF1 signaling, the axons that are supposed to project onto the lateral region of the bulb are found in ectopic positions in the ventro-medial region of the bulb [27.158].

The receptor-specific wiring pattern of olfactory axons has led to the speculation that the receptor itself may be a critical determinant in the process of pathway and target finding of the outgrowing nerve fibers. This notion is supported by experiments in which the coding sequence of one receptor type is replaced with that of another receptor type [27.159], demonstrating that with a new receptor the OSNs send their axons to a novel glomerulus, and thereby indicating that the receptor indeed plays an instructive role in positioning of the glomerulus. The precise molecular mechanism how the receptor contributes to this process remained elusive, however. It was proposed that the ORs may recognize and respond to axon guidance cues, thus not only serving as OR in the ciliary membrane, but also as receptor for guidance cues in the axon membrane. Consistent with this hypothesis, the receptor protein is in fact present in the axon terminals of OSNs [27.7, 160]. Moreover, even mRNA for ORs is present in the axon [27.161, 162], suggesting that a local translation of the receptor protein may be possible [27.163].

In search for the intracellular mechanisms underlying the targeting of olfactory axons, the level of cAMP appears to be a critical determinant for the glomerular position along the anterior–posterior (a–p) axis of the OB [27.164, 165] (Fig. 27.7b). The topographic projection pattern along the anterior–posterior axis of the bulb is not determined by the position of a neuron within

the epithelium, but rather by the spontaneous activity of an OR type. This agonist-independent activity leads to a characteristic, receptor-related concentration of intracellular cAMP in an OSN (high or low, indicated by the shaded bar in Fig. 27.7b). The level of cAMP in turn controls the expression of specific axon guidance cues, like Neuropilin1 (Nrp1) and thereby determines the sensitivity of an axon for guidance cues along the projection pathway into the OB. Olfactory neurons expressing a receptor with low spontaneous activity form glomeruli in the anterior region of the bulb, those with high-activity receptors form glomeruli in the posterior region of the bulb. An attenuated cAMP-signaling in OSNs results in an anterior shift of glomerular position, whereas an enhanced cAMP signaling results in a posterior shift [27.166]. Thus, the capacity of an OSN population to generate cAMP determines the position of its target glomerulus along the a–p axis. This phenomenon appears to be due to the fact that the level of cAMP determines the level of axon guidance cues, such as Neuropilin 1, a receptor for the repulsive Semaphorin 3A. OSNs with high levels of Neuropilin 1 project to posterior positions in the bulb, whereas neurons with low levels project to anterior positions. The question how the cAMP level within a particular OSN population is controlled turned out to be very challenging to answer. Only very recently, in elegant approaches it was discovered that the OR itself determines the cAMP level, and most interestingly not via a ligand-induced activation, but rather by its spontaneous, thus agonist-independent activity [27.167]. Indeed, the intrinsic activity of a particular OR protein correlates very well with the glomerular position of the corresponding OSNs. In this way, the position of a glomerulus along the anterior–posterior axis is not based on the location of the corresponding OSNs within the epithelium, but determined by the intrinsic activity of the OR protein.

Development and Regeneration

During development of the olfactory system, the axons of OSNs expressing a given OR project into the prospective OB; initially the projection is not as precise as in adult stages [27.168, 169]. In early stages, some adjacent glomeruli are targeted, resulting in heterogeneous glomeruli, that is, neuropil structures composed of axons from different OSN populations. These heterogeneous glomeruli are supernumerary and eliminated as the glomerular map matures after birth. If odor-evoked activity is blocked at birth, for example, by naris occlusion, the heterogeneous glomeruli persist [27.124]; conversely, if odorants are present at higher doses during the early postnatal phase, the glomeruli mature more rapidly [27.170, 171]. These observations suggest that odor induced activity is involved in the refinement of the innervation.

OSNs have only a limited life span of about 90 days and throughout life they are continuously replaced from stem cells, the globose basal cells, that reside at the base of the olfactory epithelium [27.172–174]. The newly generated cells migrate up into higher layers and differentiate to mature OSNs that express an appropriate OR type. Under normal conditions the generation of new OSNs occurs asynchronously, with only 1−2% of the cells being replaced at a given point in time. Because the vast majority of cells in the olfactory epithelium are mature OSNs that are connected to their target glomerulus, it is supposed that the axon of a newly generated neuron can grow along established tracks and most likely associates with preexisting fibers. This could either be based on a homotopic attraction between axons from OSNs with the same OR, mediated by the OR itself or appropriate cell adhesion molecules. Alternatively, residual fragments of fibers from replaced neurons may label the tracks, for example, by inducing molecular cues in the surrounding extracellular matrix.

In addition to this normal scenario, the olfactory system has the remarkable capacity to re-establish the system even after an extensive damage to the olfactory epithelium; this could either be due to an injury, a virus infection or an exposure to toxins which can cause a loss of virtually all OSNs. During a reasonable period of time, a complete population of OSNs is reproduced and the system is re-established to a level that is nearly indistinguishable from the original in terms of neuron number and spatial organization [27.113, 175]. In addition, the axonal projection patterns are newly formed and the basic olfactory functions, such as odor detection and discrimination of odorants are recovered. Only after severe events, the targeting of olfactory axons to the glomeruli seems imperfect, reminiscent of the projection during development. However, during the regeneration, these errors are apparently not repaired and receptor-specific neuron populations do not project to only two glomeruli, but multiple glomeruli are formed [27.176]. The impact of this mistargeting on odor representation is largely elusive; however, it has been reported that in humans smell deficiencies may remain after severe traumata of the olfactory epithelium.

28. Nasal Periceptor Processes

Boris Schilling

There are myriads of odorous molecules that we perceive and it is remarkable that most of us seem to have very similar odor impressions that originate from a specific stimulus and the sense of smell appears to be robust during much of a lifetime. When perceiving scents, olfactory receptor (OR) proteins are at work to translate chemical information into neuronal signals that are decoded in the olfactory cortex to provide us with an odor image. Proposed in the middle of the last century but only substantiated with intriguing laboratory data during the last decade, there are enzymes expressed at high levels in the olfactory mucosa, and they metabolize xenobiotics including odorants and produce many new chemical species. Examples demonstrate that such perireceptor events can alter the receptor-dependent activation pattern in the olfactory neuroepithelium, which has an impact on the quality and the intensity of odor stimuli. Results that do not seem to fit a model or a hypothesis may make sense if perireceptor events are brought into the equation.

Our senses provide us with an internal representation of the outside world with a straight impact on our behavior and decision-making processes. While it is generally appreciated that sight and sound are crucial for our quality of life, the important role of the sense of smell is often forgotten and goes far beyond enjoying a subtle splash of a luxury perfume. The perception of fragrances is inevitably linked with joy, well-being, mood, emotions, memories, and both physiological and psychological reactions are responsible for the power of the sense of smell. There is a strong personal flavor to the perception of odors and learning, association, context as well as a genetic predisposition all contribute to a unique individuality for olfaction that is not observed for other senses, such as vision and audition. Evidence for a striking variability for the perception of β-ionone, a floral and woody odorant with a strong freesia character, was based on a large sensory study conducted during a flower show in New York City in 1935 [28.1]. The term *specific anosmia* describes the fact that many people are *odor blind* for specific molecules. The first thorough investigation was published in 1967 by *Amoore* who described anosmia for the sweat odorant isovaleric acid [28.2]. He expanded the studies to other odorants and also discovered that specific anosmia is genetically inherited [28.3, 4]. Today, it is generally known that even for perfumery ingredients, specific anosmia exists for instance for β-ionone, salicylates, musks, and amber odorants. Androstenone is an interesting body odor, that is perceived as unpleasant/urinous/sweaty or pleasant/sweet/floral or odorless, and it has been shown that a genetic variation in one human odorant receptor (OR) is responsible for the difference in odor perception [28.5]. Besides single-nucleotide polymorphisms, receptor gene copy number variation is a possible factor for phenotypic difference in odor perception [28.6]. There is some decrease in the performance of the sense of smell during aging which is generally not dramatic unless the cause is a neurodegenerative disease, such as Alzheimer and Parkinson where an impaired sense of smell is one of the earliest symptoms [28.7]. The decline in the ability to detect and discriminate odors in aged humans is not well understood, and latest investigations suggest

that it is multifactorial, and includes reduced neurogenesis, altered synaptic organization as well as modified odor representation in primary olfactory cortices and beyond [28.8].

Many excellent studies on the sense of smell have been based on sensory behavioral experiments, psychophysical measurements, and electrophysiological and anatomical investigations. A review in National Geographic Magazine in 1986 provides a superb overview on various aspects of olfaction that were known at the time and emphasizes that the mechanisms by which odorous molecules activate neurons that convey respective information to the brain were still to be elucidated [28.9]. An explosion of research in olfaction followed the discovery of the odorant receptor proteins in 1991 by *Buck* and *Axel* [28.10]. Olfactory receptor genes are the largest gene family in the human genome with close to 1000 genes that are scattered across most chromosomes. In humans, the majority of the receptor genes have been mutated to pseudogenes leaving us with close to 400 functional genes [28.5, 11–15]. Interestingly, segregating pseudogenes have been identified, indicating that different people may have a slightly different number of pseudogenes on top of the occurrence of various alleles for each of the functional olfactory receptor genes [28.16]. Investigating and understanding the olfactory gene expression in olfactory sensory neurons, signal transduction, receptor agonist patterns, axonal projections to glomeruli in the olfactory bulb and signal processing in the olfactory cortical areas are fascinating topics that are reviewed and explained in other chapters in this book. There is a chemotopic map preserved on the level of olfactory bulb, the first relay station in the brain [28.17, 18]. Information processing beyond the olfactory bulb toward the olfactory cortical areas is multifaceted and surprisingly, the activation patterns in the piriform cortex, the next processing center for olfactory information get much more complex. The same cortical neuron responds to diverse odorants and it appears that odorants are represented by unique ensembles of active neurons in the piriform cortex. When moving from single odorants to odor mixture, strong suppression and some minor synergistic effects are observed, demonstrating that the representation of complex odors in the piriform cortex is not the integration of individual activation patterns [28.19]. Previously, Buck et al. proposed that cortical neurons might be acting as *coincidence detectors* when receiving inputs that originate from more than one receptor. More recently, it has been elegantly demonstrated that neuronal information from the olfactory bulb is conveyed to multiple cortical centers where odor representation is differently organized. While activated neurons in the piriform cortex show no discernible spatial order, the representation in the cortical amygdala exhibits spatially stereotyped projections from olfactory bulb glomeruli which overlap and allow for the local integration of neuronal signals [28.20]. The authors propose a model, where the representation of activated ensembles of neurons in the piriform cortex is vital for experience and learned olfactory responses, while the odor representations in the cortical amygdala are linked to innate behavioral responses.

The activation of olfactory receptors by odorants at the periphery of the olfactory system is the essential step toward smell perception. Yet there is evidence that perireceptor events also contribute to the shape of the olfactory percept, and this understanding may be important to compare in vitro results derived from receptor screenings and in vivo psychophysical studies, such as the determination of odor detection thresholds, as well as the assignment of odor descriptors to fragrance molecules. It has been speculated for years that enzymes in the respiratory tract and in particular in the olfactory epithelium could have an impact on the perception of odorants. The initial hypothesis that enzymatic activities (or their inhibition) are involved in the nature of the sensation of smell was proposed by the chemist *G.B. Kistiakowsky* from Harvard University more than 60 years ago [28.21]:

> *On the Theory of Odors: I cannot resist the temptation to add on more hypothesis on the nature of the sensation of smell to speculation of others to this subject. Several characteristic traits of this sense can be accounted for without infringing on the basic physical principles if it is attributed to the inhibition of certain enzymes contained in the olfactory organs* [. . .].

He proposes that sequences of metabolism, on the one hand, and inhibition of enzymes on the other contribute to high impact odors, form the basis of the large collection of molecules having a smell and determines that the complexity of odors also results from the inhibition of various enzymes to different extents. Interestingly, he also proposes that such enzyme inhibition can change the quality of smell, a concept that will be revisited later in this chapter. Around the same time, enzymes were localized in and around the gustatory and olfactory organs of the rabbit, including the olfactory mucosa, and it was suggested that they may be associated in some way with the mechanisms of smell and taste [28.22].

The first evidence of the in-nose metabolism of a volatile compound was provided at the 6th International Symposium of Olfaction and Taste [28.23]. The scientists observed that upon channeling tritium-labeled octane through a frog's nose, some of the labeled mate-

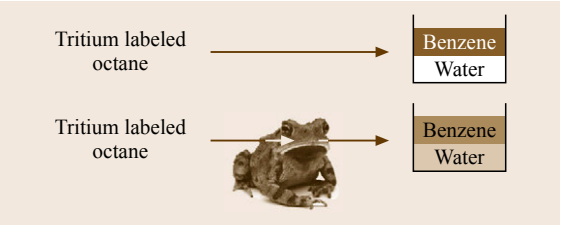

Fig. 28.1 Indication of in-nose oxidative metabolism (after [28.23])

rial became water soluble, and they speculated that the chemical got somehow transformed at the olfactory receptor site (Fig. 28.1). From today's perspective, it can be concluded that the nonwater-soluble alkane was oxidized by cytochrome P450 monooxygenases (CYPs) to produce the water soluble alcohol.

Octane is soluble in the organic solvent (benzene); however, following exposure to the olfactory tissue of a frog, some of the tritium-labeled material is soluble in the aqueous phase, indicating in-nose oxidative metabolism [28.23].

Only a few years later, it was demonstrated that high concentrations of CYPs and other enzymatic activities are located in the nasal cavity of animal species [28.25]. One paper was published showing that the fragrance material heliotropin (piperonal) inhibits rat nasal CYP activity and the author is putting forward the idea that part of the effectiveness of heliotropin as a perfumery ingredient may result from prolonging the half-life and residency time of other odorants in the nasal cavity by inhibiting their enzymatic oxidation and degradation [28.26]. An excellent review by *Alan Dahl* describes animal studies conducted in the 1980s to investigate whether nasal metabolism influences the biological fate and toxicity of inhaled materials as well as to address a potential impact on olfactory physiology [28.24]. Selected substrates and metabolites reported in this review and references cited therein are shown in Fig. 28.2 together with the original classification of olfactory mucosal enzymes.

It is further postulated that olfactory xenobiotic metabolizing enzymes might have an effect on the characteristic odors of compounds, and the author makes suggestions how to direct research efforts to provide data on the role of nasal metabolism in olfaction [28.24]. He lists five specific effects where xenobiotic-metabolizing enzymes may influence odor perception:

1. Conversion of a nonodorant into one or more odorants.
2. Conversion of odorants to nonodorants.
3. Transformation of odorants to other odorants (change in quality).
4. Transformation of lipophilic compounds into more water-soluble ones (change in physicochemical properties and elimination).
5. Inhibition of the metabolizing enzymes (may alter all the previous effects). These possibilities will be discussed in more detail in this chapter.

Another group of proteins which is prone to play a role in perireceptor events are the so-called odorant-binding proteins (OBPs) which are small soluble carrier proteins with binding activity toward volatile compounds [28.27]. These proteins belong to the family of lipocalins which are known to transport small ligands in other body fluids but their role in mammalian ol-

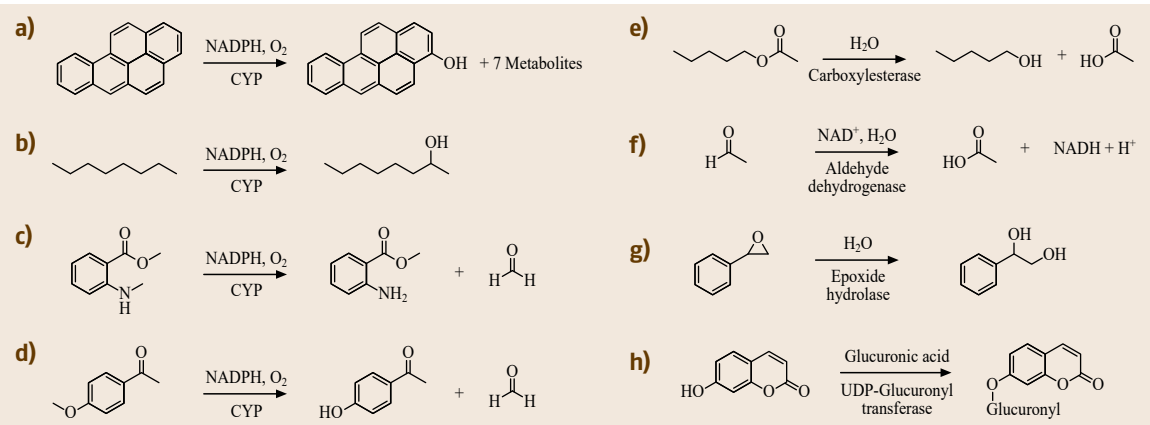

Fig. 28.2a–h Metabolic reactions catalyzed by olfactory mucosal enzymes (after [28.24]): **(a)** hydroxylation of benzo[a]pyrene, **(b)** hydroxylation of octane, **(c)** *N*-demethylation of dimethylanthranilate, **(d)** *O*-demethylation of *p*-methoxyacetophenone, **(e)** hydrolysis of amyl acetate, **(f)** oxidation of acetaldehyde, **(g)** hydrolysis of styrene oxide, **(h)** glucuronidation of 7-hydroxycoumarin (umbelliferone)

faction is still unclear. Proposed functions include the transport of the hydrophobic molecules from the nasal air space across the viscous, hydrophilic mucus layer to the ciliae of olfactory sensory neurons where receptor proteins are located, as well as a role as scavengers for excess odorants and removal of the stimuli. Since the studies on heterologously expressed olfactory receptor genes clearly indicated that they function in the absence of OBPs, their role in vertebrate olfaction is still unanswered. More evidence for the function of lipocalins in chemoreception was found for insects [28.28]. The first identified insect OBP was the pheromone binding protein (PBP) of the silk moth *Antheraea polyphemus* [28.29] shortly before the first mammalian OBP was described. Later, compelling evidence was provided that the *Drosophila* insect pheromone 11-*cis* vaccenyl acetate is requiring a specific OBP for the activation of pheromone-sensitive neurons [28.30] and it has been demonstrated that the detection of the *Drosophila* pheromone is mediated directly by the OBP upon a pheromone-induced conformational change [28.31]. Binding of the pheromone converts an inactive ligand into an activator of pheromone-sensitive neurons, which is in contrast to the general assumption that olfactory neurons are activated by volatile odorants as a result from the direct activation of the membrane-embedded receptor by the volatile stimulus.

It has been nicely demonstrated that OBP/PBP-enabled perireceptor events play an essential role in insect olfaction where a large repertoire of OBP genes are expressed; however, their role in mammalian olfaction is still not clear. Therefore, the upcoming sections are dedicated to review the current understanding on biotransformation reactions that take place in the olfactory mucosa with emphasis on the role of cytochrome P450 enzymes (CYPs) in nasal metabolism, and the potential impact of xenobiotic-metabolizing biochemical reactions for olfaction research.

28.1 Xenobiotic-Metabolizing Enzymes in the Olfactory Epithelium

Metabolism of xenobiotic molecules is primarily assigned to a role of hepatic phase-1 and phase-2 biotransformation enzymes. In phase-1 metabolism, molecules are made reactive and during phase-2 metabolism sugar or peptide moieties are added to make water soluble catabolites and allow excretion via urine. However, there has been strong evidence that xenobiotic metabolism is taking place outside the liver, and various reviews have described that biotransformation enzymes are found in the respiratory tract and in particularly high concentrations in the olfactory mucosa [28.32, 33]. In order to identify the enzyme families that are involved in xenobiotic metabolism, gene expression patterns were compared between human fetal and adult olfactory mucosa and liver specimens, using a combination of gene array analysis and ribonucleic acid polymerase chain reaction (RNA-PCR) [28.34]. A series of biotransformation enzymes which were identified in the nasal tissue are shown in Table 28.1. The family of CYPs is of specific interest, since they are involved in the phase-1 metabolism of very diverse chemical species. About one dozen CYP genes are expressed in the human olfactory mucosa and amongst them, CYP2A13 has been identified to be specifically expressed in the human respiratory tract, predominantly in the olfactory mucosa [28.35], therefore being a primary candidate to explore and test odorants as substrates or enzyme inhibitors.

Liver metabolic enzymes are known to be upregulated as a response to exposure to xenobiotic compounds, including drugs. However, the regulation of xenobiotic-metabolizing enzymes in the olfactory mucosa has been little explored. There are studies indicating an enhanced expression of specific genes following

treatment with chemicals [28.43] and a recent publication reports that inducers known to regulate hepatic gene expression also worked in the rat olfactory mucosa and phase-1, phase-2, and transporter genes were up-regulated [28.44].

28.2 Cytochrome P450 Enzymes

CYPs are peripheral membrane proteins anchored to the membrane bilayer of smooth endoplasmic reticulum by their amino-terminal domain. An iron–heme cofactor is present in the catalytic center where the oxygen-dependent monooxygenation of suitable substrates takes place. For a full catalytic cycle, two electrons are required which are supplied via an electron-transfer system from an NADPH-cytochrome P450 reductase (POR) which is also membrane-anchored and in a close proximity to the CYP. NADPH is the ultimate electron donor, and electrons are channeled via two flavin cofactors (flavin adenine dinucleotide (FAD), flavin adenine mononucleotide (FMN)) in POR to the catalytic center of the CYP. The overall reaction is shown in Fig. 28.3 and further described, for instance, in the following reviews [28.45, 46].

A comprehensive overview on classical and particularly uncommon CYP-catalyzed reactions has been published by *Guengerich* [28.47]. This family of enzymes shows low substrate specificity and frequently produces multiple products. The availability of several crystal structures of human CYPs allows rationalizing the fate of substrates and the binding site of inhibitors.

Pharmacological metabolism research and the role of CYPs in chemical toxicology have been the area of strong interest. Various excellent reviews describe recent developments in metabolism studies and safety testing, adverse effects of drugs through biotransformation, and bioactivation of chemicals. Besides identifying metabolites of active pharmaceutical ingredients (APIs) and determining the pharmacogenetics and clearance of drugs, various groups also investigated the role of CYP polymorphisms in the onset and progression of cancer and the role of genetic variability in human CYP genes [28.48–50]. It is remarkable that nasal cytotoxicity and carcinogenic activities are originating from systemically distributed organic chemicals, confirming the metabolic power of the nasal mucosa [28.51]. Several publications conclude that the respiratory tract CYP2A enzymes and particularly CYPA13 play a role in the metabolic activation of nasal toxicants [28.52] and are involved in the bioactivation of tobacco-specific nitrosamines [28.35, 53–57]. Genetic polymorphism of *Cyp2a13* can be linked to lung cancer susceptibility [28.58–64] and CYP enzymes have been mentioned as potential targets for chemoprevention of lung cancer by the use of selective inhibitors (see the following paragraphs). Active site mutations of CYP2A13 influence the orientation and results in altered kinetics for metabolite formation which can be rationalized by docking studies using the CYP2A13 crystal structure [28.65].

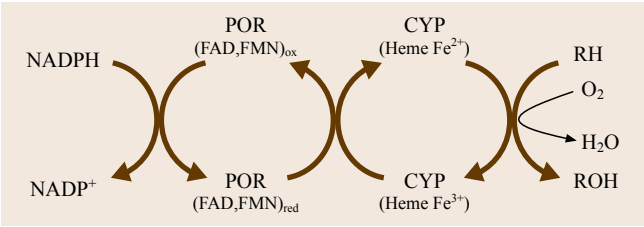

Fig. 28.3 Substrate oxidation by CYP with the concomitant reduction of oxygen to water. Electron transfer from NADPH is taking place via two flavin cofactors (FAD, FMN) which are present in POR. The iron-heme cofactor is the site of chemical oxidation in CYP

28.3 Exploring the Substrate and Inhibitor Range of Olfactory P450 Enzymes

CYP members of family 2 are strongly expressed in nasal tissue, and also known to bind small molecular weight compounds as substrates and inhibitors, including volatile odorants. Studies were conducted with various commercially available CYP sources; however, the respiratory tract-specific CYP2A13 was selected as the primary candidate for further investigations and produced from *Spodoptera frugiperda* cell line 9 (Sf9) insect cells together with the reductase partner POR [28.66, 67]. A library of odorant molecules was used to identify substrates of CYP2A13. For many molecules, a molecular weight increase [M+16] was

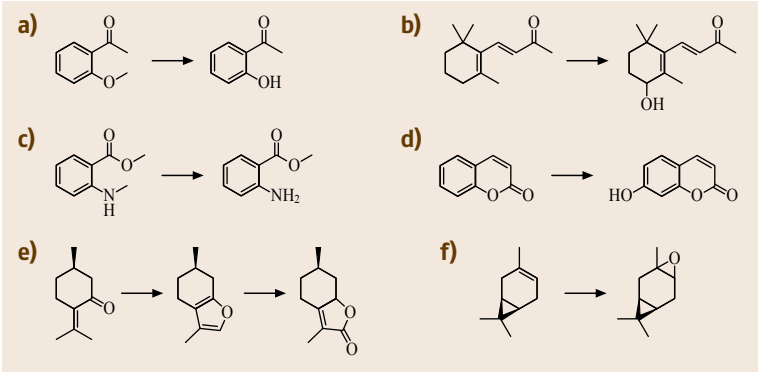

Fig. 28.4 CYP2A13-catalyzed oxidation of odorants: **(a)** demethylation of 2-methoxyacetophenone, **(b)** allylic hydroxylation of β-ionone, **(c)** demethylation of dimethylanthranilate, **(d)** hydroxylation of coumarin, **(e)** oxidation and cyclization of (*R*)-(+)-pulegone to menthofuran and further oxidation to mintlactone, **(f)** epoxidation of delta-3-carene

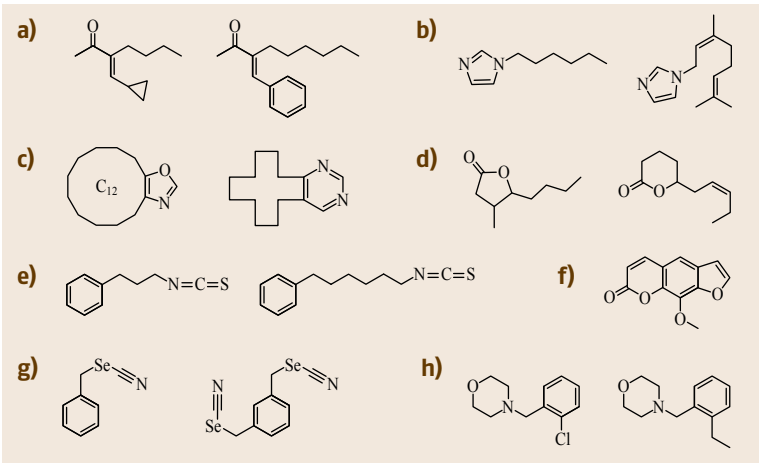

Fig. 28.5 Inhibitors of CYP2A13 exhibiting IC50 values in the low μM range: **(a)** ketone types, **(b)** *N*-heterocycles, **(c)** macrocyclic heterocycles, **(d)** lactones, **(e)** isothiocyanates, **(f)** 8-methoxypsoralen, **(g)** organoselenium types, **(h)** benzylmorpholine types

found indicating a monooxygenation reaction (either hydroxylation or epoxidation). Furthermore, demethylation of methoxy- and *N*-methyl groups was observed. A selection of odorants that are metabolized by CYP2A13 is shown in Fig. 28.4.

Two examples of CYP substrates with available odor intensity and quality data are shown in Table 28.2. In the case of methoxyphenylbutanone (Ketanone), the metabolite is the powerful raspberry ketone, whereas in the case of dimethylanthranilate, the metabolite has a slightly lower threshold and distinct but small differences in the odor description. Depending on the extent of nasal metabolism, one is never smelling the substrate alone, but always a combination of the substrate and the metabolite, which may differ between individuals.

Libraries of diverse chemical classes of small molecular weight compounds were screened for inhibitors of CYP2A13, CYP2A6, and CYP2B6 enzymes [28.68–75]. Chemically diverse inhibitors as

Table 28.2 Odor thresholds and qualities of selected substrate–metabolite pairs

Substrate		Metabolite	
	OTH: 0.05 ng/l Odor description: raspberry, floral, green		OTH: 0.005 ng/l Odor description: raspberry, fruity, sweet
	OTH: 0.59 ng/l Odor description: floral, neroli, sweet, warm		OTH: 0.12 ng/l Odor description: floral, orange blossom, neroli, mandarin

OTH: Odor detection threshold in ng/l air, determined using an olfactometer

well as various substrates were identified, further confirming that the respiratory tract-expressed enzymes CYP2A13 and 2A6 are able to catalyze detoxification as well as metabolic activation reactions of environmental molecules and are also subject to inhibition by xenobiotic compounds. Selected examples of CYP2A13 inhibitors having half minimal inhibitory concentration (IC50) values in the low micromolar range are shown in Fig. 28.5. Different small molecular weight inhibitors have recently been evaluated for their selectivity toward human CYP2A enzymes [28.76–78]. Odors are generally blends of a series of volatile molecules which activate ORs. However, all of them can also be substrates or inhibitors of metabolic enzymes. Odorants which are also CYP inhibitors will reduce the metabolism of other odorants, which can impact the intensity or the quality of odors.

The earliest demonstration of nasal bioactivation took place using insecticides and herbicides. The herbicide 2,6-dichlorobenzonitrile (DCBN) was known to cause tissue-specific toxicity at very low doses in the olfactory mucosa of rodents. Amongst all tested heterologously expressed CYP variants, the 2A subfamily showed strong activity toward DCBN [28.79]. It has recently been shown that the bioactivation of DCBN is also catalyzed by human nasal mucosa microsomes [28.80]. The study was run in parallel using wild type or *Cyp2a5*-null mice (with CYP2A5 being the mouse ortholog of human nasal CYPs 2A13/2A6) demonstrating strong olfactory tissue-specific and CYP-dependent bioactivation of systemically applied DCBN. Metabolites were identified in nasal-wash fluid and these results are particularly interesting, since they demonstrate that products that originate from metabolism in the olfactory sustentacular cells are secreted into the nasal mucus, where metabolites could act as ligands of olfactory receptor proteins, either as agonists or antagonists.

28.4 Evidence for the Role of Biotransformation Enzymes in Olfaction from Animal Studies

It is generally assumed that odorant identity is represented in the chemotopic map by the glomerular activation pattern (see also Chap. 27). *Touhara* et al. reported that there are differences between OR-derived glomerular activation in the olfactory bulb (OB) and response patterns derived from in vitro assays [28.81]. For instance, only modest or no responses were observed for a mouse olfactory receptor protein (mOR-EG) in olfactory glomeruli following exposure of the animal's olfactory system to vanillin, although this odorant was shown to be a potent agonist of mOR-EG in isolated olfactory sensory neurons, as well as in the human embryonic kidney cell line 293 (HEK293) expressing mOR-EG. Most interestingly, it was reported that the nasal olfactory mucus influences the responsiveness to some but not all odorants indicating that some metabolic enzymes appear to be present in the mucus that is surrounding the ciliae where the olfactory receptor proteins are embedded. Later, the same group demonstrated that the enzymatic conversion of odorants in the nasal mucus affects both the olfactory glomerular activation patterns and odor perception in mice [28.82]. It was presented that mucus-secreted enzymes oxidized aldehydes to the corresponding acids and hydrolyzed esters; and that selected inhibitors reduced the metabolism of the odorants. The effect of metabolism taking place at the periphery was shown to influence the pattern of glomerular responses in the olfactory bulb as monitored by calcium imaging. The final study aimed to demonstrate that the enzymatic conversion of odorants in the mucus effects perception. Mice trained to recognize the ester acetyl isoeugenol showed a clear deficit to recognize the target odorant when treated with a carboxylesterase inhibitor, while they behaved no different to the control group when exploring odorants that were not metabolized [28.82]. This study elucidated for the first time that modulated peripheral metabolism in the olfactory epithelium is manifested in the first relay station in the brain, and is influencing the perception and behavior of the animal.

A study in rats further investigated the role of xenobiotic-metabolizing enzymes in the olfactory mucosa including activities of enzymes that are not secreted into the mucus [28.83]. The two CYP substrates coumarin and quinoline, as well as the carboxylesterase substrate isoamyl acetate were investigated. CYPs produced hydroxylated metabolites, while esterase activity resulted in isoamyl alcohol and acetic acid. Electro-olfactogram (EOG) recordings on the olfactory epithelium allowed to determine the activation of olfactory sensory neurons by either substrates or metabolites. When identified metabolites were tested separately in control experiments, the EOG responses were generally lower and weaker amplitudes were recorded, indicating that metabolites are less efficient agonists. In order to determine the functional role of olfactory metabolic enzymes, EOG studies were run in the presence of CYP- or carboxyl esterase-specific inhibitors which in-

hibit the enzymes as demonstrated in in vitro assays. Interestingly, in all cases the recorded EOG signal increased when using specific inhibitors, while in controls where the substrate and the inhibitor were not targeting the same enzymatic activity, no effects were observed [28.83]. This study revealed that peripheral olfactory responses are modulated by enzymes that are located in sustentacular cells.

28.5 Human Sensory Studies

While studies with human beings must be less invasive than the above described studies, several investigations have demonstrated that the respiratory tract-specific metabolism of volatiles is fast and can influence odor perception. The human olfactory mucosa has a very high metabolic activity, and in particular, CYP2A13 acts to oxidize a broad range of substrates and is itself subject to inhibition by small molecular weight compounds.

Two approaches allowed to monitor in vivo formation of metabolites [28.84]. In one case, a mass spectrometer was used to analyze exhaled air in real-time. Saturated headspace of the odorant 2-methoxyacetophenone was inhaled, and the breath exhaled into a glass funnel that was connected to a quadrupole mass spectrometer equipped with an atmospheric pressure chemical ionization (APCI) ion source. Exhaled breath was monitored over several minutes, and the metabolite 2-hydroxyacetophone was already detectable in the first exhalation cycle [28.67]. A second approach enabled better quantification of metabolites, and exhaled breath was captured on a resin, followed by thermal desorption and analysis by gas chromatography-mass spectrometry (GC-MS), where metabolite formation was monitored, for example, for the CYP substrate 2-methoxyacetophenone, or the carboxylesterase substrate styrallyl acetate [28.84] as shown in Fig. 28.6.

Intensity rating is more challenging for panelists than detecting a change in olfactive character. While the former was successfully done for fragrance accords [28.69] the latter demonstration was important to provide evidence that mucosal biotransformation of odorants can impact the olfactory percept. During the substrate screening for CYP2A13 (see above) a metabolite was identified by GC-sniff analysis that had a strong, characteristic raspberry odor, while the substrate is commonly described as woody, fruity with raspberry aspects. The hydroxylated metabolite was isolated, its structure elucidated, and a reference material synthesized to confirm the characteristic raspberry smell of this molecule (Fig. 28.7). In order to determine if indeed that substrate is *woody*, *fruity*, *raspberry*, or if the raspberry note originates from the formation of the metabolite, a volatile odorless inhibitor was selected and used in a sensory experiment. A miniaturized olfactometer was used where the substrate was present in one channel, and the inhibitor in a second one, and a panelist could smell the odorous substrate, the odorless inhibitor, or a combination of the two by switching the pressure control valves. The majority of panelists reported that the raspberry note was reduced or completely eliminated when smelling the inhibitor together with the odor stimulus [28.67, 69]. During the study, some panelists reported that they could only identify a woody smell, while a few individuals described that odor as fruity/raspberry but without any woody facets; a possible explanation is that these panelists are hypo- or hyper-metabolizers of the substrate. This one sensory demonstration further supports the role of biotransformation enzymes as a perireceptor event that contributes to odor perception.

When designing and synthesizing novel odorants, fragrance chemists are building olfactophore models in analogy to pharmacophores, and the question is to what extent metabolism in the olfactory neuroepithelium needs to be considered in such studies to strengthen the model. The above example demonstrates that one needs to know the hydroxylated ketone metabolite to correlate the structure with other odorants that are described as having a raspberry odor. An interesting case is the search for novel green and fruity odorants,

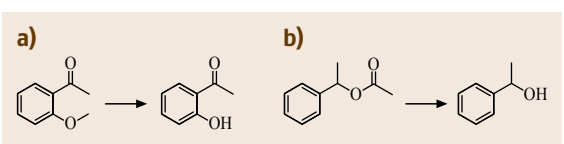

Fig. 28.6a,b Two different odorants were inhaled and exhaled breath was analyzed by real-time mass spectrometer analysis (a), or by trapping on a resin followed by thermal desorption and analysis by GC-MS (a,b)

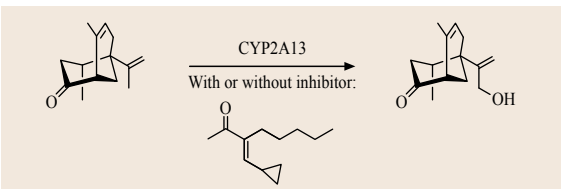

Fig. 28.7 The ketone substrate is olfactively described as woody and raspberry, while the hydroxylated metabolite has a pure raspberry note

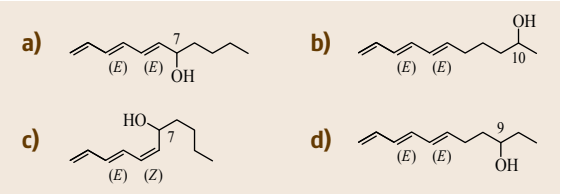

Fig. 28.8a–d Green smelling metabolites of undecatriene, which are produced by CYP2E1. Olfactory descriptions: **(a)** green, floral, metallic, **(b)** undecatriene-like, fatty, green, metallic, **(c)** green, pineapple, **(d)** fatty, oily, green, undecatriene-like, pineapple, fruity, metallic

starting from the signature hydrocarbon odorant 1,3,5-undecatriene which is found in galbanum oil. Series of molecules were synthesized over the years and an olfactophore model was developed that worked well for most molecules, but not for undecatriene that lacks a hydrogen-bonding function, which is present in other prototypic fruity, galbanum-type odorants, and it was speculated that enzymatic oxidation could take place prior to receptor interaction [28.85]. Several CYPs were tested with undecatriene as substrates, and in particular CYP2E1 which is expressed in the human olfactory mucosa produces multiple metabolites, that are described as having a fruity, green, and galbanum smell [28.67, 86] (Fig. 28.8). While the identified metabolites fit the galbanum olfactophore model much better, there is no experimental evidence to date that 1,3,5-undecatriene does not have those odor characteristics.

28.6 Discussion

At first glance, one may assume that deciphering the *olfactive code* is mastered when determining the molecular receptive range of the repertoire of roughly 380 different olfactory receptor proteins that convert the chemical information of odorants into neuronal signals and chemotopic maps in the olfactory bulb. However, recent results clearly demonstrate that the sense of smell is more complex than anticipated and is going to stay a fascinating area of research for many years to come. Latest studies demonstrate that the transformation and coding of neuronal activation patterns in the olfactory cortex is multifaceted and it has been proposed that different cortical areas are involved in learned versus innate behavioral responses providing another scientific approach to investigate emotional components of odor perception [28.20]. Olfactory receptor research has gained much interest in the last two decades, because of their discovery in 1991 and generally because of all the advancements in G-protein coupled receptor (GPCR) research, such as functional, heterologous expression and the growing number of crystal structures that are available for modeling and rationalizing agonist and antagonist interactions in the ligand binding domain of receptor proteins.

The fact that xenobiotic-metabolizing enzymes occur in high concentrations in the olfactory mucosa made scientists speculate on their role in olfaction since the middle of the last century. Recent animal studies demonstrated that inhibiting specific enzymatic activities in the olfactory mucosa changes the olfactory receptor response, the activation pattern in the olfactory bulb and even animal behavior [28.82]. Together with other data reported in this chapter, one can conclude that indeed, the in-nose biotransformation of odorants can modify the quantity (intensity) and the quality of odor stimuli. Since we are normally exposed to complex scents, such biochemistry has little impact on our perception of odors; however, when correlating olfactory receptor response patterns with the hedonics of an odorant this perireceptor event may well play a role and should not be neglected, and ideally one could include a metabolic interface that is mimicking the biotransformation events. When using receptor screening data to predict novel odorants for the fragrance industry, a solid understanding of the structure–activity and the structure–odor relationship is critical, and future activities in cheminformatics and computer modeling will help further valorize the growing number of datasets.

The destiny of xenobiotics that reach the olfactory epithelium can be manifold: receptor agonists and antagonists, enzyme substrates and inhibitors, OBP-ligands, precursors of bioactive compounds and allosteric modulators of receptors, enzymes, and other targets in the signal transduction cascade, such as the ion channels that are exposed to the mucus. The CYP2 family, and in particular the CYP2A subfamily of enzymes shows strong activity toward volatile organic molecules, and does not only oxidize odorants, but is also involved in the activation of nasal toxicants and carcinogens, and those enzymes have been proposed as pharmaceutical targets. There is evidence that olfactory biotransformation enzyme concentrations are regulated on the gene transcription level by chemicals acting as inducers of gene expression. This indicates a chance for plasticity and fast adaptation to the environment which impacts the metabolic capacity of this tissue. It is interesting to mention that the olfactory neuroepithelium is constantly regenerating and, in a way, it is remarkable that our sense of smell does not change much as a function of time.

As it invariably happens in scientific research, when answering one question, two more questions arise. Our current understanding on the code of smell advanced significantly over the last two decades and there is still much to learn and to be discovered. Hypotheses, including the ones expressed in this chapter, will be proven incomplete and there is still much incentive to further investigate chemoreception and in particular olfaction.

29. Metabolism of Odorants in Humans

Michael Rychlik

This chapter outlines the metabolism of important food odorants and its impact on their bioactivity. The first section describes general metabolic pathways including functionalization (phase 1), conjugation (phase 2) and export (phase 3). These pathways are intended to excrete the compounds, which can be regarded as xenobiotics. In the second section, the metabolism of important classes of odorants, that is, alcohols and aldehydes, esters, thiols, terpenes, and phenylpropanoids is presented in detail. Among the terpenes, the focus lies on the monocyclic monoterpene hydrocarbon carvone, the monocyclic monoterpene ketone pulegone, the bicyclic monoterpene oxide 1,8-cineole, the bicyclic monoterpene ketone thujone, and on the allylalkoxybenzenes estragole and methyleugenol and coumarin among the phenylpropanoids. Recent studies are presented and each pathway is depicted in a separate reaction scheme. The contribution of each path either to detoxification or to toxification is discussed. The last section finally deals with conclusions and an outlook for further research.

Physiology of odorants is generally regarded as interaction of the odorant molecules with odor receptors in the olfactory tissue. While interaction of these ligands with the receptors is being intensely investigated [29.1], metabolism of odorants with respect to odor activity has only scarcely been addressed. Just recently, *Thiebaud* et al. [29.2] reported on odorant metabolism in the olfactory tissue and hypothesized that the reactions observed serve to clear the receptors from its ligands to avoid permanent receptor stimulation. Further aspects in relation to such peri-receptor events are discussed in detail in the chapter of *Schilling* in this book (Chap. 28). Besides their interaction with olfactory tissue, odorants are ingested with foods along with common nutrients and are subject to common metabolic reactions. Subsequently, as potential further physiological functions in the organism are still not clearly understood, odorants can be regarded as xenobiotics and follow the general principle of xenobiotic metabolism, which intends to enable or facilitate excretion and will be explained in the next chapter. There are only few exceptions from this rule, for example, short-chained fatty acids as abundant odorants in cheese, which contain nutritive value and are transferred into lipid metabolism.

As mentioned above, the physiology of odorants apart from olfaction is still unclear, but recent reports on odorant receptor expression in many tissues point to their function in skeletal muscle regeneration, cell–cell adhesion, and sperm migration [29.3]. Apart from their bioactivity in odor sensation, odor-active compounds exhibit pharmacological properties as components of essential oils. The latter show antimicrobial or antiviral or antioxidative activities and are essential elements of phytotherapy. More specifically, in aroma therapy essential oils are applied as remedies for many different disorders [29.4]. This knowledge has not only evolved in the last decade but has been in use for centuries in different cultures thus being an important component of ethnomedicine.

Pharmacological activity of odorants has been studied almost exclusively for the unmodified molecules. However, metabolism aims at excreting these compounds by transforming them into structurally different molecules, the activity of which is mostly unclear yet.

29.1 General Principles of Metabolism and Absorption

Similarly to other xenobiotics, odorants may enter the organism by different ways with absorption from the gastrointestinal tract being the most prevalent one. As odorants are at least partly lipophilic and have a rather low molecular weight, they are absorbed from foods and subsequently distributed in the organism mainly by passive diffusion. Almost exclusively, odorants will be identified as xenobiotics and the organism intends to excrete them as fast as possible. To accomplish straightforward excretion and also to prevent accumulation of these lipophilic compounds in tissues, metabolic processes are directed toward increasing hydrophilicity to facilitate biliary and renal excretion. During this process, three different phases can be differentiated, that is, functionalization as phase 1, conjugation as phase 2, and export as phase 3.

29.1.1 Phase 1: Functionalization

The first step toward increasing hydrophilicity is introducing a polar functional group or clearing an inherent one. The former alternative is achieved either by introducing oxygen into the xenobiotic or by oxidation or by reduction. Examples for odorants being subject to introduction of hydrophilic functional groups are the hydroxylation of estragole to hydroxyestragole [29.5] or the reduction of *Strecker* aldehydes such as methional to methionol [29.6]. Hydroxylations are mainly catalyzed by cytochrome P450 monooxygenases (CYPs), which are present in a huge variety of isoforms with different specificities and catalytic efficiency. These enzymes are expressed in all tissues, but the overwhelming part of turnover takes place in the liver.

An example for clearing a functionality of odorants is the hydrolysis of esters, which is catalyzed by carboxylesterases. These enzymes are present in all types of cells and recently their activity has been detected in olfactory cells, when isoamyl acetate was found to be hydrolyzed into acetic acid and isoamyl alcohol [29.2].

Regarding influx and metabolism of odorants, functionalization already starts in saliva, where esters have been found to be hydrolyzed, thiols to be degraded, and aldehydes reacted to the respective alcohols [29.6, 7].

In some cases, functionalization decreases the odor activity of odorants. When regarding common metabolic ways of odorants, hydroxylated terpenes show significantly higher odor thresholds than their nonhydroxylated precursors, and the same is valid when comparing alcohols as the metabolic products of the respective aldehydes [29.8]. However, depending on the individual enzyme expression and the odorant, changes in odor quality were reported and metabolites may show similar or even lower odor thresholds. This aspect will be detailed in this book's chapter *Nasal Periceptor Precesses* (Chap. 28).

Functionalization leads to increased hydrophilicity, which already may be sufficient for substantial excretion. However, this is not always the case. Therefore, conjugation reactions with highly hydrophilic molecules follow phase 1 to further increase hydrophilicity and to facilitate excretion.

29.1.2 Phase 2: Conjugation

Following functionalization, many metabolites are still not sufficiently hydrophilic for excretion or show increased toxicity due to instability. Examples are epoxides, for example, coumarin epoxide (see below) with subsequent nucleophilic addition to deoxyribonucleic acid (DNA) bases, which may induce genotoxicity. Therefore, functionalization is followed by coupling of the functional group with hydrophilic molecules such as glucuronic acid, glutathione, glycine, or sulfate. These reactions are mainly catalyzed by transferases using conjugating agents such as uridine diphosphate (UDP)-α-glucuronic acid. An example is the odorant furaneole, an odor impact compound of strawberries and pineapple, which is transferred into its glucuronide that is detectable in urine [29.9]. Conjugation with glutathione is followed by further metabolism to N-acetylcystein conjugates, the so-called mercapturic acids.

Conjugates may be directly excreted by passing the kidney into the urine. The other alternative is the active transport in the liver into bile by transport proteins, which is called phase 3.

29.1.3 Phase 3: Export

Conjugates are often highly hydrophilic and are not able to pass cell membranes to be efficiently excreted. Therefore, transport mechanisms for these conjugates exist, which require energy in the form of adenosine triphosphate (ATP) as molecular pumps. During phase

3, no further metabolism takes place. These proteins are classified as ATP-binding cassette (ABC)-transporters and are highly expressed in liver and kidneys. Apart from transporters for xenobiotics, also multidrug resistence (MDR) transporters belong to this class of proteins [29.10].

29.2 Metabolism of Important Classes of Odorants

29.2.1 Alcohols and Aldehydes

Odor-active alcohols and aldehydes in foods often originate from the *Strecker* reaction of amino acids. The respective aldehydes, the so-called *Strecker* aldehydes, show lower odor thresholds than the respective alcohols with the potato-like smelling methional showing the most intense odor. Further *Strecker* aldehydes along with their precursors and odor thresholds are presented in Table 29.1. Due to their partly lipophilic character, alcohols and aldehydes can be expected to be absorbed by passive diffusion after ingestion. Thereafter, both classes of compounds are oxidized to the corresponding carboxylic acids by highly expressed nicotinamide adenine dinucleotide (NAD^+)/NADH-dependent enzymes [29.11]. Of these, alcohol dehydrogenases (ADH) are cytosolic enzymes catalyzing the oxidation of alcohols to their corresponding aldehydes. Thereafter, the latter are oxidized by aldehyde dehydrogenases (ALDH) to the acids. Linear as well as branched-chain aliphatic alcohols and aldehydes are good substrates for ADH and ALDH. The generated branched-chain and linear carboxylic acids then undergo general metabolism of fatty acids.

29.2.2 Esters

Esters are character-impact odorants particularly in fruits such as apples [29.12], and, due to their lipophilicity, are easily absorbed from foods by passive diffusion. The most effective way to transform esters into hydrophilic compounds is hydrolysis of the ester bond, which is catalyzed by carboxylesterases.

The generated alcohols and acids undergo further metabolism. Alcohols are oxidized to acids as detailed above and transferred into fatty acid metabolism.

Hydrolysis of esters already starts in saliva, where odor-active ethyl esters of butanoic acid, hexanoic acid and octanoic acid were degraded to an extent of max. 49% within 10 min [29.7]. Considering a structure activity relationship, ethyl octanoate was more efficiently degraded than ethyl hexanoate and ethyl butanoate.

29.2.3 Thiols

Thiol metabolism (Fig. 29.1) includes various reactions such as S-oxidation, oxidative desulfuration and dealkylation, methylation, and disulfide formation with glutathione (GSH). Chemical reactivity of thiols is

Table 29.1 Structures, odor qualities, odor thresholds and precursors of important *Strecker* aldehydes

Aldehyde	Structure	Odor quality	Odor threshold in water[a] (µg/L)	Precursor
Acetaldehyde		Pungent	6–25	L-Alanine
2-Methylpropanal		Malt-like	1–10	L-Valine
2-Methylbutanal		Malt-like	1–3.7	L-Isoleucine
3-Methylbutanal		Malt-like	0.4–3.1	L-Leucine
Methional		Boiled potato-like	0.2–1.8	L-Methionine
Phenylacetaldehyde		Honey-like	4	L-Phenylalanine

[a] Orthonasal thresholds [29.8]

mainly based on their easy dissociation under physiological pH to form a thiolate anion, which is highly nucleophilic. On this basis and given their reactivity with weak oxidants, thiols easily form mixed and non-mixed disulfides by reacting with endogenous thiols such as GSH or cysteine or with proteins bearing thiol groups.

In the course of S-oxidation, thiols are transferred enzymatically into reactive sulfenic (R–S–OH) acids, the further oxidation of which can lead to sulfinic (R–SO_2H) acids. Alternatively, sulfenic acids can react with excess thiols (e.g., GSH) to give the corresponding disulfides. The latter can either be reduced back to the thiols (enzymatically by thiol-transferase or chemically by exchange with GSH or endogenous thiols), or can be oxidized to thiosulfinic acid, hydrolysis of which gives rise to sulfinic acids and further oxidation to sulfonic (R–SO_3H) acids. Thiol-S-methylation as a special form of conjugation for simple aliphatic and aromatic thiols is catalyzed by thiol-S-methyl-transferases and subsequent S-oxygenation may lead to water-soluble methylsulfoxides and/or sulfones [29.13]. Parts of these pathways have been reported for methylmercaptan in microsomes [29.14] and rats [29.15] and for diethyl disulfide in rodents [29.16]. The other reactions can be deduced from pharmacokinetic studies of thiol-containing drugs.

29.2.4 Terpenes

Terpenes encompass a wealth of compounds essential in animal and plant metabolism. Their structures vary from monoterpenes containing 10 carbon atoms to tetraterpenes bearing 40 carbons. While the latter are active as natural colorants, antioxidants, and precursors

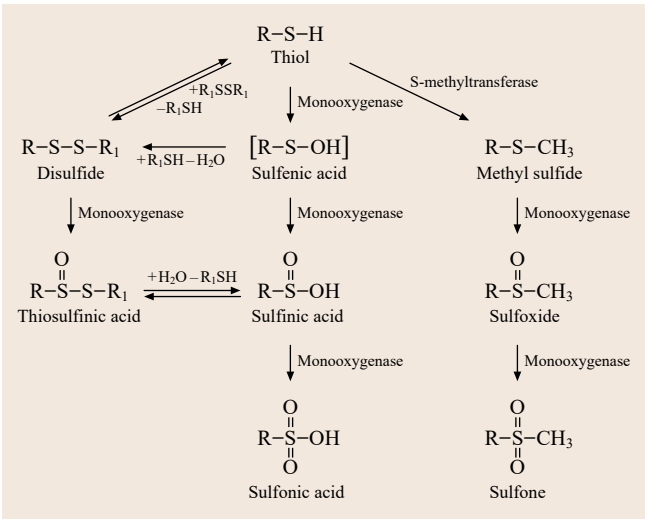

Fig. 29.1 Metabolism of thiols in humans

of vitamins, mainly monoterpenes and sesquiterpenes are regarded as odorants due to their sufficient volatility. Terpenes may bear several functional groups at their hydrocarbon backbone, the monoterpene alcohols, ketones, phenols, esters, and oxides. Moreover, monoterpenes can be acyclic or consist of one ring (monocyclic monoterpenes), two rings (bicyclic monoterpenes), or three rings (tricyclic monoterpenes). In plants, terpenes play a major role as attractants or repellents for insects, protectants from fire, hormones, antimicrobials and, therefore, are also attractive for human use in spices, aromatherapy, and as antioxidants. Generally, terpenes as lipophilic compounds are assumed to be absorbed abundantly in the gastrointestinal tract. Metabolism is often initiated by oxidation to more polar metabolites by CYP-450 enzymes.

These phase 1 reactions involve hydroxylation or epoxidation of the exocyclic or endocyclic double bond. Hydroxylated metabolites may be excreted in conjugated form or undergo further oxidation, giving rise to more polar metabolites that are also excreted, mainly in urine. Epoxides may be further metabolized either by hydrolysis to yield diols or by conjugation with glutathione to be finally excreted as mercapturic acids. Aromatic hydrocarbons may undergo epoxidation and dihydroxylation of the ring to form phenolic metabolites, which subsequently may be conjugated with sulfate or glucuronic acid and excreted in the urine. Saturated alkanes may be metabolized via omega oxidation to give the respective carboxylic acids or via so-called omega-1, -2, -3, or -4 oxidations giving rise to secondary alcohols and ketones. The generated carboxylic acids are, as mentioned above, expected to participate in the endogenous fatty acid metabolism.

Most of metabolic data for terpenes have been obtained from rats, rabbits, possums, various antipodean species or cell models by administration of terpene-rich diets or high doses of single terpenes. However, it has to be criticized that the data from these studies may not be applied to humans due to possible interspecies differences in metabolism. Moreover, these data may be restricted to pharmacological applications as the doses applied to animals or cellular models were much higher (up to 1000 mg/kg of body weight) compared to doses occurring in a normal diet. However, dose matters as for terpenes various positions of hydroxylations or epoxidations are possible and in higher dosages the capacities of single enzymes may be exceeded. This can favor pathways, which are different to those occurring in low dosage trials. Evidence for these relationships has been found for carvone [29.17] and estragole [29.5] among others. In order to refer as close as possible to the situation present in daily diet, the metabolism of ingestion correlated amounts (MICA) approach has been devel-

oped [29.17]. Quantitation often has been accomplished by using stable isotopologs as internal standards, which offers many advantages to compensate for matrix interferences and low recoveries [29.18]. As essentially no conjugates of terpenes are commercially available, the sum of conjugated and nonconjugated metabolites was determined after deconjugation using glucuronidases and/or sulfatases [29.5].

A Monocyclic Monoterpene Hydrocarbon: Carvone

Carvone is a monoterpene hydrocarbon occurring in many essential oils with the (*S*)-(+) enantiomer being the main constituent of caraway oil and dill seed oil. The (*S*)-(+) enantiomer, however, is the major impact compound of spearmint oil and due to its refreshing odor it is widely used as a flavor compound, for example, for toothpaste and other cosmetics.

In an MICA experiment (Fig. 29.2), the major in vivo metabolites of *S*-(+)- and *R*-(−)-carvone were newly identified as dihydrocarvonic acid, carvonic acid, and uroterpenolone [29.17]. In two different approaches, the author administered (1) pure carvone enantiomers [29.17] and (2) $^{2}[H]_{2}$-carvone and $^{13}[C]_{1}$-carvone [29.19] and analyzed the metabolites via gas chromatography-mass spectrometry (GC-MS) to clarify the metabolic pathways. Carvonic acid was generated by oxidation at the methyl carbon of the side chain of carvone, whereas dihydrocarvonic acid arose from oxidation at the methylene position, supposedly by an intermediate carvone epoxide. Labeling experiments indicated a *nonaromatic* National Institute of Health (NIH) shift in the pathway yielding dihydrocarvonic acid. Moreover, the former study proved dehydrogenation of dihydrocarvonic acid and hydrogenation of carvonic acid as minor metabolic ways. Oxidation at the methylene carbon of the isopropenyl group of carvone gave uroterpenolone probably formed by hydrolysis of the supposed carvone epoxide. No differences were found between the metabolism of the enantiomeric *S*-(+)- and *R*-(−)-carvone.

A Monocyclic Monoterpene Ketone: Pulegone

(*R*)-(+)-Pulegone is a major compound of the essential oils of peppermint and pennyroyal besides its occurrence in many other herbs such as oregano and tea. Its characteristic minty odor is the background of the frequent use of (*R*)-(+)-pulegone as component in mint-flavored beverages, sweets, and chewing gums. However, due to its hepatotoxicity in higher dosages, the European Union has set the following maximum levels for pulegone in foodstuffs: 25 mg/kg in foodstuffs in general; 100 mg/kg in beverages; 250 mg/kg in peppermint- or mint-flavored beverages; and up to 350 mg/kg in mint confectionery [29.20]. Toxicokinetic studies dating back to 1987 identified menthofuran as a metabolite of pulegone at high exposure to pennyroyal oil [29.21], and it is assumed that hepatotoxicity of pulegone is due, at least in part, to this metabolite [29.22].

While many studies on pulegone metabolism were performed using rats, only one human study has been reported [29.23], the results of which will be presented in the following.

In MICA experiments, both enantiomers of pulegone were applied to humans. The major in vivo metabolites (Fig. 29.3) of (*S*)-(−)-pulegone in humans were identified as *E*-2-(2-hydroxy-1-methylethylidene)-5-methylcyclohexanone (10-hydroxypulegone, P1), 2-(2-hydroxy-1-methylethyl)-5-methylcyclohexanone (8-hydroxymenthone, P2), 3-hydroxy-3-methyl-6-(1-methylethyl)cyclohexanone (1-hydroxymenthone, P3), and 3-methyl-6-(1-methylethyl)cyclohexanol (menthol, P4) on the basis of GC-MS analysis in combination with syntheses and nuclear magnetic resonance (NMR) experiments. In contrast to the studies performed before, menthofuran was not found to be a major metabolite of pulegone. On the contrary, the author assumed this compound to be an artifact formed during workup from at least one metabolite (P1). The author deduced the differences in toxicity between (*S*)-(−)- and (*R*)-(+)-pulegone from the strongly diminished ability for enzymatic reduction of the double bond in (*R*)-(+)-pulegone. In consequence, further potential oxidation of 10-hydroxypulegone (P1) to the reactive 10-pulegonealdehyde was hypothesized to ac-

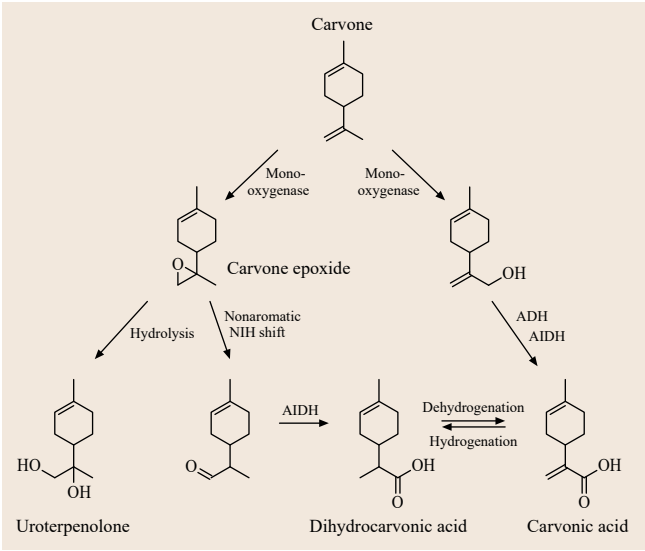

Fig. 29.2 Proposed metabolic pathways of carvone in humans (after [29.17, 19])

count for the observed hepatotoxic and pneumotoxic activity of (*R*)-(+)-pulegone in humans.

A Bicyclic Monoterpene Oxide: Cineole

A major component of essential oils from *Eucalyptus polybractea* is the monoterpene 1,8-cineole (Col), also known as eucalyptol. Besides this, 1,8-cineole is present in numerous spices, such as rosemary, sage, basil, and laurel. It has a characteristic fresh and camphoraceous odor quality and, therefore, is used for flavoring of different foods and cosmetics. Apart from its flavoring applications, 1,8-cineole is used in pharmaceutical preparations to treat cough, muscular pain, neurosis, rheumatism, asthma, and urinary stone [29.4, 24, 25]. Originally, biotransformation studies of 1,8-cineole have been performed in brushtail possum and rabbits and identified 2α-hydroxy-Col, 2β-hydroxy-Col, 3α-hydroxy-Col, 3β-hydroxy-Col, 7-hydroxy-Col, 9-hydroxy-Col (Fig. 29.4) and the respective diols, cineolic acids, and hydroxyl cineolic acids as phase I metabolites in urine and blood plasma [29.26–28]. Regarding toxicity of 1,8-cineole, the oral acute LD_{50} in rats is reported to be 2480 mg/kg bw [29.29]. Subacute toxicity was shown in rats for dose levels of 600 mg/kg bw and higher. There is no evidence for chronic or genotoxic effects of 1,8-cineole [29.30]. For the hydroxylated metabolites, no toxicological data is available.

In an approach modeling the realistic dosage from a normal diet, the metabolism of 1,8-cineol after ingestion of sage tea (dose 1.02 mg 1,8-cineole; 19 µg/kg bw) was studied [29.31]. After application of the tea,

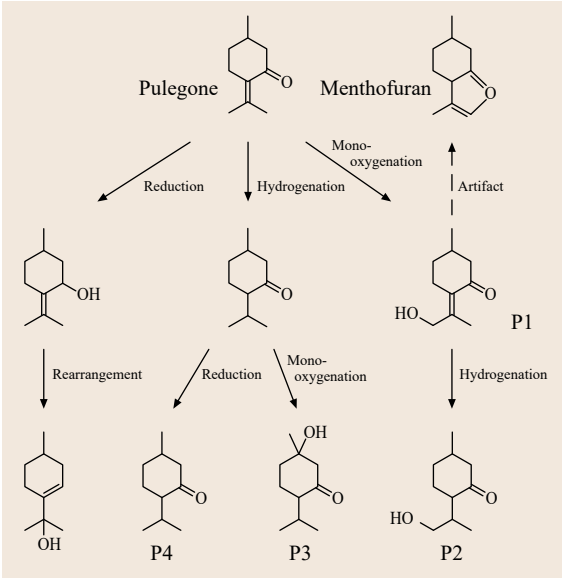

Fig. 29.3 Hypothetical metabolic pathway of pulegone (after [29.23])

the metabolites 2-hydroxy-Col, 3-hydroxy-1,8-Col, 9-hydroxy-Col, and 7-hydroxy-1,8-Col were identified in plasma and urine of one volunteer (Fig. 29.4, full arrows). For quantitation of these metabolites and the parent compound, stable isotope dilution assays were developed after synthesis of [$^2H_3$]-Col, [9/10-$^2H_3$]-2-hydroxy-Col, and [^{13}C,$^2H_2$]-9-hydroxy-Col as internal standards. Quantitation of 1,8-cineole was accomplished by solid phase microextraction (SPME) GC-MS and of the hydroxyl-1,8-cineoles by liquid chromatography-tandem mass spectrometry (LC-MS/MS) after deconjugation in blood and urine of the volunteer.

In urine, 2-hydroxy-Col showed highest contents followed by its 9-isomer. Summing up the urinary excretion over 10 h, 2-hydroxy-Col, the 9-isomer, the 3-isomer, and the 7-isomer accounted for 20.9%, 17.2%, 10.6% and 3.8% of the cineole dose, respectively. These results were not only obtained after deconjugation treatment of urine but also by direct analysis of the hydroxycineole glucuronates after synthesis of the reference compounds according to Königs–Knorr and analysis via LC-MS/MS (Fig. 29.5). Interestingly, the double peak of 9-hydroxy-Col glucuronate indicated separation of anomers. This is one of the rare examples of a direct detection of terpene conjugates.

In a recent pharmacological investigation [29.32], the metabolite profiles of 1,8-cineole in human milk were detected after lactating mothers ingested a non-prescription pharmaceutical (Soledum) containing this substance. Apart from the metabolites found before in urine (α-2-hydroxy-Col, β-2-hydroxy-Col, α-3-hydroxy-Col, 7-hydroxy-1,8-Col, 9-hydroxy-Col), three of the metabolites hitherto only found in microorganisms and insects (2-oxo-Col, 3-oxo-Col, 2,3-dehydro-Col) and the two additional derivatives 2,3-α-epoxy-Col and 4-hydroxy-Col never have been identified before as metabolites of 1,8-cineole (Fig. 29.4, open arrows). A very recent investigation was dedicated to elucidate the enantiomeric ratio of the metabolites in urine [29.33]. Interestingly, all metabolites showed an excess of one enantiomer with 3-oxo-Col revealing almost exclusive formation (99.5% enantiomeric ratio) of the (+)-enantiomer.

A Bicyclic Monoterpene Ketone: Thujone

α-Thujone is a bicyclic monoterpene, which is a common constituent in herbal medicines, essential oils, foods, flavorings, and beverages [29.4] along with its epimer at the C-4 methyl group, β-thujone. The isomer ratio is variable, with high contents of α-thujone in the essential oils of cedarleaf oil and β-thujone in that of wormwood oil [29.4]. α-Thujone is known as the active component of the emerald-green liqueur absinthe,

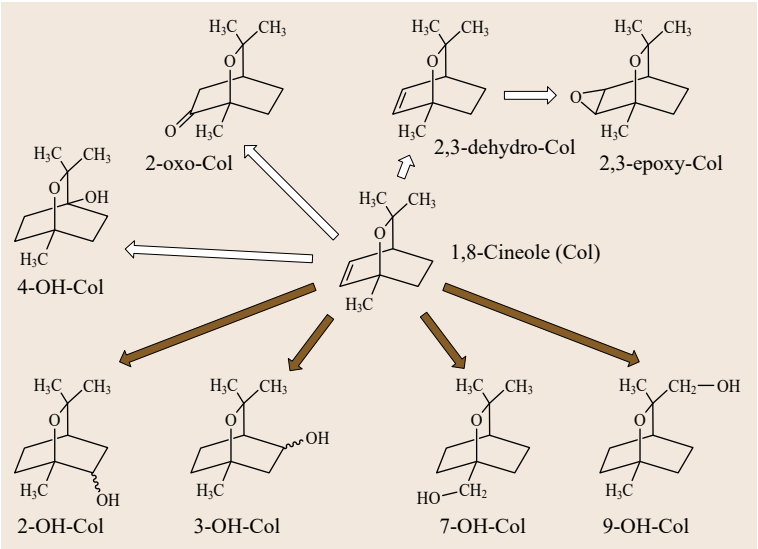

Fig. 29.4 Metabolism of 1,8-cineol after administration of a sage infusion (*full arrows*); administration of a pharmaceutical, the metabolites indicated by open arrows additionally were detected in human milk

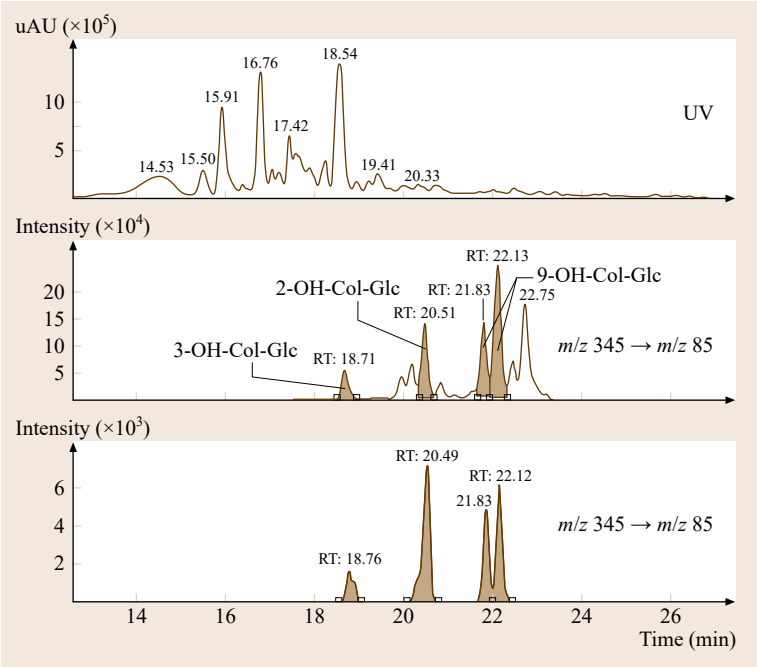

Fig. 29.5 LC-UV (*upper trace*) and LC-MS/MS (*middle trace*) chromatograms of hydroxycineole glucuronates (Glc) in human urine after ingestion of sage infusion. The *lower trace* shows an LC-MS/MS chromatogram of a mixture of the reference compounds

which was very popular in the 19th and early 20th centuries as a preferred drink of artists and writers including Vincent van Gogh, Henri de Toulouse-Lautrec, and Charles Baudelaire [29.34]. Abuse of absinthe often induced fits and hallucinations and sometimes contributed to psychoses and suicides, thus leading to a ban in many countries early in the 20th century. The actual regulation in the European Union prohibits to add thujone as odorant to foodstuffs or flavorings and it is only allowed in foods originating from flavorings or components from natural raw materials. In general, the sum of alpha- and beta-thujone may not exceed 0.5 mg/kg in foodstuffs and beverages with following exceptions: Maximum thujone levels of 5 mg/kg in alcoholic beverages with not more than 25% volume of alcohol, of 10 mg/kg in beverages with more than 25% volume of alcohol, of 25 mg/kg in foodstuffs containing preparations of sage and of 35 mg/kg in alcohol labeled as bitters (40% volume of alcohol and more) are allowed [29.20].

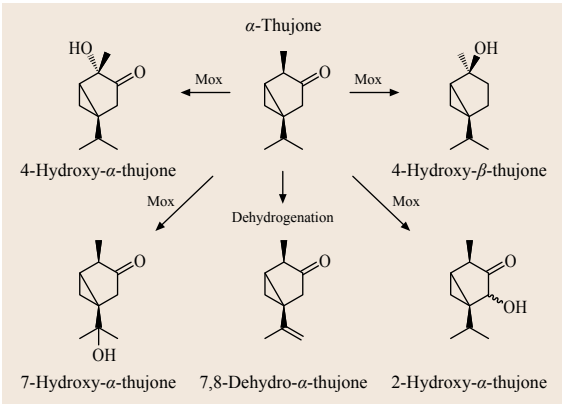

Fig. 29.6 Metabolism of α-thujone in mammals, Mox: monooxygenation

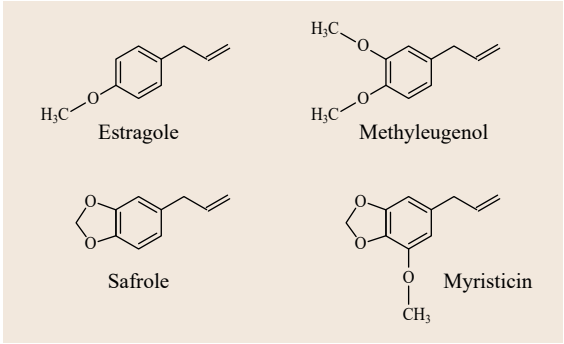

Fig. 29.7 Structures of important allylalkoxybenzenes occurring in foods

The toxicity of absinthe was attributed to wormwood oil as ingredient, which itself is a herbal medicine for treating dyspeptic disorders, liver and gallbladder complaints and to control gastrointestinal worms with records back to the ancient world [29.35]. The principal bioactive ingredient of wormwood oil and neurotoxic principle in absinthe is generally considered to be α-thujone. The acute toxicity of α-thujone has been attributed to blocking the γ-aminobutyric acid (GABA)-gated chloride channel [29.36]. However, some recent studies indicate that the toxic symptoms after consumption of absinthe were mainly due to its alcohol content. Studies of the fate of α-thujone and β-thujone in vitro and in rodents led to the identification of the hydroxythujones and dehydrothujones shown in Fig. 29.6 [29.36, 37] with different abundancies depending on the species under study. In mice urine after administration of α-thujone, mainly 2-hydroxythujone could be detected along with minor amounts of 4-hydroxythujone, 7-hydroxythujone, and 4,10-dihydrothujone. In contrast to this, the respective experiment in rats resulted in 4-hydroxythujone and 4,10-dehydrothujone as the two major metabolites along with 7-hydroxythujone at minor amounts. 2-Hydroxythujone was not detectable. In vitro studies using human microsomes indicated 7-hydroxythujone along with 4-hydroxythujone and 7,8-dehydrothujone as possible human metabolites of α-thujone. Recent syntheses of 2[H]6-isotopologues of α-thujone and of its hydroxylated major metabolites [29.38] will enable quantitation of α-thujone in future MICA studies on herbs containing thujone.

29.2.5 Phenylpropanoids

Phenylpropanoids consist of a structure that is derived from a propyl side chain attached to a benzene backbone showing several variations in its oxidation state, attachment to other phenolic systems and attachments of hydroxyl- and methoxy groups to the aromatic moiety. These compounds are important odorants of several plants and originate from metabolism of amino acids such as phenylalanine or tyrosine. Here, two examples for classes of phenylpropanoids are presented: (1) the allylalkoxybenzenes estragole and methyleugenol (Fig. 29.7) and (2) coumarin.

Allylalkoxybenzenes: Estragole and Methyleugenol

Estragole is a component of several herbs such as tarragon, basil, fennel, and anise [29.39–41]. Of these, the fruits of fennel and anise are commonly used to treat catarrh of the respiratory tract and gastrointestinal disorders. Therefore, fennel extractions are the classical infusion for nursing babies to prevent flatulence and spasms.

However, estragole as a ring-substituted allylbenzene along with the structurally similar safrole and methyleugenole have been reported as potent carcinogens in rodents [29.42]. The reason for their hepatotoxic properties is the specific 1′-hydroxylation of the side chain of allylbenzenes. In consequence, conjugation of 1′-hydroxyestragole with sulfuric acid is assumed to result in a carcinogenic potential as the sulfate might decompose readily to an electrophilic cation reacting easily with the DNA [29.43]. Reports on 1′-hydroxyestragole showing a higher carcinogenic activity than its precursor [29.42] are in line with this hypothesis. However, due to its lability, the identity of the sulfate has not yet been unequivocally proved.

The formation of 1′-hydroxyestragolesulfate has been suggested due to scavenging reactions indicating its formation [29.44] and due to the decrease in incidence of hepatocellular carcinoma by application of the sulfotransferase inhibitor pentachlorphenol to rats [29.45]. Further evidence for adverse effects comes

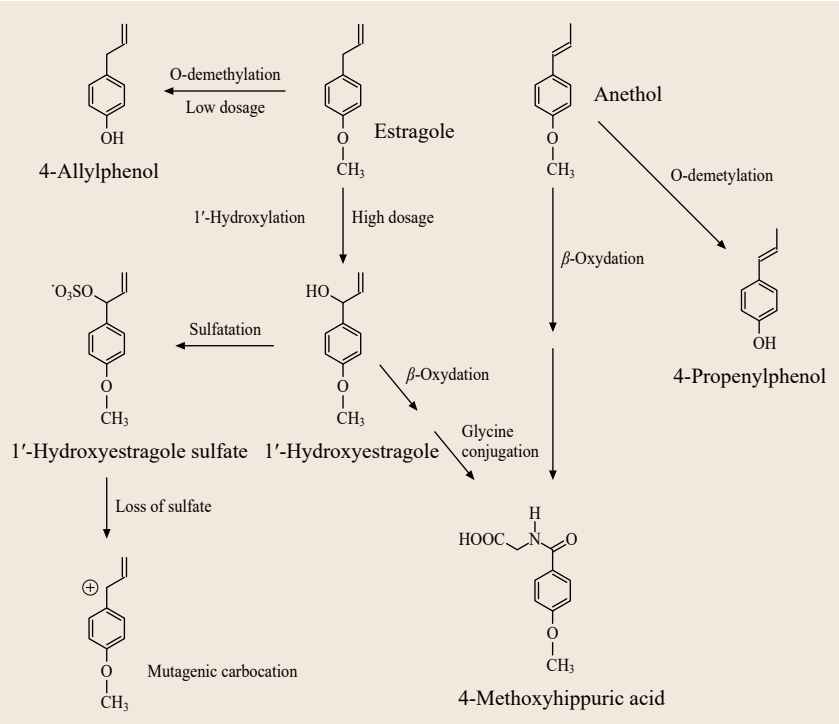

Fig. 29.8 Metabolism of the fennel odorants estragole and anethole showing the proposed generation of a mutagenic agent resulting from decomposition of 1′-hydroxyestragole sulfate

from the detection of adducts of 1′-hydroxyestragole with DNA [29.46] and DNA modifications following the carbocation formation mediated by sulfotransferase 1A1 [29.47]. Apart from the open unequivocal identification of the 1′-hydroxyestragolesulfate, the interaction of estragole metabolism with that of other highly abundant terpenes such as *trans*-anethole in doses usually administered with herbal infusions was not clarified. Therefore, in a human study, the metabolism of estragole was investigated after consumption of fennel tea (Fig. 29.8) by analyses of its metabolites in blood plasma and urine [29.5]. Stable isotope dilution assays based on LC-MS/MS detection revealed that 1′-hydroxylation of estragole happened very fast as the concentration of conjugated 1′-hydroxyestragole in urine peaked after 1.5 h, whereas it was no longer detectable after 10 h. Besides the formation of less than 0.41% conjugated 1′-hydroxyestragole of the estragole dose administered, the further metabolite *p*-allylphenol was generated from estragole in a higher percentage (17%). Both metabolites were also detected in blood plasma in less than 0.75 to 2.5 h after consumption of fennel tea. From these results, it can be concluded that an excess of the major fennel odorant *trans*-anethole principally does not interfere with estragole metabolism. Moreover, in these low dosages no evidence for the 1′-hydroxyestragolesulfate were found as the applied deconjugation for urine analyses showed no differences in the treatments with pure glucuronidase alone and that with a mixture of glucuronidase and sulfatase.

Methyleugenol is an allylalkoxybenzene occurring naturally in a variety of spices, herbs, and essential oils, such as clove oil, nutmeg, pimento, basil, anise and mace. Moreover, it is also present in blackberries, bananas, black pepper, bilberries, and walnuts [29.4].

Similarly to estragole, genotoxicity of methyleugenol is attributed to 1′-hydroxylation, sulfatation and the labile sulfate being the putative genotoxic carcinogen. In analogy to estragole, the respective sulfate of hydroxymethyleugenol has not been detected directly, but the number of evidence is also increasing to support this hypothesis. Most recently, also for methyleugenole DNA adducts and the influence of sulfotransferases on their formation have been found [29.48]. A risk assessment of genotoxic compounds such as methyleugenole is difficult as for these no zero threshold in a dose–effect relationship can be deduced. In these cases, the joint Food and Agriculture Organization of the United Nations/World Health Organization (FAO/WHO) expert committee on food additives (JECFA) and the European Food Safety Authority (EFSA) agreed upon the *margin of exposure* (MoE) approach [29.49]. In this approach, the MoE is defined as the ratio of a benchmark dose as estimation for the no-observed-adverse-effect-level (NOAEL)

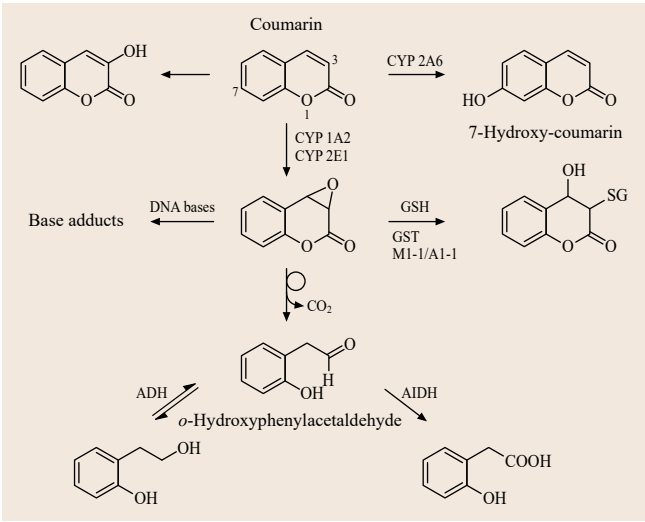

Fig. 29.9 Proposed metabolism of coumarin to hepatotoxic *o*-phenylacetaldehyde

and the estimated exposure. A relevant exposition of the consumer in Europe was found to originate from spices, particularly basil and foods flavored with spices and essential oils. From the modeling of the benchmark dose lower confidence limit at 10% (BMDL10) and the exposure data the calculated MoEs ranged from 100 to 800 depending on the assumptions used in the exposure estimation [29.50]. As a considerable risk for the consumer is assumed for MoEs below 10 000, the EFSA considers methyleugenol as one of the food components showing a distinct carcinogenic risk potential for the consumer along with acrylamide, aflatoxin B1 and furan [29.49].

Coumarin

The phenylpropanoid coumarin is a constituent of several spices, the respective essential oils, and other flavoring foods such as *Cinnamomum aromaticum* (cassia bark), *Asperula odorata* (sweet woodruff), *Dipterix odorata* (tonka bean), and species of clover [29.51]. Besides occurring naturally in these foods, coumarin has been widely used as a flavoring compound due to its sweet and aromatic odor. However, since the early 1950s, the odorant has been found to exert hepatotoxicity and was suspected to be mutagenic and carcinogenic [29.52]. Toxicity of coumarin cannot be attributed to the parent compound but to metabolites and for the metabolic pathway significant inter-individual variations have been found (Fig. 29.9). Although coumarin in humans is mainly metabolized to 7-hydroxycoumarin [29.53], a subpopulation lacks these detoxification enzymes, which have been characterized as CYP 2A6. This subpopulation has been estimated to account for 10% of Germans. This susceptible subpopulation metabolizes the odorant to its 3,4-epoxy derivative, which was suspected to form DNA adducts and may react to hepatotoxic *o*-hydroxyphenylacetaldehyde [29.54]. While the former reaction was found not to be the cause for carcinogenic effects in rodents, the latter product was confirmed to evoke hepatotoxicity by coumarin [29.55].

For these reasons, a maximum level of 2 mg/kg for foods generally and 10 mg/kg in alcoholic beverages has been set in the European Union [29.20]. Moreover, coumarin is not allowed to be used as flavoring additive to foods.

The issue of coumarin's hepatotoxicity arises particularly in winter as cassia bark increasingly substituted true cinnamon in baked goods, particularly in seasonal products such as gingerbread or cinnamon star cookies. Moreover, indications to use cassia bark powder as a supplement and remedy against type 2 diabetes mellitus [29.56] increased consumption of this spice in the Western countries. As a tolerable daily intake of 0.1 mg/kg body weight has been established by the Scientific Panel on Food Additives, Flavorings, Processing Aids, and Materials in Contact with Food (AFC) [29.57], a longer lasting consumption of products high in cassia can be expected to provoke hepatotoxic effects. Therefore, supplements containing cassia have been classified as drugs.

Traditional and seasonal bakery such as gingerbread or cinnamon stars are now restricted to 50 mg coumarin/kg, breakfast cereals to 20 mg/kg, other fine bakery to 15 mg/kg and desserts such as sweet rice flavored with cinnamon to 5 mg/kg [29.58]. Since 2012, the German Federal Institute for Risk Assessment (Bundesinstitut für Risikobewertung, BfR) recommends for children not to exceed a daily consumption of 6 small cinnamon stars and advices adults to carefully use cassia as spice [29.59].

29.3 Conclusions and Outlook for Further Research

According to the current knowledge, metabolism of odorants serves, on the one hand, to reduce or modify the odorant's affinity to the odor receptor and to clear the latter from the ligand to avoid receptor blockage. On the other hand, metabolism intends to help excreting the odorants, which almost exclusively are not

endogenously formed. The consequences of these reactions are only poorly understood. For some examples, lower bioactivity of the metabolites compared to that of the odorant has been shown, but in some cases the metabolites reveal increasing toxicity (allylalkoxybenzenes, coumarin). Moreover, the molecular mechanisms of these activities are often still unclear and, therefore, the effect of metabolism is still under discussion.

30. Olfactory Subsystems

Marc Spehr

A plethora of structurally diverse environmental chemosignals convey critical information for survival, health, and reproduction. To meet the bewildering structural complexity of the chemical *odor space*, distinct cellular mechanisms and, ultimately, sensory subsystems have evolved to detect and discriminate these varied chemostimuli. Mammalian olfactory subsystems can be categorized by the stimuli they detect, the signaling proteins they express, and the central circuits that process these information. This chapter is centered on noncanonical olfactory subsystems and their peripheral sensory structures – the vomeronasal organ, the septal organ of Masera, and the Grüneberg ganglion.

Animals, including humans, detect and respond to a plethora of structurally diverse environmental chemical cues. These chemosignals convey critical information for survival, health, and reproduction:

- Food type and quality
- The existence (and concentration) of toxins
- The presence of prey, predators, competitors, or potential mates
- Social cues that elicit stereotyped, genetically preprogrammed behaviors or hormonal responses.

To meet the bewildering structural complexity of the chemical *odor space*, distinct molecular and cellular mechanisms have evolved to detect and discriminate these varied stimuli [30.1, 2].

In recent years, it has become increasingly clear that the mammalian olfactory system is organized into multiple subsystems that can be categorized by the chemostimuli to which they respond, the receptors and downstream signaling proteins they express, and the brain circuits that process these information [30.3–6]. The diversity of olfactory subsystems manifests both in the occurrence of anatomically distinct chemosensory structures within the mammalian nose and in the coexistence of unique neuronal subpopulations within individual tissue(s).

In the following, this chapter will focus on the noncanonical chemosensory subsystems that, in part, have only recently (re)gained scientific attention. The majority of experimental research on olfactory subsystems has been carried out in mice. As their genetic amenability allows integrated investigations that span the molecular, cellular, and systems level [30.7], the findings presented below are largely restricted to this model organism.

30.1 The Subsystem Organization of the Sense of Smell

At least four different chemosensory structures are found in the rodent nose (Fig. 30.1):

1. The main olfactory epithelium (MOE)
2. The septal organ (SO) of Masera

3. The vomeronasal organ (VNO)
4. The Grüneberg ganglion (GG).

The newfound appreciation of an organizational concept of olfactory subsystems – or noses within noses [30.8] – comes with the recognition of profound differences in the molecular and cellular mechanisms that, at least theoretically, confer a substantial degree of stimulus selectivity for each subsystem and, thus, allow dedication of each structure to a particular role in chemosensation [30.9]. The high level of specialization perhaps becomes most apparent when considering the rapidly expanding repertoire of chemosensory receptor gene/protein families employed by the different systems. While the majority of putative chemoreceptor genes encode for members of the *classical* odorant receptor [30.10] gene family – which, in most mammals, accounts for as much as 2% of the whole genome – noncanonical chemosensory genes devoted to encoding the proteins of smell also make up a significant proportion of many genomes [30.11, 12]. This clear indication of the importance of the sense of smell and its underlying olfactory (sub)systems contrasts our, at present, still largely fragmentary conception of sensory signaling in many noncanonical olfactory cells and tissues.

Not too long ago, it was widely accepted that the mammalian olfactory system had only two anatomical and functional divisions: a main and an accessory (vomeronasal) olfactory system [30.9, 13]. In the 1970s, anatomical description of segregated parallel projections of the main and accessory systems to different *telencephalic* and *diencephalic* nuclei then founded the dual olfactory hypothesis [30.14]. Accordingly, the main system was believed to predominantly detect general environmental odor cues, whereas the accessory system and its peripheral sensory structure – the VNO – were considered to serve a crucial function in the detection and communication of social chemosignals that elicit stereotyped social and sexual behaviors and/or hormonal responses among conspecific animals [30.14, 15]. These two divisions of the olfactory system are by no means homogeneous [30.1]. The MOE contains various sensory neuron subpopulations that respond to distinct classes of chemostimuli, express different receptors – both *Gprotein-coupled receptors* (GPCRs) as well as non-GPCRs – and utilize a variety of transduction pathways. Similarly, the VNO contains at least three different groups of neurons that also vary in stimulus selectivity and transduction mechanisms.

As it has now become apparent that the organization of the sense of smell does not adhere to a strict anatomical and functional dichotomy, but is rather much more complex, several exciting questions now rank high on the agenda of (chemo)sensory neurobiologists:

1. Which receptor structures and signaling strategies are implemented by each different sensory tissue/cell population?
2. What coding logic underpins the anatomical segregation of the different subsystems in the nasal cavity?
3. How is subsystem-specific parallel information routed to and integrated by higher order circuits?
4. What is the exact role that each subsystem plays in regulating chemosensory-dependent behaviors?

30.2 The Vomeronasal System

In 1813, the Danish anatomist Ludvig L. Jacobson described a novel mammalian organ *located in the foremost part of the nasal cavity, in close contact with the septum, on palatal elongations of the intermaxillary bone* [30.16]. He concluded from comparative investigations in various species that *the organ exists in all mammals* and most likely functions as a *sensory organ which may be of assistance to the sense of smell* [30.16]. Originally designated as the *organ of Jacobson*, this enigmatic structure was (re)named in 1895 *organon vomeronasale* (*Jacobsoni*) or *VNO*.

The VNO is a bilaterally symmetrical paired tubular structure at the base of the anterior nasal septum, located just above the palate [30.17, 18] (Fig. 30.1). Enclosed in a bony capsule, the blind-ended organ opens anteriorly into either the oral or the nasal cavity via the nasopalatine or vomeronasal duct, depending on the species examined. Viscous lateral gland secretions fill the VNO lumen [30.1] which separates a medial crescent-shaped pseudo-stratified sensory neuroepithelium from lateral cavernous tissue that harbors a large blood vessel that is extensively innervated by nerve fibers from the superior cervical ganglion [30.19, 20]. The sensory epithelium is mainly composed of basal cells, sustentacular cells, and mature *vomeronasal sensory neurons* (VSNs). The small bipolar VSNs each extend an unbranched apical dendrite that ends in a microvillous swelling (*knob*) at the epithelial surface. At the basal soma, VSNs extend single unbranched axons that gather into nerve bundles that project below the septal epithelium, dorsally pass the cribriform plate, and project along the olfactory bulb's medial sides to the glomerular layer of the *accessory olfactory bulb* (AOB) [30.18]. The mouse VNO consists of a few hundred thousand VSNs in total [30.21]. Each neuron gains structural and metabolic support from sustentacular cells in the most superficial epithelial layer. Even in aged animals, VSNs are continuously replaced from a vomeronasal pool of adult pluripotent cells [30.22] that are located along the basal epithelial membrane as well as in the marginal zones [30.17].

How is VNO stimulus uptake achieved? In situations of stress and/or novelty-induced arousal, sympathetic activity triggers adrenergic release and, consequently, a peristaltic vascular pumping mechanism causes massive fluid entry into the VNO. This way, following direct contact with urine deposits, vaginal secretions, facial gland secretions or saliva, relatively nonvolatile stimuli, such as peptides or proteins gain access to the VNO lumen [30.23, 24].

Initially observed between embryonic days 12 and 13 in the rat [30.25], the vomeronasal neuroepithelium is embryologically derived from an *olfactory placode* evagination. As assessed by expression of the olfactory marker protein (OMP), mouse VSNs are first identified by embryonic day 14 [30.26]. The lateral vascular pattern is completed later in prenatal *ontogeny*, around embryonic day 18 [30.27]. At this stage, the vomeronasal nerve appears fully developed. While all structural vomeronasal components thus seem present at birth [30.28], VNO function in neonates and juveniles is still debated [30.29–31].

30.2.1 Molecular and Cellular Mechanisms of Vomeronasal Signaling

Vomeronasal Chemoreceptors

In most mammalian species, the VNO displays both a structural and functional dichotomy [30.31–33]. At least two topographically segregated neuronal subpopulations express distinct repertoires of receptors and other putative signaling molecules [30.34–36]. In the sensory epithelium's apical layer, VSNs express the G protein α-subunit $G_{\alpha i2}$ together with phosphodiesterase 4A (PDE4A) and a member of a multigene family that encodes class-A (rhodopsin-like) GPCRs: the V1Rs [30.37–39]. Vomeronasal receptor types 1 (V1R) appear exclusively expressed in the VNO [30.38] in a punctate, nonoverlapping pattern. The murine *V1r* gene family contains more than 150 potentially functional members and a similar number of pseudogenes [30.39, 40]. These genes are highly divergent and polymorphic. They share intron-free open reading frames that are found on most chromosomes in a clustered organization [30.40, 41]. Each of the 12 relatively isolated *V1r* families contains between 1 and 30 members [30.39, 42]. In a given VSN, *V1r* gene choice is tightly controlled. *Monoallelic expression* results in a distinct V1R chemodetector *morph* for each neuron [30.43] ensuring that individual VSNs obtain a unique functional identity. *Gene cluster* deletion of all (but one) *V1r*a and *V1r*b family members has shown that VSN chemoresponsivity critically depends on at least some V1Rs [30.44]. To date, however, the majority of *V1r* genes products remain *orphan receptors*. Remarkably, Catherine Dulac and coworkers recently determined sensitivity of ≈ 50 individual V1Rs to a variety of ethologically relevant cues [30.45]. Their data reveal that individual *V1r* subfamilies could have evolved toward the recognition of specific groups of animals or behaviorally relevant chemical structures.

The molecular mechanisms underlying monoallelic gene choice – a hallmark of *V1r* expression [30.40, 43, 46] – remain elusive. The interrupted cluster organiza-

tion of many *V1r* genes may not just reflect multiple gene-duplication events, but may also allow choice regulation to function at the cluster level [30.40]. As shown for mutually exclusive OR gene choice [30.47, 48], transcription of a nonfunctional *V1r* allele triggers coexpression of a second, functional *V1r* gene. This, in turn, then drives a negative feedback mechanism that maintains monoallelic expression. Remarkably, this negative feedback is also maintained when an exogenous OR gene is expressed from a *V1r* locus [30.41]. This surprising finding suggests a common mechanism of monoallelic chemoreceptor transcription in both olfactory sensory neurons (OSN) and VSNs.

A molecularly distinct population of neurons forms the basal VNO layer. Basal VSNs express $G_{\alpha o}$ and members V2R family of GPCRs [30.49–51]. Approximately 120 intact *V2r* genes are found in the mouse genome, whereas an additional ≈ 160 appear pseudogenized [30.52]. Members of the V2R family are typical class-C GPCRs that share a large hydrophobic N-terminal extracellular domain. This extracellular *venus flytrap* module has been attributed to function as the primary site of ligand binding [30.12]. While there is no apparent sequence homology with *V1r* genes, *V2r* gene family members are distantly related to metabotropic glutamate receptors, Ca^{2+}-sensing receptors, metabotropic glutamate receptors, and *T1r* taste receptors [30.12, 32]. Like the *V1r*s, *V2r* genes are mostly organized in clusters on many chromosomes. Based on sequence homology, four distinct *V2r* families are distinguished: family-A, -B, and -D, as well as family-C (a.k.a. *V2r2*) [30.52–55]. With more than 100 members, the vast majority of *V2r*s are family-A genes. By contrast, only four genes constitute family-D. With the exception of family-C receptors, mutually exclusive monoallelic transcription of *V2r* genes underlies a punctate expression pattern. By contrast, family-C receptors do not *obey* the chemosensory *one neuron – one receptor* rule [30.1, 5]. The seven highly homologous (> 80%) family-C proteins are found in most, if not all, $G_{\alpha o}$-positive VSNs [30.53]. Somewhat reminiscent of the atypical insect olfactory coreceptor Orco [30.56], this rather unusual coexpression of family-C *V2r* genes in basal VSNs could indicate chaperoning and/or dimerization function. Whether this holds true, however, remains to be determined [30.2].

H2-Mv (or *M10*) genes are members of a family of nine nonclassical class Ib *major histocompatibility complex* (MHC) genes that, as concurrently reported by two groups in 2003 [30.36, 57], are expressed by V2R-positive basal VSNs. Initially, H2-Mv proteins were believed to associate with V2Rs and, together with β2-microglobulin, serve as essential chaperones for V2R trafficking and surface expression [30.32, 36]. However, a considerable fraction of basal VSNs lacks *H2-Mv* gene expression [30.34] and while the *H2-Mv* family is exclusively found in rodents, other mammals such as the opossum express putatively functional *V2r* genes without intact *H2-Mv* genes [30.52, 58]. Moreover, a recent study suggests that H2-Mv proteins, while not absolutely essential for the generation of physiological responses, are required for ultrasensitive chemodetection by a subset of VSNs [30.35].

As for *V1r*s, gene deletion studies have provided direct evidence that at least some V2Rs mediate VSN chemosignals. Knockout of the *Vmn2r26* (*V2r1b*) or *Vmn2r116* (*V2rp5*) genes results in drastically diminished VSN sensitivity to the male-specific exocrine gland-secreting peptide 1 (ESP1 [30.59]) or MHC class I peptide ligands [30.60], respectively. Both stimuli, however, trigger highly sensitive VSN responses in wildtype mice.

With the notable exception of a recent study that reported promising advances in recombinant V2R plasma membrane targeting [30.61], V1R/V2R *deorphanization* attempts in *heterologous expression* systems have largely failed. We still lack a mechanistic understanding of V1R/V2R cell-surface expression.

In 2009, two groups identified a third family of five putative VNO chemoreceptors [30.62, 63]. These candidate chemosensory GPCR-encoding genes are all members of the formyl peptide receptor (FPR)-like gene family (*Fpr-rs1*, *rs3*, *rs4*, *rs6*, and *rs7*). Their predicted seven-transmembrane topology, their selective, punctate and *monogenic* vomeronasal expression pattern, and their localization in microvillous dendritic VSN endings [30.62, 63] strongly suggest a functional role of FPR-like receptors in vomeronasal chemosignaling. Interestingly, while *Fpr-rs1* is coexpressed with $G_{\alpha o}$ in basal sensory neurons, the remaining vomeronasal *Fpr-rs* genes all coexpress with $G_{\alpha i2}$ in the apical layer of the VNO neuroepithelium [30.8].

The two prototypical FPRs, FPR1 and FPR-rs2, are known for their function in immune cells, such as neutrophils and monocytes [30.64]. Here, both receptors serve crucial functions in host defense against pathogens [30.65]. A characteristic of immune system FPRs is their ligand promiscuity; a wide range of compounds are detected and function as leucocyte chemoattractants that signal direction toward sites of infection or tissue damage. Mitochondrially encoded peptides, the formylated bacterial peptide *N*-formylmethionine-leucine-phenylalanine (fMLF), and various other antimicrobial/inflammatory modulators activate immune system FPRs [30.66], suggesting functionally, rather than structurally defined ligand spectra. Interestingly, neither FPR1 nor FPR-rs2 was found transcribed in VSNs [30.62, 63].

Neither V1/2Rs nor ORs share significant sequence homology with immune system *Fpr*s or vomeronasal *Fpr-rs* genes. Liberles and coworkers suggested that vomeronasal *Fpr*s evolved from several recent gene duplications and positive Darwinian selection in the rodent lineage [30.62] since the single *Fpr-rs* gene cluster is directly adjacent to a stretch of more than 30 *V1/2r* genes. Together with recent functional data obtained from recombinant FPR expression [30.67], these theoretical considerations argue for neofunctionalization of vomeronasal *Fpr* genes. By contrast, VSNs are activated in situ by fMLF as well as the mitochondria-derived formylated peptides [30.68] and heterologously expressed FPR-rs proteins retain agonist spectra that share some similarities to immune system FPRs [30.63]. As true for most vomeronasal chemoreceptors, the exact biological role of vomeronasal FPRs remains to be determined.

Signaling Cascade(s) and General VSN Physiology

Gaining detailed conceptual insight into the transduction mechanisms downstream V1R, V2R, or FPR-rs receptor activation is central to understanding how chemosignals control social and sexual behavior. So far, translation of the chemical binding energy between any VNO receptor and its cognate ligand into a meaningful electrical signal that can be read out by the brain is only partly understood and many critical aspects of VSN physiology are yet to be revealed. Upon exposure to natural sources of semiochemicals such as urine, vaginal secretions, or saliva, VSNs depolarize, display an increased action potential firing rate and, consequently, a transient increase in cytosolic Ca^{2+} [30.62, 69–80]. A physiological hallmark of VSNs is their extraordinarily high *input resistance* of typically several gigaohms [30.81–84]. Consequently, receptor current amplitudes of only a few picoamperes generate robust trains of *action potentials*. This passive membrane property contributes considerably to the exquisitely high electrical sensitivity of VSNs, rendering vomeronasal neurons among the most sensitive sensory structures.

In addition to *conventional* Hodgkin-Huxley type voltage-dependent conductances, such as *TTX*-sensitive Na^+ and delayed rectifier K^+ currents [30.85], several other ion channels shape the electrophysiological input-output function of VSNs. Action potential discharge is, in part, driven by *L*- and *T*-type Ca_v^{2+} currents that generate low-threshold Ca^{2+} spikes [30.82, 84]. Moreover, functional coupling of these Ca_v^{2+} currents to large-conductance Ca^{2+}-sensitive K^+ (BK) channels was proposed to maintain persistent spiking [30.84]. By contrast, a similar coupling mechanism was suggested to underlie sensory adaptation via arachidonic acid-dependent BK channel recruitment during stimulation [30.86]. Another K^+ channel, the ether-á-go-go-related (ERG) K^+ channel, is expressed in a layer-specific and activity-dependent manner, serving a homeostatic function by controlling the output characteristics of basal VSNs [30.9, 81]. ERG channel expression is poised to adjust VSNs to a target output range in a use-dependent manner, thus, extending the dynamic range of the neurons' stimulus – response function. In addition, hyperpolarization-dependent I_h currents are yet another voltage-gated conductance that shapes VSN excitability [30.87].

Ever since the initial reports on layer-specific $G_{\alpha i2}$ and $G_{\alpha o}$ coexpression in dendritic tips of V1R- and V2R-positive VSNs, respectively [30.37, 88, 89], speculation thrived on the notion of a functional role of either G protein α-subunit in apical and basal signaling pathways, respectively. While being an attractive model, conclusive evidence in favor of this concept was only recently reported. *Chamero* and coworkers demonstrated an essential requirement of $G_{\alpha o}$ in VSN responses to MHC I antigens, MUPs, mitochondrially encoded FPR-rs1 ligands, as well as ESP1 [30.68]. However, neuronal responses to fMLF, a stimulus shown to activate at least some of the four $G_{\alpha i2}$-coupled FPRs [30.63], were unaltered in $G_{\alpha o}$-deficient mice [30.68]. Similar studies supporting a role of $G_{\alpha i2}$ in V1R-mediated signaling are currently lacking. As expected for unconditional knockout of abundantly and promiscuous signaling proteins such as $G_{\alpha i2}$ and $G_{\alpha o}$, constitutive gene deletion models are likely to bear a range of phenotypic defects. Accordingly, global $G_{\alpha i2}$ and $G_{\alpha o}$ deletions did not allow a clearly VNO-dependent phenotype to be unambiguously attributed [30.90, 91].

Despite the fact that genetic deletion studies are also lacking, greater consensus is achieved on a critical function of phospholipase C (PLC) in vomeronasal signal transduction [30.13]. PLC activity promotes turnover of phosphatidylinositol-4,5-bisphosphate (PIP_2), resulting in elevated concentrations of the soluble messenger molecule inositol-1,4,5-trisphosphate (IP_3) and membrane-bound diacylglycerol (DAG). While DAG either directly targets membrane proteins or is metabolized to tertiary polyunsaturated fatty acid signals, IP_3 triggers massive Ca^{2+} release from intracellular storage organelles. Over the years, different functions for either or all products of PLC-dependent lipid turnover have been proposed [30.73, 77, 80, 92, 93]. The common denominator of all such models is both a central role of cytosolic Ca^{2+} elevations and an important, though not indispensable function of the *transient receptor potential (TRP) channel* TRPC2 [30.94] that

is abundantly expressed in VNO sensory microvilli. Without a doubt, *TrpC2*$^{-/-}$ mice display severe defects in various social and sexual behaviors [30.95, 96]. There are, however, phenotypic differences when *TrpC2* deletion models are compared to surgical VNO ablation [30.97, 98]. Moreover, evidence for (residual) urine-evoked activity in *TrpC2*$^{-/-}$ VSNs is accumulating [30.73, 93, 97], adding another layer of complexity to our current concept of vomeronasal signaling. Interestingly, a recent study documents two previously unrecognized types of *Trpc2*$^{+}$ neurons in the MOE of mice of various ages, thus, challenging the conventional VNO-centric interpretation of the behavioral phenotypes of *Trpc2* knockout mice.

A variety of signaling cascade proteins are, either directly or indirectly, subject to Ca^{2+}-dependent modulation. Therefore, transient or sustained cytosolic Ca^{2+} elevation, resulting from either TRPC2-dependent influx [30.77] and/or IP_3-mediated store depletion [30.73, 93], exerts both negative and positive feedback regulation in VSNs [30.7]. VSN sensory adaptation and gain control was shown to depend on down-regulation of TRPC2 by Ca^{2+}/calmodulin [30.99]. By contrast, a substantial portion of stimulus-evoked vomeronasal activity seems to be carried by a Ca^{2+} -activated chloride current (I_{Cl}) [30.73, 92, 93], resembling OSN transduction mechanisms [30.100, 101]. Vomeronasal I_{Cl} might be mediated by members of the *anoctamin* family of Ca^{2+} -activated chloride channels [30.102–104]. Microvillar colocalization with TRPC2 suggests that either anoctamin1 or anoctamin2, or both, could represent the vomeronasal Ca^{2+}-activated chloride channel(s) [30.92, 105–107]. However, caution should be exerted when interpreting signaling cascade similarities between VSNs and OSNs. Whether I_{Cl}, analogous to OSNs, contributes to depolarization or, by contrast, induces membrane hyperpolarization depends solely on the chloride equilibrium potential at the VSN microvillar membrane in vivo. This physiological parameter, however, is currently unknown.

30.2.2 Anatomy of the Accessory Olfactory System

Compared to many other sensory systems, both the anatomy and function of VNO-dependent neural circuits is poorly investigated. In general, sensory information in mammals is primarily processed by cortical neurons that allow for associative learning and enable a plastic stimulus response, both within and across individuals. By contrast, semiochemical-dependent behavior seems invariant and highly conserved among individuals. Accordingly, the VNO primarily activates noncortical circuits. Specifically, semiochemicals predominantly activate limbic networks that utilize more hardwired mechanisms than the cortex [30.14, 18]. Furthermore, vomeronasal stimulus processing is considered to follow a relatively *simple* logic. Between sensory input and output command, the circuits activated by VNO stimulation consist of three primary processing relays: the AOB, *amygdala*, and *hypothalamus* [30.108]. Whether and, if so, how circuit processing of vomeronasal stimuli is controlled by modulatory feedback mechanisms remains to be determined.

The Accessory Olfactory Bulb

After they passed through the *cribriform plate*, VSN axon bundles target the AOB, a distinct region at the dorso-caudal end of the olfactory bulb (Fig. 30.1). The two functional subsets of VSN axons project into two distinct AOB regions, thus, maintaining the anatomical dichotomy of the accessory olfactory system [30.7]. Apical V1R-positive neurons express the olfactory cell adhesion molecule (OCAM) but project to OCAM-negative second-order output neurons, mitral cells, in the rostral AOB, whereas basal V2R-positive VSNs lack OCAM expression and synapse with OCAM-positive mitral cells in the caudal AOB [30.109, 110]. Similar inverse OCAM expression has been reported in subsets of OSN axons and main bulb mitral/tufted cells [30.111].

VSNs with a distinct vomeronasal receptor (VR) chemodetector *morph* [30.43] converge onto mitral cell dendrites in 6–10 *glomeruli* that are scattered across broad AOB regions, but restricted to either the rostral or caudal part depending on receptor identity [30.112]. While some glomeruli appear exclusively innervated by neurons of a single VR *morph* [30.112], others were found to coalesce with different, but closely related, VSN axons [30.113]. While the jury is still out on the exact organizational rules that govern VSN-to-mitral cell connectivity in the AOB, the general glomerular organization likely serves to integrate incoming sensory information [30.43, 46].

As correctly noted by *Dulac* and *Wagner*, most basic properties of AOB biology remain almost unexplored. Thus, functional analogies with described main bulb circuitry is mostly speculative [30.114]. Unfortunately, premature extrapolation of anatomical principles and physiological mechanisms from the main to the AOB has seriously hampered an unbiased assessment of AOB neurobiology. Already in 1901, Ramon y Cajal pointed out several fundamental differences between the main to the accessory bulb [30.115]:

1. AOB glomeruli are relatively small, rather confluent and less defined.

2. The *external plexifom layer* in the AOB is, at best, rudimentary.
3. Projecting neuron somata in the AOB are rarely mitral shaped.

Conventional plexifom layers are, in fact, largely missing [30.116]. Instead, an internal and external cellular layer are separated by fiber bundles of the lateral olfactory tract [30.115]. Furthermore, AOB glomeruli are indeed small, though highly variable in size (10–30 µm diameter [30.117]). They are tightly clustered, surrounded by only a few periglomerular cells and innervated by a few hundred glutamatergic VSN axons terminals [30.118].

To date, two basic mitral cell connectivity models for glomerular information processing are discussed. The homotypic connectivity model suggests exclusive targeting of glomeruli that are innervated by VSN populations that share a VR *morph*, effectively rendering a divergent pattern of sensory axonal projections convergent by second-order AOB neurons [30.30, 112]. According to the heterotypic wiring scheme, mitral cell primary dendrites specifically target glomeruli that are innervated by VSNs expressing receptors of the same subfamily [30.113]; thus forming a glomerular map of subfamily-specific domains [30.114].

While lacking an extensive lateral dendritic tree, AOB mitral cells elaborate extensively branched primary dendrites. These dendrites terminate as multiple tufts in up to 12 different glomeruli [30.19, 113, 119–121] although the tufts' size and shape are anything but uniform. Interestingly, local regenerative *tuft spikes* were observed independently of somatic spikes, suggesting modes of local nonlinear synaptic input integration [30.121]. In addition, dendritic transmitter release in response to both subthreshold and suprathreshold excitation [30.122] as well as active backpropagation of sodium spikes from the soma [30.123] increase the computational power of individual mitral cells within the AOB network. Considering their output, AOB mitral cells are relatively slow with maximum firing frequencies < 50 Hz [30.124]. While this upper limit somewhat restricts the dynamic output range, the high density of axon collaterals that project to both the anterior and posterior AOB [30.115] ensures that activity will be transmitted throughout the network, providing an ideal circuit for synchronized output.

Similar to the main olfactory bulb, GABAergic granule cells build the main type of AOB *interneurons* [30.125]. They form synapses with mitral cells both within the glomerular layer and along proximal parts of mitral cell primary dendrites [30.126].

While thoroughly analyzed in the main olfactory bulb [30.127, 128], the reciprocal *dendrodendritic synapse* in the AOB has received considerably less attention [30.129–131]. Located along the basal segments of mitral cell dendrites, dendrodendritic AOB synapses primarily seem to provide relay-like recursive self-inhibitory feedback which sharpens *projection neuron* response selectivity [30.132] and might, thus, function as a sensory *gate* during learning and olfactory memory formation [30.129, 133–135].

30.2.3 Pheromones

Pheromones (*pherin* = to transfer and *hormone* = to excite), per definition, are conspecific chemosignals that elicit a specialized behavior or neuroendocrine response upon detection by members of the same species [30.136]. When the term was coined, Karlson and Lüscher most likely did not foresee that more than 50 years later there would still be a lively and controversial debate about the biological role and even the existence of pheromones [30.137–139]. Concerning the vomeronasal system, it is clear that VSNs detect ethologically relevant odors that other animals emit. These include pheromones and other semiochemicals as well as *kairomones*, heterospecific ligands that upon detection convey an ethological benefit to the receiver. In addition, in vitro studies also showed VSN responses to odors of unknown biological function that are not secreted by other animals [30.7, 140, 141].

While the chemical identity of vomeronasal stimuli, to a large extend, remains to be uncovered, different putative semiochemicals have been identified and can be roughly categorized as follows:

1. Major urinary proteins (MUPs)
2. MHC class I peptide ligands
3. Exocrine gland-secreting peptides (ESPs)
4. Sulfated steroids
5. Formylated peptides
6. Volatile small molecules.

MUPs, MHCs, and ESPs are peptides/small proteins that evolved by species-specific gene duplication events in the rodent lineage [30.142, 143]. For members of each peptide/protein class recognition by basal V2R-positive VSNs has been reported [30.69, 76, 142, 144, 145]. Sulfated steroids and other secreted small molecules appear to signal state- or gender-specific internal physiology [30.78, 146]. These stimuli are predominantly detected by apical neurons expressing members of the V1R receptor family [30.75, 147]. Formylated peptides as well as other pro- or anti-inflammatory disease-associated compounds were proposed to activate FPR-rs receptors [30.63]. In-

deed, these ligands activate both apical and basal VSNs [30.68].

Twenty-one species-specific genes constitute the mouse MUP family [30.143, 148]. MUPs are produced in the liver in a testosterone- and growth hormone-dependent manner primarily by adult males [30.149, 150]. As members of the lipocalin protein family, MUPs fold into a β-barrel that creates an internal binding pocket, which efficiently binds small molecules [30.151]. Therefore, MUPs have initially been attributed a carrier function for small volatile ligands to facilitate their transmission to the VNO lumen and delay their release after environmental excretion [30.151]. Today, it has become increasingly clear that a *tailored* urinary MUP excretion of only 4–12 protein types per individual carries some identity information. Moreover, MUPs alone, without associated small molecules, stimulate basal V2R-positive VSNs [30.69, 79, 145], thereby promoting such different behaviors as male territorial aggression [30.69, 145], female conditioned place preference [30.152, 153], or, if emitted by heterospecifics, innate fear [30.79].

Somewhat similar to formylated peptides, MHC class I peptide ligands are another example of chemosensory signaling components with a prominent immune system function [30.154]. These relatively small peptides are detected by both V2R-positive basal VSNs as well as neurons in the MOE [30.60, 76, 155]. MHC peptides are part of the urinary *peptidome* [30.156] and, as such, they are stably secreted throughout life, providing a potential means for representation of individuality. Strikingly, MHC class I peptide ligands were the first and so far the only molecularly defined chemosignals shown to mediate selective pregnancy block (or *Bruce effect*), which is associated with the formation and maintenance of an olfactory recognition memory by the vomeronasal system [30.76, 157].

A total of 38 mouse genes encode ESPs [30.74]. These peptides are emitted in lacrimal, Harderian, and submaxillary gland secretions and differentially expressed between genders and across development [30.74, 142]. Two ESPs were studied in detail, ESP1 and ESP22. Both are found in male tear fluid and activate basal VSNs with high selectivity [30.142, 144]. While ESP1 expression is male-specific, expression of ESP22 is age-dependent. Both peptides induce robust, though very different behavioral responses in females and males, respectively: ESP1 stimulates lordosis, a receptive female mating posture [30.59], whereas ESP22 is a juvenile mouse pheromone that inhibits sexual behavior in adult male conspecifics [30.144].

Volatile urine-enriched gender-specific bioactive ligands were identified by means of gas chromatography-mass spectrometry. Among the described urinary constituents were several vomeronasal in vitro ligands such as 2-sec-butyl-4,5-dihydrothiazole, 3,4-dehydro-exo-brevicomin, 6-hydroxy-6-methyl-3-heptanone, α/β-farnesene, 2-heptanone, isoamylamine, and others [30.146, 158, 159]. Interestingly, these compounds bind MUPs [30.160], are able to directly activate VSNs at extraordinarily low concentrations [30.75], and promote behavioral responses such as puberty acceleration or delay in females [30.161, 162].

30.3 The Septal Organ

The septal organ of Masera and the Grüneberg ganglion (Sect. 30.4) are undoubtedly the most enigmatic olfactory subsystems in the mammalian nose. First described in detail in 1943 by the Italian anatomist *Rodolfo-Masera* [30.163], chemosensory research had neglected the *Organ of Masera* for a long time. Accordingly, few aspects of the SO physiology have been elucidated and various basic questions about the organ and its functional relevance remain unresolved.

In mice, the SO is a small, isolated patch of sensory neuroepithelium that, surrounded by respiratory epithelium, is bilaterally located near the base of the nasal septum close to the nasopalatine duct openings (Fig. 30.1). The SO epithelial organization closely resembles the structure of the MOE. However, the generally thinner neuroepithelium is composed of only up to three layers of ciliated bipolar OMP-expressing OSNs (compared to six to eight layers in most regions of the MOE) [30.3]. Entering the brain through a defined perforation of the cribriform plate, axons of SO neurons project exclusively to a small subset of glomeruli in the main olfactory bulb [30.1]. Approximately 30 glomeruli, clustered at the ventromedial aspect of the bulb, receive substantial synaptic input from the SO and a few of these glomeruli might actually be exclusively innervated by SO neurons [30.164].

Gene expression profiling in the SO provided evidence for a canonical signaling machinery expressed in SO neurons. While a very small subset of cells appear to express both GC-D and PDE2 (Sect. 30.5.2), the majority SO sensory neurons express canonical odorant receptors, $G_{\alpha olf}$ and adenylate cyclase III [30.165, 166]. Results from microarray analysis and large-scale reverse transcription polymerase chain reaction exper-

iments suggest that not the entire repertoire of ORs is present in SO neurons. Rather a distinct group of 50–80 OR genes, all class II receptors of various families, are expressed in both the MOE and SO [30.167, 168]. Interestingly, OR expression in the SO is not randomly distributed. While apparently abiding by the *one neuron – one receptor* rule, > 90% of SO neurons express one of only nine ORs [30.168]. SR1 (also known as *mOR256-3*) is by far the most abundant receptor found in ≈ 50% of all SO neurons. OSNs that express SR1 respond to many, structurally unrelated odorants over a wide concentration range, whereas OSNs expressing a gene-targeted SR1 locus that lacks the SR1 coding sequence do not show this broad responsiveness [30.169]. The *broad tuning profile* of this specific, most abundant SO receptor likely reflects early reports of broad general odor sensitivity of the SO [30.170].

What functional role is played by the SO? Its unique strategic location in the nasal cavity has prompted speculation about a function as an alert sensor during quiet respiration, when air flow does not reach the entire MOE [30.165]. Others have suggested that the SO may detect compounds of low volatility [30.24]. Whatever its exact role(s), the SO has evolved as a unique *outpost* of the olfactory system that is likely involved in a specific chemosensory function.

30.4 The Grüneberg Ganglion

In 1973, *Grüneberg* discovered an arrow-shaped *ganglion of unknown function* [30.171] at the anterior end of the nasal cavity [30.3]. It bilaterally lines the rostro-dorsal nasal septum close to the opening of the naris [30.172] (Fig. 30.1). Originally considered to constitute a part of the *Nervus terminalis*, the GG was ignored for decades. However, the lack of terminal nerve marker expression and more recent anatomical and functional evidence suggest that the GG represents an independent chemosensory subsystem. Since its *rediscovery* a few years back, the ganglion's peculiar anatomy and elusive physiology have sparked new interest within the field of chemosensory neuroscientists.

GG neurons express OMP and project axonal processes to glomeruli in defined olfactory bulb areas [30.172, 173]. However, GG neurons are devoid of cilia or microvilli that represent hallmarks of other chemosensory neurons in the nose. Moreover, light and scanning electron microscopy show that the GG lacks direct access to the nasal cavity [30.1, 174]. This has fueled speculation about a function as a detector of gaseous or other highly membrane permeant stimuli [30.1]. By contrast, studies have reported expression of several chemosensory receptors in GG cells, including V2Rs and TAARs [30.175, 176] as well as elements of a cyclic guanosine 3',5'-monophosphate (cGMP) pathway [30.177]. GG neurons project along the dorsal nasal septum and medial olfactory bulb surface to dorso-caudal regions near the AOB [30.172, 178] that somewhat overlap with the area occupied by the necklace glomeruli (see below).

A sensory function of the GG subsystem has been proposed on the basis of behavioral data [30.174] and later demonstrated by physiological recordings from GG cells [30.179–181] as well as immediate early gene activity assays [30.182, 183]. So far, however, different studies/approaches have yield rather controversial results. Thus, further physiological investigation is required to unify our concept of GG chemosignaling.

30.5 Noncanonical Olfactory Signaling Pathways in the Main Olfactory Epithelium

More than two decades ago, the discovery of the rodent OR gene family by *Linda B. Buck* and *Richard Axel* marked the beginning of the molecular era of chemosensory research [30.10]. As such, this landmark finding was a watershed event for understanding olfaction. Since 1991, however, a number of additional studies have greatly expanded the classes of receptor genes and proteins implicated in chemosensory signaling. Compared to major advances in understanding canonical olfactory signaling, our current concept(s) of chemodetection mechanisms, signaling pathways, and information coding principles in OR-independent olfaction are still in their infancy. We are only just beginning to unravel the secrets of noncanonical chemosignaling.

30.5.1 Trace Amine-Associated Receptor (TAAR)-Expressing Neurons

Given the vast dimensionality in *odor space* [30.184, 185], the growing appreciation for parallel processing of socially relevant odors by both the main and accessory olfactory system [30.13], as well as the

discovery of different chemoreceptor families in the VNO [30.38, 49–51], it was tempting to speculate that canonical ORs might not represent the only GPCR family serving as MOE chemosensory receptors. In 2006, *Liberles* and *Buck* identified expression of members of the trace amine-associated receptor (TAAR) family in OSN-enriched mouse cDNA samples [30.186]. Like ORs, TAARs appear to be monoallelically expressed in sparse, nonoverlapping subsets of mouse OSNs and localized both in cilia, the site of odor detection, and in axons, where they may serve a guidance function [30.186, 187]. Early on, these properties strongly suggested an olfactory role. Phylogenetically, *Taar* genes are related to other aminergic GPCRs such as metabotropic dopamine and serotonin receptors [30.188]. While $\approx 25\%$ of ORs are suspected pseudogenes [30.189], only one *Taar* gene, *Taar7c*, appears pseudogenized, suggesting that the burden of pseudogene selection is significantly lower in TAAR-expressing neurons [30.187]. Moreover, the *Taar* repertoire is evolutionarily retained in mammals and many intact *Taar* genes are also found across diverse vertebrate genomes, from zebrafish to humans [30.186, 190] further substantiating a common, rather than species-specific olfactory role that is not met by the much larger repertoire of canonical ORs.

Apparently, the expression of ORs and TAARs is mutually exclusive since fluorescence in-situ hybridization studies did not identify OSNs coexpressing both receptor types [30.186]. The regulatory logic of *Taar* expression, however, is different from OR gene choice. *Taar* genes lack the epigenetic signature of OR selection. Moreover, knockout of a specific *Taar* allele resulted in frequent expression of a second *Taar* without silencing the deleted allele [30.187]. These differences are further substantiated by recent findings indicating that TAAR neurons form a sensory neuron population restricted to *Taar* expression prior to initial receptor gene choice [30.191].

Both ORs and TAARs transduce chemostimuli through a signaling mechanism that employs G proteins and an increase in cAMP [30.1]. As initially predicted [30.188], mouse TAARs respond to biogenic amines such as isoamylamine, 2-phenylethylamine and trimethylamine (activating mTAAR3, mTAAR4, and mTAAR5 proteins, respectively). TAAR5 was shown to mediate a species-specific attraction response to trimethylamine. Interestingly, phylogenetic analysis of related rodents suggests that synchronized evolution of trimethylamine biosynthesis pathways and odor-evoked behavioral responses could ensure species-appropriate social interactions [30.192]. Further evidence for a selective function of olfactory TAARs as detectors of socially and/or behaviorally relevant odors has been provided by Ferrero and coworkers [30.193]. Heterologously expressed TAAR4 is activated by carnivore urine and the TAAR4 ligand 2-phenylethylamine enriched in urine samples from carnivore species. Furthermore, this predator-derived cue promotes innate avoidance behavior and increases stress hormone release [30.193]. The exquisite sensitivity of TAAR4 for 2-phenylethylamine gave rise to an alternate (though by no means mutually exclusive) interpretation – that this phylogenetically distinct class of aminergic receptors is simply required for high-sensitivity detection of amines: innately aversive odours [30.191].

The majority of TAAR neurons project to a discrete cluster of glomeruli in a confined bulb region between the previously characterized DI and DII domains in the dorsal olfactory bulb of the mouse [30.191]. In vivo glomerular imaging in this region confirmed that dorsal TAAR glomeruli are selectively activated by volatile amines at low concentrations and further revealed that aversive amines are represented in a nonredundant fashion [30.194].

Together, these recent findings all strongly suggest that TAAR neurons constitute a distinct olfactory subsystem with unique molecular and anatomical features. The TAAR subsystem may thus provide a hard-wired, genetically and anatomically distinct, parallel input stream in the main olfactory pathway that is specialized for the detection of volatile amines [30.191].

30.5.2 Receptor Guanylyl Cyclase-D (GC-D)-Expressing Neurons

The repertoire of olfactory receptors is not restricted to GPCRs. A small percentage of OSNs express neither ORs nor TAARs, but a type-D receptor guanylyl cyclase (GC-D) [30.195]. Receptor GCs are expressed in many tissues of numerous species. They include both orphan and peptide receptors [30.196]. Initially isolated from sea urchin sperm, receptor GCs serve diverse functions including marine invertebrate sperm chemotaxis, regulation of diuresis, transduction in mammalian photoreceptor cells as well as nematode chemosensation [30.196–198]. Receptor GCs share an evolutionary conserved structure: an extracellular receptor domain is coupled by a single transmembrane helix to an intracellular regulatory (kinase homology) and a catalytic domain [30.196, 197]. Ligand binding to the extracellular receptor domain – in mammals, these ligands are mostly natriuretic peptides [30.197] – triggers cyclase domain activity and, consequently, the elevation of intracellular cGMP.

For years, the functional role of GC-D in olfaction has remained mysterious. OSNs that express the GC-D protein also express a variety of putative signaling pro-

teins that could be involved in a cGMP-dependent transduction cascade, for example, the cGMP-gated cyclic nucleotide-dependent channel subunit CNGA3 or the cGMP-stimulated phosphodiesterase PDE2 [30.199, 200]. By contrast, GC-D$^+$ neurons lack many components of the canonical olfactory signaling pathway [30.198, 201]. The phylogenetic conservation of *Gucy2d*, the GC-D encoding gene, across many mammalian species suggests a common olfactory function. As for most vomeronasal receptors, however, humans and other primates are a notable exception.

Do GC-D neurons respond to *conventional* odors or other chemostimuli? And, if so, is GC-D itself the cellular receptor? Studies in gene-targeted mice and heterologous expression systems strongly suggest that GC-D neurons are critical for the detection of natriuretic peptides and/or gaseous stimuli [30.202–205]. As regulators of fluid balance in the kidney and intestine, uroguanylin and guanylin activate enterocytes via guanylyl cyclase C (GC-C), which leads to cGMP-dependent inhibition of Na^+/H^+ exchange and activation of the cystic fibrosis transmembrane regulator [30.206]. Both peptide hormones induce responses in the MOE, even in recordings from *Cnga2* null mice (which are often referred to as *anosmic* as these animals lack a CNG channel subunit essential for canonical OSN signaling). This peptide-induced activity, however, is completely abolished when mice lack either *Gucy2d* or *Cnga3*, the gene encoding the cGMP-dependent CNG channel subunit [30.204]. Single cell recordings from identified GC-D neurons confirmed their sensitivity to uroguanylin and guanylin as well as to diluted urine samples. Strikingly, GC-D neurons showed exquisite peptide sensitivity with half-maximal neural activity stimulated by peptide concentrations as low as 66 pM.

Small gaseous molecules have also been shown to stimulate GC-D neurons. Initially, the small population of *Gucy2d*-expressing olfactory neurons was proposed to function as a CO_2 sensor [30.203]. Coexpression of GC-D and carbonic anhydrase type II indicates that enzymatic catalysis of CO_2 by carbonic anhydrase might characterize this noncanonical olfactory signaling pathway. A few years later, another gaseous molecule, carbon disulfide (CS_2), was found to stimulate GC-D$^+$ OSNs. Using gene-targeted mice, *Munger* and coworkers showed that both chemosensory responses to CS_2 and CS_2-dependent socially transmitted food preferences are drastically reduced in mice lacking GC-D, CNGA3, or carbonic anhydrase type II [30.205]. Their findings indicate that GC-D$^+$ OSNs detect chemosignals that facilitate food-related social interactions via associative olfactory learning.

GC-D neurons not only display unique signaling protein expression, but are also distinct in their glomerular projection pattern. Necklace glomeruli, a peculiar and still poorly defined chain-like band of glomeruli that run between the main and the accessory bulb, are the sole olfactory bulb targets of GC-D$^+$ OSNs [30.207–209]. In contrast to the apparently homogeneous innervation of glomeruli from canonical OSNs, each necklace glomerulus receives heterogeneous innervation from at least two sensory neuron populations: GC-D neurons and an OMP$^+$/GC-D$^-$ neuron population [30.207]. This disparate functional topology underscores the notion that very different coding principles describe both subsystems.

30.6 Olfactory Subsystems in Humans?

Do functional olfactory subsystems exist in humans? Especially the role of a human VNO, with respect to a potential biological significance of proposed human pheromones, has been controversially discussed both within the field as well as in a more popular scientific context. So far, not a single human pheromone has been chemically identified [30.137, 139]. Among the many reasons for that are the inherent difficulties to identify robust and reproducible effects when working with human subjects [30.210]. As recently pointed out by Peter Brennan, this does not necessarily mean that human pheromones do not exist, but complexities of modern human society may diminish their biological significance and make it difficult to identify consistent effects [30.211]. So, may human pheromones yet be found in the future? Candidate sources of such chemosignals are axillary sweat, areolar secretion of lactating women, and tear fluid [30.212–214]. The existence of human pheromones as constituents of such complex bodily secretions is, for instance, suggested by odor-mediated menstrual synchrony in female roommates which was observed in some studies, but not in others [30.4]. Whatever the molecular nature and physiological function of any such behaviorally relevant chemical, designation as a *pheromone* might be particularly problematic in humans. Probably, as has been proposed by Wyatt, the term *signature odor(s)* might be a more useful classification [30.138, 139].

If human signature odors exist, they are not detected and processed by an accessory olfactory system. While an embryonic structure that somewhat resembles a VNO is present early in human fetal devel-

opment, anatomical evidence shows that any residual structure that has been proposed as the adult human VNO – the *vomeronasal pit* – is clearly nonfunctional [30.215–217]. The vomeronasal pit is an epithelial diverticulum in the adult human nasal septum that does not have a similar structure or function to the rodent VNO [30.157]. Cells in the pit do not express OMP [30.218], the signature protein of mature olfactory/vomeronasal neurons in other mammals [30.219]. Moreover, while vomeronasal nerves appear to play a vital role during human fetal development in guiding LHRH neuron migration to the hypothalamus [30.157], no axonal connections to higher brain centers remain in the adult [30.215, 216]. These anatomical findings are corroborated by an overwhelming amount of molecular evidence. Almost all genes encoding for rodent vomeronasal receptors and VNO-specific transduction proteins are pseudogenes in humans. All but five *V1r* orthologs [30.220], all *V2r*s, vomeronasal *Fpr*s, and *H2-Mv* genes, as well as *TrpC2* [30.221] are nonfunctional in the genomes of both humans and Old World monkeys. The relaxation of selective pressure on the *TrpC2* gene, and probably other VNO-specific genes, occurred approximately 23 million years ago, coincident with the acquisition of trichromatic color vision in the common ancestor of Old World monkeys and apes [30.222]. Moreover, gene families that encode important vomeronasal peptide/protein stimuli in rodents, such as MUPs and ESPs, are also absent from the human genome.

More evidence for the lack of an accessory olfactory system in humans comes from anatomical studies in the central nervous system. While an AOB of different size and degree of differentiation is found in most adult nonaquatic mammals, this structure is absent in Old World monkeys, apes, and humans [30.223]. Quite similar to the transient embryonic development of a fetal VNO, a well-developed fetal AOB that regresses in later stages of development has been reported in humans and apes [30.32].

While we know little about human signature odors and remnants of a VNO, hardly any evidence is currently available for (or against) the existence of other olfactory subsystems in humans. Although Grüneberg reported in his original publication that a Grüneberg ganglion is found in human embryos [30.171], the organ likely regresses during fetal development [30.210]. Likewise, a human septal organ has not been found. For noncanonical subpopulations of OSNs, it is clear that at least five members of the *Taar* gene family are potentially functional in humans [30.4]. Whether TAARs are expressed in neurons of the human olfactory epithelium, however, is not clear. For the other main class of noncanonical OSNs, the GC-D neurons, it has been shown that GC-D is also pseudogenized in primates, and, in addition, human necklace glomeruli have not been described [30.210].

30.7 Glossary

- *Accessory olfactory bulb (AOB)*: Structure of the olfactory forebrain in the dorsal posterior region of the olfactory bulb. All VSN axons terminate in the AOB where they form synapses with second-order mitral cells.
- *Action potential*: Short-term change in membrane potential in response to stimulation; also known as *nerve impulse* or *spike*; a neuron that emits an action potential (or *trains* of action potentials) is often said to *fire*.
- *Amygdala*: Structure in the forebrain that is an important component of the limbic system and plays a central role in emotional learning.
- *Anoctamins*: The anoctamin (TMEM16) family of membrane proteins are, at least in part, Ca^{2+}-activated Cl^{-} channels; the term *anoctamin* was coined as these channels are anion selective and have eight transmembrane segments.
- *Broad/Narrow tuning profile*: The sensitivity range of a sensory neuron that significantly changes its action potential discharge in response to either a wide range of different stimuli (broad tuning) or a very precise subset of stimuli (narrow tuning).
- *Bruce effect*: Termination of pregnancy by chemosensory cues (pregnancy block); occurs when a recently impregnated mouse aborts her litter in response to chemosensory cues from an unfamiliar male.
- *Chemotopy*: Physical distribution of neurons/glomeruli on the surface of the olfactory bulb with respect to their individual receptive fields for odorants.
- *Cribriform plate*: A sieve-like structure between the anterior cranial fossa and the nasal cavity; part of ethmoid bone that supports the olfactory bulb; perforated by foramina for the passage of olfactory nerve fibers.
- *Dendrodendritic synapses (in MOB/AOB)*: Reciprocal synapses between two dendrites (here, from a mitral and granule cell); in contrast to axodendritic

synapses that are polarized from an axonal bouton onto a dendrite.

- *Deorphanization*: The process, which results in the identification of a natural ligand acting on an orphan receptor.
- *Diencephalon (Diencephalic, adj.)*: Posterior part of the forebrain that connects midbrain with cerebral hemispheres; encloses the third ventricle, and contains the thalamus and hypothalamus, and associated areas.
- *G Protein-coupled receptor (GPCR)*: Large superfamily of receptors with a characteristic seven-transmembrane topology; binding of extracellular ligands (or activation by light in cases of *opsins*) activates heterotrimeric intracellular G protein signaling cascades; typical GPCRs are receptors for hormones, neurotransmitters, visual, and chemosensory (olfaction and taste) stimuli.
- *Ganglion*: A nerve cell cluster or a group of nerve cell bodies located in the peripheral nervous system.
- *Gene cluster*: Groups (clusters) of two to several dozens of genes belonging to the same gene family; the vast majority of OR, V1R, and V2R genes in mice are found in clusters scattered throughout the genome.
- *Glomerulus (Glomeruli, pl)*: Specific structure/functional unit of spherical neuropil in the outer layers of both the main and accessory olfactory bulb; glomeruli consist of synapses of OSN/VSN axons with apical dendrites of mitral, tufted, and periglomerular cells; they segregate and organize synaptic inputs and, thus, form an olfactory topographic map (*chemotopy*) that allows the interpretation of transmitted chemical signals to the brain.
- *Heterologous expression*: Expression of a gene (or part of a gene) in a host cell or organism, which does not endogenously express this gene or gene fragment.
- *Hypothalamus*: Complex brain structure composed of many nuclei with various functions; regulator of internal organ activities by monitoring information from the autonomic nervous system, controlling the pituitary gland, and regulating sleep and appetite.
- *Input resistance*: The input resistance of a neuron reflects the extent to which membrane channels are open; it is defined as the change in voltage associated with injection of a current (divided by the input current); an increase in input resistance means a greater change in membrane potential in response to a current, thus rendering a neuron more excitable.
- *Interneurons (in MOB/AOB)*: Periglomerular and granule cells, inhibitory neurons of both the main and accessory olfactory bulb; both function to inhibit mitral cells via feed-forward and feedback reciprocal dendrodendritic synapses.
- *Kairomones*: Chemosignals transmitted between species (interspecific chemical cues) that benefit a member of another species without benefitting the emitter. For example, the presence of a predator might be signaled by kairomones.
- *Major histocompatibility complex (MHC)*: Group of genes that code for cell surface proteins that *present* both endogenous and exogenous protein fragments to cells of the immune system; recognition of foreign substances triggers an immune response; MHC proteins are found in all higher vertebrates; the human MHC is frequently referred to as the human leukocyte antigen (HLA) system.
- *Monoallelic expression*: By default, both alleles of a gene are actively transcribed (biallelic expression); in few cases, however, a single allele of a given gene is expressed (X-linked genes in females as a result of X chromosome inactivation).
- *Monogenic expression*: Exclusive expression of a single gene (or pair of allelic genes) from a family of related genes.
- *Olfactory placode*: Thickening of ectoderm that arise through cell division during neural tube formation; the olfactory system is one peripheral nervous system component that arises from paired sensory placodes during development; olfactory placodes give rise to OSNs, supporting and basal cells of the olfactory epithelium [30.224].
- *Ontogeny*: Origin and development of an individual organism from embryo to adult.
- *Orphan receptors*: Receptors for which no ligand is known.
- *Pheromones*: Molecules used for conspecific chemical communication (intraspecific chemical cues). Originally defined by Karlson and Lüscher as chemicals that are released by one member of a species causing specific reactions in other members of the same species [30.136].
- *Plexiform layer*: Meticular layer (of the retina or the olfactory bulb) mostly consisting of nerve cell processes (neuropil) and situated between layers of cell bodies.
- *Projection neuron*: Mitral cell in the MOB and AOB (and/or tufted cell in the case of the main olfactory bulb); these neurons receive information from OSNs or VSNs and relay or *project* this information to higher order brain nuclei.
- *Telencephalon (telencephalic, adj.)*: Anterior part of the forebrain that constitutes the cerebral hemispheres and related structures.

- *Tetrodotoxin (TTX)*: A potent neurotoxin found in pufferfish; inhibits action potential firing by binding to and blocking voltage-gated sodium channels.
- *Transient receptor potential (TRP) channels*: Ion channels named after the role of the channels in *Drosophila* phototransduction; mammalian *Trp* genes are encoded by at least 28 channel subunit genes; channels form six protein families; primary structures predict six transmembrane domains with a pore domain between the fifth and sixth segments and both C and N termini presumably located intracellularly [30.225].
- *Vomeronasal sensory neurons (VSNs)*: Bipolar sensory neurons that reside in the sensory epithelium in the VNO. VSN dendrites end in microvilli, which represent the site of chemosensory transduction. Accordingly, all relevant transduction molecules, such as V1/2R and FPR receptors as well as the transient receptor potential channel 2 (TRPC2) are located in the microvilli. The axons of VSNs terminate at glomeruli in the AOB, where they form synapses with second-order projection neurons (mitral cells).

31. Disrupted Odor Perception

Thomas Hummel, Basile N. Landis, Philippe Rombaux

Olfactory loss is frequent. However, in public not many people complain of that, or they are even not (fully) aware of it. This indicates that it is possible to live a life without a sense of smell, albeit it is more dangerous, less pleasant, and food tastes much less interesting. Most common causes for smell loss are sinunasal disease (chronic rhinosinusitis with and without nasal polyps), acute infections of the upper airways, head trauma, and neurodegenerative disorders. In many people smell loss seems to be due to the aging process. Before treatment olfactory disorders are diagnosed according to cause with the medical history being a big portion of the diagnostic process. Olfactory disorders are in principle reversible, with a relatively high degree of spontaneous improvement in olfactory loss following infections of the upper respiratory tract. Medical treatment is according to cause. It also involves surgical approaches as well as conservative treatments including the use of corticosteroids, antibiotics, or *smell training*. Because today olfactory dysfunction seems to receive more attention than in previous years it can be expected that *tomorrow* we will have more specific and effective treatment options available.

31.1 Epidemiology of Olfactory Loss

Population-based studies of olfactory loss show a prevalence of olfactory impairment of 22% (25–75 years; [31.1]), 19% (≥ 20 years; [31.2]), or 24% (≥ 53 years; [31.3]), with the highest prevalence in older men. However, unawareness of olfactory loss is common [31.3–5]. It also has to be kept in mind that total loss of the sense of smell is seen much less frequently (3–10%) [31.6].

With regard to patients presenting themselves to specialized clinical centers, the most common etiologies of smell loss are post viral upper respiratory tract infection (URTI) (18–45%) and sinunasal disease (SND) (7–56%), followed by head trauma (8–20%), exposure to toxins/drugs (2–6%), and congenital anosmia (0–4%) [31.7–15]. A survey in Germany, Austria, and Switzerland shows higher results for SND [31.16].

For qualitative disorders, the prevalence is considerably lower. In the general population, the prevalence of phantosmia is estimated between 0.8 and 2.1% [31.17] and parosmia to about 4% [31.18]. Among patients with olfactory disorders, parosmia frequency ranges from 10 to 60% [31.7, 19, 20] – possibly indicating that the detection of parosmia is critically dependent on how the investigator asks for parosmia.

31.2 Definitions of Olfactory Dysfunction

31.2.1 Quantitative Olfactory Disorders

Normosmia indicates a normal sense of smell; *hyposmia* indicates a decrease in olfactory function and *anosmia* indicates the loss of olfactory function. Next to general anosmia, specific anosmias have been described, where only certain odors cannot be perceived whereas most odors are [31.21]. The term functional anosmia was chosen since many subjects with severe olfactory loss appear to be able to still perceive a few single odors. Nevertheless, those rare and weak olfactory impressions are too poor to be of any help to these patients in daily life.

31.2.2 Qualitative Olfactory Disorders

The term *qualitative olfactory disorder* reflects the qualitatively changed perception of odorous sensation [31.19, 20, 22, 23]. Their diagnosis relies on the patients' complaints [31.23]. They can be graded in four grades 0–III (frequency of occurrence: daily = 1 point; intensity: very intense = 1 point; social/important other consequences (weight loss, change of daily activities)= 1 point; the degree of parosmia/phantosmia is the sum of points).

Qualitative olfactory disorders are frequently, but not necessarily associated with quantitative olfactory disorders. *Parosmia* describes the distorted perception of smells in the presence of an odor source; parosmias are triggered by odors. They occur particularly often after infections of the URTI or head trauma [31.24]. The distorted odors are mostly perceived as unpleasant (although some exceptions seem to exist [31.25]). Parosmias are thought to be the result of changes at a peripheral or central-nervous level [31.26, 27]; at the moment it is unclear how they are generated. The diagnosis *qualitative olfactory disorder* can be supported by relatively lower scores in an odor identification test [31.19] or the presence of relatively small olfactory bulbs (OB) compared to patients without parosmia/phantosmia [31.28].

Clinically important, most parosmic impressions tend to weaken over months and finally disappear after years [31.24]. Currently it is also not entirely clear whether parosmias are a positive sign in terms of the prognosis of post-URTI and post-traumatic olfactory loss [31.29]. *Phantosmia* describes the distorted perception of smells in the absence of an odor source. Most often phantosmias occur after trauma or URTI [31.24]. Stress-related phantosmias have also been reported [31.30]. Similar to parosmia, the exact explanation of the molecular modifications leading to phantosmia is yet unknown and also the site of its generation remains unclear. Phantosmias also have a tendency to disappear over the course of years.

31.3 Otorhinolaryngological Examination

Evaluation of a patient starts with a thorough history [31.31]. This should include demographics, eating, drinking or smoking habits, listing of major illnesses and injuries, medications taken in relation to symptom onset, history of present illness, endocrine information (thyroid gland, diabetes), general nasal health including obstruction, rhinorrhea, and changes of the sense of smell (Fig. 31.1). Physical examination should include at least the patient's head and neck. Sometimes a neurological examination may be needed. Specific nasal examination should include nasal endoscopy. Radiological evaluation is helpful to rule out the presence of tumors or vascular malformations [31.32, 33], to judge the volume of the OB [31.34], measure the depth of the olfactory sulcus [31.35, 36], and to investigate the paranasal sinuses. Especially the volume of the OB seems to carry also prognostic information – the larger its volume the more likely recovery [31.37].

Additional diagnostic tests may include the search for other underlying causes of the olfactory disorders, deficiency of vitamin A or B12, or hypothyroidism. Finally, biopsies of the olfactory epithelium may be helpful in the diagnosis of olfactory disorders [31.27, 38, 39].

Questionnaire: History of smell/taste disorder

(self-adhesive label)

Phone (home):

Phone (other):

What kind of problem do you have? *You may check more than one box*	☐ a smell problem ☐ a taste problem concerning aromas (subtle taste perception) ☐ a taste problem concerning the perception of sweet, sour, bitter, or salty
When was the onset of your problem?	☐ less than 3 months ago ☐ 3 to 24 months ago ☐ more than 2 years ago ☐ it has been there as long as I can remember ☐ I dont't know
How did the problem start?	☐ slowly ☐ suddenly ☐ I never could smell in all my life ☐ I don't know
How has the situation changed?	☐ there was an improvement ☐ the situation is unchanged ☐ it has become worse
What could have been the cause of your problem?	☐ accident ☐ cold/infection ☐ medication ☐ surgery ☐ breathing through the nose/nasal polyps/sinusitis ☐ dry mouth ☐ dentures ☐ others (please name)
Do you have chronic nasal problems?	☐ no ☐ yes – please indicate: running nose, nasal obstruction, sneezing, allergy, polyps, facial pain ....
Is your condition fluctuating or constant?	☐ fluctuating ☐ constant ☐ I don't know ☐ if fluctuations are dependent on certain circumstances: please describe:
How badly does the problem affect you?	☐ very badly ☐ badly ☐ medium badly ☐ mildly ☐ hardly at all ☐ not at all
How would you describe your nasal patency?	☐ very good ☐ good ☐ bad ☐ very bad ☐ I cannot breathe through the nose at all
The following questions concern **taste** disorders only	
The taste disorder mainly concerns the perception of:	☐ sweet ☐ sour ☐ salty ☐ bitter ☐ spicy ☐ none of these
Do you suffer from any constant oral sensation?	burning mouth ☐ yes ☐ no bitter taste ☐ yes ☐ no salty taste ☐ yes ☐ no sour taste ☐ yes ☐ no dry mouth ☐ yes ☐ no foreign body sensation ☐ yes ☐ no

31.4 Questionnaires

To detect changes related to olfactory loss, several questionnaires have been developed [31.40]. The sinonasal outcome test-16 specifically addresses nasal dysfunction [31.41] (see also [31.42–46]; it is a 16-item measure that assesses the degree of rhinosinusitis based on the presence of symptoms associated with sinusitis. The relatively elaborate questionnaire of olfactory disorders (QOD) [31.47, 48] was designed to asses daily life problems associated with olfactory loss and has been used in a number of studies [31.49, 50]. It consists of 26 items that can be divided into three domains: *negative* statements indicating patients suffering from olfactory impairment and distorted odorous perceptions (parosmia or phantosmia), *positive* statements about coping with the disorder, and statements of social desirability, for control. Another questionnaire asks about the importance of olfaction in daily life [31.51]. This questionnaire does not focus on impairments, but asks how often and in which circumstances people use their sense of smell.

In addition, questionnaires are available to measure mood states or quality of life (QoL) [31.52], with the short form-36 health survey being the standard QoL questionnaire [31.53]. However, there is a choice of questionnaires that allows the selection of the best suited tool [31.54, 55]. Depressive symptoms are often assessed with the Beck depression inventory (BDI) questionnaire [31.56], or its more modern version [31.57]. However, it has to be kept in mind that olfactory loss is often confounded with comorbidity. In fact, in patients with chronic rhinosinusitis the additional effect of olfactory loss on general QoL seems to be not very high [31.58]. In order to be able to track the patients' ability to cope with the olfactory disorder, *Nordin* et al. introduced an 11-question instrument [31.59].

31.5 Psychophysical Methods of Olfactory Testing

The basic principle of psychophysical testing of olfaction is to expose a patient to an odor and to collect responses to that exposure. These procedures are easy to understand by the patient, but, importantly, they are also easily understood by the investigator. Asking the patient about his/her chemosensory function does not appear to be useful, at least not in all patients [31.60–62]; in addition, may patients confuse taste and retronasal olfactory function (*flavor*).

Numerous tests for olfactory function are available many of which are based on odor identification (for review, see [31.63]). In daily clinical life, these tests serve as quick screening tools for olfactory dysfunction [31.64]. All olfactory tests should be reliable and valid. Tests apart from screening tools should distinguish between anosmic, hyposmic, and normosmic subjects, respectively, which requires availability of normative data acquired and validated on large samples of healthy and diseased subjects, respectively. In addition, it should be known which change of the test score indicates a clinically significant change of function [31.65]. Most of these requirements apply only to a few olfactory tests [31.66–71]. The best-validated olfactory tests include the University of Pennsylvania smell identification test (UPSIT) [31.67], the Connecticut Chemosensory Clinical Research Center test (CCCRC) [31.72], and the *Sniffin' Sticks* [31.68, 69] (Fig. 31.2).

Fig. 31.2 *Sniffin' Sticks* and how they are presented to the patient (courtesy of T. Hummel)

Most odor identification tests are presented within a forced choice paradigm. The subjects have to identify odors at supra-threshold concentrations from a list of descriptors [31.73, 74]. For example, subjects receive a rose odor, and they are asked whether the odor was *banana*, *fish*, *rose*, or *coffee*; such tasks are no problem for healthy people, but they are very difficult for people with smell loss. The forced-choice procedure controls the patients' response bias. The result of the test corresponds to the sum of the correctly identified items. *Smell identification tests* are most widely used [31.66–71, 75]. The more odors the test contains the more reliable it is [31.76, 77]. Identification tests have to be

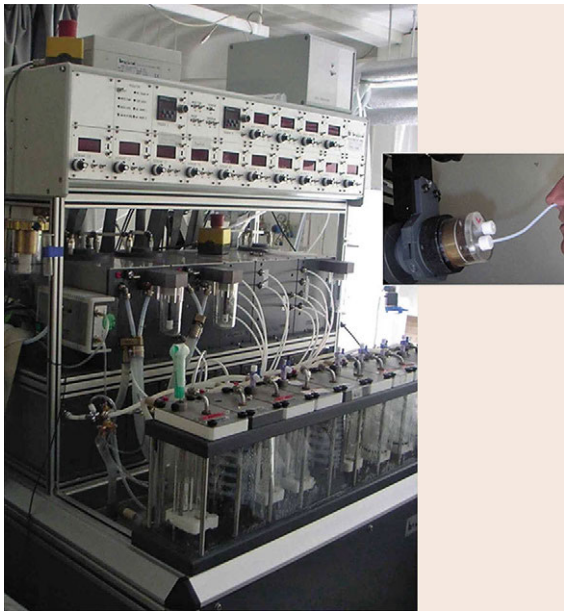

Fig. 31.3 Olfactometer *OMb6* (Burghart, Wedel, Germany) and how stimuli are presented intranasally (courtesy of T. Hummel)

adjusted to the various cultures [31.78, 79], simply because not all odors are known everywhere; for example, many Europeans do not know the smell of *wintergreen* or *root beer*, whereas this is well known in the United States.

Two other widely used test designs are threshold tests and tests of odor discrimination. The idea of threshold tests is to expose a subject repeatedly to ascending and descending concentrations of the same odorant and to identify the least detectable concentration for this individual odor [31.80–82]. Other designs are based on logistic regression [31.83, 84]. Discrimination tasks mainly consist of a three-alternative forced choice technique [31.68, 85]. Two of the administered odors are identical, one is different. The subjects' task is to find out the different one. Tests for odor threshold/odor discrimination can be easily used repetitively, which is more difficult with odor identification tests.

Generally, identification and discrimination tests are believed to reflect central olfactory processing while thresholds are thought to reflect peripheral olfactory function to a stronger degree [31.86–88]. For example, in patients with chronic rhinosinusitis a low threshold score and normal identification and discrimination are frequently seen [31.89].

In order to investigate retronasal function, simple and inexpensive flavor identification tests have been investigated for their test–retest reliability and their validity [31.90–92]. One test, the *taste powders* (*Schmeckpulver*), is also validated on a multinational level [31.93]. Other tests of olfactory function include the investigation of pupillary reflexes [31.94, 95], blinking reflexes [31.96], psychogalvanic skin reactions [31.97], or changes in respiratory/sniffing pattern [31.98, 99].

31.6 Electrophysiological/Imaging Techniques

31.6.1 Electroolfactogram (EOG)

Electroolfactograms (EOG) are electrical potentials of the olfactory epithelium that occur in response to olfactory stimulation. The EOG represents the sum of generator potentials of olfactory receptor neurons (ORNs) [31.100]. Although this technique appears to be attractive [31.101], for example, for the functional characterization of the human olfactory epithelium [31.102], there are only a handful of reports utilizing the human EOG [31.103–108]. Notably there are no published investigations in patients.

31.6.2 Chemosensory Event-Related Potentials (CSERP)

Event-related potentials are EEG-derived signals. They are due to the activation of cortical neurons, which generate electromagnetic fields [31.109]. To extract event-related potentials (ERP) from the background electroencephalogram (EEG) activity, stimuli are presented repeatedly and the individual recordings are then averaged, which improves the signal-to-noise ratio (random activity would cancel itself out; nonrandom activation would remain). In addition, stimuli are presented with a steep onset (< 20 ms) in a monotonous environment such that stimulus onset synchronizes the activity of as many cortical neurons as possible. Olfactory ERP are direct correlates of neuronal activation; they have a high temporal resolution in the range of microseconds, and they can be obtained independently of the subject's response bias, they are well-suited for medico-legal investigations [31.110].

Based on a system developed by *Kobal* [31.104, 111], odors are applied intranasally (Fig. 31.3). Presentation of odorous stimuli does not produce mechanical or thermal sensations because odor pulses are embed-

ded in a constantly flowing air stream [31.104, 112, 113]. ERP peaks are either early or late. Earlier peaks like N1 encode exogenous stimulus characteristics to a larger extent (*What is the nature of this stimulus?*) than later, so-called endogenous components (*What is the meaning of this stimulus?*) [31.114, 115]. Although there is a very clear concept available as to how to record and analyze olfactory ERP [31.116, 117] recently there have been a number of attempts to improve the signal-to-noise ratio [31.118–120] and to extract additional information from the stimulus-related EEG [31.121, 122].

Using magneto-encephalographic techniques [31.123] cortical generators of the responses to trigeminal stimulation with CO_2 were localized in the secondary somato-sensory cortex [31.124], sources in response to olfactory stimulation were found in the anterior-central parts of the insula, the para-insular cortex, and the superior temporal sulcus [31.125–127]. More recent work based on EEG [31.128] suggests that olfactory information in humans is processed first ipsilaterally to the stimulated nostril and then sequentially activates the major relays in olfactory information processing in both hemispheres.

Other EEG-related tests are based on the contingent negative variation (CNV), which occurs in response to an expectation [31.129, 130] or more general EEG changes [31.131] (Fig. 31.4).

31.6.3 Functional Magnetic Resonance Imaging (fMRI), Positron Emission Tomography (PET)

Brain imaging allows to study the human olfactory system in detail [31.132–139]. In contrast to electroencephalogram (EEG) and magneto-encephalogram (MEG), PET and fMRI largely reflect blood-flow related changes. In addition, PET and fMRI have a relatively low temporal resolution whereas they exhibit a better spatial resolution than EEG and MEG. Although there are some data available on fMRI and PET in patients with olfactory loss [31.140–142], it seems that the use of these techniques in individual patients with smell or taste disorders is difficult.

31.7 Causes and Symptoms of Smell Disorders

31.7.1 Most Common Causes

Olfactory Loss Following Infections of the URTI

The patients' history typically starts with an episode of a cold during, which they lose their sense of smell [31.20, 143–147]. Some authors claim viral (influenza, parainfluenza viruses type III, rhinovirus, coronavirus, and Epstein Barr) rather than bacterial infections to be responsible for olfactory disturbances [31.148, 149] and observed a higher incidence of dysosmias after spring and summer URTI [31.144]. Furthermore, women above 45 years of age seem to be affected at a higher percentage than men [31.7, 10, 144] – which brings up the potential olfactory protective effect of estrogens [31.150]. Nevertheless, the effect of estrogen on olfactory function remains an open debate [31.17, 151]. It is important to inform patients with post-URTI olfactory loss about the possibility of parosmia (see above). It tends to occur 1−3 months after the URTI, although it appears sometimes to occur directly after the URTI. The frequency of parosmia is in the range of 25% [31.152, 153].

Posttraumatic Olfactory Disorders

Posttraumatic olfactory disorders are said to occur after occipital trauma. The current explanation is that *coup-contre-coup* lesions or tearing of the filae olfactoriae leads to anosmia or hyposmia. Although the entity of posttraumatic olfactory loss has already been described at the end of the last century it has received little systematic attention, like most olfactory disorders [31.154]. Olfactory loss seems to correlate with the severity of the trauma [31.155–157], although several authors pointed out the fact that there is considerable individual variability in terms of the vulnerability of olfactory structures [31.157, 158]. The injured parts of the olfactory system are most often the filae olfactoriae which cross the cribriform plate. However, central structures such as the orbitofrontal cortex and gyrus rectus have also been found to be affected from head trauma [31.147, 155]. Similar to post-URTI olfactory impairment, these patients are prone to develop parosmia and phantosmia several months after the trauma. Clinical experience shows that most patients with posttraumatic olfactory disturbance realize the alteration with some latency [31.159].

Sinunasal Disorders

Sinunasal disorders constitute the most frequent causes of olfactory loss [31.16]. This is due to mechanical obstruction of nasal cavity (septal deviation, nasal polyposis, congested mucosa) and/or the inflammatory component of chronic rhinosinusitis [31.160–165]. Mild

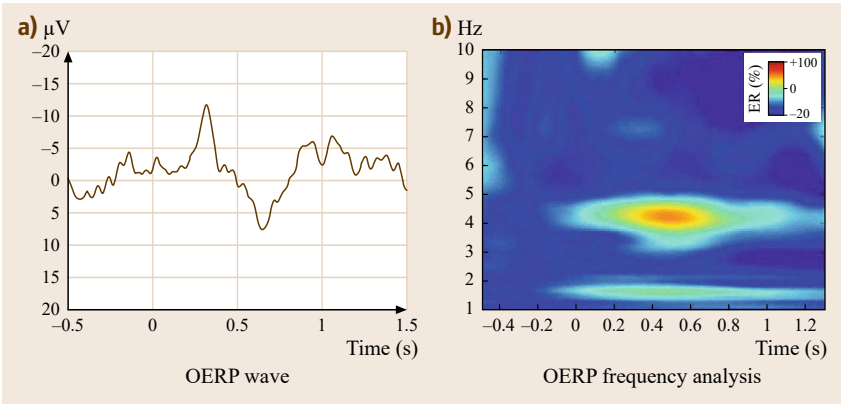

Fig. 31.4a,b Olfactory event-related activity shown in the time domain **(a)**: negativity upward or the frequency domain **(b)**. Stimulus presentation (phenylethylalcohol: PEA) started at time 0 for 200 ms

olfactory impairments could also be identified in other groups of patients with SNDs such as allergic and uncomplicated chronic rhinosinusitis [31.147, 166, 167]. In contrast to posttraumatic and post-URTI olfactory dysfunctions, these patients rarely exhibit parosmia or phantosmia.

Neurodegenerative Causes

Olfactory loss is common in patients with idiopathic Parkinson's disease (IPD) [31.168–170]. While a decreased sniff volume seems to add to the decrease in olfactory function [31.171], electrophysiological recordings in response to passive olfactory stimulation clearly established the presence of olfactory impairment in IPD [31.172, 173]. This olfactory deficit is so reliable that it can be used as a marker of IPD [31.170, 174]. In other words: If a patient with normal olfactory function presents with IPD symptoms the diagnosis should be re-investigated. Olfactory loss precedes the onset of motor symptoms by 4–6 years [31.175–177]. Olfactory loss is also observed regularly in Alzheimer's disease, and at a much lower frequency/less pronounced in multiple system atrophy, Huntington's disease, and motor neuron disease [31.178].

Idiopathic Olfactory Loss

Idiopathic olfactory loss seems to reflect the poor understanding of factors interfering with olfaction [31.147]. With further insight and research this percentage should decrease. A considerable number of these idiopathic causes might be due to SND, post-URTI dysosmias following an almost undetected URTI, or neurodegenerative diseases [31.165].

31.7.2 Less Frequent Causes

Diabetes is probably among the best investigated endocrine diseases concerning olfactory disorders [31.2, 179, 180]. Most studies reveal slight olfactory deficiencies in diabetic patients especially at threshold levels indicating a peripheral patho-mechanism compatible with a possible diabetic micro-angiopathy or peripheral polyneuropathy. However, olfactory impairment in diabetes is relatively mild. Two recent studies conducted with identification tests in large study samples could not find diabetic patients to exhibit a decreased ability to identify odors compared to healthy controls [31.2, 17]; there is evidence showing that olfactory loss is most prominent in complicated diabetes II [31.181]. Several other endocrine diseases like hypothyroidism [31.182] or adrenocortical insufficiency (Addison's disease) [31.183] have been reported to cause olfactory loss.

Affections of the kidney [31.184] and liver [31.17, 185, 186] have been associated with decreased olfactory function. Olfactory disturbances in those pa-

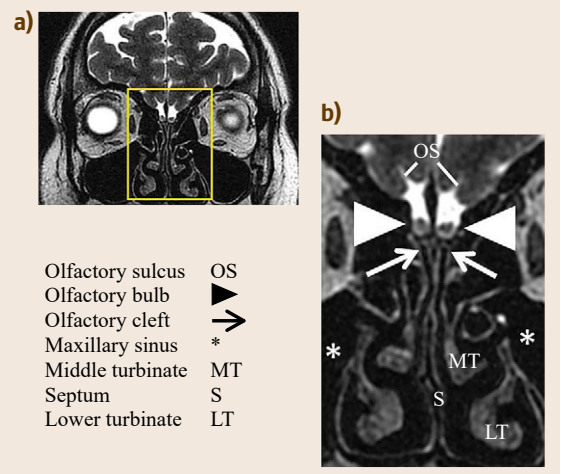

Fig. 31.5a,b Coronal sections (MR-scans) of the head including olfactory bulbs: **(a)** section through whole head; **(b)** magnification of rectangular section indicated in the whole head section

tients are of special importance because they are discussed as a potential cause of malnutrition [31.187]. Olfactory loss may be induced by drugs [31.188]. Among these cardiovascular drugs [31.189], anti-hypertensive drugs [31.190, 191], antibiotics [31.192], and chemotherapeutic agents [31.193] are frequently mentioned. However, most information has been accumulated on the basis of case reports [31.194, 195]. Typically, the chemosensory side effects disappear when the medication is discontinued.

Isolated congenital anosmia seems to appear at a frequency of approximately 1 : 8000. Only magnetic resonance (MR) imaging leads to a more definitive diagnosis [31.35, 36, 196]. In the frontal imaging planes just tangential to the eye bulbs hypoplastic or aplastic olfactory bulbs (OLB) can be visualized (Fig. 31.5). This plane also allows an evaluation of the olfactory sulcus which is flattened in case the OLB is absent or hypoplastic. This is a useful indicator of congenital anosmia, especially because the bulb is not always easy to identify. Congenital/inborn anosmia as part of a syndrome is the Kallmann syndrome [31.197, 198] – here decreased olfactory function is associated with hypogonadotropic hypogonadism meaning the missing/slowed development of the gonads because of decreased levels of hormones, so-called gonadotropins [31.199].

31.8 Symptoms/Quality of Life

Patients with olfactory disorders are impaired in areas of food intake, safety, personal hygiene, and in their sexual life [31.200, 201]. Most often, difficulties related to eating are reported [31.202], also reduced appetite [31.8, 59] and difficulties in preparing food/cooking [31.40]. Many patients have problems detecting spoiled food [31.203]. Interestingly, however, these eating problems do not lead to a general pattern of reduced food intake [31.204]. In a study by *Ferris* and *Duffy*, 18% of the smell patients described an increase in food consumption, 20% a decrease, and the majority reported no change in food consumption [31.202].

No significant weight difference and no difference in food preferences was found in patients who were born without a sense of smell in comparison to an age-matched control group [31.198]. This is also supported from observations indicating that congenital absence of olfaction does not result in markedly aberrant food preferences [31.205]. As patients with acquired olfactory disorders, congenitally anosmic people report enhanced problems with burning food and detecting spoiled food [31.198].

Another common problem is worry about failure to detect fire, gas, or smoke [31.40]. The failure to detect fire or smoke is a main risk associated with olfactory disorder [31.59, 206]. Patients also express problems related to personal hygiene and also social relations are reported to be affected by olfactory disorders [31.59]. Impaired sex life has been reported inconsistently [31.42, 207–209]. Problems in working life have been reported to various degrees [31.62].

Olfactory dysfunction also affects QoL [31.210]. However, in SND, for example, it is difficult to separate the effects of olfactory disorders from those of decreased nasal patency. A similar situation is present in posttraumatic olfactory loss, where patients not only exhibit olfactory loss, but often more severe trauma-related disorders.

Finally, most patients also suffer from a feeling of not being recognized as being sensory disabled since both healthcare professionals and peers often lack any knowledge about smell disorders. This non recognition of the smell-impaired person is reported to generate a lot of frustration and has been overlooked in the past [31.211, 212].

31.9 Spontaneous Recovery of Smell Disorders

Age-related anosmia does not seem to exhibit spontaneous recovery. Sinunasal smell disorders have a tendency to become worse over time – typical is a gradual loss of the sense of smell. This leads to a situation that the entire process may not be noticed or that patients only complain of orthonasal loss but not of loss of retronasal olfactory function. Toxic and drug-induced smell disorders may recover once the drug intake is interrupted [31.192, 193].

Several authors described recovery rates for post-URTI and posttraumatic disorders to be highest within the first year [31.20, 213–215]. This is probably due to the ability of olfactory neurons to regenerate [31.216, 217]. Post-URTI disorders have a better prognosis com-

pared to posttraumatic disorders, probably (at least in part) owing to the fact that they often cause hyposmia rather than anosmia [31.146]. In approximately 5% of the cases total recovery can be observed, while up to 60% of all patients experience partial recovery of some olfactory function over the following years [31.145].

Positive predictors of spontaneous recovery include: short duration of disease, young age, viral cause of olfactory loss better than trauma, presence of parosmia, women better than men, higher olfactory function (also indicated in the presence of olfactory/trigeminal ERP and larger volume of the OLB), and nonsmoking [31.29, 34, 146, 218]. In contrast to quantitative olfactory disorders, qualitative disorders seem to have a better prognosis of spontaneous disappearance. Parosmias tend to decrease to a bearable level after approximately one year [31.152]. However, recent work revealed that more than 50% of the parosmias still are present after 2 years [31.210]. Over time, parosmia seems to lose its devastating effect on QoL. To summarize, the best current therapeutic attitude toward post-URTI and posttraumatic olfactory disorders is to correctly inform the patient, without taking any hope of recovery nor promising quick and complete recovery. The patients should receive satisfactory olfactory testing. Follow-up investigations give both the physician and the patient the possibility to observe improvements.

31.10 Treatment of Olfactory Disorders

31.10.1 Surgical Therapy of SND-Related Olfactory Loss

Most of the patients undergo surgery to remedy decreased nasal patency, a feeling of pressure or recurrent infections of the nasal sinuses. Surgery is rarely performed to specifically treat olfactory dysfunction. However, when asked, postoperative improvement of olfactory function is reported by a majority of the patients [31.219–221]. When olfactory function is measured, a different picture emerges with 25% of patients with preoperative hyposmia and 5% with preoperative anosmia [31.222] (compare [31.223]). In terms of the sense of smell, nasal surgery produced the highest success rates in patients with eosinophilia and a high degree of polyposis [31.223]; in addition, higher success rates were found in women, and patients with aspirin-intolerance [31.224]. Neither age, presence of asthma, nor the number of preoperative surgical interventions had a major impact on the outcome of surgery [31.223, 224]. Findings of endoscopical investigations do not correlate with improvement of the sense of smell [31.225]. While beneficial in many cases, surgery may also pose a certain, albeit low risk to olfactory function [31.223, 226].

31.10.2 Conservative Therapy of SND-Related Olfactory Loss

Antibiotics

In the chronic form of putrid sinusitis *Staphylococcus aureus* and *Pseudomonas aeruginosa* are of high significance. Whenever possible antibiotic therapy should only be started after the bacteria have been identified and tested for resistances to antibiotics. It is important to note that in chronic putrid sinusitis, antibiotic treatment is not always successful.

Steroids

Among many other effects, corticosteroids act as anti-inflammatory drugs, the effects of which are produced via a number of different pathways including inhibition of phospholipase A2 through induction of lipocortin [31.227]. They reduce submucosal edema and mucosal hypersecretion and thereby increase nasal patency. Systemically administered steroids are of help in many SND patients [31.9, 228–232]. In addition to the anti-inflammatory activity it has been postulated that corticosteroids directly improve olfactory function [31.233, 234] by modulating the function of ORN through effects on olfactory Na, K-ATPase [31.227]. In fact, systemic steroids are often helpful even in patients without nasal obstruction due to polyps or obvious inflammatory changes [31.165, 231, 235].

Steroids may be administered systemically or topically. With regard to idiopathic olfactory dysfunction systemic administration is often applied for diagnostic purposes [31.165]. If systemic steroids improve olfactory function treatment is typically continued with locally administered steroids [31.167, 228, 230, 236]; however, the role of topical steroids in the treatment of SND-related olfactory loss has been questioned [31.165, 237, 238]. One reason why systemic steroids have a higher therapeutic efficacy compared to topical steroids [31.9, 239] may relate to the deposition of the spray in the nasal cavity with only few droplets reaching the olfactory cleft [31.238, 240]. In fact, it has been shown that only a small amount of nasally applied drugs reaches the olfactory epithelium which is situated in an effectively protected area of

the nasal cavity [31.241–243]. This situation can be remedied by the use of longer applicators [31.244], which allow to reach further into the nasal cavity so that the spray can reach the olfactory epithelium more effectively.

Other Treatments

Other treatments include the use of antileukotrienes [31.245, 246], saline lavages [31.247], dietary changes [31.248], acupuncture [31.249], antiallergy immunotherapy [31.250], or herbal treatments [31.251].

31.10.3 Conservative Therapy of Post-URTI/ Posttraumatic Olfactory Loss

Post-URTI smell dysfunction seems to be due to an impairment of ORN, both in function and in numbers [31.252, 253]. While numerous treatments have been tried in post-URTI anosmia no pharmacological therapy has been clearly established so far [31.254–257].

However, there are numerous candidates for the conservative treatment of olfactory dysfunction. One of them is alpha-lipoic acid (ALA) which is used in the treatment of diabetic neuropathy [31.258]. The effect of ALA is well described both in experimental animals and in humans (for review see [31.259]). It is known to stimulate the expression of nerve growth factor, substance P, and neuropeptide Y [31.260, 261]. It enhances motor nerve conduction velocity as well as microcirculation [31.262]. Further, ALA also has neuroprotective capabilities [31.263]. Preliminary work indicated that it may be useful in post-URTI olfactory loss [31.264]. Other encouraging pilot studies have been performed with the NMDA-antagonist *caroverine* (NMDA: *N*-methyl-D-aspartate) [31.265]. Potential mechanisms for the hypothesized effect included both reduced feedback inhibition in the OLB as a consequence of NMDA-antagonistic actions or antagonism of an excitotoxic action of glutamate.

Although frequently mentioned as a therapeutic option, studies on olfactory dysfunction with *zinc* have produced negative results [31.254, 266]. It may, however, be of therapeutic value in patients with severe zinc deficiency, in hemodialysis. In studies in postmenopausal women, *estrogens* have been reported to provide a certain protection against olfactory disturbances [31.7]. However, as mentioned above, recent studies [31.151] indicate that estrogens are probably ineffective in the treatment of olfactory loss. Finally, although discussed frequently, the potential therapeutic use of orally administered *vitamin A* [31.255, 267] is questionable; at least doses as high as 10 000 IU do not seem to be effective [31.268].

A different approach to the treatment of olfactory disorders is the detection and treatment of underlying causes. This approach may also involve the replacement of drugs suspect to affect the sense of smell [31.194, 269–271]. Among the nonpharmacological treatments acupuncture has been mentioned frequently [31.249, 272, 273] although its effectivity is a matter of discussion [31.274].

The use of phophodiesterase inhibitors has been described in several studies, none of which was double-blinded, throwing some doubt on the results [31.275–280]. In addition, animal studies indicated a decreased amplitude of responses recorded from the olfactory epithelium after topical administration [31.281].

Numerous studies indicate the usefulness of *olfactory training*, which is typically performed over a period of 12 or more weeks [31.282]. Patients expose themselves twice daily to four intense odors (phenyl ethyl alcohol: *rose*, eucalyptol: *eucalyptus*, citronellal: *lemon*, eugenol: *cloves*). A number of studies, from different laboratories [31.283–285], one of them performed in a blinded way [31.286], indicate that patients training with odors experience a significant improvement in olfactory function over patients who do not perform such a training. One idea about the effectivity of that training relates to the possible stimulation of regenerative capacities of the olfactory epithelium [31.287].

31.11 Concluding Remarks and Outlook

Olfactory dysfunction receives more attention than in previous years probably because modern societies not only care about simple survival but much about QoL. It can be expected that soon we will (1) have a better understanding of the processes leading to smell loss and (2) have more specific and effective treatment options available for people with olfactory disorders.

32. Human and Animal Olfactory Capabilities Compared

Matthias Laska

Humans are traditionally considered to have a poorly developed sense of smell that is clearly inferior to that of nonhuman animals. This view, however, is mainly based on an interpretation of neuroanatomical and recent genetic findings, and not on physiological or behavioral evidence. An increasing number of studies now suggest that the human sense of smell is much better than previously thought and that olfaction plays a significant role in regulating a wide variety of human behaviors. This chapter, therefore, aims at summarizing the current knowledge about human olfactory capabilities and compares them to those of animals.

Comparing olfactory capabilities between species is not a trivial task. Several potentially confounding factors have to be taken into consideration when trying to make statements as to differences or similarities concerning the efficiency of the sense of smell between species.

First, we find a high variability in results between human studies. With regard to olfactory sensitivity, for example, published mean threshold values for a given odorant may vary up to 6 orders of magnitude [32.1]. This is probably, at least in part, due to different methods used to determine such thresholds. However, there is a clear trend that more sophisticated psychophysical procedures employing signal detection methods and rigorous stimulus control yield lower threshold values than more simple procedures [32.2].

Second, the vast majority of psychophysical studies on the human sense of smell only report mean values of performance (usually plus a measure of variation), but not the distribution of values or their range. This is all the more problematic as measures of olfactory performance are notorious for a high interindividual variability. This is true for both studies on olfactory sensitivity in which individual threshold values with a given odorant have been reported to commonly vary up to 3 orders of magnitude within a study population [32.3], and for studies on olfactory discrimination performance in which subjects have been found to vary in their ability to distinguish between a given pair of odorants from chance to perfect discrimination [32.4]. However, here too, more recent studies using state-of-the-art psychophysical methods (pioneered by *Cain* and coworkers) generally report a considerably lower range between the most and least sensitive subjects within a study population [32.5].

Third, it is inevitable to use different methods for assessing olfactory performance with animals and humans, and also with different species of animals. This may affect the comparability of results. However, differences between methods employed with different species of animals are usually necessary adaptations for meeting the physiological, anatomical, and behavioral needs and limitations of the study species to successfully cooperate in a behavioral test. (In other words, even if it was possible to use the same method with different species, this would very likely put one species at an advantage over another species, thus invalidating any comparisons. Therefore, it is better to aim for optimizing a testing method for each study species.) It is commonly agreed that operant conditioning procedures are the gold standard among the methods employed with animals for assessing sensory performance [32.6], and therefore only studies based on such procedures are considered in this chapter. Figures 32.1–32.5 illustrate operant conditioning procedures for assessing

Fig. 32.1a–d Olfactory conditioning method used with spider monkeys. **(a)** Portrait of a spider monkey (*Ateles geoffroyi*). **(b)** The two-choice apparatus used, viewed from the animal's side. It consists of two manipulation boxes of which one is baited with a Kellogg's honeyloop while the other is empty, depending on the odorant applied on the absorbent paper strip attached to the box. **(d)** A spider monkey smelling at one of the absorbent paper strips bearing an odorant used either as a rewarded stimulus or as an unrewarded stimulus. **(c)** A spider monkey indicating its decision for one of the two simultaneously presented odorants by opening the corresponding manipulation box (courtesy of M. Laska)

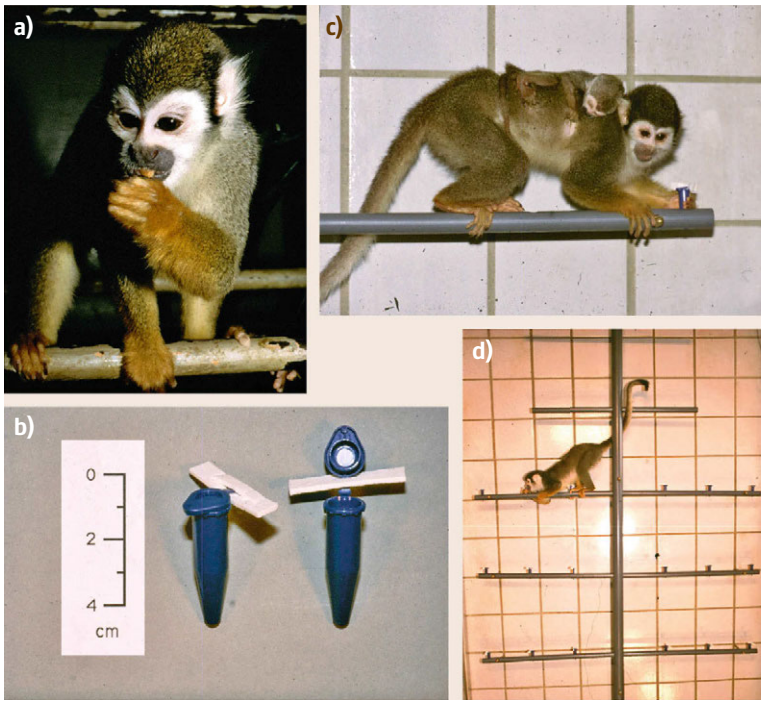

Fig. 32.2a–d Olfactory conditioning method used with squirrel monkeys. **(a)** Portrait of a squirrel monkey (*Saimiri sciureus*). **(b)** Eppendorf cups equipped with absorbent paper strips. The Eppendorf cups serve as manipulation objects (*artificial nuts*) that are either baited with a piece of peanut or not, depending on the odorant applied on the absorbent paper strip. **(d)** Experimental setup. An *artificial nut tree* is used to present numerous *artificial nuts*, half of them baited with a piece of peanut and bearing an odorant used as rewarded stimulus, and half of them empty and bearing an odorant used as unrewarded stimulus. **(c)** A squirrel monkey inspecting an *artificial nut* on a branch of the *artificial nut tree* (courtesy of M. Laska)

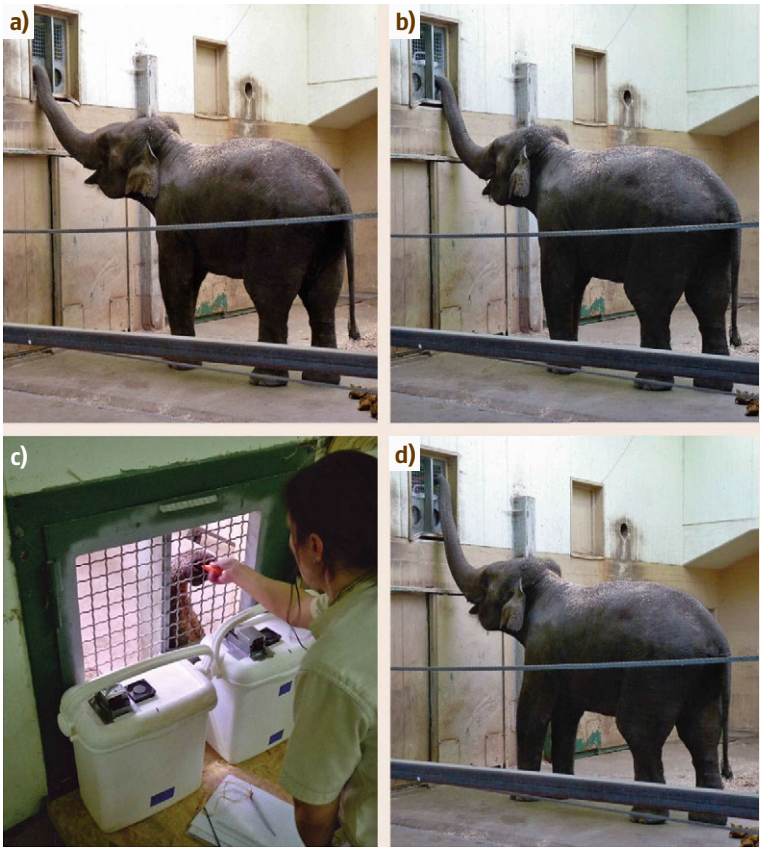

Fig. 32.3a–d Olfactory conditioning method used with Asian elephants (*Elephas maximus*). **(a)** Elephant sniffing at the left odor port. **(b)** Elephant sniffing at the right odor port. **(d)** Elephant indicating its decision for one of the two simultaneously presented odorants by placing her trunk onto the grid on top of the corresponding odor port. **(c)** Elephant receiving a carrot as a food reward after a correct choice (courtesy of M. Laska)

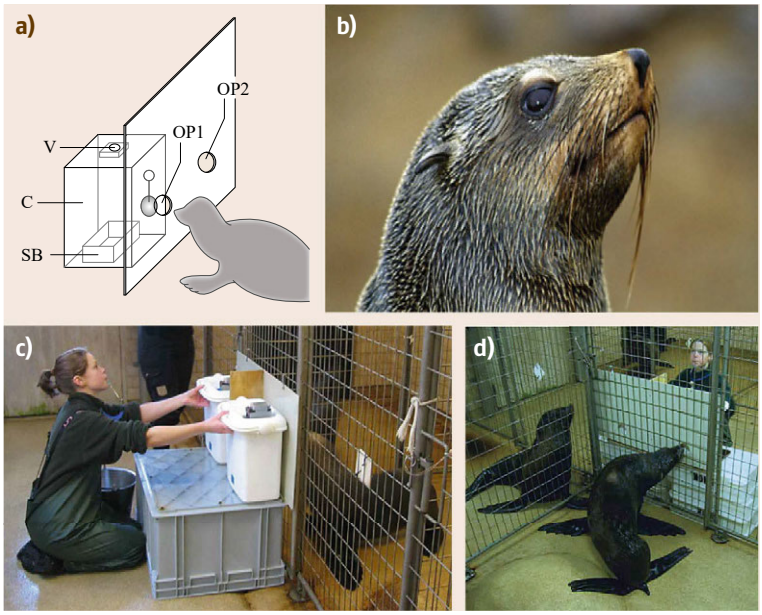

Fig. 32.4a–d Olfactory conditioning method used with South African fur seals. **(a)** Schematic drawing of the experimental set up. C: container bearing an odor stimulus; V: ventilator for ingoing airflow; O: outlet for outgoing airflow; *SB*: stimulus box; OP1: odor port 1; OP2: odor port 2. **(b)** Portrait of a South African fur seal (*Arctocephalus pusillus*). **(c)** Simultaneous presentation of two odor stimuli to a fur seal. **(d)** A fur seal sniffing at one of the two odor ports (courtesy of M. Laska)

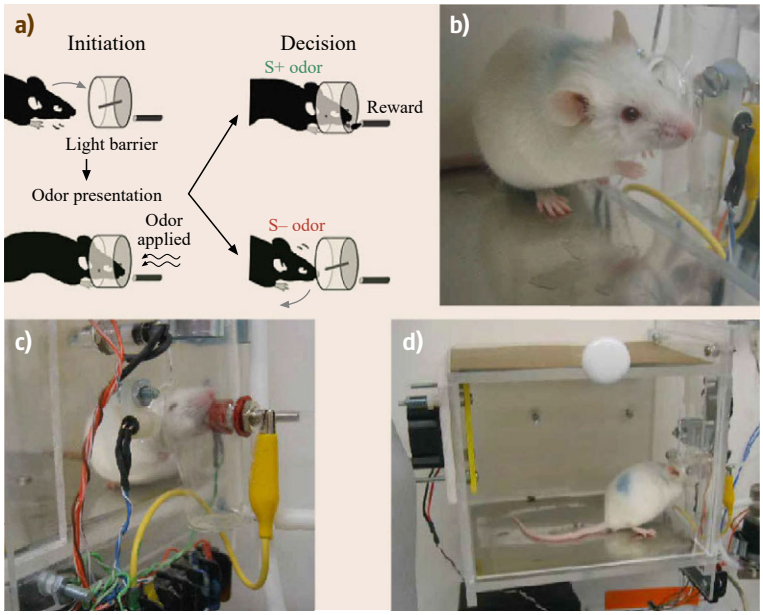

Fig. 32.5a–d Olfactory conditioning procedure used with mice. **(a)** Schematic drawing of the experimental setup. **(b)** A mouse (*Mus musculus*) in front of the odor port. **(d)** A mouse poking its head into the odor port. **(c)** A mouse licking at the water spout after a correct choice (courtesy of M. Laska)

olfactory performance in different species of mammals.

Finally, animal studies usually only employ a low number of individuals, sometimes only one or two animals per species, thus making the use of mean values arguable, and statements as to how representative the findings are for the whole species difficult.

Despite all these difficulties, there are several good reasons that make it worthwhile to compare olfactory capabilities between humans and animals: first, such comparisons allow us to study the neural and/or genetic mechanisms underlying possible differences or similarities in olfactory efficiency between species [32.7]. Second, between-species comparisons of olfactory performance allow us to test hypotheses about the evolution of sensory systems and the selective pressures acting on them [32.8]. Finally, the integration of animal and human studies on olfactory performance may help us to better understand medically relevant phenomena such as aging processes or neurodegenerative diseases, which are often accompanied by a loss of olfactory function [32.9, 10].

32.1 Olfactory Sensitivity

The sensitivity of the sense of smell is usually assessed by determining olfactory detection thresholds, that is, the lowest concentration of a given odorant that a human subject or an animal is able to detect. Human olfactory detection thresholds have been reported for a total of ≈ 3300 odorants [32.1]. In contrast, the total number of odorants tested in animals is much lower. Table 32.1 summarizes the species of mammals and the number of odorants for which olfactory detection thresholds using operant conditioning procedures have been published. The total number of species is 17 (please note that there exist about ≈ 5500 species of mammals), and the highest number of odorants tested with a given species is 81. These 17 species represent 7 of the 29 orders of mammals.

With the exception of four odorants tested with rats (one explosive substance, and three *explosive taggants*, that is, substances added to explosives to identify their sources) and one odorant tested with mice (pyridazine), all 138 odorants for which olfactory detection thresholds have been determined with nonhuman mammals have also been tested with human subjects, allowing for direct comparisons of their performance.

In the following figures (as well as in all other comparisons that follow), I compare the lowest mean threshold values reported in human subjects to the lowest individual threshold values reported in a given animal species. The rationale for this is as follows:

1. Human studies only rarely report the range of threshold values, but usually a mean value.

Table 32.1 Animal species and number of odorants for which olfactory detection threshold values using operant conditioning procedures have been published

No.	Common name	Scientific name	Mammalian order	Number of odorants tested
1	Spider monkey	*Ateles geoffroyi*	Primates	81
2	Mouse	*Mus musculus*	Rodentia	72
3	Squirrel monkey	*Saimiri sciureus*	Primates	61
4	Pigtail macaque	*Macaca nemestrina*	Primates	60
5	Rat	*Rattus norvegicus*	Rodentia	45
6	Short-tailed fruit bat	*Carollia perspicillata*	Chiroptera	18
7	Dog	*Canis lupus familiaris*	Carnivora	15
8	Common vampire bat	*Desmodus rotundus*	Chiroptera	15
9	Common mouse-eared bat	*Myotis myotis*	Chiroptera	13
10	Sea otter	*Enhydra lutris*	Carnivora	7
11	Pig	*Sus scrofa domestica*	Artiodactyla	5

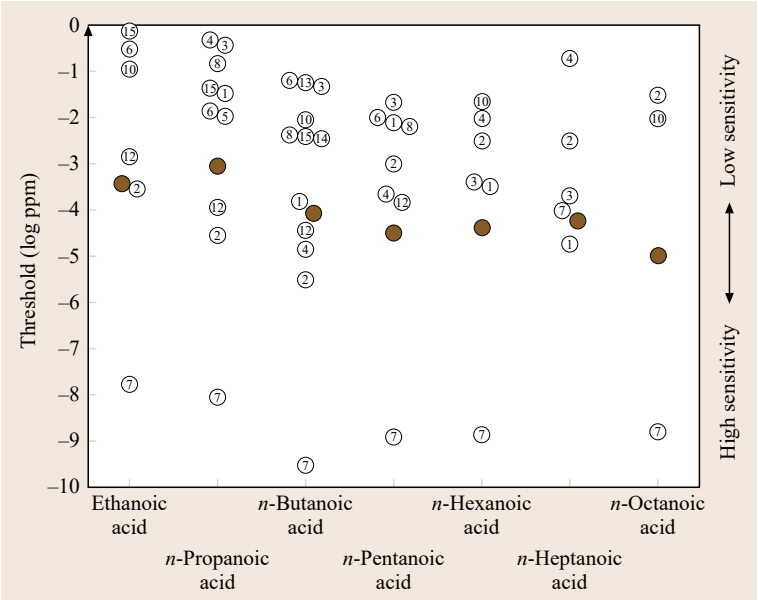

Fig. 32.6 Comparison of the olfactory detection threshold values (expressed as vapor phase concentrations) of human subjects for aliphatic *n*-carboxylic acids and those of other mammalian species. Data points of the human subjects (*brown circles*) represent the lowest mean threshold values reported in the literature, and data points of all animal species (*numbered circles*) represent the lowest threshold values of individual animals reported in the literature. *Numbers in circles* refer to the numbers assigned to each species in Table 32.1 (*human data*: [32.1]; *spider monkey data*: [32.11]; *mouse data*: [32.12]; *squirrel monkey data*: [32.13]; *pigtail macaque data*: [32.11]; *rat data*: [32.14]; *short-tailed fruit bat data*: [32.15]; *dog data*: [32.16, 17]; *common vampire bat data*: [32.18]; *sea otter data*: [32.19]; *hedgehog data*: [32.20]; *great fruit-eating bat data*: [32.18]; *pale spear-nosed bat data*: [32.18]; *common shrew data*: [32.21])

2. Animal studies usually only employ a low number of individuals (in some cases only one animal), making the use of mean values arguable.
3. Comparing the threshold value of the very best individual animal with the mean threshold value of a group of human subjects minimizes the risk of unintentionally favoring humans over animals.

Figure 32.6 compares human olfactory detection threshold values for aliphatic *n*-carboxylic acids to those from other mammalian species. With the notable exception of the dog, human subjects have a higher sensitivity, that is, lower olfactory detection thresholds, than the majority of mammalian species tested with this class of odorants. (Please note that all data points for the dog, except the one for *n*-heptanoic acid, are from a study by *Neuhaus* [32.16] who employed only one animal. Later studies by other researchers [32.17, 57] employed several dogs as well as more rigorous stimulus control, and, interestingly,

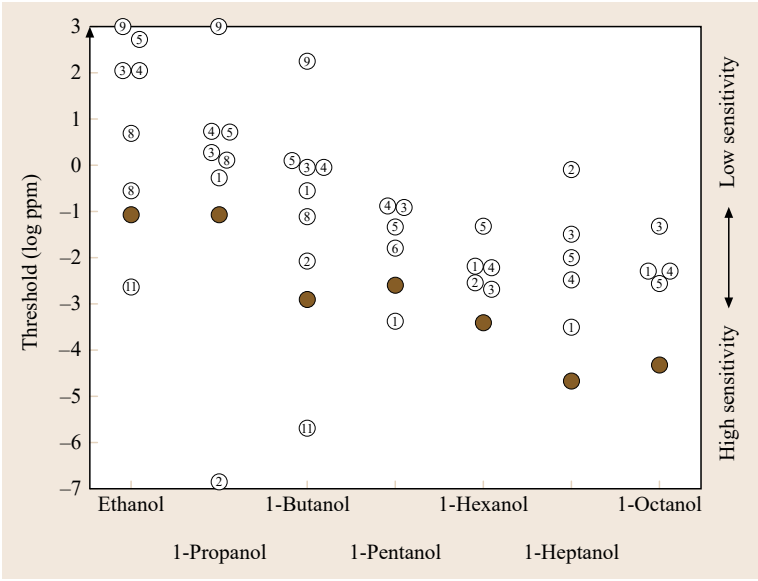

Fig. 32.7 Comparison of the olfactory detection threshold values (expressed as vapor phase concentrations) of human subjects for aliphatic alcohols and those of other mammalian species. Data points of the human subjects (*brown circles*) represent the lowest mean threshold values reported in the literature, and data points of all animal species (*numbered circles*) represent the lowest threshold values of individual animals reported in the literature. *Numbers in circles* refer to the numbers assigned to each species in Table 32.1 (*human data*: [32.1]; *spider monkey data*: [32.22]; *mouse data*: [32.23–25]; *squirrel monkey data*: [32.26]; *pigtail macaque data*: [32.26]; *rat data*: [32.27, 28]; *short-tailed fruit bat data*: [32.15]; *common vampire bat data*: [32.18]; *common mouse-eared bat data*: [32.29]; *pig data*: [32.30, 31])

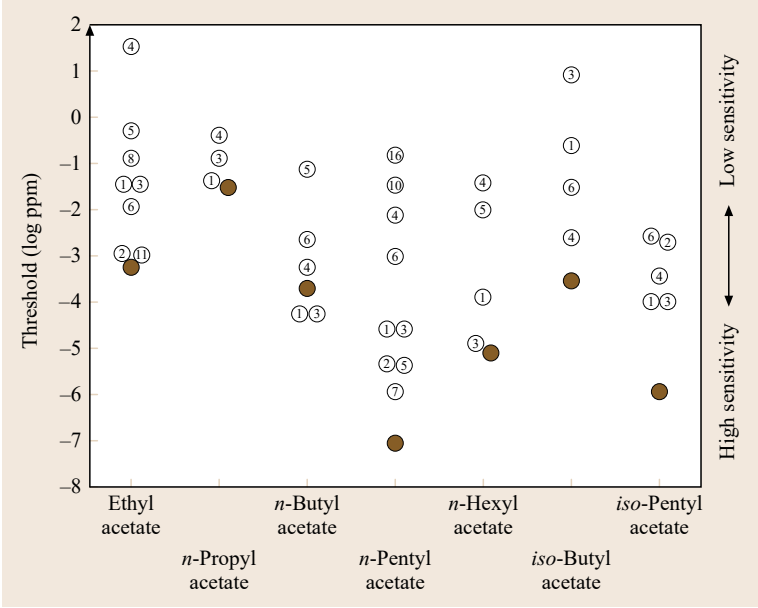

Fig. 32.8 Comparison of the olfactory detection threshold values (expressed as vapor phase concentrations) of human subjects for aliphatic acetic esters and those of other mammalian species. Data points of the human subjects (*brown circles*) represent the lowest mean threshold values reported in the literature, and data points of all animal species (*numbered circles*) represent the lowest threshold values of individual animals reported in the literature. *Numbers in circles* refer to the numbers assigned to each species in Table 32.1 (*human data*: [32.1]; *spider monkey data*: [32.32]; *mouse data*: [32.33–35]; *squirrel monkey data*: [32.36]; *pigtail macaque data*: [32.36]; *rat data*: [32.37–39]; *short-tailed fruit bat data*: [32.15]; *dog data*: [32.40]; *common vampire bat data*: [32.18]; *sea otter data*: [32.19]; *pig data*: [32.31]; *rabbit data*: [32.41])

obtained markedly higher threshold values with these odorants compared to those reported by Neuhaus.) The mouse, another mammal with a reputation for a keen sense of smell, is more sensitive than humans with only three of the seven *n*-carboxylic acids whereas humans outperform this rodent with four of these seven odorants.

Figure 32.7 compares human olfactory detection threshold values for aliphatic 1-alcohols to those from other mammalian species. Here, too, human subjects have a higher sensitivity, that is, lower olfactory detection thresholds, than most of the other species tested. It is interesting to note that humans outperform the rat, another mammal believed to have a highly developed sense of smell, with all seven 1-alcohols. Similarly, humans generally have lower olfactory detection thresholds than the bats and nonhuman primates tested with these odorants. The pig, in contrast, is clearly more sensitive than humans with the two alcohols tested in this species.

Figure 32.8 compares human olfactory detection threshold values for aliphatic acetic esters to those from

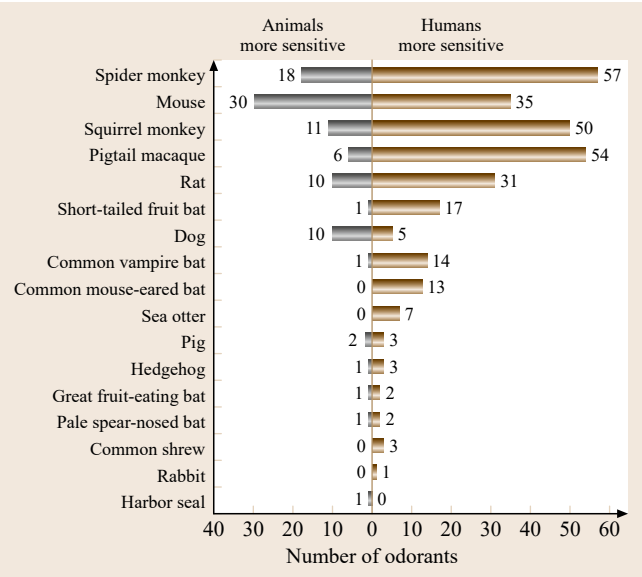

Fig. 32.9 Comparison of all olfactory detection threshold values between human subjects and animal species. Depicted are the number of odorants for which either human subjects or a given species of mammal are more sensitive (*human data*: [32.1]; *spider monkey data*: [32.11, 22, 25, 32, 42–49]; *mouse data*: [32.12, 23, 25, 33–35, 42–44, 50, 51]; *squirrel monkey data*: [32.13, 26, 36, 45–48]; *pigtail macaque data*: [32.11, 26, 36, 45–48]; *rat data*: [32.14, 27, 28, 37–39, 45]; *short-tailed fruit bat data*: [32.15]; *dog data*: [32.16, 17, 40, 52–54]; *common vampire bat data*: [32.18]; *common mouse-eared bat data*: [32.29]; *sea otter data*: [32.19]; *pig data*: [32.30, 31, 55]; *hedgehog data*: [32.20]; *great fruit-eating bat data*: [32.18]; *pale spear-nosed bat data*: [32.18]; *common shrew data*: [32.21]; *rabbit data*: [32.41]; *harbor seal data*: [32.56])

other mammalian species. With only two exceptions (spider monkeys and squirrel monkeys with *n*-butyl acetate), human subjects have lower olfactory detection thresholds, that is, a higher sensitivity for these odorants than all other mammal species tested, including dogs, mice, and rats. With only few exceptions, humans are also more sensitive for aliphatic acetic esters than spider monkeys, squirrel monkeys, and pigtail macaques. This is remarkable given that these nonhuman primates are highly frugivorous suggesting that a high olfactory sensitivity for fruit-associated odorants such as acetic esters should be adaptive for these species. However, both human and nonhuman primates generally outperform granivorous species, such as rats, insectivorous species such as bats, and herbivorous species such as the rabbit with this class of odorants.

Figure 32.9 summarizes all comparisons of olfactory detection thresholds between human subjects and other mammal species. Depicted are the number of odorants for which either human subjects or a given species of mammal are more sensitive. With the exception of the dog (and the harbor seal, which has been tested with only one odorant), human subjects have lower olfactory detection thresholds, that is, a higher sensitivity with the majority of odorants tested so far compared to all other mammal species tested so far. This includes species traditionally considered to have a highly developed sense of smell, such as mice, rats, hedgehogs, shrews, pigs, and rabbits.

It is interesting to note that humans outperform even the dog, often considered as the undisputed supernose of the animal kingdom, with 5 of the 15 odorants tested with both species. The fact that these 5 odorants comprise plant odor components such as β-ionone and *n*-pentyl acetate suggests that the behavioral relevance of odorants rather than neuroanatomical or genetic features may strongly affect a species' olfactory sensitivity. This idea is further supported by the fact that 7 of the 10 odorants for which the dog has been reported to be more sensitive than humans comprise carboxylic acids and thus typical components of the odor of prey species of the dog.

Thus, based on these comparisons, and contrary to traditional textbook wisdom, humans are not generally inferior in their olfactory sensitivity compared to animals.

32.2 Olfactory Discrimination Ability

Olfactory discrimination can be defined as the ability to reliably respond differently to the successive presentation of two nonidentical odorants. Thus, olfactory discrimination is usually assessed by determining the proportion of correct responses with repeated presentations of a given pair of odorants. A statistical criterion can then be used to decide whether a human subject or an animal is able to discriminate between the two odorants in question or not.

Human studies on olfactory discrimination capabilities usually either employ structurally related

Table 32.2 Between-species comparison of olfactory discrimination performance with aliphatic odorants sharing the same functional group but differing in carbon chain length

Success rate	**18/18**	**18/18**	**18/18**	**9/9**

A "+" symbol indicates that the group of human subjects or animals succeeded in discriminating a given aliphatic odor pair, a "−" symbol indicates failure to do so, and a ø symbol indicates that this odor pair was not tested. The three symbols in each table cell refer to the discrimination of odorants that share chain lengths of either 4, or 6, or 8 carbon atoms, respectively. *Human data*: [32.68]; *squirrel monkey data*: [32.69]; *mouse data*: [32.66]; *honeybee data*: [32.67]

monomolecular odorants (to investigate correlations between structure and perceived quality of odorants), or complex odor mixtures of commercial use such as fragrances (perfumes, body care products) or food odors (wines, coffees, artificial flavors). In contrast, the vast majority of animal studies assessing olfactory discrimination capabilities employ naturally occurring complex odor mixtures that are behaviorally relevant for the species under study such as conspecific body odors, species-typical food odors, or predator odors. As a consequence, there is only little overlap in the stimuli used between human and animal studies on olfactory discrimination. However, at least a few animal species have also been studied for their ability to distinguish between some of the structurally related monomolecular odorants tested with humans.

Table 32.2 compares the ability of humans and several species of animals to discriminate between members of homologous series of aliphatic odorants. These are odorants sharing the same oxygen-containing functional group (e.g., an alcohol- or an aldehyde group) but differing in carbon chain length. With this set of odorants, the proportion of successfully discriminated odor pairs is slightly lower in humans compared to squirrel monkeys, fur seals, honey bees, Asian elephants, and mice. Nevertheless, humans succeeded with more than 80% of these odor pairs, which are both structurally and qualitatively similar to each other.

Table 32.3 compares the ability of humans and several species of animals to discriminate between aliphatic odorants sharing the same carbon chain length but differing in functional group. With this set of odorants, not only squirrel monkeys, mice, and honey bees, but also human subjects successfully discriminated between all odor pairs tested.

Table 32.4 compares the ability of humans and several species of animals to discriminate between enantiomers. These are pairs of molecules with mirror-image structures that exhibit identical chemical and physical properties except for their optical activity, that is, rotation of polarized light. They are particularly useful for assessing how molecular structure is encoded by olfactory systems as perceptual differences between enantiomers cannot be caused by differing

Table 32.4 Between-species comparison of olfactory discrimination performance with enantiomers

A "+" symbol indicates that the group of animals or subjects succeeded in discriminating a given enantiomeric odor pair, and a "−" symbol indicates failure to do so. *Human data*: [32.70, 71]; *squirrel monkey data*: [32.72, 73]; *Asian elephant data*: [32.63]; *fur seal data*: [32.74]; *mouse data*: [32.75]; *honeybee data*: [32.76]; *pigtail macaque data*: [32.73]; *rat data*: [32.77, 78]

diffusion rates in the mucus covering the olfactory epithelium or differing air–mucus partition coefficients, but must originate from chiral selectivity at the receptor level [32.79].

Human subjects, as a group, are only able to discriminate between 5 of the 12 enantiomeric odor pairs tested and thus perform similar to squirrel monkeys, which succeeded with 6 out of 12 pairs. Asian elephants, mice, and rats, in contrast, succeeded with 12 out of 12, 11 out of 11, and 3 out of 3 of these odor pairs. South African fur seals, pigtail macaques, and honeybees are able to discriminate between the majority, but not all enantiomeric odor pairs tested with these species (Table 32.4).

Based on these comparisons, humans appear to have a slightly inferior olfactory discrimination ability compared to some species such as mice and Asian elephants. However, their performance in discriminating between structurally related monomolecular odorants appears to be comparable to that of squirrel monkeys, fur seals, and honeybees.

A special, and only rarely investigated, aspect of olfactory discrimination performance is the ability to distinguish between different concentrations of a given odorant. The smallest concentration difference that a nose can reliably detect is often referred to as *just noticeable difference* (JND) and is usually expressed as a so-called Weber fraction (according to Weber's law, which states that the JND between two stimuli is proportional to the magnitude of the stimuli: $\Delta I/I =$ constant). A Weber fraction of 0.3, for example, indicates that a stimulus has to be presented at a 30% higher intensity, relative to a standard stimulus, in order to be reliably perceived as *stronger* than the standard.

The human JND has been found to be odorant-dependent and Weber fractions have been reported to range from 0.09 for *n*-pentyl butyrate, 0.16 for *n*-pentanol, 0.30 for pyridine, 0.35 for *n*-butanol, to 0.47 for phenylethanol [32.80–82]. The only study that directly compared JNDs between species found the Weber fraction for *n*-pentyl acetate to be 0.041 in rats and thus considerably lower than the 0.315 found with this odorant in humans [32.83]. However, a later study reported the rat's Weber fraction for the same odorant to be 0.28, and thus comparable to that of humans [32.84].

A possible explanation for the extreme paucity of animal data on olfactory JNDs is their difficulty in learning the concept that two different concentrations of the same odorant should have different reward values. To understand this difficulty, one must know that in operant conditioning procedures an animal learns that an odorant A is rewarded and that an odorant B (or a blank stimulus) is not rewarded. Once an animal has successfully learned the association between odorant A and a reward, it will consider this odorant as a rewarded stimulus irrespective of its concentration. Biologically, this makes perfect sense as odors that are behaviorally relevant for an animal hardly ever change their significance as a function of concentration: a food odor will always be attractive, whether detected at high or low concentrations, and a predator odor will be always avoided, whether at high or low concentrations. Thus, it takes an animal extensive training to overcome this perseverance with regard to the learned reward value of odorants.

32.3 Qualitative Comparisons of Olfactory Capabilities Between Species

In addition to using quantifiable measures of olfactory performance, such as sensitivity and discrimination ability, one can also try to compare the sense of smell between species using qualitative measures. In the simplest case, this means to assess whether a given species possesses a certain ability or not. To this end, it might be useful to take a look at different behavioral contexts in which the sense of smell is known to play a role for animals and then to ask whether human subjects are able to use their noses for the same purpose.

32.3.1 Gathering Information About the Chemical Environment

The ability to gather information about the chemical environment is almost ubiquitous in the animal kingdom. In most species of animals, the detection of chemical hazards, for example, leads to adaptive behavioral responses intended to minimize further exposure. Humans are no exception to this rule and display adaptive behaviors such as head turning, eye closure, apnea (suspension of breathing), sneezing, and coughing when exposed to harmful volatile chemicals. Although some of these reflex-like responses involve the nasal trigeminal system, the significance of the olfactory system in this context becomes apparent when considering anosmic subjects: humans without a functioning sense of smell run a significantly higher risk of suffering from gas poisoning [32.85] and of not detecting fire [32.86] compared to healthy controls.

32.3.2 Foraging and Food Selection

The ability to find and select food using the sense of smell is also widespread among animal species. Human babies, similar to the offspring of other mammals, already display adaptive behavioral responses such as positive head turning and gaping mouth movements when presented with the odor of their mother's breast or the odor of breast milk [32.87]. Although humans nowadays hardly ever need to use their noses to forage, that is, to search for food, they do possess the ability to follow a food odor scent trail [32.88]. The involvement of the sense of smell in human food selection is more obvious: anosmic subjects run a significantly higher risk of suffering from food poisoning compared to healthy controls with an intact sense of smell [32.89]. Similarly, the risk of suffering from malnutrition is markedly higher in anosmic subjects compared to normosmic control subjects [32.90]. Not surprisingly, anosmic subjects – particularly those who lost their sense of smell instantaneously, for example, due to head trauma – often report a considerable loss of quality of life with regard to enjoying food [32.91].

32.3.3 Spatial Orientation

Quite a number of animal species rely on their sense of smell for spatial orientation. This is particularly true for nocturnal and subterranean species. There are two basic mechanisms that allow animals to find their way through their habitat using their sense of smell: they can either use existing landmarks that emit an odor, or they can deposit scent marks themselves at certain points in their habitat. Both types of odor sources serve as navigational landmarks that can be used by animals to recognize their position in space.

Although humans with an intact sense of vision hardly ever need to use their noses for finding their way, they do possess the ability to follow scent trails laid by conspecifics and when blindfolded [32.88]. A recent study suggests the existence of spatial information processing in the human olfactory system and thus of an implicit ability for directional smelling [32.92]. Further, there is anecdotal evidence that blind persons use olfactory landmarks as sensory cues for spatial orientation [32.93, 94].

32.3.4 Social Communication

Many species of animals have been shown to use body-borne odors for social communication. Such odors may convey information about species, social group, sex, age, reproductive status, health status, social rank, individual identity, genetic relatedness, dietary habit, and emotional state of the odor donor.

Psychophysical studies have demonstrated that humans are able to correctly assign body odors to sex [32.95] and to age classes [32.96]. Similarly, it has been shown that humans are able to correctly assign body odors to reproductive status [32.97, 98] and to health status [32.99, 100].

Further, humans are able to distinguish between individual body odors [32.101] and between body odors of kin and nonkin [32.102, 103]. This includes mutual recognition of the body odors between mothers and their babies [32.104].

Humans are also able to distinguish between the body odors of vegetarians and meat eaters [32.105] and

thus they can sniff out the dietary habits of conspecifics. Recent studies suggest that humans are also able to detect emotions via body odors [32.106, 107].

Dogs, mice, and rats are not only able to discriminate between the odors of individual conspecifics, but also between the odors of individuals of other species, for example, of individual humans. However, it has been demonstrated that human subjects are also able to correctly identify the odor of their own pet dog among other dog odor samples [32.108], to correctly assign body odor samples to individual gorillas [32.109], and to correctly discriminate between the body odors of mouse strains that only differ from each other in their major histocompatibility complex (MHC) genes [32.110].

32.3.5 Reproduction

The ability to correctly identify the reproductive status of potential mates using olfactory cues is widespread among mammals. Similarly, mate choice has been shown to be based on or at least influenced by olfactory cues in a number of mammal species. Human males are able to distinguish between female body odors from different phases of the estrous cycle and prefer the body odor of females produced around the time of ovulation [32.97, 98, 111]. Several lines of evidence suggest that human mate choice may be influenced by body odors and that, as is the case in mice, MHC genes are involved in the formation of individual odor signatures [32.112–114]. A recent study found that congenitally anosmic men exhibit a strongly reduced number of sexual relationships compared to normosmic men, and that congenitally anosmic women feel less secure about their romantic partner compared to normosmic women [32.115]. Further, anosmia-related depression has been shown to reduce sexual appetite in humans [32.116].

32.3.6 Learning and Memory

Learning and memory are inevitably linked to sensory input. Many species of animals rely on olfactory cues for learning about their environment or about situational contexts as well as for building and retrieving memories. Humans are no exception to this as they are able to rapidly and robustly learn long-lasting associations between food odors and positive or negative physiological consequences of ingestion [32.117]. Similarly, humans are able to rapidly and robustly learn appetitive and aversive associations between odors and visual stimuli [32.118]. Several studies reported human long-term memory for odors to be outstanding and superior to that for other sensory modalities [32.119]. The longest interval tested so far with humans for successful odor recognition was 1 year [32.120], and for above-chance level retention of odor–name associations even 9 years [32.121].

From these qualitative comparisons of olfactory capabilities, one must conclude that humans have at least the basic ability of using their sense of smell in all behavioral contexts in which animals are known to use their noses.

32.4 General Conclusions

The amount of published data on quantifiable measures of olfactory performance, which allow for direct comparisons between humans and animals, is rather limited. However, based on this limited set of data the following conclusions can be drawn:

Human subjects have lower olfactory detection thresholds, that is, a higher sensitivity with the majority of odorants tested so far compared to most of the mammal species tested so far. This includes species traditionally considered to have a highly developed sense of smell such as mice, rats, hedgehogs, shrews, pigs, and rabbits.

Human subjects appear to have a slightly inferior olfactory discrimination ability compared to species such as mice and Asian elephants. However, their performance in discriminating between structurally related monomolecular odorants appears to be comparable to that of species such as squirrel monkeys, fur seals, and honeybees.

Qualitative comparisons of olfactory capabilities suggest that human subjects have at least the basic ability of using their sense of smell in all behavioral contexts in which animals are known to use their noses. This includes gathering of information about the chemical environment, food selection, spatial orientation, social communication, reproduction, as well as learning and memory.

Taken together, these findings suggest that the human sense of smell is not generally inferior compared to that of animals and much better than traditionally thought.

33. Ectopic Expression of Mammalian Olfactory Receptors

Sophie Veitinger, Hanns Hatt

Olfactory receptors (ORs) are not exclusively detectable in the olfactory epithelium but are ectopically expressed in all other body tissues tested so far such as brain, heart, lung, testis, intestine, and skin. Within these tissues, a specific subset of ORs can be found with some of the ORs being exclusively expressed in only one specific nonolfactory tissue and other OR subsets being more widely distributed throughout different tissues of the body. It is assumed that ectopically expressed ORs, which are nothing but highly specific chemosensors, play a role in the regulation of cell–cell recognition, migration, and pathfinding processes. Additionally, they are attributed to have potential as diagnostical and therapeutical tools as ORs are differentially expressed in pathological tissues (e.g., cancer tissue). Besides the canonical signaling pathways of ORs, as found in the olfactory tissue, alternative pathways are activated in the diverse nonolfactory tissues. In this chapter, the expression and function of ORs outside the olfactory epithelium of the nose will be highlighted.

One of the criteria that led to the initial identification of olfactory receptors (ORs) was that they seemed to be exclusively expressed in the olfactory epithelium [33.1]. However, only one year after their discovery, the first OR genes were shown to be expressed ectopically in the testis of dogs [33.2]. Within the last two decades ORs were found to be ectopically expressed in every tissue investigated so far [33.3–7]. The number and types of present ORs seems to be specific to the respective tissues. However, the function of only a minor portion of ectopically expressed ORs could be revealed to date. Evidence accumulates that ORs take over specific tasks in nonolfactory cell types which might be explained by the enormous discriminating capacity of this huge G-protein coupled receptor (GPCR) family. Actually, this subcategory of ORs that are found to be ectopically expressed is considerably higher conserved between primate species than those receptors that are exclusively expressed in the olfactory epithelium. This fact points to a positive selection pressure and crucial functions in non-neuronal tissues [33.5].

33.1 Discovery of Ectopically Expressed Olfactory Receptors

Only one year after their discovery in the olfactory epithelium [33.1], the first study revealed the expression of OR genes in the dog and human testis [33.2]. Using degenerate primers, Parmentier and his coworkers

identified 3 and 21 OR transcripts that are expressed in dog and human testis, respectively. Within the following decade, numerous studies corroborated this finding and identified OR transcripts in the testis of various species, including human, dog, mouse, hamster, and rat [33.8–18]. Using antibody stainings in in situ hybridization approaches, ORs were located to late round and elongated spermatids and the midpiece of mature spermatozoa. However, although it was speculated that ORs might participate in germ cell development, in the detection of HLA peptides, and in sperm chemotaxis, none of these early studies could experimentally support a functional necessity for the ectopic expression of ORs in testicular tissue.

With the improvement of transcriptome analysis, microarrays were conducted to investigate comparative OR expression patterns revealing the presence of OR transcripts in numerous tissues of several rodents, humans, and chimpanzees [33.3, 5–7, 19]. Recently, next generation sequencing (NGS) technique was employed to operate the first comprehensive RNA-Seq expression analysis of ectopically expressed ORs in multiple human tissues [33.4]. Taken together, about 80 tissues and cell types have been investigated in several species and all of them with no exception expressed at least one OR (Table 33.1). However, the number of ORs found to be expressed in the distinct tissues varies between studies and also depends on the screening approach and the stringency of the analysis, the highest number of expressed ORs being either testis [33.3, 4] or heart and lung [33.7] or brain and pancreas [33.19].

The expression rate for the majority of ORs in nonolfactory tissue is moderate to low [33.8]. However, it is not clear whether the overall expression in the respective tissues is generally low or if only a distinct subtype of cells expresses the particular OR. Besides intact ORs, a multitude of pseudogenes are also expressed in nonolfactory tissues, in the majority of tissues exceeding the number of intact genes [33.4]. In each tissue, specific ORs showed a high expression [33.3] and in most cases, one or more OR genes were exclusively expressed in the respective nonolfactory tissue [33.3]. In contrast to the olfactory sensory neurons, which are believed to express only one type of OR [33.20], cells in nonolfactory tissues tend to express more than one individual OR gene [33.21–27].

The ectopic expression of OR genes is not correlated to their belonging to a specific structural subgroup, or to a specific gene cluster or chromosomal segment [33.3–6]. However, OR genes located adjacent to non-OR genes have a higher tendency to be expressed in nonolfactory tissues than others [33.3, 4]. This suggests that the genomic environment has an influence on the OR expression. It was also shown that OR genes are post-translational modified by alternative splicing in the 5′-untranslated region (5′-UTR) [33.4, 17, 28]. In some cases, OR genes might even be differentially processed in the olfactory epithelium and in the nonolfactory tissue [33.8, 15]. However, this is not a general phenomenon as other ORs were found to utilize the same initiation site for transcripts in the olfactory epithelium (OE) and other tissues [33.17, 29].

33.2 Functionality of Ectopically Expressed ORs

Since their first discovery, considerable controversy exists about the functionality of ectopically expressed ORs. One point that led to questioning the functionality of ORs in nonolfactory tissues in the past was that orthologous expression profiles did not always correlate well in contrast to that of other gene families. In one study, 64 OR pairs of human and mouse were compared in two tissues and only few orthologous OR pairs were found to be expressed in the same tissues [33.3]. The authors claim that this could argue in favor of neutral or nearly neutral transcription mechanisms, e.g., small DNA sequence changes in regulatory regions, fixed in the population by random drift and not necessarily related to function or fitness. An additional possibility would be that ectopic OR transcription is due to leaky promoters [33.3, 7] as gene activity is not necessarily related to gene function [33.30]. In a few hundred million years, a relatively short time on the evolutionary scale, humans silenced two-thirds of all the genes for ORs that are present in other higher mammals, and converted them to nonfunctioning pseudogenes. Having this rapid evolvement in mind, the genetic distance between rodents and humans might be too big. In contrast, orthologous OR genes of humans and chimpanzees are expressed in the same nonolfactory tissues more often than expected by chance alone [33.5], which underlines the notion that ectopically expressed ORs have additional functions. Furthermore, some orthologous genes that exhibited conserved patterns in nonolfactory tissues evolved under stronger evolutionary constraint than those that were expressed exclusively in the nose [33.5]. This again favors the assumption that ectopically expressed OR genes are functional. Regarding the numerous studies that revealed several distinct functions of ectopically expressed ORs in the past years, the question about their functionality seems to be clarified.

33.3 Olfactory Receptors as Cell–Cell Recognition Molecules

Among the proposed functions for ectopically expressed ORs is the cell–cell recognition and organ construction during development [33.31, 32]. In line with this, ORs are expressed in the developing heart [33.33] and spleen [33.34] and in the chicken notochord where they were suggested to play a role in proper positioning of the neural tube and the somatic mesoderm [33.35]. This led to the speculation that ORs may be the *last digits in a cell surface code for assembling embryos* [33.36, 37]. According to this theory, it is assumed that the precision of cell migration and tissue assembly requires a complex addressing system. Each cell would be equipped with a hierarchic repertoire of recognition molecules encoding the cell identity that enables the cells to find the appropriate position and interaction partners. As this task would require an enormous number of similar molecules, the large superfamily of ORs has been considered as possible candidates serving this function [33.36].

33.4 Olfactory Receptors in Migration and Pathfinding Processes

Another proposed function for ectopically expressed OR genes is that in migration and pathfinding processes. It has been shown that axonal OR expression is crucial for the axon guidance and correct wiring of the glomeruli in the olfactory bulb [33.38, 39]. Spermatozoa swim up a gradient of OR ligands (bourgeonal or lyral) which might be of importance for the localization of the oocyte in the female genital tract [33.23, 25, 26, 40]. Moreover, myocytes' migration during muscle regeneration seems to be influenced by the MOR23 ligand lyral [33.41]. Similar, it was suggested that ORs play a role in the migration of primordial germ cells to the developing gonad [33.42] and participate in proper positioning of the chicken neural tube and somatic mesoderm [33.35].

33.5 Diagnostical and Therapeutical Potential of Olfactory Receptors

Multiple studies about ectopically expressed ORs suggest a significant diagnostical and therapeutical potential for this receptor family that has been pharmacologically underestimated so far. Activation of ORs in enterochromaffin (EC) cells of the human intestine leads to food-induced release of serotonin and regulation of the cytosolic calcium balance [33.21, 43]. Serotonin secretion is implicated in pathologic conditions such as vomiting, diarrhea, and irritable bowel syndrome. Thus, targeting ORs of the EC cells might serve as pharmacologic therapy of irritable bowel syndrome, of conditions such as diarrhea with vomiting caused by anticancer therapy, and of other gastrointestinal disorders [33.21]. Moreover, ORs expressed in the rat colon have been implicated in anion secretion of the mucosa and the increase of the permeability to substances such as dextran [33.44]. ORs present in the rat duodenal enterocytes seem to be significantly upregulated in obesity when a high fat diet is consumed [33.45]. These receptors may play a role in the sensing and regulation of dietary fat, and may be important for the individual susceptibility to obesity. Altogether, ORs in the gastrointestinal tract could be relatively accessible targets for future therapeutics for obesity, diabetes, and malabsorption syndromes.

A further functional relevance of ORs has been suggested in human blood cells. Down-regulation of OR expression in peripheral blood mononuclear cells (PBMC) has been correlated with traumatic brain injury [33.27]. The degree of downregulation is tightly correlated with the severity of the brain injury. The combinatorial expression pattern of two ORs (OR4M1 and OR11H1) in PBMC provides a reliable criterion for segregating traumatic brain injury patients from control cases with 90% accuracy and 100% specificity [33.27].

Furthermore, also in human skin ORs seem to play a significant role. Activation of OR2AT4 promotes cell proliferation and migration and as a result accelerates wound healing in human keratinocytes [33.22]. Odorant stimulation of human keratinocytes also induces adenosine triphosphate (ATP) and cytokine release [33.22, 46]. Javanol-induced ATP release was shown to activate trigeminal neurons via Pannexins [33.46].

In the murine kidney, ORs play a role in the regulation of renin secretion and the glomerular filtration rate [33.47–49]. Olfr78 (the mouse ortholog of OR51E2/PSGR) activation by the short-chain fatty acid

propionate was shown to cause a dose-dependent drop in blood pressure and *Olfr78* knockout mice have significantly lower plasma renin levels and baseline blood pressure compared with wild-type littermates [33.49]. However, the propionate-mediated blood-pressure drop is intensified in *Olfr78* knockout mice indicating that Olfr78 activation antagonizes (rather than mediates) the acute hypotensive effects of propionate [33.49].

Interestingly, a lot of ORs were also found in carcinoma tissue in which they usually seem to be higher expressed compared to the corresponding normal healthy tissue [33.50–57]. Class I receptor OR51E2 is probably the receptor that is investigated the most. It was first discovered to be highly expressed in the prostate and thus initially named prostate-specific G-protein coupled receptor (PSGR). Later it was found to belong to the superfamily of ORs. The expression of OR51E2 and the closely related OR51E1 (PSGR2) is upregulated in prostate carcinoma cells in comparison to normal prostate epithelial cells. Consequently, these ORs have been discussed as potential biomarkers for identification of prostate tumors [33.54–59]. Matsueda and coworkers developed an immunotherapeutic concept for cancer treatment based on these findings: imprinting of CD8+T cells on OR51E2 peptide sequence recognition allows targeted elimination of OR51E2-expressing tumor cells [33.60]. Latest studies reveal that overexpression of OR51E2 in the xenograft mouse model promotes the development of prostate neoplasia and tumors [33.61]. Activation of OR51E2 by its specific ligands β-ionone and the steroid hormone 1,4,6-androstatriene-3,17-dione (ADT) inhibited proliferation of human prostate cancer cells in vitro [33.58]. ADT inhibits aromatization of androgens to estrogens and it has already been used as pharmacological treatment of prostate and other carcinoma [33.62]. Moreover, it has been known for years that the isoprenoid β-ionone has an anti-proliferative effect on carcinoma cells [33.63–66] and it seems very likely that this effect is at least partially mediated via OR51E2. However, the terpenoid β-ionone might have additional roles in vivo as application of β-ionone seems to promote metastases formation of induced prostate tumors in xenograft mouse models [33.67]. OR51E2 is not exclusively expressed in the prostate but was identified also in various other human tissues [33.3, 4, 60, 68, 69], although generally at lower expression rates. Nonetheless, the widespread expression of OR51E2 might hamper the idea to establish an anti-cancer therapy using OR51E2 as a target. OR51E1 was also suggested as a biomarker for small intestine neuroendocrine carcinoma (SI-NEC) cells and lung carcinoma cells [33.50, 52, 70]. Furthermore, OR1A2 and OR1A1 are expressed in hepatocellular carcinoma cells [33.24, 71]. Again, proliferation of carcinoma cells was inhibited by activation of OR1A2 by its ligand (-)-citronellol [33.24]. In a genome-wide association study, OR4F15 was found to be among the top genes associated with salivary gland carcinoma in humans [33.72]. Despite the known overexpression of ORs in different kinds of carcinoma cells, data on their functional role remain sparse. OR2A4 and OR1A2 have been shown to be expressed in human cervical carcinoma cells (HeLa cells). Here they seem to play a role in cytokinesis as shown by RNAi studies [33.73]. OR2A4 knockdown resulted in 4–10-fold increase of bi- or multinucleated cells, possibly by exerting a regulatory role on the actin cytoskeleton [33.73].

GPCRs and their downstream signaling cascades play a pivotal role in the pharmacological treatment of diseases such as cancer [33.74]. Multiple studies demonstrate an overexpression and a functional role of GPCRs in human carcinoma of lung, skin, liver, and the intestine [33.75–77]. Strikingly, despite the fact that more than 25% of pharmacological tools target GPCRs [33.76], relatively few cancer treatments target GPCRs [33.75]. In the mammalian genome, ORs by far represent the largest group within the GPCR gene superfamily. This in combination with the known dysregulation of certain ORs in malignant tissues, renders ORs as promising markers and potential therapeutical targets in cancer treatment.

Besides the known connection to cancer, ectopically expressed ORs have also been implicated in the development and progression of neurodegenerative diseases such as Alzheimer's disease, Creutzfeldt–Jakob, progressive supranuclear palsy and Parkinson's disease [33.78, 79]. Four of eight ORs that are expressed in the frontal and entorhinal cortex have been shown to be dysregulated in Alzheimer's disease and the degree of dysregulation increased with the progression of the disease [33.78]. In Parkinson's disease (PD), OR expression is altered (mainly downregulated) even at premotor stages indicating that OR expression may serve as an early indicator of PD [33.79].

Despite the obvious potential of ectopically expressed ORs in development of medical treatment, knowledge about the function of ORs in both normal and pathological tissues remains sparse. The few existing studies point to involvement of ectopically expressed ORs in the regulation of growth processes, being particularly relevant in tumor formation. Recently, ORs were identified as specific targets for the anesthetic ketamine [33.80]. This again underlines the role of ORs as promising drug targets.

Table 33.1 Olfactory receptors expressed in diverse nonolfactory tissues

Tissue/cell type Reproductive system	Species	Olfactory receptors	Putative function/signaling	Detection method	References
Testis	Dog	DTMT (OR1E2)	Not determined	RT-PCR, NB RNase protection assay, ICC	*Parmentier* et al. [33.2], *Vanderhaeghen* et al. [33.12]
Testis	Rat	Olr825, Olr1696	Not determined	RT-PCR, WB, ICC	*Walensky* et al. [33.16]
Testis	Mouse	MOR23 (OR10J5)		RT-PCR, RNase protection assay	*Asai* et al. [33.8]
Testis	Human, dog, rat, mouse	Various ORs	Not determined	RT-PCR, RNase protection assay	*Vanderhaeghen* et al. [33.13, 14]
Testis	Human	Various ORs	Not determined	RT-PCR, ICC	*Ziegler* et al. [33.18]
Testis/spermatozoa	Human	OR1D2	Chemotaxis	RT-PCR, Ca^{2+} imaging, chemotaxis assay	*Spehr* et al. [33.40]
Testis	Human	Various HLA-linked ORs	Not determined	RT-PCR	*Volz* et al. [33.15]
Testis/spermatozoa	Mouse	MOR23 (OR10J5)	Chemotaxis	RT-PCR, ISH, Ca^{2+} imaging, TG mouse model	*Fukuda* et al. [33.23]
Testis	Mouse	Various ORs	Not determined	Microarray	*Zhang* et al. [33.6]
Testis (spermatids & spermatocytes)	Mouse	Various ORs	Not determined	RT-PCR, ISH	*Fukuda* and *Touhara* [33.28]
Testis	Human, mouse	Various ORs	Not determined	Analysis of microarray and EST data	*Feldmesser* et al. [33.3]
Testis	Human	Various ORs (83)	Not determined	Microarray	*Zhang* et al. [33.7]
Testis	Chimpanzee	Various ORs (11)	Not determined	Microarray	*De La Cruz* et al. [33.5]
Testis/spermatozoa	Human	OR4D1, OR7A5		RT-PCR, Ca^{2+} imaging	*Veitinger* et al. [33.25, 26]
Testis	Human	Various ORs (55)	Not determined	NGS	*Flegel* et al. [33.4]
Prostate, prostate carcinoma	Human	OR51E2 (PSGR)	Not determined	NB, RT-PCR, ISH	*Xu* et al. [33.56]
Prostate, prostate carcinoma	Human	OR51E2 (PSGR)	Not determined	NB, RT-PCR	*Xia* et al. [33.55]
Prostate, prostate carcinoma	Human, mouse, rat	OR51E2 (PSGR)/ Olfr78 (MOL2.3)/ Ra1c	Not determined	NB, RT-PCR	*Yuan* et al. [33.69]
Prostate, prostate carcinoma	Human	OR51E2 (PSGR)	Not determined	RT-PCR, ISH	*Weng* et al. [33.81, 82]
Prostate, prostate carcinoma	Human	OR51E1 (PSGR2)	Not determined	RT-PCR, ISH, NB	*Weng* et al. [33.54]
Prostate, prostate carcinoma	Human	OR51E2 (PSGR)	Not determined	RT-PCR	*Cunha* et al. [33.68]
Prostate carcinoma, LNCaP	Human	OR51E2 (PSGR)	Inhibition of proliferation via MAPK pathway	Ca^{2+} imaging, RT-PCR, WB, ICC, siRNA,	*Neuhaus* et al. [33.58]
Prostate carcinoma, LNCaP	Human	OR51E2 (PSGR)	Src kinase-dependent influx of Ca^{2+} via TRPV6	Patch-clamp, Ca^{2+} imaging, siRNA	*Spehr* et al. [33.83]
Prostate	Human	OR51E2 (PSGR)	Not determined	NGS	*Flegel* et al. [33.4]

Brain	Human	Various ORs	Not determined	NGS	*Flegel* et al. [33.4]
Trigeminal ganglia, dorsal root ganglia	Mouse	Various ORs (98 and 33)	Not determined	NGS	*Manteniotis* et al. [33.100]
Cortex	Human	OR2L13, OR1E1, OR2J3, OR52L1, OR11H1	Dysregulation in Parkinson's Disease	RT-PCR, microarray, ICC, WB, Lipid raft isolation	*Garcia-Esparcia* et al. [33.79]
Entorhinal and frontal cortex, cerebellum	Human, mouse	Olfr110	Dysregulation in several neurodegenerarive diseases	RT-PCR	*Ansoleaga* et al. [33.78]
Muscle					
Skeletal muscle	Mouse	Various ORs	Not determined	Microarray	*Zhang* et al. [33.6]
Skeletal muscle	Human, mouse	Various ORs	Not determined	Analysis of microarray and EST data	*Feldmesser* et al. [33.3]
Skeletal muscle	Mouse	MOR23 (12 other ORs)	Myocyte migration, muscle regeneration (cAMP-dependent)	RT-PCR, ICC, cAMP-Assay, cell migration and adhesion assay	*Griffin* et al. [33.41]
Skeletal muscle	Human	Various ORs	Not determined	NGS	*Flegel* et al. [33.4]
Skin					
Skin	Human, mouse	Various ORs	Not determined	Analysis of microarray and EST data	*Feldmesser* et al. [33.3]
Keratinocytes, HaCaT	Human	OR2AT4 (OR6M1, OR5V1, OR11A1, OR6V1)	Proliferation, migration and wound healing (cAMP-dependent)	RT-PCR, ICC, Ca2+ imaging, wound scratch assay, proliferation assay, siRNA	*Busse* et al. [33.22]
Bladder					
Bladder	Mouse	Olfr544, olfr558, olfr1386, olfr1392, Olfr78, Olfr181, Olfr288	Not determined	RT-PCR, ICC, IP, WB	*Kang* et al. [33.91]

33.6 Endogenous Ligands for Ectopically Expressed Olfactory Receptors

Most groups that have identified OR–ligand pairs so far, have used chemical libraries for deorphanization [33.40, 67, 101–103]. A great proportion of these ligands are synthetically produced and do not occur in body fluids. When it comes to ectopically expressed ORs inside our body, the question arises what are the ligands of these receptors and how do they reach their respective receptors. A lot of odorants that are also detected by the OE are included in our food, especially in plant products. The known OR ligand, β-ionone, for example, is an isoprenoid widely found in plants and plant products as a degradation product of carotenoids [33.104]. Ingredients of spices known to activate specific ORs are, for example, thymol from thyme, eucalyptol from basil, rosemary, ginger and other herbs and eugenol, a chemical component from clove and nutmeg. Eugenol and other odorants are not only present in spices but also are ingredients of most cosmetics, perfumes, detergents, deodorants, cigarettes, and others and we are constantly exposed not only via the nose but also directly through food ingestion and via skin and lung. It is known that odorants enter the blood stream within minutes [33.105] and thus, are transported to their site of action in the various tissues. Around 20 min after percutaneous exposure the plasma concentration of linalool and linalylacetat was 121 and 100 ng ml^{-1}, respectively [33.105]. Roughly 1–5 h after ingestion of an eucalyptol capsule, which is commonly prescribed as an expectorant, eucalyptol can be detected in breath gas [33.106], demonstrating the wide distribution of ingested odorants throughout the whole body. Furthermore, metabolites of eucalyptol were identified in human breast milk in concentrations of up to 100–250 µg kg^{-1} milk [33.107], indicating that odorants from the mother's food and their metabolites are passed on to the breastfed child.

After consumption of asparagus, a variety of odorous molecules can be identified in the urine [33.108]. Interestingly, the number and identity of odorants present in human urine seems to depend on the individual's health status. Fourteen different odorants were found in the urine of healthy human beings, whereas 24 could be detected in glucuronidase-treated samples showing that further phase II metabolization is common for odorant derivatives [33.109]. This finding holds the potential of being used as a future diagnostic tool [33.110]. Short-chain fatty acids (SCFA) such as propionate are also known ligands for human OR51E2 and mouse Olfr78 [33.47, 102]. Interestingly, SCFAs are primarily produced by gut microbiota [33.111] and reach concentrations of up to 100 mM in the colon. It is thus conceivable that sufficient amounts of SCFA enter the blood stream and are transported to their target receptors in various tissues. And indeed it has been shown that the plasma concentration of SCFAs ranges from 0.1–10 mM [33.112]. The physiological effects mediated by propionate via ORs were observed with similar concentrations [33.47, 48, 102]. In line with this finding, diaminopimelic acid is a component of Gram-negative bacterial cell walls and an intermediate in the bacterial biosynthetic pathways for lysine and peptidoglycans [33.113], which has recently been identified to act as an OR agonist [33.114]. This again corroborates the thought that some endogenous OR ligands are gut microbiota-derived.

Besides the digestive system, also fluids of the reproductive system seem to contain endogenous OR ligands. In an attempt to identify the active substances that attract spermatozoa to follicular fluid using gas chromatography-olfactometry, 5α-androst-16-en-3-one and 4-hydroxy-2,5-dimethyl-3(2*H*)-furanone were identified as endogenously produced OR ligands and were shown to elicit Ca^{2+} signals in human spermatozoa [33.115].

Moreover, some ORs such as the OR51E2 and OR7D4 are also activated by endogenously produced steroid hormones [33.58, 116]. The steroid androstenone has been detected in several bodily fluids such as sweat [33.117, 118], saliva [33.119], blood [33.117], breast milk [33.120], and seminal fluid [33.121].

33.7 Signaling Pathways of Olfactory Receptors in Non-Olfactory Tissues

Several studies investigated the expression of canonical olfactory signaling molecules in diverse nonolfactory tissues [33.4, 122]. Signaling components such as olfactory marker protein (OMP), adenylate cyclase III, and $G_{\alpha olf}$ (*GnaI*) were shown to be expressed in numerous tissues such as testis, ovary, colon, brain, white blood cells, kidney, heart, liver, lung, skeletal muscle, skin, and thyroid [33.4, 22, 41, 48, 78, 79, 91] to name only a few (for detailed information see Table 33.2). However, despite the widespread expression of canonical olfactory signaling components, some of the signaling pathways in nonolfactory tis-

sues seem to involve completely different constituents. The well-characterized signaling pathway induced by PSGR1 activation in prostate cells, for example, includes the activation of *Sarcoma* (Src) kinase followed by a *transient receptor potential vanilloid type 6* (TRPV6)-mediated Ca^{2+} influx [33.83]. Thereby, nonreceptor protein tyrosine kinase 2 (Pyk2) is phosphorylated which in turn activates p38 kinase and inhibits the tumor suppressor *N-myc downstream regulated gene 1* (NDRG1) [33.84]. In parallel, PSGR1 also activates the proton transporter *sodium/hydrogen exchanger 1* (NHE1) in the plasma membrane by a yet unknown mechanism, leading to an increase in intracellular pH [33.84]. OR1G1 was shown to increase intracellular Ca^{2+} levels through L-type Ca^{2+} channels in a PLC- and IP3 receptor-dependent manner in enterochromaffin cells [33.21]. OR1A1 does not evoke an intracellular Ca^{2+} increase in a human hepatocellular carcinoma cell line. Instead, it induces a change in gene expression and thereby modulates hepatic triglyceride metabolism. In detail, accumulated cAMP leads to *cAMP response element-binding* (CREB) protein phosphorylation and upregulation of the CREB-responsive gene *hairy and enhancer of split* (HES)-1, a corepressor of peroxisome proliferator-activated receptor-γ (PPAR-γ) [33.71].

33.8 Is it Really *Ectopic* Expression?

The term *ectopic* originates from the Greek word ektopos, which means *out of place* (ex – out and topos – place), so it means that something is occurring in an abnormal position or in an unusual manner or form. This might be a misleading nomenclature when it comes to ORs as they are expressed in the majority of cell types albeit in far less multiplicity compared to the olfactory epithelium. On the other hand, the term *OR* implies specific expression in the nose and exclusive function as odorant sensors in the process of smelling. Maybe, it would facilitate to think of ORs as chemosensors belonging to the GPCRs that mediate the sense of smell as one of their scope of duties but also fulfill a diversity of other tasks in numerous other tissues and cell types.

33.9 Challenges and Future Prospects of Ectopic OR Research

Although in the recent years, more and more studies demonstrated distinct functions of ectopically expressed ORs in various cell types, ectopic OR expression research is still in its infancy. In the past, it was very difficult to detect OR proteins because OR antibodies were not available or poor in quality. This is due to the high homology between ORs (40–90%). However, in recent years, an increasing number of high-quality antibodies became available. This allows more studies with higher through-put based on protein detection [33.127].

Another reason for the slow progression in ectopic OR research is that despite immense effort only a tiny proportion of mammalian ORs has been deorphanized [33.102, 128–130]. Many studies on ectopically expressed ORs use ligands in high concentrations, probably because the known ligands are not the most effective ligands. This raises the possibility to investigate unspecific effects. The discovery of endogenous, presumably more potent ligands would immensely facilitate research on putative OR functions in diverse cells and tissues. In line with the need for agonists, discovery of (endogenous) antagonists would be beneficial. To date, only very few antagonists are published: undecanal for OR1D2 [33.40], hydrocinnamaldehyde, bourgeonal, and methyl cinnamaldehyde for OR3A1 (hOR17-40) [33.131], and α-ionone for OR51E2 [33.58]. Methyl isoeugenol was identified as a partial agonist for mOR-EG [33.132]. Moreover, it was reported that rat OR17 recognizes octanal as primary agonist whereas citral was shown to be a partial agonist or antagonist [33.133]. As known for other GPCRs, OR antagonists seem to be structurally similar to agonists [33.132, 134]. Some odorants have dual functions as an agonist to one and an antagonist to other ORs. This provides complexity in the encoding mechanism of an odorant mixture at the receptor level and, thus, also hampers ligand screening using chemical libraries. Furthermore, it is known that some ORs have a rather broad ligand spectrum whereas others are more narrowly tuned [33.135]. The fact that one receptor may bind multiple ligands and one ligand may activate multiple receptors makes it also more challenging to identify specific OR–ligand pairs.

Moreover, as typical for GPCR research, the establishment of an in vitro assay system to study ORs proved to be difficult. The heterologous expression often is poor due to insufficient intracellular trafficking.

Thus only very few cells express ORs in their plasma membrane and the majority of ORs accumulate intracellularly. The heat shock protein Hsc70t was shown to facilitate the cell surface expression of at least some ORs [33.136]. Matsunami's group established an assay system with co-transfection of numerous cofactors (such as RTP1S and REEP1) known to be important for OR expression in the OE [33.137]. These attempts enhanced plasma membrane localization of ORs. However, despite the clear improvement, this assay system is still far from being optimal.

Another challenge of ectopic OR research are the pronounced species differences in sequence and functional GPCR properties which render basic discoveries in model systems such as rodents only conditionally feasible as the results may not be directly transferable to the human setting. This also applies to knockout models. However, there may be human *knockout* available due to polymorphisms that in some cases result in nonfunctional receptors. ORs belong to one of the most polymorphic gene families. The best known selective anosmia is to isovaleric acid, the ligand of OR11H7, which is one of the main unpleasant component of body odor. About 6% of the human population cannot detect this substance [33.138]. However, the correlation between this anosmia and an actual gene defect has to be confirmed. Another well-described polymorphism is that of OR7D4 which responds to androstenone and its derivatives [33.116]. Different people report a wide range of perceived odors from androstenone and androstadienone, from unpleasant and urinous to sweaty, woody or even pleasantly floral or citrussy, and nearly 30% of the human population claims not to be able to smell these substances at all [33.139, 140]. An increase in knowledge about anosmia and the discovery of more human *knockouts* could immensely contribute to our comprehension about OR expression in nonolfactory tissues.

34. Spices and Odorants as TRP Channel Activators

Kristina Friedland, Christian Harteneck (deceased)

Flavors and odorants are important aspects in our daily life controlling a diversity of selection processes like food intake, social interactions, aversion or love. The detection of flavor and odorant compounds by our sensory organs for taste, olfaction and chemesthesis are important for the detection and discrimination among chemical cues in the environment. Flavors and odorants have impact on food selection as well as social interaction by being influential for feelings of pleasure and discontent, sexuality and mood. Most of flavors and odorants originate from spice plants like capsaicin from chili or vanillin, the odorous principle of vanilla. They activate a large set of receptors and ion channels. In this review, we summarize the recent findings regarding the effects of flavors and odorants on the activity of the transient receptor channel family (TRP) and their potential role in olfaction, taste and chemesthesis. Potential health benefits of spices are discussed in the light of their bioavailability of the flavors and odorants after systemic intake.

Olfaction and gustation, our capability for perception of odors and tastes, depend on detecting and transducing the appearance of chemical structures to electrical activity. The senses are thereby involved in detection of threats, represent lifeguards in the selection of nutrition, but also contribute to social interaction, pleasure and general wellbeing in humans [34.1]. The chemical compounds trigger preference and avoidance reaction by a variety of receptor molecules such as G-protein-coupled receptors, enzyme-coupled receptors or ion channels. G-protein-coupled receptors function as taste and odorant receptors comprising the taste receptors for sweet, umami, or bitter and the canonical odorant receptors, the trace amine-associated receptors, as well as the vomeronasal type 1 and 2 receptors [34.2]. For a comprehensive review summarizing all molecular mechanisms mediating taste, chemesthesis or smell please refer to *Roper* et al. and *Spehr* and *Munger* [34.2, 3].

TRP channels form a large family of nonselective ion channels involved in olfaction, gustation and chemesthesis. Mainly, plant-derived volatile or nonvolatile compounds such as cineol, menthol or capsaicin directly activate TRP channels (Fig. 34.1) contributing to the distinct flavors of individual foods [34.4]. In the following chapter, TRP channels and plant-derived activators, which are involved in taste, chemesthesis and olfaction, are summarized and their potential to cause physiological effects in our body via TRP channel activation beside olfaction, taste and chemosensation is discussed.

34.1 TRP Channels – Olfaction, Chemesthesis and Taste

In the context of olfaction, chemesthesis and gustation mainly, TRP channels of the classical TRP channel subfamily (TRPC) such as TRPC1, TRPC2, TRPC4, TRPC6, of the vanilloid TRP subfamily (TRPV) TRPV1, and TRPV3 of the melastatin subfamily (TRPM) TRPM4, TRPM5 and TRPM8 are dis-

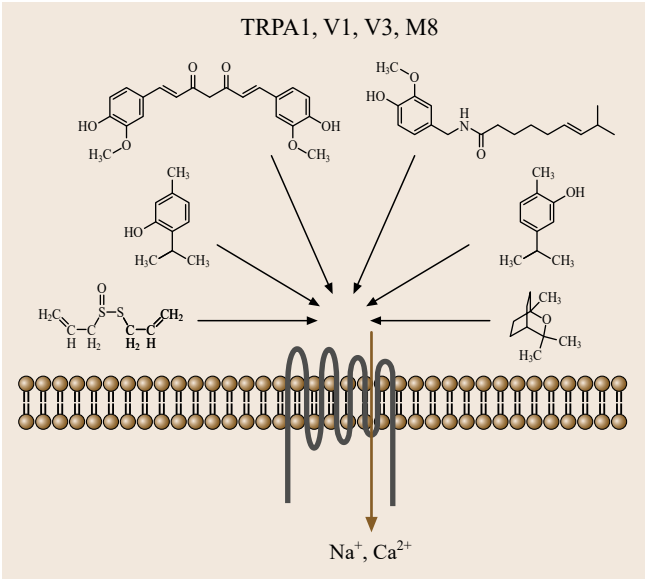

Fig. 34.1 TRP channels in the sensation of plant-derived volatile and nonvolatile compounds

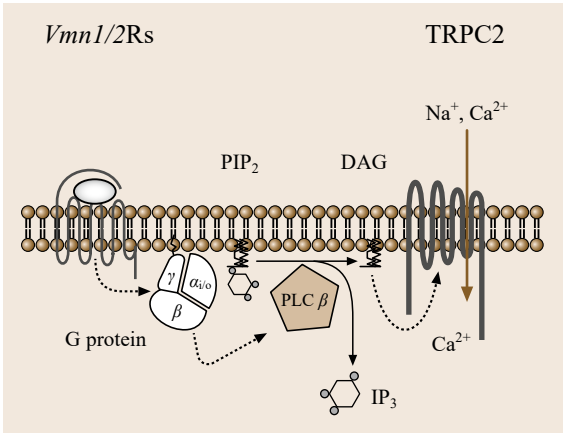

Fig. 34.2 Signal transduction cascade leading to the activation of TRPC2 in the vomeronasal organ

cusses to be involved in the transduction of odor, taste and chemosensation [34.5, 6].

The best characterized TRP channel regarding its role in immediate olfaction is TRPC2 [34.5, 7–11]. In TRPC2-deficient mice, innate sexual and social behavior is altered, comprising impaired sex discrimination, failure to initiate aggressive attacks to intruders, and lowered maternal aggression and lactating behavior [34.7, 8]. In humans, TRPC2 is a pseudogene. TRPC2 is highly expressed in the sensory neurons of the vomeronasal organ responsible for pheromone sensation in rodents modulating innate sexual and social behavior. Pheromones released by the urine of conspecifics are sensed by receptors of the vomeronasal organ *Vmn1r/Vmn2r* transducing the extracellular signal to intracellular processes initiated by G-proteins of the Gi/o family. Subsequent breakdown of phosphoinositides results in the activation of calcium entry mediated by TRPC2 (Fig. 34.2) and subsequent neuronal activity. Other TRP channels belonging to the classic TRP channel subfamily integrated in GPCR signaling are TRPC1 and TRPC4, as well as TRPC6 channels which are expressed in different cells of the olfactory system with a yet unclear role in olfaction [34.5].

From other subfamilies, TRPM5 channels have also been detected in the olfactory systems, in the main olfactory endothelium where pheromones might lead to an activation of TRPM5 channels [34.12].

Like TRPC2, TRPM5 is a downstream target of G-protein-coupled receptors (GPCR). TRPM5 is expressed in taste receptor cells and other chemosensory cells of the taste signaling cascade comprising the large intestine, pancreatic β-cells, duodenum, stomach, lung, brain e.g., brainstem and the vomeronasal organ [34.13]. In enteroendocrine cells of the intestine, TRPM5 regulates the release of the incretine hormons glucagon-like peptide-1 (GLP-1) and gastrin-inhibitory polypeptide as well as the appetite-stimulating hormone ghrelin. GLP-1 upon release reduces food consumption, facilitates gastric emptying and promotes insulin release in response to glucose consumption. In addition, TRPM5 channels directly regulate glucose-mediated insulin secretion in pancreatic β-cells. In enterochromaffine cells of the small intestine, TRPM5 mediates the release of cholecystokinin (CCK), which stimulates gallbladder contraction and suppresses hunger. There might be also a role of TRPM5 in weight control. TRPM5 channels are also expressed in brush cells of the ileum and the colon where they are considered to detect the presence of dietary nutrients.

TRPM5 plays a central role in taste and is required for sweet, amino acid and bitter perception [34.3, 14]. In addition, TRPM5 might also be activated by free fatty acids and may elicit fat taste [34.15]. Ligand-binding to GPCR results in the activation of gustducin and phospholipase Cβ2 mediated breakdown of phosphoinositides (Fig. 34.3). Phospholipase C enzymes generate the intracellular second messenger diacylglycerol and inositoltrisphosphate. The latter being the ligand of IP3 receptors induce the release of calcium from intracellular endoplasmic stores. The increase in intracellular calcium concentration results in activation and membrane depolarization mediated by TRPM5, which is exclusively permeable to monovalent cations.

In contrast to TRP channels of the TRPC family and TRPM5 being integrated in odor and taste signaling cascades, several plant-derived compounds

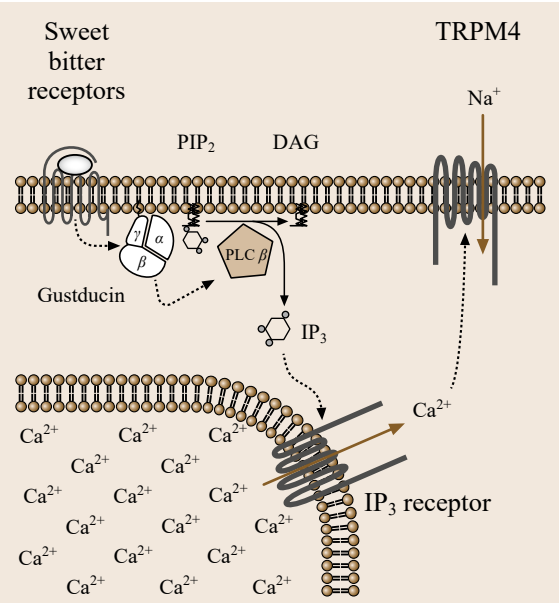

Fig. 34.3 Signal transduction cascade leading to the activation of TRPM5 in taste buds

directly activate TRPA1 (ankyrin), TRPV1, TRPV3 and TRPM8 (Fig. 34.1), which are also involved in mediating trigeminal stimuli and chemesthesis [34.13, 16]. They are activated by a wide range of secondary plant constituents which are summarized in part 2 of this chapter.

The involvement of TRPV1 in salt perception is currently discussed. A polymorphism in the TRPV1 gene (rs8065080, $C > T$, Val585Ile) modifies suprathreshold taste sensitivity where carriers of the T allele were more sensitive to salt solutions [34.17]. However, there are also controversial studies (for an excellent summary please read [34.3]) such as a study in TRPV1 KO (knockout) animals which showed no alteration in the two components, the amiloride-sensitive and amiloride-insensitive salt perception [34.18]. Interestingly, a TRPA1 polymorphism detected in twins was associated with different chemosensory ratings for basil and cilantro [34.19]. Therefore, TRPA1 channels might also be involved in taste perception.

Importantly, these channels are not only expressed in organs involved in olfaction, taste and chemosensation such as nasal trigeminal neurons. Every TRP channel has a specific expression profile. TRPV1 channels, for example, are considered to be expressed in the central nervous system (CNS) comprising the olfactory bulb, the cerebellum as well as the cortex and basal glia [34.13, 20]. However, the exact tissue expression pattern of TRPV1 in the brain is still under discussion because a recent study using a TRPV1 reporter mouse only reported minimal TRPV1 expression in only a few CNS areas. In the periphery, TRPV1 is expressed in kidney, pancreas, testes, uterus, spleen, stomach, small intestine, liver, lung, bladder, skin, skeletal muscle, mast cells, macrophages as well as leucocytes [34.21]. In this chapter, we focus on spices, which activate TRP channels and will discuss their physiological effects in respect to their bioavailability (for a comprehensive review please read the excellent article by [34.13]). The bioavailability of the compounds in food as well as nonfood matrices is questionable. However, these compounds show profound effects on the function of the gastrointestinal and the respiratory system which will be discussed below.

TRPV1, one of the major pain sensing channels for the detection of thermal stimuli and chemical irritants, was also suggested to be involved in visceral pain. TRPV1 channel expression is upregulated in reflux esophagitis and might be involved in heartburn as the major acid sensor [34.22]. TRPV1 immunoreactivity in the gastrointestinal tract is also increased in patients suffering from the irritable bowel syndrome, *Morbus Crohn*, and ulcerative colitis [34.23, 24]. In addition, TRPV1 channels control appetite, satiety, nausea as well as bloating and discomfort [34.25]. However, in TRPV1 KO animals, controversial results were found regarding body weight, therefore its physiological role in metabolism is still under debate [34.25]. Furthermore, several lines of evidence suggest that TRPV1 in rodents regulates the development and maintenance of insulin resistance in Type 2 diabetes [34.13, 26, 27]. TRPV1 activation using acute capsaicin administration by gastric gavage increased GLP-1 and insulin secretion in vivo in TRPV1 wild-type (WT) mice but not in TRPV1 KO mice [34.26]. Furthermore, chronic dietary capsaicin (24 weeks application) not only improved glucose tolerance and increased insulin levels but also lowered daily blood glucose profiles and increased plasma GLP-1 levels in WT mice. In a recent study, TRPV1 KO and WT mice were fed a high-fat diet, and metabolic studies were performed to measure insulin and leptin action [34.28]. The TRPV1 KO mice became more obese than the WT mice after high fat diet, partly attributed to altered energy balance and leptin resistance in the KO mice. In addition, TRPV1 KO mice were more insulin resistant. In the respiratory system, TRPV1-positive nerve fibers innervate the nose, larynx, the trachea of the upper airways, lung parenchyma as well as alveoli and smooth muscle cells and blood vessels [34.29]. However, expression levels in the healthy respiratory system seem to be rather low. In disease-state in patients with emphysema [34.30] or in patients suffering from refractory asthma [34.31], or in other conditions of lung inflam-

mation [34.30], TRPV1 expression is increased. Interestingly, single nucleotide polymorphisms (SNPs) in TRPV1 channels are associated with cough in subjects without asthma and enhanced susceptibility to cough in smokers [34.32]. In childhood asthma, a SNP was described leading to decreased TRPV1 channel activity associated with a lower risk of current wheezing or cough [34.33]. For an excellent review regarding TRP channel function in airway disease, please refer to *Grace* et al. [34.30].

TRPV3 is highly expressed in tongue, testis and skin keratinocytes and is considered to be essential for different skin functions such as skin barrier formation and hair morphogenesis [34.34]. Besides, TRPV3 channels are also involved in heat sensing.

TRPA1 channels are mainly expressed in nociceptive neurons, dental pulp as well as the organ of Corti in the mammalian cochlea [34.35–39]. Furthermore, these channels are also widely expressed in brain, heart, small intestine, lung, skin, skeletal muscle, bladder, prostate, vascular endothelial cells, pancreas and taste cells [34.13]. TRPA1 channels are essential in sensing irritant compounds of our food and harmful airborne irritants [34.30, 40]. TRPA1 are important nociceptors and are involved in epigastric pain in functional dyspepsia [34.41, 42]. They might also be involved in the regulation of gastric emptying (delaying gastric emptying) [34.43], promotion of satiety and suppression of food intake via the release of the gastric peptide cholecystokinin (CCK) [34.44, 45]. TRPA1 channels are also expressed in vagal airway neurons and activation of TRPA1 channels evokes cough in guinea pigs [34.46] and healthy humans suggesting that TRPA1 channels are part of the lungs defense system [34.30].

TRPM8, the cold sensor, is mainly expressed in sensory neurons but also in the bladder, the prostate, hippocampus, skin, brown adipose tissue, vascular smooth muscle, macrophages and sperm [34.13, 47]. Together with TRPA1, TRPM8 represents the cold sensors in human. Noxious cold is mediated by TRPA1 [34.48, 49]. TRPM8 agonists induce a transient body temperature rise by stimulating brown adipose tissue thermogenesis. Therefore, this might be an interesting target to treat obesity [34.50]. In addition, TRPM8 regulates lacrimation and basal tear flow [34.51]. TRPM8 channels are expressed in trigeminal ganglia but only sparsely in whole lung tissue [34.30, 52]. However, TRPM8 channels are expressed in human bronchial epithelial cells [34.53, 54]. The role of TRPM8 in lung in health and disease is rather unexplored even if there is the hypothesis that cough induced by cold air might be initiated via the activation of TRPM8 channels [34.30].

34.2 Secondary Plant Compounds Activating TRP Channels

Different ingredients of flavors and spices are potent TRPA1, TRPV1, TRPV3 and TRPM8 channel activators [34.6, 13, 20, 55, 56]. However, several of these compounds are not selective for one TRP channel or they even also activate other molecular targets, as is the case for curcumin. For TRPC1, TRPC4, TRPC6, TRPM4, or TRPM5, until now no compound isolated from spices is known to activate these channels.

Several pungent and irritant constituents of spices are TRPA1 activators. They are electrophilic compounds, which induce a covalent modification of N-terminal cysteins or lysines of TRPA1 channels. TRPA1 is for example activated by allylisothiocyanate (EC_{50} 22 μM in TRPA1-expressing CHO cells or 2.5 μM in TRPA1-expressing HEK293 cells (HEK: human embryonic kidney cell)) [34.35, 57], allicin (EC_{50} 2 μM) [34.36], diallylsulfide (EC_{50} 125 μM) [34.36], cinnamaldehyde (EC_{50} 61 μM in TRPA1-expressing CHO cells or 6.8 μM in TRPA1-expressing HEK293 cells) [34.35, 58], hydroxyl-α-shangool (EC_{50} 69 μM) [34.58], shogaol (EC_{50} 11.2 μM) [34.58], 6-gingerol (EC_{50} 10.4 μM) [34.57], carvacrol (EC_{50} 690 μM) [34.59], curcumin (pronounced TRPA1 activation in TRPA1-expressing HEK293 cells at 30 μM). Allylisothiocyanate is responsible for the pungent taste of mustard, radish, horseradish and wasabi [34.55]. Allicin gives garlic its specific odor. Allicin is a conversion product when young garlic is chopped and the alliinase converts alliin into allicin which is again degraded to diallylsulfide. Cinnamaldehyde is the ingredient of cinnamon which is important for the flavor and odor of cinnamon. Carvacrol, the isomeric of thymol, is a main component of oil obtained from oregano, thyme, pepperwort or wild bergamotte.

TRPV1 channels are activated by capsaicin (EC_{50} 0.037 μM) [34.58], camphor (5 mM) [34.60, 61], carvacrol (not determined), thymol (EC_{50} 100 μM) [34.62], piperine (EC_{50} 38 μM) [34.63], allicin (51 μM), 6-gingerol (EC_{50} 3.3 μM) [34.57], hydroxyl-α-shangool (EC_{50} 1.1 μM) [34.58], shogaol (EC_{50} 0.2 μM) [34.58]) or eugenol (EC_{50} 10 μM) [34.62] (Fig. 34.2). The hotness of chili peppers is mediated by TRPV1 activation by capsaicin. Camphor has a strong aromatic odor and can be found in evergreen trees, the camphor laurel, kapur trees or dried rosemary leaves. Thymol is found in thyme and

many other different plants. Piperine is the constituent of pepper which induces its pungency. Eugenol is one of the active ingredients of cloves.

TRPV3 channels are activated by eugenol (10 μM) [34.62], carvacrol (0.5 μM) [34.64], camphor (EC_{50} 6 μM) [34.64], incensole (EC_{50} 10 μM) or thymol (EC_{50} 0.9 μM) [34.64].

TRPM8 is activated by menthol (EC_{50} 80 μM) [34.65], linalool, geraniol, or eucalyptol (EC_{50}7700 μM) [34.66].

34.3 Health Benefits of Spices

Most of these compounds have a pungent note, which might even be slightly painful. The question that arises, is why do humans consume hot and pungent spices and what could be the evolutionary advantage [34.67]? There are several hypotheses ranging from hedonic experiences to certain health benefits [34.67]. These potential health benefits were already known in ancient cultures and were passed down to present time. Antifungal, antibacterial effects, anticancer, anti-inflammatory, cytoprotective, cardioprotective as well as anti-pain effects are discussed [34.67]. Pungent spices were first used in countries with subtropical and tropical climate and the addition of antifungal and antibacterial spices to daily food makes perfect sense. However, these effects are not mediated via TRP channel activation. Regarding the other discussed health benefits, the important and still unanswered question remains if the constituents are able to reach pharmacologically active concentrations if they are taken up with the daily food. Most data supporting the protective health effects on cancer, inflammation or the cardiovascular system are mainly epidemiological studies. In the case of epidemiological studies, it is very hard to distinguish whether the intake of a certain spice or the overall life style might influence the prevalence of certain diseases. Further supporting data comes from preclinical studies using cell and animal models where often very high concentration of the respective compound is used. Whether or not the required concentration can be reached by daily consumption of spices in our food or by intake of highly enriched food supplement is controversially debated. Only for a few compounds, data regarding bioavailability is available. One of the best-investigated molecules is curcumin, which is the principal curcumimoid of turmeric [34.68]. Its bioavailability is low; several clinical trials investigate its anticancer properties in patients suffering from pancreatic cancer where curcumin was applied in a high concentration of 8 g/d, a plasma concentration of 85 ng/ml was reached [34.69]. However, the plasma concentration, which would need to be achieved to activate TRPA1 channels, is 100-fold higher. Even if we assume that a certain accumulation in different organs is possible, this concentration gap between the detected plasma concentration and the concentration needed to activate TRPA1 channels seems to be too pronounced. In daily food consumption, around 250 mg curcumin in an indian curry can be reached. This complex food matrix also contains fatty ingredients and surfactants such as lecithin which might improve curcumin absorption [34.13]. However, the pharmacological needed concentration will probably not be reached by daily food consumption. In addition, several TRP activating compounds also activate other targets, which might also contribute to beneficial effects in the mentioned diseases. Again, curcumin is a very good example. Over 30 targets are discussed such as the nuclear transcription factor NF-$\kappa\beta$, the matrix metalloproteinase, the cyclooxygenase-2, or the vascular endothelial growth factor just to name a few [34.70]. For most odorants and spices further data is required to estimate if they might have systemic effects after they are inhaled or orally consumed.

The best-characterized spice ingredient regarding its effects on gastrointestinal function and weight control is the selective TRPV1 activator capsaicin. Capsaicin inhibits gastric acid secretion in modest concentrations which can be reached by spicy food consumption and also shows protective effects in the gastric mucosa [34.71, 72]. However, in higher concentrations capsaicin is able to enhance gastric acid secretion and to damage the gastric mucosa confirming an old toxicologic/pharmacologic principle *the dose makes the poison*. Capsaicin also shows an antibacterial effect against Helicobacter pylori, the main trigger for gastric ulcer. However, its protective effect is not mediated by TRPV1 activation. Similar effects on gastric acid secretion and protective effects on mucosal integrity are also described for 6-gingerol, also a TRPV1 activator [34.73].

In addition, an increase in TRPV1 receptor expression was detected in the gut mucosa of patients with conditions associated with visceral hypersensitivity, including in the esophagus of patients suffering from the nonerosive reflux disease and in the colon of patients with irritable bowel syndrome (IBD) belonging to the class of functional gastrointestinal disorders (FGID) [34.74]. Patients with functional dysplasia

and IBD show a hypersensitivity to singular oral capsaicin application reflected in higher abdominal pain and burning symptom scores. These results and others from animal experiments suggest that the hypersensitivity of TRPV1 pathways in patients with FGID is likely a result of low-grade inflammation and may be an important pathogenesis of gut hypersensitivity, abdominal pain, and abdominal burning symptoms in FGID [34.74].

However, chronic ingestion of capsaicin is considered to have different effects due to TRPV1 desensitization. A small clinical trial in 30 patients suffering from functional dyspepsia receiving 2.5 g/d of red pepper powder or placebo showed that the overall symptom scores, epigastric pain, and nauseas improved compared to placebo [34.75, 76]. In a clinical trial including 50 patients with IBD treated with 600 mg red pepper/d, abdominal pain and bloating mean score values was reduced in week 6 of the treatment compared to placebo [34.77]. These results are supported by the epidemiological findings that the prevalence of heartburn is much lower than the prevalence of acid regurgitation in Asian countries with a high intake of spiced food compared to western countries [34.74]. However, further clinical trials are needed to confirm the hypothesis that chronic chili intake might facilitate pain and burning symptoms in FGID patients.

Several lines of evidence suggest that TRPV1 agonists, especially capsaicin, trigger cellular mechanisms against obesity. In a clinical trial, healthy lean individuals received once a hedonically acceptable red pepper dose of 1 g/d. Postprandial energy expenditure and core body temperature were increased, and skin temperature was lower after the intake of red pepper [34.78]. Interestingly, the desire to consume fatty, salty, and sweet foods were decreased more in the individuals who did not consume spicy food regularly before. This finding suggests a desensitization of individuals with long-term intake of spicy foods. Two recent meta-analyses recapitulate clinical trials investigating the effects of capsaicin and the nonpungent TRPV1 activator capsiate found in CH-19 sweet peppers [34.79, 80]. The authors conclude that the studies provide evidence for the role of capsaicin and capsiate on weight control [34.79, 80]. However, the magnitude of the thermogenic and appetitive effects is small and their long-term sustainability is uncertain. The authors calculate that a 10 kcal negative energy balance, which is predicted for hedonically acceptable capsaicin doses in an average weight, middle-aged man would produce an ultimate weight loss of 0.5 kg over 6.5 years, whereas a 50 kcal negative energy balance (predicted for encapsulated dihydrocapsiate) would yield a total weight reduction of 2.6 kg over 8.5 years [34.79]. Several mechanisms of action are discussed ranging from the enhanced expression of proteins involved in lipid catabolic pathways and thermogenesis in skeletal muscle, liver or white fat tissue. Capsaicin was also found to stimulate the brown adipose tissue which is a metabolic active tissue responsible for nonshivering thermogenesis [34.13].

TRPA1 channels are expressed in cranial visceral vagal neurons. These neurons convey chemical signals from the gut to the solitary nucleus participating in peripheral satiety signaling as mentioned above. The TRPA1 agonist cinnamaldehyde, one of the active ingredients of ginger, reduced cumulative body weight gain and improved glucose tolerance without affecting insulin secretion in obese mice in a daily dosage of 250 mg/kg BW reflecting a daily dose of 3 g [34.81]. This dosage can only be reached by food supplementation and not as a hedonically pleasant ingredient of our daily food. 1 g of a specific Ceylon cinnamon hydroalcoholic extract reduced postprandial glycemia in 18 healthy volunteers by 21% without affecting insulin secretion [34.82]. However, these initial results need to be supported by additional clinical trials in obese patients.

Interestingly, the food supplementation with TRPM5 inhibitor quinine (0.1%), which tastes bitter, showed in mice fed with a regular balanced diet a significantly lower increase in body weight and fat mass [34.83]. However, no clinical data is available which would support these preclinical results.

Another organ where pharmacologically active concentration of TRP channel activators can be reached is the lung. Menthol, camphor as well as eucalyptus oil are the active ingredients of Vicks Vaporub and are traditionally used as topical agents to relieve symptoms of chest congestion or other upper respiratory disorders [34.84]. Interestingly, many remedies contain menthol to counteract coughs. In conscious guinea pigs, the antitussive effect of menthol, 1,8-cineole and camphor was investigated. Menthol showed the best activity and reduced the cough frequency at concentrations of 3 and 10 µg/kg about 28 and 56%, respectively [34.85]. Its antitussive effects are considered to increase mucosal blood flow, relief in bronchoconstriction and direct or indirect effects on cough-initiating sensory neuronal pathways [34.66, 86, 87]. Importantly, in patients with chronic cough, pre-inhalation of menthol reduces cough sensitivity to inhaled capsaicin and influences inspiratory flows [34.88]. However, the outcomes of clinical trials using menthol against cough, which was initiated by a single application of capsaicin or citric acid, are controversial with positive effects [34.89, 90] as well as no effects [34.91] on cough suppression. These differences might be due to the administration route – menthol inhalation seems to be more effective than topical application of menthol. The underlying molecular

mechanism of cough suppression by menthol seems to be initiated by a reflex initiated from the nose via TRPM8 channels [34.92, 93].

The suppression of respiratory irritation by menthol is also used in cigarettes. Menthol is present in 90% of commercial cigarettes sold in the United States including brands which are not labeled to be mentholated [34.94]. Epidemiological studies suggest that mentholated cigarettes are preferred in young smokers and thereby might increase smoking initiation [34.95]. In addition, smoking menthol cigarettes seems to be associated with reinforcing nicotine dependence, impeding cessation, and promoting relapse compared with nonmenthol smoking [34.96]. How does menthol interfere with smoking? Cigarette smoke contains numerous irritants that stimulate chemosensory nerves. *Willis* and *Morris* [34.97] investigated the effects of 16 ppm menthol in mice, which is a concentration lower than found in the smoke of mentholated cigarettes (200 ppm $\approx$ 8 μM) on the respiratory sensory irritation response in mice elicited by the smoke irritants acrolein, acetic acid and cyclohexanone. Importantly, menthol was absorbed with high efficiency ranging from 65% or greater depending on the experimental group. Menthol as well as eucalyptol immediately suppressed the irritation response to acrolein, acetic acid and cyclohexanone via TRPM8 and thereby act as potent counterirritants against a broad spectrum of smoke constituents. These effects of menthol might interfere with smoke inhalation and thereby might promote nicotine addiction and smoking-related morbidities such as lung cancer.

Campher is an agonist of the heat sensing channel TRPV3 [34.60, 61], a partial agonist of TRPV1 [34.60], and an antagonist of the noxious cold sensor TRPA1 [34.60]. Interestingly, camphor shows a bimodal activity on TRPM8, it activates TRPM8 but also inhibits the response to menthol [34.98]. Camphor is also used traditionally to treat cough. Recently, *Patberg* et al. suggested that camphor might mediate its antitussive effects via TRPV1 channels [34.99]. They demonstrated that camphor initially stimulates but then strongly desensitizes TRPV1. However, camphor is not a selective TRPV1 desensitizer but also inhibits TRPA1 channels which are also involved in bronchoconstriction [34.60], and also activates TRPM8 channels which are also involved in antitussive action [34.98].

34.4 Negative Effects of TRP Channel Activators

Another organ where the pharmacologically active concentration of capsaicin is reached to activate TRPV1 channels is the lung. Everyone knows the tussigenic effect of inhaled red pepper powder. Importantly, capsaicin is slowly degraded in the lung and the metabolic inactivation is incomplete at the pulmonary level. In patients suffering from the cough variant of asthma as well as from the sensory airway hyper-reactivity syndrome, capsaicin provokes an exaggerated cough response [34.100, 101]. Therefore, these patients should be extremely cautious eating spicy food.

In addition, menthol should be used with caution in small children or patients suffering from asthma or chronic obstructive disorders because menthol might trigger an uncontrolled upper airway muscle reflex resulting in spasms and significant breathing difficulties [34.102]. It might also cause allergic reactions.

Umbellone, a TRPA1 activator, is known as the major volatile constituent of the leaves of the California bay laurel, which is also known as the *headache tree* because inhalation of its vapors can cause severe headache. Inhalation of umbellone caused a painful cold sensation in the nasal mucosa. *Nassini* et al. [34.103] demonstrated that umbellone induced a calcium-dependent release of calcitonin gene-related peptide (CGRP) from rodent trigeminal nerve terminals in the dura mater. Release of CGRP seems to play a prominent role in the activation of specific brain areas and the trigeminovascular system.

34.5 Conclusion

Several molecular constituents of spices and flavors are potent TRP channel activators. They are not only involved in the smell, taste or chemesthesis of our food but are also discussed to mediate health benefits in several diseases including gastrointestinal diseases, cancer, inflammation, pain just to name a few. Several preclinical experiments including cell and animal experiments and epidemiological data support this view. However, the bioavailability of the molecules often embedded in complex matrices is very low enabling to scrutinize their systemic effects. However, in the gastrointestinal system as well as the pulmonary system, the pharma-

cologically active concentrations are reached. In these organs, spices show pharmacological effects which are beneficial such as the moderate effect of TRPV1 agonists on weight control or the antitussive effect of menthol mediated by TRPM8 channels. Further research is needed to clarify the potential role of several odorants and spices in health and diseases. In addition, several odorants and spices as well as their metabolites are not yet investigated regarding their effects on TRP channels.

35. Anti-Inflammatory Effects of Odor Compounds

Jessica Walker, Veronika Somoza

Food-derived odor compounds determine the flavor of foods. However, these volatile compounds are known to elicit biological activities beyond their flavor function. Plants rich in volatile compounds, for example mint, have been used in traditional medicines worldwide to improve wound healing and to treat inflammation-related illnesses. In this chapter, we focus on the anti-inflammatory activity of different plant essential oils and individual odor compounds. Here, it is reviewed that odor compounds possess anti-inflammatory activity in pre- and postabsortive model systems, in vitro, ex vivo, and in vivo. Monocytes, macrophages, and fibroblasts are cells that play an important role in the innate immune response. In vitro models of these cells are commonly used to identify the mechanisms of action of the anti-inflammatory activity of volatile compounds. An inflammatory stimulus initiates the toll-like receptor-mediated signaling pathway, resulting in the gene expression and further the release of cytokines. Thus, an anti-inflammatory effect of odor compounds is measured by a reduction of cytokine messenger ribonucleic acid (mRNA) expression or release from stimulated cells. For example, eucalyptol, borneol, and camphor have been identified as anti-inflammatory active compounds that may be used to prevent or treat inflammation-related diseases.

35.1 Relevance of Identifying Anti-Inflammatory Active Odor Compounds

Increased standard of living has caused the population to constantly grow older. This wealth has been accompanied by an increase in average body weight, cases of obesity, and obesity-associated diseases. Among those diseases are cancer, coronary heart diseases, and diabetes mellitus type II, which have also been linked to

chronic inflammation [35.1–3]. Increasing rates of patients with chronic inflammatory diseases show the urge of treatment and prevention. Thus, research focused on counteracting inflammation by treatment with anti-inflammatory compounds. The advances in research on an anti-inflammatory activity of aroma active compounds are determined by technological progress in the field of analytical food chemistry and sensory, the access to documentation of traditional medicines and the biochemical and molecular biological research investigating inflammatory signaling. Odorants are small volatile molecules that interact with chemical receptors in the olfactory cells. However, these small molecules are discussed to exhibit biological activities beyond their odor activity.

35.1.1 Analytical Advances in Chemistry of Odor Compounds

The flavor of foods and beverages is determined by the composition of odorants and gustatory compounds, responsible for aroma and taste, respectively. The aroma is characterized by the interaction of different compounds in the essential oil. However, the essential oil constituents that contribute to the flavor are called key aroma compounds. These key compounds, may not necessarily dominate in quantity, but have a low aroma threshold level [35.4, 5]. Sensory analyses determine flavor thresholds of volatile compounds, allowing the identification of flavor profiles and characteristics of foods [35.4]. Moreover, method development played a crucial role in the analytics of flavor compounds. Here, olfactory gas chromatography [35.6] allows the simultaneous detection of a compound by chromatography and the assertion of its smell. These advances in analytical chemistry over the past decades allowed the identification and quantification of hundreds of aroma compounds in different natural and processed foods [35.7, 8] and beverages [35.9–11].

35.1.2 Odor Compounds Used in Traditional Medicine to Treat Inflammation

One strategy to identify anti-inflammatory active compounds is to search for the literature reports about plants used in traditional medicines to treat pain, fever, and local inflammation and test their anti-inflammatory potential. The access to historic documents and the preservation of traditional uses of plant material allows the gain of knowledge in which plant and plant preparations have been used to treat symptoms of inflammation.

Little is known about traditional medicines of South America and Africa. In Europe, historic documents like the *Naturalis historia* by Pliny the Elder report about the use of plants to treat health problems, for example, mint to treat headaches, gastric problems, and nose malfunctions when drinking or inhaling mint juice. Today, mint aroma is not only popular in beverages, drops, or chewing gums, but is also used in hygienic products, toothpaste, or medical formulations for inhalation. Even though alternative medicine exists in many Western countries, the majority of people use pharmaceutical products to treat illnesses and diseases. In contrast, the practice of traditional medicine is still very common in China, but the documentation is sparse. The Western approach to use Chinese medicine in drugs was to identify individual compounds for testing their individual pharmaceutical impact on different diseases. Traditionally, herbs, herbal extracts and plant extracts are used in combination, which hinder the identification of active ingredients and also raise the question whether combinatory effects are required to gain curing success. However, to prove a potential anti-inflammatory activity, both extracts and individual compounds are to be considered.

35.1.3 Traditional Applications of Odor Compounds

Traditionally, odor compounds were not used as individual products but in complex mixtures, like infusions, crèmes, or pastes. Reports include the use of plants to treat inflammation, symptoms of inflammation like swelling or fever, or inflammatory-linked diseases like tooth aches or cardiovascular diseases. A review article summarized the medicinal plants used in Chile and their applications, for example, treatment of inflammatory diseases [35.12]. The described application forms range from chewing stem latex to treat tooth

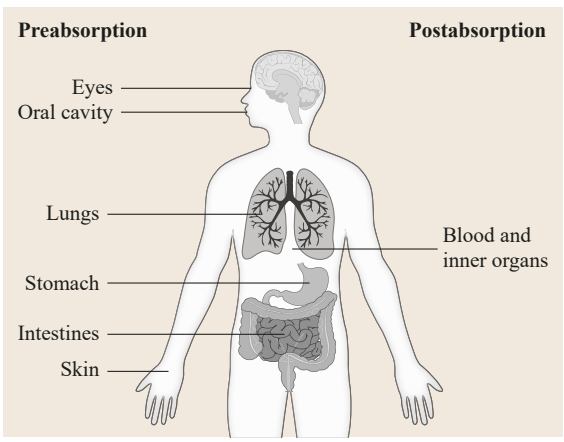

Fig. 35.1 Target sites of plant extracts containing odor compounds to treat inflammation

aches to topical applications and infusions of leaves and stems. Infusion of *Cestrum parqui* stem and leaves were used to treat inflammation, coughs, heart and bladder pain, stomach ache, and also for wound washing [35.12].

In African medicine, infusions and decoctions were the preferred forms of medical preparations for cattle. The plant infusions were either applied topically or as drinks. The preference toward fresh plant material indicates a role of odor compounds [35.13]. Italian traditional medicine used infusions of chamomile to treat eye inflammation and skin conditions like dermatitis [35.14]. Chamomile has been registered as a medicinal plant in Germany for treating mucous membrane and skin inflammation as well as bacterial skin disease.

In summary, plant extracts containing odor compounds are widely used to treat symptoms of inflammation systemically as well as directly. Figure 35.1 summarizes the pre- and postabsorptive inflammatory sites, where plant extracts containing odor compounds have been described as beneficial. Treatment of inflammation of skin, eyes, oral gum, or mucosal tissue of the gastrointestinal tract and the lung do not require absorption of the odor compound. In contrast, a treatment of symptoms like fever and pain may require the absorption of the odor compounds, including possible structural changes of the compounds upon metabolism.

35.2 Mechanisms Underlying the Anti-Inflammatory Activity

The mechanisms underlying ananti-inflammatory activity are closely connected to the mechanisms inducing inflammation. Inflammation, as part of the innate immune response, is a reaction of an organism to pathogens, for example, viruses or bacteria. If pathogens pass the mechanical barriers (Table 35.1), they enter the body, may damage cells and allow foreign substances (antigens) to enter the organism. Antigens can be proteins, toxins, or other foreign chemicals that are specific for a pathogen. Thus, bacterial endotoxins or the filament protein flagellin or viral ribonucleic acid (RNA) represent potential recognition targets. In the host, immune-active cells detect and react to these antigens. Toll-like receptors play a crucial role in the detection of antigens from viruses and bacteria and transmit the information by signaling cascades.

Table 35.1 Key factors of the mechanical, cellular, and humoral innate immune response

Defense type	Barrier	
Mechanical defense	Skin	*Sweat*
	Gastrointestinal tract	*Gastric acid*
	Nasopharynx	*Saliva*
	Lungs	*Mucus*
	Eyes	*Tears*
Cellular defense	Epithelial cells	
	Fibroblasts	
	Natural killer cells	
	T-Cells	
	Phagocytes	
Humoral defense	Chemokines	
	Interleukins	
	Enzymes	
	Adherence factors	
	Interferons	

35.2.1 Antigen Detection by Toll-Like Receptors

The mammalian toll-like receptor (TLR) family can be divided into at least 11 members and are part of the pattern recognition receptors. Humans possess functional TLRs 1 to 10, while TLR11 has only been found to be functional in mice. Toll-like receptors are trans-membrane proteins and are located in the outer membrane as well as in the endosomal membrane intra-cellular [35.15, 16]. TLR2 forms heterodimers with TLR1 or TLR6 and recognizes a variety of patterns, while other TLRs are active as monomers or homodimers with specific ligands. The ligand-binding domain is located in the extra-cellular region or in the endosome. The cytosolic Toll/IL-1 receptor (TIR) domain of TLRs is linked to an adaptor protein, myeloid differentiation primary response gene 88 (MyD88) or TIR-domain-containing adapter-inducing interferon-β (TRIF) [35.17].

The different types of TLRs (TLR1-9) recognize different specific patterns, so-called pathogen-associated molecular patterns (PAMPs) [35.18]. The patterns recognized by the TLRs are diacyl or triacyl lipopeptides, flagellin, lipopolysaccharide (LPS), single or double stranded RNA, or CpG desoxyribonucleic acid (DNA), all different types of microbial components. LPS is one of the most effective PAMPs and is known to activate TLR4 [35.19]. However, it has been shown that LPS from an oral bacterium, *Porphyromonas gingivalis*, is recognized by TLR2 and exploits different actions as *Escherichia coli* LPS [35.20]. Thus, the TLR type responsible for the recognition of LPS depends on the source and structure of the endotoxin. Ligand binding to a TLR results in the onset of signaling cascades

and gene expression (Fig. 35.2), depending on which TLR is activated [35.17].

35.2.2 Intracellular Signaling Pathways Involved in Inflammation

The most important signaling pathway involved in inflammation is the nuclear factor kappa B (NF-κB) pathway (Fig. 35.2). In immune active cells, cytosolic NF-κB is bound to inhibitory kappa B (IκB) and thereby inactivated. After ligand binding to TLRs, the adaptor molecule MyD88 recruits an intracellular interleukin-1 receptor-associated kinase (IRAK) in the cytosol, which activates TNF receptor-associated factor 6 (TRAF6). This signal molecule further activates the IκB kinase (IKK) complex, which phosphorylates IκB resulting in a cleavage of IκB and NF-κB [35.21]. The free NF-κB migrates into the nucleus and binds to NF-κB binding sequences in the DNA, leading to a gene expression of inflammatory cytokines in the early phase and interferon-β (IFN-β) in the late phase. TLRs that are linked to TRIF mediate a signal via kinases (e.g., IKK) resulting in the activation of the interferon regulatory factor 3 (IRF-3) and gene expression of IFN-β [35.22].

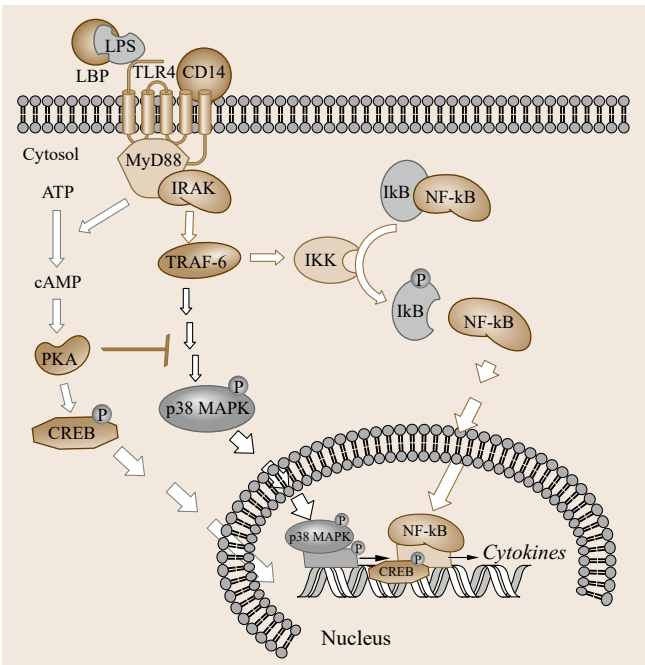

Fig. 35.2 Toll-like receptor 4 (TLR4)-mediated signaling. Lipopolysaccharides (LPS) and LPS-binding protein (LBP) activate the complex of TLR4 and CD14, leading to the recruitment of IL-1 receptor-associated kinase (IRAK) by the adaptor protein MyD88. TRAF6 further activates inhibitory kappa B (IκB) kinases (IKK), which phosphorylate IκB, inducing its cleavage from NF-κB. TRAF6 also induces elements of the p38 MAPK pathway, resulting in the phosphorylation of p38 MAPK. In the nucleus, both NF-κB and pp38 MAPK induce the gene expression of cytokines. Induction of the TLR also activates cAMP-mediated signals, inhibiting the MAPK cascade

Additionally, other signaling pathways, the mitogen-activated protein kinase (MAPK) pathway (Fig. 35.2), have been shown to be involved in inflammatory gene expression. TLR-stimulated TRAF6 activation also leads to the onset of the p38 MAPK phosphorylation cascade. In the nucleus, p38 MAPK phosphorylates and, thereby, activates transcription factors leading to the expression of genes encoding pro-inflammatory factors [35.23, 24].

Furthermore, TLR-independent signaling pathways, including cyclic AMP (cAMP) and calcium signaling, modulate the TLR signaling cascades (Fig. 35.2). Protein kinase A, activated by cAMP, inhibits elements of the MAPK pathway and also phosphorylates and activates cAMP responsive element binding protein (CREB). After entering the nucleus, pCREB competes with NF-κB for the binding site on CREB-binding protein and thereby inhibits the NF-κB-induced gene expression of pro-inflammatory cytokines [35.22].

35.2.3 Pro-Inflammatory Factors Induced by TLR Signaling

The stimulation of TLRs results in the mRNA expression of pro-inflammatory cytokines and enzymes, for example, inducible nitrite oxidase (iNOS) or cyclooxygenase-2 (COX-2). After mRNA expression and translation, iNOS produces NO, which is released by the immune cells as an anti-microbial compound. The COX-2 protein triggers the reaction of arachidonic acid to prostaglandins. Prostaglandin E2 (PGE2) has been known as a pro-inflammatory factor in the early stage of inflammation. However, in later stages of the inflammatory process, PGE2 activates the cAMP pathway and inhibits functions of NK cells or granulocytes [35.21, 22, 25].

Cytokines include chemokines, tumor necrosis factors (TNF), interferons, lymphokines, and interleukins (IL). The nomenclature does not follow a specific pattern. One strategy was naming after the location of production: monokines (monocytes), lymphokines (lymphocytes), and originally interleukins (leukocytes). However, interleukins can also be produced and released by other cell types, such as fibroblasts. Furthermore, it has been shown that IL-8 may also be considered a chemokine. Chemokines are named after their function (chemotraction), recruiting immune cells to the center of inflammation. All cytokines bind to specific receptors and mediate a target signal.

35.3 Assessing the Anti-Inflammatory Activity of Odor Compounds

Inflammation plays a crucial role in the defense against pathogens. During inflammation, partial tissue destruction is used to remove the pathogens from infected cells by cells of the immune system, macrophages or T-cells. Local tissue cells like fibroblasts are known to recruit leukocytes by releasing pro-inflammatory cytokines [35.26]. If the epithelial cells continue their immune activity beyond the fight against pathogens, chronic inflammation may lead to the development of an inflammatory disease, for example, inflammatory bowel disease [35.27] or asthma [35.28]. Nevertheless, inflammation is an important part of the innate immune response and is controlled by the presence of mechanical, cellular, and humoral immune defense (Table 35.1). The body reacts to an attack with the following symptoms: swelling, redness, loss of function, and heat. The latter is also responsible for the term *inflammation* which means *setting on fire* or *ignition*.

To assess an anti-inflammatory activity, immune competent model systems need to be chosen. The outcome markers of an immune response are mRNA expression and release of cytokines. Thus, model systems of the innate immune response, expressing, or releasing cytokines, are the most common cell models in investigations of anti-inflammatory effects. Endothelial cells, fibroblasts, monocytes, macrophages, and peripheral blood mononuclear cells (PBMCs) provide immune competence and are therefore preferred in vitro or ex vivo model systems. However, an effect seen from in vitro experiments should be confirmed in vivo. Here, working with odorants, originating from foods, ethically allows both animal studies and human intervention studies. Effects that require an induction of inflammation using LPS or other toxins may be done in animal models or using ex vivo experimental settings.

35.3.1 In Vitro Cell Models to Investigate Anti-Inflammatory Effects of Odorants

The choice of an in vitro cell model is determined by the research question and how the test compounds enter the organism. Odorants that can be inhaled may pass through the skin, or are consumed with foods. Thus, a variety of endothelial cells, lung, oral or esophageal, as well as connected fibroblasts serve as a well-established immune active model systems. Human gingival fibroblasts (HGF) are known to express TLRs and respond to stimulation with different types of LPS [35.29]. The cell line HGF-1 expresses mRNA and release cytokines, IL-6 and IL-8, upon stimulation with LPS from *P. gingivalis* for at least 6 h [35.30]. Thus, HGF-1 cells have been established as a cell culture model to investigate anti-inflammatory effects of food compounds or orally ingested extracts [35.31]. However, the endothelium is the first barrier of the oral cavity in response to pathogens. Thus, an oral endothelial cell-line is also used as a model system to study the anti-inflammatory properties of food constituents on periodontal tissue. These cells have shown to respond to 24 h stimulation with 10 $\mu g\,ml^{-1}$ LPS from *P. gingivalis* with an increased release of IL-6, IL-8, and CCL-5 [35.32].

Furthermore, pharmacokinetic studies showed that after consumption, volatile compounds or their metabolites can be detected in plasma. In rats, α-cedrene was detected in the plasma in concentrations of up to 2.4 μM after oral administration of 25 $mg\,kg^{-1}$ [35.33]. After intake of 30–40 oz lemonade, peak plasma concentrations of the main limonene metabolite perillic acid were reached within the first hour with $37 \pm 24\,\mu M$ in 12 healthy volunteers [35.34]. Thus, blood cells, involved in the innate immune response, may also serve as model systems. Especially, monocytes and macrophages are widely used as cell model system to investigate the effects of odor compounds and their respective plasma metabolites. Different animal, murine macrophages (RAW 264.7), and human, THP-1 or U937, cell lines have been established. Both, THP-1 and U937 cells are monocytic cells which can be differentiated into macrophages using phorbol esters, for example, phorbol 12-myristate 13-acetate. LPS stimulation leads to mRNA expression of *iNOS*, *COX-2*, *TNF*α, and different interleukins (*IL-1*β, *IL-6, IL-8*, and *IL10*) in THP-1 monocytes and macrophages. Therefore, these cell lines were established as model systems to identify anti-inflammatory effects of food compounds [35.35]. In differentiated U937 cells, IL-1α/β, IL-6, and TNFα mRNA expression have been detected, and an anti-inflammatory effect of the red wine constituent resveratrol and its monosulfated metabolite has been determined [35.36]. The advantage of the murine cell line RAW 264.7 is that no differentiation is needed to obtain macrophages, which also can be stimulated to express pro-inflammatory cytokines [35.37].

Experimentally, different strategies can also be chosen for the determination of preventive or therapeutic effects. For a preventive effect, a preincubation with the potential anti-inflammatory compound followed by stimulation of the immune response, should be the experimental set-up. In contrast, co-incubation of the

compound with a stimulant shows the therapeutically anti-inflammatory potential of the compound in the presence of a given pathogen or endotoxin.

35.3.2 In Vivo and Ex Vivo Experimental Settings to Investigate Anti-Inflammatory Effects of Odorants

In vivo studies primarily focused on the reduction of symptoms related to inflammatory diseases, testing for anti-asthmatic [35.38], anti-colitis [35.39], or wound-healing [35.40] effects of odor compounds in animal model systems. In contrast, human intervention studies on anti-inflammatory effects of food constituents are sparse. No conclusive data on anti-inflammatory effects of odor compounds in vivo have been collected. Broadening the search for information, including gustatory compounds, the bitter tasting flavonoids can be referred to as aroma-active compounds. A meta-analysis of the effects of flavonoids on the plasma concentrations of TNF-α and IL-6 showed no effect of the flavonoid on either of the two parameters in a random model. However, decreased levels of plasma TNF-α were detected with a fixed effect model after flavonoid intake [35.41].

Ex vivo studies generally use whole blood [35.42] or biopsied tissue [35.43], and stimulate an immune response outside the organism. Moreover, investigation directed toward anti-inflammatory diseases of the oral cavity may be done in primary gingival endothelial cells. These cells, isolated during dental surgery, can be treated with LPS ex vivo [35.44].

35.4 Identification of Anti-Inflammatory Odorants

Foods rich in essential oils are fruits, herbs, and spices. Essential oils of all of these foods have been studied for their anti-inflammatory potential. However, in the essential oil of a plant, a variety of different structured molecules are present. Aromatic food constituents can be separated into different groups, according to their chemical structure, for example, aldehydes, phenols, lactones, or terpenes. Previous research studies of anti-inflammatory effects of odorants either used the crude essential oil or further identified individual compounds of the essential oil that are responsible for the anti-inflammatory effect. Furthermore, depending on the target site (Fig. 35.1), absorption and structural changes to the compounds due to metabolism have to be considered. Preabsorption target sites, the oral cavity or the lung mucosa, are in direct contact with the essential oil, while in the blood metabolites may be present in higher concentrations than the parent odor compounds.

35.4.1 Anti-Inflammatory Effect of Odor Compounds Preabsorption

In previous studies, our research group has shown anti-inflammatory effects for odor compounds on cells of the oral cavity. Orange juice essential oil was shown to reduce the intra-cellular IL-6 concentration in buccal cells [35.45]. The orange juice volatile, α-terpineol, has been identified as the anti-inflammatory active compound, reducing intra-cellular IL-6 concentration in buccal cells, stimulated with PMA/ionomycin (PMA: phorbol-12-myristate-13-acetate) [35.45]. In HGF-1 cells, sage infusion inhibited the PMA/ionomycin-stimulated release of IL-6 and IL-8. The volatile fraction was analyzed using gas chromatography with mass spectrometry (GC-MS) and five compounds were identified, 1,8-cineole, borneol, camphor, and α- and β-thujone. These individual compounds exploited anti-inflammatory properties in sage infusion representative concentrations. Furthermore, using a combination of the individual compounds, reconstituting the essential oil, inhibited the PMA/ionomycin-stimulated IL-6 and IL-8 release, proving that the volatile compounds contribute to the anti-inflammatory potential of sage infusion [35.46].

While limited information is available on the anti-inflammatory effect of thujone, borneol, and camphor as individual compounds, the anti-inflammatory potential of eucalyptol (1,8-cineole) has been investigated in vitro and in vivo. Thereby, one research group focused on the anti-inflammatory activity of 1,8-cineole with regard to a treatment of airway infections. In animal models, the monoterpene decreased biomarkers of colitis [35.47] and attenuated LPS-induced lung inflammation by suppression of TLR4 and NF-κB expression [35.48]. Moreover, in a double-blind placebo-controlled human intervention study, 200 mg cineole, administered three times per day over a period of 6 months improved the symptoms of asthma, respiratory rate, and subjective quality of life [35.49]. A similar study was performed by *Juergens* et al. [35.50], using the same dose of cineole and also investigating a beneficial effect of the compound against asthma. After 12 weeks of intervention, the patients who received cineole tolerated lower doses of steroids and were stable on lower steroid doses for a longer period of time than the patients of the placebo group.

35.4.2 Postabsorptive Anti-Inflammatory Activity of Odor Compounds

Various essential oils and individual odor compounds have been tested for an anti-inflammatory potential in postabsorption test systems, monocytes, and macrophages. The essential oil of striped African pepper, traditionally used to flavor soups, was demonstrated to possess anti-inflammatory properties in vitro. In concentrations $\geq 6\,\mu g\,ml^{-1}$, this essential oil inhibited the $1\,\mu g\,ml^{-1}$ LPS-stimulated NO production in RAW 264.7 macrophages after a 24 h co-incubation [35.51]. In the same test system, essential oil of cinnamon (*Cinnamomum osmophloeum*) inhibited the LPS-induced NO production by 69% and the PGE_2 release by 65% in concentrations of 25 and $10\,\mu g\,ml^{-1}$ cinnamon twig essential oil, respectively [35.52]. α-Thujone (48.3%), β-thujone (12.7%), and camphor (6.7%) have been identified as the main constituents of the essential oil of *Artemisia fukudo* Makido, a plant used in South Korea and Japan to flavor cosmetics. The essential oil of this plant was shown to inhibit NO and PGE_2 production, *iNOS* and *COX-2* mRNA expression as well as cytokine mRNA expression and release via the MAPK and NF-κB pathway in LPS-stimulated RAW 264.7 macrophages [35.53].

Furthermore, essential oils of common herbs used to flavor food exploit anti-inflammatory properties systemically [35.54]. Rosmary (*Rosmarinus officinalis* L.) oil inhibited the leukocyte migration in different animal model systems for inflammation [35.55, 56]. In a murine macrophage model, *Thymus vulgaris* L. essential oil inhibited the mRNA expression of *iNOS* and NO release. In THP-1 cells, $10\,\mu g\,ml^{-1}$ sage (*Salvia officinalis* L.) and oregano (*Origanum vulgare*) reduced the oxidized LDL-stimulated release of TNF-α, IL-6, and IL-1β and increased the release of the anti-inflammatory cytokine IL-10 (LDL: low density lipoprotein) [35.57]. The volatile compounds 1,8-cineole, borneol, camphor, and thujone are found in many herbal essential oils. In THP-1 monocytes, 1,8-cineole inhibited the translocation of the MAPK activated transcription factor early growth response protein 1 (egr-1) to the nucleus, suggesting an anti-inflammatory potential [35.58]. In a study in 2004, the authors showed that $1\,\mu M$ 1,8-cineole inhibits the release of IL-1β, IL-6, IL-8, and TNF-α in human monocytes after 20 h concomitantly stimulated with PMA/ionomycine. Additionally, the release of IL-1β, IL-4, IL-5 and TNF-α by stimulated lymphocytes was decreased by $10\,\mu M$ eucalyptol [35.59].

In most of the here cited studies, the essential oil composition was identified, individual constituents quantified, and tested for their anti-inflammatory potential. Of the different types of volatiles, terpenes have been determined to exploit anti-inflammatory properties. Among the terpenes, especially the monoterpenes possess anti-inflammatory potential [35.60].

35.5 Risk Assessment

Eucalyptol (1,8-cineole) is available in Germany as licensed medicinal product. In a human intervention study, patients receiving 200 mg three times per day reported adverse effects, for example, severe headache, heartburn, or gastritis, all considered as side effects of the intervention [35.50]. This raises the question whether essential oils and volatiles are safe to consume, even in large amounts. To evaluate the safety of a volatile compound, the following points need to be considered:

1. In vitro toxicology data
2. Administration and exposition
3. Distribution
4. Metabolism
5. Excretion.

Food and food additive safety is controlled by the Food and Drug Administration (FDA) in the United States and the European Food Safety Authority (EFSA) in Europe. Volatiles are known to be added to foods and cosmetics as flavoring compounds. Hence, volatiles are not only taken up by oral ingestion and inhalation but also through the skin in cosmetics. It has been shown that camphor and menthol were absorbed dermally after 8 h application and detected in the plasma [35.61]. Here, two examples of volatile compounds and their toxic potential and risk assessment are presented: (1) thujone, the absinthe constituent and (2) eugenol, found in clove oil, nutmeg, or bay leaves.

35.5.1 Toxicity of Thujone

Absinthe has already been known in Roman times as a psychoactive drug and was popular over centuries among artists like van Gogh, Degas and Picasso, who consumed and painted the *green fairy*. Later, absinthe was banned in Europe until the 1990s. A characteristic sensory constituent of this beverage is thujone. How-

ever, the maximum thujone concentration in absinthe is now limited to 35 mg kg^{-1}. The abuse and chronic ingestion of absinthe is associated with stimulation, hallucinations, and depression [35.62]. The toxic potential of thujone was reviewed in 2012 by a Finnish research group [35.63]. In vitro data on the mechanism of neurotoxicity showed that α-thujone modulated the γ-amino butyric acid $(GABA)_A$-gated chloride channel. The intake sources of thujone are sage-flavoured sausages and other meats, herb vinegar, liqueurs/bitters, and sweets, resulting in an estimated mean total daily intake of 1.175 mg per person per day.

In different animal studies, single dose toxicity was determined. LD_{50}-values of mixtures from α- and β-thujone were measured with 192 mg kg^{-1} in rats, 230 mg kg^{-1} in mice and 396 mg kg^{-1} in guinea pigs when orally administered. To determine a no observed adverse effect level (NOAEL), repeated dose toxicity experiments were needed. In 1963, a study was conducted in rats with gavages in doses of 0, 5, 10, and 20 mg kg^{-1} and six times per week for 14 weeks. In addition, studies with doses up to 100 mg kg^{-1} per day were performed in mice and rats. In summary, a NOAEL of 30 mg kg^{-1} per day was released. Based on human intervention data and the NOAEL, an acceptable daily intake (ADI) of 0.11 mg kg^{-1} bodyweight was calculated [35.63]. For a normal adult (70 kg) this would mean a daily intake of 7.7 mg thujone or, considering the maximum concentration of 35 mg kg^{-1} thujone in absinthe, 220 g (approx. 235 ml) absinthe per day.

35.5.2 Toxicity of Eugenol and Related Compounds

The EFSA reviewed the toxic potential of eugenol and related compounds in 2006 and adopted this review in 2008. The EFSA procedure is based on the opinion of the Scientific Committee on Food (SCF), derived from the joint FAO/WHO expert committee on food additives (JECFA). The JECFA estimated the intake based on the maximized survey-derived daily intake (MSDI). However, the more realistic approach considered the modified theoretical added maximum daily intake (mTAMDI), which is based on the normal levels used by industry. For eugenol, estimated intakes based on the MSDI model of 0.950 mg per capita per day in Europe and of 3.364 mg per capita per day in the United States were calculated. Based on the mTAMDI approach, an intake of 2.3 mg eugenyl isovalerate per capita per day was determined. First, the toxicology and genotoxic data were evaluated with generally no genotoxic potential for in vitro and in vivo toxicology of eugenol even at doses of up to 800 mg kg^{-1} bodyweight (bw). A NOAEL for eugenol has been determined with 300 mg kg^{-1} bw.

In addition to eugenol, typical volatile food compounds were evaluated in the same report, for example, thymol and carvacrol. Thymol, found in the essential oil of thyme, did not possess any genotoxic potential in the Ames test. The compounds evaluated by the expert panel of the EFSA remained to be safe for a regular and normal intake with foods.

35.6 Summary and Outlook

In summary, food odorants have been shown to possess anti-inflammatory potential in various model systems. Both, the complex mixture of volatiles in essential oils and individual compounds, for example, 1,8-cineole, borneol or camphor, exploit anti-inflammatory effects in cell model systems of inflammation-related diseases and systemic inflammation. These anti-inflammatory effects resulted in the inhibition of the NF-κB signaling pathway, the mediated mRNA expression, and release of cytokines. The main outcome measures were mRNA expression of *iNOS*, *COX-2*, *IL-1β*, *IL-6*, *IL-8*, and *TNF-α* as well as the release of the encoded interleukins, NO and PGE_2, although further studies are needed to provide more comprehensive mechanistic data. Moreover, toxicological information is needed for safety evaluation and risk assessment of food and cosmetic flavor compounds and essential oils. However, volatile food constituents comprise beneficial anti-inflammatory properties and, therefore, are a promising class of compounds in the treatment and prevention of inflammatory-related diseases.

36. Skin Sensitization of Odorant Materials

Andreas Natsch, Graham Ellis

Many natural and synthetic odorant materials contain structural features such as aldehyde functionalities or conjugated double bonds which lead to a certain chemical reactivity. Such molecules have the intrinsic ability to modify skin proteins, and if they are applied to skin at too high doses this may trigger an immune reaction leading in sensitive individuals to an allergic reaction. Here we review the underlying molecular mechanisms, the key structural classes of sensitizing odorant molecules, the predictive tests to identify fragrance allergens, the epidemiology of fragrance allergy, and the measures taken to avoid such reactions based on a risk assessment.

A skin sensitizer may be defined as a chemical which has the intrinsic ability (hazard) that, given sufficient skin exposure, can lead to the modification of the immunological state referred to as induction of skin sensitization or, clinically, as contact allergy. The induction of sensitization (contact allergy) refers to a nonsymptomatic condition which an individual has when they are sensitized to a specific chemical. Once sensitized, a subsequent and sufficient skin exposure to the same material in an individual who has contact allergy may lead to a skin reaction (eczema) also referred to as allergic contact dermatitis (ACD; Fig. 36.1 for an allergic reaction to a deodorant). The primary aim of safety assessment and risk management must therefore be to avoid the induction of contact allergy by skin sensitizers.

Materials with odorant properties may be naturally or synthetically sourced and cover a wide and varied possibility of chemical structures which provide for a large diversity in toxicological as well as olfactive properties [36.1]. Some of these odorant materials may have the ability to induce a skin sensitization response which may be predicted through animal, human, or in vitro and in silico models.

This chapter describes the mechanisms behind skin sensitization and how this relates to different classes of odorant materials with potentially sensitizing properties. Currently available methods to determine the intrinsic skin sensitising property (hazard) of a material and tools used to determine skin sensitization potency and therefore allow appropriate risk management are also presented. Finally, an overview of what is currently known about the epidemiology of allergy to odorant materials in the clinical and general population is discussed along with the tools used to manage safe use of such materials.

36.1 Molecular Mechanism Behind Skin Sensitization

Skin sensitization is a complex chain of reactions, involving a number of chemical and biological steps. It is generally divided into two key phases: (a) the sensitization phase, when the organism for the first time comes in contact with a sufficient amount of a chemical to trigger an immunological reaction (i. e., expansion of specific T-cell clones) and (b) the elicitation phase, when the expanded T-cell clones recognize their corresponding antigen and trigger an inflammatory reaction in the skin leading to the disease state known as allergic contact dermatitis. Some of the molecular events described in the following are common to both the sensitization and the elicitation phase, whereas others are specific to one phase. The key steps were recently described as an *adverse outcome pathway* (AOP) [36.2].

In a first step, a topically applied molecule must reach the viable epidermis, and skin penetration or more specifically *bioavailability in the skin* therefore is thought to be a prerequisite for the skin sensitization reaction. However, bioavailability appears not to be a key rate determining factor as chemicals of very different physicochemical properties can trigger sensitization [36.3]. Indeed, odorant molecules are sufficiently small and lipophilic that they can gain access to the epidermis if topically applied.

Chemicals with low molecular weight (MW < 500 Da) are too small to be immunogenic and cannot directly trigger an immunological response. However, if these molecules are able to change the molecular conformation of larger molecules, especially proteins, they can render endogenous proteins in the body immunogenic. Therefore reactive chemicals, which are able to covalently modify proteins under physiological conditions, do have the ability to generate novel antigens in the skin. Such protein-modifying chemicals are also referred to as *haptens* [36.4]. Once the hapten binds to the skin protein/peptide, a novel epitope is formed, a novel structure not previously known to the immune system. This new structure may then be recognized as *foreign* by the immune system. Chemically speaking, sensitizers therefore are mostly electrophilic chemicals able to react with nucleophilic residues (predominantly cysteine and lysine) in proteins. The key step for the initiation of skin sensitization is therefore the formation of a covalent adduct between the skin sensitizer and endogenous proteins and/or peptides in the skin. This event is also referred to as the molecular initiating event (MiE) [36.2]. Certain molecules are considered *pro-haptens*, indicating that they themselves are non-sensitizers and need to be metabolically converted by skin enzymes to form reactive metabolites which then react with the proteins [36.4].

Fig. 36.1 Allergic contact dermatitis to a deodorant (photo by An Gossens)

In the next step, the modified peptides must be processed and presented by the Langerhans cells (the dendritic cells in the skin) on their major histocompatibility (MHC) proteins in order to be recognized by T-cells. The Langerhans cells must also migrate to the lymph nodes, as only there they come in contact with the T-cells to present the novel epitopes. This migration must be actively initiated, and it is thought that the mere binding of modified peptides on the dendritic cells is not sufficient to initiate the activation and migration of dendritic cells, but that a second signal often referred to as *danger signal* is needed at this stage [36.5]. The danger signal appears to be a part of the innate immune reaction and it is formed in the absence of specificity conveyed by T-cells. Recent work shows that activation of Toll-like receptors (TLRs) [36.6] and the inflammasome [36.7, 8] to form interleukins (IL-1β and IL-18) play a central role in the danger signal. These pathways are also involved in the innate reactions against pathogens. At the molecular level, the sensitizer-triggered release of ATP [36.9], the formation of fragments of hyaluronic acid [36.10], and the formation of reactive oxygen species (ROS) [36.11, 12] appear important to trigger chemical-induced TLR-signaling and inflammasome activation.

Stimulated by the danger signals, the dendritic cells maturate and emigrate from the skin into local lymph node where they finally present the hapten-modified peptides to the T-cells and stimulate the proliferation and differentiation of specific T-cell clones. Cytotoxic CD8+ T-cells are then the key effector cells. This complete process depicted on the left hand of Fig. 36.2 is referred to as the *sensitization phase* of the skin sensitization reaction. In the *elicitation phase*, the specific expanded cytotoxic T-cell clones then trigger skin inflammation on secondary contact with the causative

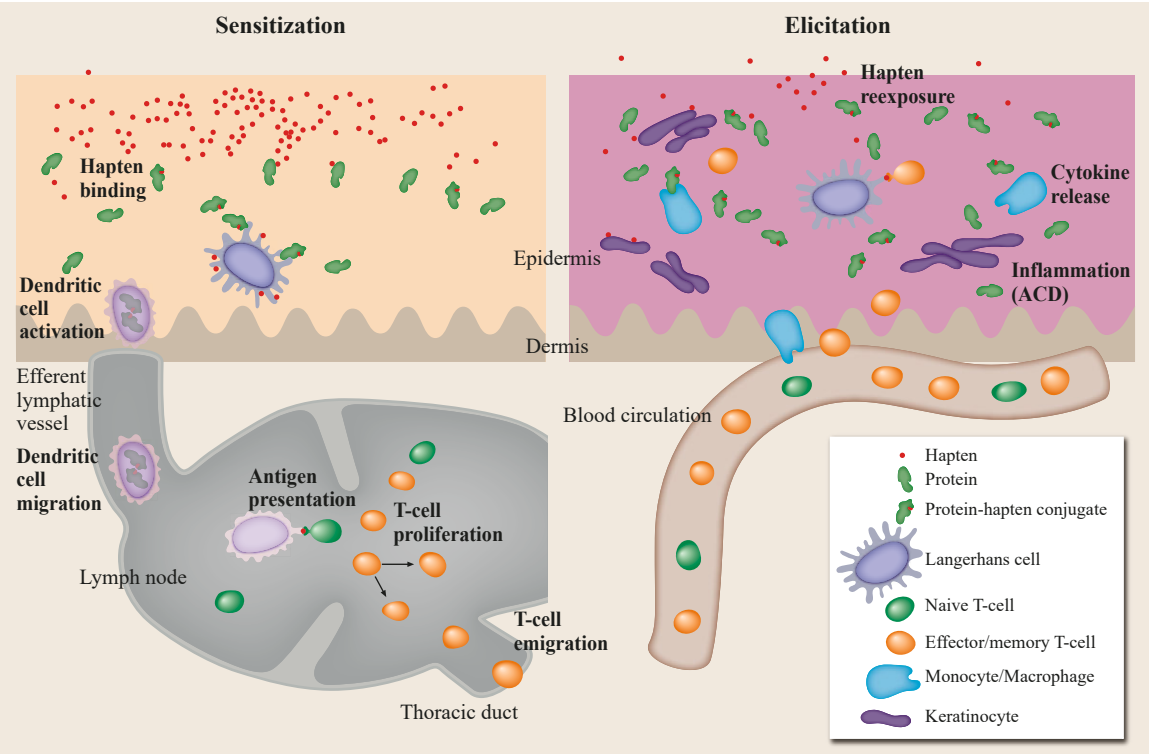

Fig. 36.2 The mechanistic steps leading to allergic contact dermatitis (after [36.4])

agents when they recognize the hapten-modified peptides presented by the keratinocytes.

In summary, according to the current model, skin sensitizing molecules must be able to both (i) form novel epitopes due to their reactivity and to (ii) trigger the danger signal. Since both requirements are needed, skin sensitization in most individuals only occurs above a given threshold. For each sensitizer, a given dose is therefore tolerated [36.13], and it appears that only above a certain threshold-dose sensitizers trigger sufficient danger signal and form sufficient epitopes to initiate the sensitization phase.

36.2 Structural Classes of Sensitizing Molecules with Special Emphasis on Odorants

Based on the molecular understanding of the MiE, skin sensitizing chemicals can be classified according to their chemical reactivity and whether they are directly reactive (haptens) or whether they need metabolic or oxidative activation to become haptens (pro-haptens). Classification can be performed either by structural alerts (reactive functional groups) [36.14] or by predicted chemical reaction pathways [36.15]. Here we give no systematic overview on all classes of sensitizing molecules, but highlight the key functional groups present in odorants and the key reaction pathways which have been associated with their skin sensitization potential. A more general overview can be found elsewhere [36.16]. It is noteworthy that key structural features determining the odor of important natural scents are often also determining their reactivity – thus, aldehydes, α,β-unsaturated aldehydes, α,β-unsaturated ketones, substituted phenols, and aromatic aldehydes: These are the main structural features highlighted as follows but these structural features are also present in key ingredients in many essential oils. Our olfactive

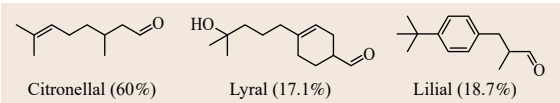

Fig. 36.3 Aliphatic aldehydes and their skin sensitization potential according to the LLNA

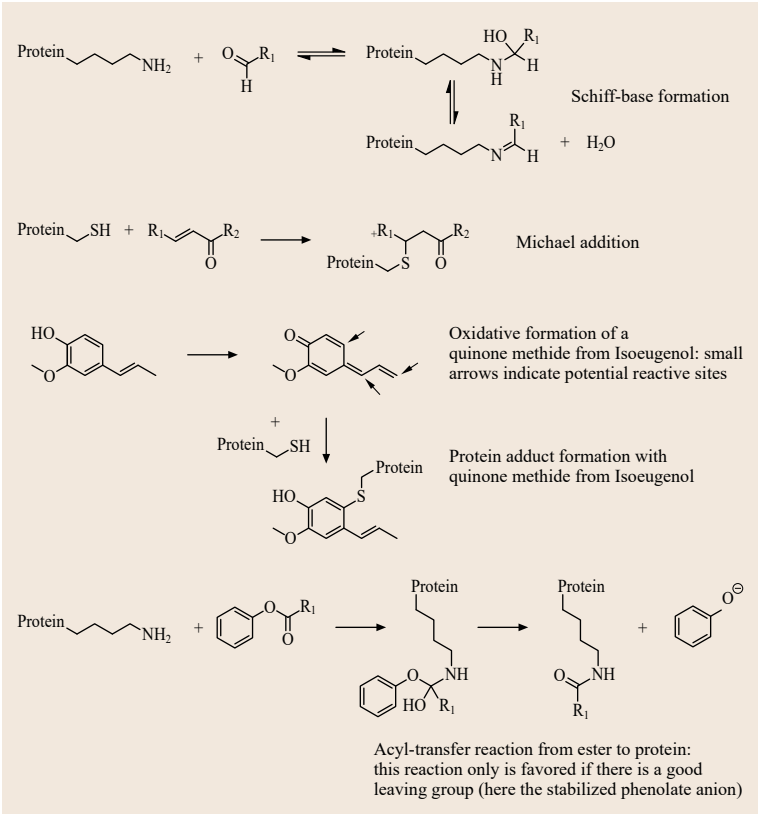

Fig. 36.4 Theoretical reaction mechanisms between the discussed classes of skin sensitizers and skin proteins (mainly cysteine and lysine side chains). Note: these mechanisms are largely based on chemical knowledge and in vitro experiments – the actual proteins modified and the epitopes formed in vivo are unknown

system appears to be tuned to these structural features in natural scents, which makes formulation of appealing scents without any structural alerts for skin sensitization challenging, if not impossible. In the following, the key classes are discussed and exemplary structures are given in the figures, associated with the EC3 values from the local lymph node assay (LLNA) to indicate their potency in animal test (concentration in percentage to induce three-fold lymph node cell proliferation; see as follows).

36.2.1 Aliphatic Aldehydes

Branched and unbranched aliphatic aldehydes (some containing ring systems in the chain) are widely used as odorants and include natural compounds such as citronellal or synthetic chemicals, such as the lily-of-the-valley aldehydes exemplified here by Lilial and Lyral (Fig. 36.3). As aldehydes, they can in principle form Schiff-bases with skin proteins (Fig. 36.4 for overview of putative reaction mechanisms). However, in the aqueous milieu of biological tissues this reaction is not favored due to rapid reverse reaction. This is most likely the reason why this group is mostly rated as weak sensitizers in animal tests and frequency of positive reactions in humans is quite low, despite widespread use. An exception here is Lyral which has given rise to frequent positive reactions in humans [36.17] – it is unclear currently whether this is due to high use or an unknown intrinsic feature of this molecule.

36.2.2 Aromatic Aldehydes

A number of aromatic aldehydes are very important for their unique scent. Most widely used is not just vanillin, but also benzaldehyde and heliotropin are the key balsamic odorants (Fig. 36.5). With the exception of benzaldehyde, these are very weak sensitizers – an observation which could be linked to a very low reactivity of these molecules [36.18]. This structural group also contains two aldehydes found as minor components in oakmoss extract: atranol and chloratranol. These two molecules are potent skin sensitizers [36.19–21] and were found to be the culprit for the high frequency of sensitization to oakmoss. Their sensitization potential appears to be due to their ability to form Schiff-bases which are stabilized by tautomerism in aqueous conditions [36.18]. Commercial oakmoss qualities now must follow stringent limita-

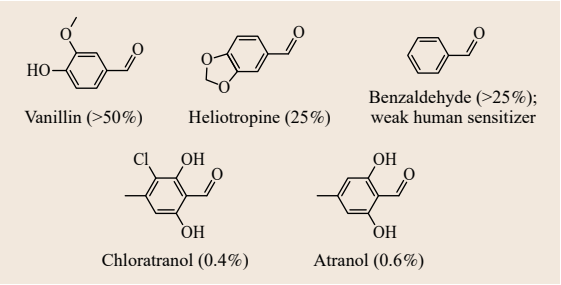

Fig. 36.5 Aromatic aldehydes and their skin sensitization potential according to the LLNA

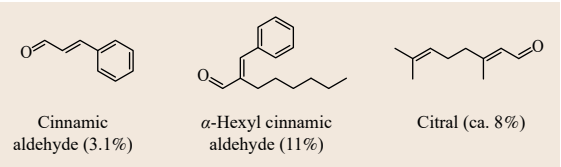

Fig. 36.6 α,β-unsaturated aldehydes and their skin sensitization potential according to the LLNA

tions for these two chemicals to avoid the sensitization risk.

36.2.3 α,β-Unsaturated Aldehydes

These aldehydes are more reactive as compared to the aliphatic aldehydes as they can react (next to potential Schiff base formation) with a Michael addition at the conjugated double bond (Fig. 36.4). The key representative in this group is cinnamic aldehyde, the main component of cinnamon bark essential oil. Aldehydes that are branched at the α-atom, such as α-hexylcinnamic aldehyde or at the β-atom such as citral have much lower reactivity, accompanied with a reduced sensitization potential (Fig. 36.6).

36.2.4 α,β-Unsaturated Alcohols

The α,β-unsaturated alcohols are pro-haptens and are thought to be predominantly oxidized by skin enzymes to the corresponding aldehydes (Fig. 36.7). This is reflected by frequent cross-sensitization: Thus, patients who are sensitive to cinnamic alcohol often do also react to cinnamic aldehyde [36.22], and this observation is most elegantly explained by oxidation of cinnamic alcohol in the skin and subsequent reaction of sensitized individuals to the formed cinnamic aldehyde. However, cross-sensitization is not the case for all individuals and, therefore, alternative metabolic routes such as formation of an epoxide at the double bond of cinnamic alcohol and subsequent addition of the nucleophile to the epoxide bond were proposed [36.23]. A similar pair

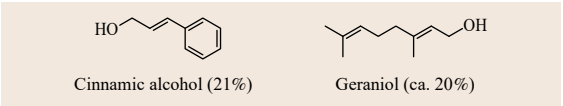

Fig. 36.7 Unsaturated alcohols and their skin sensitization potential according to the LLNA

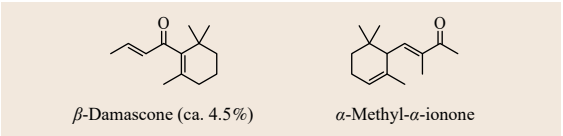

Fig. 36.8 α,β-unsaturated ketones and their skin sensitization potential according to the LLNA

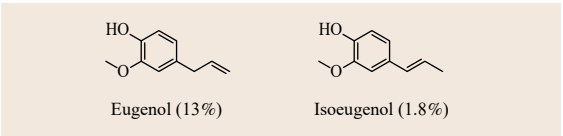

Fig. 36.9 Phenols and their skin sensitization potential according to the LLNA

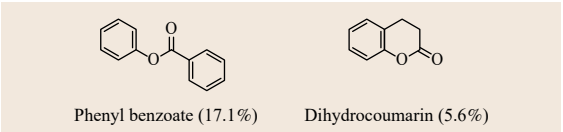

Fig. 36.10 Reactive acyl transfer esters and their skin sensitization potential according to the LLNA

is geraniol and citral. Also in this pair, cross-reactions are frequent and the true sensitizing hapten may often be identical.

36.2.5 α,β-Unsaturated Ketones

As for the α,β-unsaturated aldehydes, α,β-unsaturated ketones (Fig. 36.8) contain an activated double bond which is prone to Michael addition, especially by free sulfhydryl groups in proteins. This group comprises the damascones, key contributors to rose odors. As for the aldehydes, the substitution pattern strongly affects reactivity and sensitization risk. Thus, to note a striking example, while damascones are highly peptide-reactive, the substituted α-methyl-ionone has no detectable reactivity and was found nonsensitizing even if applied at very high doses in human tests.

36.2.6 Substituted Phenols

This chemical group comprises key allergens in other product types (such as hair dyes and biocides), but only few odorants belong to this class. The most frequently

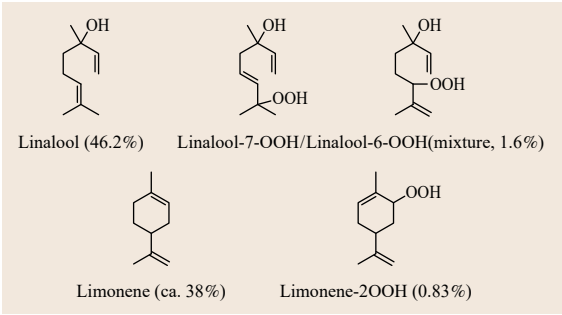

Fig. 36.11 Unsaturated terpenes and their primary oxidation products: skin sensitization potential according to the LLNA

cited odorant sensitizers in this group are isoeugenol (a key component for carnation scents) and eugenol (key component in clove buds and cinnamon leaf oil, which is essential in spicy scents) (Fig. 36.9). Eugenol appears to be a pro-hapten, requiring metabolic activation to become reactive, but isoeugenol appears to become reactive already upon abiotic oxidation (Fig. 36.4). This difference is also reflected in a clearly higher sensitization potency of isoeugenol. However, the enzymes in the skin which may be involved in activation of for example eugenol are unknown. It is proposed that both enzymatic and abiotic oxidation can lead to quinone methides as highly reactive intermediates which then can modify skin proteins (Fig. 36.4 for putative mechanism).

36.2.7 Reactive Esters

Esters with a good leaving group such as the phenolate anion are prone to acyl transfer reactions (Fig. 36.4). Such chemicals, thus, have the ability to modify proteins by the transfer of the acyl group onto the skin proteins also rendering them immunogenic. This appears to be the reaction mechanism explaining the sensitization potential of 3,4-dihydrocoumarin or phenyl-benzoate (Fig. 36.10). Although esters are very widely used in perfumery, the use of such phenyl esters has largely been phased out.

36.2.8 Terpenes

Unsaturated terpenes are unreactive as such and when tested in predictive tests are rated in most cases as very weak or nonsensitizing (Fig. 36.11). However, it was shown that essential oils containing such molecules or pure preparations of certain chemicals are prone to autoxidation, and that the oxidation products do have sensitization potential [36.24]. This risk is being mitigated by careful quality assurance of raw materials, but nevertheless frequent reactions to high concentrations of such oxidation products were recently reported [36.25]. Currently, it is not known whether these reactions are highly specific (whether patients only react to the selected oxidation products and whether sensitivity was indeed induced by exposure to these oxidation products from fragrances).

36.3 Testing for Skin Sensitization

Many methods are available and have been described for determining the skin sensitization potential of chemicals. Early developments relied on human studies [36.26] before the development of animal studies, such as the Guinea Pig Maximization Test (GPMT) [36.27], which have been the cornerstone of determining skin sensitization hazard. Nowadays, the LLNA performed in mice is the animal model of choice as it provides an indication of the potency of a material to cause sensitization which allows classification into stronger versus weaker groups of sensitizers and risk assessment [36.28]. Significant progress has been made in the last decade on the use of in vitro methods to predict skin sensitization hazard to the point where suitable and authority approved nonanimal alternatives are now available (OECD test guidelines 442c, 442d and 442e). The challenge over the next few years will be to adapt the understanding of the information from the in vitro methods to allow a reliable prediction of potency as is currently available from the LLNA. In silico tools complement the picture and remain most effective when used and interpreted with expert judgement, with the better tools providing not only predictive information, but also a detailed and well-referenced rationale behind each prediction. Finally, the use of human studies such as the human repeat insult patch test (HRIPT) to confirm the no effect levels observed from animal studies remain a useful tool when performed to high ethical standards. Clinical data is also instructive to provide information on materials that are able to cause sensitization in humans.

Here we provide an overview of the more commonly used methods with specific observations for the prediction of sensitization to odorant materials.

36.3.1 Animal Tests

Animal studies have long been the methods of choice for investigating the sensitization properties of chemicals. Several methods have OECD approved guidelines,

the GPMT and the Buehler Test (OECD 406) as well as the LLNA (OECD 429).

In the LLNA, dilutions of the test chemical are applied to the ears of mice three times on consecutive days. After a two days rest period, the mice are injected with radiolabeled thymidine into their tail vene (alternatively nonradioactive labels are also used), 5 h later the animals are sacrificed and the local lymph nodes draining the ears are excised. Pools of cells of the lymph nodes are then evaluated for the inclusion of labeled thymidine (and hence active DNA synthesis). This measure correlates to active proliferation of cells in the local lymph nodes, and thus provides for a quantitative measure of the sensitization phase (Fig. 36.12).

The LLNA has been the most commonly used assay on odorant chemicals in recent years and large datasets of information have been published which include many odorant chemicals [36.29, 30]. The LLNA has proved to be most useful for a quantitative evaluation of the sensitization potential and classification of materials into extreme, strong, moderate, weak, and very weak or nonsensitizers. This is based on the reported EC3 value: the concentration required to induce a threshold positive response [36.31]. The EC3 value has been demonstrated to generally correlate well with the no observed effect levels (NOEL) from human sensitization tests designed to confirm lack of induction [36.31–36], and it is therefore used for risk assessment. For odorant materials, some limitations to the use of the LLNA have been observed. For example, certain classes of ingredients show a strong trend of being over-predicted for their sensitization potency when compared with other animal studies and human data. Salicylate esters are an important class of odorant materials which are routinely over-predicted as moderate sensitizers in the LLNA whereas human experience and other animal data indicate they are not or only very weakly sensitizing, although the reason for this discrepancy is not well understood. Conversely, some materials, in particular those with high volatility, may have their sensitization potency under-predicted by the LLNA. Two examples are benzaldehyde and 2-hexenal which show a sensitization potential under occluded conditions in humans which is not seen following open application in the LLNA. For odorant materials, the avoidance of false positive results in the LLNA due to irritation is also an important factor and measurements of ear weight and thickness are important indicators in addition to the visual observation of irritation when conducting a study. For odorant mixtures, such as essential oils, attempts have been made to determine sensitization potential in the LLNA [36.37]. Whilst a good correlation is seen between the EC3 value for a simple mixture with one main component versus the EC3 value of that main component, no such correlations are seen for more complex mixtures. It is worthwhile to note that during validation, the LLNA was not tested on complex mixtures such as essential oils (which were not included in the chemical validation set) and therefore the value of conducting a study on such materials remains questionable.

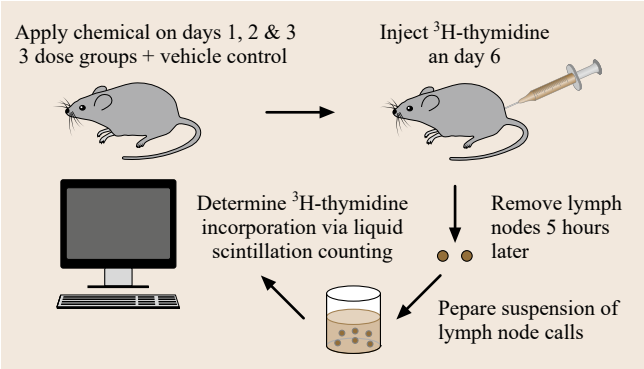

Fig. 36.12 A schematic representation of the experimental steps in the LLNA

Other methods such as the GPMT are nowadays less commonly used but much historical data exists which provide important information. While the GPMT has been used primarily for the hazard prediction of sensitization, some potency information may be obtained to be used in risk assessment. Other adjuvant tests in animals such as the Freund's complete adjuvant test (FCAT), mouse ear swelling test (MEST) and nonadjuvant tests such as the Buehler Test, open epicutaneous test (OET) and closed epicutaneaous test (CET) may be used to contribute information to a potency assessment [36.38].

36.3.2 Human Tests – Predictive and Diagnostic Tests

The predictive test most typically conducted is the human repeat insult patch test (HRIPT) [36.39]. The HRIPT is the most reliable test method by which confirmatory human data can be made available for use in risk assessment following pre clinical studies. The test exaggerates exposure from normal use of consumer products and can be used to confirm a safe level determined from animal studies such as the LLNA. Details of the standard HRIPT protocol used for odorant materials are described by *Politano* and *Api* [36.40]. A standard HRIPT protocol consists of a 3 week induction phase (weeks 1−3), a rest period of 14−17 days (weeks 4 and 5), and a 1 week challenge (elicitation) phase (Week 6). In the induction phase, patches are applied for 24 h, three times a week for a total of nine patches. This is then followed by a rest period which allows time for

any immunological response to develop and also allows any previous reactions developing at the induction sites to subside prior to the re-application of the test substances at challenge. Challenge patches are applied to the original application site and to a naive alternate site for 24 h. The sites are visually graded for skin responses 48 and 96 h after patch application, although intermediate or longer readings may be performed. This phase is used for the assessment of delayed skin responses, which may be indicative of contact sensitization. A re-challenge can be performed between 4 and 12 weeks after the initial challenge phase to provide more information about doubtful reactions. Each test typically includes just over 100 panellists.

All studies must follow good clinical practice (GCP) which includes requirements for the pre study safety assessment, informed consent, and Institutional Review Board (IRB) or Ethics Committee review. The HRIPT receives criticism, particularly in Europe, from an ethical perspective but remains a useful tool which is ethically acceptable when done under GCP and is routinely performed in the United States and other major geographies. A review of the ethical situation [36.41] concludes that where there is a specific rationale for testing, for example, to substantiate a no-effect level for a sensitizing chemical or to ensure that matrix effects are not making an unexpected contribution to sensitizing potency, then rigorous independent review may confirm that an HRIPT is ethical and scientifically justifiable. However, the possibility that sensitization may be induced in volunteers dictates that HRIPTs should be conducted rarely and in cases where the benefits overwhelmingly outweigh the risk. Today, for odorant materials, the HRIPT is conducted only as confirmatory assay at a dose where no induction in humans is expected based on pre clinical data.

The use of patch testing to diagnose allergic contact dermatitis was first developed by Josef Jadassohn in 1895 [36.42]. In diagnostic patch tests, patients with symptoms of allergic contact dermatitis are tested with multiple materials (grouped into the so-called baseline series). Materials are applied as occluded patches to their backs for 2 days, and development of symptoms are visually scored after 3–7 days. Patch testing indicates whether a patient has contact allergy to a particular substance or group of substances. Although patch testing remains the gold standard for the diagnosis of ACD, the actual procedure involves several steps and is usually carried out at specialized clinics. Selection of an appropriate series of allergens requires the physician to have sufficient knowledge of numerous allergens and to have them on hand in his or her clinic. Obtaining a history of the patient's exposures both at home and work is vital in determining the appropriate materials to patch test. The preparation of the patch test panels can be time consuming, but can be done ahead of time and standard series on fragrance materials are commercially available. Patients need appointments both for the application as well as first and second readings. When reading a patch test, correctly identifying a positive allergic versus irritant reaction requires experience and skill. When patch testing is complete, identifying clinical significance of the positive allergen in the patient's environment requires detective work and patient education. All of these factors may contribute to a dermatologist's decision to not offer patch testing in his or her office [36.43]. However, patch testing remains a very useful tool. Future development of in vitro and in situ diagnostic tools to complement the patch test and to allow a rapid and more readily available determination of contact allergy and the causative agent has been recognized as a need and development of such methods may lead to complementary diagnostic tools in the future [36.44].

Information from clinical studies such as the diagnostic patch test performed in specialized dermatological clinics may inform the risk management of substances, in particular where causative information linking the allergy to a specific exposure (product or occupational) is available. A scheme for the identification of the cause of allergy to fragranced products has been proposed [36.45]. However, causative information is often not available and closer cooperation between dermatologists and the industry is required to maximize the value of diagnostic patch test information for use in appropriate risk management decisions.

Finally, use tests such as the provocative use test (PUT) or repeated open application test (ROAT) are available and used to better understand the clinical significance of patch test results. The repeat open application test (ROAT) procedure is a useful tool to determine whether the positive patch test result may be relevant and a cutaneous reaction is seen from normal use of a product [36.46]. The ROAT protocol may vary according to product type tested but typically involves repeated once or twice daily applications of a product (either neat or in diluted form as used) to the volar forearm over several weeks with inspection for irritant or allergic contact dermatitis reactions between each application. ROATs are a valuable tool to provide information in the risk management of common allergens and studies have been conducted on fragrance ingredients. For example, *Schnuch* et al. [36.47] demonstrated that 90% (50%) of people allergic to the odorant material hydroxyisohexyl 3-cyclohexene carboxaldehyde (HICC) would be protected by restricting presence in products to 0.009–0.027% (0.18–0.34%) depending on product type. A recent ROAT study simulating day-

to-day use showed that the weak sensitizer Eugenol would not elicit a reaction in patients with a positive patch test to Eugenol when used at levels as allowed within the current International Fragrance Association (IFRA) Standard [36.48].

36.3.3 In Vitro/In Silico Assessment

For cosmetic ingredients, a ban on animal testing has been put into force in 2013 in the European Union. Thus, chemicals used only for cosmetic purposes shall no longer be tested in the predictive animal tests. This legislation is a major driving force behind significant recent research initiatives to find alternative testing strategies. Basically different steps of the mechanism as formalized in the AOP and summarized in Sect. 36.1 can be tested in isolated in vitro tests. Thus, a number of different peptide reactivity assays were proposed to assess reactivity with model peptides [36.49–51]. The extent of the reaction, especially the kinetics of the reaction, does correlate to sensitization potential and can at least be used to make predictions within some structural classes [36.52–54]. Such reactivity assays are also called *in chemico* assays. A standardized protocol was developed and nicknamed DPRA (for direct peptide reactivity assay [36.55]) and has undergone validation at the European Center for the Validation of Alternative methods to animal testing (ECVAM). Measuring reactivity, which is the key MiE and most likely also the rate limiting step in the sensitization reaction, is clearly the most straightforward approach.

A different approach focused on the activation of dendritic cells. Contact allergens were found to trigger phenotypic changes and intracellular signaling pathways in dendritic cells cultivated in vitro. The key phenotypic markers identified were: up-regulation of the surface markers CD86 and CD54 on dendritic cells, release of Interleukin-8, and activation of the mitogen activated kinase p38 [36.56]. Based on these findings, a predictive test for dendritic cell activation (h-Clat, human cell line activation test; [36.57]) was developed and also underwent ECVAM validation. Next to phenotypic changes, also changes at the transcription levels triggered by sensitizers were investigated in detail. A common pathway triggered by sensitizers found in several studies is the electrophile-sensing pathway involving the sensor protein Keap1, the transcription factor Nrf2 and its cognate binding site EpRE/ARE (elecrophile/antioxidant response element) present in the promotor region of many cytoprotective genes. This pathway responds to most electrophilic skin sensitizers. An assay based on this pathway (KeratinoSens) has also been validated by ECVAM [36.58].

These three assays measuring chemical reactivity and cellular responses do not directly measure immunogenicity; nevertheless a combination of these assays may be sufficient to recognize the majority of skin sensitizing chemicals [36.59, 60]. A more relevant assay would be to directly measure *ex vivo* with a mixed lymphocyte reaction the clonal expansion of specific hapten-specific T-cell clones. This is now feasible for very strong sensitizers [36.61, 62] but so far not sufficiently developed for weaker sensitizers.

Several in silico tools exist for the prediction of skin sensitization with the most useful of these commercial tools providing mechanistic explanation of the prediction such a DEREK and TIMES-SS [36.63, 64]. These tools remain best used in knowledgeable hands and when combined with expert judgement and information from other methods (in vitro and in vivo) in providing understanding and a weight of evidence prediction of sensitization hazard and potency of substances.

The key remaining hurdle is to quantify the sensitization potency: as discussed earlier it is not always possible to create odorants without any chemical alert for sensitization, and therefore a careful risk assessment is needed to stay well below the threshold for sensitization in product applications. As point of departure for the risk assessment, quantitative data are a key requirement – up to now these were mostly generated in animal tests.

36.4 Epidemiology of Allergy to Odorants

36.4.1 Fragrance Allergy in Dermatology Patients

Dermatological patients represent a subset of the general population suffering from allergic contact dermatitis who present themselves to specialized dermatological clinics for evaluation and diagnosis. Extensive data on contact allergy to odorant materials is available from different regions around the world and standard patch test series are available to aid the diagnostic process. Routinely Fragrance Mix I (FM I), a mixture of commonly found fragrance substances, is used where allergy to fragrance may be suspected [36.65] and Fragrance Mix II (FM II) and Hydroxyisohexyl 3-cyclohexene carboxaldehyde (HICC) [36.66] have also been introduced into the European baseline se-

ries. Globally, it has been reported that 6–14% of patients presenting with allergic contact dermatitis react to FMI, reactions to FMII are lower (0.6–9.3% of patients) and 0.4–2.4% positive reactions were reported for HICC [36.67]. Geographical variation to fragrance allergy in patients and in particular that to HICC in patients is seen with a general, although variable, trend to lower rates in the USA and southern Europe versus northern and central Europe. Significantly lower rates of reaction to HICC are seen in the United States as compared to Europe and a recent report shows declining rates in EU possibly following tighter industry restrictions on the use of this substance [36.68]. Data on clinical relevance, that is, the confirmation that the patch test response in the patient is relevant to the current illness (allergic contact dermatitis), is mixed. Clinical or *current* relevance has been explored by *Frosch* et al. [36.69, 70] who estimated between 2% and 55% of reactions seen to FMI were relevant depending upon whether relevance was classified as *certain*, *probable*, or *possible*. Data on other fragrance ingredients and subsequent studies by the same group showed similar ranges.

Significant amounts of information are available in this area and for an extensive information source the reader is invited to review the relevant chapters in the recent European Scientific Committee on Consumer Safety report on fragrance allergens [36.67].

36.4.2 Fragrance Allergy in the General Population

The earlier given data refer specifically to patient populations. The most comprehensive study to date in the general population was conducted recently by the European Dermatological Epidemiology Network (EDEN) sponsored by The Research Institute for Fragrance Materials, Inc. [36.71]. This study recruited over 12 000 people from 6 centres in Europe and patch tested a random sample of 3000 subjects [36.72]. Overall the crude prevalence of patch test positive responses to FMI, FMII, and single substances was between 1.0% and 2.4%. When a conservative estimate of clinical relevance was considered, it was 0.4–1.1%. Reactions to individual materials within FMI and FMII, with the exception of HICC, were all at or below 0.5% again accounting for lifetime clinical relevance. This data is similar to that of the SCCS which reported 1–3% of the general population as having contact allergy (a positive patch test response) to fragrances. Data on actual current cases of allergic contact dermatitis due to odorant materials in the general population are missing and therefore extrapolation has to be made from the above; however, data collected from adverse effects reported by consumers may be useful in this regard.

36.4.3 Risk Assessment and Risk Management to Control Skin Sensitization

Significant progress has been made in recent years in the risk assessment for skin sensitization due to the availability of better exposure data and the use of the LLNA and HRIPT which has allowed determination of safe levels of use for skin sensitizers using a quantitative approach versus. previous more qualitative assessments. The quantitative risk assessment (QRA) methodology [36.73] is now widely used when assessing and setting risk management measures for fragrance materials. Since the introduction of the QRA in 2008, the International Fragrance Association (IFRA) has gradually introduced Standards setting limits for the use of fragrance ingredients, with now over 100 substances restricted in their use. The QRA approach follows general toxicological risk assessment principles where a no effect level for sensitization (so-called no sensitization induction level – NESIL) is defined and a series of safety factors accounting for inter individual, vehicle/product matrix effects, and product use considerations are applied to derive safe use levels in consumer products. Using the QRA, safe use levels may be defined for individual product types provided adequate exposure, use, and product formulation information are available. In implementing safe use levels, IFRA has adopted 11 categories within which over 50 common consumer products are defined. For fragrance ingredients with sensitization potential, each category is assigned to a specific maximum use level determined to ensure induction of sensitization to the substance does not occur [36.74]. More information and guidance may be found on the IFRA Website [36.75]. The QRA as applied by the fragrance industry is currently limited in scope to consumer products. Occupational exposures, pharmaceutical products, aromatherapy and massage oils, natural exposures, and other unregulated areas are not covered by the fragrance industry approach and IFRA standards and this may still represent an important gap for risk management of consumer safety and prevention of allergy. As with all toxicological risk assessment approaches, further investigation and refinement will undoubtedly occur in the future to ensure continuous improvement of approaches.

37. Aroma Therapy in Neonatology

Michael Thiel

Aroma therapy has become a well-established part of complementary and alternative medicine in pediatrics mainly because it is accepted and desired by many parents. However, the scientific base of several of these methods is often contradictory. This chapter provides an overview of data on aroma therapy in neonatology and tries to explain its physiological background.

The prognosis of preterms and seriously ill newborns has substantially improved during the last 25 years. To reduce or avoid the adverse effects of conventional therapies like antibiotics or mechanical ventilation, several attempts have been made to practice gentle medicine, including complementary and alternative methods.

A number of tools from this field, such as kangaroo care [37.1, 2], glucose [37.3], breast milk [37.4, 5] or massage [37.6, 7], have played a crucial part in this improvement. Often the aim is to reduce pain, but also to stabilize vital parameters like oxygen saturation, heart rate and blood pressure, or to foster bonding. A highly important aspect in this context is developmental care, being an inherent and almost natural part of the holistic approach of neonatology [37.8].

However, the exact pathway of these methods is not always clearly defined. For example, it is a common assumption that the pain score is lower in infants that received glucose. But recent findings have suggested that it is actually not the pain itself that is influenced by glucose, but rather the changing facial expression which coincides with measuring pain. So the validity of the evidence ultimately depends on the question of what has actually been measured [37.9].

Furthermore, the use of complementary and alternative methods is not always based on evidence. For instance, although there is some significant data on music therapy, it is not as widely spread as other methods [37.10]. The same is true for some therapies like homeopathy, which are being used without or with only little evaluation or evidence [37.11]. There are theoretical approaches to apply acupuncture in neonates, but again, very little data is available [37.12, 13].

Figure 37.1 illustrates the discrepancy of use and evidence in some complementary and alternative medicine (CAM) methods in neonatology.

Even though a systematic review on phytotherapy in neonatology showed some encouraging aspects of aroma therapy [37.14], it is still not very common in the care of preterms. The following section provides an overview of the current literature on this topic and suggests possible explanations of the observed effects.

37.1 Data on Aroma Therapy in Neonatology

37.1.1 Aroma Therapy and Pain in Neonatology

Pain has an enormous impact on the development of a preterm. Many complementary and alternative attempts have been made to improve analgesic management in neonatology, such as glucose, music therapy, massage, mother milk, or kangaroo care.

Probably the most common painful procedure is taking blood from the child. Therefore, numerous nonpharmacologic pain-relieving interventions are practiced and have been evaluated, including swaddling, holding, skin-to-skin care, pacifiers, sweet-tasting solutions and breastfeeding [37.15].

There are several studies on aroma therapy whose results suggest its use at least as an additional means to reduce pain and stress, thereby improving the prognosis of the preterm.

Vanillin

In a study, 31 healthy preterms (32 weeks of gestational age, mean birth weight 1730 g, and aged 6 days) were divided into three groups. The infants in the first group were exposed to vanillin flavor prior to venipuncture on the hand or a capillary puncture of the heel, the second group smelled vanillin for the first time, and the third group had no odor exposure during the procedure. An independent video score before, during and after venipuncture assessed the preterms' reaction. Exposure means that a swab with 10 drops of vanillin solution was placed in the incubator for 10 min. If the infant was lying in an open bed it was placed close to its head. The neonatal pain score was significantly reduced if vanillin was familiar to the child before venipuncture. An interesting incidental finding of this study – beside its main outcome – was that heel sticks were more painful than venipuncture [37.16].

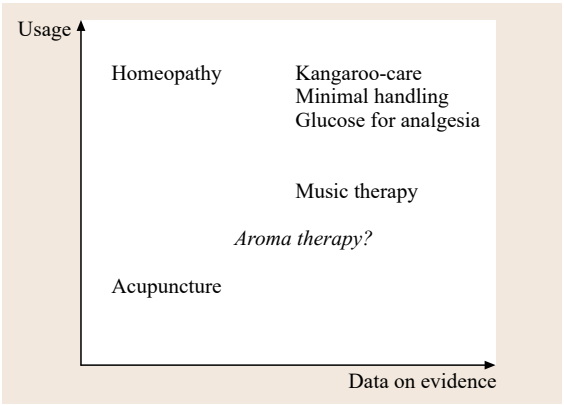

Fig. 37.1 Discrepancy of usage and evidence of some complementary and alternative methods in neonatology

Test and results of another study with 44 healthy newborns were quite similar: Odor of the infants' mother's milk, vanilla smell, unfamiliar odor and no odor were compared. The pain score before, during and after a routine heel stick was significantly lower in the group of children with familiar odors, i. e., vanillin and mother's milk. All children were breastfed [37.17].

A very similar study revealed a reduction of the pain score in the group of vanillin and mother's milk in 44 healthy newborns. Again, mother's milk, vanillin familiar, vanillin not familiar and no odor were compared before, during and after venipuncture [37.18].

To discriminate the effect of vanillin from other influences, a further study of 44 healthy newborns (gestational age 39 weeks and mean birth weight 3440 g) was performed. Vanillin being familiar, venipuncture in bed, vanillin unfamiliar, venipuncture in bed, vanillin not familiar, venipuncture on mother's arm and venipuncture without no vanillin were compared, again by measuring the pain score before, during and after venipuncture. In this study, the pain score was significantly lower in the group with exposure to vanillin before venipuncture [37.19].

In yet another study, 135 neonates were divided into 3 groups. An arterial puncture was performed on the infants. The first group was exposed to vanillin overnight and then exposed to vanillin during the painful procedure. The second group had no exposure before, but during arterial puncture, while the third group was not exposed to vanillin at any time. Less crying and less fluctuation of oxygen saturation – probably indicating less pain – were observed in infants exposed to vanillin before and during the procedure. These findings were interpreted as a pain-relieving effect of vanillin, especially when the infant is familiar with this odor. The focus was set on the assessment of a nonmaternal, but familiar scent. Familiarization was achieved by placing a scented gauze pad in the incubator next to the infants' head for an average duration of 8.65 h. Another difference to the other studies results from the fact that arterial puncture is known to be more painful than venipuncture or a heel stick. So with regard to the neonates' reaction to pain, the findings of this study indicate a benefit of vanillin even with stronger pain triggers [37.20].

All of the studies suggest that vanillin can be helpful in decreasing pain in neonates, especially when the

Table 37.1 Comparison of studies on the effects of vanillin on pain in neonates

	Patients	Interventions	Results
Goubet et al. [37.16]	31 healthy preterms	• Exposure to vanillin before and during venipuncture • No exposure to vanillin before and during venipuncture • No odor before and during venipuncture	Significant reduction of pain score when vanillin was familiar before venipuncture
Rattaz et al. [37.17]	44 healthy newborns	• Odor of mother's milk during heel stick • No exposure to vanillin before but during heel stick • Unfamiliar odor during heel stick • No odor during heel stick	Significant reduction of pain score before, during and after heel stick when odors were familiar, i. e., vanillin and mother's milk
Williams et al. [37.18]	44 healthy newborns	• Odor of mother's milk during heel stick • Exposure to vanillin before and during heel stick • No exposure to vanillin before but during heel stick • No odor before and during heel stick	Reduction of pain score in the group of vanillin and mother's milk
Goubet et al. [37.19]	44 healthy newborns	• Exposure to vanillin before and during venipuncture • No exposure to vanillin before and during venipuncture • Venipuncture without odor	Significant reduction of pain score when exposed to vanillin before the procedure
Sadathosseini et al. [37.20]	135 preterms and newborns	• Exposure to vanillin before and during arterial puncture • No exposure to vanillin before but during arterial puncture • No odor before or during arterial puncture	Less crying and less fluctuation of oxygen saturation when exposed to vanillin before and during the procedure

Table 37.2 Comparison of studies on the effects of vanillin on apneas in preterms

	Patients	Intervention	Results
Marlier et al. [37.21]	14 extreme preterms, 24–28 gestational weeks, with severe apnea under intensive therapy	Day 1: standard therapy Day 2: plus vanillin Day 3: standard therapy	Addition of vanillin reduces apnea
Edraki et al. [37.22]	36 preterms, 32–33 gestational weeks, without present apnea	Control (standard therapy) versus vanillin for 5 days	Vanillin significantly reduces apnea, bradycardia and fluctuation of oxygen saturation

child is exposed to the odor before undergoing a painful procedure.

The results are summarized in Table 37.1.

37.1.2 Aroma Therapy for Stress in Neonatology

Stress is a more general parameter than pain, but the tools used for measuring stress and pain are quite similar. Animal studies have shown that genetic differences in temperament may determine how lavender oil influences anxiety [37.23].

Lavender

One published study has tried to assess the influence of lavender on stress parameters of the child, but also of its mother.

In this study, 30 healthy mother-newborn dyads were exposed to lavender, compared to no odor and lavender plus the information given to the mother that lavender has a positive influence on her and her baby. The results indicate a reduction of stress parameters on behavior, sleep duration and cortisol level in saliva in the lavender group. A *pseudo-placebo effect* by providing additional information about the positive effects of lavender could not be confirmed. However, the results of this study were not significant [37.24].

37.1.3 Aroma Therapy and Apnea-Bradycardia-Syndrome of the Neonate

Apnea and bradycardia due to immaturity of the brain stem are severe problems in the care of neonates. At a heart rate below 80 beats/min, a reduction of the cerebral blood flow can be observed. Yet the influence on the long-term neurological development is not clear.

Vanillin

There is one study that assessed the influence of a specific odor on high-risk preterms. 14 infants, gestational age 24–28 weeks, suffering from severe apnea despite analeptic therapy with caffeine and/or Doxapram, were part of this study. On day 1 of the study, apneas were counted as baseline, on day 2, the infants were exposed to vanillin, and on day 3, vanillin exposure was stopped. The infants showed significantly less apnea on day 2 [37.21].

Focusing on the same problem, another study with 36 preterms was conducted. In contrast to the study

mentioned before, the infants did not belong to a high-risk group. These infants had a mean birth weight of 1936 g in the intervention group and 1848 g in the control group. Their gestational age was 33 and 32 weeks. The study started when the infants were 2 days old. Every 12 h, 2 ml of a 2% vanillin solution was dropped on a cotton swab placed in the incubator while vital parameters were measured. After 5 days, the intervention group had significantly less apneas than the control group. There was also a significant difference regarding oxygen saturation and heart rate between the two groups [37.22].

It is remarkable that both high-risk preterms and late preterms seem to benefit from vanillin exposure regarding apneas and bradycardia.

A comparison is shown in Table 37.2.

37.1.4 Aroma Therapy and Energy Expenditure in Neonates

Based on the assumption that there is an influence of odors on the metabolic system by vegetative and endocrine pathways, attempts have been made to evaluate this correlation. It has been observed that several factors influence the reactions of preterms and newborns when exposed to milk, for instance whether they are hungry or not [37.25].

Vanillin

In the only published study in neonates, 20 healthy preterms were exposed to vanillin and energy expenditure was measured by indirect calorimetry. An influence on energy expenditure could not be observed [37.26].

37.1.5 Weaknesses of the Studies

Unfortunately, pain scores are not sufficiently precise. Thus it is difficult to discriminate pain from stress or just discomfort. Objective measurement tools would be helpful [37.27].

In addition, cortisol is not an obligate stress parameter. Endonasal suctioning is known to be painful for a preterm. However, it was shown that cortisol levels are not significantly changing during the procedure [37.28].

37.2 Possible Explanations

37.2.1 Considerations of Physiology

The rhinencephalon and the limbic system are phylogenetically and ontogenetically old parts of the human brain. Olfactory sensations are being transported by the olfactory bulb and then reach structures of the thalamus and hypothalamus, which explains vegetative reactions as well as effects on endocrine function. The amygdala and limbic system connect these sensations to the orbito-basal, fronto-basal and temporal cortex which mediate olfactory reactions to our consciousness.

It has been shown by near-infrared spectroscopy studies that this theoretical background is present in the physiology of newborns as well. They revealed that olfactory stimulation is followed by reactions in the olfactory cortex of newborns [37.29, 30], to the extent that even a relatively precise discrimination of odors is possible [37.31]. Furthermore, it is known that the fetus is able to smell and that the food of the mother has an influence on the fetus as well [37.32–35].

Phylogenetically, smelling is a mechanism of noticing danger. This behavioral pattern can be transferred into our long-term memory by several mechanisms. So it is still reflected in our reactions to particular olfactory stimuli: An uncomfortable odor is often followed by holding breath, escape or vomiting. By remembering odors that have led to an uncomfortable situation, the odor itself can cause such reactions. For example, a particular smell can evoke a feeling of sickness even years after having consumed soured milk or rotten fish. In many people, the odor of vomitus is enough to induce sickness. But on the other hand, an odor can also be associated with a pleasant situation and act as a trigger to recall this situation unconsciously [37.36, 37].

37.2.2 Parallels to Adults

The findings in neonates outlined above are underpinned by various results of studies on adults.

Development and Involution

It is known that the early olfactory development starts in the first trimester. As we grow older, more and more junctions to cerebral functions, memories, moods and cognitive abilities develop [37.38]. But this development can be reversed when we reach higher ages. One of the most extreme forms of this reversal is dementia. This raises the question whether aroma therapy could also be a useful tool in the treatment of dementia as a pathological condition. In fact it has shown benefits for disorders associated with dementia [37.39].

These positive results can be explained by pathways similar or even identical to the ones described above

for neonates. However, the results on aroma therapy are still ambiguous [37.40].

Pain

Another clinical condition where aroma therapy is being used in adults is pain. In patients undergoing hemodialysis with arteriovenous fistulas, the authors of a study showed reduction of pain when lavender essence was presented during needle insertion [37.41].

Vital Signs

Similar to the findings of studies on infants, a recent study tested the effect of lavender oil inhalation not only on patients' vital signs, but also on the perceived quality of sleep in an intermediate care unit. Like in neonates, it was an underlying aim of this study to save drugs for sedation. Effects were observed in modulation of vital signs. Also quite similar to the study on infants mentioned above (Sect. 37.1.2, *Lavender*) [37.24], the quality of sleep improved under lavender aroma therapy. This difference was not significant [37.42].

37.2.3 Essence

For aroma therapy in neonates, the database is small. Yet, the published data is encouraging and new hypotheses could be developed. For example, the positive effect of kangaroo care could partially be explained by the odor of the mother. No adverse effects were reported. Even though effects of early exposure to certain odors are well known [37.43, 44], the long-term effects of aroma therapy, i. e., the application of odors for therapeutical use, cannot be estimated due to the lack of data [37.43, 44].

So it can be concluded that the theory appears to be plausible, but is not sufficiently precise yet. Further studies are needed before a general recommendation is possible.

37.3 Neonatology-Related Research and Aroma Therapy

In modern neonatology of the 1980s, intubation was the most common treatment of the immature lung. Then, in the 1990s, intubation was complemented by the application of surfactant, which strongly improved the prognosis of a preterm. Since the early 2000s, the application of surfactant was not necessarily followed by endotracheal intubation, but by continuous positive airway pressure (CPAP), a method for noninvasive ventilation.

The historical development of neonatal management also included an increasing tolerance towards pH, pCO2, pO2, blood pressure and oxygen saturation. All of this was accompanied by the general insight that children are not little adults, and moreover, that preterms are not simply little children.

The historical change started with a practice of *maximal handling*, few analgesia, invasive ventilation and progressed to minimal handling, adequate analgesia as well as rooming-in, kangaroo care, general reduction of stress, breastfeeding, the use of glucose for analgesia and a general awareness for developmental care. Data on music therapy as well as aroma therapy might lead to even smoother neonatal medicine where complementary methods like aroma therapy have their evidence-based place. The further we go, the more simple principles become relevant: touching, i. e., body contact by kangaroo care or massage, glucose (at least partially) as taste, music therapy as auditory stimulation as well as aroma therapy as olfactory stimulus – all of these methods are based on phylogenetically and ontogenetically old mechanisms, but at the same time, they are simple, basic tools with increasing evidence. Besides, they are cheap and easy to perform.

Part E

Psycho-P

Part E Psycho-Physical and Cognitive Aspects of Odor Perception

The human body has learned to detect and respond to odorants by physiological responses and cascades, as detailed in the previous section, as did the human brain and mind. Humans are not only consciously aware of smells, provided the threshold levels of odorant mixtures and concentrations are met, but they are also capable of generating meaning of these smell impressions, to a lesser or greater extent.

Of course an important aspect of generating meaning is (lifelong) learning, and learning again is strongly dependent on motivation and experience. This dedication might arise from a person's interest in learning about smells, for example, in a professional context to become a perfumer, flavorist, enologist, or odorant scientist. However, specific situations and circumstances may also enhance learning attention in humans, especially situations that are linked to strong emotional experiences or those that are clearly linked with survival. Humans do not only learn to link specific smells to objects, situations and environments, but they also learn to rate them, to judge if smells are good or bad (or rather, their related sources), if they should respond with aversion, attraction, or not at all. As experience is a major dimension in these processes, odor memory, interpretation, and reaction may be strongly divergent in different phases of human life. Adults may even acquire preferences for smells or aromas that are rejected by young children, as adults learned to enjoy these smells, for example, in a social context. On the other hand, experiences with smells in relation to threatening situations or toxic objects might translate from early childhood into a lifelong aversion.

Unconscious processing of smells is also of major importance. Sometimes we even do not really know or cannot explain why we react in a certain way to specific smells. Moreover, smells are rarely perceived and interpreted in a mono-sensory dimension, but commonly in a complex interplay with input from other sensory modalities such as taste, appearance, and/or sound (i. e., via verbal communication) alongside the respective smell. If these diverse inputs do not fit the expectation or individually acquired learned concepts of the receiver, even pleasant smells can be rejected, or conversely, unpleasant smells might be accepted because they fit into a specific concept. In any case, it becomes clear that psycho-physical and cognitive aspects of olfaction are highly individual, as are human responses to smells.

38. Cortical Olfactory Processing

Jessica Freiherr

The act of smelling is a fundamental perceptual process mediated by the evolutionary very old olfactory system. Smells influence human behavior strongly related to survival, such as food consumption, hazard avoidance, sexuality, and reproduction. Hence, olfactory stimuli are of high ecological importance and are processed in phylogenetically old brain areas. This anatomical deviation leads to changes in the cortical organization of networks responsible for olfactory processing in comparison to other sensory systems that can be perfectly examined with the help of neuroimaging methods.

Within this chapter insights about the anatomy of the peripheral and central olfactory structures will be provided and physiological processes that are the basis for olfactory perception will be explained. The way of the olfactory information processing – starting with the molecules that are sniffed and bind to the receptors in the olfactory epithelium, to information transmission to the olfactory bulb and onward to olfactory cortical areas – will be traced. Alongside this, the reader will be informed about the clinical implications of the sense of smell.

38.1 Sniffing of Odors

To sniff or to draw air into the nose is the physiological precondition of olfactory perception. A sniff is defined as a reflex elicited by chemicals – either irritants or odors. This olfactomotor activity causes a certain level of turbulence in the nostrils responsible for the transport of odors to the olfactory epithelium located in the upper part of the nasal cavity. A sniff is traditionally viewed as a simple transport mechanism carrying the odors to the receptors; however, it can also be considered the earliest stage of olfaction as compared to eye movement in vision [38.1]. Sniffing does not only influence olfactory intensity but also odor identity or quality perception, and sniffing patterns can be quite divergent between individuals, and depending on task [38.2, 3]. Odorant molecules depending on their shape have a distinct sorption rate on the mucosa and high sorption rate odorants are better perceived at high velocities and vice versa [38.4–6]. This is of special interest since the human nose underlies a nasal cycle during which the mucosa alternates between congestion and decongestion from one nostril to the other leading to low and high velocities of the sniffed air [38.7]. In other words, at a given time we find low velocity and a better uptake of low sorption rate odorants in the congested nostril and vice versa in the decongested nostril. Consequently, a different olfactory percept is conveyed through each nostril at a given time [38.5].

Natural sniffing provides optimal chemosensory perception [38.8] and sniff magnitude is largely related to olfactory pleasantness – humans sniff less intense in response to an unpleasant as compared to a pleasant odorant [38.8, 9]. Additionally, breathing patterns during olfactory perception and olfactory imagery are similar [38.10] and even imagery of pleasant odors evoked larger sniffs in comparison to unpleasant odors [38.11–13]. Sniff magnitude is not only of interest with regard to common odors but also due to chemosensory emotional cues. Evidence stares that sniff magnitude increases when smelling fear sweat and decreases after smelling disgust sweat. This phe-

nomenon is interpreted as sensory acquisition and rejection behavior [38.14].

As stated earlier, sniffing is needed for the conscious perception of odorants; however, the adjustment of sniff response also appears during unconscious odor perception. Therefore, the measurement of sniff response offers a great opportunity to examine processing of consciously undetected stimuli [38.15] and renders possible an implicit measure, for example, during sleep [38.16].

Another interesting aspect of sniffing behavior is that humans unconsciously mimic olfactory acquisition behavior of their conspecifics: *Arzi* et al. used the movie *Perfume* to show that the observers sniffed as soon as the characters in the movie started sniffing. This mirror sniffing effect was strongest when subjects heard the sniff but did not see the object emanating a smell. Mirror sniffing is interpreted as a form of mimicry, contagious behavior, such as laughing or yawning or a form of orienting response [38.17].

Regarding the activation of brain areas, sniffing of odorless air alone leads to an activation in the olfactory bulb [38.18] as well as in piriform and orbitofrontal cortices [38.19, 20]. Probably, this activation of typical olfactory brain areas is related to the airflow in the nostrils and provides important hints for the computation of olfactory information. In other words, the sniff prepares the olfactory cortical network for incoming chemosensory information. Further, the hippocampus and the cerebellum are considered the neural control centers of olfactomotor response. The hippocampus receives olfactory information from the entorhinal cortex and projects to respiratory centers [38.1, 21]. Activation of the cerebellum during olfactory perception is interpreted as a feedback mechanism adjusting breathing volume according to odorant concentration [38.22].

Since sniffing is necessary for odor perception, neurological or psychiatric disorders that are accompanied with smell dysfunction might be related to impairments of sniffing [38.1]. Sniffing deficiencies that are at least partly related to olfactory impairment have been proven for patients suffering from Parkinson's disease [38.23]. Additionally, children with autism spectrum disorder showed an altered sniff response in comparison to typically developing children and did not adjust sniff magnitude with regards to odor pleasantness [38.24]. The measurement of sniff response can thus be considered as novel diagnostic tool and biomarker for several neurological and psychiatric diseases. To go one step further, sniffing is also a helpful tool in emergency medicine: sniffing enables communication and environmental control in severely disabled people. In an elegant study, *Plotkin* and colleagues [38.25] established that sniffing provides a control interface to write text and drive an electric wheelchair in patients suffering from locked-in syndrome.

38.2 Olfactory Epithelium

The molecules that are sniffed, reach the olfactory epithelium situated in the upper part of the nasal cavity. The olfactory epithelium lines the mucosa right below the cribriform plate and the mucosa of the superior turbinate and houses the olfactory receptors, G-protein coupled receptors [38.26]. Humans possess approximately 340–400 different functional olfactory receptor genes coding for olfactory receptors [38.27–29]. Odor molecules retain different functional groups activating different receptors. In other words, the olfactory receptors are units that detect molecular features of the odorants [38.30]. One study provides a first hint for a topographical organization of the olfactory receptors in the epithelium based on pleasantness of the odors that activate the receptor [38.31].

Olfactory receptor cells are bipolar cells; their apical end is situated in the nasal mucosa where the odorants bind to the receptors. This causes an action potential that travels along the long axon of the receptor cell (fila olfactoria, that are grouped into the olfactory nerve – cranial nerve I) through the lamina cribrosa directly into the olfactory bulb [38.26]. Please see Chap. 27 for more details on odorant sensing.

By means of a combinatorial code, it is possible that thousands of different odor molecules are recognized with a relatively low number of receptors [38.32]. In scientific literature of the last decades it is assumed that humans can perceive about 10 000 different odors. Recently, psychophysical testing was used for an estimation of the actual number of discriminable smells. In contrast to the existing literature, the authors approximate that humans can discriminate more than one trillion different substances by their smell [38.33] and hence provide evidence that the olfactory system outperforms other sensory systems with regards to the number of physically different perceivable stimuli.

Although humans can distinguish such a great number of smells, they perform surprisingly bad at naming familiar olfactory impressions [38.34]. The interactions between language and olfactory perception are complex (see also Chap. 53).On the one hand, it is more difficult to assign words to an olfactory experience than to any

other sensory experience. It is supposed that this shortcoming is based on the early development of the olfactory system in relation to the relatively late development of the language system during evolution [38.35]. On the other hand, olfactory stimuli can be processed without any linguistic involvement – smelling an odor without identifying it can lead to episodic memory recall and a strong emotional response. Controversially, in case a word and an odor are presented concomitantly and thereby linked to each other, words and verbal context are more powerful modulators of olfactory information than stimuli of any other sensory modality [38.36]. More recent studies established that the odor-language integration network consists of the orbitofrontal cortex and the anterior temporal lobe/temporal pole for odor object coding and semantic integration and the inferior frontal gyrus for olfactory naming and verbalization [38.37–39]. Another area that might be of importance for olfactory identification processes is the olfactory bulb. In a voxel-based morphometry study, olfactory bulb volume of the subjects predicted behavioral performance in an olfactory identification test – the larger the olfactory bulb the better are humans in identifying the odor [38.40]. Within the network of the brain areas described earlier, smells are linked to their name and odor identification takes place.

38.3 Olfactory Bulb

The olfactory bulb is considered the first relay station in the olfactory system. In the glomeruli of the olfactory bulb, olfactory information is transmitted from the primary neuron, the olfactory receptor cell to a secondary neuron, the mitral cell. Glomeruli respond to a range of different odorants that share a particular pattern of molecular characteristics. Further, glomeruli that receive input related to a similar molecular range group together and form molecular-feature clusters in the bulb [38.30]. Thus, odorant-specific activation of receptors is translated into an odorant-typical spatial activation pattern in the olfactory bulb [38.41, 42]. At this stage, we find a high level of convergence from thousands of neurons onto a few glomeruli.

The olfactory bulb also contains periglomerular neurons and interneurons transmitting inhibitory signals to neighboring glomeruli, as well as to the contralateral olfactory bulb. Those cells also receive retrograde inhibitory signals from higher order brain areas. The functional importance of those cells is to enhance the contrast between olfactory stimuli and background noise resulting in an increase of discriminability and sensitivity of the system.

Until recently, the olfactory bulb was largely underestimated regarding its function and importance. Nowadays, it is recognized that the olfactory bulb fulfills tasks comparable to that of other primary sensory cortices. In the olfactory bulb, the signal is condensed and amplified and a basal cognitive processing already takes place. Although traditionally the piriform cortex (pirC) has been termed as primary olfactory cortex, due to the discovery of the sophisticated functions of the pirC (see in the following) this concept does not hold true. Thus, the olfactory bulb serves as primary olfactory cortex encoding the chemical features of odorants and organizing them in a spatial pattern [38.43–46].

One of the anatomical deviations of the olfactory system is that olfactory information can be transmitted to cortical areas without a thalamic relay [38.47]. Thereby smells have the capability to bypass attentional gating processes. The olfactory bulb can hitherto also be considered the olfactory thalamus [38.48]. This is reasoned since the olfactory bulb has a bottleneck and relevance filter function regarding information processing before the cortex, comparable to the function of the thalamus in processing of other sensory stimuli.

38.4 Central Olfactory Pathways and Networks

From the olfactory bulb, the information about the chemical structure of an odorant is transmitted via the lateral olfactory tract to a set of small structures: the pirC, the entorhinal cortex, the amygdala and periamygdaloid cortex, the olfactory tubercle, and the anterior olfactory nucleus. An overview about the olfactory pathways and network can be found in Fig. 38.1.

The pirC is one of the key nodes in the cortical olfactory system. In a recent meta-analysis of olfactory brain imaging data the pirC revealed the highest activation consistency across all included functional imaging studies (Fig. 38.2) [38.50]. The pirC is anatomically divided into two parts that are responsible for different tasks. The anterior or frontal part of the pirC is

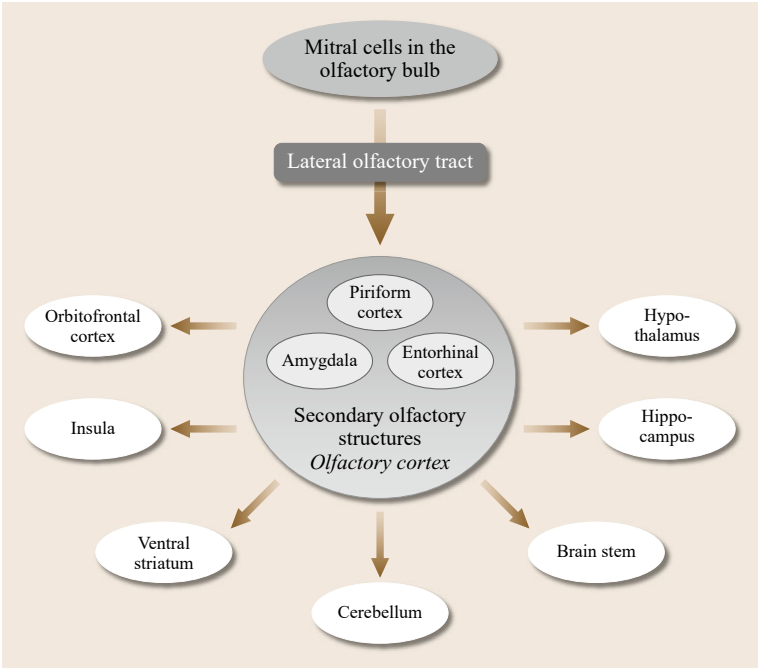

Fig. 38.1 Brain areas involved in olfactory processing (after [38.49])

related to an initial neural representation of an odorant and encoding of its molecular features [38.51], whereas the posterior or temporal part of the pirC is responsible for a holistic odor object formation, hedonic quality coding, and categorization [38.52, 53]. In the pirC the perceptual quality of an odor is shaped by attention [38.54], expectancy [38.55–57], learning [38.58], recognition and memory [38.59], as well as valence-dependent responses [38.60]. The pirC can consequently be considered association cortex connecting olfactory perception with behavioral, cognitive and contextual information [38.43, 46].

The olfactory bulb and pirC send projections to the entorhinal cortex that renders the gateway to the hippocampus responsible for memory processes [38.61]. From rodent studies, it is suggested that the entorhinal cortex projects back to the pirC and the olfactory bulb and thereby serves as a *powerful top-down modulator of olfactory cortical function and odor perception* [38.62]. The entorhinal cortex, especially the transentorhinal region is one of the first brain areas showing a neuropathology in patients suffering from Alzheimer's disease [38.63, 64] and is thus responsible for early olfactory deficits seen in Alzheimer's disease patients. For further insights about disrupted olfactory perception please refer to Chap. 31.

The amygdala and periamygdaloid cortex receive input from the olfactory bulb and the pirC and are responsible for a cognitive evaluation of olfactory input. In a recent meta-analysis about predictors of amygdala activation it was established that olfactory and gustatory stimulation had the highest amygdala activation probability in comparison to other sensory modalities [38.65]. Traditionally, the amygdala was considered the neural substrate for odor pleasantness assignment [38.66, 67]. More recently, evidence arose

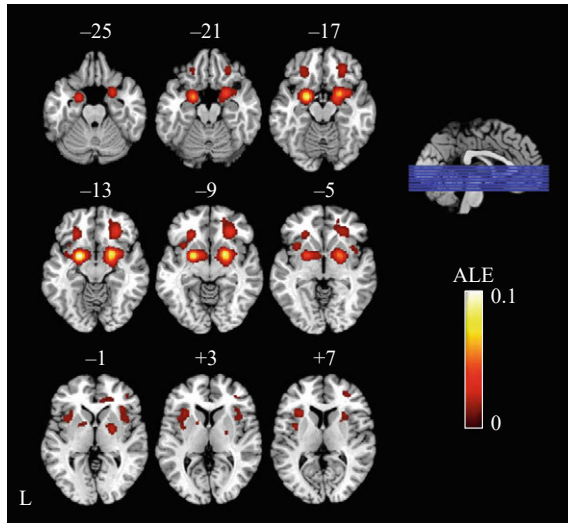

Fig. 38.2 Typical brain activation during olfactory stimulation. Depicted are the results of a meta-analysis of olfactory brain activation in 45 functional imaging studies. Bilateral activation of the pirC, the OFC, as well as anterior insula can be found (courtesy of Elesvier, after [38.57])

that the amygdala is rather responsible for olfactory intensity coding but only if the odor is considered pleasant or unpleasant. In other words, emotional or behavioral salience encoding takes place in the amygdala [38.68], whereas odor pleasantness or valence is coded in the orbitofrontal cortex [38.69]. Please see Chap. 39 for a detailed review on olfactory valence.During studies using chemosensory stimulation, amygdala response was correlated with response in pirC, orbitofrontal cortex, and insula hinting toward a network of those areas responsible for processing of chemosensation [38.70].

An attempt to describe the temporal pattern of odor perception is the cascade model of olfactory perception by Jonas Olofsson. This model states that odor detection is the first and fastest step followed by a direct odor valence determination. An indirect path links odor detection with odor valence by way of identification of the odor object. The slowest perceptual process is the rating of edibility of the odorant [38.71]. Hence, olfactory perception is based on a hierarchical and partial parallel organization of the olfactory system [38.72].

From this set of smaller brain areas, olfactory information is passed on to brain areas that are not specific for olfactory processing but rather convey cognitive processes related to the perception of odors: the orbitofrontal cortex (OFC), the insula, hippocampus, thalamus, hypothalamus, ventral striatum, cingulate cortex, and the cerebellum.

Here the OFC is considered a key node in the olfactory system and a crucial center for cognitive odor processing. In the OFC higher order processes shape the odor signal coming from the pirC and create the final conscious smell percept. While olfactory bulb volume predicted olfactory identification of healthy subjects, OFC volume rather predicted threshold scores and olfactory discrimination ability [38.40]. Thus, the OFC mediates processes related to olfactory sensitivity and discrimination tasks. Further, experience-dependent modulation of the signal as well as affective coding (as stated earlier) are computed in the OFC. It is also known, that the OFC is the brain area in which olfactory information is integrated with information from other sensory modalities [38.73] and the language system [38.39]. With regards to food odor perception, the OFC involves mechanisms of reward assignment [38.74]. Hence, the OFC does not exclusively process odor information but rather engages in processes important for human perceptual decision-making and resolving sensory uncertainty.

The insula is traditionally considered primary gustatory cortex [38.75]; however, displays frequent activation as response to odors. It receives input from not only pirC and amygdala, but also from OFC [38.76]. Evidence exists that the anterior insula plays a role in integrating chemosensory information especially with regards to food [38.45] leading to an integrated flavor perception [38.77]. Furthermore, the anterior insula is crucial for the elicitation of avoidance behavior and is thus correlated not only with the perception of negatively valenced olfactory or trigeminal stimuli [38.78] but also negative multisensory stimulus combinations [38.79]. The insula moreover is involved in regulation of autonomic interoception. In the context of a strong connectivity of the insula with pirC, amygdala, and OFC it can be suggested that chemosensation influences interoception and interoceptive processes are regulated within this network [38.70].

The olfactory system is unique in the sense that sensory information passes only two synapses and reaches brain areas involved in emotion and memory processing. The hippocampus conveys memory processing associated with odorants. Smells indeed can elicit very vivid and emotional memories. On a timeline, smells in comparison to pictures or language have the capability to evoke memories of early life – smells remind us of earlier events in comparison to pictures or language [38.80]. For a more detailed description of olfactory memory processes please refer to Chap. 42. The hippocampus further seems to be involved in integration of olfactory with other sensory stimuli [38.73].

As already mentioned, the main direct pathway of olfactory information processing is from the olfactory bulb and pirC to the neocortex; however, an indirect pathway through the mediodorsal thalamus to the neocortex also exists. The mediodorsal thalamic nucleus (MDT) is considered a part of the thalamus responsible for odor processing as it receives afferents from pirC, amygdala, enthorhinal cortex, and projects to the OFC [38.81, 82]. In an elegant study, *Plailly* and colleagues [38.83] demonstrated that attention toward an odor strengthened the connectivity between the MDT and the neocortex (OFC). As described earlier, in olfaction the OB and pirC inherit functions of a primary sensory thalamic control including sensory coding, gain control and state-dependent modulation. Hence, the MDT might rather be seen as a higher order olfactory thalamus [38.82].

The cingulate cortex, especially the anterior cingulate is traditionally involved in odor–taste integration and is therefore considered a part of the flavor network [38.84]. Cingulate cortex belongs to the limbic system and its activation is also frequently found following olfactory stimulation and might therefore be

involved in attention processes in relation to odors. Especially the anterior cingulate is responsible for detection of conflicts of attention [38.85].

As stated earlier, the involvement of the cerebellum in olfactory processing was established as a kind of regulation center that adjusts sniff magnitude to concentration of the smell [38.22]. The sniffs of patients with cerebellar lesions were invariant with regard to odor concentration and thus olfactory identification was impaired. The authors suggest an olfactocerebellar pathway that is important for identification of odorants [38.86].

38.5 Conclusion

Taken together, the olfactory system involves three anatomical deviations. First, the main central gate for olfactory input is the olfactory bulb; here we find a topical map of odor representation. Olfactory information does not pass a thalamic relay on its way from receptors to neocortex, which might be the reason for a multitude of unconscious processes involved in olfactory perception. Second, olfactory information is first processed in the paleocortex (olfactory bulb, pirC) and then passed on to the neocortex while sensory information in other modalities is mainly processed in neocortex. Third, the olfactory system is strongly connected to the limbic system resulting in strong emotionally toned responses to odors and robust relation to memory processing. Those characteristics of the olfactory cortical system form the basis for smell perception which renders unique among other sensory perceptions.

39. Behavioral and Neural Determinants of Odor Valence Perception

Janina Seubert, Christina Regenbogen, Ute Habel, Johan N. Lundström

This chapter serves as an introduction to our current understanding of the stimulus-driven and experience-driven mechanisms, which give rise to affective evaluation of odorants. We will start by focusing on the potential evolutionary benefits of rapid elicitation of affective responses to odors and provide an overview of paradigms and approaches that can be used to quantify these experiences in an experimental setting. We will then outline evidence in favor of stimulus-driven and experience- or learning-driven accounts of odor valence perception, representing two prevalent theories. Finally, we provide an overview of the cortical networks that support the assignment of valence to odors.

The pleasantness or unpleasantness of an odor, which is commonly referred to as its valence, is usually experienced as its most pervasive perceptual property. This is eloquently described in Marcel Prousts' book *In Search of Lost Time* (Vol. I, Swann's Way, 1913) in the *episode of the madeleine* (a famous description of an involuntary memory episode which the protagonist experiences while enjoying a piece of French small cake). These emotional reactions to odors, whether they occur in the context of a food aroma or the perfume of a loved one, not only color the emotional evaluation of a situation, but also form the basis of many traditions that constitute an integral part of human culture: for example, the shared consumption of familiar foods, or the usage of scents, such as incense or patchouli, during spiritual gatherings [39.1, 2]. Unlike visual information, where conscious identification of the object generally precedes the elicitation of approach or avoidance reactions, affective responses to odors can occur even in the absence of any knowledge about the identity or source of the odorant. It is this immediacy that gives smells the unique ability to involuntarily and profoundly change affective experiences of our sensory surroundings, supporting the prevailing notion that valence, rather than quality, may constitute the principal dimension of olfactory perception [39.3–5]. Emotional evaluations of odors range from strongly appetitive, as might be the case for the smell of freshly cut grass, to strongly aversive, as when we smell a pair of dirty socks. While this valence attribution appears to arise naturally and apparently without conscious effort, the mechanisms behind the generation of positive or negative responses to odors are far from trivial: while smells like *freshly cut grass* or *dirty socks* are perceived as holistic objects, they are formed by complex mixtures, and may even overlap in a number of their odorous compounds. Sometimes, a fraction of the molecular components of an odor can make a fundamental difference to its evaluation, for example, when distinguishing between *grilled fish* and *rotten fish*. The matter is further complicated by the observation that emotional responses are quite unstable over time and

susceptible to changes based on additional knowledge about the emitting object: finding out that the disgusting smell of *dirty socks* is actually released by a fancy French cheese quickly results in a reappraisal of the odor, which is now perceived as appetizing and edible, and no longer elicits disgust and withdrawal tendencies [39.6]. Despite this fundamental importance of valence to odor perception, our understanding of how it is formed, modulated, and processed is still poorly understood.

39.1 Odor Valence and Behavior

39.1.1 Relevance of Odor Valence Perception for Adaptive Behavior

Emotional experiences are commonly classified along two principal axes: valence and arousal [39.7]. Valence is commonly considered the principal dimension underlying more complex odor-elicited feelings [39.3] (see Chap. 23 for an in-depth discussion on these).Forming a core element of motivation [39.8], valence describes the intrinsic attractiveness or aversiveness of an experience [39.9], while arousal, discussed in more detail below, quantifies the amount of physiological or psychological reactivity.

Valence qualities also form the basis of many evolutionarily adaptive behavioral responses, which occur as a direct consequence of olfactory perceptual experiences. These responses fall into two broad categories: those which subserve a behavioral warning mechanism through elicitation of a withdrawal impulse (avoidance responses, [39.10, 11]), and those which assist the elicitation of appetitive responses as a contribution to the maintenance of health. These include for example the elicitation of a desire to consume food, or affiliative behaviors toward potential mates and social groups (approach responses).

In a recent overview, *Stevenson* [39.12] further separates the evolutionary functions of odor valence perception into three broad category domains in parallel to the approach/avoidance dimension: ingestion, hazard avoidance, and social communication. *Ingestion* hereby refers to responses to odors relevant for food intake, and includes the elicitation of an appetitive response toward familiar edible items, but also to the regulation of appetite through state-dependent elicitation of approach or avoidance behaviors toward them: although a chocolate chip cookie generally constitutes an edible object, we may not feel a strong preference for its aroma after just having finished a brownie. On the other hand, *hazard avoidance* describes aversive reactions contributing to an olfactory warning system. This olfactory-based warning response aids detection of environmental dangers such as smoke and fumes (through elicitation of fear, as during detection of the smell of a gas leak), as well as the prevention of spoilt food items (through elicitation of disgust, as during detection of the smell of rotting meat). Finally, *social communication* includes appetitive aspects relating to the perception of body odors [39.13], which may contribute to the communication of emotions and fitness detection [39.14, 15], but also avoidance aspects, as evident in the negative responses to body odors signaling high genetic overlap to avoid inbreeding [39.16], and aversive reactions to the smell of illness [39.17].

Given that odor valence evaluations can bypass object identity identification, which typically precedes valence attributions in other sensory modalities, their role as a warning signal can be considered of foremost importance. For example, quick and reflex-like negative emotional responses are crucial when it comes to spitting out a spoilt food object or withdrawing from toxic fumes.

Correspondingly, valence attributions to unidentifiable odors, without *knowing* what is smelled, tend to be subject to a negativity bias, as they are usually less positive than attributions to familiar odors [39.18]. For example, people frequently report the odor of 1-octen-3-one to be unpleasant when presented by its chemical name; the same odor, however, elicits positive valence ratings when presented as *mushroom odor*. This response pattern meets the criteria for a behavioral warning system as put forward by error management theory [39.19]: any system designed for self-protection should, in doubt, be biased toward elicitation of a warning response, given that an erroneous failure to respond could potentially lead to fatal consequences [39.11]. The health impact resulting from impairment of the sense of smell further demonstrates the importance of these immediate avoidance reactions to odors for survival: decrease or complete loss of olfactory function, for example, during old age, results in failure to elicit withdrawal reactions and thus an increase in hazardous events, for example, a fire or gas leak [39.20], and a lowered rejection threshold for rotten food [39.21]. A recent retrospective cohort study demonstrated that the chances of experiencing such a hazardous event increases from 18% in individuals with an intact sense of smell to 39.2% in anosmic patients [39.22].

Immediate rejection responses, however, are of course not the only pathway for odor valence assignment; many odors that we encounter in our day-to-day lives are a source of pleasant affective experiences. These positive emotional responses are thought to be more strongly driven by the perceived *identity* of the smelled objects. Typically, such processes are labeled as *top-down processing* to distinguish them from the stimulus-driven, or *bottom-up*, negative evaluations explained above. These more cognitive, top-down controlled attributions are associated with a so-called *high-road* of olfactory perception, meaning that *object representations activate emotional responses downstream* [39.23, p. 1209] before a conscious valence attribution to the olfactory percept arises.

Absence of the ability to perceive the positive affective properties of an odor can equally result in severe consequences: In the elderly, the loss of olfactory function is thought to be a key factor contributing to appetite loss, and thereby to the incidence of undernutrition observed in this population [39.24, 25].

39.1.2 Assessing Odor Valence Perception in an Experimental Setting

Qualitative and quantitative measures of odor valence evaluation are predominantly assessed by studying the participant's perceptual experience, as observed through stimulus ratings or response time toward certain stimuli. The other dimension of emotional experience, its arousal value [39.26], tends to be less reliably captured by behavioral measures, however; it is thus more commonly characterized by measurements of central and peripheral nervous system responses to the stimulus material.

Behavioral Measures

Self-reported stimulus ratings and response times are frequently used methods that provide experimenters with a holistic picture of the participants' subjective odor perception and evaluation (Fig. 39.1).

In a typical experimental setup for self-report of olfactory properties, participants are directly asked to evaluate the sensory attributes of odorants, which are presented to them in a controlled manner. This presentation can take place manually, via glass jars that are opened and closed by the experimenter, or by means of an air-delivery device, such as an olfactometer [39.28] (see Chap. 24 for a detailed description).

Most studies assess stimulus valence by means of a rating procedure, in which the pleasantness of each odorant is evaluated on either a continuous scale between *highly pleasant* and *highly unpleasant* (digital analog scale, [39.29]), or by a two-alternative forced choice task, which yields a *pleasant* or *unpleasant* rating outcome [39.23]. Depending on the research question, the identities of the presented odors are either openly presented to the participants [39.6], or concealed from them [39.30]. Familiarity of the odor may bias toward top-down or bottom-up evaluations of valence, and thus constitutes an additional variable of interest in this context. Familiarity may change over the course of an experiment and thus can also be used as an experimental manipulation to study recognition effects of previously unfamiliar odors on valence perception [39.31].

Participants' response times, another measure of differential effects of positive and negative odor valence, have been shown to be influenced by the direction of valence [39.2]. In addition, the ecological relevance of the presented stimulus, particularly as related to food ingestion [39.32], affects the speed at which an affective evaluation is reached. As an example, a study by *Boesveldt* and *colleagues* [39.10] showed that the detection of unpleasant compared to pleasant food odors was faster and more accurate, strengthening the idea of the olfactory systems' preferential processing of odors that constitute ecologically relevant warning signals such as rotten food smells. Other studies have used the dimension of *edibility* as a measure capturing the motivational aspects (approach versus avoidance) of odors [39.23]. On the other end of the valence spectrum, the concept of *wanting* captures an odor's incentive value, salience, and propensity to elicit consumption in addition to mere *liking* [39.33]. *Wanting* tends to change in relation to a person's satiety state, while *liking* remains less affected.

Neurophysiological Measures

Physiological indicators of arousal, such as sweaty palms or a fast heartbeat, are prominent features of the experience of an emotional event. As such, they offer a unique window into the intensity of the experience of odorants' affective properties [39.34], which com-

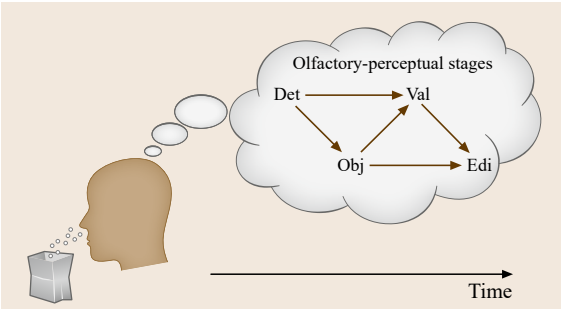

Fig. 39.1 A cascade model of olfactory perception (with permission from [39.27])

plements valence assessments. Physiological indicators further provide valuable insights into the biological basis of psychological constructs underlying affective odor perception and the evolutionary relevance of the associated emotional responses [39.35]. Changes in both autonomous and central nervous system activity, are recorded in the periphery of the nervous system and generally occur independently of the participant's awareness.

Alaoui-Ismaïli and *colleagues* [39.30] were among the first to include physiological markers to an odor hedonic rating task. These markers included skin potential and resistance, skin blood flow and temperature, as well as instantaneous respiratory frequency and heart rate. The authors showed that the presentation of odors engaged several of these autonomic markers, demonstrating that odors carried an emotional load comparable to the presentation of emotional auditory or visual signals. It was further shown that skin conductance and heart rate measurements significantly correlated with the intensity of participants' emotional experience, which indicated a direct relevance of these autonomous measures for subjective emotional experience (However, note that there is evidence that frontotemporal lesions can lead to impairments in autonomic responses but not of subjective ratings, limiting the interdependence of these two [39.36]). Furthermore, skin potential data showed a difference based on whether pleasant or unpleasant odors were presented, demonstrating that this activity was additionally modulated by the direction of valence.

Neurophysiological brain imaging techniques, such as electroencephalography (EEG) measurements, offer an indirect way to capture central nervous system activity through scalp recordings of postsynaptic potential change in large assemblies of neurons. Desynchronization of alpha-band activity in the EEG-signal, an indicator of cortical activity or arousal [39.37], has long been shown to be sensitive to odor stimulation [39.38]. A study by *Brauchli* and *colleagues* [39.39] investigated the valence-dependence of this autonomous response to odors, and found a significant decrease in the upper alpha-band activity of the EEG (9.75–12.5 Hz) within 8 s after stimulus presentation of an unpleasant odor. On the other hand, a pleasant odor condition did not result in a change of alpha-band activity, therefore suggesting that observed changes in cortical arousal captured by alpha desynchronization could be specific to odors with a negative valence. Similar to the above studies, the authors observed increased skin conductance amplitudes to negative odors, which were not, however, mediated by the amount of decrease in upper alpha-band activity. This indicates that central and peripheral physiological responses may capture independent processes. Another EEG study by *Schupp* and *colleagues* [39.40] determined the time course of the EEG signal following olfactory stimulus presentation, and found a difference in the amplitude of the late positive event-related potential (LPP) to odorants as a function of valence. The LPP is a positive potential arising approximately 400–500 ms after stimulus onset, which has been generally implicated in coding affective content and motivational relevance. An association of LPP amplitude change with different odor valences therefore suggested an important role of the late even-related potential in signaling the perceived pleasantness of odors [39.41, 42].

The studies above manipulated odor valence perception by presenting different odors, and thus cannot dissociate whether the observed effects are a direct result of perceived quality, or of specific influences of the odorant's different chemical composition. A more recent study by *Lundström* and *colleagues* [39.43] addressed this concern through the usage of androstenone, an odor for which a common genetic polymorphism results in fundamentally different perceptual experiences. Depending on a person's genetic variation of the olfactory receptor *OR7D4* [39.44], the odor is either perceived as urinous, hence negative, or flowery, hence pleasant [39.43]. Another portion of the population, who is completely anosmic to the odor, was excluded from the study. The main difference in cerebral processing of the androstenone odor between subjects with positive and negative valence perception was specific to the peak of the LPP amplitude; thus demonstrating its clear link to odor valence processing [39.43] and individual variation in genetic composition [39.44].

A final aspect of the experimental assessment of odor valence that we will discuss here relates to its relevance for social communication of affective information. The human face contains over 100 facial muscles, which, in certain combinations, express the elementary emotions of joy, anger, disgust, fear, and sadness, but can also communicate more subtle and culture-dependent mood states and feelings. Facial muscle activity is measured by electromyography (EMG) [39.45, 46]: small surface electrodes are hereby attached to the facial skin above the specific muscle and measure its electromyographic activity in relation to the stimulus presentation. Electromyographic activity is quantified by an amplitude change between baseline and response level. One particular study by *Jäncke* and *colleagues* [39.47] assessed facial EMG responses toward pleasant and unpleasant odors and demonstrated higher EMG activity toward disgust-eliciting stimuli at the highest odor concentration; however, no direct correlations with odor valence ratings were observed. An additional experimental manipulation investigated the

effects of the *social context* in which the odors were presented: individuals smelled the different odors either in a private setting or in the presence of another person (the experimenter). As expected, the display of facial emotions to unpleasant odors, as measured by the EMG response, was significantly stronger when the experimenter was present than when the participants were tested in solitude, indicating that facial responses are driven by social factors rather than directly by olfactory–facial reflexes (see [39.48] for a discussion). Facial muscle activity accompanying odor valence perception is thus thought to be embedded in a context-dependent higher order modulation, and dissociable from peripheral nervous responses that occur as a result of autonomous nervous system activity, such as skin conductance changes. Pleasant odors and positively rated odors, in contrast, were *not* associated with a facial response (participants smiling). This suggests that communication of odor-evoked emotion may primarily serve the evolutionary function to communicate danger or contamination to our conspecifics, rather than joy and content.

39.2 Determinants of Odor Valence

While the evidence outlined above clearly demonstrates that odor valence shapes both our behavior and physiological responses, the perceptual processes determining whether an odor is perceived as pleasant or unpleasant have long remained elusive. As we elaborate below, two separate lines of research can be identified, focusing on the one hand on the relationship between the molecular properties of odors and their perceived valence, and on the other hand on the cognitive mechanisms, which give rise to an affective valence percept on the cortical level. Both these factors need to be taken into account to grasp the construction of an odor percept with distinct valence properties.

39.2.1 Effects of Molecular Features on Odor Valence Perception

Similar to the colors, edges, or spatial frequencies that make up visual scenes, monomolecular volatile chemicals, such as alcohols and aldehydes, form the smallest perceptual units of all odors. These structures can be viewed as basic features that construct the olfactory objects we perceive, and as such, their influence on perceived qualities of odors are of significant interest for understanding the emergence of the pleasantness or unpleasantness of the final odor percept. Research has focused on the identification of possible innate approach or avoidance responses to individual chemical compounds, which may subserve the evolutionarily adaptive functions of odor valence perception outlined above. Indeed, work on rodents has convincingly demonstrated that the detection of specific volatile chemical compounds can elicit hard-wired emotional reactions, which likely constitute evolutionary advantages in the context of threat detection. Laboratory rats, for example, while never having been exposed to cats in their lifetime, still demonstrate strong avoidance reactions when exposed to a cat odor: relative to their peers who are exposed to a control odor, they spend significantly more time in a *hide box* and assume a distinctive defense-related body posture [39.49]. Immunoreactivity patterns further indicate that these effects do not originate from accessory olfactory bulb activity, which is frequently implicated in reflex-like adaptive behavior in rodents, but rather from the main olfactory bulb. This strengthens the possibility that analogous mechanisms may exist across species. More specifically, a later study by *Kobayakawa* and *colleagues* [39.50] identified the locus of innate odor-elicited fear responses in the dorsal olfactory bulb, indicating that a distinct subset of receptors may be responsible for these responses. While the precise coding mechanisms for aversive responses to specific chemical compounds remain unclear, recent work by *Dias* and *Ressler* [39.51] indicates that, at least in part, aversive responses to odors in mice may be produced by epigenetic inheritance mechanisms. Traumatic odor exposure in a parental generation was found to carry over to the following, unexposed, two generations who showed neuroanatomical and genetic modifications contributing to behavioral manifestations of increased sensitivity to the conditioned odor.

In humans, however, conclusive evidence for hard-wired behavioral responses to odors remains scarce. Earlier work has argued in favor of some innate preferences for specific odorants in humans [39.52] by demonstrating differences in facial expressions to odors in neonates. However, recent data has demonstrated relationships between early olfactory preferences and feeding modes [39.53], as well as prenatal exposure to food flavor by way of the newborns' mothers' diets during pregnancy [39.54]. These findings challenge the idea that postnatal behavior provides conclusive evidence for a hardwired biological basis of early odor preferences, and raises the possibility that even early olfactory preferences may be the result of learning mechanisms occurring during gestation and early life.

An alternative approach for the assessment of innate odor preferences, which has more recently gained popularity, explores relationships between the chemical composition of odors and olfactory perceptual space in humans with the help of big population-based datasets: these allow identification of robust correlations between human psychophysical assessments and structural molecular properties [39.55–58]. Stable relationships between perceptual ratings and molecular structures across participants are hereby interpreted as evidence for the existence of systematic and potentially innate relationships between affective evaluation, molecular structure, and interindividual variability in receptor expression.

In one of the most comprehensive studies of this type to date, *Khan* and *colleagues* [39.59] pursued a two-step procedure. First, they applied principal component analyses to an existent database of perceptual odor characteristics to reduce the dimensionality of perceptual descriptors. The component with the highest factor load emerging from this analysis, which the authors labeled *pleasantness*, accounted for 30% of the explained variance in perceptual feature space, and thus provided support for the idea of valence as the primary dimension of olfactory perception, much as described above. Second, they applied an identical approach to the molecular and physical descriptors of the same odorants; here, a primary axis emerged that was anchored by the attributes of *molecular weight* and *molecular extent*. Comparisons of the ranks of each odorant on the respective principal components in perceptual and molecular space indicated a high degree of overlap between these factors. This suggests that certain chemical properties are, in the absence of any contextual information, simply perceived as more pleasant than others. It is important to note, however, that the study was conducted on isointense concentrations of all odors only. Given that intensity perception is known to interact with pleasantness perception, future studies will need to incorporate intensity modulations to reflect this complexity.

While this work provides support to the idea of hardwired relationships between chemical properties and affective value independent of individual learning experiences, population-based models, which do not account for effects of interpersonal variability in perceptual experience, leave a substantial portion of variance unaccounted for. In a search for explanations for this remaining variability on the level of sensory encoding, studies have highlighted effects of interpersonal differences in olfactory-receptor expression on the phenomenological experience of odors. As explained above on the example of the odor androstenone, genetic dimorphisms in odor-receptor expression are linked to variances in glomerular activity to different odorants and, as a result, to differences in perceived odor quality and the resulting affective valence attribution [39.44, 58, 60]. Popular examples of such differences include dislikes for certain food items, which have been related to dimorphisms in receptors encoding distinct olfactory components of their aroma, causing some people to perceive a *soapy* note in cilantro that may be absent for other people, and a sweaty, urinous note in celery that others perceive as sweet and floral [39.61, 62].

In an effort to grasp this variability on a larger scale, *Mainland* and *colleagues* [39.58] identified agonists to 18 different odor receptors and demonstrated that polymorphisms in 63% of these were linked to differences in their in-vitro response patterns. To assess the functional consequences of this genetic variability, these patterns were related to receptor expression in a DNA population database, showing that on average, individuals differed in around 30% of these functional olfactory polymorphisms, and that geographical factors predicted the amount of observed genetic overlap between individuals (Fig. 39.2a). Finally, to demonstrate the behavioral relevance of this interpersonal variability, the authors singled out one receptor (Olfactory Receptor 10G4; *OR10G4*, which has four allele variants occurring with high frequency in the general population), for comprehensive behavioral testing (Fig. 39.2b). They found that possession of allele 3 or 4 accounted for a substantial increase in perceived valence of its agonist guaiacol. The perceived valence of two other agonists, as well as of 63 other odors not known to bind to *OR10G4* (Fig. 39.2c), remained unaffected.

These experiments show that receptor-binding patterns are not only likely to play an important role in the prediction of the perceived valence of an odorant, but also that variants within the population in the expression of these receptors significantly contribute to the variability in odor preferences between individuals.

39.2.2 Contextual Influences on Odor Valence Perception

As explained in the beginning of this chapter, any theory of odor valence perception needs to take into account the changes in valence evaluation that usually occur when a particular smell is linked to an anticipated positive or negative outcome. Highly variable between individuals and contexts, such top-down controlled evaluations are thought to account for a large portion of differences observed in odor valence assignments between individuals. For an impression of cognitively modulated influences on pleasantness perception, one only needs to revisit the above-mentioned example of a cheese odor that is presented as freshly grated parmesan cheese: it will likely stimulate appetite and

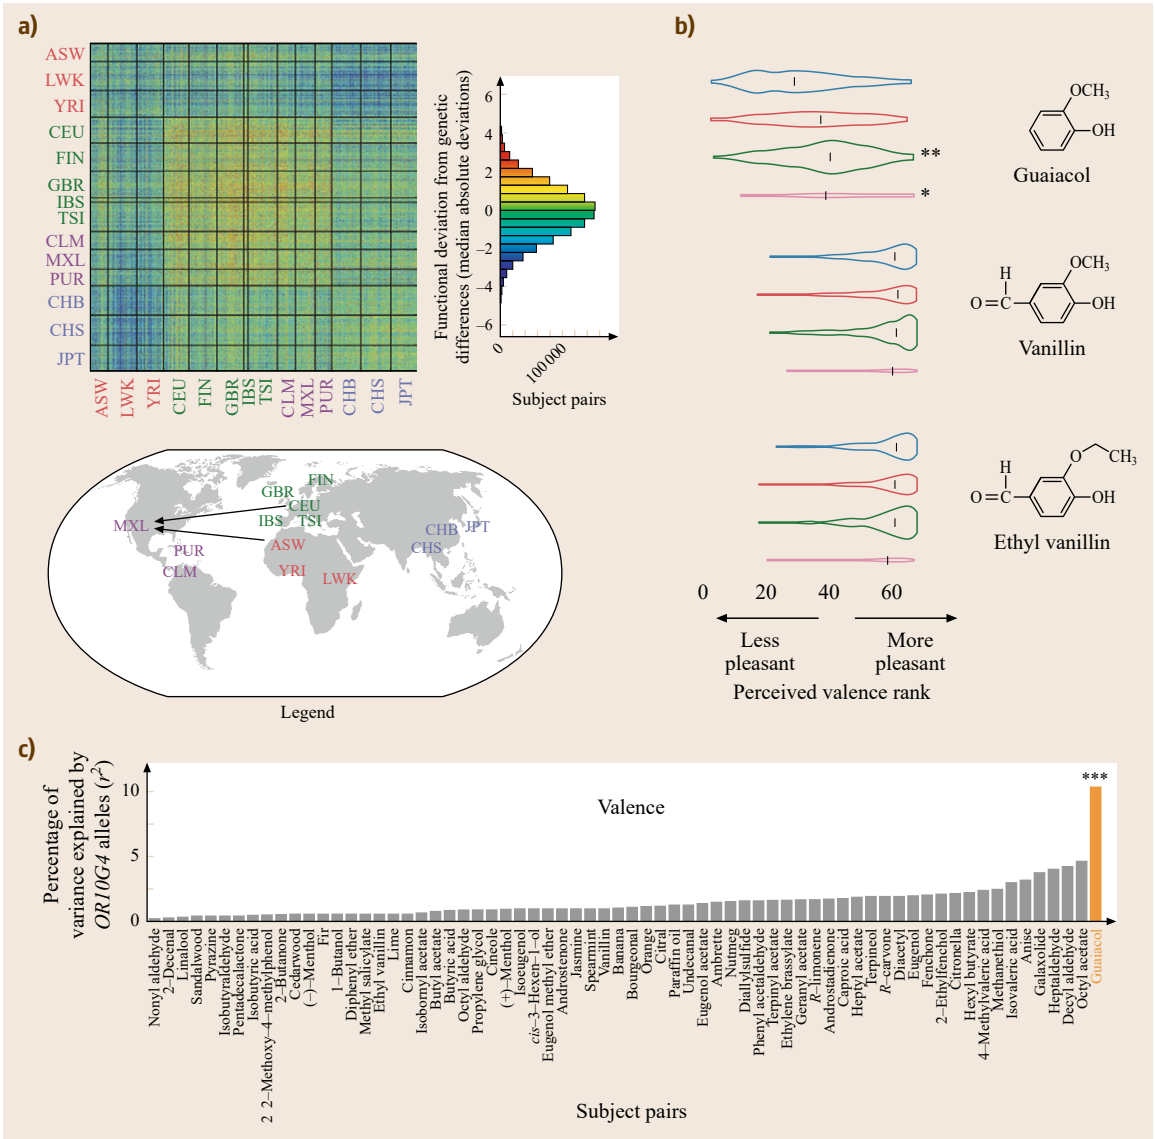

Fig. 39.2a–c Effects of functional variability in the human odorant receptor repertoire on the perception of odor valence (modified from [39.58], with permission from Nature Publishing Group). **(a)** *z*-Scored functional differences minus *z*-scored nucleotide differences among 27 odorant receptors of 1092 participants from the 1000 Genomes Project. Participant populations are labeled on the axes and separated by black grid lines. **(b)** Perceived intensity and valence rank for three in vitro *OR10G4* agonists by receptor variants of *OR10G4*. **(c)** Percentage of perceptual variance (r^2) in valence ranking explained by *OR10G4* allele types

will be perceived as pleasant, and even more so before dinner time than after finishing one's meal. The same odor, however, will likely elicit disgust and rejection when labeled as vomit or used sweaty socks. Similar effects have been demonstrated in experimental settings, and can be extended to a number of odors [39.6, 63, 64].

Difficulties to assign object labels to odors in the absence of additional cues are well documented; this instability of odor object representations makes us vulnerable to cognitively mediated shifts in valence assignments. Without the prior knowledge present in most real-life contexts, or the presentation of response alternatives, as in standardized tests of odor quality identification (Sniffin Sticks, see Chap. 31, University of Pennsylvania Smell Identification Test, UPSIT), humans perform extremely poorly when asked to name an

odorant [39.5, 65, 66] yet are overconfident in the veracity of their odor identifications [39.67]. Indeed, an equivalent of the surprisingly common confusion between parmesan and sweaty socks is difficult to imagine in any other sensory modality. The high dimensionality of odor mixtures likely plays an important role in this identification deficit. The large number of different chemical molecules with specific receptor-binding patterns means that humans can distinguish a near endless number of different odors [39.55]. In contrast to sounds and images, where any possible stimulus can be described on the basis of two dimensions (frequency and amplitude of its physical waveform), accurate memory retrieval of every possible odor encountered over one's life would require storage of a near infinite number of unique different receptor-activation patterns. In addition, the large extent of molecular overlap between odors from different sources means that matching a current perceptual impression to the memory of a previously encountered odor could yield several, equally plausible, response alternatives for an object source, all of which can vary vastly in their affective attributes.

Several authors have proposed that cortical processing of odor recognition solves these problems by matching odors to object-based templates, ultimately allowing the system to use similar mechanisms of pattern recognition, -completion, and -separation as observed in other sensory modalities [39.68–70]. Such a mechanism would reduce the high dimensionality of olfactory stimuli by matching noisy perceptual input to discrete memory templates, each of which are associated with specific object properties and affective connotations. Within this model, multisensory or memory cues would serve to facilitate access to particular object memory templates [39.69, 71] and, in turn, would lead to a particular identity assignment and elicitation of the associated affective response. In other words, cognitively mediated valence assignments would arise not directly from the sensory properties of the odorant per se, but rather from the learned affective properties of an olfactory memory trace.

In line with this idea, psychophysical evidence demonstrates that cognitively controlled identification processes might precede the conscious emergence of odor valence assignments. A behavioral study by *Olofsson* and *colleagues* [39.23] used mediation analyses on response times during identity and valence assessments to demonstrate that odor valence may only partly arise as the result of a direct feed-forward relationship between molecular properties and affective responses. Response times to identity judgments preceded those for pleasantness evaluations, favoring an indirect pathway to odor pleasantness evaluation based on the object properties of the presumed underlying source.

Work from other authors suggests that such cognitively mediated valence assignments may be particularly relevant in the determination of positive valence attributes; odors, rated as *pleasant* tend to be processed more slowly than unpleasant ones [39.72], indicating a higher cognitive processing load. In line with this idea, naming an odorant, and thus assigning an identity to it, was shown to influence hedonic judgments of neutral odors, making them likely to be perceived as more pleasant [39.73]. A negative object label, on the other hand, resulted in stimuli being rated as more intense and less pleasant compared to a neutral or positive name [39.6].

Li et al. [39.74] investigated learned odor valence responses through changes in odor perception following classical fear conditioning. After coupling an odor as a conditioned stimulus (CS+) with an electric shock (unconditioned stimulus, US), subjects were able to discriminate between that odor and a previously indistinguishable odor that had been presented as a CS− (i. e., without being coupled to the US). Odor preference can also be influenced by positive associative learning [39.75]. Depending on the valence of affective pictures presented to subjects, neutral odors were rated differently [39.76]: they were identified as more intense and unpleasant following negative picture presentation, while neutral odors following positive images induced greater odor pleasantness. Studies on populations from different cultural backgrounds have used existing differences in food object knowledge between ethnic groups to demonstrate systematic effects of learned associations on odor valence perception. *Distel* and *colleagues* [39.77] presented Japanese and German participants with odor samples that were either specific to the Japanese or German culture (such as fermented soybeans, dried fish, green tea, versus cheese, salami, incense) or familiar to both groups (such as chocolate, peanuts, beer). Unfamiliarity with an odor, and thus an inability to apply an object label with positive associations, resulted in the odor being rated as more unpleasant [39.18, 77]. These findings are in line with the above discussed idea that lacking identity information favors negative valence evaluation.

Top-down control of odor perception not only helps to understand contextual and interpersonal differences in valence assignment, but may also contribute to its fluctuations over time; most commonly, such effects are described in the context of metabolic changes, where hunger can heighten positive evaluations of food odors while satiety can dampen them [39.78, 79].

These state-dependent valence assignments in olfactory perception have been linked to similar phenomena in thermal perception, where the perceived pleasantness of temperature is evaluated relative to the self (warmth is perceived as pleasant when one feels cold,

while cold is perceived as pleasant during heat). Labeled *alliesthesia* [39.78], the appetitive value of an object is determined by the *milieu interieur*, internal signals, such as body temperature, or, in the case of chemosensation, by satiety status. Importantly, alliesthesia describes a phenomenon that generalizes to all stimuli related to the specific internal state in question: in the case of olfactory perception, valence ratings to all food-related odors, which are increased during a hungry state, and decreased during a satiated state. A related, but clearly distinct concept named *sensory-specific satiety* describes a phenomenon where state-dependent valence affects one distinct sensory stimulus: a particular food aroma is no longer perceived as appetizing after repeated exposure, however, without necessarily causing a generalization of valence changes in other food odors. Commonly, this phenomenon can be experienced during buffet-style meals, and is implicated as a potential cause for overeating [39.80]: because of the diversity of available sensory experiences, the motivational value of food flavors (a combination of their smell and taste) is maintained over much longer periods of food intake, compared to the rapid decline in affective responses elicited by a single dish with a comparatively monotonous flavor profile. Additional factors known to modify the occurrence of sensory-specific satiety include nutrient composition, texture, and visual impressions of food [39.79].

In sum, the perceptual phenomena described above demonstrate that the relationship between chemosensory properties and olfactory object identities, as well as the relationship between these object identities and their affective and motivational properties, are highly plastic and undergo constant changes depending on their perceived personal relevance. As a result, the role of olfactory valence evaluation during cortical encoding of odor perception should be viewed not just as a step in a linear processing cascade, but rather as a dynamic process that encompasses various feedback loops between molecular properties, receptor repertoire, learning experiences (such as associations with threat), and internal states (such as hunger). The next subsections of this chapter will address our current knowledge of how these processes are integrated during cortical and peripheral neural encoding of odors to give rise to an olfactory experience.

39.3 Valence Coding in the Human Brain

As outlined above, odor valence perception is not a unified concept, but rather constructed through the integration of bottom-up processing of relevant molecular characteristics combined with top-down learned assignments of object identities, which in turn evoke specific assignments of affective properties. These affective evaluations can be captured by various cognitive measures such as edibility judgments or incentive salience, and can be related to characteristic modifications of peripheral nervous activity. Given the multidimensionality of factors driving odor valence perception, the neural activations contributing to the emergence of affective perceptual properties need to be equally considered from this multidimensional perspective.

In the following, we will first discuss the role of direct integration of olfactory processing and emotional brain networks as a unique anatomical property of the olfactory system, which may provide a structural basis for the high automaticity of the emergence of affective properties in the absence of cognitive evaluation. We will then provide an overview of the extended network of subcortical and cortical structures known to contribute to the conscious assignment of affective properties through the identification of a distinct odor object identity. Finally, we will discuss data that demonstrates how the network activity regulating odor valence perception may change as a function of contextual characteristics and relevant experiences.

39.3.1 Subcortical and Limbic Processing of Odors – A Pathway for Automatic Threat Detection?

In primate olfactory perception, odor molecules bind to their primary sensing cells in the olfactory epithelium, which is located at the roof of the nasal cavity. All axons of neurons expressing the same receptor then converge onto the same two spatial locations in the olfactory bulb, yielding organization patterns, which are laid out in a chemotopic fashion [39.81–83]. Similarity between the bulbar patterns evoked by odorants has been linked to the experience of perceptual similarity [39.84, 85], and thus represents a crucial early stage for the representation of separable sensory experiences with distinct affective qualities. Importantly, behaviorally relevant stimulus knowledge formed during reward learning or aversive conditioning can lead to an enhanced separability between previously similar activation patterns of odors already at this early processing stage, as a result of lateral inhibition within the bulb [39.86–88], as well as a modification of receptor firing patterns. Early chemotopic odor representations are thus never, strictly

speaking, camera-like depictions of our chemosensory environment. Rather, they reach cortical and subcortical stages of processing as a selectively sparsened or enhanced code, which reflects the evolutionary significance of the stimulus at hand and thus contains information relevant for subsequent valence assignments.

Monosynaptic projections transmit olfactory signals directly from the olfactory bulb to the amygdala and hippocampus [39.89, 90], a unique anatomical feature of the olfactory system that is considered of key relevance for the speed and automaticity of odor valence assignments. This *low-road* pathway, which lacks the obligatory thalamic relay that gates information from other modalities before entering subcortical nodes implicated in affective processing [39.91], allows olfactory information to directly interface with memory and emotional processes in the absence of cognitive modulation, after it has passed the initial processing steps in the periphery.

Several studies have probed amygdala involvement in the affective experience of odors by separating activity changes to independent manipulations of odor valence and intensity. *Anderson* et al. [39.92] were the first to compare blood-oxygen-level-dependent (BOLD) signal changes measured with functional magnetic resonance imaging (fMRI) to a pleasant and an unpleasant olfactory stimulus, and found that both elicited increased activation in the amygdala, while separable patterns by stimulus valence were found in the orbitofrontal cortex (OFC). Importantly, an extension of this work by *Winston* and *colleagues* [39.93] demonstrated that the amygdala is not unresponsive to the emotional value of odor stimuli, but rather takes it into account in a more complex interactive manner; namely, by including an additional neutrally valenced odor, Winston et al. could demonstrate that the strength of the amygdala response increased with intensity for odors of affective relevance, as demonstrated by Anderson et al., but in contrast, remained unresponsive to intensity changes when the odor was emotionally neutral. The amygdala activation to olfactory stimuli, therefore, likely represents a merged representation of intensity – and valence information as an overall index for the emotional value of the percept. This pattern of amygdala reactivity ties in with current theories of its role in emotion perception postulated on the basis of research using visual stimulus material, which has equally demonstrated that experiences of both positively and negatively valenced stimuli can activate this region [39.94]. While earlier models have postulated a specific role of the amygdala in fear perception, it is now thought that it may respond more generally to valence-unspecific detection of saliency in terms of arousal and biological significance [39.95]. In the absence of cognitive control processes, automatic amygdala activation to odors may actually bias toward negative affective responses to presented stimuli, and thus play a crucial role in the above postulated odor-based threat-detection mechanism [39.12]. On the other hand, when an object has been identified as emotionally arousing, but cognitively evaluated as nonthreatening [39.96], such automatic amygdala responses are thought to be counteracted by cognitive reappraisal processes. These processes downregulate the elicitation of what, in this case, would constitute an unnecessary and resource-consuming avoidance response. In line with this idea, anxiety induction, which predisposes individuals to vigilance toward potential threats, has been demonstrated to induce shifts in olfactory network connectivity, creating a stronger bias toward amygdalar influences on cortical odor processing [39.97].

The elicitation of aversive reactions to odors is often accompanied by visceral and autonomic nervous responses, which go beyond a mere detection of threat and likely regulate the sensation of disgust or revulsion and an impulse for behavioral withdrawal [39.98]. A number of studies have demonstrated that such sensations toward odors arise from ventral anterior insular cortex, in addition to amygdala activation [39.99–101]. As a supramodal area forming a core part of all chemosensory pathways including smell, taste, and chemical irritation, this region has also been connected to the recognition of disgusted facial expressions [39.102, 103]. Studies incorporating both visual impressions of disgust and negative olfactory stimulus material [39.2, 104] have provided evidence that disgusting stimulus material shares a supramodal common neural substrate in the insula and have as such strengthened the idea of the insula as a key node in a *behavioral immune system* [39.105], which allows individuals to automatically engage in disease prevention behaviors, and, as such, should be considered to form part of an extended network for valence representation of olfactory stimuli.

39.3.2 Role of Cortical Object Processing for Odor Valence Perception

The subcortical pathways for odor valence perception are thought to permit a quick and highly automatized, almost reflex-like response to odor valence and chemical threats. Cortical encoding of odor attributes, on the other hand, underlies the emergence of affective qualities in a *high road* of affective evaluation, which permits the representation of complex emotions linked to the identity of the stimulus. Giving rise to learned representations of odor objects, prefrontal cortex is thought to provide the neural basis for the pleasant or unpleasant

feelings elicited by odors that we consciously experience as their *valence*.

As described in Chap. 38, the cortical mechanisms that transform the complex chemotopic bulbar codes into holistic identity and experience-based odor object representations with a distinct valence, have been the subject of intense research efforts over the last decade. A particular focus has hereby been placed on the role of the piriform cortex, as well as its tight reciprocal connections with the olfactory portion of the orbitofrontal cortex (OFC).

Receiving by far the largest portion of neural projections from the olfactory bulb, the piriform cortex is frequently labeled as primary olfactory cortex and is separated into an anterior portion, located in the frontal lobe, and a posterior portion, which forms part of the temporal lobe. The main secondary processing area of the olfactory system, human olfactory OFC, has reliably been placed rostrally to an analogous area in nonhuman primates, and is located at the intersection of the medial and transverse orbital sulci and bordered by visual, gustatory, and somatosensory areas [39.1, 106].

Evidence from the animal literature indicates that piriform cortex transforms the chemotopy of the peripheral olfactory signal into dispersed activation patterns [39.107, 108], which help to create a representation of an odor's behavioral relevance [39.109]. The presence of an analogous mechanism in humans is supported by functional neuroimaging studies: pattern analyses of MRI signal to odors in piriform cortex show that odors are grouped into similar activity patterns depending on their perceived quality or behavioral relevance in the external world [39.110]. This grouping pattern occurs even for odors that are substantially different in chemical structure, indicating additional processing steps beyond the chemotopic coding patterns of the olfactory bulb, which shift perceptual processing toward a representation of a perceived object identity.

Both the anterior portion of piriform cortex and the olfactory projection area of OFC have consistently been shown to be modulated by odor-valence characteristics [39.73, 111, 112]. Strongly connected with each other through reciprocal connections [39.111, 113], these areas are thought to form a core network for behavioral relevance assessment of olfactory stimulus properties. Most robustly, patterns of differential activation for pleasant and unpleasant stimuli (with higher activity levels tending to correspond to higher levels of aversiveness) [39.111, 114–116] have been reported in olfactory OFC, an area which has been implicated by lesion studies [39.74] and fMRI studies [39.117] to be essential for the emergence of odor representations into consciousness. These findings suggest, despite evidence for early sensory modulations by perceived valence in the periphery, that this region may play a necessary role in the emergence of affective properties into conscious perception.

Within OFC, some reports favor an anatomical separation between subsections that respond to positive and negative valence, with mediofrontal sections coding for stimulus reward, and dorsolateral portions preferentially responding to aversiveness [39.114]. To investigate the relevance of these spatially separable subsections for the formation of the final odor percept, *Grabenhorst* and *colleagues* [39.118] presented subjects with odors that were purely pleasant and purely unpleasant, as well as with a mixture of the unpleasant and pleasant odorant. By correlating BOLD signals with subjective ratings of pleasantness and unpleasantness, they were able to not only separate subsections of the OFC preferentially responding to pleasantness and unpleasantness, but also to show that the mixed odorant, while perceptually rated as pleasant, activated both subsections. The finding that pleasant and unpleasant valence associations can be *simultaneously* represented in higher order cortical areas potentially has important implications for top-down controlled changes in valence attribution: the latter might bias the conscious percept toward a preferential weighting of one or the other depending on the context in which the stimulus is perceived.

Grabenhorst and *Rolls* [39.119] further suggested a separation between continuous representations of stimulus value in the OFC and binary approach/avoidance decisions in the dorsolateral prefrontal cortex. This work ties in with the economic decision-making literature's view on prefrontal functions, where it is thought to serve an important role in the translation between reward encoding on the one hand and approach-avoidance decisions on the other [39.120]. Reflecting these influences, models of orbitofrontal involvement in olfactory perception have recently been extended beyond the notion of a linear representation of valence as a fixed property: rather, the emergence of a sensation of like or dislike is increasingly viewed as the result of evaluations of *actual* against *predicted* outcomes that are subsequently combined to signal reward value (a better outcome than predicted, rendering a positive valence assignment) or punishment (a worse outcome than predicted, rendering a negative valence assignment).

While studies investigating these questions in the context of flexible adjustments of valence perception are still lacking, recent work by *Zelano* and *colleagues* [39.121] has looked at the encoding of actual versus expected odor outcomes in the OFC, and thus provides a neural basis for potential encoding mechanisms of subjective value in olfactory cortical

networks. The authors tested the representation of real and predicted outcomes in the olfactory system by comparing neural responses to two odorants while paying attention to either one or the other (while the perceptual experience was identical, odor A would sometimes be represented as *YES, odor A*, and at other times as *NO, not odor B*). This modulation resulted in significant differences in activation between the two conditions within OFC and its projection area in the anterior piriform cortex. The neural response in both areas was strongly influenced by whether or not the sensory event matched the predicted event, representing the expected rather than the actual stimulus, and thus providing support for the idea of odor evaluation in the OFC as an inherently comparative task. In addition, recent work by *Rudebeck* and *colleagues* [39.122] has been able to demonstrate OFC involvement in olfactory stimulus–outcome expectancies more directly in a monkey model by means of single neuron recording, yielding first evidence that flexible OFC responses may contribute to reevaluations of odor stimuli dependent on current motivational states.

While further research is needed to form a unifying model of OFC function in olfactory valence perception, these findings demonstrate that valence representation in olfactory cortex is likely a multidimensional concept, rather than a clearly localized, linear representation of an abstract reward value. The OFC, due to its position at the intersection of various sensory systems, cognitive, and affective networks, appears to form an important relay function in this emergence of a unified perceptual experience. Along with a representation of valence in the form of a motivational value of a real or expected outcome, OFC maintains the flexibility to adjust this representation to varying requirements imposed by changes in internal and external states. Likely, these states include learned contingencies with positive and negative outcomes as well as multisensory influences, such as associations with positive primary rewards as is the case of sugar and salt taste; as such, they are likely contributors to some of the biggest public health challenges of the 21st century and deserve increased research efforts.

A reformulation of the role of OFC and anterior piriform cortex in valence perception as regions integrating the value of *real* in relation to *expected* outcomes also presents an opportunity for a reevaluation of the role of posterior piriform cortex in valence coding, which, despite its crucial involvement in the formation of identity-based perceptual quality, odor learning, and memory [39.110, 123], has traditionally been assumed irrelevant for valence encoding. The aforementioned study by *Zelano* and *colleagues* [39.121] directly compared response patterns between the two piriform subsections in addition to OFC activity and demonstrated that posterior piriform cortex maintained a state-independent representation of the stimulus while anterior piriform cortex activity was modulated by expected outcomes. In light of this functional separation, a model of cortical valence representation completely disregarding the posterior piriform cortex' role in pleasantness perception may fall short of providing a complete picture: a *high road of valence perception* relies on the integration of expected value on the one hand, and identification of perceptual evidence on the other. It could, therefore, be speculated that posterior piriform cortex, at the intersection of emotional and memory networks, might constitute an important relay for linking perceptual input to object-specific odor memories, which carry information on behavioral relevance [39.113]. In other words, posterior piriform cortex may play a key role in the retrieval of olfactory memories and the evaluation of these memories against expectations generated by present mental states constitute a crucial subprocess for affective valence perception. Future work will show whether such a model provides a reasonable approximation of the cortical processes that give rise to odor valence representations. In addition, the role of additional cortical support structures that might exert influences on olfactory valence encoding through multisensory influences, including, among others, the olfactory tubercle [39.124], and the entorhinal cortex [39.125, 126], needs to be defined.

39.4 Conclusion

As reviewed above, valence perception, or the ability to perceive olfactory input as pleasant or unpleasant, is not only one of the most basic and intuitive features of the perceptual experience of odors; this emotional experience is also fundamental to the most common interactions with our chemosensory environment, including the rapid rejection of contaminated materials or the elicitation of appetite by familiar foods. As such, valence perception of odors is a mechanism that contributes greatly to the maintenance of human health.

Given this immediacy and apparent one-dimensionality of odor valence perception, the complexity of neural processes contributing to its emergence and our continued search for answers to some of even the most basic questions, such as what makes an odor pleasant, remain

puzzling. Yet, as we review here, immense progress has been made over the last years, tackling the manifestation of emotional responses to odors from all possible angles, ranging from behavioral studies in humans and animals, through physiological and cortical responses, down to the level of early receptor coding patterns. Recent attempts to integrate these different levels of analysis begin to show a complex system, which, at high speed, captures not only the chemical composition of a stimulus at hand, but at the same time also attempts to identify possible sources, evaluates their potential behavioral relevance, and elicits the appropriate visceral response that, in the case of a negative evaluation, is often crucial to prevent a contaminated food item from entering our digestive system.

Taken together, the research reviewed above shows that odor valence coding in the human brain is a multilevel process involving early peripheral modulation as well as subcortical mechanisms for rapid behavioral responses and conscious cognitive evaluations. Given the growing public health issues that arise from dysfunctional approach and avoidance behavior to chemosensory stimuli, in particular during food consumption, understanding the molecular and neural mechanisms that cause some odors to spontaneously make our mouth water, while others make our stomach turn in disgust, will likely prove to be crucial for the development of strategies to counteract such dysfunctional valence attributions, and, as such, deserve our continued research efforts.

40. Odor and Emotion

Sylvain Delplanque, Géraldine Coppin, David Sander

This chapter advocates for adopting a theoretical and experimental approach that goes beyond the use of valence as the most interesting dimension in emotional reaction to odors.

Although valence is a dominant dimension of odor perception, limiting the description of emotional response to positive versus negative (valence) and activating versus calming (arousal) feelings is perhaps oversimplified and not well suited for a comprehensive view of odor-related effects. Just as inappropriate are basic emotions, usually defined as six states (fear, anger, sadness, surprise, joy or happiness, and disgust) putatively characterized by specific neural, physiological, expressive, and feeling components. Here, we present an appraisal approach of emotions as a plausible alternative. This kind of approach reconciles a priori incompatible characteristics observed in odor perception like the immutability and the flexibility of chemosensory preferences. After having exemplified this aspect with several studies from the recent literature, we will particularly emphasize feelings. We provide an empirical demonstration that feelings are broader than valence and both stable and variable across cultures. We argue that this approach provides an ecological model of the emotion process where olfactory emotions are understood considering their functional role, which is to adjust or to solve olfactory-linked survival-relevant problems.

Across cultures, odors have always been considered powerful elicitors of emotions [40.1, 2]. In the last few decades, a growing scientific literature has started to provide evidence for this claim [40.3–5], and a series of findings even speak in favor of a privileged link between odors and emotion as compared to other senses. For instance, it has been reliably shown that experiencing an odor as pleasant or unpleasant (its hedonic tone) is a key aspect of olfactory experience [40.6]. Accordingly, smells can influence mood – pleasant odors tend to induce positive moods while unpleasant odors tend to induce negative moods [40.7–9]. Olfactory-induced changes in physiological parameters, such as heart rate or skin conductance, correspond to typical emotional reactions elicited by emotional stimuli [40.10–19]. Results from numerous experiments suggest that odors can impact cognition and behavior in a similar fashion than do emotional stimuli in other perceptual modalities [40.20–26]. Such an effect is particularly studied on memory: odors can evoke autobiographical memories that are emotionally intense and thought to be forgotten [40.27]. These effects are usually interpreted as a interdependence of olfaction and emotion in overlapping neural systems [40.28]. Consistently, recent neuroimaging data has demonstrated that both the brain network processing olfactory stimuli and the circuitry processing subjective hedonic evaluations are modulated in a similar fashion after an anxiety induction [40.29].

In this chapter, after having proposed a definition of emotion, we aim at presenting an overview of the two dominant psychological approaches to emotion – namely basic emotion theories and dimensional theories – as they have been used as the major research frameworks when investigating the links between olfaction and emotion. We will underline the strengths and limitations of these two approaches and, then, we

will introduce an appraisal model of emotions that could be used as an alternative model to investigate odor-elicited emotions. These theories reflect a third approach in emotion research that has only been scarcely used as a framework in olfaction research. However, this approach deserves much more consideration, as we believe that it has the potential to lead to significant improvements in olfaction research, for reasons we will describe.

40.1 Emotion as a Multicomponential Phenomenon

Across almost all theoretical approaches of emotion, there is a clear consensus: emotion constitutes a multicomponential phenomenon.

The term emotion is usually defined as a short period of time during which several functionally defined components are coupled or synchronized to produce an adaptive reaction to an event that is considered central to the individual's well-being [40.30–32]. For instance, according to the *component process model* [40.33], these components are:

1. The cognitive system that is responsible for the evaluation of the situation and the determination of emotion.
2. The autonomic system that is in charge of the organism' regulation and physiological support.
3. The motor system that is responsible for the expressive aspects, for the communication of reactions and behavioral intentions.
4. The motivational system that is responsible for the preparation and direction of actions (approach/avoidance).
5. The monitoring system, in charge of the subjective feeling.

Similar to the emotion literature in general, experiments in the subfield of emotion and olfaction have focused on one or two of these components (subjective feeling and/or physiological response), mainly for practical reasons. Thus, it is important to keep in mind that the differentiation of emotions on the basis of only one of these components (hedonic ratings) may not adequately reflect the complexity of the phenomenon. For instance, any putative emotional response obtained at the subjective level needs to be associated with concomitant responses on a cognitive, behavioral, or physiological level to be fully considered as a true emotional response (see [40.34] for a discussion on this topic). Adopting methods derived from the multicomponential approach (see description below) that consists of measuring simultaneously behavioral, physiological, cerebral, and subjective reactions to the odors is consequently an extremely valuable avenue of research.

Although there is widespread agreement on the multicomponential nature of emotion, the question of its theoretical and mechanistic underpinnings lacks such consensus. A majority of studies that have investigated the relationship between olfaction and emotion have been conducted within the framework of one of the two major approaches in emotion research: basic emotion theories and dimensional models.

40.2 Basic Emotions

The basic emotions theory postulates the existence of a small number of so-called *basic* emotions, such as anger, disgust, fear, enjoyment/happiness, sadness, and surprise [40.35]. Basic emotions are supposed to share a common set of characteristics that consist of specific neural, bodily, expressive, and feeling components [40.35, 36].

In the olfactory literature, there is no consensus regarding the number of basic emotions elicited by odors. When authors ascribe to the strict definition of basic emotions as described above, their smallest number appears to be six (anger, disgust, fear, sadness, surprise, happiness) [40.10, 37]. Broader definitions can lead to the enumeration of as many as 22 distinct basic emotions (shame, jealousy, fear, anger, sadness, pride, hope, relief, boredom, contempt, admiration, disgust, desire, disappointment, love, dissatisfaction, amusement, stimulation, satisfaction, unpleasant surprise, enjoyment, and pleasant surprise) [40.38, 39].

According to the tenets of this approach, basic emotions are based on phylogenetically stable neuromotor programs and are characterized by emotion-specific response patterns [40.40–42]. In this framework, a perceived event will be automatically evaluated via what is essentially a database lookup. A positive match with a specific stored scheme will automatically trigger a prototypical affect program that includes a specific action tendency, physiological response pattern, motor

expression, and feeling state. This evaluation process or appraisal is characterized as *immediate, unbidden, opaque, unconscious, and automatic* [40.35, p. 70]).

Olfaction studies that adopt the framework of basic emotion theories focus on response patterning, that is, trying to determine whether specific odors elicit specific basic emotions with a specific set of physiological responses [40.10, 11, 19, 37, 43, 44]. To the best of our knowledge, this research trend never explored the causal mechanisms underlying differences in emotion elicitation. Thus, in accordance with this theory, *the perception of the smell of feces may match the scheme of contamination in the emotion schema database, triggering the emotion of disgust* [40.35, p. 70].

However, many studies have underlined that emotional responses, states, or descriptions in response to odors do not match basic emotions categories, such as anger, fear, or sadness [40.1, 2, 10, 11, 14, 19, 38, 39, 45–50]. It is also difficult to reconcile the assumption that basic emotion systems are impermeable to modification by learning and throughout lifespan [40.35] with the profound hedonic plasticity observed empirically. The hedonic perception of an odor changes as a function of associative learning contexts [40.51], in perceived intensity [40.52], and familiarity [40.15, 53]. It is also modulated by the perceiver's physiological and psychological states and the context of perception. For example, verbal labels can greatly affect the hedonic perception of ambiguous smells, such as cheese versus smelly feet [40.54]. Olfactory preferences are also modulated by individual needs, goals, values, and decision-making processes [40.55]. In sum, a large set of empirical data demonstrates that the emotional perception of odors is far from being fixed, rendering difficult any interpretation in terms of basic emotions elicitation based on a fixed look-up database.

Even in instances where basic emotions would be reliably triggered by olfactory cues, we still believe that the basic emotion account may paint an incomplete picture. In particular, the context in which the odor induces the reaction is rarely accounted for. This may be problematic if the selection of basic emotions depends on other environmental cues and not on the odor itself [40.38]. Yet, in studies on the relationship between olfaction and emotion, specific situations are not usually provided to the participants when assessing their feelings or physiological reactions in response to odors. The possibility that basic emotions require an appropriate – possibly motivational or social – context to be elicited via odors remains to be tested. However, if the odor presentation is contextualized, it cannot then be ruled out that the emotion is also caused by situational factors rather than by the odor alone. If the situational factors play a role, then this would question the uniqueness of the mapping from odors to basic emotions that would be claimed by the theory. Future research may shed light on these questions by manipulating the context of the emergence of odor-elicited emotions. For instance, a crucial question would be to investigate to what extent specific patterns of physiological and subjective responses are influenced by the manipulation of the context of delivery.

A recent trend in chemosensory research – the investigation of human communication skills via social emotional chemosignals [40.56] – is also permeated with concepts derived from basic emotion theories. This line of research evolves around the following question: Are humans able to express affective information via body odors? If so, what kind of affective information is conveyed by body odors: specific emotions or valence? While many of those studies are interested in anxiety or stress-related chemosignals that could be emitted [40.57–63], others have proposed that more specific basic-emotions-related chemosignals may be linked to induced emotions of happiness, fear, sadness, and disgust [40.64–68]. Globally, this approach suggests that certain basic emotions felt by the emitter are associated with the emission of specific chemosignals, which can in turn be perceived by recipients. In this emerging field, an alternative way of thinking could be rather to question which emotional component is conveyed by the signal rather than if the signal corresponds to a particular basic emotion. For instance, do emotion-related chemosignals reflect a feeling (i. e., disgust or joy) or any action tendency (approach or avoid) experienced by the emitter of the signal? Does the receiver expresses the same feeling or action tendency as the emitter (i. e., mimicry and/or emotional contagion) or any complementary aspect to adapt to the situation?

40.3 Dimensional Approaches

Dimensional approaches assume that all affective phenomena are essentially described via positions in a two-dimensional valence-by-arousal space, or sometimes a three-dimensional space that includes an additional dimension of dominance or potency [40.69–74]. Authors embracing this approach in olfaction characterize individual feelings mainly using a pleasure, arousal, and dominance (PAD) questionnaire. In this case, the

affective terms are chosen to characterize the extremes of the underlying two or three bipolar dimensions (happy/unhappy, excited/calm, powerful/without power [40.12–14, 17, 18, 20, 75–80].

This model is the one of most frequently used in olfaction research because pleasantness is one of the major if not the primary perceptual dimensions of odors [40.6, 81]. Moreover, many studies emphasize the relation between the intensity of the odor and the subjective and/or physiological arousal. Whether the intensity and arousal dimensions of odor perception are independent or not is still debated (see [40.28] for a recent discussion on this topic). Historically, arousal was defined as a short term increase in excitatory processes resulting in an increase in behavior or physiological activity, mainly linked to the activity of the sympathetic nervous system [40.82, 83]. This definition emphasizes the physiological aspects of the arousal dimension [40.84]. Congruently, olfaction research using dimensional models has investigated physiological differences associated with verbally reported pleasantness and arousal produced by an odor [40.12, 13], as well as the underlying brain structures associated with these dimensions [40.28].

For experimental applications, adopting dimensional approaches has practical appeal, as reporting an emotion on scales of pleasantness and arousal is easy to implement, and allows using continuous measures for data analysis.

But what does this approach tell us about the elicitation and differentiation of the resulting feelings of valence and arousal? Unfortunately, dimensional theory remains largely agnostic about the processes underlying emotion elicitation and differentiation in general [40.85]. Research in olfaction research is no exception. According to the tenets of dimensional theory, the perception of an event (either an actual or an imagined odor) results in a primitive core affect, constituted by valence and arousal, on the basis of which the participant will construct the emotional meaning. The resulting feeling is dependent on both situational and sociocultural factors. However, the theory does not propose specific production mechanisms for the genesis of the core affect.

Some of the work in olfaction postulates that hedonic/valence coding may be (at least partially) innate in nature, the probability of an odor being pleasant or unpleasant being dependent of its physico-chemical properties (molecular complexity; [40.86]). These properties can allow an artificial nose to categorize the odors according to their pleasantness with high accuracy [40.87]. These accounts suggest a potential direct mechanism for valence determination in core affect elicitation. However, this does not account for the high variability observed in odor valence perception, except if one accepts the highly flexible nature of this pre hardwired mechanism. Imaging techniques have revealed differential valence activations at the early stages of odor processing in humans (in the anterior piriform cortex [40.28]. However, neuroimaging techniques do not have the fine grained temporal resolution that would be required to tease apart whether these differentiations result from a bottom-up processing of valence or top-down influences from high-order structures.

In sum, to date, most of the work in olfaction that investigates the neural and cognitive mechanisms leading to odor-elicited emotions adopts dimensional approaches. Unfortunately, these approaches do not propose clear elicitation mechanisms for valence or arousal determination.

40.4 Beyond Valence: The Case of Feelings

In any experiment on the relationship between emotion and olfaction, the measurement of the monitoring component of emotion, the subjective affective experience or feeling is constrained by the choice of the theoretical model adopted by the researchers. In most cases, participants are requested to characterize their perception of the hedonicity/valence of the odors using a visual analogue scale varying from unpleasant/dislike/negative to pleasant/like/positive. Recently, several results have seriously questioned the theoretical grounding for restricting the description of feelings to the unique scale of valence, liking, pleasantness, or acceptability [40.1, 2, 7, 39, 45, 48, 80, 88]. The underlying assumption of these studies is not to question the valence as a fundamental aspect of odor perception. It is rather argued that describing odor-elicited feelings with one dimension of valence (or two dimensions of valence and arousal or tri-dimensions of valence by arousal by dominance) loses most of the important qualitative differences between the affective effects of different types of odors. Even if every feeling could be positioned in an uni-, bi-, or tri-dimensional affective space – as feelings associated with basic emotions can be – the use of these simple representations may not be sufficient to answer relevant questions related to olfaction [40.47]. This point was particularly emphasized by *Rétiveau* et al. [40.7]. *Rétiveau* et al. observed that some fra-

grances that were similarly evaluated in a valence by activation space were clearly differentiated when participants evaluated them with several mood adjectives [40.50].

This is why research aiming at establishing a systematic, empirically derived taxonomy of olfactory-induced feelings was developed. For instance, acknowledging the strong influence of culture on hedonic perception of odor, a series of studies were conducted in six different countries (French-speaking part of Switzerland [40.45]; United Kingdom and Singapore [40.48]; USA, China, and Brazil [40.2]). The two main objectives of this project were: (1) the identification of cultural invariants and differences in odor-elicited feelings and, (2) the investigation of whether these feelings are well predicted by the dimensional and basic emotions theories. In each country, a list of terms selected for their relevance to describe affective feelings induced by odors was assessed while participants were exposed to a set of odorant samples. The data was submitted to a series of exploratory and confirmatory factor analyses to reduce the set of variables to a smaller set of summary scales and to get a sense of the differentiation of affective feelings elicited by odors. The originality of the methodology adopted in each country was threefold [40.45]:

1. The initial list of affective terms included (among others) the terms of the different versions of the pleasure/arousal/dominance questionnaire and the most exhaustive list of terms derived from the basic emotions approach applied to olfaction.
2. The choice of the relevant feelings terms was based on a data-driven approach derived from respondents' evaluations; the authors did not impose a strong theoretical framework in the selection of the relevant terms.
3. The selected odorants covered a large range of everyday odors that tend to reflect different odor-related contexts (56 different odorants: sweet aroma, savory aroma, cosmetic-household odors, woody-earthy odors, fruity odors, floral odors, spicy odors, animal odors, and medicinal odors).

These odorants were complex mixtures, not monomolecular compounds, not specifically selected for being extreme in valence but rather to be familiar and evoke as many associations as possible. In this respect, this line of research is not subject to the issue underlined by *Mohanty* and *Gottfried* [40.28], which is why a lot of studies could have favored the dimensional models since the stimuli they used were sampled as extremes in the valence scale.

The resulting feeling landscape that emerges from these studies [40.1] is represented by several affective categories that were recurrent in all the countries examined: disgust/irritation, happiness/well-being, sensuality/desire, energy, but also soothing/peacefulness and hunger/thirst. Practically, a new set of scales was created and freely distributed (emotion and odor scales: EOS [40.89]). Each category of feelings is characterized by three representative relevant affective terms and is evaluated with the help of a feeling intensity scale varying from *not experienced* or *not intense at all* to *strongly experienced* or *intense* [40.45, 50]. It is worth mentioning that similarities and differences in odor-elicited feelings are influenced by the geographic proximity (the closer the countries, the more similar the feelings elicited by a set of odors). In addition, culture-specific feeling categories also emerged [40.2]. These two last results reflect again the strong influence of cultural aspects on odor-elicited feelings. But the main result of this line of research was that the emotional categories observed in many different cultures go well beyond those described by the traditional basic emotions or dimensional approaches applied to olfaction.

This line of research also permitted a formal evaluation of which of these sets of terms (i. e., derived from basic emotions, dimensional, or EOS approaches) is optimally suited to verbally measure the feeling associated with odor perception. This point was statistically tested both during each step of the EOS constitution [40.45, Table 5] and in a supplementary validation study [40.47]. Psychometric approaches revealed that by using the valence by arousal (by dominance) dimensional approach, one misses crucial qualitative differences in odor-elicited feelings. For instance, *Porcherot* and colleagues [40.50] have demonstrated that fine fragrances that did not differ in valence were differentially evaluated in terms of sensuality/desire feelings [40.7, 80].

Research using verbally reported valence or more complex feelings should consequently acknowledge that it does not capture the whole emotional phenomenon (though this may not always be necessary for answering the question of interest). Researchers should carefully consider the sense in which the chosen affective terms represent or capture true emotions, and the usefulness of the chosen framework in the context of their research question. This is complicated by the fact that although there is a general consensus that emotions are multidimensional (i. e., emotions are composed of a subjective feeling, action tendencies, a physiological arousal, appraisal processes, and expressions), there is no generally accepted agreement on what an emotion exactly is [40.90]. Thus, when using a particular set of terms to characterize emotional reactions to odors, researchers can at present merely assert that they used *potential emotions*, as the

differentiation on the feeling level would need to be confirmed by differentiations on the cognitive, behavioral, or physiological level to be fully considered as true emotions [40.34].

40.5 From Traditional Models to Appraisals

Given the limitations of the two classical models of emotions described above, we would like to argue that an alternative theoretical model of emotion may be needed to better predict a wider range of olfactory phenomena. We suggest that the theoretical models of emotion based on appraisal theory [40.91] may be more appropriate to explain and predict – two major functions of a theory – the processes underlying emotion elicitation in general and through olfactory stimulation in our particular case.

The basic premise of appraisal theories is that the elicitation and the differentiation of emotions are determined by appraisals, which are continuous, recursive evaluations of events. These appraisals can occur at different levels of information processing, that is, sensory-motor, schematic, and conceptual [40.92] and they correspond to the cognitive component of emotions. Appraisals should not be seen exclusively as high level, and conscious conceptual processes, since they include automatic, low level and unconscious ones [40.93] and can be investigated by neuro-scientific techniques [40.16, 94–96].

Although there has been some mild controversy among theorists regarding the precise number of the classes of appraisals they believe to be most important in emotions elicitation and differentiation, these disagreements concern details, and are small in comparison to the wide overlap of commonly held conceptions. Appraisals are organized into major types or classes of information that an organism needs to process to adaptively react to a salient event [40.31, 33, 93]. These types of information are:

1. The relevance of the event (how relevant is this odor for me?).
2. The implication of the event (what are the implications or consequences of this odor being around and how do these affect my well-being and my immediate or long-term goals?).
3. The coping potential (how well can I cope with or adjust to the consequences of this event?).
4. The normative significance of the event (what is the significance of this odor with respect to my self-concept and to social norms and values?).

Each of these four classes of appraisals is itself more finely organized in subevaluations. For instance, the relevance evaluation includes the novelty detection, the intrinsic pleasantness, and goal/need relevance appraisals as subevaluations. A complete description of all evaluations and subevaluations in the different appraisal models is beyond the scope of this contribution (for a more complete account [40.85, 91–93]. Appraisal models propose that emotion elicitation and differentiation result from the temporal unfolding of these different evaluations, their resulting values and consequences. Once an evaluation is completed, the outcome changes the state of all other components of emotion. Moreover, changes produced by the result of a preceding evaluation are modified by a consequent evaluation. The unique combination of values for these appraisal criteria determines which specific emotion is elicited and with which intensity [40.33]. Recent work has directly investigated the unfolding of cognitive appraisals [40.95, 97] and their consequences on peripheral responses [40.16, 94]. Together, they revealed sequential effects of novelty, pleasantness, and goal congruency appraisals, in this order.

A recent review of neuroimaging research investigating the processing of major appraisals [40.96] underlines that many appraisal mechanisms (e.g., novelty detection, intrinsic pleasantness, or goal-relevance) have been the focus of intense empirical research in cognitive and affective neuroscience, but typically without links being made directly to emotion elicitation [40.84]. In line with a growing number of investigations [40.94, 95, 98–100], we would like to emphasize the utility of using appraisal theories as a framework of research. More particularly, an appraisal-based approach consists in experimentally manipulating different appraisal criteria (i. e., novelty, goal relevance, coping potential . . .) and measuring their efferent effects over time and the resulting outcomes on the different emotional components (e.g., measuring the reported feeling with questionnaires or the autonomic support with physiological indicators). By directly manipulating the putative processes underlying emotion elicitation and differentiation, this approach allows us to characterize more precisely which and to what extent any process is crucial in emotional response to odors [40.16].

Applied in olfaction research, appraisal models may also reconcile both the immutability and the flexibility of odors hedonics as reported in the literature [40.28, 55]. Let us consider relevance detection again. Organisms constantly scan their external and internal

environments for the occurrence of events (or the lack of expected events) requiring further information processing, and to eventually adopt an adaptive reaction. During this relevance detection process, the first subevaluation is related to novelty detection – any change in the ongoing flow of processed stimuli could require attention and demand further processing (novelty evaluation). In the second step, the organism evaluates, with the help of genetically fixed schemata or over learned associations, whether a stimulus event is likely to result in pleasure or pain (intrinsic pleasantness evaluation). What is described in the appraisal literature as *genetically fixed schemata* could refer to what is presented in the olfaction literature as the innate nature of hedonic coding – through the physico-chemical structure of the odorant molecule [40.86, 87]. In contrast, according to appraisal models, this intrinsic pleasantness could also be the product of over-learned associations, leaving the door widely open to influences due to learning, exposure, contextual, and cultural factors. As already mentioned, hedonic variability linked to these factors is a key characteristic in olfaction perception [40.28, 55].

Appraisal models have not been extensively used in olfaction research but we feel that, in contrast to traditional discrete emotion or dimensional theories, appraisal models could provide a highly differentiated and flexible framework that can explain both the elicitation and the reaction patterning in a dynamic perspective. Moreover, they could account for the changeability and high degree of qualitative differentiation of emotional experience, as well as individual differences in emotional reactions.

40.6 Functions of Emotions in Olfaction

Emotions are viewed as intelligent interfaces that mediate environmental input to adaptive output [40.101]. Emotions are thought to allow an adjustment or to solve survival-relevant problems, such as forming attachments, maintaining cooperative relations, or avoiding physical threats (for a review about the functions of emotions [40.102]. In this way, emotions motivate organisms to respond in an appropriate way. This view is well accepted, whatever the theoretical point of view adopted, from an evolutionary perspective adopted by the majority of the basic emotions theorists [40.35] to the constructionist viewpoints mostly adopted by the advocates of the dimensional theories [40.85].

As mentioned before, emotions motivate organisms to adapt their behaviors to the changing situations [40.103]. The most fundamental forms of these motivational states are the approach/avoidance tendencies [40.104]. These states are coherent with a bidimensional view of odor-elicited emotions for which the reported feeling of pleasantness is assumed to be associated with approach tendencies. Conversely, unpleasantness is assumed to be associated with withdrawal tendencies. However, motivational states can be associated with much more action tendencies than approach or avoidance solely [40.105]. They encompass various intended behavior including freezing, attack, nurturance, or exploration among many others [40.105]. Odour-elicited feelings depicted by more complex approaches (EOS, [40.1]) could account for this variety in action tendencies. The categories of feelings (disgust/irritation, happiness/well-being, sensuality/desire, energy, soothing/peacefulness. . .) depicted by the EOS may represent the way respondents' feelings are related to the different functions of olfaction. We claim that experiencing these feelings will motivate the individual to adopt the optimally suited reaction to an odor's perception.

In a review on the functions of human olfaction, *Stevenson* [40.106, p. 3] defined three major classes of functions related *to ingestion (detection/identification prior to ingestion; detection of expectancy violations; appetite regulation; breast orientation and feeding), avoiding environmental hazards (fear related; disgust related), and social communication (reproductive [inbreeding avoidance, fitness detection in prospective mates]; emotional contagion [fear contagion, stress buffering])*. In this respect, most of the terms gathered under the EOS categories of feelings called *disgust-irritation* could reflect the unpleasant subjective affective experience associated with the detection of *expectancy violation* or *environmental hazards*, described as key functions of olfaction. These unpleasant feelings could, for instance, motivate a withdrawal behavior. The terms from the *well-being-happiness* category could reflect the feeling associated with the fulfilments of *expectancies* or *food intake*. We can also mention that the terms gathered in the *sensuality* category could reflect the feelings associated with many situations of *social communication*. The terms gathered in the *energizing-refreshing* and *soothing-peacefulness* categories could depict the feelings that motivate responses in relation to many functions of olfaction, such as being energized prior to ingestion to enhance the search for food, or feeling relaxed after smelling the known odor of a partner.

In summary, while adopting a valence by arousal space as a representation of feelings would not fully account for many of odor-elicited action tendencies, more complex representations of feelings as the one proposed by EOS constitute a better picture of the way individuals adjust to solve olfactory-linked survival-relevant problems, representing a key function of emotion [40.2, 45, 47].

40.7 Conclusion

In this contribution, we have introduced the major psychological theories of emotion and their current applications to olfactory research. This field is dominated by the two classical approaches corresponding to basic emotions theories and dimensional approaches. Despite their wide use in olfactory research, these classical models have difficulties to explain two main characteristics of emotional reactions to odors: (1) to account for fine-grained physiological, motor, motivational, cognitive response pattern, and feeling states due to intrinsic chemosensory quality differences between odors and (2) to account for the highly flexible nature of the response determined by the preferences, needs, goals of an individual at a particular point in time, and contextual and sociocultural conditions. In this chapter, we have tried to emphasize the need for grounding fundamental research activities in an ecologically and theoretically plausible model of the emotion process. We have introduced, as an alternative model in olfactory research, the appraisal model of emotion that possesses the potential to overcome the generally atheoretical stance of research in this area. This model requires specific experimental methodologies designed to better understand the olfactory emotion elicitation at different levels (unconscious processing, subjective feeling and verbalization) using a multicomponential approach (consisting in measuring behavioral, subjective, physiological, and brain reactions to these odors).

41. Aversive Olfactory Conditioning

Valentina Parma, Donald Wilson, Johan N. Lundström

The mammalian olfactory system is intertwined with emotional and memory centers of the brain, thus providing an ideal model to study olfactory-based fear conditioning, a behavior lying at the intersection of perception, emotion, and cognition. In the present chapter, we first outline a brief overview of the olfactory system's anatomy, and then, we define the structural and functional changes induced by aversive olfactory conditioning with a clear focus on rodent and human models. In detail, we discuss aversive experience-dependent modulations at each level of the olfactory pathway, differentiating between experimentally presented (shock) and naturally occurring aversive pairings (toxicosis). Whenever possible, developmental trajectories are reported. The description of aversive olfactory conditioning mechanisms are finally used to provide insights on psychiatric and medical conditions characterized by aversive odor memories which may open up future possibilities of developing novel treatment options.

> *But as present pleasures are tremendous reinforcers, and present pains tremendous inhibitors of whatever action leads to them, so the thoughts of pleasures and pains take rank amongst the thoughts which have most impulsive and inhibitive power. James* [41.1, pp. 550]

Valence – the affective evaluation centered on liking – is arguably the dominant dimension in olfactory perception [41.2, 3]. Although lately it has been suggested that odor valence is hard-coded into its chemical properties [41.4], perception of odor valence is commonly thought to be predominantly derived from a learned association with the emotional context in which an odorant is encountered [41.5–7]. The emotional context can be related to positive and negative experiences, and the ability to discriminate between the two is an adaptive trait that promotes reproductive fitness [41.8]. Indeed, organisms who correctly distinguish safe from threatening stimuli can more strategically guide perception and attention to the environment, and as a consequence, anticipate and escape harmful events [41.9].

Pavlovian conditioning is the prototypical form of all types of learning [41.10, p. 103], resulting *from exposure to relations among events in the environment. Such learning is a primary means by which the organism represents the structure of its world.* [41.11]. It is such a fundamental form of learning that it is expressed between species (from invertebrates to humans) as well as within species, in all individuals [41.12].

Aversive olfactory conditioning is a specific form of Pavlovian learning. It involves an unpleasant unconditioned stimulus (US), that produces a vigorous negative response irrespective of training (or unconditionally) and a neutral cue that acts as a conditioned stimulus (CS) [41.13]. The CS is a stimulus that at first induces only a minor orienting response. However, fol-

lowing contingent associations with the US (such that the CS predicts the occurrence of the US), the CS can acquire aversive properties itself and evoke an aversive conditioned response (CR). Imagine a rat wandering in his cage and suddenly receiving a foot shock. Without any previous exposure to this aversive stimulus, the rat freezes. Freezing, the behavioral counterpart of acute stress responses in many prey animals, is a typical measure for unconditioned responses (UR) in rodents. If the same rat is exposed to a stimulus neutral in valence, such as a colored light, an auditory tone, a tactile stimulation, a flavored solution, or a smell, no negative unconditional reaction (no freezing) is expected. However, if the presentation of the neutral stimulus – such as rose – is paired with the foot shock in such a way that a clear association can be established between the two events, the neutral stimulus will acquire aversive properties. In other words, after a certain number of pairings between rose and foot shocks, the sole presentation of the rose odor will trigger a freezing reaction in the rat. Thus, the rose odor has become a conditioned stimulus, a stimulus whose response has acquired an aversive power by the repeated pairing with the stressful event (foot shock). However, by virtue of their rich affective connotation, odors can additionally play the role of US. When odors are perceived as markedly unpleasant – such as, for instance, in the case of rotten eggs for humans – odors can act as an aversive stimulus.

Pavlovian aversive olfactory conditioning is a unique source of information for unveiling the rules and functions underlying sensory-mediated learning processes for several reasons. For example, olfaction is the most archaic sense, thought to be the earliest to appear during ontogeny and the oldest sensory informant from a phylogenetic perspective [41.14, 15]. In virtue of this, the olfactory sense has evolved to a complex and highly sensitive organ [41.16]. In all vertebrates, olfactory information is rapidly distributed to multiple central targets, which are confined to the anteromedial temporal and posterior orbitofrontal lobes rather than being widespread across the whole brain [41.17, 18]. In fact, the first central brain area that process odors is situated only one synapse away from the olfactory receptor body, a distinctively short pathway between the periphery and the central sensory brain [41.17]. Furthermore, olfactory information does not require a mandatory thalamic relay from the periphery to the cortex, as for our other sensory modalities [41.19]. In addition, even if ancient, olfaction can be considered the most *dynamic* modality. Neurons in the olfactory epithelium uniquely regenerate on a monthly basis [41.20] and experience-dependent morphological and functional changes in the adult olfactory system have been revealed at many different stages of the pathway [41.21, 22]. This flexibility is essential to sustain the highly complex and versatile representation of odors in the brain [41.22].

As reviewed in Chap. 38 as well as elsewhere [41.23], cerebral areas in the inferotemporal and frontal lobes are linked to lower and higher order emotional and memory processes and are profoundly related to odor processing. It will suffice to mention the famous Proustian effect – in which smells have the power to unleash a flood of emotional memories, present in the life of almost every normosmic person [41.24]. To add biological credence to the anecdotal connection between olfaction and emotions is the fact that neural representations of odors with different valence are separable in the olfactory structures also implicated in emotional processing [41.25]. The nature of this architectural feature, that again makes olfaction a special sense as compared with other modalities, raises interesting questions about the peculiarity of olfactory-mediated aversive learning.

Olfaction also offers an exclusive prenatal-postnatal sensory continuity, which allows for the development of adaptive behavioral and neural mechanisms in utero [41.26–28]. Prenatal olfactory learning favors adaptation to the postnatal environment and the development of the neural structures supporting that learning. Critically, within the early postnatal period when altricial neonates are entirely dependent on the mother for food, warmth and protection, odor learning is heavily biased to produce an attraction to the maternal odor, regardless of whether the mother causes the infants pain or not [41.29, 30]. Thus, at a crucial period during early development, aversive olfactory conditioning is suppressed to prevent infants from learning an aversion to an odor their life depends on.

Olfaction is further the only sense that allows the receiver to have a dual experience of a unique stimulus. On the one hand, when an odor is smelled orthonasally, both animals and humans are able to make sense of it at a relative distance from its source. In an aversive context, this distal feature of the system allows for the implementation of actions that more successfully will attain the goal of avoiding the threat. On the other hand, food odors can access the system through an additional route – the retronasal pathway, which is also characterized by an internal (or proximal) evaluation of the stimulus. Humans experience this retronasal smell as flavor. Perceptual as well as neural underpinnings of the two routes are not completely overlapping and therefore can contribute differently to olfactory learning mechanisms [41.31–33].

The functional role of olfaction is differently expressed in mammals at different levels of the phylogenetic scale. Although humans have been demonstrated

to outperform many nonhuman species in odor sensitivity [41.34], certain animals, such as rodents, depend heavily on olfactory information to navigate the world, whereas humans are considered to be less reliant on orthonasal olfactory cues [41.35], though may be expert at retronasal olfaction. A comparative perspective can offer the opportunity to study the impact of this aversive olfactory information in the full behavioral context and account for the variability that can specifically be found within species. As an example, animal models are critical for the definition of the molecular and physiological mechanisms of aversive olfactory conditioning, whereas humans offer the possibility to directly assess how the participants evaluate the nearby stimuli [41.3]. If on one hand, defining how mice pair the smell of banana with gastric malaise using single cell recordings can help us determine the neuronal mechanisms of aversive olfactory learning [41.36], it would prove fairly difficult to acquire a verbal report of the animal's preference of said odor. On the other hand, one can simply ask human participants to gain information about odor pleasantness; however, obtaining information from single neurons using the same gastric malaise paradigm as for the mouse would face rejection by most ethical committees.

From a theoretical standpoint, defining how specific olfactory memories are created and stored represents an opportunity to better define cognition in rodent models, which show impressive odor-based memory abilities [41.37]. From the clinical (human) perspective, aversive olfactory conditioning represents the key to unveiling mechanisms that promote and maintain certain pathologies, such as post-traumatic stress disorder (PTSD) [41.38, 39], multiple chemical sensitivity (MSC) [41.40] and pretreatment chemotherapy nausea [41.41]. Historically, the scientific community has primarily relied on animal models to uncover etiopathogenetic and maintenance mechanisms of fears and phobias. However, given that humans exhibit behavioral vulnerability to odors in certain instances, it is timely to validate the functional anatomy of human olfaction and olfactory memory to unveil how aversive olfactory conditioning contributes in humans to the etiology and the treatment of fear-related disorders [41.42], in which odors might play a critical role.

Considering the nature of the olfactory system's architecture and its close anatomical connections to emotional and memory brain centers, it seems to us that olfaction is the sense allowing for the most reductionist and naturalistic study of aversive conditioning processes. It is worth noting, however, that this observation should not be interpreted as derived from the principle of Occam's razor. As Occam stipulated, in the absence of certainty among competing options, the one with the fewest assumptions [aka the simplest] should be selected. However, complexity has its intrinsic value and alternatives with a greater number of assumptions may ultimately prove correct. Indeed, olfaction is a simple, yet not a trivial system. Instead, it is characterized by a level of complexity that needs to be valued and manipulated to extend the boundaries of our actual knowledge on this system, whose potential is still underappreciated. Aversive olfactory conditioning is particularly interesting because it allows us to join sensory, cognitive, and emotional information to provide an effective model to study where and how these pieces of information are encoded and, importantly, integrated in the brain.

To better account for this holistic view of olfactory aversive experience, in the next section we will first broadly sketch the anatomy of the olfactory system as well as known fear circuits in mammals; then we will review how each structure along the olfactory pathway alters the signal based on experience-dependent dynamic plasticity, according to functionally different types of aversive olfactory conditioning. As we will review, important aspects of this plastic system are age-dependent; therefore, for the sake of completeness, a developmental perspective will be included.

41.1 The Anatomy of Neural Circuits Involved in Mammalian Aversive Olfactory Conditioning

The functional and organizational structure of the olfactory system is conserved across the animal kingdom [41.43]. Whether this is the result of homology or it reflects an independent evolution due to similar constraints has yet to be clarified. However, the organizational and structural similarities are an opportunity to explore the neuronal processing of aversive olfactory conditioning between species. The goal of this section is not to provide a complete review of the neural systems involved in olfactory perception and aversive conditioning; rather, it is to outline the primary factors underlying olfactory-dependent aversive conditioning. For a more complete overview, please see Chap. 38).

As depicted in Fig. 41.1, olfactory perception is initiated in the periphery of the olfactory system with an interaction between volatile odorant molecules and

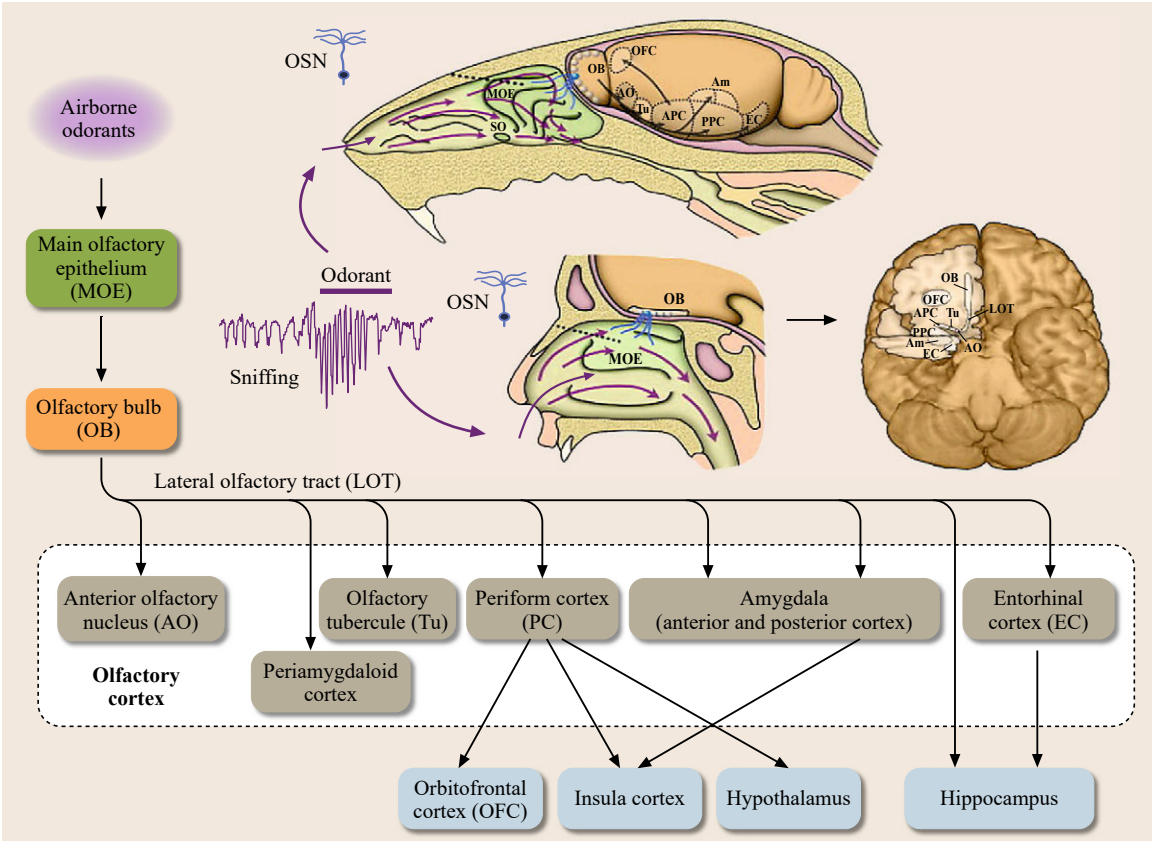

Fig. 41.1 Neural organization of the mammalian olfactory system. Sensory pathways in the main olfactory system of mammals are illustrated for mouse (*upper image*) and human (*lower images*). Volatile odorant molecules enter the nasal passages as a result of phasic sniffing, and interact with olfactory sensory neurons (OSNs) in the main olfactory epithelium (MOE). OSNs project into the olfactory bulb (OB). Discrete sets of glomeruli in the OB are targeted by the OSNs expressing the same receptor, forming odotopic spatial maps. Dozen of mitral/tufted (M/T) cells project from each glomerulus to the lateral olfactory tract (LOT), which distributes the information to the olfactory cortex. Major recipients of OB input include the piriform cortex (PC) with anterior (APC) and posterior (PPC) subdivisions, the olfactory tubercle (Tu), the anterior olfactory nucleus (AO), the hippocampus, the amygdala, the periamygdaloid cortex and the entorhinal cortex (EC). From here, odor information is routed to higher-order centers such as the orbitofrontal cortex (OFC), the agranular insula, and the hypothalamus. Adapted with permission from [41.44]

receptors expressed on the cilia of olfactory sensory neurons (OSNs) located in the main olfactory epithelium (MOE). Individual olfactory sensory neurons express a single olfactory receptor gene from the large family of olfactory receptor protein encoding genes. The axons of these bipolar neurons project to a single glomerulus, or module, situated in the olfactory bulb (OB). Each glomerulus is odorant-receptor specific in that it receives input from olfactory sensory neurons all expressing the same receptor gene. This creates an odotopic spatial organization in the OB, similar to what occurs in the visual or somatosensory systems [41.43, 44]. Dozens of mitral/tufted (M/T) cells constitute second-order projections that transmit via the lateral olfactory tract (LOT) information to the primary olfactory cortices. This group of cortices is dominated by the piriform cortex – structurally and functionally divided into anterior (APC) and posterior (PPC) regions – and it is complemented by the olfactory tubercle, anterior olfactory nucleus (AO), hippocampus, anterior and posterolaternal amygdala, periamygdaloid cortex, and entorhinal cortex (EC). Subsequently, the olfactory information is processed in other regions such as the orbitofrontal cortex (OFC), agranular insula, mediodorsal thalamus, and the hypothalamus [41.23, 45].

This system constitutes a powerful tool to model the functional neurocircuitry of fear. In fact, topograph-

ical representations of the olfactory sensory inputs exist only one synapse away from the amygdala, which is considered a key structure enabling aversive conditioning. The main olfactory bulb directly targets the cortical nucleus of the amygdala, which in turn targets the basolateral amygdala (BLA) [41.46]. The central nucleus of the amygdala (CeA) acts as an output regulator for fear responses, by targeting midbrain and brainstem structures that initiate and control the expression of fear or reactions to threat, such as freezing. This neural circuit is identified as the medial hypothalamic defensive circuit [41.47, 48]. Although it is not involved in cue fear conditioning per se, the hippocampus is a fundamental limbic structure involved in adult contextual aversive olfactory conditioning [41.49].

In the present chapter, we will consider only the structures critically contributing to the learning of representations processed in the context of aversive olfactory conditioning. For the sake of cross-species comparison, we assume that structural changes in the brain have functional correlates, whether behavioral or physiological.

41.2 Aversive Olfactory Conditioning–Induced Structural and Functional Plasticity

After repeated pairings with an aversive stimulus (US), a neutral stimulus (CS) develops an emotionally salient response (CR). Electrical shocks or nonlethal levels of toxins are commonly the stimuli that artificially or naturally induce aversive olfactory conditioning. However, in virtue of the hedonic trait of odors, unpleasant odors (and tastants) have been used as behaviorally salient US with unconditioned aversive properties [41.50]. Although few direct comparisons have been reported, the potency of the different aversive stimuli has been deemed equitable [41.25, 50]. However, provided that the acquisition of olfactory object perception is a prerequisite for aversive olfactory conditioning to occur [41.51], the involvement of different brain structures depends on the task used to elicit aversive reactions. We will therefore explore the neural plasticity shaped by the use of different aversive stimuli separately. To this end, we will initially focus on experimental (arbitrarily chosen) stimuli used in pairings or associations, which do not naturally occur in the ecological niche of an organism (electrical shock-odor coupling) with the goal of providing the basic theoretical and mechanistic principles of aversive olfactory conditioning. We will then focus on more ecologically relevant and naturally occurring phenomena of the odor-induced aversive conditioning (toxin effects odor coupling). For the sake of brevity and clarity, we will limit this review to studies using odors that are experimentally paired with aversive stimuli or unpleasant (aversive per se) odors and food-related biologically relevant stimuli (toxicosis). For odor aversion induced by predator chemosignals, please refer to the thorough review by *Staples* [41.52]. Since anatomical development is not always matched with functional development [41.53, 54], whenever possible, we will report how the mechanisms change across maturation to approximately define at which age a brain area is involved, in rodents and humans alike.

41.2.1 Somatosensory Stimulation US

Different noxious somatosensory stimuli have been used to induce threat associations with an odor (CS). In adult rodents, the use of strong tail pinches – whose limits rely on the inability of maintaining a constant stimulation over time and across subjects [41.55] – have been attempted. However, the by far most utilized stimuli in both rodent and human studies are electrical shocks of different intensities [41.56–59].

In the following sections, we will consider aversive olfactory conditioning-induced plasticity at different levels of the olfactory system, beginning from the periphery and moving towards the more central cerebral substrates.

Olfactory Sensory Neurons

The olfactory sensory neurons constitute the first order of synapses of the olfactory system and they represent the interface between the environment and the central nervous system. Experience-dependent structural plasticity has been revealed as early as at this level during the first phases of development [41.60] and during adulthood in mice [41.61, 62].

For example, mice trained in a fear conditioning paradigm with the odor acetophenone as the CS, an odorant specifically activating the M71 olfactory receptor (M71OR), demonstrated an increase in number of M71 specific sensory neurons within the olfactory epithelium and a related increase in size of the targeted glomeruli within the OB of adult mice [41.61]. This aversive learning plasticity does not appear in untrained mice, mice trained to a non-M71 activating odorant, or mice exposed to nonassociative pairings of

acetophenone, therefore confirming the link to the aversive experience. This hypothesis has also been tested with other odors and demonstrated that synaptic output of olfactory sensory neurons (OSNs) is modulated by odor-shock conditioning [41.62]. In other words, aversive learning-dependent modulation occurs already at the level of the receptor neuron.

Moreover, neonatal exposure to acetophenone in association with aversive olfactory conditioning promotes glomerular refinement, revealing not only experience-dependent structural changes but also modulation of the speed of glomerular development [41.60]. At present, it has not been conclusively settled whether the association between the CS+ and the US takes place in the epithelium or whether it is the result of a top-down link. As demonstrated by Kawai and colleagues [41.63], it is possible that an instantaneous increase in adrenaline in the olfactory epithelium (as a result of the US) might mediate an increase in receptor activity.

Although it is assumed that the human brain is able to similarly adapt its structure following aversive experiences, the technical challenges have so far prevented us from empirically testing this hypothesis, especially at such an initial level of the olfactory system. Nevertheless, it seems plausible that the regeneration of olfactory neurons throughout a lifetime [41.64] will support enhanced olfactory experience.

Olfactory Bulb

The axons projecting from the olfactory sensory neurons terminate within specific glomeruli in the OB, and synapse with M/T cells and juxtaglomerular interneurons [41.65–67]. Considering that each glomerulus represents input regarding a single odorant receptor, the glomerular and M/T layers of the OB constitute odorant receptor maps [41.68], which can be molded by experience. Studies conducted in rodents demonstrated that early in postnatal development, the repeated, daily exposure to odor-shock pairings induces fear responses in the pups. It also intensifies the CS+ odor-evoked brain activity as measured by an increase in focal uptake of glucose (precisely, 2-deoxy-D-glucose, 2-DG) in the OB glomerular layer, as well as changes in M/T cell responses [41.69]. In adult rats, even a single exposure to an odorant paired with shock will result in subsequent CS-evoked freezing and increased odor-evoked 2-DG uptake in OB glomeruli [41.70].

These aversive olfactory conditioning-induced changes in OB response to the CS may be mediated by long-term potentiation-like mechanisms within the olfactory bulb [41.71, 72], as well as learned changes in olfactory sensory neuron input [41.61, 62]. Importantly, the olfactory bulb also undergoes continued neurogenesis of inhibitory granule cells throughout life, and several studies have demonstrated that the incorporation of these newborn neurons into the OB circuit is shaped by odor experience and learning, and the inclusion of these new neurons significantly contributes to the odor memory [41.22, 73, 74]. This effect is true for both appetitive odor conditioning and aversive olfactory conditioning [41.75]. Although aversive conditioning does not reorganize the glomerular representation, mice exposed to the odor-shock pairings demonstrate an increase in the size of glomeruli within the specific odor representation [41.61, 76]. Moreover, the activation of glomeruli that were originally only weakly activated by the CS pre-training increased after conditioning [41.76]. Together, these data suggest that aversive olfactory conditioning, even in immature animals, helps tune the olfactory bulb to an increased and more specific representation of the CS odor. The tuned representation is expressed at the level of both glomerular layer spatial activity patterns and M/T output activity, and includes neuroanatomical changes such as local addition of granule cells.

At present, noninvasive neuroimaging techniques that can be applied in human studies do not allow for the characterization of the functional plasticity of the OB in an aversive olfactory conditioning paradigm. However, it seems plausible that humans do also show some sort of learning-dependent OB plasticity after aversive olfactory conditioning. This area deserves further study.

Piriform Cortex

Second-order projections bridge the information from the OB to the primary olfactory cortices, by means of the lateral olfactory tract (LOT) [41.77]. In contrast to the odor-specific spatial maps expressed in the OB, both connections in the olfactory cortex [41.78, 79] and odor-evoked activity are distributed in the piriform cortex [41.80–82], revealing the presence of diffuse projections and an internal system of long association fibers. In other words, as theorized by *Haberly* [41.83], the olfactory cortex acts as a *content-addressable memory* in which each site in the system contains information about the entire input. The anterior piriform cortex (APC) receives strong afferent inputs from M/T neurons and is hypothesized to play a primary sensory cortical role in olfaction [41.84–87], as well as having some functions in odor memory. For example, single-unit recordings showed post-conditioning changes at [41.87–90] the level of the APC in awake rats [41.91, 92]. In animals trained to fear a specific odor (CS+) and not fearing a similar odor that was not paired with shock (CS−), APC expressed more selective odor coding. In contrast, rats trained to have a generalized behavioral fear response demonstrated impaired odor discrimination at the level of APC single units [41.92].

Contrary to the APC, the anatomy and the functionality of the posterior part of the piriform cortex (PPC) are reminiscent of higher-order associative areas and are thought to be responsible for odor quality and categorization. The PPC receives a relatively strong input from the basolateral amygdala, while the APC does not [41.93, 94]. As postulated by *Li* [41.95], this may be the primary locus of representation for olfactory aversive stimuli in humans. Since early development (post natal (PN) day 7–8]), odor aversion learning is associated with PPC activity [41.96]. This is maintained around the weaning age (PN12–13) with shocks of different intensity (0.5 and 1.2 mA). Post-conditioning plasticity in this area has been repeatedly demonstrated via different techniques. Animals trained with odor-shock conditioning display stronger local field potentials [41.97, 98], higher synaptic plasticity as measured via the expression of brain-derived neurotrophic factor (BDNF) [41.99], increased gamma-aminobutanoic acid (GABA) and glutamate concentrations that resist approximately for 30 minutes [41.100]. Also, lesions at the level of associative olfactory cortices (PPC included) one month after training eliminate the CR [41.101]. Taken together this indicates that the piriform cortex is an essential structure for long-term storage and retrieval of odor-paired threat. In other terms, the synthetic function of the piriform cortex as a whole complements the specificity of elaboration found in previous stages of the olfactory system (OB) and promotes a more comprehensive and stable representation that serves as the base of the holistic perceptual experience of the odor object [41.102]. Furthermore, convergent support of this statement comes from the study of the slow-wave sleep (SWS) activity in an aversive olfactory conditioning paradigm. Even if PC is usually hyporesponsive to odors during SWS, during post-conditioning its activity is enhanced and significantly correlates with subsequent memory performance [41.91]. In other words, it is possible that the PC's reduced reactivity during SWS indicates a preferential mechanism to facilitate memory consolidation of relevant information (threat) while external noise can remain unattended [41.91].

In agreement with findings from the rodent literature, the human piriform cortex has been identified as a key structure in aversive odor conditioning. PPC, but not APC, exhibits odor-paired specific plasticity [41.103] that seems to be based on response enhancement following prolonged exposure to an odor [41.104]. Critically, the PPC post-conditioning odor plasticity is evident also when the initial neural (and perceptual) representation of the odor to-be-paired with the shock (CS+) and the odor to-be-unpaired with the shock (CS–) are not discriminable [41.103]. Associating one of two entianomers, odors with chemical mirror non-superimposable images, with a shock significantly increases discrimination performance of the paired odor [41.103]. This elegantly suggests that human aversive olfactory conditioning is based on sensory augmentation processes that are independent of attention [41.103]. In line with the above-mentioned studies demonstrating that aversive olfactory conditioning-plasticity is present already at earlier stages of the system, *Åhs* and colleagues [41.105] demonstrated in human participants that the increase in discriminatory performance after aversive olfactory conditioning was based on an odorant-dependent shift in absolute sensitivity rather than on a change in discrimination performance per se. Interestingly, eight weeks after the documented aversive olfactory conditioning-dependent increase in sensitivity, the increase was no longer present [41.106]. This indicates that these effects of rapid plasticity may be of a transient rather than permanent nature.

At present, while aversive olfactory conditioning-induced changes can occur throughout the piriform cortex (especially in rodents), the site of most likely anatomical convergence between threat signals and the odor CS is the posterior part of the piriform cortex. Accordingly, the PPC is the structure that most reliably demonstrates odor-shock induced plasticity in humans.

Hippocampus

A key player in the formation and storage of memories across mammals is the hippocampal formation [41.106]. The hippocampus is thought to be responsible for the acquisition of the association between stimuli, and among stimuli and the context in which they are presented during aversive olfactory conditioning [41.106]. Critically, the development of the hippocampus is responsible for the emergence of contextual aversive olfactory conditioning that appears in rat pups at PN24, but not before that developmental stage [41.49]. Neural and immunohistochemical correlates indicate an increased activity evoked by CS odors after aversive olfactory conditioning in several subregions of the hippocampal formation, such as the Cornu Ammonis (CA) 1, CA3, and the dentate gyrus (DG). This learned odor-evoked activity presumably reflects the fact that the DG receives strong afferent input from the entorhinal cortex, which is a highly multisensory cortex including serving as a direct, monosynaptic target of the olfactory bulb and piriform cortex (Fig. 41.1) [41.49]. The DG in turn projects to the CA3.

The $GABA_A$ agonist muscimol infused into the hippocampus, which silences hippocampal activity, prevents rat pups from coherently representing the stimuli in the environment and therefore inhibits contextual

aversive olfactory conditioning [41.49]. These results are in line with most literature on adult contextual aversive olfactory conditioning.

In human participants, it has been demonstrated that the representation of an object becomes fully consolidated by involvement of the hippocampus [41.107]. In aversive olfactory conditioning, the sensory (piriform) cortex plays a key role in supporting the long-term storage of the representation [41.108], as evident also for other sensory modalities (audition) [41.109]. Recent data also indicate that the strength and precision of aversive olfactory conditioning memories can be modified by sleep [41.110, 111]. Re-exposing adult participants during the sleep stage to the odor associated with threat during the previously wake state induced a reduction in hippocampal activity (as well as a reorganization of neural patterns in the amygdala) prompted by stimulus-specific extinction. Therefore, the extinction of the feared odor can be favored during sleep, simultaneously avoiding the traumatic conscious re-exposure of the threatening odor [41.110].

Amygdala

The amygdala has historically been thought to be the key structure for initiating and controlling fear reactions. However, more recent data indicate that the amygdala codes for the biological significance, intensity, or salience of sensory stimuli [41.112, 113]. It projects outputs to the sensory cortices, which may enable perceptual analysis of potentially threatening stimuli [41.112, 114]. Although this is not the only possible pathway enabling threat perception [41.115], the amygdala remains a central area for aversive olfactory conditioning given its role in emotional, memory, and olfactory processes.

Among the amygdalar nuclei, the basolateral complex (BLA), which includes the lateral, basal and accessory basal nuclei, is the area most strongly linked to aversive olfactory conditioning processing [41.116]. The lateral nucleus has been implicated as the primary site of acquisition and consolidation of aversive memories, given its increased spike firing and long-term potentiation [41.117]. This has been confirmed specifically for aversive olfactory conditioning [41.118] as early as in the first stages of development [41.96]. Learning-associated changes in the BLA are impacted by the strength of the shock, but only from PN23–24, when BLA is involved at all intensity levels of electric shock (0.5–1.2 mA) [41.96]. Immunohistochemistry measures further confirm that amygdala involvement critically mediates the development of aversive olfactory conditioning at PN10 [41.119–123]. This structure, although sufficiently mature to respond to aversive odor stimuli during the sensitive period [41.124], is involved in the mechanisms in interaction with corticosterone levels [41.119, 121, 125–127]. Further, attenuated aversive olfactory conditioning in adulthood has been demonstrated to be associated with a deficit in CS odor-evoked 2-DG uptake in the cortical nucleus of the amygdala and the PPC, effects that have been linked to reduced local inhibition, as assessed by means of electrophysiological techniques [41.128]. In other words, odor-shock pairing experienced early in life induces functional changes in areas beyond those involved in infant learning and they are potentiated by contingencies [41.128].

In adult rats, the amygdala is critical for threat acquisition and consolidation. Pre-training lesions or pharmacological inactivation or inhibition of BLA as well as post-training lesions prevent the full formation of a CS-paired odor aversion [41.129–131]. Increased expression of BDNF [41.99] and heightened concentrations of GABA and glutamate [41.100] in trained rodents are biomarkers of the BLA synaptic plasticity following aversive olfactory conditioning.

Learning-dependent responses in the amygdala are also revealed in human studies showing time-dependent post-conditioning plasticity. In other words, the amygdala response is maximal in early conditioning trials and a progressive decay of activity in this area is subsequently seen [41.103]. This finding is in line with the exponential decay in activity observed in imaging studies using visual stimuli in association with shocks [41.132, 133] and provides an indication of how the aversive experience shapes perception. More recently, it has also been shown that odors paired with painful (trigeminal) stimulation (carbon dioxide, CO_2) elicits an enhancement of functional activation of the amygdala during conditioning [41.134].

In summary, the amygdala, especially the BLA, is strongly implicated in aversive olfactory conditioning in both humans and rodents. The BLA expresses localized changes in network function that contribute to stored memory and subsequent CR behaviors. Furthermore, BLA output to target areas, such as the PPC, may contribute to learned changes directly within the sensory cortex, a mechanism that can contribute to odor-evoked fear.

Orbitofrontal Cortex

The orbitofrontal cortex (OFC) is a vital part of the neural olfactory network in both nonhuman and human animals. In rodents, it receives olfactory input through both reciprocal connections with the piriform cortex [41.135] and via projections from the mediodorsal thalamus [41.136, 137]. The OFC is important for odor-taste multisensory integration [41.138, 139] as well as for olfactory reward evaluation and odor-guided be-

haviors [41.140]. The OFC and its connections with primary olfactory areas [41.135] demonstrates experience-dependent plasticity [41.141, 142] and this may contribute to learned odor behaviors. Important for this discussion, the prefrontal cortex, including the orbitofrontal, is also a strong modulator of amygdala activity and is involved in emotional regulation and anxiety [41.143]. However, to the best of our knowledge, the OFC has received very little attention in aversive olfactory conditioning paradigms in either humans or nonhuman animals.

41.2.2 Chemosensory Stimulation

The extent of the literature covering the use of chemosensory stimuli as the US in aversive olfactory conditioning paradigms is scant when compared to the previous section. Therefore, we present a more integrated view and we merge our discussion of the various neural structures involved. In rodents, although predator odors can be used as US in contextual conditioning paradigms [41.144, 145], we are not aware of any published odor US – odor CS conditioning data. Perhaps the closest example of such work in rodents is the recent work demonstrating transgenerational odor fear [41.146]. Female rats were conditioned (odor-shock) to fear an odor. They were subsequently bred and allowed to have litters. If the mothers were exposed to the CS odor in the presence of her pups, her fearful response to that CS induced odor-specific fear in her pups. The alarm odor she emitted in response to the fearful CS was sufficient to train her pups to fear the CS themselves [41.146]. This form of transgenerational odor fear is amygdala dependent [41.147, 148].

In humans, unpleasant odors have been used as aversive stimuli to produce aversive reactions comparable – although not identical – to those dependent on electrical shocks [41.25, 50, 147]. For instance, odors are stimuli that can induce emotional reactions closer to disgust rather than fear. In fact, simple odor exposure does not induce the same brain activations as revealed by the pairing of a neutral visual stimulus and an aversive odor [41.50]. *Gottfried* and collaborators [41.50] used neutral faces as CS and paired half of their presentations with 4-methyl-pentanoic acid, a pungent cheese-like odor acting as US and consistently rated as unpleasant. Functional magnetic resonance imaging limits the extent to which we can spatially zoom in on task-related activations and therefore does not allow assessment of learning-dependent plasticity before the information arrives in the piriform cortex, and it does not enable the analysis of single nuclei within subcortical structures. However, the PPC seems to play a critical role in salient associative activity, thus confirming using a different type of US that this area cannot be considered a strictly unimodal cortex, but rather an associative brain center [41.50]. Amygdala responses were not, however, reported [41.50]. This lack of amygdala activity could potentially be attributed to an insufficient arousal magnitude by the unpleasant odors [41.149], some of which might have triggered disgust rather than fear [41.150].

Further, an interesting aversive olfactory conditioning-dependent effect has been demonstrated in the orbitofrontal cortex (OFC), an area that has been attributed to higher-order complex processing and by some labeled as the secondary olfactory cortex [41.149]. Both the medial and the lateral portion of this cortex have been related to learning-dependent computations that outperform simple odor processing [41.50]. In other words, OFC is an essential contributor to the creation of stimulus-reward associations that are used to organize odor-guided behaviors.

41.2.3 Naturally Occurring CS–US Associations

The prevalence of object learning in the environment makes it a useful heuristic for identifying CS-US pairings in nature [41.51]. An interesting case is represented by conditioned odor aversion (COA). COA is a robust and long-lasting odor association that generates avoidance of the odor stimulus due to the contingent association of an ingested tasteless solution (CS) rapidly followed by toxicosis (US) [41.151]. COA is a phenomenon that has been shown to be present in intrauterine life and throughout development [41.70, 152–160] [41.161]. Although it has been suggested that COA learning depends exclusively on the taste modality [41.162], it is now clear that retronasal olfaction has a significant impact on post-ingestive outcomes [41.36, 163]. In fact, the distal exploration of the food via its odor acquires predictive value of the sensations experienced while consuming the food [41.36].

In the following sections, we will report the characterization of the neural activity associated with olfactory-induced malaise, following the olfactory pathway. It is worth reiterating that for many other paradigms, the investigation of the lower levels of the olfactory hierarchy has yet to be performed on human participants. Researchers working on the topic are in the process of adjusting current techniques or developing new tools to resolve the issues preventing the online neuroimaging of the OSN and olfactory bulb. Nonetheless, a direct comparison between the human and nonhuman literature is often difficult due to the necessity of experimentally inducing the malaise paired with the olfactory stimuli; a practice that is ethically difficult to perform in humans due to the long-term aversive out-

comes [41.164]. For this reason, this section will focus on knowledge derived from experiments in nonhuman animals. Observational information regarding specific cases of odor-malaise associations will instead be provided in the next section addressing the role of aversive olfactory learning in clinical conditions. To the best of our knowledge, the effects of naturally occurring odor CS-US associations on olfactory sensory neurons have not been explored. Therefore, we will start our hierarchical report at the level of the olfactory bulb.

Olfactory Bulb

In the rodents, COA has been deemed possible to induce as early as in fetal rats [41.70, 152, 157–161, 165–169] and it relies on the contribution of the OB, at least until the pup approaches weaning age. However, data gathered in older pups and adult rats [41.170] indicate that the plasticity of the OB is reduced as compared to the first phases of development. Critically, in COA paradigms, the contribution of the OB lasts longer as compared to aversive olfactory conditioning paradigms involving shock [41.49, 158, 171]. Considering that COA relies on the olfactory retronasal stimulation of a food item, the nutritional state of the animal is a critical variable in modulating the activity in the OB. As an example, single-cell recordings demonstrate that the activity of the mitral cells increases when an animal is satiated and receives an odor previously paired with malaise [41.172]. Taken together, these findings indicate that the activity in the OB reflects the coding of the conditioned relevance of a stimulus induced through natural exposures.

Piriform Cortex

Although relatively unstudied, the impact of odor-malaise learning on the APC does not seem to be robust during early development, whereas PPC seems to play a critical role [41.96]. By capitalizing on Fos immunoreactivity, a technique that allows for the quantitative analysis of the neurons activated following stress and pain by visualizing the expression of the c-Fos protein product, it was evident that the odor-evoked trans-synaptic neuronal activity increased in PPC during the retrieval of taste potentiated odor aversion (TPOA) [41.173, 174]. In line with this evidence, *Chapuis* et al. [41.36] demonstrated that COA learning clearly modified transient oscillations reflecting synchronous activities in large-scale neural assemblies. In detail, odor-induced fast oscillations in the beta frequency (15–40 Hz in rats) of local field potentials registered at the level of PPC predicted the aversive behavior to the odor in concert with the emergence of a strong beta oscillatory activity in the OB, OFC, and BLA. Altogether, these pieces of evidence seem to support the idea that specific neuronal populations in PPC respond to odors paired with aversive stimuli and have enhanced temporal coherence, allowing for experience-dependent odor representations specific to the way the aversion was acquired [41.36].

Amygdala

The amygdala contribution to COA arises post-weaning in rat pups [41.96, 158] and is maintained in adult life [41.175]. The BLA, in particular, has been described as the critical structure involved in the acquisition, consolidation, and retrieval of the COA [41.170, 176–179]. *Chapuis* and colleagues also provided evidence of experience-dependent modulation of BLA oscillatory activity in response to odors [41.36]. In line with the idea that this structure integrates the affective salience of chemosensory stimuli [41.180, 181], it is plausible that it plays a role in the representation of a general aversive connotation of the olfactory signal.

Insula

The insula, also known to be a prime processor of gustatory information [41.182], is critically involved in aversive paradigms involving tastants [41.183]. With reference to the COA paradigm, the more ventral agranular zone of the insula (an area labeled by some as primary gustatory cortex) is a particular target of projections for primary olfactory areas [41.184, 185]. *Chapuis* et al. [41.36] described how the pattern of beta oscillatory activity in both the agranular and the granular division of the insular cortex are modulated in response to the learned odor cue, but only when ingested before the animal experienced malaise. This would represent *the signature of a network supporting odor representation as a consequence of the animal experience* [41.36].

Orbitofrontal Cortex

The OFC is known to integrate the inputs of various food-related sensory stimulations and has been suggested to play an important role in flavor perception in rodents and humans [41.139, 186, 187]. *Dardou* and collaborators have shown that both olfactory and taste cues activate this structure during taste potentiated odor aversion retrieval [41.174]. Several studies have shown the existence of both anatomical and functional connectivity between the PC, the BLA, and the OFC [41.135, 188], and that these pathways are capable of learning-dependent plasticity [41.141, 142]. Thus, this network is a good candidate for the integration of both sensory and affective signals about food odor cues.

It has been suggested that retronasal stimuli are more effective than orthonasal stimuli in modulating the gustatory or flavor neural code. As an example,

De Araujo and colleagues [41.138] measured brain response to retronasally delivered odors in combination with a taste and demonstrated selective activity in an anterior region of OFC, suggesting that the region was therefore important in integration of taste and smell. Moreover, *Small* and colleagues [41.187] determined that the modulation of preceding experience (whose valence was not, however, taken into account) affects OFC, as well as the insula and anterior cingulate cortex.

41.3 Clinical Applicability

Up to this point, we have reviewed the neural changes associated with aversive olfactory conditioning across different stages of the olfactory pathway and across specific developmental ages. These modifications have a striking impact on the individual's physiology, whether nonhuman or human animals, and on the manifested behavioral correlates. Independently of the sensory modality considered, the fear-conditioning paradigm has proven to be one of the more prolific and valuable experimental models for assessment of human psychiatric disorders associated with abnormally heightened fear, anxiety, and other dysfunctional behaviors [41.189–196]. The natural response to sensory cues, the acquisition of aversive memories, and the extinction of the already acquired fear memories are mechanisms that have characterized the study of aversive olfactory memory and set the base for explaining a range of pathologies and psychopathologies. Besides etiopathogenetic explanations, behavior therapy has used aversive olfactory conditioning to reduce a variety of dysfunctional or unwanted behaviors [41.197]. Below, we will analyze some of the most relevant applications.

41.3.1 Anxiety and Trauma-Related Disorders

The range of fears is immeasurable, and some clearly present an olfactory component. Besides phobias triggered by odors of animals (for instance, dog odor for cynophobics) [41.198], post-traumatic stress disorder (PTSD) has a strong olfactory connotation [41.192]. PTSD is a mental sequela that may occur after a traumatic event, such as war, assault, or a natural disaster [41.199]. Experimentally, studies reported in the literature have used combat-related stimuli in different sensory modalities. Odors have long been noted in the clinical practice to have a strong emotional and memory component that seems to precipitate or trigger the individual to re-experience the traumatic event [41.200]. The characterization of the mechanism of aversive olfactory conditioning constitutes a model for threat perception and reaction that can be useful in the explanation of the general principles underlying these types of fear-related clinical issues. The amygdala and the hippocampus, both of which are central to the mechanism as previously outlined, are structures that have been consistently included in neural models of anxiety and mood disorders [41.201]. Specific to PTSD, a positron emission tomography study revealed a bigger change in cerebral blood flow in the amygdala and odor cues retrieved more memories of life events [41.39]. Furthermore, aversive olfactory conditioning can either induce very stimulus-specific fear (selective to the CS) or generalized odor fear depending on the events during the conditioning (presence of a CS− and a CS+ [41.92]) and experiences during consolidation of those fearful odor memories (during post-training SWS [41.110, 111]). These different features of aversive olfactory conditioning experience can change the precision with which the olfactory system encodes the learned odor. Failure to have precise stimulus control of our learned fears can contribute to PTSD and other fear-related disorders. Thus, understanding how traumatic events affect sensory coding itself will significantly contribute to our understanding of these disorders and will open up the possibility of expanding treatment options.

Well-established treatments for both specific phobias [41.202] and PTSD [41.203] are exposure-based behavioral strategies, which involve the experience of the feared object or situation in a nondangerous, controlled environment. Exposure therapy encourages the systematic confrontation of stimuli associated with fear, with the goal of reducing the person's fearful reaction [41.204]. Confrontation of external (feared objects, activities, situations) or internal feared stimuli (feared thoughts, physical sensations) can occur in imagination or in vivo [41.202–205]. Nevertheless, positive therapeutic results are critically dependent on the emotional engagement of fearful memories, [41.206] whose replay is often actively contrasted by patients [41.206]. Smells, in virtue of their automatic emotion-producing feature, are ideal candidates to increase emotional engagement [41.207] and reduce the frequency and the intensity of episodes of anxiety, flashbacks, and dissociation triggered by odors. Attempts have been made to increase the usability of exposure therapy and

the compliance to the therapy by reducing its side effects. As an example, technological advancements offer the opportunity to control odor presentation by exposing patients to sensory rich virtual reality (VR) environments [41.208, 209]. As another example, techniques have been proposed to replay the traumatic event in states of faded consciousness. Besides the scant evidence on hypnotherapeutic olfactory conditioning [41.210], which helps the hypnotized patient to develop new (positive) olfactory associations with the traumatic event, interesting potential comes from the study by *Hauner* and colleagues [41.110]. The authors exposed their participants to face images and electrical shocks in the presence of an olfactory background. During an afternoon nap, the olfactory cue paired with the aversive association was reproposed. In the ensuing wake period, arousal, amygdala, and hippocampal activations were reduced for the feared face. In other words, these findings suggest that odors are sensory cues able to target which memories can be reactivated during sleep and favor fear extinction. Although these results were reported for a group of healthy young adults, they trace a pathway for research including patients with anxiety disorders and, in general, everyone who would like be relieved of an unwanted fear.

41.3.2 Multiple Chemical Sensitivity

Another pathology that heavily relies on olfactory-based conditioning issues is multiple chemical sensitivity (MCS) [41.211], also defined as idiopathic environmental intolerance [41.40]. MCS incorporates a range of chronic polysymptomatic conditions among which low levels of common environmental chemicals (pesticides, solvents, etc.) have been reported to cause disabling problems in the sufferers. The high comorbidity with affective disorders [41.212] and the findings from the animal literature of links to the mechanism of kindling (or neurogenic sensitization), support the idea that olfactory-based conditioning and/or sensitization mechanisms might be the base of the disorder. Aside from maladaptive cognitive products (i. e. beliefs, expectations), repeated associations between multi-componential aversive responses (e.g. psychophysiological, motor) and low levels of inhaled and ingested chemicals, may condition aversive response symptomatology [41.40, 213]. In fact, it has been demonstrated that healthy participants exposed to harmless odors (i. e. butanoic acid) in association with CO_2 show post-conditioning somatic symptoms like altered respiratory behavior that can be reduced in a typical Pavlovian extinction paradigm [41.214].

The olfactory-limbic mechanisms previously described, and in particular the use of odors as US and odor-malaise paradigms, are mechanisms that offer testable hypotheses, which are urged to be explored to better characterize this still controversial syndrome [41.215]. In addition, in rodents it has been reported that norepinephrine, released in response to arousal, can prevent habituation and/or induce dishabituation of odor evoked neural [41.90] and behavioral [41.216] responses. Thus, cognitive factors could differentially maintain or heighten olfactory responsiveness to odors in individuals predispositioned to MCS via elevated norepinephrine levels. This should be the target for future studies.

41.3.3 Pretreatment Chemotherapy Nausea

The odor-malaise condition type is an optimal model to explain the phenomenology of anticipatory nausea in patients undergoing cancer chemotherapy. Many cancer chemotherapy drugs provoke nausea and stimulate the emetic reflex [41.217], resulting in approximately 25% of patients developing anticipatory nausea and vomiting [41.218]. The most common cause of pretreatment nausea has been found in the odor that the patients associate with the clinical environment or odors previously associated with a vomiting experience [41.219]. Given the repetitive aversive association with the treatment and the emetic episodes, the patients might refuse or experience the treatment as disgustful. Therefore, the patient's compliance in the treatment, essential for the recovery process, is threatened and quality of life impaired [41.40]. At present, antiemetic drugs acting on the neurochemical control of vomiting are primarily used to treat chemotherapy nausea [41.220]. However, some types of administrations, such as intramuscular delivery, prove to be painful and carry a plethora of side effects (e.g. erratic absorption of drug, sterile abscess formation, fibrosis of the tissues, etc., [41.221]). Therefore, understanding the learning mechanism of the conditioned response offers the possibility of making behavioral recommendations [41.218, 222].

Systematic desensitization processes contrast the maladaptive learned responses of anticipatory nausea and vomiting with relaxation under the assumption that fear and relaxation cannot coexist at the same moment [41.205]. This process, which often happens in imagination, facilitates the creation of an alternative response to the dysfunctional behavior. Specifically to anticipatory nausea and vomiting, olfactory stimuli associated with the chemotherapy sessions can be presented to the patient who has reached a deep stage of relaxation, promoting the counterconditioning of the unwanted response. This behavioral approach has been proven more effective than other treatments such as counseling [41.223] and relaxation alone [41.224].

41.3.4 Addiction and Substance-Related Disorders

Conditioning mechanisms involving olfactory stimuli can be used, as just reviewed, to reduce nausea and vomiting but they also have often been used to produce them in order to avoid other sorts of unwanted behaviors. Classically, aversion therapy has been an effective approach to reduce excessive drinking in alcoholics [41.225]. Pairing the odor of alcohol with electrical shocks as US has been one of the techniques [41.226], although not the most successful. Indeed, chemically based aversions, appropriately pairing the smell (or the taste) of alcohol with other chemical cues such as ammonia-like smelling salts [41.227] or with emetic drugs [41.225] resulted in longer-lasting alcohol avoidance. Aversion therapy lived its golden age between the 1940s and the 1950s, and then progressively declined. Recently, few to no uses of this technique have been reported [41.228].

Odor-based aversion therapy was not only confined to alcoholism issues but it proved useful in reducing other types of addictions [41.228, 229]. For instance, isovaleric acid, a cheese or sweat-like foul smell, presented during covert sensitization, namely the mental rehearsal of the undesired behavior, discouraged cigarette and marijuana smoking as well as paint and glue sniffing [41.230]. It successfully reduced both manifest and implicit behaviors (thoughts) [41.230]. A naturally occurring aversive therapy has been described in smoking pregnant women who after associating the cigarette odor with nausea reactions will temporarily and spontaneously terminate their smoking [41.229]. Interestingly, *Arzi* and colleagues [41.231] offered an opportunity for a broader number of smokers. In a group of nicotine addicts who wanted to quit smoking, *Arzi* et al. [41.231] presented the cigarette's odor paired with two nonarousing, yet disgusting, odors (ammonium sulfate and rotten fish) during short-wave sleep. In the following wake period, participants exposed to the negative conditioning during their natural sleep reduced the number of reported cigarettes smoked (as compared to baseline) without any additional aid. Smoking cessation persisted for a week. These promising findings open up future research endeavors to fully disentangle the physiological process and evaluate the feasibility of sleep learning as a therapy.

41.3.5 Inefficient Therapeutic Use of Olfactory Aversive Conditioning

Besides the important insights that olfactory aversive conditioning has brought to the understanding and treatment of a variety of mental health disorders, the cases in which aversive therapy using olfactory stimuli has been attempted have not always been successful. As in the case of excessive drinking, overeating is a dysfunctional behavior that has often been treated with aversion therapy involving olfactory stimuli. *Cole* and *Bond* [41.232] paired appealing foods with noxious odors and temporarily succeeded in facilitating weight loss in a group of obese patients. They also demonstrated that at the end of the eight-week program, olfactory aversion therapy produced the highest weight loss as compared to two control groups (placebo and waiting list) not exposed to the foul odors [41.232]. Measurements at the eight-week follow up revealed, however, no differences with pretreatment weight levels, thus suggesting that olfactory aversion therapy is not efficient in targeting obesity long term [41.232].

Even considering the momentum gained by olfactory aversive therapy throughout a series of behaviors considered dysfunctional, it is striking that such a technique has been widely applied to limit noncanonical sexual practices [41.197]. Sadistic sexual arousal [41.233] and homosexual behaviors [41.234], have been routinely treated by behavioral therapists by associating the unwanted behavior with unpleasant olfactory stimuli such as ammonia or sulfurous compounds (rotten egg smell). In none of these studies can the therapy be considered as successful, either short or long term. Only in a single case study of child harassment tendencies did olfactory-induced aversions, in concert with other simultaneously proposed approaches, reduce the dysfunctional behavior [41.235].

41.4 Conclusions

The ensemble of the evidences reported here leads us to conclude that the olfactory system in rodents and humans alike is dynamically regulated at all (testable) levels of the olfactory system, starting from prenatal development and lasting throughout adult life. Indeed, tentative evidence even suggests that aversive odor learning transcend generations via epigenetic modulation [41.148].

The same core brain areas (PPC, amygdala) are responsible in all types of olfactory-based aversive learning mechanisms for mediating the association between the odor and the negative emotional experience. The

changes induced in the piriform cortex by the aversive experience have a cascading impact on a large network of cerebral areas, including the reciprocal ascending connections to OB and the descending connections from OFC [41.188]. As a result, the rich experience-dependent and plastic responses have the ability to associate memories with emotional content. As recently proposed by *Li* [41.95], a sensory-cortex-based threat perception model would explain the constitution of aversive experiences. Life experiences will form negative odor-threat associations that will first be stored at the level of the olfactory cortex, enabling encoding of threat cues as early as the first stages of sensory processing. Subsequently, as the representation of the odor-threat association is consolidated in the amygdala and elsewhere, the piriform cortex may undertake both rapid and long-term plastic changes, ultimately resulting in modified neural response patterns underlying the association. Unfortunately, limits to now available methods and usability in respect to ethical standards prevent research from extending this model to the lower levels of the olfactory pathway in humans, such as the olfactory sensory neurons. Moreover, as we highlighted above, whether the stimuli to be associated with the threat (either a shock, or a toxin) are presented orthonasally or retronasally will differently impact the neural network underlying the experience both in animals and in humans.

From a developmental perspective, the literature indicates that different conditioning methods trigger different neural pathways for odor aversion learning, each demonstrating different developmental trajectories [41.96]. The amygdala is a structure whose activation is highly sensitive to the specific learning protocol involved (aversive shock as compared to odor-malaise associations) and the reinforcement condition being assigned. Unfortunately, insights on developmental trajectories of human aversive olfactory conditioning are currently lacking.

Finally, a thorough characterization of aversive olfactory conditioning mechanisms constitutes a model for threat perception that can be useful in the explanation of the general principles underlying a variety of mental health disorders and their treatment. Specifically, a detailed knowledge of these mechanisms will be vital to solve problems related to memories triggered by odors in a variety of psychiatric and medical conditions, thus opening the possibility of developing novel therapies, even directly involving aversive olfactory conditioning. Considering the peculiarity of odor-based aversive learning mechanism, an experimental model with a high ecological relevance, it is our belief that there is an urgent need to fully uncover the behavioral psychophysiological and neural underpinning underlying aversive olfactory conditioning and that the field is set for major discoveries in the near future.

42. Odor-Based Context Dependent Memory

Maria Larsson, Artin Arshamian, Cornell Kärnekull

Even though rarely thought of, all environmental spaces contain odor information. It has been proposed that the preconditions for episodic olfactory memory may not be optimal. For example, environmental olfactory information often goes unnoticed and barely evokes attention in humans and semantic activations that are a prerequisite for optimal episodic memory functioning are typically restricted. Still, it is highly likely that olfactory information will become part of a memory representation that is linked to a specific event. This implies that an event-congruent exposure of an odor carries the potential to trigger all, or parts of, a previous episode. Indeed, available evidence shows that odors may serve as powerful reminders of past experiences. This is demonstrated by studies exploring the nature of odor-evoked autobiographical memories and by controlled experimental paradigms where odors have been embedded in a learning context and later reinstated at retrieval where an increased memory recollection for the target information is often observed. These observations converge on the notion that odor memories are retained over long periods of time.

In this chapter, we will highlight olfactory cueing of memory and how odors may act as reminders of the recent and distant past.

42.1 Odor-Based Context-Dependent Memory

Our memories of events are often a result of experiences that occurred within a physical context. Memory scientists have shown that one way to increase the access to memory information is to reinstate the original learning context, that is to maximize the congruence between retrieval and the conditions that prevailed during acquisition [42.1]. Episodic memory consists of many different types of information (spatial, temporal) originating from several different senses. These features may act as memory cues, or *triggers* for the original learning event to eventually promote retrieval of the target information. Context-dependent memory (the encoding specificity principle; [42.2]) refers to the fact that retrieval of specific episodes or information improves when the context present at encoding (learning) and retrieval are the same. Hence, it is assumed that environmental features (e.g., an ambient odor) are merged with target information during learning and that presence of the same odor at testing functions as an additional retrieval cue to the target event. A related theoretical notion is that of *transfer appropriate processing* [42.3] where retrieval is regarded as being mediated by the extent to which the cognitive processes required at testing overlap with the cognitive processes that occur at encoding. As noted above, the study of environmental context-dependent memory and the related concepts has gained empirical support from work that has used a range of different ambient and environmental contexts [42.1]. For example, context effects have been documented for background music [42.4–6], noise [42.7], and location [42.8, 9]. Still, it should be noted that positive retrieval effects following context reinstatement is not a rule [42.10]. A number of studies have failed to show beneficial context effects on retrieval performance [42.1]. Possible explanations for the lack of context effects will be highlighted below.

Olfactory stimuli can serve as effective contextual cues in the recollection or recognition of information encountered in the recent or distant past. Although available evidence is scarce, the overall pattern of findings suggests that reinstatement of olfactory contextual information that was present in a learning phase affects retrieval of the original information. Odor-based context effects have been observed for a variety of different

learning paradigms including recall, recognition, and relearning performance. Focusing on incidental verbal learning, *Schab* [42.11] presented a list of common adjectives with instructions to write down the opposite to each word with or without the smell of chocolate present. The participants were not aware of that their memory for the words they had written would be tested for the following day. Those individuals who were exposed to chocolate both at encoding and retrieval recalled more words than participants who were exposed at learning only, recall only, or did not receive any odor at all. To investigate whether odor valence could have influenced the context effect, a follow-up experiment using the smell of mothballs was performed. The results from this study mimicked the one obtained for chocolate, suggesting that odor pleasantness is of minor importance for olfactory context-dependent memory. In a similar vein, *Pointer* and *Bond* [42.12] measured prose recall performance using a context-dependent memory paradigm. Here, university students learned a prose passage in the presence of a visual or an olfactory stimulus. Specifically, the prose passage was presented on paper that was impregnated with a peppermint odor or on yellow paper. After a short distractor task, participants were asked to recall the text either with the original context reinstated or not reinstated. The results indicated a context-dependent effect such that prose recall was selectively higher following olfactory reinstatement whereas no memory benefits were observed for the visual congruent condition. *Smith* et al. [42.13] used a relearning-savings technique as a measure of memory and reported that relearning in the same odor environment improved memory performance reliably. Further, using a recognition paradigm, *Cann* and *Ross* [42.14] presented faces to a group of younger adults in the presence of an ambient odor. Two days later, an old-new recognition test was presented where either the same or a different ambient odor was present. The results showed that recognition performance was higher when the same odor was present at both encoding and test than when a different odor was used.

It is well established that there is a fast and strong connection between brain structures processing emotion, memory, and olfactory information [42.15, 16]. Given that the olfactory sense is an emotional system, it is of particular interest to investigate whether odors also are more efficient reminders of emotional information than other modality cues. *Herz* [42.17] examined whether an ambient odor is more effective as a retrieval cue of verbal information if experienced in an emotional (pre-exam state) than in a neutral state. The results indicated that odor cueing in emotional individuals resulted in higher word recall than a neutral state. She concluded that heightened emotion experienced during encoding can enhance the effectiveness of odors as cues to memory. It is well established that stress influences learning and memory processes. Stress induces an activation of the hypothalamic-pituitary-adrenal (HPA) axis leading to release of glucocorticoids that primarily act in the hippocampus, amygdala, and prefrontal regions; key structures for the emotional memory processes [42.18]. In this vein, *Toffolo* et al. [42.19] let participants watch an aversive film while being exposed to olfactory (blackcurrant), auditory (music), or visual information (colored light). Blackcurrant was chosen as olfactory information because of its supposedly neutral odor. One week later, their memories were evaluated following one of the triggers. The results showed that odor-evoked memories of the aversive events were more detailed, unpleasant, and arousing than memories evoked by the auditory cues. However, no difference was observed between the olfactory and the visual cues. Relatedly, a recent study investigated whether olfactory information can serve as an effective retrieval cue for memories of a stressful episode [42.20]. The stress condition involved a public speaking task in front of a committee and the control group was exposed to a well matching but not stressful situation. For both conditions, an odor (methyl benzoate) was present and a set of visual objects that were either bound and central to the stressor (committee; e.g., pencil, stop watch) or peripheral (e.g., dustbin) were arranged in the experiment room. Overall, central details were better remembered than peripheral and provision of a congruent odor cue in combination with stress led to enhanced memory performance relative to the non-stressed group. Exposure of a non-congruent odor (bornyl acetate) did not produce any performance difference between the stress and control group. Hence, retrieval of information experienced in a stressful event comprising a smell benefited from reinstatement of the olfactory source.

In contrast to studies manipulating olfactory contexts to explore effects on verbal and visual information, a recent study investigated whether episodic odor recognition memory might be affected by physical context [42.21]. Here, participants encoded odors and words after which recognition memory and word recall was assessed in the same or in a different location that differed in the color of the light (neutral versus red-colored). The results indicated no effects of context change on recognition memory for odors and words or on word recall. As noted, absent context effects on memory performance are not rare [42.22, 23]. In their meta-analysis, *Smith* and *Vela* [42.1] stated that context effects are less likely to occur in tasks that promote suppression of the subjects' immediate environmental surroundings. For instance, learning paradigms that

put heavy demands on attention or association formation (learning a set of new odors) will eventually reduce the role of context (see below) on memory recollection.

Few studies have investigated context-dependent memory with odors outside the laboratory. However, *Aggleton* and *Waskett* [42.24] asked a group of young adults to recall details of a visit to a museum that had occurred about seven years previously. At the museum seven distinctive smells related to a Viking's life (e.g., burnt wood, apples, earthy) had been dispersed. Recollection for the museum exhibits was more accurate when participants recalled memories in the presence of the same distinctive odors that were present in the museum during the original visit, as compared with novel odors (e.g., coffee, peppermint, rose) or no odors. In the experimental setting, the odors were presented in bottles and the participants could smell them as long as they wished. Hence, the museum odors appeared as effective retrieval cues for information that was acquired incidentally in a real-world episode. In contrast, a recent study found no evidence of odor-based context effects. *Roos af Hjelmsäter* et al. [42.25] investigated the influence of physical odor reinstatement at retrieval on memory in a group of children in the real world. Here, children experienced a magic show where a vanilla odor was present. One week and six months after the magic show, children were interviewed about their memory of the event. During the interview, half of the children were exposed to the vanilla odor at recollection. In contrast to previous work on adults, no odor reinstatement effects were observed. Specifically, children who did not re-experience the vanilla odor during the interview recalled the same amount of information and were as accurate as children who did re-experience the odor. A less accurate and reduced level of information was also recalled after six months compared to the performance observed one week after the event. In contradiction with the hypothesis, the reinstatement of the vanilla odor at the six-month follow up for half of the group neither affected the amount nor the accuracy of the recalled information.

It has been proposed that absent context reinstatement effects may relate to the status of the contextual cue in relation to other cues. According to the *outshining hypothesis* [42.1, 26], contextual information can cue memory when better cues are absent at retrieval. If there are other, stronger cues, as is often the case for recognition but not recall paradigms, the contextual cue can be completely *outshone*, implicating that the cue does not contribute to any more recollected information. Further, in their *overshadowing hypothesis*, *Smith* and *Vela* [42.1] argued that if contextual cues are suppressed at encoding, due to, for example, a high focus on the information to be remembered, context reinstatement effects are less likely to occur. Hence, the absent context effect in *Roos af Hjelmsäter* et al. [42.25] may be due to the fact that the interview questions offered enough cues to memory so that the vanilla odor cue was superfluous. Alternatively, the children may have found the magic show more exciting than the odor.

To summarize, the overall pattern of experimental well-controlled findings shows that olfactory cues may act as significant reminders of recent events. Also, some evidence indicates that olfactory cues may be especially apt to trigger emotionally laden information.

42.2 Autobiographical Odor Memory

As noted above, most of the studies targeting odor-based context-dependent memory have been performed in the laboratory with highly controlled encoding and retrieval conditions. In related work targeting autobiographical memory (AM), reinstatement of contextual information that was present in a learning episode is also the typical method used. AMs are personally experienced events that may be located in time and space [42.27]. Here, the most common cueing procedure is the Galton–Crovitz method, where individuals are given unimodal cues (e.g., words, pictures, or sounds) and asked to retrieve any AM for each cue [42.28]. With successful retrieval, a short description of the event is provided along with ratings of experiential factors (e.g., vividness of the evoked memory, emotionality) of the recollected event. Typically, when all cues have been presented, the participant is asked to go back to each evoked event and date it (e.g., to indicate the age-at-event). Hence, in contrast to laboratory-based context-dependent memory assessments there is a lack of control regarding the veridicality of the retrieved memories [42.29]. It is also unknown to what extent odors are vulnerable to the generation of false memories.

A central theme in AM research concerns the age distribution of memories across the life span. The age distribution of memories evoked by verbal and visual information follows a specific pattern involving three components: childhood amnesia, the bump, and recency [42.30]. Childhood amnesia refers to the dramatic reduction of memories reported from early childhood. In contrast, a substantially larger number of

memories are recalled from the ages of 10–30, a phenomenon that has been termed the *bump*. The third component, recency, reflects a generally good retention of events occurring in the last 10 years [42.31]. A common explanation for the bump is that the age span in question, 10–30, typically involves significant life experiences (identity formation), which in combination with a highly functional nervous system promote an elaborated and distinct encoding of events [42.32, 33]. However, in sharp contrast to what has been thoroughly established for our primary senses, AMs cued by smells originate from the first decade of life [42.34–36] and not from young adulthood. Hence, associative odor learning begins very early in life and may become accessible in old age through exposure to event-congruent olfactory information. *Arshamian* et al. [42.37] explored the neural correlates of olfactory-evoked AM in a group of young adults. When brain activity between evoked AMs from childhood (3–10 years) and young adulthood (11–20 years) were compared, differences were observed. Specifically, odor memories clustered in childhood were related to a stronger activity in the secondary olfactory cortex (i. e., orbitofrontal cortex), whereas odor memories originating from young adulthood were associated to a more pronounced activity in the left inferior frontal gyrus, a brain region that supports semantic memory processing. Tentatively, it may be hypothesized that early childhood olfactory representations may be more perceptually and imagery based, that eventually shift to a more semantically driven consolidation with increasing age.

Odor-evoked AMs also differ with regard to phenomenology. For instance, olfactory-evoked memories are described as more emotional than verbally and visually evoked memories ([42.38–40]; but [42.19, 36] for different outcomes). They are also often reported as more vivid [42.35] and accompanied by stronger feelings of being brought back in time to the occurrence of the events [42.36]. Further, they are thought of less often, which most likely relates to our difficulties in imagining and recreating olfactory information in our minds [42.41, 42]. The key features of olfactory-evoked AMs were recently summarized in the LOVER acronym – *l*imbic, *o*ld, *v*ivid, *e*motional, and *r*are [42.43].

The nature of olfactory consolidation and why our odor-based personal memories show a distinct clustering in childhood remains unclear. We are regularly exposed to odors (e.g., orange, coffee, gasoline) in our everyday lives, but when we experience a distinct AM from a smell, it appears that we recall the first association where the odor was encoded in memory, and not any of the subsequent events where the particular odor was processed. It has been proposed that the longevity of odor memory could be understood through a resistance to interference in the olfactory system. Retroactive interference is a phenomenon that occurs when new learned information impedes retrieval of previously learned information, and is a common cause for why visual and auditory information is often forgotten [42.44]. Little is known regarding interference in odor memory, although an early study reported that after a two-week retention interval, the first of two associations to an odor was better retained [42.45]. Similarly, when *Dempsey* and *Stevenson* [42.46] let individuals learn new word associations for the same set of odors, results showed that the new learning did not affect the retention of the previously learned material. In contrast to these findings, *Köster* et al. [42.47] reported evidence for retroactive interference in odor memory, but only among individuals who were unable to name the target odors. A more recent study indicated that an odor's pleasantness also influenced its persistence to interference, such that interference was lower for unpleasant odors [42.48]. Overall, available data indicate that odor associations are difficult to alter once they are acquired, although odor knowledge and the emotional valence of the olfactory information may act as moderators in the degree of interference resistance.

It is noteworthy that most of the knowledge on odor-evoked AM is based on unimodal cueing (i. e., cues pertaining to one modality). A unimodal retrieval procedure entails that sensory information from different modalities are treated as separate entities rather than as components of integrated multimodal representations. However, in everyday life, we experience a multimodal environment, and it is still unknown to what extent sensory modalities may differ in their relative efficiency to trigger recollection of autobiographical information [42.49]. In a recent study, *Willander* et al. [42.50] randomized participants to three unimodal (pictures, sounds, odors) and one multimodal condition (picture + sound + odor). To maximize ecological validity, the three unimodal conditions were presented simultaneously in the multimodal condition, whereas in the unimodal conditions cues were presented separately. The unimodal cues were selected so that they could be combined into a multimodal naturalistic context. For example, a context of an indoor swimming hall could be represented by a photo of a swimming hall, sounds of water splashes, and laughter, and the smell of chlorine. The unimodal cueing of AM replicated previous findings by showing a significant clustering of odor memories to the first decade of life, whereas memories following visual and auditory cueing peaked in young adulthood [42.51]. However, when individuals were presented with multimodal information, the age distribution clustered in young adulthood, sug-

gesting that multimodal retrieval is mostly driven by visual and auditory information and to a lesser extent by olfactory information. Similarly, by modeling the semantic content of the retrieved memories, *Karlsson* et al. [42.49] found that the multimodal content differed from odor-evoked content but not from visual content and marginally from auditory-evoked events. This outcome suggests a hierarchy among the sensory modalities that are represented in multimodal cue information and that the subordinate role played by the sense of smell may underlie the rare occurrence of odor-evoked AM. Also, the results outcome favors the notion of visual cue dominance in multimodal contexts.

Taken together, the overall pattern of findings indicates that odors can serve as significant reminders of both the recent and the distant past. Olfactory stimuli embedded in a learning context and later reinstated at retrieval often produce an increased recollection of the target information. Likewise, exposure of event-congruent olfactory information in adult or old age enables accessibility of distant personal events experienced in our first decade of life.

43. Infants and Children Making Sense of Scents

Benoist Schaal

This chapter summarizes research on the development of human olfactory skills to rely on different cues conveyed by odorants, such as odor quality, intensity, position in space, novelty/familiarity, and hedonic value. The sensory, neural, and psychological dimensions at the root of these early aptitudes remain poorly explored in humans, but one can safely affirm that any weak odor to which the infant has previously been nonadversely exposed will have a higher reinforcing value than any novel odor. Developmental differences in odor discrimination and appreciation are certainly causally multiple and may depend on general or olfaction-specific cognitive factors which can be traced back to prenatal or neonatal olfactory exposure effects. But some odors may also be unconditionally attractive or aversive from birth due to genetic or epigenetic factors.

Increased and systematic research efforts on olfactory development during the neonate, infancy, and childhood periods are important for several basic and applied reasons. First, they can illuminate general issues on the biological, psychological, ecological, and sociological mechanisms underlying human perception. Second, findings suggest that infantile experience with specific odors can canalize lifelong perceptual abilities. These long-term effects of early chemosensory experience relate to notions, such as sensitive periods, cerebral plasticity, and memory, and also to the early *programming* of food liking, addictive habits, and affiliative choices.

Research on human adults has repeatedly shown that odorants can mediate a wealth of informative cues that depend either on the stimulus (perceived quality and intensity, complexity, variety, etc.), on the perceiving individual (gender, physiological status, psychological age, motivational state), or on the perceiving subject's prior interactions with the stimulus [the rate of exposure to it (familiarity/novelty), expertise, hedonic valence (pleasantness/unpleasantness), or affordances conveyed by it (eatability, wearability as perfume, toxicity), position in space]. However, these properties are interdependent and their processing rests on the cognitive and semantic abilities of perceivers, which linguistic abilities facilitate some aspects of perception but may render other aspects suboptimal (memory). For example, the perception of odor quality is linked with the perception of odor intensity, odor-intensity detection favors the analysis of odor position in space, and hedonic valence relates with intensity and/or familiarity [43.1–4].

To which extent are these cues conveyed by odor percepts that are relevant in early development? How are meanings extracted from the innumerable percepts that odor objects or contexts produce, and how are they segregated into nested categories of known versus unknown, pleasant versus unpleasant, eatable versus noneatable, fruit versus meat, etc., to assist the developing brain to command adequate actions? In an attempt to synthetize *some* of the research conducted on the development of human olfaction, we will assess some of the above *dimensions* as they are processed by fetuses, newborns, infants, and children.

43.1 Nasal Chemosensation in the Fetus

It is a recently accepted fact that the functional onset of olfaction traces back to the fetal period. Long ago anatomical knowledge had shown that the chemosensitive structures of the nose are differentiated during early embryogenesis and reach stages that seem compatible with function before birth (Table 43.1; reviewed in [43.5, 6]). The three subsystems of human nasal chemoreception can then be clearly visualized at the periphery:

1. The main olfactory system shows adult-like ciliated neuroreceptors by gestational week 11.
2. The trigeminal system, which free nerve endings can be seen in the nasal mucosa by gestational week 4, responds to tactile stimulation by week 7.
3. Finally, the accessory olfactory system, composed at the periphery of the vomeronasal organ, initiates its development by gestational weeks 5–8 and reaches its maximum development at the central projection region (the accessory olfactory bulb) by week 20, but it later seems to decline or reorganize [43.7].

More recent evidence from neuroanatomy and brain imaging indicates that the peripheral structures of the main olfactory system and those of the trigeminal system are functionally connected with higher structures in the brain [43.8–11]. Despite recognized anatomical precocity at all levels of these chemosensory tracts, nasal chemoreception was long thought to be impossible due to nasal passages obstructed by mucus plugs or filled with fluid. The discovery by William P. Smotherman's group [43.12, 13] that young rats can retain odors to which they were merely exposed or conditioned in utero changed these views. Subsequent research proved the generality in vertebrates, including humans, that embryos and fetuses are capable of acute responsiveness to intra-amniotic infusions of odorants or of sensing and remembering odor from the prenatal environment [43.14, 15].

43.1.1 Amniotic Odorants

Amniotic fluid is the most obvious substrate mediating chemical stimulation to the fetus. Its composition changes along gestation due to the changing ratio in maternal/fetal contributions to its synthesis and due to its constant turnover due to fetal uptake and emission of fluid. The fraction of this fluid that contacts nasal chemosensory receptors is indeed constantly replaced due to frequent inhaling and swallowing activities of the fetus. Fetal nasal chemoreceptors may also be stimulated by odorants conveyed by the blood stream, as these may be passed from the capillaries that are adjacent to olfactory sensory neurons. But so far, this hematogenic route of stimulation has only been experimentally ascertained in adults.

The amniotic fluid composition changes along pregnancy and, in late stages, it depends strongly on fetal micturition and maternal intake of foods or any other odorous or sapid agents. The gestational increment in placental permeability may elevate the placental transfer rate of dietary odorants. It is well known by midwives that the amniotic fluid can be odorized by the food that mothers ingested shortly prior to delivery [43.16]. Odorants from a wide spectrum of foodstuffs were indeed shown to be transferred into the fetal compartment in either animal [43.17] or human pregnancies [43.18–20], including garlic, cumin, anise, carrot, mint, fenugreek, or curry. This cross-placental transfer of odor-active metabolites into the amniotic fluid can be fast. For example, in the ewe, odorants of cumin are detected in the fetal bladder 30 min after an intravenous injection of the maternal animal with cumin extract [43.21]. But much shorter placental transfer times were noted for compounds, such as nicotine or various drugs, and it is, thus, not excluded that some odorants can pass to the fetus quickly after the mother's ingestion, inhalation, or percutaneous absorption.

43.1.2 Fetal Chemoreception

From the third trimester of gestation, all chemosensory systems of the nose appear functionally ready: the nostrils are patent and nasal pathways convey flows of amniotic fluid-borne stimulations set in motion in the nasal passageways by the pseudorespiratory activity of the fetus. So far there is no direct, stimulus-response demonstration of fetal olfaction in the human species. However, studies in animal models indicate that such responses are clearly effective [43.15]. In the fetal rat and sheep, for example, intranasal infusions of odorants induce marked heart rate changes, while a control solution has no such effect. In addition, different odor qualities can elicit opposite autonomic responses indicating the discrimination of odor qualities [43.14, 22].

Indirect demonstrations of functioning olfaction in the human fetus are derived from tests on infants born prematurely. A sample of such infants whose age ranged from less than 28 up to 36 gestational weeks was screened for responses to the odor of mint [43.23]. The infants tested in the gestational age ranges of < 29, 29–32, and 32–36 weeks responded in 16% ($n = 6$), 73% ($n = 11$), and 100% ($n = 15$) of the cases, respectively. The 32–36 week group of premature infants

Table 43.1 Anatomical and functional findings on the antenatal development of chemoreceptive subsystems in the human nose

Gestational age (in post-ovulatory weeks)	Structural and functional events
3.5–5	Formation of the olfactory placodes
4–14	Trigeminal nerve endings in the respiratory mucosa, including olfactory mucosa
4.5–6	Formation of nasal grooves
7–8	Mesenchymal proliferation forming a miniature nose with two nasal cavities, with anterior nostrils and posterior choanas
4.5–7	Formation of the olfactory nerves
5–8	Formation of the vomeronasal grooves
5–13	Presence of sensory cells in the vomeronasal regions
5.5–7.5	Reactivity to touch on the surface of the nose (receptive fields innervated by the maxillary division of trigeminal nerve)
5–8	Terminal-vomeronasal pathways differentiated
6–6.5	Formation of the main olfactory bulbs (MOB)
6.5	Formation of the accessory olfactory bulbs (AOB)
7.5–9.5	Trigeminal nerve differentiated (ophthalmic and maxillary divisions)
8–10	Reactivity to touch on the main olfactory mucosa (receptive fields innervated by the ophthalmic division of trigeminal nerve)
8.5–18.5	Clearly localizable AOBs, but regressive or reorganizational changes occur during this period resulting in a rudimentary structure in older fetuses
11	Evidence of ciliated olfactory neuroreceptor cells
11–18.5	MOBs visualized by MRI. Clearly delineated mitral cell layer in the MOBs
25	Erratic and instable motor responses to mixed olfacto-trigeminal stimuli (in premature newborns aged 25–28 weeks)
29	Reproducible motor responses to mixed olfacto-trigeminal stimuli (in premature newborns aged 29–36 weeks)
30	Discriminative motor and brain (NIRS) response to purely olfactory stimuli (in premature newborns aged 29–36 weeks)
32–35	Olfactory marker protein (marker of functional maturity) in the olfactory neuroepithelium, the olfactory nerve, and glomerular layer within the MOBs

For details about references, see [43.5, 6]

did not differ in the rate of responding subjects from a group of term newborns. Thus, at least during the last gestational weeks, nasal chemoreception can sense an odorant, such as mint, which carries both olfactory and trigeminal properties. Subsequent tests on preterm infants showed that other odorants devoid of the trigeminal effect (nonanoic acid, anethole, vanillin) are efficient stimuli at high and low concentrations [43.24–26]. Thus, olfactory abilities of premature infants tested under aerial conditions right after birth may predict comparable abilities in fetuses of equivalent gestational age.

Another source of evidence for human fetal olfaction is derived from studies on responses of term-born neonates to stimuli which they could only have encountered in utero. For example, choice tests opposing the odors of amniotic fluid differing in familiarity (own versus *alien* fluids) and a control odorant (water) indicated that infants respond positively to any amniotic fluid. But when simultaneously exposed to the odors of their own amniotic fluid and of the amniotic fluid from another fetus, they preferred the most familiar stimulus [43.27, 28]. Thus, amniotic fluids from different individuals are endowed with idiosyncratic odor qualities that 3-day-old newborns can process selectively, indicating their perception in late pregnancy (or their very rapid encoding right after birth).

The nature of the prenatal odor cues that mediate such responsiveness in the neonate is uncertain. The idiosyncratic odor of amniotic fluid may be encoded either as a unique, momentarily dominant odor quality, as

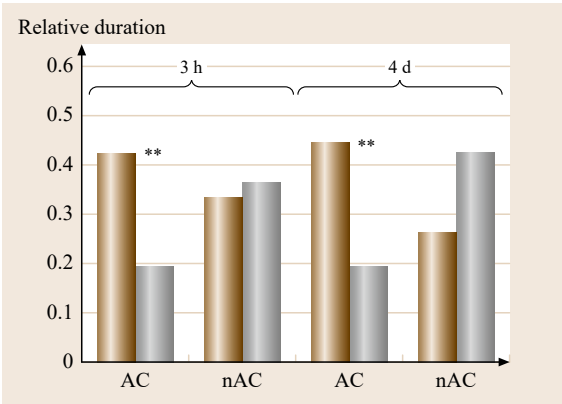

Fig. 43.1 Relative duration of head (nose) orientation of 3 hour-old (3h) and 4 day-old (4d) newborn infants exposed to a simultaneous choice between the odor of anethole (anise) (*yellow bars*) and the control stimulus (*blue bars*) as a function of their mother's consumption (AC) or not (nAC) of (nonalcoholic) foodstuffs containing anise during the last 10 days of pregnancy ($n = 12$/group; **: $p < 0.01$; after [43.29])

a complex chemosensory pattern giving rise to a unique odor blend, as a given intensity of chemosensation, or as several of these possibilities concurrently. These amniotic odor cues may be derived from various sources in maternal or fetal metabolisms, such as the mother's diet, inhaled aromatic compounds, or percutaneously transferred compounds, genetically determined odortypes, or fetal acute reaction to stress (often inducing fetal urine release). One confirmed effect is that odorants introduced into the fetal compartment through the pregnant mother's diet affect subsequent odor responses in newborns. For example, the frequency of maternal alcohol consumption during pregnancy is linked with the 1–2 day-old infants' increase in motor activation when alcohol odor is presented to them [43.30, 31]. Likewise, the maternal ingestion of anise-scented foodstuffs during the last 10 days of pregnancy induces clear acceptance responses to the diluted odor of anethole in the newborns tested 3 hours post-birth [43.29]. In contrast, 3 hour-old infants born to mothers who never consumed anise expressed the rejection of this odor. When retested later on postnatal day 4, the infants that were exposed to anise in utero displayed a clear preference for anethole in a choice test opposing it with a control stimulus, whereas nonanis-exposed infants behaved indiscriminately under these conditions (Fig. 43.1). A convergent postnatal effect was found when mothers ate garlic during gestation [43.32]. Thus, fetal experience with given odorants can foster selective odor responses in neonates, demonstrating that fetal olfactory encoding is active and connected to stable memories for at least several days post-birth (but see in the following, for much longer-lasting reminiscence of fetal odor experience).

In sum, the above results indicate that chemoreception does support the qualitative discrimination of odorants:

1. In fetuses tested in or ex utero (best established through animal research [43.14]).
2. In infants born prematurely up to 2 months before gestational term.
3. In term-born infants exposed to odorants they have experienced previously under prenatal conditions.

Research on animal models (rat, sheep) also demonstrates an early ability to differentiate odorants in terms of intensity and/or trigeminal potency [43.14, 22]. The mere fact of introducing an odorant into the amniotic fluid subsequently appears to increase its perceptual saliency, generally in the sense of reducing its aversive value or of increasing its reinforcing value. However, there are exceptions to this *familiarity-breeds-preference* rule. A recent investigation of human neonates' response to androstenone, an odorous steroid detected in the amniotic fluid, showed indeed that it elicits negative responses, even at levels within the range of concentrations measured in amnio [43.33]. Thus, pure, highly diluted androstenone odor appears to carry negative valence for newborns, as it does in most adults because of irritative effects and/or of intrinsic unpleasantness. In amniotic fluid, androstenone may not be perceived on its own, but as blended into a mixture which perceptual effect differs qualitatively from the percepts of its elementary compounds. Thus, the odor of pure compounds may sometimes be processed as qualitatively different from the odors carried in original mixtures, so that their separate perception can be received as reflecting novelty and, hence, tends to convey negative hedonic valence. Taken together, the above data reveal that nasal chemoreception may be already perceptually sophisticated in the fetus.

43.2 Newborn Infants

When empirical interest in infant olfaction begun in the mid-19th century, it was falsely (see Sect. 43.1) believed that this sense was not stimulated before the first breath and that the fetal brain was a Tabula rasa in terms of odor experience. Neonatal olfaction was then investigated, along with the other senses, in order to

trace the original state of the human mind and consciousness [43.34]. This research was initially driven by adultocentric questions using methods and nonecological stimuli aiming to establish when infants attain adult performance in terms of acuity and discrimination. But more recently, under the impetus of European ethology and American developmental psychobiology, infant olfaction was considered on its own value in fostering adaptive responses that are specific to the early challenges of normal development [43.5, 20, 35, 36]. Accordingly, the interests of initial psychophysical research based on odorants devoid of ecological validity to human newborns progressively shifted toward the use of biological odorants associated with the maternal organism or of artificial odorants previously experienced under rewarding conditions.

43.2.1 Quality

It is often claimed on the basis of differences in the responses elicited by distinct odorants delivered against water or other reference odorants that nasal chemoreception can differentiate odor qualities from minutes after birth. This detection ability was, in fact, a central issue of the very first investigations on olfaction in infants. Since the 1850s, more than 80 distinct odor qualities were delivered to newborns by numerous experimenters [43.34, 37–39], yielding unsure conclusions about the functional status of human olfaction after birth because of unsatisfactory control of stimuli. Often, these stimuli were indeed delivered undiluted, conveying pungency and irritation, and leading to the prevailing assumption that newborns mostly react to the trigeminal side effects of these stimuli.

This situation changed when experimental psychologists investigated neonatal perception using better controlled stimulations and better defined and more objective responses. Using such objective variables, *Engen* et al. [43.40] monitored body and leg movements (using a crib transformed into a kind of actimeter), as well as variations in respiratory rhythm, of 20 newborns aged 32–68 hours in two tests presenting odorants on Q-tips while they were sleeping. From the first test showing that acetic acid was more reactogenic than phenylethyl alcohol, they assumed stronger behavioral potency of trigeminal or unpleasant stimulants. In a second test, the same authors presented the odors of anise and asafetida, two weak stimulants of (adult) trigeminal sensors, which increased neonatal responses. But the latter stimulus was more potent than the former to activate the infants, confirming that an unpleasant odorant appears more potent than a pleasant one to elicit neonatal response. *Engen* et al. [43.40] showed that newborns could differentiate trigeminal from nontrigeminal stimulants by the fact that their responses to the former (acetic acid and phenylethyl alcohol) did not habituate at the same rate and magnitude than their responses to the latter. In a later study, *Self* et al. [43.41] tested infants in their first 3 postnatal days using complex odorants presumed to be free of trigeminal effects, such as anise, lavender, valerian, or asafetida extracts, and water as control. The recorded responses relied on respiratory rate variations and various motor reactions from the face and body. From day 1, two-thirds of infants reacted to most odorants, but also to the water stimulus (nearly 70% on days 1 and 2). Those infants' responses to the odorants increased over 3 days, and decreased to the control stimulus, showing rapid developmental changes in odor reactivity (see also [43.42], in terms of an increase in olfactory reactivity in newborns followed up longitudinally between days 1 and 4). Interestingly, in these studies, newborns could already be sorted into low, moderate, and high responders, but without further causal understanding of such early individual differences.

Surprised by the newborns' high response rate to the scentless water stimulus, *Self* et al. examined that case in two later studies. They first found that sleeping 3-day-old newborns failed to differentially respond to orthonasally presented odors of anise, asafetida, lavender, valerian, and water as the control (for example, in the light sleep state, the newborns ($n = 36$) responded as much to water (54%) than to valerian and anise odors (54% each), and more than to asafoetida odor (27%) [43.43]). In a second study, 3-day-old newborns were habituated to distilled water until they ceased any response on two consecutive trials; subsequently, they were dishabituated to the sensation triggered by water in being presented anise, lavender, valerian, or water stimuli. The rate of subjects responding to these stimuli was 30, 17, 22, and 25%, respectively [43.44], showing again that a scentless humid Q-tip was efficient to elicit responses, and even more efficient than certain odorants delivered at clearly suprathreshold values. This result raised the authors' doubts about the functionality of neonatal olfaction. Alternatively, it may be that some unnoticed parasite stimulus contingent with testing was ongoing (uncontrolled odor released by humidified cotton or from experimenters' hand; noise or air flux associated with experimenter's movements) or that newborn infants are chemosensitive to the hygrometry of inhaled air. In the first 3 days following birth, infants are indeed in a state of relative dehydration, as they can lose physiologically up to 10% of their body weight, and they may accordingly exhibit increased chemoreactivity to stimuli conveying humidity. The possibility of water sensing in newborns is open to further investigations, although recent data using near-

infrared spectroscopy (NIRS) did not find water-related activation of the orbitofrontal cortex in newborns aged 6 hours to 8 days [43.45]. But this may not exclude differential responses to the vapor of water at peripheral levels of the olfactory and/or trigeminal tracts.

In contrast to Self et al. mentioned above, *Engen* and *Lipsitt* [43.46] demonstrated the neonatal discrimination of odor qualities in applying the habituation paradigm to odor mixtures and their components. They first habituated respiratory disruption to a mixture of anise and asafetida, and then showed the recovery of the initial response to asafetida, but not to anise. As similarity assessments by adults indicated that the anise compound was dominant in this mixture, they inferred that newborns could not differentiate it from the whole odor of the mixture. They repeated then the same habituation procedure with a mixture (heptane-amyl acetate) the odor of which differed from that of its components. In this case, both components were efficient to dishabituate the infants' respiratory disruption, but the magnitude of the dishabituation of each compound was proportional to its dissimilarity with the mixture. Engen and Lipsitt concluded that 3 day-old newborns can not only discriminate odors, but they also can detect similarities between odors much like adults do. Later investigations focusing on odor *preferences* (see below) further confirmed the ability of human neonates to differentiate odor qualities. These studies generally indicated convergent odor-quality evaluation in infants and adults, although some studies reported notable differences [43.47].

Several psychophysiological investigations also support the notion that odor qualities are discriminated in the first postnatal days, and even before as attested by preterm infants' responses. Although some earlier studies indicated indiscriminative electro-encephalographic responses to the odors of coffee, citral, vanillin, and pyridine in less than 6 day-old infants [43.48], others found differential EEG responses in neonates for the odors of orange versus mother's milk [43.49]. In more recent studies using NIRS imaging, the odors of vanilla and of mother's colostrum were shown to elicit patterns of oxygenated hemoglobin (indicative of local vascular activation) over the left orbitofrontal region that were different in both magnitude and time-course [43.45]. A related NIRS study showed differences in oxygenated hemoglobin in the orbito-frontal cortex caused by the odors of the mother's milk and formula milk, the former causing on average a larger response than the latter [43.50].

43.2.2 Intensity

Research on the early capacity to process intensity cues from odor stimuli (i. e., differentiating stimuli triggering a weak odor sensation from stimuli triggering a strong odor sensation) has so far ended in inconsistent results. *Rovee* [43.51] thought it possible in 3-day-old infant because of the enhanced amplitude of their motor response with increasing concentration of aliphatic alcohols delivered orthonasally. The increasing mobilization of defensive responses (negative orientation, increased fussiness and crying) due to the increased recruitment of trigeminal chemoreceptors is probably responsible for this effect (see review in [43.52]). But in another study, increasing concentrations of vanilla, an odorant considered free of the trigeminal effect [43.53], or of butyric acid in low concentration levels, did not greatly affect latency, amplitude, or duration of variations in neonatal respiratory or facial responses [43.47]. Thus, one can only suggest here that much more research is needed on the infant's perception of odor intensity and on the interactions of the trigeminal and olfactory subsystems in explaining the early processing of chemical stimuli.

43.2.3 Position in Space

The ability of nasal chemoreception to sense spatial cues has long been discussed to occur through inter-narinal temporal differences of olfactory [43.54] or trigeminal stimulation [43.55]. *Kobal* et al. showed, for example, that odorants bearing trigeminal effects could be laterally localized, but that odorants devoid of trigeminal effects could not. Trigeminally mediated orientation was noted in newborns, which, on average, turned away from pungent ammonia vapor [43.56]. But such negative head-turns were easier to elicit when the ammonia odor was presented from the left side, that is, when the irritative/aversive nature of ammonia corresponds with the strong rightward bias of neonatal head-turns. Another study on odor-induced head turning of neonates used nontrigeminal odors chosen to be hedonically positive or negative (as determined a priori by adults). Positive vanilla and almond odors elicited significantly more *toward* than *away* head-turns when they were delivered to the left nostril, as compared to when they were delivered to the right nostril [43.57]. A similar trend was seen for the negative rotten egg or sour milk odors. Thus, the nature of the odor and the stimulated side of the nose (and brain) interact in determining an infant's response.

Under experimental conditions where the movement of the whole organism is considered, human adults were shown to be able to creep in following an odor-track left on the soil through bilateral sampling actions (active sniffing) along this track [43.58]. Infants' performance in localizing odor intensity gradients may be similarly facilitated by sampling movements, such as those involved by newborns' bilateral rooting move-

ments toward nipples. But it is not clear whether active sniffing co-occurs with neonatal rooting actions. As will be further described, such infants' abilities to turn their head (and hence nose) toward natural odorants has been largely used to examine their discriminative and hedonic performances.

43.2.4 Familiarity/Novelty

The detection of familiarity or novelty is increasingly thought to be the very first *dimension* involved in the perceptual sequence of olfactory analysis, even before the hedonic screening of the stimulus [43.59, 60]. The faculty of sensing familiarity/novelty in odor stimuli depends on the functionality of detection and of all steps of memory from encoding to retrieval. In adults, familiarity with an odor noticeably increases its detectability and discriminability [43.61], and similar processes may operate in early development. But almost no research has been conducted on this topic in early development.

However, familiarity effects have been reported from the neonatal period onward as infants orient or mouth more insistently toward stimuli encountered previously during reinforced interactions with the mother [43.62–64] or as mere contextual cues. Odorants can indeed be recorded as familiar by neonates when merely diffused into the sleep environment for several hours [43.65]. Even preterm infants can already encode and retain an odor introduced in their incubator's atmosphere [43.26] and olfactory familiarization can occur even earlier in the fetus (see earlier). The above-mentioned research with newborns shows indeed that they are more attracted to the odor of their familiar amniotic fluid than to the odor of unfamiliar amniotic fluid, both stimuli being attractive against water.

Odor familiarity effects are well illustrated by everyday or experimental situations that consist in deodorizing or in odorizing given contexts/objects, namely, in disrupting an infant's expectation of olfactory continuity. For example, when the natural odor of mother's breast is adulterated by adding a novel odorant, newborns refuse to latch on the strangely odorized nipple, often becoming fussy and crying, while they immediately accept the other, intact nipple [43.38, 66]. Likewise, 3 day-old neonates manifest less frequent appetitive oral movements after the odor of their mother's breast is abolished by covering it with a scentless alimentary plastic film [43.67]. Thus, newborns react to violations of odor cues habitually associated with the mother, and probably also with the wider environment (especially the sleep environment or food). But newborns are also highly plastic under these conditions as they rapidly learn novel odor cues introduced in their environment [43.64, 68], especially when these novel odors are brought together with a familiar odor background and with sensory inputs from the other senses [43.69].

Multiple ways of olfactory familiarization operate in newborns, including nonassociative processes, such as exposure repetition (habituation) or more or less prolonged mere exposure (which we here call *familiarization*), and associative processes, such as evaluative, classical, or operant conditioning, social learning or individual learning by trial and error. Such processes by which the brain acquires an odor as familiar or *known* may operate more easily under certain conditions (e.g., suckling at the breast) or at certain times in development, delimiting so-called sensitive periods. For example, an exposure period of only 30 min after birth is sufficient to shift an odorant from novelty to familiarity, but when this 30-min exposure is made 12 h after birth, this shift is not effective, and the odor does not become especially attractive [43.70]. This result, already known in neonates of other species [43.71], has been related to a special neurochemical stage associated with the normal birth process and which eases the encoding and/or retention of odors. Thus, studies of perception, perhaps especially in early development, should always be precisely situated in the background of an organism's prior or concurrent physiological or affective states.

43.2.5 Hedonic Valence

Numerous studies have sought to determine whether odorants have an inherent affective value, and thought resolving this issue by testing newborn infants because they were considered as devoid of any prior odor experience. In addition to this latter false assumption, the testing of newborns was, moreover, mostly run in comparison with adult performance, leading to assess neonatal response to odorants known to evoke feelings of pleasantness or unpleasantness in adults. From the first postnatal hours, odors considered to be pleasant for adults (e.g., orange, geranium) were indeed reported to evoke appetitive oral activation in infants, whereas odors considered as unpleasant for adults (e.g., asafetida) were reported to cause facial and oral expressions of disgust and head-turning away from the odor source [43.72]. *Canestrini* [43.39], and later, *Pratt* et al. [43.73], established that odorants (acetic acid, valerian, and clove) elicit facial, oral, and sucking responses in 1−11-day-old infants. *Stirnimann* [43.74] also established differential orofacial expressions emitted by newborns, including a premature infant born at 6 gestational months, in response to odorants that are pleasant or unpleasant to adults.

These initial studies were systematized by *Steiner* [43.75, 76] who exposed newborns less than 12 h of

age, before any postnatal experience of ingestion, to cotton buds soaked with odorants known to provoke pleasant (banana, vanilla, milky) or unpleasant (shrimp, rotten egg) sensations in adults. These stimuli were presented at high concentrations, via the orthonasal route, while the infants' facial reactions were photographed at their apex. The pictures of the infants' facial response were then evaluated by a panel of adult judges who ignored the nature of the presented odorant and had to guess whether it was pleasant, unpleasant, or indifferent. Generally, the odorants considered pleasant by adults induced facial responses read as expressing pleasure and acceptance (relaxed facial muscles, raising of mouth corners, licking and sucking), whilst unpleasant odorants elicited expressions read as reflecting dislike and disgust (lowering of mouth corners, lip and tongue protrusion, gaping) (Fig. 43.2). Steiner assumed that facial expressions that were morphologically similar in neonates and adults imply the same underlying affective functioning, and accordingly that some odors are more pleasant than others for newborns as they are for adults. He proposed that neonatal facial reactivity to odors depends on a hard-wired *hedonic monitor* that he located in the brainstem after having tested an infant lacking cerebral cortex and who responded to banana, fishy, and rotten egg odors by facial expressions similar to those of normal infants. He concluded the *olfacto-facial reflex* to be innate [43.76]. However, this study used high-intensity stimuli [43.76, p. 274] reporting that some of them were *offensive*, so that trigeminal percepts might in part account for the responses. In addition, a firm conclusion on the *inherent* hedonic value of odorants would have needed to ensure that such odorants were never experienced in utero. Finally, the term reflex means a high level of automaticity and inter- and intra-individual repeatability of the response, which are difficult to deduce from a response captured at only one time on a single-shot picture.

In an attempt to replicate and extend Steiner's study, *Soussignan* et al. [43.47] used highly diluted odorants intensities of which were matched (by adult noses) to the natural odor of several biological substrates infants encounter in their everyday life, such as amniotic fluid, human milk, and infant formula. The infant's facial-oral responses were videotaped in the same time as their respiratory rate was recorded. The 3 day-old newborns were exposed (in different states of arousal) to 12 stimuli, including 4 unfamiliar biological odorants (amniotic fluid, human milk, and two infant formulas), 4 dilutions of vanillin and of butyric acid matched by adults on the intensity of these biological odorants, and 4 odorless controls. The infants' videotaped oral–facial responses were then decoded in using a quantitative coding system devoid of any a priori hedonic construal,

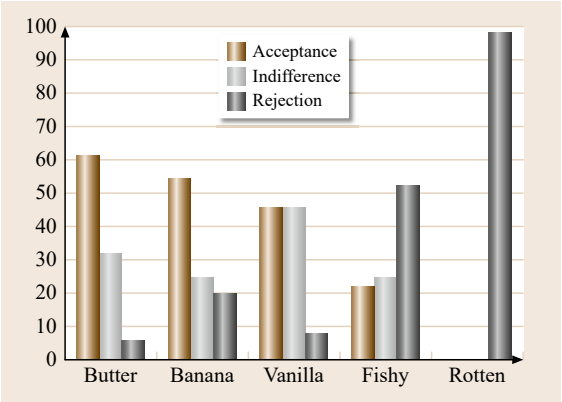

Fig. 43.2 Distribution (in %) of hedonic judgments (in terms of acceptance, indifference or rejection) by 6 adult judges based on photographs of the facial responses of infants ($n = 25$) exposed to 5 undiluted odor stimuli presented on Q-tips. The infants were aged less than 12 h at the moment of testing and had no postnatal ingestion experience (after [43.76])

Ekman and *Friesen*'s [43.77] Facial Action Coding System that itemizes the movements of each of the 44 facial muscles. The patterns of newborn response to the odor stimuli were then interpreted using prior data from newborns and infants exposed to stimuli of known affective valence (sometimes in other sensory modalities, such as taste, where stimulus-related hedonic responses were more clearly established). Under such conditions, neonatal facial actions to the different odorants were highly variable between individuals and could thus not be considered *automatic*, as predicted by Steiner's olfacto–facial reflex model. However, the infants' facial responses were differentiable (from that elicited by the control) as a function of the hedonic value of the odorant, but in an asymmetrical way. While unpleasant butyric acid odor elicited more negatively valenced responses than vanilla odor, the pleasant-to-adult odor of vanilla did not elicit more positive facial responses than butyric acid. Both odorants were very low and matched in subjective intensity (at least for adult noses); the negative response could only be due to the neonates' detection of qualitative and/or hedonic cues in the odors, thus partly confirming Steiner's view. Although clearly unpleasant to adults, unfamiliar infant formula odors did not elicit negative facial responses in newborns. Therefore, at least in these cases, the hedonic cues that newborns and adults detect in odors did not appear to overlap.

Odorants affect various responses controlled by the autonomic nervous system (i. e., heart and respiration rates, release of endocrine and exocrine secretions in the digestive tract). Conversely, the metabolic state

(hunger/satiety) influences hedonic responses to odors and this bottom-up regulation of sensory responsiveness operates already in newborns. When 3-day-old bottle-fed infants are exposed to the odor of their usual formula milk 1 h before a feed, they expectedly display positive facial responses. But, when this same test is run 1 h after a feed, when they are satiated, their faces express clearly negative responses [43.78]. This fluctuation in hedonic responsiveness to a food-related odor in infants resembles the phenomenon of negative alliesthesia described in adults. Thus, even in newborns, aged several days, a participant's motivational state is an important factor of variation to be considered in the testing of olfactory performance.

Neonatal hedonic processing is more strongly corroborated by studies involving an active choice response between two paired odorants. When infants simultaneously face two attractive odorants, they are able to express which one they prefer most in terms of head (nose) orientation and of mouthing movements toward one stimulus more than toward the other. *Macfarlane* [43.62] was the first to use such behavioral indices in a two-choice paradigm to infer olfactory discrimination and preference in neonates. He videotaped newborns lying supine while they were exposed to two odorous gauze pads hanging alongside each cheek. In a test in which the odor of their mother's breast was paired with the odor of another lactating mother's breast, 2 day-old newborns turned their nose equivalently to either stimulus, but 6 day-old newborns oriented significantly longer toward the mother's breast odor, suggesting that the individual odor of the maternal breast is learned as rewarding during the first week. Using a less demanding indicator of discrimination (viz., the mere reduction of motor activity of head and arms), another study showed, however, that such discrimination could be effective from 2 days of age [43.63]. Subsequent series of experiments made clear that lactating women emit from their breasts an odor factor that is attractive to newborns, even when mothers and newborns are unrelated [43.79].

In the same way, human milk conveys an odor factor that is attractive for any newborn [43.80], although breastfed infants prefer their mothers' milk odor to the odor of an unfamiliar mother's milk odor [43.81]. Thus, human milk conveys multiple odor cues that are either proper to the newborns' own mother, or common to all post-parturient, lactating mothers, and it appears that newborns can differentiate between them. The preferential responses elicited by odor compounds from the lactating breast or from human milk do not seem to depend on previous direct exposure to the breast or milk, as infants exclusively fed formula (based on cow milk) from birth also express them. However, the positive behavioural effects of these biological odors on newborns cannot be excluded to depend on their exposure to (at least partly) similar odor compounds in the amniotic fluid.

These results raise the issue of whether some odorant compounds of biological origin have a special significance in early development, for example, in favoring the unconditional expression of attraction or appetence or soothing in newborns [43.82, 83]. As suggested above, the odors of conspecific milk or that of the breast during lactation may emit such inherently reactogenic compounds. Potential sources that are common to milk and breast are the secretions of the areolar glands of Montgomery, which enlarge during lactation and can give off a latescent fluid made of milk and sebum [43.84, 85]. When this Montgomerian secretion is presented separately under the nose of asleep newborn infants, it acutely elicits mouthing responses and stimulates respiration, even when these infants were never exposed to breastfeeding before the test [43.86]. This Montgomerian secretion may play a special role in the infant's attraction, coordinated oral and respiratory actions to the lactating breast [43.87].

43.3 From Preverbal Infants to Prepubertal Children

Beyond the neonatal period extending during the first postnatal month, infants and children undergo biological, psychological, and social-ecological changes, the range and depth of which are obviously considerable. Their body and more so their brain grow by several orders of magnitude, their perception becomes increasingly multisensory and embodied in action (although they already are from the newborn period; cf. [43.69]), their eating modes and digestive processes change from exclusive lactivory to omnivory, their emotional style stabilizes in temperamental phenotypes, their cognition becomes increasingly dependent on language which expands their semantic and symbolic processing abilities, and from initial selective attachments to primary caregivers they integrate more and more complex social networks. All sensory systems continue their maturational agenda along that protracted childhood period which ends with puberty (note that the olfaction-related specificities of puberty is beyond the scope of this chapter). The perceptual performance of these sensory

systems is shaped by gene–brain–environment interactions in the experiential context provided by caregiving, education, and the local culture at large [43.88]. Olfaction certainly contributes to all of these facets of development, although we only have small snapshots on how it works at given times and in different situations. In the underlying context of developmental change and exposure to multiple and complex experience, infants' and children's abilities to extract different meanings from their odor world should, in principle, expand rapidly. But, as in neonates, the sensory impact and deferred consequences of odor experience are not linear across development and appear far from being homogeneous across individuals.

43.3.1 Quality

Several lines of evidence indicate that toddlers and children are fairly reactive and discriminative toward odor qualities. First, behavioral measures indicate that preverbal children are differentially affected by distinct odorants, whether these are presented as features of objects or of contexts. When odors are presented on age-adapted objects (fluffy toys, rattles, toothing rings, bottles) in age-adapted protocols, infants react to them more or less clearly. For example, 9 month-old infants given a succession of objects scented pleasantly, unpleasantly, or neutral (for adults) failed to yield conclusive data in terms of behavioral discrimination at first sight, although a systematic fine-grained coding of related videotapes indicated that the odor quality of the handled object was subtly differentiated [43.89], especially by girls who explored the odorized toy more than the matched scentless toy [43.90]. However, this gender difference in odor *attention* was not evident in a study investigating food odor discrimination (presented on bottles) in infants followed up between 8 and 22 months of age [43.91].

Persons themselves are ecological conveyors of scent qualities through their natural body odor or artificial odors (perfumes), or their mixtures, and infants and children clearly attend to these qualities. Natural odor signatures are indeed accurately recognized by infants and children, as shown by the recognition of a T-shirt worn by their mother (in 3.5–4.5 year-old children; [43.63]), by siblings (3–7 year-old children; [43.92]), or by an unrelated friend presented among distractor T-shirts from other same-age children (4–5 year-old children [43.93, 94], 9 year-old children [43.95]). Children are also able to accurately categorize gender from body odors (9 year-old children [43.95]). They can further identify the artificial perfume used by their mother: among six odor stimuli presented in small flasks, including four perfumes (among which the mother's one was surreptitiously introduced) and two controls, 5 year-old children were required to rate their preference for each stimulus, to tell which one they would use to self-scent, and lastly to identify their mother's perfume. Although under these conditions these children failed to express reliable preference for their mother's perfume, they nevertheless expressed greater wanting for it to use as a body scent, and accurately recognized their mother's perfume among the reference stimuli [43.96].

Toddlers and young children also react to the odor quality of contexts. For example, [43.97] exposed 1–2 year-old infants to the odors of lavender, amyl acetate, butyric acid, and dimethyl disulphide (as well as water as control) while they were absorbed playing a game at a table. Although more than 48% of the stimulations did not lead to any discernible facial reaction, the remaining responses indicated differential responsiveness to the odors (more details on Bloom's study in the following section on hedonic responses). In another series of interesting studies, 3 month-old newborns had to fulfill Carolyn Rovee-Collier's operant conditioning paradigm: they had to realize that their moving leg can activate a hanging mobile to which it was attached by a string. When this association between kicking and setting the mobile in movement was established in the presence of an odor, and when this odor was delivered to assess the retention of the contingence 1, 3, and 5 days later, the infants re-exposed to the same odor remembered well the conditioned response. In contrast, those in the control group exposed to no odor exhibited only partial recall, while those exposed to a novel odor displayed no signs of remembrance [43.98–100]. Thus, contextual odor qualities are detected and encoded by infants, and on subsequent occasions, they are differentially used to facilitate memory retrieval. The better recall of the conditioning when infants are re-exposed to the odor they faced during the acquisition phase may be due to the absence of emotional and/or attentional interference caused by olfactory contextual novelty [43.60].

Research studies assessing brain response to odorants in infants and children give another argument in favor of odor-quality perception. But, so far, this approach remains inconsistent and underlines the decisive nature of the stimulus and recording conditions to reveal brain responses. While some studies reported undifferentiated EEG responses to food odors in wake infants [43.101], others revealed differential brain activation to distinct odor qualities. For example, olfactory evoked response potentials (OERP) were recorded in 3.5–5 year-old children in response to odorants administered orthonasally with an air-dilution olfactometer. The late positive peak of OERP increased in latency

with age, a change which was provisionally interpreted as reflecting more in-depth perceptual and semantic processing in older, as compared to younger, children [43.102]. But much more psychophysiological research is needed with infants and children.

Some attempts were made to standardize psychophysical testing of olfaction in very young children. But these efforts were generally based on methods designed to test older children or adults, and they revealed to be globally inadequate before the age of 4–5 years [43.102]. The application of psychophysical approaches to children older than 4–5 years was more frequent, when language mastery is sufficient to fully understand procedures (An attempt was made to devise an olfaction test for 3-year-olds [43.103]). Several tests were used to quantitatively assess children's olfaction, firstly for clinical purposes. (e.g., University of Pennsylvania Smell Identification Test (UPSIT) [43.104]; Match to Sample Odor Identification test [43.105], Sniff Magnitude test [43.106], Biolfa test [43.107], San Diego Odor Identification test [43.108], Sydney Children's Hospital Odor Identification Test [43.109], Sniffin Sticks test [43.102], Lyon Clinical Olfactory Test [43.110], and NIH Toolbox Pediatric Odor Identification Test [43.103]). Each of these tests has its advantages and limitations (see [43.111], for more details).

In most children's studies, odor-quality perception is generally conceived in terms of an individual's knowledge of the accurate identity of an odor source. Related research used various tasks involving suprathreshold identification and naming in children [43.112–115]. In simple discriminative tasks where the verbal identity of the stimuli did not matter, 5–8 year-old children's performance nearly equalled adult performance (in similarity judgments [43.116]), or were slightly below it (oddity test [43.117]). But when the verbal recognition of odors was required, children were clearly lower as compared to adults, with the magnitude of this disadvantage depending on the task, children's age/gender and familiarity of odor stimuli. Some normative tests were implemented to characterize how odor identification develops over wide age spans. For example, the University of Pennsylvania Smell Identification Test (UPSIT), which is composed of 40 suprathreshold odorants each cued by 4 response alternatives as words or icons to lessen age/individual variations in mnesic proficiency, was applied cross-sectionally over the lifespan. The performance of smell identification followed an n-shaped curve, the average recognition score of 5–9 year-old children being equivalent to that of adults in the 7–8th decades, when olfactory abilities appeared to sharply decline (Fig. 43.3). But by the age of 10–19 years, children's UPSIT scores reached as high as adults' highest levels of performance [43.104]. Otherwise, across the 6–21 year age-range, females had better UPSIT recognition scores than males [43.104], suggesting female advantages in either sensitivity, cognitive abilities relevant to language or memory, or familiarization with odor qualities. Although such standardized approaches allow for the establishment of norms of olfactory performance that may have some validity in clinical settings, they certainly underestimate the abilities of olfaction in the everyday life conditions of infants and children (and even adults).

As younger children are clearly disadvantaged in the identification of odor qualities that require naming of a veridical source, some researchers investigated odor-quality recognition in terms of wider categories or affordances of source objects (e.g., eatability, wearability as perfume) [43.113, 118]. This strategy revealed children's much more elaborate odor cognition than was thought earlier, even under cultural conditions which do not favor training and teaching of olfaction (as in Western or Westernized general lifestyle). For example, when 8–14 year-old American children had to tell the identity of 17 odorants and whether they belong to edible/nonedible categories, they were expectedly lower than young adults by accurate naming of the odor source, but equalled them by the edibility criterion [43.113]. A related study asked French 5–6-year-olds to classify 12 odorants along criteria, such as origin (in-/outdoor, natural/artificial, vegetable/animal) and subjective function (edibility, wearability) [43.119]. While these children categorized the odorants accurately for edibility, and moderately ac-

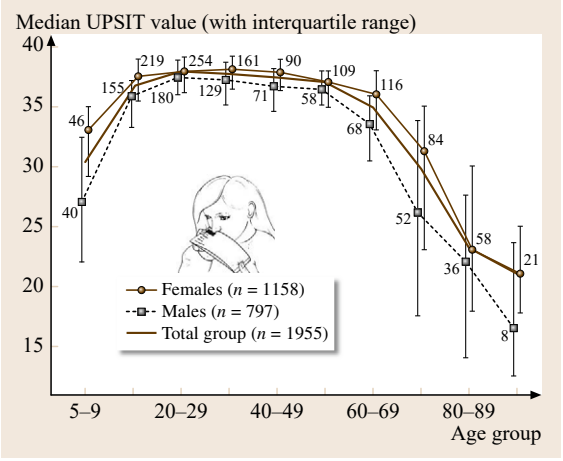

Fig. 43.3 Olfactory scores in a heterogeneous group of subjects submitted to the University of Pennsylvania Smell Identification Test (UPSIT) along the lifespan, presented by age in decades and by gender (after [43.104])

curately for wearability, they could not use the more abstract (or less useful) classificatory criteria. Another important study required 4–11 year-old French children and adults to rate 6 fruit and 6 flower odors in terms of typicality, familiarity, liking and edibility, and to classify them as members of either fruit or flower categories [43.118]. Results indicated a high classificatory agreement from age 5 years for some odorants in the series. But, interestingly, these children did not overlap in their semantic (fruit versus flower) and hedonic categorizations, suggesting that while processing odors, young children can separate semantic from emotional operations. From age 8 years, most odorants were systematically classified in the expected category, as well as assigned a name in the correct semantic category. Finally, when children were required to assign an odor one color (selected among several colors in a chart), they came out with nonrandom odor–color associations that reflected the underlying knowledge of the color of the odor source [43.120, 121]. Thus, long before the ability to accurately name odor sources is acquired, the ability to attribute self-centered functional or semantic meanings to odors prevails in infant and child cognition.

43.3.2 Intensity

As noted above for newborns, our understanding of children's perception of the subjective intensity of odors remains limited. We know that children are as accurate as adults to express quantitative judgements about odors. When participants aged 6–94 years had to evaluate the subjective intensity of 7 dilution steps of propanol in displaying simple finger actions (index–thumb distance) commensurate with their intensity estimates, psychophysical functions were stable at all ages [43.122]. Furthermore, in 7 year-old children as in adults, the intensity judgments correlate negatively with preference judgments for many odorants [43.1]. However, other sources suggest that children may diverge with adults in intensity judgements. For example, when 5–6 year-old French children were compared with a group of young adults for their rating of the subjective intensity of a set of 6 odorants, children rated the perceived intensity of the odors higher than the adults. This may be explained in terms of higher olfactory sensitivity in children or in age-related differences in the use of rating scales [43.123]. Thus, sensing of intensity cues in odors is an important part of olfactory development expectant of further investigation.

43.3.3 Familiarity/Novelty

Infants and children are clearly able to extract familiarity or novelty information from odor impressions, and such abilities are basic to their olfactory attention and attraction or avoidance responses. The so-called *Proust effect* is an extreme demonstration of this ability to acquire and retain over long periods of time – sometimes life-long – familiar odor imprints of given contexts, foods or persons, or of given internal states. For example, *Mennella* and *Beauchamp* [43.124] and *Delaunay-El Allam* et al. [43.125] assessed the behaviour of infants (aged 6–13 and 5–23 months, respectively) while they handled identical objects carrying different odors, one of which had been associated with the mother's breast. The infants expressed more positive facial and bodily reactions toward the objects that carried the odor to which they were familiarized earlier. Another study [43.126] introduced olfactory novelty to assess odor detection in 7–15 month-old infants; videotaped in consecutive sessions while playing the first time with scented or unscented versions of visually/tactually similar, attractive toys, these infants manipulated and mouthed the unfamiliarly scented toy less and for lower duration (than the nonscented toy), indicating relative withdrawal from olfactory novelty against all other highly attractive objects' features.

In a loose sense, the notion of familiarity means that one recognizes that something has been encountered previously, without knowing precisely what and when: *I already smelled that before*! A contrario, infants and children react to the irruption of olfactory novelty into familiar situations, a circumstance that has rarely been exploited in developmental studies of olfaction. For example, it is a common observation that soft objects (blankets, clothing, fluffy toys, etc.) are carried around and used as a *secure base* by a great proportion of toddlers in Western cultures at the age of 1.5–2 years when they move away from the mother [43.127, 128]. But the use of such *attachment objects* goes far beyond toddlerhood. A recent survey in 6–10 year-old French children showed that 96% of them owned or still own one such object, and at the moment of the study between 82% (at 6 years) and 52% (at 10 years) were still fond of them, and especially of the odor they themselves, or their mother, impose on it [43.129]. Among these children, 27% reported to react to the odor change of the attachment object after its washing, some in negative terms, others in positive terms. In infants and younger children, the odor constancy of such attachment objects may be more important than in older children, however, and their importance as a *transitional object* [43.130] has been recognized by many behaviour scientists or clinicians to manage disturbances caused by mother–infant separation [43.5, 128, 131–133]. Infants and children do also very easily pick up contextual olfactory side-effects of emotionally arousing events and implicitly label them in negative or positive terms

depending on the emotional nature of the situation (see in the following). When such odor cues are subsequently re-encountered, they can re-evoke the affective states in which they were acquired [43.134, 135].

In stricter acception, the notion of familiarity was often operationalized in terms of the ability to accurately name an object, person or context, or categories to which they may belong (see above). Numerous studies have sought to assess odor identification and naming in children of various ages [43.104, 110, 112, 113, 117, 119, 136–139]. Odor-identification tasks were variable across this set of studies, generally based on the free remembrance of an accurate name or, to make mnesic effort more easy, on a choice among 4 or 5 alternative words or images. Under these conditions, younger children had generally lower identification and denomination performances than older children and adults, who themselves have generally low abilities to name accurately the exact source object of an odor. Difference with adults tended to fade when children were semantically primed by a name/picture to the identity of the odor, indicating that early limitation in odor-recognition memory may depend on producing/remembering explicit verbal associations [43.60].

The general effect of age further interacts with gender, girls being generally better than boys in odor identification and naming. This age by gender interaction is often interpreted as resulting from superior verbal fluency or broader odor-related semantic knowledge in females, even from early ages on [43.110, 129]. But this apparent gender bias may originate in antecedent cultural factors related to the explicit or implicit education of sex roles. A questionnaire study prompting self-reports of active seeking of awareness and affective reactivity to odors of food, people, and the environment in French children aged 6–10 years revealed indeed that girls were more olfaction-oriented than boys, especially in everyday life domains related to the body, to odor cues in the general environment, and to the actual use of scents as means of self-comforting [43.129]. This gender bias was confirmed in Czech and Namibian children based on the same questionnaire approach [43.140].

43.3.4 Hedonic Valence

During infancy and childhood, odor-based preferences fluctuate until a time when they come to stabilize and more or less overlap with those of surrounding adult culture. Infants' and children's hedonic reactivity to odors and its alignment with adult preferences have been (and still are) a source of long-standing theoretical arguments on how olfactory preferences emerge and stabilize [43.1, 83, 141].

Early studies report young children's relative tolerance to odorants that are unanimously rejected by adults [43.141]. For example, based on behavioural or declarative responses of (hospitalized) Hungarian participants aged 1 month to 16 years to the offensive odors of oil of Chenopodium, trimethylamine or asafoetida, *Peto* [43.142] pinpointed age 5 years as a turning point in the hedonic appraisal of odors; before that age, negative responses occurred only in 3% of the subjects, whereas beyond that age 72% expressed dissatisfaction. A convergent pattern was noted among American children's responses sampled between 3 and 14 years age groups [43.143] with fruity (amyl acetate), sweaty, and fecal odorants: 3–4 year-old children were reported to find all stimuli equally likeable, whereas older children discerned fruity from sweaty and fecal odorants, and clearly rejected the latter. As Peto and Stein et al. were of psychoanalytic obedience, they interpreted their findings as perceptual correlates of the resolution of the anal phase. Using better controlled methods, *Engen* and *Katz* [43.144] later found that the liking response for the unpleasant odor of butyric acid drops sharply between ages 4 and 5–6 years, while the liking for pleasant odorants remains steady. In an effort to elucidate this apparent shift in the hedonic appraisal of odors around age 5 year, *Engen* [43.1] suggested the involvement of a nonspecific age-related response bias in a situation where an infant is questioned by an unfamiliar experimenter, rather than endorsing less parsimonious psychoanalytic explanations. He showed that, at 4 years of age, American children smelling an unpleasant odor answer more often *yes* than *no* to either questions *Tell me if it smells pretty/... ugly*? This tendency fell sharply after 5–6 years, when the answers *no* and *yes* prevailed to the former questions, respectively. Thus, a tendency to acquiesce to a dominant adult experimenter may best explain why younger children report positive responses to negative odorants. A similar conclusion was reached when facial responses to odors were recorded; the mere presence of an adult experimenter who presents odor stimuli to the children participants biases the communication of their hedonic feelings, and more so in girls than in boys ([43.145] see in the following).

Studies asking American or British children older than 6 years to rank series of odorants in terms of pleasantness resulted in responses roughly similar to those of adults [43.141, 146]. However, children ranked some odorants bearing fecal notes lower in unpleasantness than adults did [43.141], suggesting either that rating scales are used in different ways at different ages or that preferences assessed through relative judgments (rank ordering or pair comparisons) are more prone to age-related variations [43.147]. Finally, a study compared

6–12 year-old children (males only) from contrasted cultural backgrounds in Québec, Syria, and Indonesia for their ranking of 14 odorants on a hedonic scale ranging from very unpleasant to very pleasant [43.148]. Their responses were consensual across cultural groups for the most negative odors (although with between-group differences), while the most preferred ones were very variable between cultural groups, reflecting locally appreciated scents. Thus, verbal responses to pleasant and unpleasant odorants appear asymmetrical in infants and children, unpleasant stimuli generally eliciting more consensual responses than pleasant stimuli (a point already noted above in neonates).

Do measurements based exclusively on behavioural variables (devoid of any verbal declaration) provide more reliable developmental trends about odor preferences? In the study by *Bloom* [43.97] already mentioned above, pleasant (lavender, amyl acetate) and unpleasant odors (butyric acid, dimethyl disulphide) were discreetly sprayed in front of 1–2 year-old children who were playing at a table. Their facial reactions were rare under these conditions as most odor puffs were inefficient to cause a response detectable to hidden observers. But when analyses were restricted only to the stimuli that effectively elicited a facial response, pleasant odorants triggered more positive than negative facial actions, and conversely for unpleasant odorants. The hedonic ordering derived from these data in 1 and 2 year-old children was consistent with that predicted by adult ratings, that is, from best to least preferred, lavender > amyl acetate > butyric acid > dimethyl disulphide. When these same odorants were presented to 3, 4 and 5 year-old children, their facial reactions led to the same hedonic ordering of them. Thus, at least for these four odorants, orderly preferences begin to develop in 1 and 2 year-old children and appear stable through age 5 years [43.97]. But even earlier, by age 9 months, American infants act differentially on identical objects scented pleasantly or unpleasantly for adults (using methyl salicylate and butyric acid, respectively) or not at all (mineral oil) [43.89]. While some infants expressed reliable hedonic facial actions, others seemingly ignored the scented object. A similar test situation in 7 and 21 months-old infants came out with more positive (as indexed by object mouthing) and less negative responses for an odor encountered during breastfeeding in the first postnatal weeks [43.125]. Finally, a greater consensus about disliking odorants which are unpleasant to adults was also documented in infants tested longitudinally at 8, 12, and 22 months of age with 8 odorants (four pleasant, four unpleasant) presented in bottles [43.91]. At the three ages, and similarly for girls and boys, the duration of mouthing was shorter for unpleasantly-scented bottles compared to pleasantly-scented bottles. From this and earlier studies [43.19, 47, 76, 125, 149, 150], one may thus hypothesize more generally that negative responses of infants appear clearer in communicative value to adult observers than positive responses.

However, returning to the issue of whether behavioral responses are more reliable than declarative responses to assess odor preferences, one may highlight that both types of responses can be strongly biased by the social context of experiments. The accuracy of facial cues to reveal an infant's or child's hedonic experience can be mitigated by the social context, in terms of exaggeration or inhibition of facial responses [43.145]. For example, when the odor stimuli were presented by an unfamiliar adult, as compared to when they were self-administered by the children themselves, 5–12 year-old children responded more positively to pleasant odors and less negatively to unpleasant odors (and girls were even more sensitive to the social context than boys). A less time-consuming alternative to facial responses in vivo or *in video* was proposed through electromyography (EMG), the recording of electrical activity of facial muscles before any visually detectable response. EMG has been used successfully in 7 year-old children exposed to pleasant versus unpleasant odorants [43.151]. However, EMG responses are far from being totally immune of social constraints [43.152].

Another approach to assess the development of hedonic processes in olfaction has relied on the subject's ability to translate hedonic judgments from odors onto visual stimuli eliciting pronounced judgments of value. For example, *Strickland* et al. [43.153] required 3–5 year-old children to inhale hedonically contrasted odorants and make the dichotomous decision to place them on *smileys* displaying contrasted hedonic responses. In these conditions, the pleasant (to adults) benzaldehyde and the unpleasant dimethyl disulphide were more often assigned to the smiling and frowning smileys, respectively, but with 3-year-olds' attributions being more ambiguous than those of 4–5 year-old. In a further study, 3-year-olds and adults were asked to give nine odor bottles to one of two characters well-known to American children looking at the *Sesame Street* television show, Big Bird and Oskar the Grouch considered as desirable and undesirable figures, respectively [43.154]. Both age groups showed overall agreement in their preference pattern, although they differed in their hedonic assignments of some odorants to the positive or negative figure. These studies corroborate that young children at the fringe of language acquisition and schooling can consciously attend and distinguish odor stimuli in hedonic terms and that they can do so in relative consensus with adult judgments.

43.4 Conclusions and Prospects

The research summarized here clearly establishes the capacities of newborns, infants, and children to attend, detect, discriminate, and categorize olfactory stimuli along different cues. On top of this is their aptitude, through nonverbal or verbal means, to subdivide the olfactory environment into familiar/novel and attractive/repulsive stimuli. The sensory and psychological dimensions at the root of these early preferences remain poorly explored in humans, but one can safely affirm that any weak odor to which the infant has previously been nonadversely exposed will have a higher reinforcing value than any novel odor. This general principle has, however, its exceptions. For example, sensory specific satiety, alliesthesia, or boredom effects can induce the occasional aversion of familiar odor stimuli [43.78, 155, 156], or even initiate attraction toward olfactory novelty. Other exceptions are either odor stimuli (such as androstenone) which can remain paradoxically aversive to newborns despite they occurred in their developmental environment [43.33] or evolved chemoperceptual specializations that emerge uninfluenced (or minimally influenced) by experience (see discussion in [43.83]). But, globally, the principle of preference (or lower aversion) for familiar odors is massively verified, and, beyond the domain of preferences, children's odor discrimination, identification or categorization abilities also depend strongly on the width and depth of their prior experience with odors. Exposure creates indeed familiarity with some features of objects or contexts, possibly increasing the perceptual salience of such features and enhancing the ability to (consciously or nonconsciously) sense their alteration or to track them analytically.

Developmental differences in odor discrimination and appreciation are certainly causally multiple. They presumably involve olfacto-motor and sensory variations, such as changes in odor-sampling ability (active, volitional sniffing emerging after 2–3 years of age [43.5, 157]) or in odor sensitivity due to varying properties of olfactory structures and processes. Such developmental differences may depend on general or olfaction-specific cognitive factors. Expanding experience with odors leads not only to enhanced odor-related semantic stores without necessary link with verbal abilities, but also to increased ability to verbally label odor stimuli [43.123, 139, 158–160], longer spans of working memory [43.136], or better recognition memory [43.139, 161]. The latter psychological factors are also often evoked to explain early gender differences in olfaction. Performances in odor discrimination and preferences in older infants or in children can trace back to perinatal [43.19, 125, 162] and prenatal olfactory exposure effects [43.163], or to postnatal windows when the encoding of odors may be facilitated during sensitive periods [43.164]. All along infancy and childhood, sensory cues contingent with particular contexts can also be monitored and stably recorded. For example, 5–10 year-old children dislike alcohol-related odors more when raised in families where parents consume alcohol to cope with dysphoria, as compared to children whose parents usually drink for fun [43.165, 166]. Similarly, children whose mothers smoke to alleviate stress dislike the odor of tobacco smoke more than children whose mothers report smoking for other reasons [43.167]. The emotional tone of early exposure to food is another context of very efficient acquisition of persistent odor likes and dislikes [43.168]. In sum, children rely on odors to differentially *tag* objects, persons or contexts related to attachment figures or to (negatively or positively) challenging emotional situations.

However, some odors may be unconditionally (i. e., without the necessity of direct exposure) attractive or aversive right from birth. So far, this was best shown in several mammals (rabbit: [43.169]; mouse: [43.170]), but not yet in humans (although the odor of androstenone was reported to be aversive right from birth [43.33]). In the case of these mammals, it may be assumed that functional loops between given odor ligands, olfactory receptors, and responses are specified by evolved genetic and developmental mechanisms. Recently, an additional, nongenetic way of elaboration of selective olfactory responses in the absence of direct exposure has been suggested in the mouse [43.171] where male or female mice trained to fear the odor of acetophenone produce offspring that respond negatively to that odor up to two generations despite they were never directly exposed to it. This study highlights unexpected ways of structuration of (parts of) the olfactory system as a function of parental or grand-parental odor-related emotional experience. It complexifies the gestational role of the mother in shaping fetal olfaction in also involving both parents' pre-conceptional experience. Evidence for such transgenerational inheritance of sensory abilities and preferences acquired from ancestral experience will probably expand during the next decades [43.172].

Increased and systematic research efforts on olfactory development during the neonate, infancy, and childhood periods are important for several basic and applied reasons. First, such research can illuminate general issues on the biological, psychological, ecological, and sociological mechanisms underlying human perception: How does perception change according to chronological, biological and psychological ages?

Which biological, psychological, or social-cultural processes modulate fluctuations in odor-related preferences and cognition (conscious and unconscious attention, discrimination, categorization, memory)? Do certain early chemosensory skills result from specializations evolved to optimize adaptive responses to early transitions (birth, weaning, puberty)? Second, some rare findings suggest that infantile experience with specific odors can canalize lifelong perceptual abilities and subsequent attitudes [43.162, 163, 168, 173, 174]. These long-term effects of early chemosensory experience relate to notions, such as sensitive periods, cerebral plasticity and memory, and also to the early *programming* of food liking, addictive habits, and affiliative choices.

Overall, this chapter emphasizes the importance of a developmental approach in understanding the mechanisms and functions of human olfaction. It will be a rewarding challenge for future research programs to integrate longitudinally in single multidisciplinary studies the biological, psychological and environmental determinants of chemosensory performance during human ontogeny. But innovative ways to study olfactory function and functioning should be designed, and the proposal of *Köster*, *Møller* and *Mojet* to shift research methods toward more ecological paradigms should be taken into account to this aim [43.60, p. 7]:

> *... odors are ... not meant to be identified, but should ... be recognized as the ephemeral and unnoticed providers of feelings of safety and comfort, unless they are unknown and unexpected or out of place, we may need to devote more time to emotional effects of odor associations and to the investigation of incidentally learned situational odor memories instead of investigating how* odor objects *are constructed and changed by odor-odor and odor-taste learning under laboratory conditions with odors from bottles or olfactometers.*

Acknowledgments. This chapter is dedicated to the memory of Prof. Gerald Turkewitz who was a great source of intellectual inspiration. It was written in the context of funding from the Centre National de la Recherche Scientifique, the Agence Nationale pour la Recherche (Grants "Colostrum" and "Milkodor"), and the Regional Council of Burgundy (PARI grants) and European Community (FEDER grants).

44. Olfaction and Eating Behavior

Sanne Boesveldt

The olfactory sense plays an important role in food and flavor perception, and thus in our eating behavior. This chapter provides an overview of the current status of research in this field. It describes the two-way relation between subdomains of olfactory function (detection sensitivity, pleasantness; ortho- and retronasal odor exposure) and various aspects of eating behavior (appetite, food choice, intake), and discusses the difficulties in this type of research. Findings are summarized which show that metabolic status might affect odor perception and vice versa odor exposure can affect appetite. Determination and anticipation of the type of food by odor cues may tailor the preparation of the body to the specific macronutrient composition of the anticipated foods. However, this does not automatically lead to subsequent specific food intake. Eating behavior is a complex phenomenon that entails more than simple liking or wanting of foods induced by olfactory cues, rendering the need for more research to get a better grip at understanding the underlying and interacting mechanisms to be ultimately able to customize nutrition to individual needs.

What we perceive as flavor when we eat or drink something is a combination of different senses. We integrate sensations from mainly smell and taste, but also texture or mouthfeel and irritation in our nose and mouth. All this combines together to form a unique flavor percept of food or beverage. And since taste only consists of five primary qualities (sweet, salty, sour, bitter, and umami), the olfactory sense plays an important role in food and flavor perception, and thus in our eating behavior. Moreover, smell does not only play a part in the consummatory phase of eating (flavor perception by means of retronasal olfaction) but also orthonasal olfaction has been suggested to influence our anticipatory behavior, by modifying the selection of foods, meal size, and increasing appetite,even in the absence of physiological hunger. An everyday example can be the smell of food or fresh bread from a bakery that is enough to make you feel hungry and perhaps even walk into that bakery to buy some croissants. On the other hand, when you have a cold, and your nose is plugged, you do not taste your food so good anymore, and do not enjoy eating as much, because the olfactory component is missing. In addition, early exposure to volatile flavors in breast milk or formula can shape our food preferences in later life [44.1].

Although this evidently is a vital area of research, not much work has been done so far investigating (solely) the effect of odors on food anticipation and consumption. This chapter will provide an overview of the current status of research in this field.

Unlike taste, it is commonly accepted that the olfactory sense is difficult to categorize into primary qualities [44.2, 3]. From a functional point of view however, it is possible to distinguish between food-related and nonfood-related odors. Although what constitutes food or not is culturally determined [44.4] and can be subject to change, some behavioral studies suggest that humans respond differently to food versus nonfood odors. For example, food odors are identified more accurately than nonfood odors [44.5, 6]. Moreover, from an ecological perspective, the classification of odors into the

food or nonfood category can be of eminent importance. Reaction speed is typically considered a measure of biological relevance of a stimulus: threatening stimuli are thought to be prioritized by the brain to effect faster preparation for *fight or flight* action [44.7–9]. This fast response not only applies to negative stimuli [44.7–11], but also to other biologically relevant stimuli [44.12]. More importantly, human responses to food odors (fish and orange) were also found to be faster, and more accurate than to perceptually similar nonfood odors (dirty socks and rose), regardless of their pleasantness [44.13], suggesting food odors comprise a separate category of odors, that are of ecological importance for us.

44.1 Metabolic Influences on Odor Perception

Already from the early 20th century on, there has been a keen interest in trying to relate energy homeostasis to olfactory sensitivity. Indeed, it is an intuitively appealing concept to be more sensitive to odors, signaling food, when in an energy-deprived state. Nevertheless, this hypothesis still remains subject to some debate, despite many studies that have been done ever since the first scientific work in 1928 [44.14]. In that study, *Glaze* reported on two subjects (himself included) who fasted for 5−10 days, and demonstrated an increased sensitivity to various odors during that period, as measured with a Zwaardemaker olfactometer. An additional experiment, in which subjects were more sensitive to odors before a meal than after, replicated this finding [44.14]. In concurrence, some 20 years later, using a blast-injection technique, *Goetz* et al. supported such claims and showed that diurnal variations in olfactory sensitivity were associated with the ingestion of food: meals were stated to be preceded by a period of increasing and followed by one of decreasing olfactory acuity [44.15, 16]. However, at the same time, *Janowitz* et al. failed to find any effect of time of day or lunch on odor (recognition) thresholds using the same method [44.17]. Since then, more discrepant results have been reported in the literature, ranging from an increase in olfactory acuity when hungry [44.18–21], no change in sensitivity [44.22–27], to even an increase in acuity after lunch [44.28]. It is problematic to directly compare all those studies to each other, since they used different measurement techniques (an olfactometer, a blast-injection technique, a walk-in olfactorium, method of constant stimuli), different odors (both food and nonfood: coffee, citral, butanol, iso-amylacetate, etc.), different *fasting* durations (ranging from a few hours after lunch, to up to 3 months) and different types of meal (possibly initiating *sensory-specific satiety*, see later). After a *silent period*, research activity on this topic has sparked again in recent years. Although those studies used partly similar methods (the Sniffin' Sticks detection threshold for *n*-butanol, [44.29]), their results were contradictory as well [44.30–32], both with respect to the nonfood odor as to used food odors.

The inconsistency of results in the literature mentioned earlier may be considered as a reflection of the magnitude or relevance of the effect: Effects of hunger on olfactory sensitivity may be small, and perhaps less essential for the detection and subsequent consumption of foods or for the regulation of energy intake in humans.

Though the effect of hunger or satiety on olfactory sensitivity remains to be determined, the effect of food intake on odor pleasantness is more clear. *Rolls* and *Rolls* first coined the term *sensory-specific satiety* in 1981 [44.33], and described it as

> *the decrease in the pleasantness of a food after it has been eaten to satiety, and the smaller amount of that food, relative to other foods, that is subsequently eaten in a meal.*

This phenomenon is probably not driven by postingestive effects, but more by external factors such as the sensory properties of a food. As humans are omnivores, we seek variety in our meal. Typically, the sensory characteristics (taste, smell) of a meal reflect its' macronutrient content [44.34, 35]. As noted earlier, not only does the definition of sensory-specific satiety adhere to a change in food intake, but also to a change in the pleasantness of a food and its' sensory signals. For instance, after ad libitum consumption of banana, pleasantness ratings for banana as well as for banana smell decreased significantly, compared to the pleasantness of other odors; an equivalent result occurred for chicken [44.36]. Similarly, a decrease in the pleasantness for isoamyl-acetate (banana odor), but not *n*-butanol, was found after consumption of a breakfast that contained banana [44.30]. In addition, these effects of sensory-specific satiety can be revealed in brain areas related to reward processing: by means of functional magnetic resonance imaging (fMRI), activity in the orbitofrontal cortex has been shown to decrease in response to an odor of food that has been eaten to satiety [44.37].

The change in pleasantness that occurs in sensory-specific satiety should not be confused with alliesthesia,

that the pleasantness or rewarding value of a given stimulus is dependent on the subject's internal state [44.38], which is a more general effect. Several studies have indicated that the pleasantness of food odors declines (negative alliesthesia), whereas that of nonfood odors remains stable, after food intake [44.39–41]. Moreover, this effect was more pronounced for high-energy dense food odors; the decrease in appetite and liking when satiated was greater for fatty food odors than for nonfat food odors [44.40, 41].

In conclusion, metabolic status seems to mainly impact the hedonic evaluation of odors, and appears to be intake-specific, that is, sensory-specific satiety, and may thereby guide our eating behavior toward variation in nutrient intake. The effect of hunger on olfactory sensitivity may be small and of less importance for regulating energy balance. On the other hand, odor exposure can have a profound effect on shaping food preferences and modulating eating behavior, as will be described in the next section.

44.2 Anticipation Effects of Odor Exposure

Although metabolic status can influence olfactory perception, the reverse is also true. In the presence of food, olfactory (and visual) cues are perceived before any intake, and may trigger so-called cephalic phase responses in anticipation, to prepare the body for ingestion and digestion of foods (for a detailed review of the relation between olfaction and appetite hormones, see [44.42]).

Pleasantness or liking is considered to play a substantial role in food choice and preferences, and if odor exposure affects (food) pleasantness, it may be consequently expected that odors are also able to modulate appetite, food preferences, and eating behavior similarly. In their publication, *Rolls* and *Rolls* not only described sensory-specific satiety, but also (partial) olfactory sensory-specific satiety; that the pleasantness of an odor decreased after smelling that odor for a period of time (5 min, approximately as long as it would be in the mouth during a meal), in contrast to the pleasantness of other (food) odors. The intensity of the smelled odor did not change which implies that this is not an effect of peripheral sensory adaptation [44.36]. Although they did not assess craving or appetite for the specific foods under question, later studies did. Most research on food cue reactivity, however, has focused on visual cues of foods [44.44, 45], or a combination of olfactory and visual stimuli [44.46–48]. Food cue exposure appears to lead to an increase in appetite or craving for the cued food specifically [44.43–49], and this effect is similarly found in the few studies that solely looked at

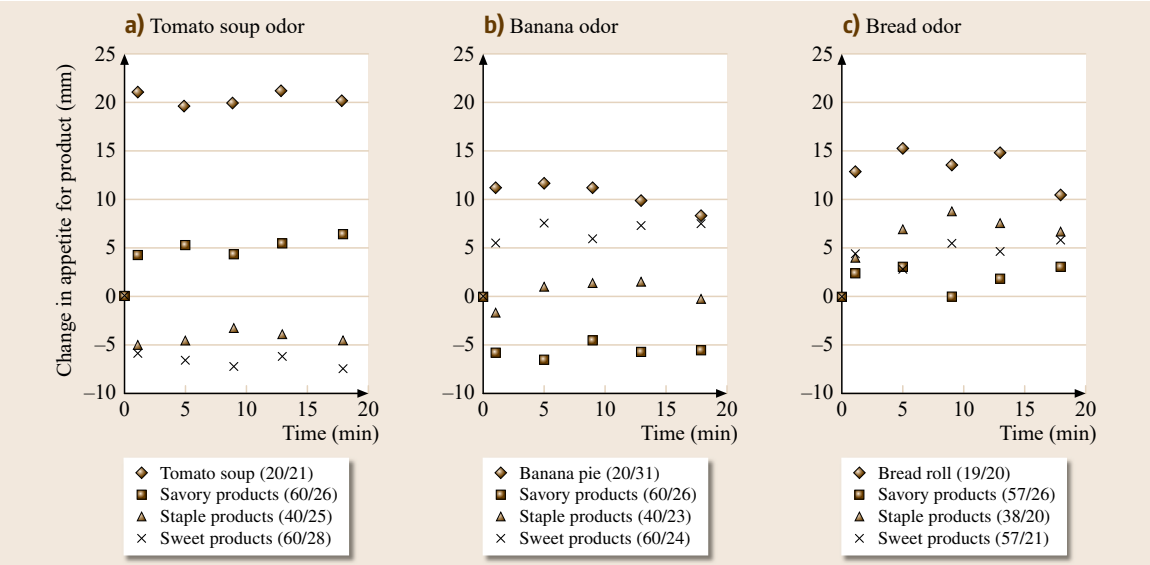

Fig. 44.1a–c Average change in appetite for odor-specific and category-specific foods, during exposure to **(a)** tomato soup odor, **(b)** banana odor, and **(c)** bread odor, measured on 100 mm VAS (visual analog scale). The numbers between the brackets represent (number of observations/average s.d.) (after [44.43])

odors [44.43, 49]. This phenomenon is termed sensory-specific appetite, the specific effect of cue/odor exposure on congruent appetite. In addition, this effect seems to *spill over* other, similar foods that share common super-ordinate characteristics, such as taste category. For instance, after exposure to banana odor, the specific appetite for banana not only increases most, but also stimulates appetite for other sweet products, such as a chocolate brownie. Moreover, exposure to food odors not only increases the appetite for congruent foods, but also decreases the appetite for incongruent foods (such as tomato soup, after banana exposure; Fig. 44.1) [44.43].

It is thus likely that food odors communicate information about the nutrient composition of their associated foods [44.35] that elicit cephalic phase responses to help the body prepare for the ingestion and digestion of that specific food/macronutrient, rendering it unfavorable to consume foods that are very different from the cued food [44.43]. Perhaps it is not so surprising then that the effect of odor exposure on general appetite or hunger is less clear. Some studies showed an increase in hunger during odor exposure [44.43, 46], whereas others found that participants experienced less appetite and felt more satiated after smelling a food odor [44.50].

Similarly, the effects of odor exposure on subsequent food choice and preference are inconsistent; some studies have shown that ambient exposure to fruity odors (citrus, pear) increased congruent food choice during a subsequent buffet [44.51, 52], while such an exposure effect was not found for other odors, or using a different method to measure food preference [44.51, 53, 54].

To summarize, odors have an anticipatory function for eating behavior, in that they are able to generate appetite, specific for the cued product, but do not consistently increase general appetite. The effect of odor exposure on pleasantness ratings can perhaps be attributed to different underlying mechanisms that include sensory stimulation and lead to a form of habituation. How food cues and appetite subsequently affect eating behavior, in terms of food choices and actual intake that both may rely on more cognitive reasoning, remains to be determined.

44.3 Consumption

The studies described so far have looked into the behavioral responses to food (odor) cues mainly using subjective ratings [44.36, 43, 48, 55]. Although subjective hunger and appetite ratings often predict food intake [44.56], they cannot be directly extrapolated; the type and amount of food people indicate that they want to eat is not necessarily equivalent to what they eventually consume [44.57–60]. Indeed, literature shows a distinction between prospective measures of eating (appetite ratings, preference) and actual food intake, resulting in conflicting findings of an increase [44.44, 46, 49, 61–64], decrease [44.46, 61, 65] or no effect [44.48, 54, 64, 66] of cue exposure on subsequent food intake. When limiting the focus specifically to odors as food cues, the results remain inconsistent. Studies by *Fedoroff* et al. [44.62], and more recently *Larsen* et al. [44.64], have shown an increase in intake of the cued food after odor exposure, but surprisingly only for restrained eaters or low-impulsive participants, respectively. On the other hand, *Coelho* et al. [44.65] found that exposure to chocolate-chip cookie odor led to a decreased food intake for restrained but not unrestrained eaters. Lastly, *Zoon* et al. [44.54] observed no difference in intake after exposure to odors signaling different types of food (high and low energy-dense) versus a non-food control odor, neither for total food intake, nor for specific foods congruent with the odor cue. These results indicate that eating behavior, actual consumption, is not an easy phenomenon to study, and that personal characteristics and individual traits can have a large impact. Other internal factors, such as hunger or satiety [44.54, 67–69], but also weight status [44.46, 54], attention or awareness of the odor cue [44.64] and similarity between the odor cue and the food to be consumed (general versus specific; [44.43, 49, 65] can affect the outcome of a study. Even though people report general hunger or craving for specific foods, this should not be taken as a direct indicator that they will also readily consume these foods. Actual food choice and intake is influenced by more factors than liking or wanting of foods; situational context, cognitive appraisals, or the focus on longer-term goals, such as health or weight concerns, can affect the current eating behavior despite the appetites induced by odor exposure.

Most of the studies stated earlier have focused on short-term effects of experimental interventions to study the influence of olfaction on eating behavior. If our sense of smell indeed plays an important role in the dietary choices we make in our daily lives, this may exert longer-term effects, such as changes in body weight or BMI (body mass index). Additionally, patients suffering from eating disorders (anorexia nervosa or bulimia) may display altered chemosensory function; alternatively, specific subgroups that experience

olfactory dysfunction (elderly, anosmics) may show differences in their food preferences and intake. It can be argued that a decline in olfactory function could either lead to a decrease in food intake (by negatively affecting food pleasure), or to an increase in food intake (in order to achieve a similar sensory experience). In the early days, *Thompson* et al. [44.70] reported no differences between normal weight and obese subjects in their intensity ratings or hedonic responses of olfactory stimuli, while later studies on (morbidly) obese adults and children have shown impaired olfactory functioning and a greater likelihood to be anosmic [44.71, 72]. *Boesveldt* et al. examined the correlation between olfactory function and BMI in a large national probability sample of older adults in United States, and found that a higher BMI was associated with higher scores on an odor identification task [44.6]. Yet this is only a cross-sectional study, from which it is difficult to draw conclusions regarding cause or consequence, or whether the effect is mediated by related underlying metabolic processes. Moreover, weight status or BMI is a crude, proximal measure of eating behavior, and is likely not directly affected by olfactory (dys)function. For example, several studies have indicated that a decreased sense of smell is related to a poor appetite, lower interest in food-related activities, or changes in food preferences and dietary patterns [44.73–78], but not necessarily to low energy intake or low BMI [44.73, 74, 76]. Moreover, research has shown no relation between (loss of) olfactory function and liking of (flavor enhanced) foods [44.79, 80] or degree of sensory-specific satiety, either measured by changes in pleasantness [44.81] or intake [44.36], indicating that changes in olfactory performance can, but do not automatically, lead to changes in dietary patterns. It is therefore suggested that when the sense of smell is absent, the pleasantness of food stimuli is judged on the basis of the remaining available sensory attributes (visual cues or taste), but possibly also by the help of mental images of pleasantness based on previously acquired product concepts, in order to compensate for the olfactory losses [44.80, 82, 83].

Patients suffering from anorexia nervosa or bulimia demonstrate disturbed eating behavior, however, it is unclear whether this can be related to alterations in their chemosensory perception, that is, their sense of smell. Several studies showed that anorectic patients had lower olfactory test scores than their healthy normal-weight counterparts, but this pattern was not consistent over different olfactory function subtests. *Schreder* et al. [44.84], *Roessner* et al. [44.85], and *Dazzi* et al. [44.86] found reduced scores on olfactory discrimination, while *Rapps* et al. [44.87], and *Schreder* et al. [44.84] found lower scores for odor identification, and *Roessner* et al. [44.85] showed a decrease in olfactory sensitivity in anorectic patients. Fewer studies have been done on bulimic patients [44.86, 88], however those also present no clear relation with olfactory functioning. Heterogeneity of patients (age, weight), and small sample sizes seem to play a role in the divergent results of all these studies. More importantly though, it is likely that, as in normal healthy subjects, the influence of olfaction on eating behavior is not based on (changes in) olfactory acuity or perception, but via the hedonic evaluation of (food) odor stimuli, leading to a difference in reward responses that may subsequently alter eating behavior.

44.4 Effect of Retronasal Odors on Eating Behavior

As discussed earlier, the olfactory sense has an important role in our eating behavior, by shaping our appetite and preferences. However, smell does not only contribute to the anticipatory phase of eating, but retronasal olfaction is considered a fundamental part of flavor perception during the consumption of foods. By chewing, oral breakdown of foods, and swallowing, volatile molecules are released into the oral cavity, which travel through the nasopharynx during exhalation and subsequently stimulate receptors on the olfactory epithelium in the nose [44.89]. Identical to orthonasal olfaction, the signals are then carried via cranial nerve I to the olfactory bulb, and from there to the piriform cortex and orbitofrontal cortex, among other structures [44.90]. Unlike orthonasal olfaction that is used to identify objects in the external world, retronasal odors refer to objects inside the body, and are thus principally related to foods [44.91, 92].

Considerably fewer studies have been done in the field of retronasal smell and eating behavior than orthonasally, most likely due to the difficult nature of stimulus presentation. Typically, the extent of retronasal aroma release during consumption appears to be a physiological feature that characterizes a person as well as depends on the physical structure of a food [44.93]. For odors to be administered retronasally in an experimental setting, a tube has to be inserted via the nose to the back of the mouth to deliver the aroma onto the nasopharynx [44.94] (Fig. 44.2).

Fig. 44.2 Image (magnetic resonance imaging [MRI]) of subject's head after tubes for ortho- and retronasal stimulus presentation have been inserted into the nasal cavity. The distal end of the two tubes lies in the epipharynx (*white arrowhead*), the end of the other tubing lies in the antrum of the nasal cavity (*thin white arrow*); for this MRI scan, the tubes have been filled with a contrast agent (after [44.94])

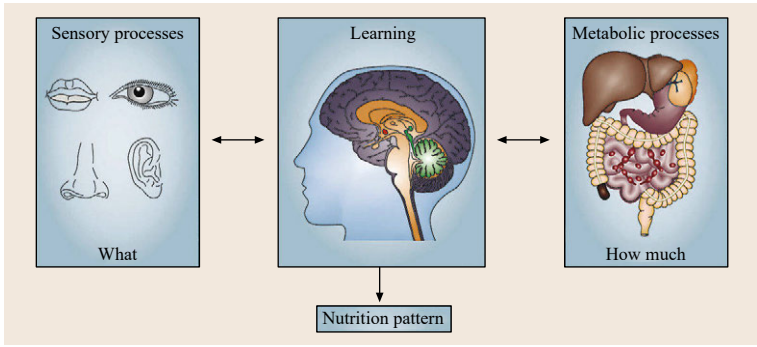

Fig. 44.3 Factors that affect eating behavior (after [44.95])

It was found that presentation of a retronasal odor stimulus increased the intensities of thickness and creaminess of a liquid (milk) in the mouth [44.96]. From this it can be inferred that enhancing retronasal odor stimulation may be used to induce satiety during consumption and ultimately may contribute to a decrease in food intake. Indeed, *Ruijschop* et al. [44.97] demonstrated that participants felt significantly more satiated and had less desire to eat congruent (sweet) foods if they were stimulated with a longer retronasal odor profile during (sweet) milk consumption. However, in that study there was no effect of retronasal odor exposure on the subsequent milk intake, while a later study did establish a 9% lower food intake when participants were exposed to a *high* retronasal condition versus other conditions with lower concentrations or shorter exposure duration [44.98]. These results indicate that changing the retronasal aroma released by concentration and exposure time may affect perceived satiety and food intake, but perhaps not in all situations or for all participants. As mentioned earlier, subjects differ in the extent of retronasal aroma due to differences in oral processing, salivation, or eating rate [44.99, 100], which may account for the differences in effect on satiety and intake. For example, the microbiota composition of saliva composition can differ between normal weight and obese subjects, and may influence the retronasal release of volatiles in a food [44.100], altering its' perception, which can subsequently lead to a change in eating behavior. Longer sensory exposure times of foods in the mouth are consistently associated with lower food intakes; sensory signals during eating are linked to the metabolic consequences and need time to inform the brain and the gastrointestinal tract about the inflow of nutrients [44.95, 101] (Fig. 44.3).

Eating rate is positively associated with ad libitum intake; liquid foods are typically ingested faster than solid foods [44.102], and also the duration of retronasal aroma release differs between various liquid and solid foods [44.97]. Indeed, higher retronasal aroma intensities resulted in significantly smaller bite sizes

in a controlled lab environment [44.103]. Accordingly, longer or higher retronasal aroma release may help the human body to associate the sensory signals from food with their metabolic consequences and may therefore lead to lower energy consumption and ultimately to weight loss. Nevertheless, *Zijlstra* et al. [44.104] were not able to confirm this idea in their study and did not see clear differences in retronasal aroma release, ad libitum intake or eating rate between normal weight and overweight subjects, nor was there a correlation between eating behavior and the extent of retronasal aroma release.

Similar to orthonasal odor exposure, the influence of retronasal aromas seems to be mainly in the subjective domain; where orthonasal odors affect the hedonic evaluation and specific appetite for foods, but remain limited in their influence regarding actual food intake, retronasal exposure is likewise able to modify the subjective feelings of satiety but does not automatically lead to a decrease in consumption.

44.5 Methodological Considerations

It is clear from the earlier given information, that combining olfaction and eating behavior is an exciting area of research, in which much work remains to be done in order to understand the intricate relationship between them. Though it is intuitively appealing that odors can influence appetite and food intake, and vice versa, that metabolic status can influence olfactory perception, the results of experimental studies are sometimes inconsistent. Understandably, methodological factors may be in part causative of this; a few of which that are common in olfactory or eating behavior research will be discussed next.

Since odors are considered difficult to categorize into primary qualities, its main perceptual dimension is valence or pleasantness ([44.105, 106]; for more information on odor valence perception, see Chap. 39). Not only the pleasantness, but also the concentration of an odor can thus play a role in the responses it elicits. Most odors that are used in studies on eating behavior are food related or edible, and are typically well-liked [44.5, 6], thereby limiting the possible role of pleasantness. Nonetheless, palatability of odor cues may depend on the food category it represents, sweet/savory, or high/low energy dense foods, and appetite and liking for fatty food odors appears to be more prone to changes in internal state than nonfat food odors [44.40, 41].

Additionally, the sensation and perception of an odor are partly dependent on sniffing behavior [44.107]. Active sniffing may lead to a higher concentration of volatile molecules in the nose and greater awareness of the odor, and hence may affect the (magnitude of) results of a study. However, *Ramaekers* et al. performed studies with similar setup except for the way of odor presentation, active sniffing or passive ambient exposure, and showed that this did not affect the development of sensory-specific appetite [44.43]. Also, adaptation to the odor may occur when exposure is prolonged over time, leading to a decrease in perceived intensity (see for instance review by [44.108]). Nevertheless, in separate studies, duration of odor exposure did not affect appetite ratings or subsequent food intake [44.43, 64]. Furthermore, it has been suggested that subconscious or subthreshold odor exposure may lead to stronger behavioral influences than when we are consciously aware of them (for review, see [44.109, 110]), perhaps due to the direct link with memories and emotion centers in the brain [44.90].

Odors appear to have an anticipatory function for eating behavior; in that they are able to generate appetite, specific for the cued product, but do not consistently increase general appetite or intake. This difference may be due to the distinction between subjective, prospective measures of eating (appetite ratings, preference), and actual consumption. The inconsistency in the results on general appetite and food intake most likely reflect small effect sizes and reveal the complexity of food cue reactivity. Moreover, different methods of measuring appetite or consumption may also have an effect on the outcome. The visual analog scale (VAS) is a commonly used approach that can serve multiple purposes, ratings on liking for the odor, liking for the product, general appetite, hunger, prospective consumption, desire to eat, appetite for a specific product, etc., [44.43, 46, 50, 111]. It is sometimes difficult for a participant to distinguish between the various questions, that relate to different underlying constructs (liking and pleasantness versus wanting and appetite, [44.112]), and it is clear that this may yield different results or interpretations. One should be equally careful when applying a food preference task, in which participants have to choose between two presented food products and indicate which one they would like to eat most at that particular moment; the preferred choice for one product may implicitly be a rejection of the other product.

Lastly, when studying food cue reactivity it is important to take into account personal characteristics such as restrained eating, impulsivity, or weight sta-

tus and internal state [44.46, 62, 64, 67, 68, 113], which may affect the way or magnitude in which people respond to food odors. Moreover, investigating the (subtle) impact of the olfactory system on eating behavior requires a tight control over the experimental conditions, which is much easier to achieve in animal studies, and may explain the sometimes small or conflicting findings in human studies.

44.6 Conclusion

Though it is clear that the olfactory sense is vital for food and flavor perception, and anecdotal evidence and personal experience suggests that odor exposure plays an important role for the anticipation and consumption of foods, experimental data is limited and sometimes inconsistent. Metabolic status seems to mainly impact the hedonic evaluation of odors, not sensitivity, and appears to be intake-specific, that is, sensory-specific satiety, and may thereby guide our eating behavior toward variation in nutrient intake. The reverse is also true, odors have an anticipatory function for eating behavior, in that they are able to generate appetite, specific for the cued product. How food cues and appetite affect subsequent eating behavior, actual consumption, remains to be determined and is likely influenced by more factors than the liking or wanting of foods that is induced by odor exposure. However, smell does not only contribute to the anticipatory phase of eating, but retronasal olfaction is also considered a fundamental part of flavor perception during the consumption of foods. Similar to orthonasal odor exposure, the influence of retronasal aromas seems to be mainly in the subjective domain, and is able to modify the subjective feelings of satiety but does not automatically lead to a decrease in consumption.

The relation between olfaction and eating behavior is complex and entails more than plain liking or wanting of food induced by odor cues, rendering the need for more research to get a better grip at understanding the underlying and interacting mechanisms to be ultimately able to guide people toward better dietary patterns.

45. Olfaction and Sleep

Ofer Perl, Anat Arzi, Ilana S. Hairston, Noam Sobel

As far as I know, the only reason we need to sleep that is really, really solid is because we get sleepy. Coming from William C. Dement, one of the pioneers of contemporary sleep research, this statement depicts sleep as a *neurobiological black box*. One of the best ways to probe such black boxes is through exceptions, and olfaction stands out as such an exceptional sensory system during sleep. Specifically, whereas sensory stimuli presented during sleep typically wake, this is not the case with odors. In fact, odors may promote sleep. In turn, they remain processed by the sleeping brain, and provide a telling window onto sleeping brain capabilities. Here, we briefly review the foundations of sleep, and then extensively detail the literature on olfaction in sleep, concentrating on studies in humans. We speculate that the unique interplay of sleep and smell whereby odors are processed in sleep without causing wake reflects unique aspects of olfactory neurophysiology, particularly the direct projections from periphery to cortex without a thalamic relay. Finally, although the mechanisms allowing odor processing during sleep without arousal remain unclear, this phenomenon lends itself to using olfaction as a window onto sleep mentation. This approach has uncovered several aspects of learning and memory during sleep. We review these efforts, and conclude with detailing their potential application in the treatment of disease.

45.1 Sleep: Architecture and Measurement

To the observer, sleep may seem a more or less uniform state of inactivity. This is interrupted by phases where the eyes apparently rapidly shift from side to side under the closed eyelids, a phase of sleep therefore referred to as rapid eye movement (REM) sleep. Only by harnessing the power of physiological signal measur-

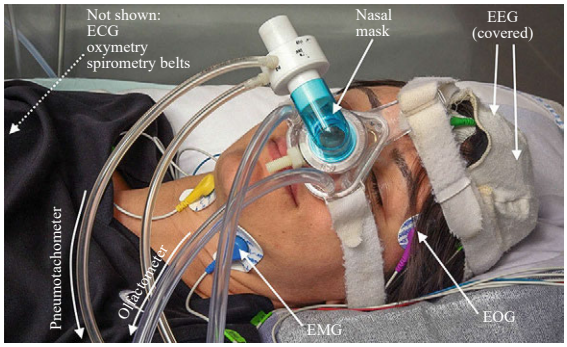

Fig. 45.1 Olfaction polysomnography setup (photo by Michal Cooper) ◄

ing techniques, however, it becomes apparent that sleep contains clearly distinguishable states that alternate in a cyclic manner throughout the night. These states that are not REM (NREM) sleep are collectively referred to as NREM. The physiological signals measured during sleep are chiefly electroencephalography (EEG), the electrooculogram (EOG), the electromyogram (EMG), and measures of posture and respiration, collectively referred to as polysomnography (Fig. 45.1). The core

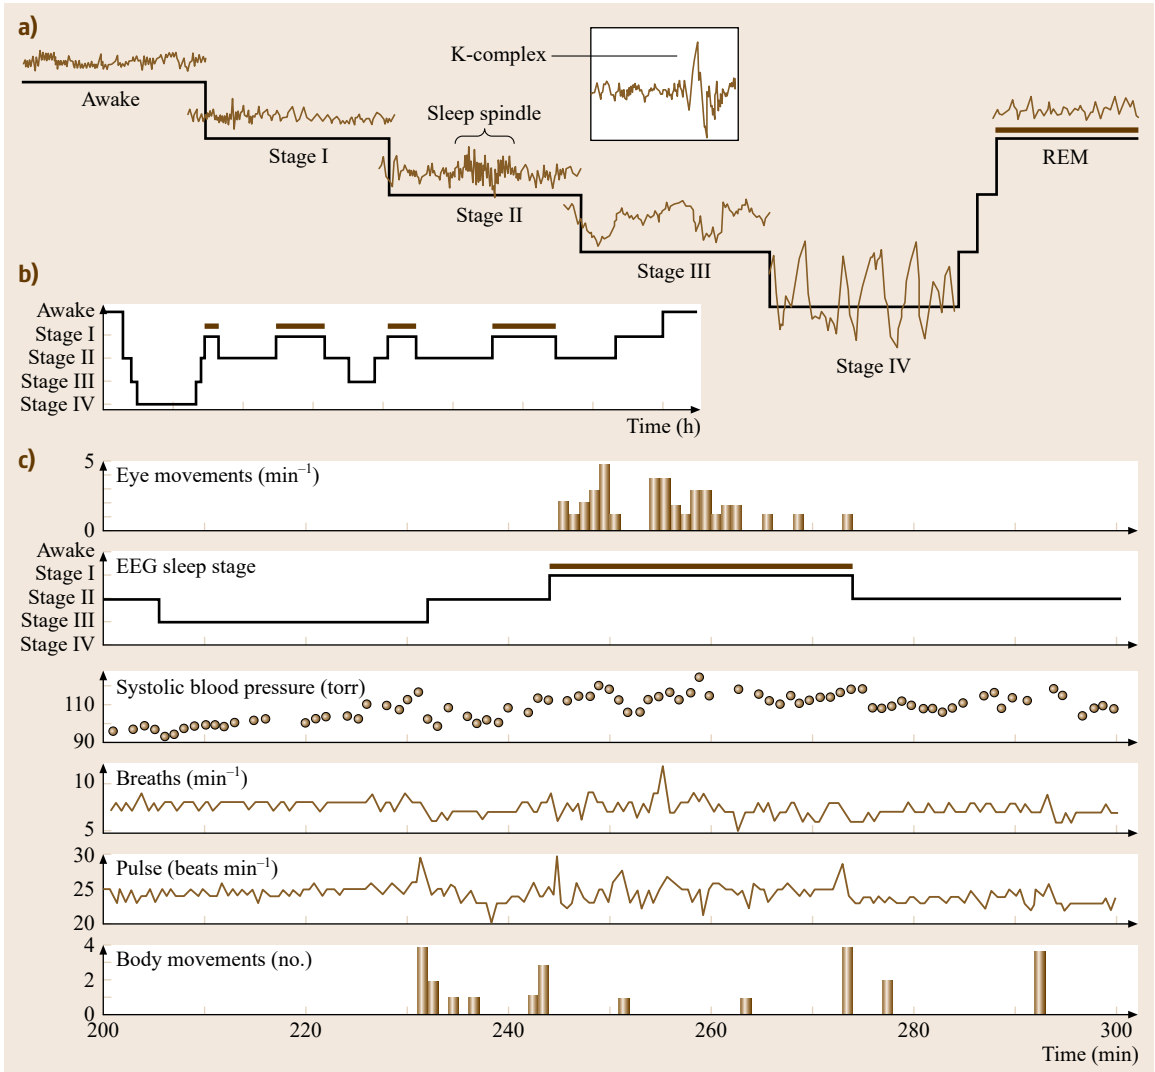

Fig. 45.2a–c An overview of human sleep: stages, cycling, and architecture. **(a)** Sleep is divided into stages according to EEG brain activity. **(b)** Progress of sleepstages over night. **(c)** Physiological and behavioral phenomena evident during sleep (after [45.1])

of polysomnography entails recording of brain activity (EEG), eye movements (EOG), and muscle tone (EMG). When required for research or diagnostic purposes, respiration, heart rate, blood oxygenation, limb movement, body position, and snoring sounds may also be sampled. Note that in this setup, designed for olfactory studies, a nasal mask delivers olfactory stimuli from a distant olfactometer. The mask is subserved with a vacuum line pulling the air from the environment of the nose to assure a temporally accurate presentation of the stimulus and a clean-air state between trials.

45.1.1 NREM

Polysomnography reveals that humans spend most of their sleeping in NREM. According to the contemporary sleep-scoring technique, NREM is further subdivided into three stages on the basis of EEG criteria [45.3]. These stages represent to some degree, a depth-of-sleep continuum, with arousal thresholds generally lowest in stage 1 sleep (Fig. 45.2b). Moreover, neuronal activity becomes increasingly synchronized as sleep stages progress. Nocturnal sleep adheres to a more or less constant scaffold, usually referred to as sleep architecture. Sleep stages orderly progress across the night in a cyclic manner, each cycle lasts about 80–120 min. Note that normal sleep onset is through NREM sleep. However, as the night progresses, time spent in REM is increased, on the account of stages 3 and 4 sleep (SWS).

45.1.2 Stage 1 Sleep (N1)

Stage 1 sleep is the stage of transition from wake to sleep. As sleep takes over, alpha rhythms (8–13 Hz) that dominate brain activity during wake diminish to less than 50%, and are often intermixed with theta (4–7 Hz) and beta (13–30 Hz) waves. Stage 1 sleep is light, thus easily interrupted by environmental cues reverting the sleeping brain back to wakefulness. Due to its resemblance to wake, stage 1 sleep is somewhat difficult to quantify or manipulate.

45.1.3 Stage 2 Sleep (N2)

Stage 1 sleep lasts only a few minutes and then quickly transitions into stage 2 sleep. The primary indication of stage 2 sleep is the appearance of sleep spindles, short bursts of 11–16 Hz activity, and K-complexes (KCs) (Fig. 45.2a). KCs are distinguished singular waveforms resembling high-amplitude slow waves, first described by *Loomis* et al. in the late 1930s [45.4]. KCs occur in stage 2 NREM sleep, both spontaneously and

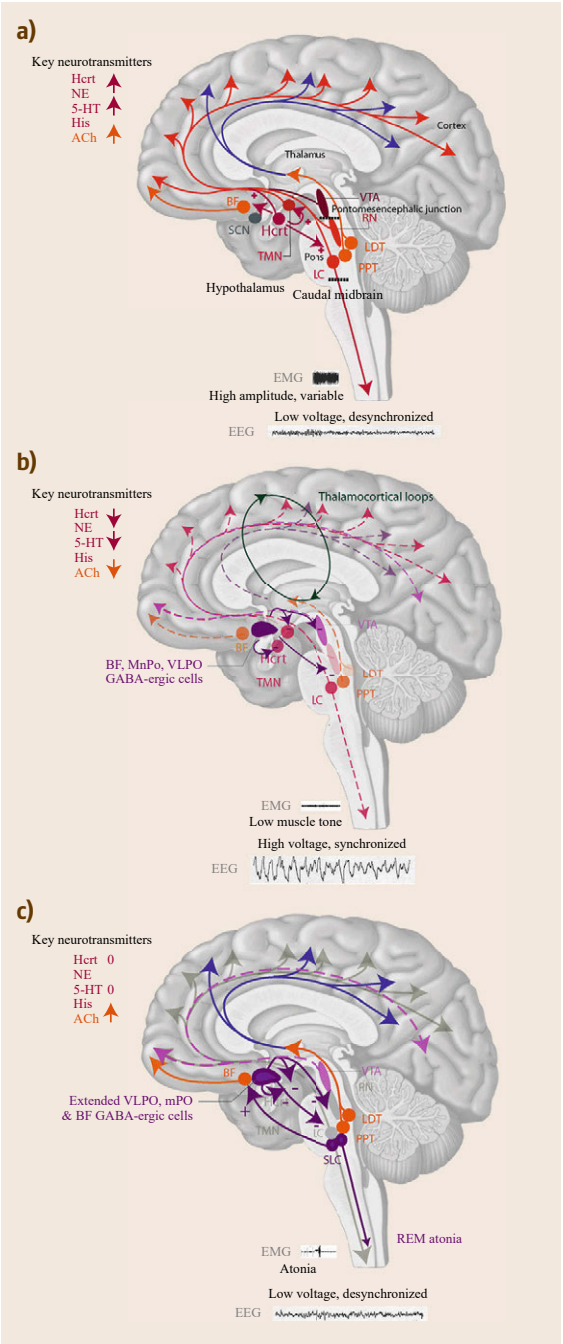

Fig. 45.3a–c Activity of major neural networks during wake, NREM sleep, and REM sleep. **(a)** Wakefulness. **(b)** NREM SWS sleep. **(c)** REM sleep (after [45.2])

in response to sensory stimulation [45.5]. KCs may have a sleep protective function as their appearance following a sensory stimulus prevents EEG characteristics of arousal [45.6]. Sensory thresholds in stage 2

sleep become elevated and thus require a more intense stimulus to produce arousal. The same stimulus that produces arousal from stage 1 sleep often results in an evoked KC but no awakening in stage 2 sleep [45.7].

45.1.4 Slow-Wave Sleep (SWS or N3)

This deepest stage of sleep is characterized by slow rhythm delta waves (0.5–4 Hz), and is termed slow-wave sleep (SWS). SWS replaced stages 3 and 4 of the original Rechtschaffen and Kales scoring criteria in the new American Academy of Sleep Medicine (AASM) sleep staging manual. Delta oscillations reflect synchronized fluctuations of neuronal membrane potentials, shifting between a depolarized upstate and a hyperpolarized downstate. They originate from both corticothalamic and intra-cortical regions. Power of delta activity is higher in adult women than men, and has right hemisphere dominance [45.8–10]. By orchestrating the coherence of rhythmic oscillations, slow waves are thought to take part in the promoting of sensory deafferentation of the cortex during sleep, thus enhancing sleep continuity and depth [45.7]. During SWS GABAergic projections are highly active. Thalamocortical loops contribute to the generation of light NREM sleep. As NREM sleep deepens, slow-wave oscillations appear on the EEG. Muscle tone is low. Experimental findings of reduced responsiveness in cortical neurons during slow-wave activity corroborate this model [45.11]. For this reason, as with the case of threshold elevation from stage 1 to stage 2 sleep, an incrementally stronger stimulus is required to produce wake from SWS than from lighter sleep stages. The first SWS episode usually lasts 20–40 min, typically phasing into REM through a short period of stage 2 sleep.

45.1.5 REM (R)

Whereas NREM sleep may be referred to as a *power-saving mode* for brain activity, REM sleep is quite the opposite. The generation of REM sleep is orchestrated by groups of REM-on cells located in the brainstem. Hypothalamic and basal forebrain sleep-on cells, as well as glutamatergic cells are active during REM. Atonia is accomplished through caudal projections. Brainstem cholinergic activation leads to EEG desynchronization similar to wakefulness. During REM sleep, EMG is low, but may occur. REMs are evident. Apart from the typical episodes of saccadic REMs after which the term *REM* was coined, these brainstem nuclei exert a neck-down muscle atonia (Fig. 45.3c). Brain activity during REM sleep resembles that recorded during wake: EEG during REM consists of low-amplitude beta frequency (13–30 Hz) mixed with theta (4–7 Hz) and alpha (8–13 Hz) rhythms. Similarly, brain metabolism during REM may reach the same levels as in wakefulness [45.12]. For these reasons, REM sleep is sometimes termed *paradoxical sleep*. Despite the seemingly active cortex, arousal thresholds during REM sleep remain high as in other sleep stages. In research, REM sleep can be subdivided into a tonic and phasic stage, according to the lack or presence of saccades, respectively. In healthy adults, REM sleep accounts for 20–25% of total sleep time. When awoken from REM sleep, subjects will often report vivid dreams [45.13] (Sect. 45.7.3).

45.1.6 Arousals and Wakefulness (W)

The typical sleep cycle sometimes terminates with a transient period of arousal linking between the cycles. Arousal (with eyes still shut) is differentiated from sleep by the presence of alpha rhythm activity for 3 s or more. If such arousal endures for more than 15 s, it will probably be remembered in the following morning and is termed *wakefulness*. During wakefulness multiple systems are active and contribute to EEG desynchronization through thalamic and cortical projections. Hypocretin cells excite monoaminergic cells. Muscle tone (EMG) is variable and high, reflecting movements. However, brief discontinuation of sleep lasting less than 15 s is referred to as *arousal* and is most likely not to be remembered.

45.2 Sleep Mechanisms

The different EEG patterns evident during sleep are the result of interplay between multiple brain regions (Fig. 45.3). During waking, the high-frequency desynchronized neural activity is the outcome of a mix of arousing signals originating from brainstem monoaminergic projections (specifically, the serotonergic raphe nucleus and the noradrenergic locus coeruleus) to the diencephalon and cortex, cholinergic projections from the pontine reticular formation and basal forebrain, and hypothalamic arousal signals including hypocretin/orexin and histamine. During NREM sleep, these systems are largely quiescent due to GABAergic in-

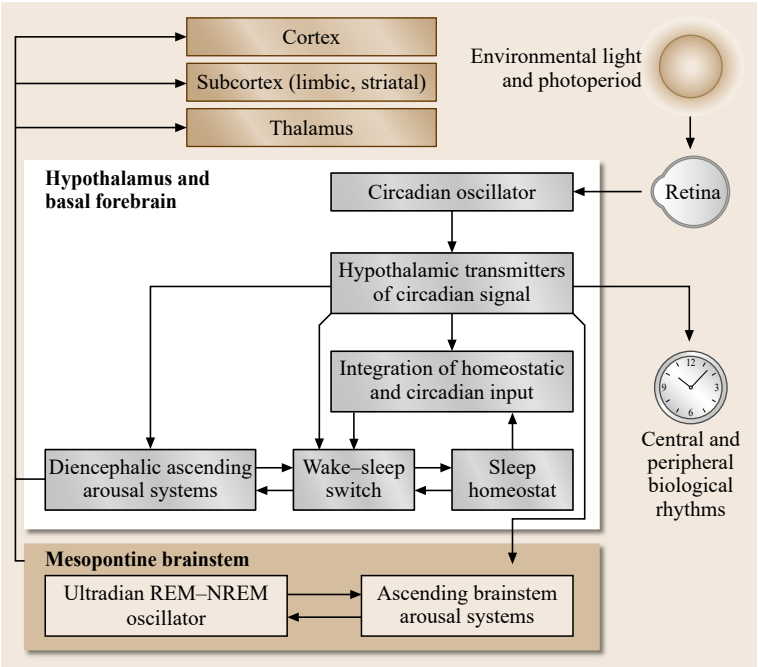

Fig. 45.4 Regulatory circuits involved in sleep (after [45.1])

hibition generated from the ventrolateral preoptic area (VLPO). This inhibition helps disengage the cortex from external stimulation, resulting in the aforementioned slow oscillations. During REM sleep both pontine and forebrain cholinergic systems are re-engaged. This leads to the activation of cortical circuits expressed as high-frequency desynchronized activity. Simultaneously, inhibition of the brainstem monoaminergic systems is augmented to maintain muscle atonia during sleep. The interplay of aminergic and cholinergic systems results in an ultradian oscillation of NREM and REM sleep, of approximately 80–120 min [45.14]. Finally, arousal from sleep is generated through a mechanism reflecting combined activity in the reticular formation of the brainstem, the hypothalamus, and the thalamus (see Fig. 45.4) [45.15].

45.2.1 Why Do Animals Sleep?

Sleep as a behavior is universal [45.16]. Most mammals spend a substantial part of their lives asleep and humans are no exception. The paramount importance of sleep is best demonstrated by its deprivation; organisms who regularly sleep cannot function normally, up to the point of death, when deprived of sleep [45.2, 17, 18]. Though obviously essential, and despite advances in brain sciences, mapping of genetic pathways, and neuroimaging, the functional purpose of sleep remains obscure.

An ecology-centered hypothesis claims sleep offers a state of energy conservation, in order to reduce energy demands in times when conditions (temperature or daylight) are not optimal. Such a metabolic perspective further suggests that sleep may have developed to allow for the biosynthesis of depleted biologically relevant macromolecules [45.19]. Indeed, there is evidence supporting a role for sleep in timing the expression of genes involved in endocrine regulation (specifically growth), immunity, and tissue regeneration processes following injury [45.20, 21]. However given that metabolic activity during some sleep stages is similar to that of wakefulness, this hypothesis alone may fall short of providing a comprehensive explanation for sleep [45.16, 22]. From a neurobiological perspective, cortical functions, such as cognition, attention, and memory are rapidly affected by sleep deprivation, with the latter being improved by subsequent sleep. Therefore, sleep is likely important for mechanisms of brain plasticity that underlie learning and memory facilitation [45.2, 23, 24]. One model for the role of sleep in synaptic plasticity proposes sleep exerts a synaptic downscaling effect for the sake of synaptic homeostasis, correcting an overall gain in synaptic strength accrued during wake [45.25].

45.3 Olfactory Stimulation, Unlike Most Forms of Sensory Stimulation, Is not Sleep-Perturbing

Administration of supra-threshold sensory stimulation during sleep will typically either wake (even if just for a short, often unrecalled arousal) or evoke EEG KCs. Studies involving somatosensory stimulation, such as touch, pain, or thermoperception have repeatedly demonstrated how salient sensory stimuli perturb sleep by inducing arousals, and disrupting the regular sleep period [45.29]. The term *salient* implies that the sleeping brain is able to distinguish between recurring, already habituated stimuli, and novel ones. Yet despite habituation mechanisms, continuous or repeated sensory stimulation impacts sleep quality. For example, when a continuous ambient acoustic stimulus was introduced, a decrease in total sleep time, particularly of SWS was evident, and frequent returns to wakefulness were reported [45.30, 31].

Although the majority of evidence favors the idea that sensory stimuli of varied characteristics disturbs sleep, some exceptions exist. One particular exception is that a rhythmic acoustic stimulation at 0.8 Hz (a frequency which falls well within the intrinsically generated slow wave activity) can effectively enhance slow oscillation activity during adult human sleep [45.32]. A much broader exception is olfactory stimulation.

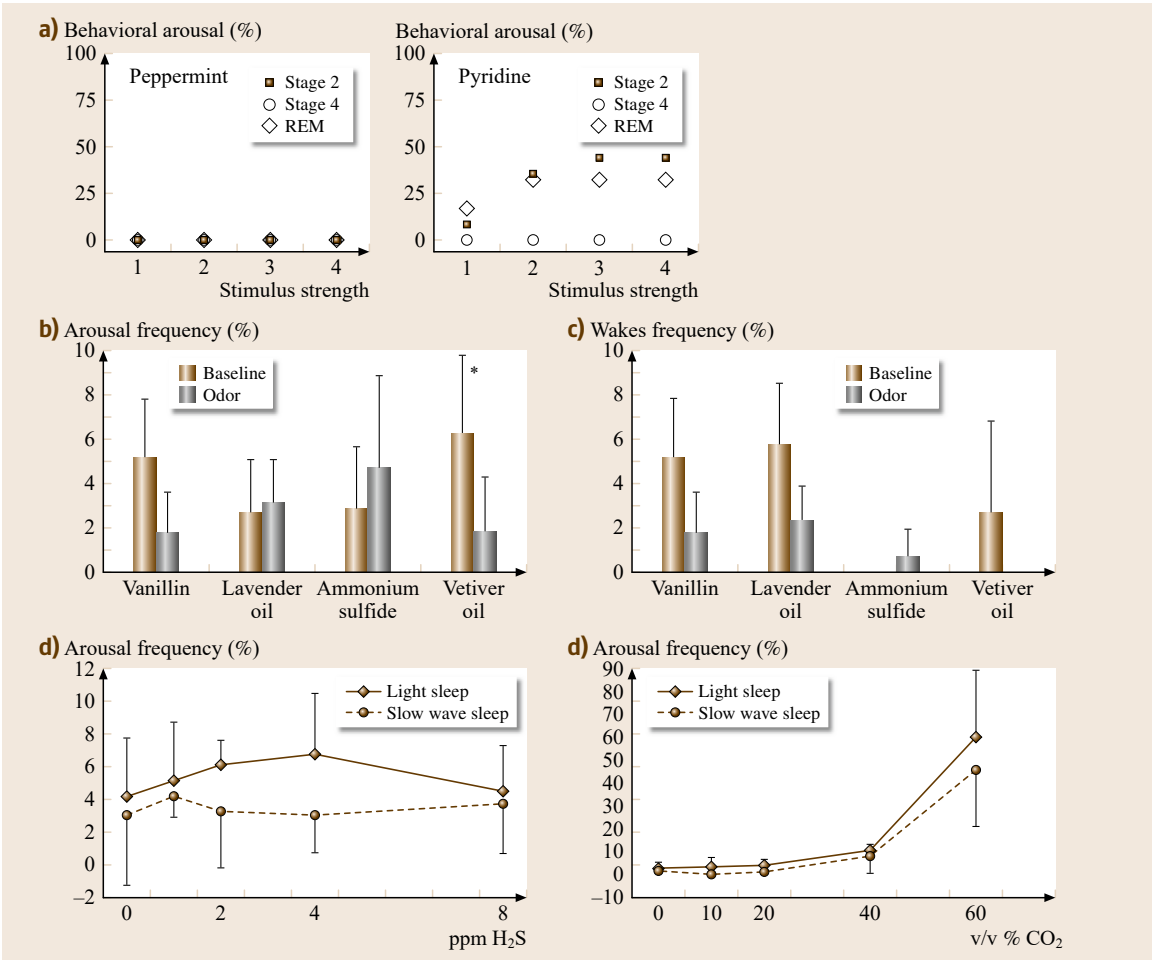

Fig. 45.5a–e Administration of purely olfactory odorants result in minimal physiological and behavioral arousal. **(a)** Arousal frequency following exposure to peppermint (*left*) and pyridine (*right*) stimulation of increasing strength in different sleep stages (after [45.26]). Frequency of arousals **(b)** and wakes **(c)** associated with odor (compared with a baseline of clean air) (after [45.27]). Arousal frequency following exposure to different concentrations of H_2S **(d)** and the trigeminal CO_2 **(e)** during light and slow-wave sleep (after [45.28])

45.3.1 Purely Olfactory and Mildly Trigeminal Odorants Do not Wake

Odorants can be divided into two main categories according to their mechanisms of detection and transduction: the first category includes *pure olfactants*, so called because they selectively activate olfactory receptors of the olfactory epithelium alone [45.33]. Examples of such pure olfactants are hydrogen sulfide (H_2S), vanillin, and phenyl ethyl alcohol (PEA) [45.26, 33, 34]. The second category includes *trigeminal odorants*, so called because these odors simultaneously activate receptors found at the end of the trigeminal nerve as well as olfactory receptors [45.35]. A large body of evidence suggests that exposure to pure olfactants during sleep (as opposed to trigeminal olfactory stimulation) does not lead to arousal or wake [45.26, 28, 36] (Fig. 45.5). Some studies suggest that this general notion can be extended to mildly trigeminal odorants as well [45.26, 27, 37].

A study by Carskadon and Herz was one of the first to address the question of whether olfactory stimuli wake from sleep, with an emphasis on the difference between auditory and olfactory processing. The authors presented two odors, four concentration of each, of comparable trigeminal strength but opposite hedonic values: peppermint, which is generally perceived as pleasant and pyridine which is unpleasant and at high concentrations, aversive. Subjects readily detected the odors at wake and were then re-exposed during the night with the instruction to report the detection of odors. Behaviorally, the overall response rate was about 90% in trials conducted in stage 1 sleep, but when tested in stage 2 sleep, REM, and SWS, response rates to pyridine exposure dropped to 45%, 33%, and none, respectively. Trials conducted during the same sleep stages but with the presentation of peppermint did not induce wake at all. In contrast, response rates for the auditory stimuli remained higher than 75% during all sleep stages (Fig. 45.5a). This dissociation was echoed humorously in the article's title – *Why odor alarms will not work for humans* [45.26]. With that in mind, it is further amusing to note that a different research group proceeded to design exactly that, namely an odor-emitting fire alarm designed for the deaf. This, however, is not a contradiction, as the alarm used the odor of Wasabi, a highly trigeminal odorant [45.38].

The notion that olfactory stimuli do not wake was further established in a series of studies. In one, subjects were exposed during sleep to four concentrations of either the odorless trigeminal carbon dioxide (CO_2) or the purely olfactory odorant hydrogen sulfide (H_2S). While exposure to CO_2 resulted in an increase in EEG frequency indicative of brief arousal, the presentation of H_2S did not have such an effect, even at high concentrations (Fig. 45.5d) [45.28]. A second study assessed the latency of arousal following olfactory stimulation. The authors reported a concentration-dependent increase in frequency and latency of arousals only for trigeminal odorants [45.36]. Moreover, whereas administering combinations of trigeminal and olfactory odorants increased arousals from light sleep, no effect was observed for REM or SWS [45.39]. An interim conclusion of the above is that exposure to purely olfactory and mildly trigeminal odorants during deeper stages of sleep does not cause an arousal.

45.4 Odors May Act as Sleep-Promoters: From Aromatherapy to Neuroscience

In the previous paragraph we reviewed evidence implying that odors presented during sleep do not wake. Whereas the neurobiological mechanisms permitting this are being studied, evidence for potential applicative benefits of this phenomenon has been around for millennia.

Aromatherapy is the therapeutic use of essential oils, usually applied through the skin or via the olfactory system. It is an ancient practice claiming significant physiological and psychological effects, particularly on sleep. Although Egyptian, Chinese, and Romans were already practicing aromatherapy in ancient times, the term *aromatherapy* was coined in the late 1920s by the French chemist Rene-Maurice Gattefosse [45.40]. The sleep-promoting effects of specific odorous oils such as lavender or jasmine administered near sleep onset are still widely practiced.

Lavender (*Lavandula spica*) oil is often reported to improve sleep-efficiency parameters (e.g., time awake during the sleeping period and total time asleep) both in healthy individuals and those in need of special care [45.41–43]. A 3 min exposure to lavender oil increased the percentage of time spent in SWS and stage 2 sleep on the account of REM time. This was backed by self-reported increases in vigor the following morning [45.44]. Lavender oil not only enhanced normal sleep but also improved abnormal sleep in a similar magnitude as medication. Total sleep time of insomnia patients who underwent two weeks of medication withdrawal resumed the same levels of sleep as under

medication when ambient lavender was diffused in the room [45.45].

Lavender is not the only aromatic essence known to affect sleep. Cedar extract shortened NREM sleep stage 2 latency in human daytime nap and increased NREM sleep duration in rats [45.46]. Plant-derived odorants such as α-pinene increased paradoxical sleep (PS) duration during a specific night-time zone in adult rats [45.47]. Valerian (*Valeriana officinalis*) inhalation shortened sleep latency in rats and prolonged total sleep time, and both valerian and rose odor prolonged pentobarbital-induced sleeping time [45.48].

Not all aromatic extracts enhance sleep: some exert no influence on sleep while other specific odors may interfere with sleep; Presentation of peppermint essential oil before bedtime did not influence human night sleep when subjective factors were not taken into consideration [45.49], and reduced sleepiness during daytime [45.50]. Similarly, inhalation of lemon odor increased sleep latency in rats [45.48].

Apart from possessing an olfactory percept, many essential oils contain volatile chemical agents capable of exerting a pharmacological effect that cannot be disregarded when discussing their sleep-promoting abilities. These volatiles may readily reach the central nervous system through the blood stream, upon being absorbed by the mucous membranes of the respiratory tracts. For instance, substances found in lavender and valerian oils interact with γ-aminobutyric acid (GABA) receptors, inducing systemic sedative and anxiolytic effects [45.51–53].

Another aspect of the sleep promoting effects of specific odors is cognitive. Peppermint odor enhanced SWS and total sleep time in subjects who perceived it as very intense, in comparison to subjects perceiving peppermint as moderately intense. Furthermore, subjects who found peppermint stimulating had more NREM and less REM sleep while those perceiving it as sedating took longer to reach SWS [45.54]. One may speculate that odors contextually linked with familiar settings or positive experiences can also exert an anxiolytic effect, perhaps through a reduction in sympathetic tone.

Finally, in an international bedroom poll conducted by the USA National Sleep Foundation in 2013, bedroom odors received a central role in sleep hygiene. The majority of respondents answered that they feel more relaxed if their bedroom has a fresh, pleasant scent and reported that they will take steps to make sure their bedroom smells this way. Malodors reported to have a most detrimental effect on sleep quality varied across nationalities but the *usual suspects* were mold, body or pet odor, and stale air [45.55].

The above findings converge to suggest that inhalation of aromatic substances can enhance sleep in terms of reducing sleep latency and affecting sleep architecture. While some of the effects attributed to aromatherapy may be exerted pharmacologically, others are more idiosyncratic as they are modulated by the perceived characteristics of the odor. In turn, the notion that odors may promote sleep follows animal studies as well. For example, high-frequency stimulation of the olfactory tubercle of cats elicited sleep, similar in every respect to physiological sleep, and facilitated SWS [45.56]. Further support for the role of the olfactory tubercle in the physiological mechanism of sleep came from lesion studies which reported decreased sleep time following the lesion of the olfactory tubercle [45.57]. Taken together, these findings imply that beyond not waking, odors may in fact promote sleep.

45.5 Processing of Olfactory Information in Sleep

While basic science and aromatherapy converge to suggest that odors do not wake, odors remain processed by the sleeping brain. For example, rhythmic activity in the rodent olfactory bulb was detected following the sensory stimulation of other modalities [45.58]. Additionally, the biologically relevant odor of fox urine presented during sleep in rats induced increased Fos (an immediate early gene whose expression is an indirect marker for neural activity) expression in the olfactory system [45.59]. In an initial assessment of cortical chemosensory event-related potentials (ERPs) during human sleep, olfactory and trigeminal ERPs were detected in some but not all the participants. Consistent with other sensory modalities, olfactory ERPs latencies were longer, and amplitudes larger, during NREM sleep in comparison to wakefulness [45.60]. In a separate study, fully monitored participants were repeatedly presented with 3 min periods of either clean air or peppermint odor. In a minority of the cases, odors modulated heart rate, as well as EEG and EMG activity [45.37]. Finally, the sniff response is an odorant-specific change in nasal airflow whereby pleasant or mild odors drive stronger sniffs and unpleasant or intense odors drive weaker sniffs [45.62, 63]. The sniff response is therefore a nonverbal implicit measure of olfactory processing. The sniff response remains conserved during sleep [45.27]. For example, the pleasantness of the odorant modified subsequent inhalation

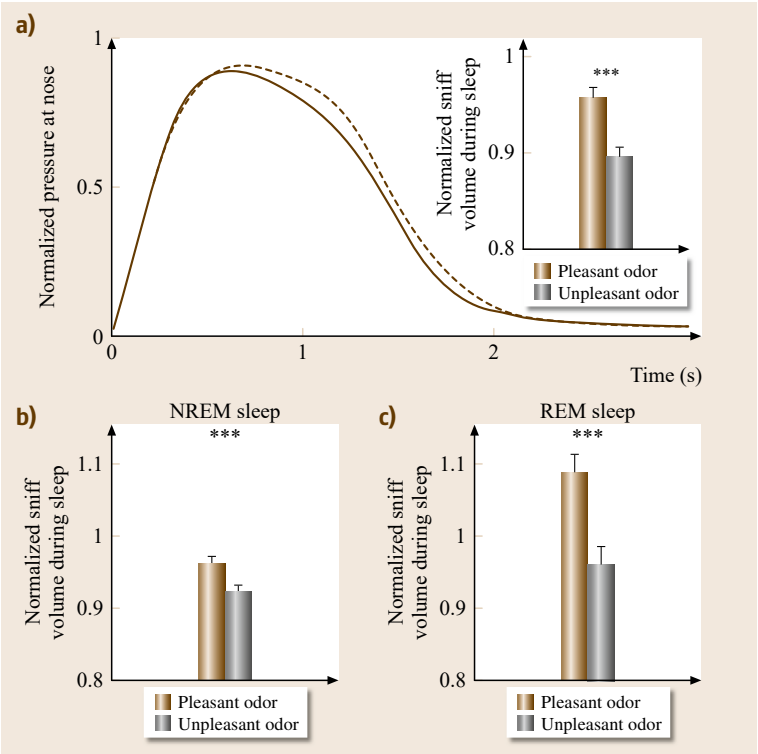

Fig. 45.6 (a) The sniff response, an odorant-specific change in nasal airflow is conserved during sleep, both in REM (b) and NREM (c) stages (after [45.61])

volume in a hedonic valence-dependent fashion, during sleep (see Fig. 45.6) [45.61]. In conclusion, odors do not wake and perhaps even promote sleep, yet they remain processed by the sleeping brain. In this, olfaction differs from other sensory modalities that typically wake from sleep. What is it that allows this special relationship between sleep and smell? Although we do not have a mechanistic answer to this question, we speculate that the answer lies within the unique aspects of olfaction neurophysiology as they relate to sleep neurophysiology. Here, we will detail these unique characteristics of olfaction.

45.5.1 Unique Aspects of Olfaction Neurophysiology May Underlie the Unique Interaction of Sleep and Smell

Olfactory information is projected from the olfactory epithelium to the olfactory bulb, and from bulb directly to olfactory cortex in the ventral temporal lobe [45.64]. This is in contrast to other sensory systems that relay information to primary cortical regions via the thalamus. Synchronized thalamo-cortical oscillatory activity evident during SWS is assumed to aid in the attenuating of sensory processing during sleep [45.65–70]. Given that olfactory information reaches the olfactory cortex directly, it remains independent of this potentially attenuating mechanism (note that olfactory information does traverse a thalamic relay downstream [45.71]). That said, given that olfactory processing during sleep differs from wake, an alternative gating mechanism is likely in effect. Two plausible candidate substrates for such sensory gating are the olfactory bulb and the olfactory cortex. The olfactory bulb and thalamic nuclei share gross structural similarities, and are both subjected to modulation by similar neuronal circuits [45.72]. In addition to the anatomical resemblance, the electrical properties of the olfactory bulb also support its candidacy for a sensory-gating mechanism. The olfactory bulb presents fast electrical activity (30–40 Hz) that decreases during sleep [45.73]. The patterns of electrical activity in the olfactory bulb varied during different states of wakefulness, during physiological sleep, and during unconsciousness produced by central anesthesia or by brain stem lesions [45.58]. The olfactory system of rodents generates slow-wave activity, tightly locked with respiration during sleep and under anesthesia [45.74, 75]. These oscillations between the olfactory bulb and cortex share characteristics with oscillations between the thalamus and cortex during SWS. The periodic respiratory rhythm, specifically the sensory signal resulting from the entry of air into the nasal cavity was speculated to be the driving force of these sleep-

like oscillations in the bulb. Such respiration-induced oscillations are capable of further propagating in the rodent brain, thus contributing to global slow-wave activity [45.76].

An alternative brain region proposed to act as a sensory gate in the olfactory system is the olfactory cortex. Neocortical EEG of anesthetized rats exhibits periodical alternation between a slow wave and a fast-wave state (FWS). Olfactory cortex neurons responded more strongly to odorants during FWS than during SWS. Olfactory bulb neurons however, rarely exhibited such contrast. The authors therefore concluded that during SWS, the olfactory cortex acts similar to thalamic gating mechanisms [45.77].

45.6 The Olfactory System and the Wake–Sleep Regulation System are Highly Connected

An additional distinctive feature of the olfactory system is its widespread connection with the arousal system controlling the sleep-waking cycle. The sleep-waking cycle is regulated by a group of nuclei located in the brainstem through the release of neuropeptides and neurotransmitters. It is established that these nuclei project monosynaptically and polysynaptically to primary and secondary areas of the olfactory system [45.78–80].

A key player in the induction of an alert waking state is the locus coeruleus, a noradrenergic pontine nucleus [45.81]. Approximately, 40% of all locus coeruleus neurons of rats project to the olfactory bulb. This dense connection to the olfactory bulb is almost 10 times greater than to any other part of the cerebral cortex [45.82, 83]. Norepinephrine released by the locus coeruleus disinhibited olfactory bulb neurons [45.84, 85], enhanced detection of relatively weak odors [45.86], and was implicated in olfactory bulb neural responses toward learned odors [86-88].

Orexin, also known as hypocretin, is a hypothalamic neuropeptide implicated in promoting wakefulness. Orexin absence results in difficulty to maintain wakefulness, and REM sleep intrusions. Orexin receptors are present at different levels of the olfactory system, from the olfactory epithelium, through the mitral-tufted cells of the olfactory bulb, and up to the piriform cortex and amygdala nuclei. Although the vast distribution of orexin along the olfactory system suggests a possible modulation of olfactory perception by this neuropeptide [45.87, 88], Orexin's role in olfaction may be more tightly linked to its role in regulating feeding than to its role in sleep [45.89]. Nevertheless, orexin produced hyperpolarization of the olfactory bulb [45.90], and reduced mitral cell firing, without changing the olfactory bulb responsiveness to odors. Other studies report contradicting evidence for the effect of orexin on the olfactory bulb; Orexin significantly increased the firing rate in one study [45.91] and increased olfactory sensitivity in another [45.89]. Even if contradicting, the above findings support a role for orexin in the modulation of olfaction, and provide the grounds for a mechanistic link between olfaction and the wake-sleep cycle.

While it is clear that olfactory function is modulated by brainstem and hypothalamic arousal signals, there is evidence of a reciprocal or complementary effect of olfaction on arousal. The suprachiasmatic nucleus (SCN) located in the anterior hypothalamus is considered the *master* circadian pacemaker, orchestrating the timing of physiological functions and behaviors [45.92] (Fig. 45.4). To adjust the internal clock to outside conditions, the SCN receives input from different systems, including olfactory regions [45.93]. Elimination of free-running circadian rhythms of locomotion by SCN lesions was partially restored using a rhythmic administration of odors [45.94]. Moreover, under constant darkness, cedar oil-induced c-Fos circadian rhythms were observed in the olfactory bulb and in the piriform cortex of mice kept under constant darkness [45.95]. Taken together, these results imply that olfactory stimuli can act as circadian time cues to modulate circadian behavior.

45.7 Olfaction in the Study of Sleep Mentation

So far, we have seen that odors do not wake and possibly promote sleep. Nevertheless, the sleeping brain processes odor information. We speculate that this unique interaction is related to the unique path of odor information in the brain, reaching cortical targets without a thalamic relay. Although a detailed mechanistic explanation for the interplay of sleep and smell remains lacking, this interplay provides a unique window into the study of mentation in both sleep and wake.

45.7.1 Odors as Cues in the Study of Memory and Consolidation

It is largely accepted that sleep plays a central role in facilitating learning. An ever-growing body of evidence demonstrates that memories acquired during prior wake and later reactivated during sleep, were better recalled following the sleeping period. The phenomenon of memory reactivation during sleep, as part of the process of consolidation, is memory type- and sleep stage dependent [45.96–98]. Spontaneous reactivation of neuronal patterns activated during prior wake is widely reported [45.99, 100]. From rodent hippocampal place cells replaying their sequence of activation during a recently learned route [45.101, 102], through juvenile songbirds attempting to master their tutor's song pattern [45.103], to human brains displaying correlation of activation patterns between sleep and preceding wake [45.104–107].

The experimental reactivation of specific memories during sleep, sometimes referred to as *targeted memory activation* (TMR) is a method for the study of the role of sleep in memory processes. Crossing the boundary from scientific research to everyday life, it is a captivating concept that one can achieve such self-augmentation simply by sleeping.

The unique ability of purely olfactory odors to be processed without inducing wake renders them a compelling tool for the study of the role of sleep in the mechanisms of learning, memory, and particularly, memory consolidation. Odors serve as an elegant and covert cue for the reactivation or modification of mental processes experienced or learned prior to the sleep session and even to some extent, to enable learning of new information within the sleep period. For example, task performance was improved by the presentation of an odor cue, as context in prior learning in humans; Volunteers learned a visuospatial object-location task while an odor was present. Next, the odor was presented again during SWS or REM to selectively reactivate the memory linked with it. Re-exposure to the odor during SWS, but not during REM improved the retention time of object location. Functional magnetic resonance imaging (fMRI) revealed hippocampal activation in response to odor presentation during SWS, concurrent with the behavioral findings [45.108]. Another study highlighted the broad state dependence of memory reactivation. Memory reactivation by an odor cue during waking destabilized memories; however, its presentation during SWS immediately stabilized memories. fMRI scans aimed at capturing the differential brain activation responsible for this phenomenon revealed that reactivation during SWS mainly activated hippocampal and posterior cortical regions, whereas reactivation during wakefulness primarily activated prefrontal cortical areas [45.109]. In an ensuing study, odors again served as cues for the reactivation of previously acquired memories, this time within the frame of a short sleep period rather than a full-night sleep. External reactivation by an odor cue during a 40 min sleep period enhanced memory stability to the same extent as 90 min of sleep without odor reactivation, further supporting the role of odor as a potent cue for memory reactivation [45.110]. Employing a similar visuospatial memory task, the authors also looked into the role of odor specificity in the context of memory reactivation, that is, whether odor-induced memory activation requires the same odor during learning and subsequent sleep. Odor re-exposure during sleep significantly improved memory when the same odor was presented both during wake and sleep. This was not the case however, when a new odor or an odorless vehicle was presented (Fig. 45.7) [45.111].

As with the case of consolidation, sleep is suspected to exert a beneficial effect on creativity, and specifically creative insights. While the mechanism responsible for

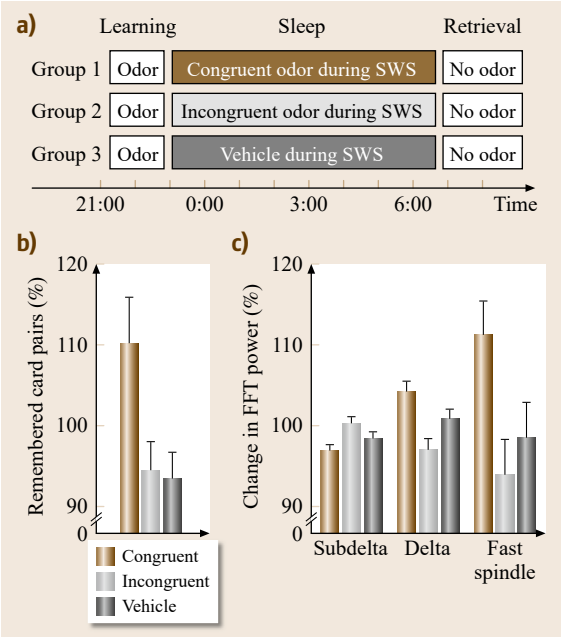

Fig. 45.7 **(a)** Procedure: Participants practiced an object-location task under the presence of a specific odor. Next, the same odor (congruent), a novel odor (incongruent) or an odorless stimulation (vehicle) was presented during SWS. Retrieval took place the morning after sleep without odor. **(b)** Percentage of remembered card pairs after sleep relative to the session before sleep. **(c)** Odor-induced changes in EEG delta power imply consolidation (after [45.111])

producing such *Eureka!* exclamations remains elusive, it has been proposed that reactivations during sleep benefit from the cognitive flexibility of the sleeping state, thus allowing remote associations [45.112, 113]. In a study by *Ritter* et al. subjects were presented with a problem that required a creative solution, while an ambient odor was present. Presenting the same odor in the following sleep session resulted in an increased creativity score when facing the same problem the following morning [45.114]. These results suggest that similar to memory consolidation, the creative process is also reliant on nighttime reactivations, which can be covertly prompted using olfactory cues.

45.7.2 Learning New Olfactory Associations During Sleep

So far, we reviewed the use of olfactory cues promoting the strengthening of memories previously acquired during wake. But can new information be acquired while we are asleep? Studies focused on the subject repeatedly argued that unless an arousal had occurred while information was presented, it became irretrievable upon ensuing wake. A recent study revisited learning of new information during sleep, with the aid of olfactory cues. Partial-reinforcement trace conditioning was used to pair pleasant and unpleasant odorants (shampoo or perfume and rotten fish or carrion, respectively) with two distinct tones during sleep. Respiration was monitored as part of full polysomnography with emphasis on the sniff response following odor presentation (Sect. 45.5). Sniffing following the presentation of tones alone was modulated according to the hedonic value of the odors paired during sleep. Specifically, a tone alone previously paired with a pleasant odor yielded larger sniff volume in comparison to a tone alone previously paired with an unpleasant odor. This implied that a novel association between tones and odors was formed and implemented while asleep. Remarkably, this acquired behavior persisted well into ensuing wake, without any awareness of the learning process. Nighttime effects of tone on sniffing were stronger in REM than in NREM; however, only conditioning which took place during NREM was successfully transferred to wake. This study implies that simple forms of learning such as associative conditioning can be activated during sleep [45.61].

Further support for the concept that new information can be learned during sleep comes from a study which focused on extinction, the process of *forgetting*, or relearning of associations. Subjects underwent contextual fear conditioning during wake in which images of faces were associated with electrical shock while a specific odor was implicitly introduced. Reapplying the odor during a short afternoon nap did not reinforce fear memory. Instead, it reduced fear responses for the face linked with the specific odor, relative to other faces, implying stimulus-specific fear extinction. The physiological fear response was backed up by a parallel reduction of hippocampal activity and reorganization of amygdala activation [45.115]. When an odor was used as a conditioned stimulus in odor-electrical shock fear conditioning, and not as a context, presentation of the odor during sleep resulted in an enhanced fear response when tested during subsequent wake. Injecting the amygdala of mice with a protein synthesis inhibitor following memory reactivation attenuated the previously conditioned fear response in the following wake [45.116]. Despite several methodological differences and possibly contradicting results, both studies illustrate that olfactory stimulation during sleep is a potentially powerful tool for the extinction of painful or maladaptive memories. These methods provide potential treatment for traumatic memories that may lead to phobias or post-traumatic stress disorder (PTSD) [45.116, 117].

45.7.3 The Effects of Odor Stimuli on Dreaming

Dreaming is a profound element of human experience. It is a state of consciousness in which incontrollable internally generated sensory-motor stimuli are experienced. An amalgam of complex, often emotionally charged experiences, woven into intangible plots. Despite its importance, there is little we can confidently say about a phenomenon that takes place every night, in each of our minds (and probably our pet companions' minds too). Our understanding of the function of dreaming is even less clear than that of the functions of sleep in general.

Dreaming was initially associated exclusively with REM sleep because dream recall was more frequently associated with arousals from REM. Nevertheless, it is widely accepted that dreaming takes place during NREM sleep as well [45.118, 119]. As dreams are an altered state of consciousness, a systematic, quantitative study of the dreaming state is a formidable task. The memory of dreams is ethereal, rapidly decaying, and often unintentionally distorted upon being recalled, due to memory-reconstruction mechanisms, verbal description difficulties or self-censorship [45.120].

Most readers will agree that the average dream is rich in visual and auditory experiences, but relatively few olfactory or gustatory experiences. According to a questionnaire-based wide range study only about 1% of all dreams analyzed were reported to contain olfactory or gustatory experiences. Most olfactory reports

came from women, a finding that the authors ascribed to higher olfactory awareness among women. The overall low prevalence of nocturnal olfactory experiences, was linked with the poor ability of humans to generate olfactory imagery in general [45.121]. Despite the fact that the dreaming brain is engaged in internal representations, external stimuli influence dream content. External stimuli may exert an effect on dream *ambiance* and themes, and in some cases even undergo direct incorporation (e.g., experimentally spraying water on skin was reported as being soaked in the dream). In a standard procedure for investigation of such influences the subject is presented with a stimulus in the middle of an REM sleep epoch. Next, the subject is woken up in order to interrogate him or her about their dream content. Tones, words, rocking of the bed, somatosensation, and even pain were demonstrated to be occasionally incorporated into dreams [45.122].

An initial anecdotal report regarding odors in dreams came from a clever self-experimentation session conducted by Hervey de Saint-Denys, a French oneirologist (a specialist in the study of dreams) of the nineteenth century. During a trip that lasted a few weeks, he used a new perfume and hermetically closed the bottle of perfume before traveling back home. A few months later, de Saint-Denys asked his servant to put a few drops of the perfume on his pillow, also instructed his servant not to tell him what night that would be. Ten days later, Hervey de Saint-Denys suddenly dreamed of the same place that he visited during his trip, the very same night the servant had put some of the perfume on his pillow. Such results led him to hypothesize that the stream of dreams is guided by associations, or as he defined them – *psychological affinities* [45.123].

About a century later, a small-scale study examined effects of various olfactory stimuli (both pleasant and unpleasant) on dream content through subjective reports. An incorporation rate of 19% was reported [45.124]. Twenty years later, the question of the effect of olfactory stimuli on dream content was revisited. Considering the direct connectivity between the olfactory pathway and the amygdala, the authors hypothesized that the strongest effect will be on dream emotions rather than direct incorporation of the stimulus. Using an air-dilution olfactometer, they presented two purely olfactory odorants of opposing hedonic values – the pleasant PEA (smell of roses) and the unpleasant H_2S (smell of rotten eggs). The odorants were embedded in constant airflow to prevent additional somatosensory stimulation and odorless stimuli were presented as controls. Reports obtained following odor presentation were scored for realism and dream emotions. Indeed, olfactory stimuli significantly affected the emotional ambiance of dreams, such that the positively toned stimulus yielded more positively toned dreams whereas the negative stimulus led to more negatively toned dreams. Direct incorporations however (the perception of the very object whose odor was presented) were not reported. The authors proposed a clinical application of this finding as a treatment for recurring nightmares, a sleep disorder common among children [45.122].

45.8 Olfaction and Sleep Disorders

Sleep disorders have tremendous physiological, behavioral, and psychological ramifications on life quality. Not only do they affect our sleep they also shape the way we perceive the world when we are awake.

Narcolepsy is a chronic sleep disorder characterized by the inability to regulate the sleep-waking cycle. Narcolepsy patients exhibit persistent daytime sleepiness, abnormal short REM latency, sleep paralysis, and cataplexy, and sudden episodes triggered by strong emotional responses [45.125, 126]. Orexin, a neuropeptide essential for maintaining wakefulness and regulating sleep and wake transitions, is associated with narcolepsy [45.127]. In a recent study, both appetitive and aversive odors presented to orexin-deficient mice, significantly increased the number of narcoleptic attacks. This provided further support for the tight link between odors and the emotional system [45.128]. Furthermore, olfactory dysfunction was observed in narcolepsy patients as reflected from poor scores in olfactory tests as well as a significantly higher olfactory threshold and impaired odor identification in comparison to controls [45.129]. Finally, intranasal orexin administration improved the olfactory threshold for PEA [45.130].

REM sleep behavior disorder (RBD) is characterized by loss of normal skeletal atonia during REM sleep, with prominent motor activity and dreaming. RBD can be linked with neurodegenerative disorders such as Parkinson or dementia with Lewy bodies manifest as an idiopathic disorder (iRBD) which is not linked with any comorbidities [45.131, 132]. Assessment of olfactory tasks revealed higher olfactory threshold, lower discrimination and lower identification scores in individuals with iRBD in comparison to age and sex-matched controls [45.131, 134–137].

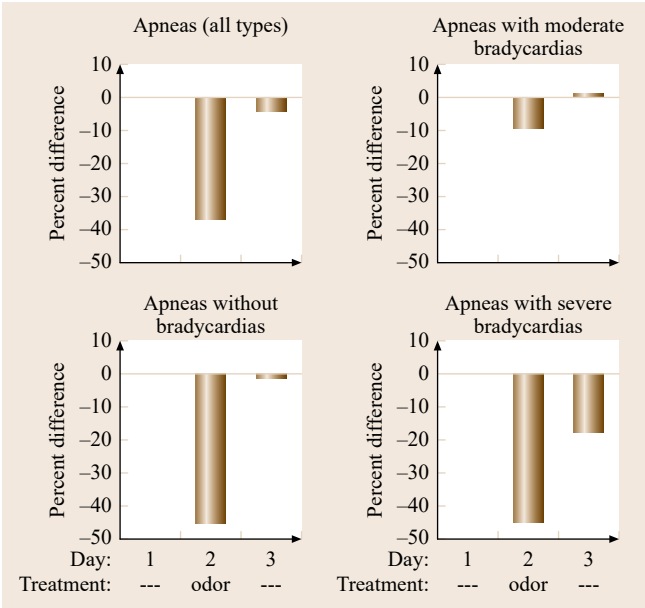

Fig. 45.8 Olfaction stimulation prevented apnea in premature newborn infants. Mean percent difference in the number of apneic spells of different types occurring during (day 2) and after (day 3) exposure to vanillin compared with baseline (day 1) (after [45.133])

45.8.1 Odor Administration During Sleep as a Treatment for Sleep-Disordered Breathing

Sleep apnea is a prevalent sleep-disordered breathing condition, characterized by the repetitive cessation of breathing during sleep leading to brief arousals. The clinical consequences of this disruption of normal sleep architecture cover a wide spectrum of metabolic, neurocognitive and cardiovascular disorders. The majority of sleep apnea is due to obstruction of the soft tissues of the upper airway [45.138, 139]. Sleep apnea is also associated with a deteriorated sense of smell. Sleep apnea diagnosis and severity are assessed by the rate of apneic events per hour named apnea-hypopnea index (AHI) [45.3]. In a recent study in which a comprehensive evaluation of olfactory performance was conducted, a correlation between AHI and score in olfactory tests was reported portraying poorer performance as apnea severity increased. Moreover, the volume of both left and right olfactory bulbs was negatively correlated with AHI [45.140].

Administration of vanillin, a purely olfactory pleasant odorant, to the periphery of a baby's pillow ameliorated bradycardia-associated apnea of prematurity in preterm babies who did not respond to standard pharmacology [45.133] (Fig. 45.8). Recently, the beneficial effects of vanillin on apnea of prematurity were replicated and extended in another study [45.141].

The transfer of this paradigm from prematurity-related apnea (which occurs both in wake and sleep) to adult sleep apnea was attempted as a method to influence respiratory patterns by olfactory stimulation, without inducing arousal or wake. The authors proposed a test of feasibility for treating sleep apnea with olfactory stimulation. Odorants (both pleasant and unpleasant) were introduced during sleep-modified respiration patterns, such that they decreased nasal inhalation and increased nasal exhalation. These findings provided evidence for the manipulation of respiratory patterns during sleep using olfactory stimuli [45.27].

45.9 Final Words

The evidence reviewed in this chapter implies that pure olfactory odors do not wake or arouse during sleep. In turn, the sleeping brain clearly processes these stimuli, and they continue to influence the sensory-motor loops of olfaction, namely sniffing, during sleep. This combination allows the use of odors in the study of sleep mentation. Such use has revealed that odors presented during sleep can strengthen memories of events associated with them during wake. Moreover, pairing of novel odors with novel information during sleep can be learned, and this pairing can later influence behavior during ensuing wake. In conclusion, the nonwaking features of olfaction have already uncovered novel aspects of sleep mentation, and we speculate that they will continue to serve in the study of sleep neurophysiology on one side, and olfactory neurophysiology on the other.

46. The Intranasal Trigeminal System

Johannes Frasnelli, Simona Manescu

The trigeminal nerve is the fifth and thickest cranial nerve and not only it is responsible for facial sensation and motor functioning, but it is also responsible for chemosensory perception. On top of innervating the skin of the face, the trigeminal nerve also innervates the mucosa of the nose and mouth. Here, chemosensory perception starts with the activation of different receptors, the most important and best known ones being the transient receptor potential (TRP) channels which give rise to sensations such as burning, warmth, coolness, coldness, and pain. From the mucosa, the trigeminal chemosensory information is conveyed through the trigeminal ganglion to the thalamic nuclei in the brain stem; from here fibers project to both, the somatosensory cortex and chemosensory areas of the brain.

Most odors stimulate the trigeminal system, in addition to the olfactory system, especially in higher concentrations. However, overlaps between both sensory systems are not limited to the stimulus level, as they interact with each other on peripheral (mucosa) and central (brain) levels. As a consequence, subjects with a lacking olfactory system show lower trigeminal sensitivity and subjects with a lack of trigeminal sensitivity show lower olfactory activations.

Different techniques are available to assess the state and the functionality of the trigeminal system. Such techniques include behavioral assessment by testing participants lacking a sense of smell – in order to exclude olfactory interference – as well as administrating different types of stimuli (pure odorants, pure trigeminal, or a mix of both). More objective measures include electrophysiological methods that evaluate the peripheral and central activations via the negative mucosal potentials (NMPs) and the trigeminal event-related potentials (ERPs), respectively, as well as functional magnetic resonance imaging, and to a lesser extent, positron emission tomography (PET).

The trigeminal nerve is responsible for facial sensations (touch and pain) and to a considerably lesser degree to motor functioning (masticating). In addition, it also provides chemosensory information from the oral and nasal mucosa, such as the perception of piquancy when eating something spicy. Although a limited amount of

research has focused on the chemosensory part of the trigeminal system, this chapter aims at providing an overview over key knowledge on the trigeminal system. Specifically, the anatomy, the different pathways, the various methods of studying the system, the interactions between the olfactory and the trigeminal system as well as the impact of the loss of one system on the other are discussed.

46.1 General Neuroanatomy of the Trigeminal System

The trigeminal nerve is the fifth cranial nerve (CN V). It is the largest of the 12 cranial nerves; its name stems from the fact that it has three major branches (tri = three; geminus = twin; hence triplets). These three branches are the ophthalmic nerve (CN V1), the maxillary nerve (CN V2), and the mandibulary nerve (CN V3). The trigeminal nerve is primarily a sensory nerve with some motor functions.

46.1.1 Trigeminal Ganglion, Trigeminal Nuclei

Sensory information from the three branches converges on the trigeminal ganglion (Gasserian ganglion, semilunar ganglion); here, the cell bodies of the incoming sensory fibers are located. The trigeminal ganglion has analogous features as the dorsal root ganglia of the spinal cord. Although the cell bodies of the neurons are located in the trigeminal ganglion, there are no synapses; thus the neurons are called pseudo-unipolar. Somatotopic information from the three branches is preserved [46.1], which means that the relative location of the three branches maintains the same location within the trigeminal ganglion. To illustrate, the branches from the ophthalmic nerve will be placed above the branches from the mandibular nerve as their layout on the human face. From here, afferent fibers enter the brain stem in the angle between pons and the middle cerebellar peduncle [46.2]. In the brain stem, they travel to the trigeminal nuclei, which are arranged from the mesencephalon (mesencephalic nucleus) to pons (main sensory trigeminal nucleus) and the rostral portions of the spinal cord (spinal trigeminal nuclei). It is important to note that the fibers are still arranged somatotopically [46.3]. See Fig. 46.1 for an overview over the trigeminal pathway.

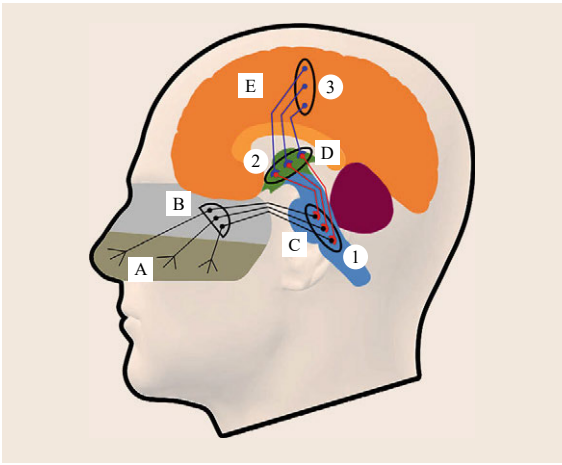

Fig. 46.1 The trigeminal pathway. A: Fibers of the trigeminal nerve (neurons) are located throughout the epithelium of the nasal cavity (*gray*). B: Cell bodies of the trigeminal neuron are located in the trigeminal ganglion. Nevertheless, no information is transferred between neurons at this stage. C: The first (1) relay station is located in the brainstem (*blue*). D: The second (2) relay station is located in the thalamus (*green*). E: Third-order neurons (3) project from the thalamus to the somatosensory regions of the cortex (*orange*). Note that somatotopic information is preserved throughout the pathway. *Purple*: cerebellum; *light orange*: corpus callosum

46.1.2 Central Nervous Processing Structures

The first synaptic relay is found in the trigeminal nucleus, a structure located in the brainstem. Here the information is transmitted to neurons projecting to the second relay station in the thalamus which is a regulator for consciousness and alertness. Specifically, trigeminal information travels to lateral (ventrobasal) and central (centromedial and parafascicular) thalamic nuclei. From here, the third neuronal projection sends the information mainly to the somatosensory cortex which represents the brain area responsible for sensations, such as touch, pain, or heat. In humans, the ophthalmic regions are represented in the inferior portion of the postcentral gyrus, whereas information from the mandibular nerve is processed in more superior regions in the central sulcus [46.4, 5]. Consequently, the relative layout of the three trigeminal branches is preserved in all portions of the trigeminal pathway, from the trigeminal ganglion to the somatosensory cortex.

46.2 Chemosensory Trigeminal Neuroanatomy

In addition to the facial skin, different branches of CN V innervate the mucosa of nose and mouth. Specifically, the ethmoidal nerves from the ophtalmic nerve and the nasal and some alveolar branches from the maxillary nerve innervate the nasal mucosa; further, other branches of the maxillary nerve innervate the oral mucosa together with the lingual nerve, the buccal nerve, and the alveolar nerves from the mandibular nerve. In the mucosa, the nerve endings of the trigeminal nerve are capable to detect chemosensory information in addition to somatosensory information, via specific chemoreceptors.

46.2.1 Peripheral Structures, Receptors

On receptor levels, chemical stimuli activate specific receptors of the trigeminal nerve, most of them being ion channels belonging to the subfamily of transient receptor potential (TRP) receptors, which have been discovered only relatively recently and are discussed in detail in Chap. 34 of this book. One of their main characteristics is that they are activated by both, a certain temperature range and chemical stimuli, such as capsaicin, menthol, camphor, and many more.

In addition to the TRP channels, there is also evidence for non-TRP receptors. These receptors are activated by nicotine (nicotinic acetylcholine receptors) [46.6] and acids (proton-gated ion channels) [46.7–10]. Further, in addition to these receptors on free trigeminal nerve endings solitary chemoreceptor cells have been described in the nasal cavity, although not yet in humans [46.11]. These cells are activated by bitter substances via specific receptors and reach the surface of the nasal epithelium and form synaptic contacts with trigeminal afferent nerve fibers. They may add to the repertoire of compounds that can activate the intranasal trigeminal system.

46.2.2 Central Nervous Processing Structures

Chemosensory information shares the processing units with this classical somatosensory pathway. However, chemosensory trigeminal stimuli activate brain regions in addition to these somatosensory structures such as the insula, the orbitofrontal cortex, and the piriform cortex [46.12–14]. Usually, these additional areas are considered being olfactory and gustatory regions. In order to include trigeminal processing, the term *chemosensory areas* has been put forward to describe the ensemble of these regions. While most trigeminal stimuli also evoke odorous sensations, that is, have a smell [46.15], it is unclear whether the activation of the chemosensory areas occurs via the olfactory pathway – stimulation of olfactory receptors by the trigeminal stimulus leads to the activation of olfactory nerves – or whether there is a direct and chemosensory-specific connection between the somatosensory pathway and the chemosensory processing areas, with a hitherto unknown exact neuroanatomy. The latter hypothesis is supported by the fact that even the odorless trigeminal stimulus carbon dioxide leads to the activation of chemosensory brain areas [46.12]. In fact, there are some collaterals of the trigeminal nerve that end within the olfactory epithelium; some even re-enter the central nervous system and terminate within the olfactory bulb [46.16]. While the exact function of these fibers is unclear, they may provide one of the links by which the trigeminal and the olfactory system interact.

46.3 Trigeminal Perception

Compared to the olfactory nerve, chemoreception within the trigeminal system is relatively unspecific. Still, the sensations arising from trigeminal chemosensation are well beyond simple pain perception as trigeminal stimulation may lead to such diverse perceptions as cooling, burning, stinging, or tingling. The TRP channel receptors play a key role in trigeminal perception.

46.3.1 Receptors and Perception

The first TRP receptor to be discovered and described in detail is the TRPV1 receptor. It is activated by noxious heat above 43 °C [46.17] as well as a variety of chemical stimuli, including capsaicin (the spicy ingredient of hot peppers) [46.17], eugenol (the key compound of essential oil of cloves) [46.36], and acids [46.33]. Stimulation of TRPV1 receptors leads to the perception of a tingling perception, which in higher intensities becomes sharp, burning, and painful [46.44]. There are several other TRPV such as TRPV3. This receptor is activated at lower temperatures starting from 39 °C [46.45, 46]. This receptor is also chemosensitive as different compounds, such as thymol (a main component of spices such as oregano and thyme) [46.24, 26], act as agonists. Activation of TRPV3 is associated with the sensation of warmth [46.26].

Table 46.1 Different stimuli activate different TRP receptors

Substance	Receptor	
Acetylcholine		[46.17]
Adenosine triphosphate		[46.17]
Amyl actetate		[46.18, 19]
Allicin		[46.20–22]
Benzaldehyde		[46.18, 19, 23]
Borneol		[46.24]
Bradykinin		[46.17, 25]
6-tert-Butyl-*m*-cresol		[46.24]
Camphor		[46.24, 26–32]
Cannabinoids		[46.21, 33, 34]
Capsaicin		[46.17, 19, 26, 33]
Capsazepin		[46.17]
Carvacrol		[46.24, 26]
Carveol		[46.24]
L-Carvone		[46.25]
Cinnamaldehyde		[46.25, 28]
Citral		[46.35]
Diallylsulfide		[46.20]
Dihydrocarveol		[46.24]
Eucalyptol		[46.27, 31]
Eugenol		[46.23, 25, 26, 36]
Formalin		[46.21, 37, 38]
Geranial		[46.35]
Geraniol		[46.35, 39]
Gingerol		[46.25]
Glutamate		[46.17]
HC-030031		[46.37]
Helional		[46.39]
Heliotropyl acetone		[46.39]
cyclo-Hexanol		[46.27]
cyclo-Hexanone		[46.19, 23]

Table 46.1 (continued)

Substance	Receptor	
Histamine		[46.17]
4-Hydroxynonenal		[46.21, 38, 40]
Hypertonic saline		[46.17]
Icilin		[46.27]
Incensol acetate		[46.41]
Isopulegol		[46.25]
Javanol		[46.39]
Limonene		[46.19]
cis-p-Menthane-3,8-diol		[46.25]
trans-p-Menthane-3,8-diol		[46.25]
Menthol		[46.25, 27, 28, 42]
Menthone		[46.27]
Menthyl lactate		[46.25]

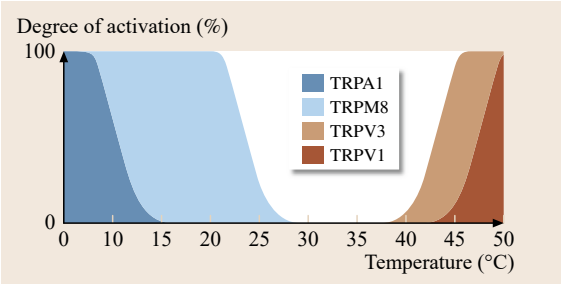

Fig. 46.2 Receptive range of four intranasal TRP receptors. The *green area* indicates the physiological temperature in the nasopharynx, that is, the temperature to which the nose conditions the inhaled air (after [46.49])

On the other side of the physiological temperature range, we find the TRPM8 receptor. This particular receptor is activated by cool temperatures starting from 39 °C [46.27], as well as chemical substances such as menthol (main component of peppermint) [46.27], and eucalyptol (eucalyptus) [46.47]. Stimulation of this receptor provides the sensation of cooling without being particularly painful. Further toward the range of noxious cold is the TRPA1 channel, which is activated by cold temperatures below 17 °C [46.25, 33]. Again, this receptor is chemosensitive as compounds such as allyl thioisocyanate (mustard oil) [46.25, 33] serve as agonists. TRPA1 stimulation gives rise to a dull, painful sensation. See Fig. 46.2 for an overview over the temperature ranges of these four receptors. It is interesting to note that many of the stimuli are ingredients of spices and herbs, such as hot pepper, cloves, oregano, thyme, eucalyptus, peppermint, mustard, etc. See Table 46.1 for an overview of the different stimuli that activate the four TRP receptors mentioned in this chapter.

When humans breathe air at room temperature normally, inhaled air is heated within the nasal cavity to an average of 28–32 °C [46.48, 49]. This temperature lies between the temperature ranges of TRPM8/TRPA1 on one hand and TRPV3/TRPV1 on the other hand. Thus, none of these receptors should be activated when we breathe clean air at room temperature. Upon stronger inhalation of air at room temperature, however, the TRPM8 receptor may be activated, since intranasal temperature drops [46.49]. Further, changes of the air temperature induce receptor potentials and, as a consequence, the perception of cold, cool, warm, or hot. Similarly, the presence of one of the multiple trigeminal stimuli may induce receptor potentials evoking according sensations even in the absence of a real temperature change. In fact, the inhalation of menthol does lead to the perception of coolness and, by analogy, the sensation of an increased nasal patency. Objective measures of nasal air temperature and nasal patency however show that menthol inhalations do not affect any of both measures [46.48].

We do not yet know how different trigeminal receptors are distributed within the nasal epithelium. In this context, it is interesting to note that three different trigeminal stimuli, which most likely bind to different receptors, evoked comparable activation patterns at different sites within the nasal epithelium [46.50]. Therefore, different areas of the nasal cavity seem to exhibit distinct concentrations of receptors, but the ratios between different receptors seem to be stable throughout the nasal cavity.

46.4 Assessment of the Trigeminal System

Different methods are available to assess the sensitivity of trigeminal system in humans in vivo. One challenge a researcher faces is the fact that olfactory and trigeminal system are intimately related. Specifically, most trigeminal stimuli activate the olfactory system in addition to the trigeminal system, and they do so at lower concentrations [46.51]. Therefore, although the intensity of the trigeminal sensation is usually stronger than the olfactory one, there usually is some form of interference from the olfactory input. Several methods have been used to overcome this problem, each of which has its own advantages and disadvantages.

46.4.1 Behavioral Methods

Different methods are available to assess sensitivity in the trigeminal system with behavioral measures. In order to avoid the effects of olfactory interference, one could either test participants with anosmia, i. e., lack of

olfactory perceptions, or focus on tests which rely more or less exclusively on trigeminal sensations.

Behavioral Testing in Anosmia

Anosmia, acquired or congenital lack of olfactory function is a relatively common finding as 1 in 20 is affected in the general population [46.52, 53]. Of course, persons with anosmia do not perceive the olfactory component of mixed olfactory-trigeminal stimuli; thus minimizing olfactory interference. In fact, persons with anosmia can only detect mixed olfactory-trigeminal stimuli by virtue of the test compound's trigeminal component. This can be used to assess the trigeminal impact of a substance, since the percentage of subjects with anosmia who detect a stimulus is correlated with the stimulus' trigeminal impact [46.15, 54]. The typical method to assess olfactory thresholds in persons with normal olfactory function is to ask participants to detect an odorous substance in different concentrations amongst several odorless blanks. If the same stimulus with the same paradigm is used in subjects with anosmia the resulting threshold will be based on the trigeminal sensation [46.55, 56], thus providing a method to assess trigeminal thresholds.

However, one has to be careful when generalizing the findings from persons with anosmia to the general population. We know that anosmia is associated with a reduced trigeminal sensitivity [46.57–60]. The difference in trigeminal sensitivity between subjects with anosmia and participants with a normal sense of smell may be small, and therefore not be detected when investigating only a small number of subjects [46.55, 56, 61], but is a clear limiting factor of this approach.

Tests Depending on Trigeminal Stimulation

In addition to testing subjects who cannot perceive olfactory information, olfactory interference can be excluded in those tests, which depend solely on trigeminal perception. One exemplary method is the lateralization task, in which subjects are asked to identify the nostril to which a stimulus has been delivered (lateralization task). This task is based on the fact that humans are unable to localize pure odorants [46.62, 63], but can do so for stimuli which activate the trigeminal system, mixed olfactory/trigeminal stimuli. Depending on the trigeminal impact [46.44], such stimuli can be localized with high accuracy [46.51, 62, 64–67]. Using this fact allows for two different tasks: first, one can determine the sensitivity of the trigeminal system in a given population or compare sensitivity between two groups of subjects [46.66, 68]; second, one can determine the trigeminal potency of different chemical compounds [46.44, 56]. Thus, by using the lateralization test, one can determine the threshold for a given substance, by using a staircase procedure [46.51]. Such a procedure is often used as an experimental design to assess the thresholds by lowering or elevating the task difficulty until we find the minimally intense stimuli to which the participant would respond accurately. Alternatively, a single concentration of a test compound with strong trigeminal impact may be used in a semiquantitative screening protocol. Here, the sum of correct identifications is used for further statistical analyses. The latter is mostly used in a clinical setting. The lateralization test can be cumbersome, since it is important to keep a relatively long inter stimulus interval of at least 40 s in order to avoid habituation [46.69]. An alternative method is to register response times in a lateralization task [46.70], which has the advantage to provide parametric data with fewer trials and thus shorter test times.

As an alternative, some groups take advantage of the fact that the cornea and conjunctiva of the eye are also innervated by the trigeminal nerve. These epithelia, in fact, allow for the perception of painful sensations, but do not respond to pure olfactory stimuli. Thus, vapor-phase chemical stimuli which evoke the sensations of burning or stinging in the cornea can be used to assess trigeminal irritation thresholds in the eye. However, one has to be careful to avoid co-stimulation of the nose and thus the olfactory system. Corneal thresholds can be used as estimates of trigeminal sensitivity since irritation thresholds obtained in the eye and nose are significantly correlated [46.71].

Another approach is to instruct subjects with a normal olfactory function to distinguish between olfactory and trigeminal sensations. Therefore, after being trained to focus on trigeminal sensations subjects learn to disregard the simultaneous olfactory sensation. Typically, subjects receive instructions such as *have you felt any sensation like burning, stinging, cooling, or tickling?* By using this method, one can assess trigeminal perception thresholds [46.58, 72–74]. However, one has to keep in mind that olfactory interference will occur and can unconsciously affect subjects' responses, which limits the application of this method.

Another method rules out olfactory interference, by using *pure* trigeminal stimuli, stimuli which exclusively activate the trigeminal system. However, a possible concomitant olfactory stimulation is very difficult to exclude. Only few stimuli are available in this category; they include CO_2 or capsaicin. Here it is important to note that CO_2 acts as a trigeminal stimulus only in very high concentrations ($> 100\,000$ ppm) [46.75], which may be dangerous for participants' safety. Thus, CO_2 as a nasal trigeminal stimulus can safely be employed only as brief (< 3 s) stimulus, or alternatively with mouth breathing and velopalatine closure (isolation of the nasal cavity).

46.4.2 Electrophysiological Methods

In contrast to behavioral techniques, electrophysiological measures rely less on participants' response and collaboration. They therefore provide a more objective assessment of trigeminal sensitivity. Still, the problem of olfactory interference is difficult to avoid.

Event-Related Potentials

Trigeminal ERP are electroencephalography (EEG)-derived polyphasic signals obtained at the surface of the scalp [46.76] due to the activation of cortical neurons that generate electromagnetic fields. In other words, trigeminal ERP are a central nervous representation of the processing of trigeminally mediated sensations. The EEG is a noisy signal containing activity from many cortical neurons; therefore ERP have to be extracted from the background activity; this can be done by averaging responses to single stimuli reducing the random background noise [46.77]. Again, single stimulations have to be separated by a relatively long inter-stimulus interval of at least 30–40 s to avoid effects of habituation [46.69]. Further, in order to obtain meaningful averages with an acceptable signal-to-noise ratio, at least 10 single responses have to be recorded resulting in ERP sessions of 45 min to 2 h. This requires subjects' vigilance to be stabilized by simple tasks, such as a tracking task on a computer screen [46.78]. The main advantage of ERP is the very high temporal resolution in the range of milliseconds. However, this comes with a relatively poor spatial resolution. Further, ERP are prone to artifacts; therefore successful ERP recording requires an olfactometer, a device which allows for the delivery of stimuli with:

1. A sharp onset
2. Exactly defined duration
3. Without concomitant mechanical co-stimulation
4. Without concomitant thermal co-stimulation [46.76].

The nomenclature of the trigeminal ERP responses follows that of other sensory domains; a small first positive peak (P1) typically occurs at latencies later than 200 ms, followed by a first major negative peak (N1; approximately 400 ms), and the late positive complex (P2 or P2/P3; approximately 650 ms) [46.77, 78] (Fig. 46.3 for an overview). Largest responses are obtained from central and parietal electrodes; measures of interest are usually amplitudes and latencies of the major peaks. ERP are mostly used in a research setting, since they require a relatively high effort in terms of cost and time. Further, the discussion on olfactory interference also applies to trigeminal ERP: since most trigeminal stimuli also activate the olfactory system, trigeminal ERP will in most cases also contain signals from olfactory processing areas.

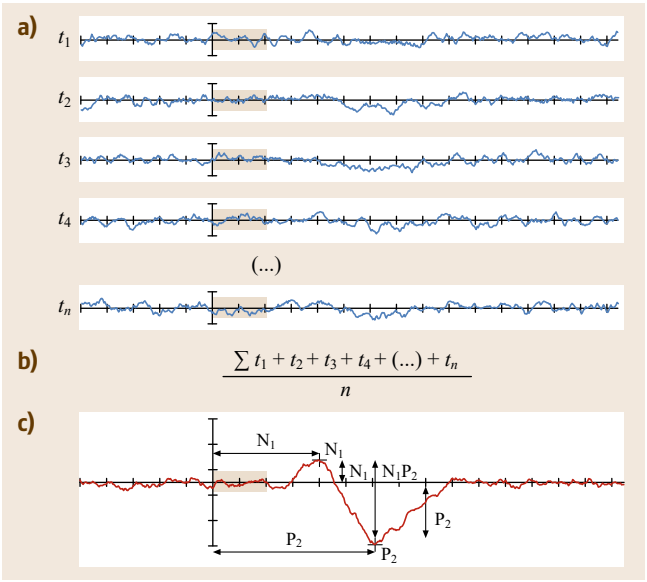

Fig. 46.3a–c Procedure of trigeminal ERP recording: **(a)** Single EEG recordings in response to a 200 ms stimulus (*shaded area* indicates stimulus). Note that response to the stimulus is overlapped by random brain activity. In order to extract specific response, several trials are recorded (t_1 to t_n). **(b)** EEG response are averaged. **(c)** Event-related potential is visible after averaging. The most important peaks, N1 and P2 are indicated by *crosshair*. For each peak one can analyze latency (*blue*; N1 and P2), and amplitude (*red*; baseline to peak amplitude: N1 and P2; peak-to-peak amplitude: N1P2)

Negative Mucosal Potential

Another electrophysiological procedure is relatively free from olfactory interference: the NMP is measured on the level of the nasal mucosa and thus the periphery of the trigeminal system [46.79–83]. The NMP is the summating receptor potentials of chemoreceptors of the trigeminal nerve [46.84] and thus an electrophysiological correlate of trigeminal activation of the nasal respiratory epithelium [46.79–83]. As such it is independent from olfactory stimulation. NMPs are recorded by means of an electrode placed on the respiratory mucosa [46.85]; electrode placement should be done under endoscopical control [46.86]. Again, the signal is averaged, but due to the lower background noise, fewer recordings are needed to obtain a meaningful NMP. In fact, one single recording may be enough for interpretation. Similar to ERP, NMP recording requires an olfactometer for stimulus presentation to assure a sharp stimulus onset and exactly defined duration and to avoid concomitant mechanical and thermal co-stimulation.

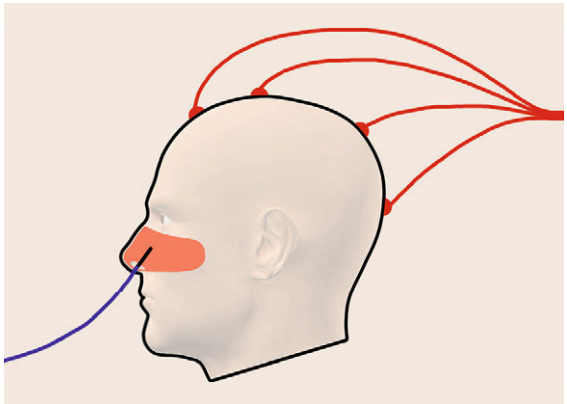

Fig. 46.4 Electrophysiological recording sites: event-related potentials are EEG derived signals and recorded from the surface of the skull (*red*), central responses; negative mucosal potentials are mucosa-generated responses and recorded from the epithelium (*blue*), peripheral responses

NMP consist of a slow negative wave with a latency of approximately 1000 ms [46.87]. The largest NMP indicating the highest sensitivity is observed at the nasal septum, lowest on the nasal floor and the olfactory cleft [46.50, 88]. See Fig. 46.4 for an overview over electrophysiological recording sites.

46.4.3 Brain Imaging

Over the last three decades, several techniques have been made available to neuroscientists, which allow for the investigation of brain structure and brain function in vivo. The most commonly used technique is functional magnetic resonance imaging (MRI), which measures the ratio of oxygenated hemoglobin/deoxygenated hemoglobin in the brain. From this one can infer the activation level of different brain areas (neurovascular coupling). Specifically, researchers can observe which areas of the brain are activated by different tasks. Functional MRI permits the investigation of brain activation with a relatively high spatial resolution. Still, a voxel – the 3D analog of a pixel – typically has the size of 27 mm^3 (3 mm × 3 mm × 3 mm); thus each voxel contains the information of the average activation of ten thousands of neurons. Functional MRI has been used to explore sensory processing; in some studies the trigeminal system has been examined with this technique. Functional MRI has shown that chemosensory trigeminal stimulation leads to the activation patterns which only partly overlap with somatosensory stimuli (brainstem [46.14], thalamus [46.13], SI/SII [46.89], anterior cingulate [46.14]). However, chemosensory trigeminal stimuli also activate olfactory regions, piriform, orbitofrontal, and insular cortex [46.12, 14, 90]. It is worth mentioning that especially orbitofrontal areas are susceptible to image distortion in MRI due to the proximity of the nasal sinuses making the examination of this chemosensory area somewhat difficult.

Other brain imaging techniques can be used to investigate the trigeminal system, but have so far only been used in a few studies. One of these techniques, PET assesses the concentration of radioactive markers. Importantly, it allows for imaging of the orbitofrontal areas of the brain free of distortion; however, this comes with a weaker spatial and temporal resolution compared to functional MRI. PET-based experiments reported additional activation in the amygdala, claustrum, and lateral hypothalamus due to trigeminal chemosensory stimulation [46.91].

46.5 Interactions Between Olfaction and Trigeminal System

As mentioned earlier, most stimuli activate the trigeminal system as well as the olfactory system [46.51, 92, 93]. Additionally, psychophysical and electrophysiological findings report that these two systems interact [46.93], by suppression and enhancing each other [46.92, 94–98]. It is hypothesized that this interaction occurs at three levels:

1. On the stimulus level
2. In the periphery (mucosa)
3. On central levels (brain; Fig. 46.5) [46.92].

In order to understand this interaction, it is necessary to evaluate both sensory systems separately. However the fact that they are usually stimulated together raises a serious methodological challenge. One possibility to overcome this problem is to investigate the trigeminal function in subjects without a working sense of smell [46.93].

46.5.1 Stimuli

Subjects with anosmia are able to detect a large number of volatile chemicals despite the lack of functionality of the olfactory nerve, suggesting that stimuli perception was processed by the trigeminal nerve [46.15]. Moreover, patients with olfactory dysfunction also demonstrate lower trigeminal sensitivity which highlights the interdependence of the two systems [46.99, 100]. Additionally, healthy subjects have higher trigeminal thresholds compared to olfactory ones suggesting

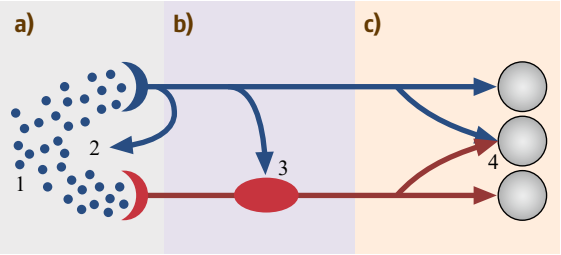

Fig. 46.5 Sites of interaction between the trigeminal system (*blue*) and the olfactory system (*red*). (a) Mucosal level: 1. The same molecules can stimulate both, the olfactory system and the trigeminal system; 2. Trigeminal reflexes may alter nasal patency. (b) Olfactory bulb: 3. Some trigeminal nerve endings terminate in the olfactory bulb. (c) Central nervous system: 4. The trigeminal system and the olfactory system share central processing units

that it takes a higher concentration of an odorant to stimulate the trigeminal nerve as compare to the olfactory nerve [46.51]. Thus, most odorants also activate the trigeminal system. It should be noted however that although most odorants activate both, the trigeminal and the olfactory nerves, there are a few exceptions. For instance, CO_2 activates the trigeminal system with little or no concomitant olfactory stimulation [46.101–103]. On the other hand only a few odorants activate the olfactory nerve selectively with little activation of the trigeminal nerve [46.15] such as vanillin [46.104] decanoic acid [46.15], hydrogen sulfide (H_2S) [46.104] and phenylethyl alcohol (PEA) [46.51, 63].

Further, most irritants that stimulate the trigeminal system can activate the olfactory system as well. This has been shown indirectly, as trigeminal stimulation activates regions typically involved in the olfactory processing such as piriform cortex [46.12, 105], the anterior orbitofrontal cortex [46.12, 106–108], rostral insula [46.12, 109], and the superior temporal gyrus [46.12, 110]. In addition, CO_2, which is usually considered to be a selective trigeminal stimulus, recruited the olfactory pathways in low concentrations [46.111]. Moreover, roughly 10% of piriform cortex neurons responded to both, olfactory and trigeminal stimuli, further highlighting the overlap between the two systems. Altogether, these studies show that both sensory systems exhibit a large extent of promiscuity already on the level of the stimuli.

46.5.2 Indirect Interaction

On top of an interaction at the level of the stimuli, there is also an indirect interaction between the trigeminal and the olfactory systems. For instance, trigeminal reflexes trigger alteration of nasal patency and respiration as well as changes in the mucus covering the epithelium as a result of the stimulation of glands and secretory cells [46.112]. Additionally, electrophysiological studies indicate that odors can modify, via local axon reflex, the spontaneous activity of olfactory receptor cells which triggers the release of different peptides as well as analgesic effects from trigeminal fibers innervating the olfactory epithelium resulting in a modification of odor perception [46.113–115]. Putting together, these studies indicate that other substances can influence the olfactory and the trigeminal systems [46.93].

46.5.3 Peripheral Interaction

In addition to a complete loss of olfaction, subjects with anosmia also have a lower trigeminal function, when assessed with behavioral measures [46.93, 100, 103, 116, 117]. On peripheral levels however, subjects with anosmia exhibit larger NMP, which indicated increased peripheral susceptibility [46.68, 87]. Thus, a model with mixed sensory adaptation/compensation was put forward to explain the interaction between the two systems at a peripheral level. Some neuroanatomical studies provide underpinnings for these interactions. For example, axons of the trigeminal nerve re-enter the central nervous system (CNS) and terminate in the glomerular layer of the olfactory bulb [46.16, 118]. They may be activated by the lateral excitatory network within the olfactory glomeruli [46.119] of a working olfactory system, which is associated with a reduced peripheral responsiveness [46.74]. In the case of olfactory loss, however, this excitatory network is no longer activated; as a consequence, the intrabulbar trigeminal collaterals become disinhibited, resulting in an increased activation of the trigeminal system at peripheral levels [46.93]. In other words, the lack of a functioning olfactory system leads to the disinhibition of the intrabulbar trigeminal collaterals which results in higher NMP activations. This type of mechanism is also found in the gustatory system in which input from the chorda tympani inhibits that of the glossopharyngeal nerve. Damage to the chorda tympani abolishes this inhibition which increases the input from areas innervated by the glossopharyngeal nerve [46.120].

46.5.4 Central Interaction

Studies on patients with anosmia also revealed interactions of the two systems at central levels. When evaluating such interaction at central levels, electrophysiological measures are particularly useful. Trigeminal event-related potentials (tERPs) are electrophysiological responses generated by the cortex. Compared to controls, subjects with acquired anos-

mia exhibited smaller tERPs [46.87], whereas those with congenital anosmia presented similar activations as controls [46.68]. Moreover, low concentrations of isopentyl acetate (an odor with trigeminal components), triggered odor-like responses in the piriform cortex of mice whereas at high concentrations triggered trigeminal-like responses providing support that some neurons of the piriform cortex can be modulated to respond to both types of stimuli [46.121]. Additionally, the duration of olfactory dysfunction and tERP amplitudes are positively correlated [46.59] suggesting that anosmia-triggered reduction of trigeminal sensitivity could improve over time. Therefore, these studies advocate that on one hand, a fully functional trigeminal system relies on the functionality of the olfactory system [46.58–60, 68, 122, 123], and on the other hand, longer the period of time of olfactory loss, better the adaptive mechanisms. FMRI studies provide further evidence as to the key areas of central interaction between olfactory and trigeminal stimulation [46.12, 90]. While each sensory system has unique central processing areas, they share a considerable amount of central processing areas. For example, activation of brainstem, ventrolateral posterior thalamus, anterior cingulate, precentral gyrus, and somatosensory areas are commonly observed following trigeminal stimulation, but not after exposure to odors [46.14]. In turn, activation of amygdala and the ventral putamen is a typical feature of olfactory but not of nonpainful trigeminal stimulation [46.124]. However, both trigeminal and olfactory stimulation activate piriform cortex, the orbitofrontal cortex and the rostral insula [46.14, 124]. Thus, these are the prime candidates on the quest for the areas of interaction between the trigeminal and the olfactory system. In fact, patients with anosmia exhibited, when compared to controls, less activations in, amongst other regions, the orbitofrontal cortex and the insula, but also primary somatosensory cortex [46.89]. This may help explaining smaller tERP amplitudes and higher trigeminal thresholds in this patient group [46.93]. In healthy subjects a mixture of CO_2 (trigeminal stimuli) and PEA (pure odorant) led to higher activations than the sum of activation of CO_2 and PEA presented independently, in both, chemosensory areas (orbitofrontal cortex) and multisensory integration centers (intraparietal sulcus) [46.125].

Putting together, these imaging studies suggest a great overlap between the two chemical senses highlighting the intimate connections between the two systems.

46.6 Clinical Aspects of the Trigeminal System

Different factors may affect trigeminal sensitivity. The most prominent amongst them is aging as older people consistently exhibit lower trigeminal sensitivity [46.83, 123]. Additionally, different diseases and olfactory dysfunction also impact the trigeminal function [46.59]. As previously mentioned, the olfactory and trigeminal systems interact with one another at different levels and therefore examining a clinical population with olfactory and trigeminal dysfunction could shed some light on the co-dependence of the two systems.

46.6.1 Olfactory Dysfunction and Trigeminal Perception

Hyposmia (a reduced sense of smell) and anosmia are relatively common in the normal population. It is estimated that around 15% of the population exhibit hyposmia and 5% suffer from anosmia [46.52, 53]. Generally, typical causes of hyposmia and anosmia include sinunasal disease, head trauma, upper respiratory tract infections, or neurodegenerative diseases whereas congenital anosmia occurs only in around 2% of those with anosmia [46.126–128]. Anosmia and hyposmia are associated with lower trigeminal sensitivity when tested with several different techniques. Specifically, subjects with anosmia exhibit less changes in their breathing pattern when inhaling airborne chemicals [46.122, 129], have lower intensity ratings of trigeminal stimuli [46.60], exhibit higher thresholds to irritants [46.58, 130], and have fewer correct answers on lateralization tests [46.62, 123]. Lower trigeminal chemosensitivity seems to be a general feature of acquired anosmia and independent of its etiology [46.123], while congenital anosmia is somewhat different from acquired anosmia. As a matter of fact, congenital anosmia is associated with similar behavioral measures of trigeminal sensitivity as controls [46.68]. Interestingly, somatosensory measures (such as responsiveness to touch) are not affected by olfactory dysfunction [46.57]. Further, peripheral susceptibility seems to be larger in patients with anosmia (congenital or acquired), in sharp contrast to the findings from central and behavioral measures [46.93].

The interactions between anosmia and the trigeminal system seem not be stable over time: the duration of the olfactory loss and the functionality of the trigeminal system are correlated as the latter gets better over time [46.87]. Further, those 10–30% [46.131] of cases

of anosmia which show recovery of olfactory function actually exhibit even larger peripheral responses than those without recovery [46.87] suggesting additional complex mechanisms taking place. Puttting together, these studies show that acquired anosmia is associated with lower trigeminal sensitivity, while anosmia in general is associated with increased peripheral responsiveness in the trigeminal system.

46.6.2 Trigeminal Dysfunction and Olfactory Perception

As previously mentioned, the trigeminal nerve is the thickest of the cranial nerve which makes it more resistant to trauma compared to the olfactory nerve [46.87]. Consequently, cases in which the trigeminal nerve is damaged are very scarce. In one experiment, local anaesthesia of the middle nasal meatus resulted in an elevation in detection thresholds of *n*-butanol suggesting that blocking the trigeminal system results in a reduced olfactory function [46.132]. In another report, two subjects with a total unilateral destruction of the trigeminal nerve due to the removal of an acoustic neuroma, reported lower odor intensity ratings compared to controls with normal trigeminal function [46.133]. In another case study, a women who, as a result of a meningioma, had a loss of trigeminal function on her left side, exhibited lower olfactory function on the affected side [46.103]. Specifically, NMPs responses, tERPs responses to H_2S (pure odorant) as well as to CO_2 (trigeminal irritant) were reduced on the left side compared to the right side. Additionally, pure odorant detection threshold was 64 times higher on the left side compare to the right side. Puttting together, a damaged trigeminal system may have an impact on olfactory perception highlighting once more the interdependence of the two systems at different levels of odor processing.

47. Cross-Modal Integration in Olfactory Perception

Han-Seok Seo, Thomas Hummel

In everyday life, odorous sensations are a multisensory experience. In other words, odors are perceived before, during, or after inputs of other sensory systems like the visual, gustatory, auditory and tactile system. Thus, multisensory processing of olfactory cues should be assumed as a realistic stimulation for the perception of odors.

Odors are perceived through two main pathways: orthonasal and retronasal routes and odors are processed in a different manner depending on the pathway. Therefore, before reviewing effects of other sensory cues on olfactory perception, both orthonasal and retronasal olfactory systems are discussed at psychophysical, cortical electrophysiological and neuroanatomical levels.

This chapter introduces cross-modal correspondence between olfactory and other sensory cues; it also features the effects of other sensory inputs, such as visual, gustatory, auditory, trigeminal and tactile cues, on olfactory perception, with a focus on key modulators in cross-modal integration.

Overall, most of the cross-modal integration between olfactory and other sensory cues appears to occur at a central nervous level. Many studies have emphasized the role of congruency between bimodal cues in cross-modal integration. The modulatory effect of congruency was found to be influenced by many factors such as odor delivery route (orthonasal and retronasal pathways), selective attention, experience (associative learning), cultural background, type of given task (analytical versus synthetic) and characteristics of a given stimulus.

Odors are rarely experienced without accompanying other sensory cues. For instance, while consuming potato chips, we experience potato chip odor with its visual (shape and color), gustatory (taste), tactile (texture) and auditory (the sound of biting chips) cues. This example shows that olfactory perception is subject to the multifaceted combination of diverse sensory inputs. That is, perceived intensity or pleasantness for a certain odor (e.g., coffee odor) may be altered by different sensory input. For instance, let us assume that someone is asked to describe odor quality of a white wine artificially colored red. Can the person identify it as a white wine? Interestingly, *Morrot* et al. [47.1] showed white wine-colored red was identified as red wine by tasters, indicating that odor perception can be altered by visual input.

This chapter is composed of three main sections:

1. Orthonasal and retronasal olfaction
2. Cross-modal correspondence between olfaction and other sensory cues, and
3. Influences of different sensory inputs on olfactory perception.

There exists a difference in the perception of aromatic volatile compounds depending on whether they are perceived through the nose or the mouth. In this way, as a result of eating and drinking, odors which are perceived via the mouth will be more frequently encountered with other specific sensory cues such as gustatory, somatosensory and tactile stimulations, compared to those perceived via the nose. This point suggests that cross-modal integration of olfactory cues can be different depending on whether the odor is perceived via the nose or via the mouth. Therefore, the concept of a *dual olfactory system* [47.2] will be addressed at psychophysical, cortical electrophysiological and neuroanatomical levels. Next, earlier studies regarding the concept of *cross-modal correspondence* will be reviewed. Finally, this chapter will emphasize influences of different sensory cues on olfactory perception.

47.1 Orthonasal and Retronasal Olfaction

There are two main pathways through which aromatic volatile compounds reach the olfactory epithelium: via the nose and via the mouth (*dual olfactory system*, [47.2]).

47.1.1 Conceptual Definitions

By inhaling or sniffing, airborne volatile compounds arrive at the olfactory epithelium (e.g., sniffing roasted coffee beans), which refers to as *orthonasal olfaction* [47.2]. Orthonasally perceived odors provide the information about the external world associated with edibility, acceptability, toxicity and danger/threat [47.2–5]. It is also well known that body odors carry information about emotional states [47.5, 6], age-related information [47.7], individual identity [47.8], or social interaction [47.9]. In this way, people who have lost their sense of smell tend to be more exposed not only to the risks of poor food intake [47.10], food poisoning [47.11, 12], gas leaks and smoke [47.11, 12], but also to a decrease of social relationships [47.13], compared to people with normal olfactory function.

When people consume foods and drinks, aromatic volatile compounds are released from the food matrix by masticating and swallowing [47.14]. The released volatiles are then pumped from the back of the oral cavity up though the nasopharynx to the olfactory epithelium [47.15, 16]. This pathway of smelling is called *retronasal olfaction* [47.2].

Are humans able to differentiate the location where aromatic volatiles come from? Yes, they are. There is empirical evidence that human subjects can localize whether the odors came from either the front of the nasal cavity or the back of nasal/oral cavity [47.17, 18]. An interesting point to note is that since retronasal olfaction occurs in the mouth, people often refer to the retronasally perceived odors as taste; this is known as *smell-taste confusion* [47.2, 19, 20]. For example, when food being eaten is delicious, people are used to describing it as *It tastes good* rather than *It smells good*. Furthermore, certain languages, such as Swiss German, have adequate vocabulary of expressing *tasting*, but not *smelling* [47.18].

47.1.2 Comparison Between Orthonasal and Retronasal Olfaction

As summarized in Table 47.1, orthonasal and retronasal olfaction are different in terms of odor pathway, odor sensitivity and identification, odor-associated information and odor-activated brain regions.

Psychophysical Level

Generally, humans are more sensitive (lower detection/recognition threshold) when they smell the odors

Table 47.1 Comparison between orthonasal and retronasal olfaction

	Orthonasal olfaction	Retronasal olfaction
Delivery route	Through the external nares	From the back of the oral cavity through the nasopharynx
Information	External worlds	Ingested substances (e.g., foods)
Odor sensitivity	Orthonasal perception > retronasal perception At suprathreshold level, orthonasally perceived odors are more intense	
Odor identification	At low concentration, orthonasal perception is more accurate At high concentration, there is little or no difference	
Differences in neural activation	Anticipatory phase (e.g., food availability)	Consummatory/reward phase (e.g., foods being eaten)

via the nose (orthonasal route) than via the mouth (retronasal route) [47.21, 22]. At suprathreshold levels, humans perceive odors as being more intense when the odors are delivered through the orthonasal route than the retronasal one [47.17, 22–25]. A plausible explanation for the relatively lower sensitivity for retronasal odors can be found in the fact that airflow from the pharynx to the olfactory epithelium may differ from airflow pattern seen for orthonasal stimulation, resulting in a lower concentration of odors reaching the olfactory cleft [47.18]. Furthermore, since humans experience retronasal odors together with other sensory attributes (taste and tactile components), mechanic movements (mastication and tongue movement) and salivation in the mouth ([47.14, 15]; for a review see [47.27]), humans' attention to the retronasal odors may be decreased [47.28, 29], thus leading to a lower sensitivity for retronasal odors (Table 47.1).

During normal breathing, humans identify aromatic volatiles more correctly when they are perceived via an orthonasal route than via a retronasal one [47.30–32]. However, the effect of odor delivery route on odor identification is not observed when subjects receive relatively highly concentrated odorants or when they perform deep breathing [47.32].

Cortical Electrophysiological Level

Clinical studies using olfactory event-related potentials (OERPs) demonstrate that orthonasal and retronasal stimuli produce different cortical electrophysiological responses [47.26]. *Landis* et al. [47.26] observed patients who exhibited olfactory loss when stimuli were presented orthonasally but not retronasally. Figure 47.1 shows recordings from a 54-year-old woman who lost her sense of smell for more than 10 years following an infection of the upper respiratory tract. While there were no detectable OERPs in response to orthonasal stimulation (A), retronasal stimulation with hydrogen sulphide (H_2S) produced noticeable activation (B). This result is in line with her result of psychophysical tests measuring orthonasal or retronasal olfactory function. That is, corresponding to the difference in OERPs, this patient correctly identified 35% of the retronasally perceived odors, whereas she correctly identified only

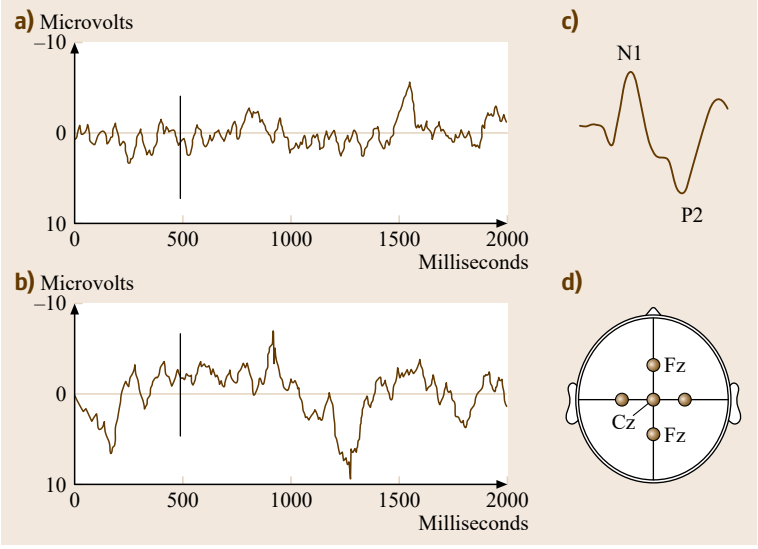

Fig. 47.1a–d Olfactory event-related potentials (OERPs) from a female patient who lost her orthonasal sense of smell following an infection of the upper respiratory tract. OERPs (recording position, Cz; for a schematic drawing of the recording sites, see **(d)**) were measured in response to orthonasal **(a)** and retronasal **(b)** stimulation with hydrogen sulfide (H_2S, 4 ppm). A schematic drawing of an OERP **(c)** and the recording sites **(d)** of electrodes are shown (after [47.26])

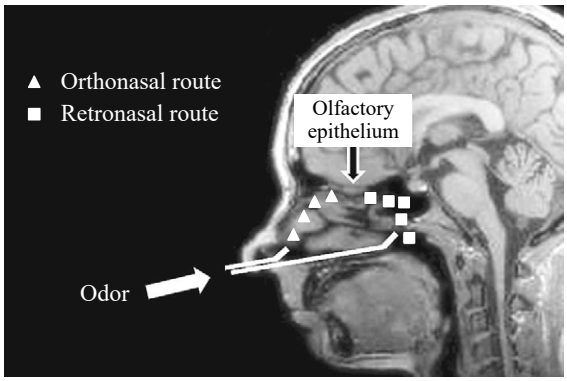

Fig. 47.2 A model for providing retronasal odor stimulation designed by [47.22]. This model allows odor stimuli to reach the olfactory epithelium through either orthonasal or retronasal route at approximately the same concentration and time course

12% of the orthonasally perceived odors. These clinical observations suggest that retronasal function may constitute a separate chemosensory entity [47.26].

In healthy people, when compared to retronasal stimulation, orthonasal stimulation appears to produce greater peak amplitudes and shorter latencies in the olfactory event-related potentials [47.22, 33]. However, when a nonfood odor, which is typically sniffed, is presented retronasally, subjects may be surprised due to this unfamiliar stimulation, leading to an increase in OERP peak amplitudes (especially, in the late positivity, P2) [47.25]. Generally, while the N1 peak, as shown in Fig. 47.1c, is associated with stimulus characteristics such as intensity and quality, the late positivity P2 is strongly related to cognitive processing of olfactory information [47.34, 35].

Neuroanatomical Level

Brain imaging studies demonstrate similar, yet different patterns of brain activation in response to orthonasal and retronasal odor stimulations [47.17, 36, 37]. *Cerf-Ducastel* and *Murphy* [47.36] demonstrated brain regions in response to retronasal stimulation by odorants delivered in aqueous solution. The brain regions activated by retronasal stimulation, such as piriform cortex, orbitofrontal cortex (OFC), hippocampus, amygdala and insula, are known as the regions activated by orthonasal stimulation. In other words, some brain regions are associated with both orthonasal and retronasal odor stimulation [47.36]. *De Araujo* et al. [47.37] also showed that anterior ventral insula was activated by both orthonasal and retronasal odor stimuli.

In a subsequent study, *Small* and colleagues [47.17] provided four different odors (food and nonfood odors) via the orthonasal and retronasal routes and measured brain responses using the functional magnetic resonance imaging (fMRI) technique. In earlier studies [47.36, 37], retronasal odors were presented via the oral cavity, but this may also activate other sensory attributes such as thermal, mechanical and/or gustatory stimulation [47.18]. To examine the sole effect of retronasal odor stimulation without other sensory influences, *Small* et al. [47.17] used a technique of odor administration which allows the presentation of odor stimuli directly to the epipharynx above the soft palate [47.22], as illustrated in Fig. 47.2. The identical odors produced more neural activation in the brain regions (e.g., a region of the Rolandic operculum at the base of the central sulcus) that typically respond to the stimulation of oral cavity when they were presented via retronasal route than via orthonasal route [47.17]. This result suggests that subjects perceive retronasally administered odors as originating from the oral cavity [47.17, 19]. Furthermore, in their study [47.17], while orthonasally perceived chocolate odor showed greater neural activation in the insular, opercula, thalamus, hippocampus, amygdala/piriform and caudolateral OFC, retronasally perceived chocolate odor demonstrated larger activation in the perigenual cingulate, posterior cingulate, medial OFC and superior temporal gyrus. However, these differences were not obtained for nonfood odors. The different pattern of neural responses between orthonasal and retronasal odor stimuli seems to be related to associative learning (experience) and/or reward context (anticipatory phase versus consummatory phase) [47.17]. For example, since food odors, but not nonfood odors, are experienced in the retronasal route (oral cavity), only the food odor (i. e., chocolate odor) led to neural response difference between orthonasal and retronasal odor stimulations. In addition, brain regions activated by orthonasally perceived odors were associated with the anticipatory rewards (i. e., food availability), whereas those preferentially responding to retronasal odors were related to the consummatory rewards (i. e., foods being eaten) [47.17]. In that orthonasal and retronasal odors are mainly perceived before and during eating, those results are understandable.

47.2 Cross-Modal Correspondences Between Olfactory and Other Sensory Cues

The terms *synaesthesia*, *synaesthetic correspondence*,or *synaesthetic association*are characterized by [47.38, p. 36], [47.39–41]:

> *a conscious experience of systematically induced sensory attributes that are not experienced by most people under comparable conditions.*

That is, synaesthesia refers to a phenomenon that one sensory cue uniquely induces conscious experience of another sensory cue in certain individuals; for example, seeing colors in response to pain [47.42]. *Martino* and *Marks* [47.42] called this form of synaesthesia *strong synaesthesia*, which is rarely observed (approximately 1 out of 2000 people) [47.43].

By contrast, *cross-modal correspondence* or *cross-modal association* does not mean that one sensory cue necessarily induces conscious experiences of another sensory cue [47.44]. The terms cross-modal correspondence or cross-modal association refer to [47.45, p. 973], [47.42, 46]:

> *a compatibility effect between attributes or dimensions of a stimulus (i. e., an object or event) in different sensory modalities (be they redundant or not).*

The cross-modal correspondences appear to be shared by many individuals (be often universal) and exist between all possible pairs of sensory modalities [47.45]. Cross-modal correspondences are innate and they are developed by perceptual learning [47.47]. Cross-modal correspondences seem to be considered as a form of *weak synaesthesia*, being characterized by [47.42, p. 61]:

> *cross-sensory correspondences expressed through language, perceptual similarity and perceptual interactions during information processing,*

but this idea remains controversial [47.44]; thus, further clarification is needed.

Cross-modal correspondences of olfactory cues with other sensory cues are reported below.

47.2.1 Cross-Modal Correspondences Between Olfactory and Visual Cues

Table 47.2 demonstrates examples of the cross-modal correspondences between olfactory and visual cues. It has been reported that certain odors can be matched with specific visual cues such as color brightness [47.48–51], color hue [47.46, 52] and symbol/shape [47.53, 54].

Color Brightness

Von Hornbostel [47.48] provided empirical evidence of the cross-modal correspondences among colors, tones and odors based on their brightness. High pitch tone and light odor (e.g., lemon odor) might be paired according to their similar characteristics of brightness [47.48, 49]. Furthermore, odor intensity was found to be inversely matched with color brightness. For example, stronger odors appear to be matched with darker colors [47.51].

Color Hue

Gilbert and colleagues [47.46] asked subjects to select a color chip that best represented each odor following sniffing 20 fragrance odors one after another. Subjects could match certain odors with specific color chips. For example, cinnamon aldehyde odor was paired with red color; this relationship seems to be mediated by a familiar name of popular cinnamon-flavored candy, *red hots* [47.46]. Similar results were also observed in other studies [47.52]: for example, strawberry odor and pink color; spearmint odor and turquoise color. Using the implicit association test (IAT), the color-odor associations were found to be strong enough for the subjects to implicitly respond to the associations, without relying on explicit cross-modal matching [47.52]. Subjects implicitly responded more accurately and quickly to compatible matching (e.g., strawberry odor and pink color) than to incompatible matching (e.g., spearmint odor and pink color). Furthermore, the color-odor associations were shown to have a high test-retest correlation of 0.53 after a 2-year interval [47.46], indicating that the cross-modal correspondences of colors and odors are robust and replicable.

Symbol/Shape

Several studies have demonstrated empirical examples of cross-modal correspondences between odors and abstract symbols/shape [47.53, 54]. *Seo* et al. [47.53] asked subjects to match 8 odors with 19 different abstract symbols. As illustrated in Fig. 47.3, pleasant odors (e.g., banana, honey melon, mint, vanilla and violet odors) were matched with circle or curve shaped symbols, while unpleasant odors (e.g., parmesan cheese, pepper and truffle odors) were matched with angular or square shaped ones, reflecting that emotional similarity between bimodal cues may mediate the cross-modal correspondence of symbols/shapes and odors. In

Table 47.2 A list of studies showing cross-modal correspondences between olfactory and visual cues

Olfactory cues	Visual cues	References
Orthonasal odors		
Fragrances/food odors	Color brightness	[47.48]
Fragrances	Color brightness	[47.50]
Fragrances/food odors	Color brightness	[47.51]
Fragrances	Color brightness	[47.47]
Fragrances/food odors	Color hue (Munsell color system)	[47.46]
Fragrances/food odors	Color hue (color patches)	[47.52]
Masculine/feminine fragrances	Color hue	[47.55]
Fragrances	Color hue	[47.56]
Fragrances/food odors	Symbols/shapes	[47.53]
Fragrances/food odors (wine)	Angular and rounded shapes	[47.54]

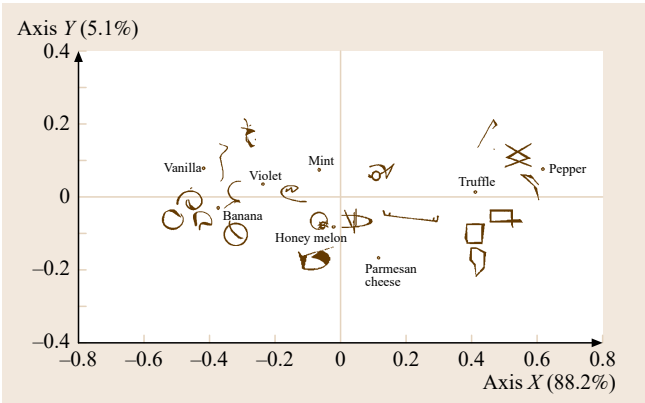

Fig. 47.3 Cross-modal association between abstract symbols and odors. The correspondence analysis shows that certain odors can be matched with specific odors. Overall, pleasant odors are paired with circle or curve shapes, whereas unpleasant odors are paired with angular or square shapes (after [47.53])

a more recent study [47.54], subjects were asked to rate how much 20 individual odors are associated with an angular or rounded shape. The angular shape was matched with more intense, sour and unpleasant odors (e.g., lemon and pepper odors), while the rounded shape was found to be best matched with more subtle, sweet and pleasant odors (e.g., raspberry and vanilla odors).

47.2.2 Cross-Modal Correspondences Between Olfactory and Gustatory Cues

As a result of eating and drinking, gustatory cues are often perceived with olfactory cues (especially retronasal odors). Thus, people tend to confuse the co-occurrences of olfactory and gustatory cues in a mouth as a unitary sensation [47.2, 57]. In this way, when people sniff odors, they often describe the stimulation as *taste-like sensation* [47.58, 59], and they are used to matching certain aromas/flavors with specific tastes. For instance, caramel or vanilla aromas/flavors are commonly paired with sweetness, while lemon aromas/flavors are frequently paired with sourness.

47.2.3 Cross-Modal Correspondences Between Olfactory and Auditory Cues

Previous psychophysical studies demonstrated examples of cross-modal correspondences between olfactory and auditory cues [47.60–65]. As shown in Table 47.3, people match certain odors perceived via orthonasal route (odor, aroma, or scent) with specific pitches [47.60, 66]. For instance, in an earlier study, subjects could consistently match certain auditory pitches (e.g., 200 and 1000 Hz) with specific fragrant odors based on odor quality cues rather than odor intensity cues [47.60].

A recent study by *Crisinel* and *Spence* [47.63] demonstrated that certain odors, often found in wine, could be matched not only with specific pitches, but also with timbres of musical notes. For example, fruit odors were consistently matched with high-pitched sounds. Also, pleasant odors were paired with the tone of a piano instrument more than tones of other instruments. More recently, *Crisinel* et al. [47.65] reported similar findings showing the cross-modal correspondences between odors and pitches. As odors judged as *happier*, *sweeter*, *brighter* and *more pleasant* (e.g., iris flower and candied orange odors), they were well matched with the instrumental sounds of higher pitch (e.g., tone of piano).

Table 47.3 presents that people can match retronasally perceived odors (flavors) with specific timbres of musical notes [47.61, 62, 64]. Flavors were found to be also matched with specific pitches of musical notes [47.61, 62]. However, the cross-modal association of flavors and pitches appears to be relatively weaker compared to the association with timbres [47.61, 64]. That is, the association of flavors

Table 47.3 A list of studies showing cross-modal correspondences between olfactory and auditory cues

Olfactory cues	Auditory cues	References
Orthonasal odors		
Essential oils	Pitch	[47.66]
Fragrances and essential oils	Pitch (200 and 1000 Hz)	[47.60]
Wine aroma kit	Pitch	[47.63]
Aroma kit	Pitch	[47.65]
Wine aroma kit	Timbre (instrumental note)	[47.63]
Aroma kit	Timbre (instrumental note)	[47.65]
Retronasal odors (flavors)		
Flavors (foods and flowers)	Pitch	[47.61]
Flavors (milk)	Pitch	[47.62]
Flavors (foods and flowers)	Timbre (instrumental note)	[47.61]
Flavors (milk)	Timbre (instrumental note)	[47.62]
Flavors (chocolate)	Timbre (instrumental note)	[47.64]

(retronasal odors) and pitches has not been consistently observed in previous studies [47.61, 64]. While a cross-modal correspondence of flavors with timbres appears to be mediated by subjective hedonic valence (e.g., pleasantness versus unpleasantness), the correspondence with musical pitches seems to be driven by other factors, such as *potency* (strong versus weak) and *activity* (active versus passive), of bi-modal cues [47.61, 64].

Deroy et al. [47.67] proposed three hypotheses that explain the cross-modal correspondences between olfactory and auditory cues. Firstly, auditory and olfactory perceptions may share a common amodal dimension such as space (*the amodal hypothesis*). Secondly, another independent dimension, such as emotional similarity of bimodal cues (e.g., pleasantness or unpleasantness), may mediate the olfactory and auditory association (*the indirect hypothesis*). For example, olfactory and auditory cues can be paired because both of them are pleasant. Finally, a network of cross-modal correspondences between sensory cues (or dimensions) may be formed based on statistical (or nonstatistical) co-occurrences (*the transitivity hypothesis*). Furthermore, these hypotheses would be applied to cross-modal correspondences of olfactory cues with other senses (visual or gustatory cues).

47.3 Influences of Visual Cues on Olfactory Perception

Olfactory perception is found to be affected by other sensory cues such as visual, gustatory, somatosensory, auditory and tactile cues as described below. The cross-modal integration between olfactory and visual cues will be introduced with a focus on key modulators in individual integration.

47.3.1 Congruency Between Bimodal Cues

A *congruency* between bimodal cues is the concept that has been most often used in many studies investigating the cross-modal integration involving the sense of smell. Thus, prior to introducing the effect of congruent visual cues on olfactory perception, a concept of the congruency will be addressed.

In the cross-modal study using olfactory and gustatory cues, *Schifferstein* and *Verlegh* [47.68] defined the congruency as *the extent to which two stimuli are appropriate for combination in a food product*. However, since cross-modal integrations of olfactory cues with other sensory cues are not limited to food products, in this chapter the congruency is characterized as *the extent to which bimodal stimuli are appropriate for combination in everyday life* as modified by [47.69, p. 6]. Three types of congruency are proposed: *synaesthetic congruency*,*spatiotemporal congruency*, and *semantic congruency* [47.45, 70]. Synaesthetic congruency refers to *the correspondences between more basic stimulus features (e.g., pitch, lightness, brightness, size) in different modalities* [47.45, p. 972]. Aforementioned examples of *cross-modal correspondence* are close to synaesthetic congruency. Spatiotemporal congruency refers to *the proximity between two unisensory events in time and space* [47.70, p. 992], which has been a main theme of multisensory integration of visual and auditory cues. Finally, semantic congruency refers to *a cross-modal match (versus mismatch) in terms of the identity or meaning of the unisensory component stimuli* [47.70, p. 992]. While synaesthetic congruency (or cross-modal correspondence) occurs mainly between

the more basic (low-level) cues, semantic congruency exists between more complex (high-level) cues [47.45]. For example, a high pitch note can be synaesthetically congruent with a bright color (versus a dark color), whereas it can be semantically congruent with a violin (versus a cello).

Effects of Congruent Visual Cues on Odor Detection, Discrimination and Identification

People have a difficulty in identifying odors without verbal descriptors/labels even when they are everyday odors [47.71]. However, most people are unaware of their poor ability to identify odors because they usually smell the odors with visual cues which assist in identifying the odors [47.72]. For instance, people usually smell coffee aroma while looking at the coffee placed in their mugs. Another example is that people tend to expect a specific flavor of a beverage from the color of the beverage [47.73, 74]. According to *Shankar* and her colleagues' study [47.74], more than half of British subjects could expect lemon flavor when they looked at yellow-colored beverage. Likewise, visual cues may lead people to expect specific odors/flavors associated with the visual inputs based on their experience and associative learning.

Congruent visual cues, such as colors and pictures, facilitate odor detection [47.53, 75], discrimination [47.76] and identification [47.75, 77–80]. For example, people detect orthonasal odors more quickly and correctly when they are presented with semantically congruent visual cues (colors or images) compared to incongruent visual cues [47.53, 75, 77, 78]. On the other hand, when the color of the odorant is not seen (clear odorant) or is inappropriate (e.g., red color for banana odorant), people tend to be slower and less accurate in identifying the odor [47.72].

The enhancement effect of congruent visual cues on the accuracy of odor identification has also been found in the cross-modal integration between visual cues and retronasal odors [47.73, 81–83]. For example, *Blackwell* [47.83] found that 79 and 92% of subjects correctly identified the flavors of orange and blackcurrant solutions when the solutions were colored appropriately. However, the correction rates of identifying the orange and blackcurrant solutions were reduced to 31 and 29% when they were colored inappropriately.

The facilitation effect of congruent visual cues (particularly colors) on odor identification is more obvious when the olfactory cue is more familiar [47.77]. For example, if individuals consume bananas every day but they consume a lemon once a year, they are expected to have a stronger association of yellow color with banana odor rather than with lemon odor. As a result, when the individuals are exposed to yellow color, they are more likely to retrieve the image of banana than of lemon. In this way, yellow color assists the individuals in detecting, discriminating and identifying the banana odor. Likewise, congruent visual cues increase the speed of identifying their corresponding odors, as well as the correction rate of identifying them [47.72].

Herein, one can raise a question. Do red-colored solutions increase the ability to identify the flavors of all reddish foods and beverages, such as strawberry, apple, tomato? The answer would be *yes* or *no*. Aforementioned, the effect of congruent visual cues appears to be dependent on the strength of color-flavor association. *Zampini* et al. [47.73] reported that inappropriate colors deteriorate the ability to identify flavors only when the connection of color and flavor is strong enough. In addition, the congruency effect is modulated by the degree of discrepancy between individuals' expectation-based flavor and the actual perception of the flavor. Based on the *assimilation-contrast* theory [47.84–86], as long as the degree of discrepancy is so small that the individuals can admit that the combination of color and flavor is congruent, the color cue helps in identifying the flavor. By contrast, if the discrepancy is so big that individuals cannot allow that the combination of color and flavor is congruent, the color cue may reduce the individuals' ability to identify the flavor [47.74, 80, 87]. This idea reflects that the effect of congruent visual cues on odor perception is mediated by a *top-down* process at the cognitive level, and this point has been supported by numerous empirical evidence at psychophysical [47.1, 74, 88, 89] and neuroanatomical [47.75, 90] levels. As previously addressed, when a white wine was artificially colored with a red dye, wine tasters described its sensory attributes by using descriptors related to red wine [47.1]. That is, visual inputs alter not only olfactory expectation, but also olfactory perception.

Effects of Congruent Visual Cues on Odor Pleasantness

Likewise, congruent visual cues assist people in identifying the served odors and in being familiar with them, which may result in increasing odor pleasantness. It is generally understood that people like odors significantly more when they are presented with congruent (or appropriate) visual cues compared to when presented with incongruent (or inappropriate) visual cues and/or no additional visual cues [47.78, 91]. However, it should be noted that congruent visual cues do not always enhance odor pleasantness [47.53, 87]. When the hedonic tone of odor is unpleasant, congruent visual cues can increase the unpleasantness of the odor [47.53, 87]. *Seo* et al. [47.53] have demonstrated that congruent symbols increased not only pleasantness for pleasant

odors (2-phenylethanol), but also unpleasantness for unpleasant odors (1-butanol). That is, congruent visual cues appear to strengthen their own hedonic valence of the odors.

Furthermore, incongruent (or inappropriate) visual cues decrease odor pleasantness, which may result from the reduced ability to correctly identify the odors paired with incongruent (or inappropriate) visual cues [47.72, 78]. Notably, in the study conducted by *Zellner* and colleagues [47.78], correctly identified odors were always more pleasant than incorrectly identified odors even when the odors were inappropriately colored. This finding indicates that odor identification plays a critical role in modulating the effect of visual cues on odor pleasantness. Furthermore, these results support the above notion that congruent visual cues facilitate odor identification, thereby enhancing odor pleasantness.

Effects of Congruent Visual Cues on Odor Intensity

An effect of congruent visual cues (especially colors) on perceived intensity of orthonasal and retronasal odors remains unclear because previous results regarding the color effect have not shown a consistent pattern ([47.53, 73, 91–93]; for a review, [47.94]).

It appears that colors affect perceived intensity of odors in a different manner as a function of the route of administration of the odor (orthonasal route versus retronasal route). Overall, when odorants are sniffed through the nostrils, color cues increase perceived intensity of odors [47.23, 92, 93, 95]. *Christensen* [47.95] found that when subjects sniffed appropriately colored processed cheese, they perceived its odor more intense compared to when they sniffed inappropriately (e.g., bright blue) colored cheese. *Zellner* and *Kautz* [47.93] also found that orthonasal odors of flavor solutions (e.g., strawberry flavor) were rated more intense when the solutions were appropriately colored (e.g., red) than when colorless; however, the color-induced odor enhancement did not result from certain color-odor association. That is, the effect of color cue on perceived intensity of the orthonasal odor was not modulated by the congruency between bimodal cues, but by the inherent presence of the color cue. Orthonasal odor intensity seems to be influenced by color intensity whether the color is appropriate for the odor or not. The perceived intensity of orthonasal odor is usually more intense in dark-colored solutions than in light-colored solutions. Furthermore, the orthonasal intensity is often rated weakest in colorless solutions. However, the relationship between the intensities of color and odor has not always been found [47.92, 93].

In contrast to the color-induced orthonasal odor intensity, color cues tend to show no influence or even reduce the intensity of odors when the odorants are smelled through the mouth [47.23, 73, 95]. What makes the difference between orthonasal and retronasal odors in the effect of color on perceived odor intensity? *Zellner* [47.72] argues that the color-enhanced orthonasal odor intensity might be due to a combination of 1) the actual odor experience and 2) the color-induced conditioned percept elicited by the previous experience associated with the pair of color and odor. For example, the odor percept caused by looking at a red solution might be an odor blend of red-colored foods and drinks that the individual has previously experienced [47.72]. In addition, *Zellner* [47.72] proposes that the color-reduced retronasal odor intensity might be due to 1) relatively less visible color cues and 2) intensity contrast between orthonasal and retronasal odors. For example, when subjects try tasting a colored odorous solution, they first see the colored solution, eliciting the color-enhanced orthonasal odor intensity of the solution. Subsequently, when the colored solution is placed in the mouth for judging its retronasal odor intensity, the color cue is no longer available. Thus, the subjects perceive the retronasal odor without the color cue and therefore the retronasal odor might be perceived weaker than the orthonasal odor, resulting in the intensity contrast between the orthonasal and retronasal odors. In this way, color cues may affect odors differently depending on the odor delivery route [47.72].

Compared to the effect of color, relatively little attention has been paid to an influence of other visual cues such as images on odor intensity. It has been reported that visual images such as pictures and symbols also modulate odor intensity [47.53, 91]. *Sakai* et al. [47.91] found that orthonasal odor intensity was increased when the odor was presented with an appropriate picture than when presented with an inappropriate picture. Using olfactory event-related potentials (OERPs), *Seo* et al. [47.53] showed that for phenyl ethyl alcohol (PEA) odor, in comparison to the incongruent symbol, a congruent symbol significantly enhanced the amplitude of the N1 peak, which is associated with stimulus intensity. Based on previous findings, the effect of congruent visual cues on odor intensity appears to be stronger in an image-odor association than in a color-odor association. Compared to the color-odor association, visual images may have a stronger connection with the odors. Due to this point, the visual image-elicited conditioned percept, in comparison to a color-induced conditioned percept, can be more profound and thus the visual image cues might show greater impacts on odor intensity than color cues.

Neuroimaging Evidence for the Effects of Congruent Visual Cues on Odor Perception

Previous neuroimaging studies have found that the left orbitofrontal cortex (OFC) is predominantly involved in the cross-modal integration between visual and olfactory cues [47.75, 96], while the right OFC is more engaged in an odor perception [47.97]. Using fMRI, *Österbauer* et al. [47.96] showed the super-additive neural activation in the OFC in response to congruent color-odor pairs (congruent color-odor pairs > (odors + colors)). Also, the left OFC was more activated in response to a congruent color-odor combination than incongruent combination or odor alone. Furthermore, *Gottfried* and *Dolan* [47.75] found that subjects detected odors more quickly and accurately when the odors were provided with semantically congruent pictures than when provided with incongruent pictures. Further, neuroimaging revealed that the congruent image-induced odor detection and identification was mainly associated with the anterior hippocampus and rostromedial OFC.

47.3.2 Cultural Background

As shown in numerous studies, cross-modal interactions between olfactory and other sensory cues are dependent on experience and associative learning [47.98, 99]. This idea has been supported by studies demonstrating the effect of cultural background on the cross-modal integration between olfactory and visual cues [47.74, 100]. *Shankar* et al. [47.74] sequentially displayed each of the beverages of seven different colors to British and Taiwanese participants and asked them to write down the first flavor or beverage that came to their minds based solely on the color of beverages. Interestingly, a large portion (70%) of British subjects associated the brown beverage with a *cola* flavor (none expected it would be a grape flavor), while almost half (49%) of the Taiwanese subjects associated the same color beverage with a *grape* flavor (none expected it would be a cola flavor). This result appears to be due to a cultural difference between the experience of British and Taiwanese subjects with the brown beverage in their home countries. For example, cola is the most common brown beverage in Great Britain, while grape juice or drink is a common brown beverage in Taiwan [47.72]. *Wan* et al. [47.100] also showed such a cultural difference in the color-odor association between US and Chinese adults. For instance, many American subjects paired the red drink with a *cherry* flavor, whereas Chinese subjects paired it with a *watermelon* flavor.

These findings suggest that the effect of congruent colors on olfactory perception can be different as a function of cultural background. Let us assume that British and Taiwanese subjects are asked to identify a flavor of the brown-colored solution including the mixture of cola and grape flavors. Based on the above finding [47.74], it can be expected that British subjects, in comparison to Taiwanese subjects, may detect and identify the cola flavor more quickly and accurately from the solution because they are apt to judge brown color to be congruent with cola flavor since brown color and cola flavor are strongly connected by their experiences; however, further study is needed to validate this assumption.

47.4 Influences of Gustatory Cues on Olfactory Perception

Odors are perceived with concurrent gustatory stimulation in the mouth while consuming foods and drinks. As a result, it is frequently observed that patients who have lost their sense of smell complain of their taste-loss in the clinic, although they have a normal sense of taste (referred to as *flavor disturbance*) [47.101, 102]. So far, most of the studies regarding the cross-modal integration between olfactory and gustatory cues focused on effects of olfactory stimulation on gustatory perception ([47.68, 103–109], for a review, see [47.29, 99, 110–112]). For example, it has been found that congruent odors increase the perceived intensity of taste stimuli although the enhancement effect was not consistently obtained in earlier studies [47.113, 114].

This section will focus more on the effect of gustatory cues on olfactory perception.

47.4.1 Congruency Between Bimodal Cues

Congruency between olfactory and gustatory cues is a key modulator in their interaction. As seen below, it has been found that congruent gustatory cues affect odor localization, odor intensity and pleasantness.

Effects of Congruent Gustatory Cues on Odor Localization

Using the aforementioned technique (Fig. 47.2), several studies demonstrated that subjects were able to differentiate whether an odorous stimulus was coming from the tip of the nose or from the back of the mouth [47.17, 22]. These findings indicate that nasal airflow direction (anterior delivery versus posterior delivery) across the olfactory epithelium may be adequate to generate

oral localization of the odorous stimulus [47.17, 22, 115].

Von Békésy [47.116] asked subjects to localize the place of odor stimulation when a taste stimulus was presented to the mouth before, during, or after delivering odors through the nose. When the subjects received the odor and taste stimuli (e.g., clove odor and acid solution) simultaneously, they perceived them as a single sensation occurring in the mouth. Based on the result of *von Békésy* [47.116], it seems that the nasal airflow direction is not a necessary condition because subjects could experience the oral localization although the odor was delivered via the orthonasal route [47.117]. *Murphy* and *Cain* [47.20] suggested that the trigeminal system may integrate olfactory and gustatory systems into a single perceptual system during eating. That is, tactile (somatosensory) or trigeminal stimulation in the mouth is expected to capture taste [47.20, 118], thereby inducing the odor localization to the mouth. In a recent study, *Stevenson* et al. [47.117] demonstrated that when subjects sniffed an odor stimulus in the absence of a somatosensory or taste stimulus in the mouth, they accurately localized the location of the odor (at nose). However, in the presence of a taste stimulus in the mouth, subjects localized the orthonasally presented odor to the mouth. *Stevenson* et al. [47.117] proposed that taste stimulation may induce subjects' attention toward the taste stimulus, resulting in an impaired ability to selectively attend to an odor stimulus. Opposite to *Murphy* and *Cain* [47.20] and *Green's* [47.118] suggestion, somatosensory stimulation alone was not a sufficient condition to generate the oral localization when an odor stimulus was sniffed [47.117]. Contrary to taste stimulation, during involuntary swallowing, breathing and talking, oral somatosensory stimulation is constantly present in the mouth [47.117]. Due to such a frequent occurrence, oral somatosensory stimulation seems to be unable to capture selective attention toward it [47.117]. In this way, while a minimum level of somatosensory stimulation may be a necessary condition, somatosensory stimulation alone is relatively ineffective at eliciting oral localization [47.117].

Lim and *Johnson* [47.119, 120] and *Lim* et al. [47.121] demonstrated an oral localization of retronasal odor (retronasal odor referral). Specifically, *Lim* and *Johnson* [47.119] asked subjects to localize an odorous stimulus when food odors were inhaled through a straw and exhaled through the nose in the presence or absence of taste stimuli (water or various taste solutions) in the mouth. When vanilla and soy sauce odors were simultaneously presented with sucrose and sodium chloride solutions, subjects reported that those odors were present on their tongue. This finding indicates that the referral of retronasal odor to the tongue depends on the presence of its congruent taste [47.119]. This effect (i. e., congruent taste-induced odor localization to the tongue/mouth) was also obtained in a more natural food condition (e.g., flavored gelatin samples) [47.120]. However, a presence of tactile stimulation alone was not a sufficient condition to enhance the retronasal odor referral [47.120].

Effects of Congruent Gustatory Cues on Odor Sensitivity and Intensity

As previously mentioned, relatively few studies have been conducted to answer the question as to whether congruent taste increases olfactory perception. *Dalton* and her colleagues [47.122] found that taste stimulus enhances sensitivity to orthonasal odor. For example, following ingestion of 10 mL of the respective solutions (saccharin, monosodium glutamate (MSG), or deionized water), subjects sniffed the odor of benzaldehyde (cherry/almond odor) at subthreshold level. Subjects' sensitivity to the odor was increased in the presence of congruent taste (i. e., saccharin) in the mouth, while their odor sensitivity was decreased in the presence of incongruent taste (i. e., monosodium glutamate) or of deionized water.

Recent studies demonstrated that tasting substances (particularly sucrose solution) can enhance perceived intensities of retronasal odors [47.121, 123, 124]. In a recent study by *Lim* and her colleagues [47.121], subjects rated perceived intensities of three taste substances (sucrose, citric acid and caffeine), as well as of two retronasal odors (citral and coffee odor), both alone and in taste-odor mixtures. The subjects also rated the degree of congruency of all combinations of taste and odor stimuli. The pair of citral odor and sucrose was rated most congruent among the three taste-odor pairs. Also, coffee odor was rated most congruent when it was paired with sucrose or caffeine solutions. That is, sucrose solution was judged congruent with both citral and coffee odors. Sucrose solution significantly increased perceived intensity of its congruent odors (i. e., citrus and coffee flavors) than did either other taste solutions or retronasal odor alone. Furthermore, using olfactory ERPs, *Welge-Lüssen* et al. [47.33] demonstrated that orthonasal or retronasal stimulation of vanillin odor produced shortened latency of P2 peak in the presence of its congruent taste stimulus (sweet taste solution) compared to in the presence of incongruent taste stimulus (sour taste solution), suggesting that congruent taste facilitates retronasal olfactory processing. Similarly, in comparison to incongruent taste stimulus (sour taste solution), congruent taste stimulus (sweet taste solution) produced shorter latencies of P1 and N1 peaks for orthonasally presented vanilla odorant [47.125].

47.5 Influences of Auditory Cues on Olfactory Perception

Recent animal studies have found that the olfactory and auditory sensory inputs converge in the mammalian cerebral cortex [47.126–130]. *Wesson* and *Wilson* [47.128] demonstrated that single units of the olfactory tubercle were activated by tones, as well as by odors [47.128]. Furthermore, 29% of the single units in the olfactory tubercle showed either enhanced or suppressed activations in response to the simultaneous stimulation of odors and tones, suggesting that the olfactory tubercle may play a major role in influencing the cross-modal interaction between olfactory and auditory cues. In addition, *Plailly* et al. [47.131] showed that human brain regions associated with a familiarity to music pieces or odors were overlapped in the left hemisphere: specifically, the superior and inferior frontal gyri, the angular gyrus, the precuneus, the hippocampus and the para-hippocampal gyrus. Building on these findings, this section will address effects of auditory cues on olfactory perception with a focus on congruency between bimodal cue and background noise.

47.5.1 Congruency Between Bimodal Cues

Several studies have demonstrated that congruency between olfactory and auditory cues plays an important role in their interaction, especially for modulating odor pleasantness [47.132, 133]. That is, congruent sounds, in comparison to incongruent sounds, increase odor pleasantness. For example, food odors (e.g., potato chip odor) were rated more pleasant when they were presented with their matching sounds (e.g., the sound of eating potato chips) than when presented with un-matching sounds (e.g., the sound of drinking coffee) [47.132]. Further, as subjects rate the combination of odor and sound stimuli to be more congruent, they rated the odor as more pleasant. More recently, *Seo* et al. [47.133] corroborated the congruent sound-enhanced odor pleasantness. For example, cinnamon odor was rated as congruent with a Christmas carol (Jingle bells), which is based on previous experience that cinnamon-based foods/drinks and ornaments are popular during the Christmas season. The cinnamon odor was more appreciated in the presence of a congruent sound (the Christmas carol) compared to in the presence of an incongruent sound (pop music). In other cross-modal integrations of olfactory cue, congruent visual or gustatory stimuli assisted subjects in identifying the presented odors and in being familiar with them, thereby enhancing odor pleasantness [47.75, 78, 87, 134, 135]. In the same manner, the congruent sound-enhanced pleasantness for cinnamon odor was mediated by an increase in odor identification, as shown in Fig. 47.4 [47.133].

Unlike odor pleasantness, odor intensity was not modulated by congruent (or incongruent) sounds [47.132, 133]. Furthermore, no significant correlation has been reported between the degree of congruency and perceived odor intensity [47.132, 133]. The lack of significant effect on the odor intensity can be explained by the *analytic* characteristics of intensity rating. That is, when subjects rate the odor intensity, they are likely to be attentive to the intensity of odor stimulation. Thus, relatively little attention is paid to the background sound, which may reduce the impact of background sound on odor intensity. By contrast, when subjects rate

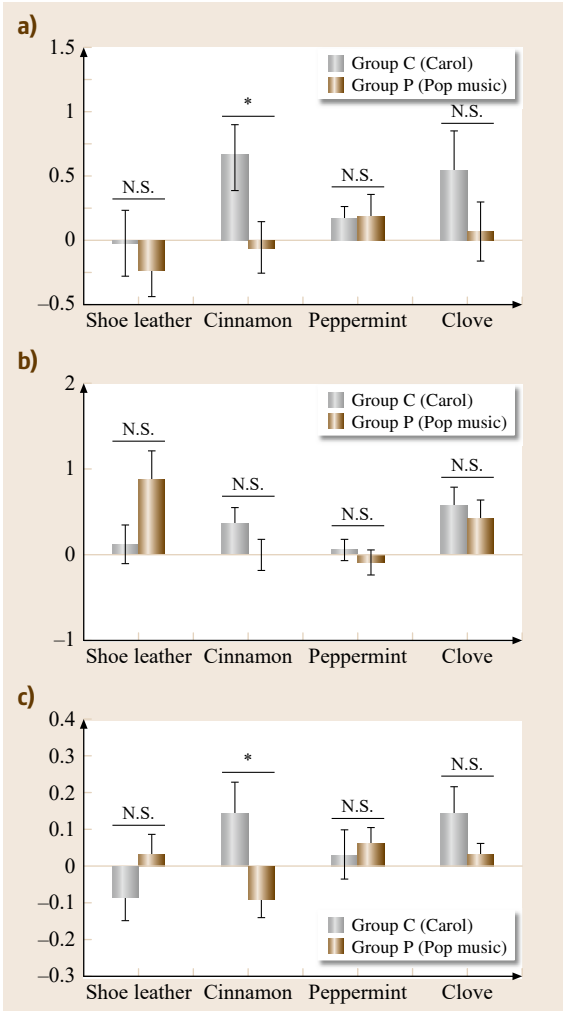

Fig. 47.4a–c Comparisons between Groups C and P in mean ratings for (a) sound-induced odor pleasantness, (b) sound-induced odor familiarity, and (c) sound-induced odor identification (after [47.133])

odor pleasantness, they tend to judge their hedonic impression for the odor stimulation in a *holistic* manner with consideration of the background sound given during the test, which may result in augmenting the impact of background sound [47.133].

47.5.2 Cultural Background

As addressed in the odor-color interaction [47.74], there is additional evidence that culture affects the cross-modal interaction between olfactory and auditory cues. *Seo* et al. [47.133] asked German and North American (the US) subjects to rate the degree of congruency between background sounds and orthonasal odors. Both German and American subjects judged that cinnamon and clove odors are matched well with the Christmas carols because foods and drinks contained cinnamon and clove are very common during the Christmas season in both countries. However, there was a cultural difference for the peppermint odor. Peppermint odor was rated congruent with the Christmas carol by American subjects, but not by German subjects. During the Christmas season, a candy cane flavored with peppermint is very popular in the United States. Especially, December 26th is called *National Candy Cane Day*. Likewise, culture plays an important role in formulating a culture-specific cross-modal interaction. Based on their experience and associative learning, people are likely to show specific cross-modal expectation, determining whether the pair of bimodal cues is matched or not. If people judge a pair of bimodal cues as congruent, the effect of congruent sound on olfactory perception would be obtained.

47.5.3 Background Sound

People are exposed to everyday odors in the presence of various background sounds. Earlier research has highlighted the effect of background sound on taste perception [47.136–138] or texture perception [47.139], but little is known about its influences on odor perception.

It has been reported that background sound interfered with the ability to discriminate odors compared with a silent condition [47.140]. Furthermore, the effect of background noise on an odor discrimination task was dependent on the type of background noise. For example, subjects showed more deleterious performance on the odor discrimination task in the presence of verbal noise (audio book) than nonverbal noise. It is known that an odor discrimination task is highly dependent on cognitive function [47.141]. Since verbal noise relative to nonverbal noise needs more cognitive load, selective attention to the background noise might reduce, to a higher degree, the ability to discriminate odors [47.140].

Olfactory sensitivity tasks are less dependent on cognitive function [47.141]. Thus, the question arises whether background noise would not interfere with the olfactory sensitivity. The answer appears to be *yes* or *no*. *Seo* et al. [47.142] asked subjects to conduct odor sensitivity tasks in the absence and the presence of the same types of background noise (i. e., verbal and nonverbal noise) which was used in the aforementioned research [47.140]. Overall, odor sensitivity was not different across the three background noise conditions: verbal noise, nonverbal noise and silence. However, with regard to odor sensitivity, the effect of verbal background noise was observed in a different manner between extrovert and introvert groups. For example, verbal noise, in comparison to silence, improved or impaired subjects' odor sensitivity in the extrovert or introvert group, respectively. These results suggest that the type of background noise and the degree of extraversion should be considered when investigating the effect of background sound on odor perception.

47.6 Influences of Trigeminal Cues on Olfactory Perception

People are exposed to odors/flavors with trigeminal stimulation, which is characterized as irritation, tickling, or burning, when they consume spicy foods or carbonated beverages. The cross-modal integration between olfactory and trigeminal cues has been reported with a focus on 1) congruency between bimodal cues and 2) odor localization elicited by trigeminal sensation.

47.6.1 Congruency Between Bimodal Cues

Little is known about whether certain combinations of olfactory and trigeminal cues can be judged as congruent. Recently, *Bensafi* and his colleagues [47.143] provided empirical evidence that a trigeminal sensation can be matched with a specific odor. For example, subjects judged orange odor as congruent with intranasal carbon dioxide (CO_2) stimulation, whereas they judged rose odor as incongruent with carbon dioxide stimulation. This result seems to be due to their exposure to the mixture of orange odor and carbon dioxide in soda drinks [47.143]. By contrast, the incongruent mixture of rose odor and carbon dioxide is not common in everyday life.

A congruent mixture of olfactory and trigeminal cues (orange odor and CO_2 stimulation) can be perceived as more pleasant than an incongruent mixture (rose odor and CO_2 stimulation) [47.143]. Further, neuroimaging (fMRI) revealed that the congruency-enhanced pleasantness was associated with increased neural activities in the hippocampus and anterior cingulate gyrus [47.143].

47.6.2 Trigeminal Cue-Induced Odor Localization

It is generally understood that humans have difficulties in purely lateralizing olfactory stimuli when they are presented to the right or left nostril ([47.144–147]; but [47.148]). However, it is known that trigeminal stimulants such as carbon dioxide can be lateralized with a high degree of accuracy [47.145, 147]. Notably, high concentrations of most known odorants evoke, in addition to olfactory sensation, trigeminally mediated sensation [47.149, 150]. *Doty* et al. [47.149] reported that subjects who lost olfactory, but not trigeminal, nerve function were unable to detect only 2 odorants (i. e., vanillin and decanoic acid) among 47 odorants. In that the human nasal mucosa contains not only olfactory receptors, but also cells that respond to mechanical, thermal, or nociceptive stimulation [47.147, 151, 152], odorants eliciting also trigeminal sensations can be localized [47.144–147, 153]. *Kleemann* et al. [47.147] demonstrated that subjects were not able to localize odorants exciting only the olfactory system, independent of their concentration, but they were able to localize the odorants activating both olfactory and trigeminal systems when the odorants were presented to either the right or left nostril.

47.6.3 Trigeminal Cue-Induced Odor Perception

The cross-modal integration between olfactory and trigeminal stimulations has been observed at several sites [47.154]: for example, at central nervous sites such as mediodorsal nucleus of the thalamus where olfactory and trigeminal afferents information converges [47.155, 156]; at the olfactory bulb [47.157]; at the olfactory epithelium [47.158]; and indirectly through nasal trigeminal reflexes [47.159].

It has been reported that trigeminal stimulation (pungency or irritation) suppresses orthonasal odor intensity [47.160–163] when the two stimulations were simultaneously presented. *Cain* and *Murphy* [47.160] also examined whether sequential presentation of trigeminal stimulus (CO_2) before odor stimulus (amyl butyrate) can alter the pattern of olfactory suppression. Trigeminal stimulation reduced perceived intensity of the subsequently presented odor, but its impact was less pronounced compared to the influence of simultaneous presentation. By contrast, *Jacquot* et al. [47.158] found that former trigeminal activation resulted in an increase in olfactory sensitivity. These inconsistent results reflect that both time and intensity of olfactory and trigeminal stimulations modulate the cross-modal integration between the two bimodal cues [47.156].

The effect of trigeminal cues on odor perception has also been investigated in food matrices. Trigeminal stimulation, such as carbonation, irritation and spiciness, appears to reduce perceived intensities of aroma and/or flavor [47.164, 165]. Conversely, it was also reported that trigeminal sensation enhanced aroma or flavor intensity [47.166–168]. *Saint-Eve* et al. [47.167] found that the presence of carbonation in beverages enhanced perceived intensity of retronasal odors compared to noncarbonated beverages. Furthermore, no significant effect of trigeminal stimulation on retronasal odor intensity has been observed in food matrices [47.165, 169, 170].

Likewise, for interpreting the effect of trigeminal stimulation on odor perception, key factors should be considered: for example, stimulus type, stimulus concentration, stimulation duration, inter-stimulus interval and environmental temperature [47.156, 165].

47.7 Influences of Tactile Cues on Olfactory Perception

While eating and drinking, tactile stimulations dynamically interact with olfactory cues (particularly retronasal odors). Nevertheless, little attention has been paid to the effect of congruency between olfactory and tactile cues in olfactory perception. Especially, the two tactile cues, *viscosity* and *hardness* (or *firmness*), have been used to investigate the cross-modal integration between olfactory and tactile cues.

47.7.1 Congruency Between Bimodal Cues

Only a few studies have reported the influence of congruency between olfactory and tactile cues on olfactory perception. It was found that certain aromas and texture can be matched [47.171]. For example, *Harthoorn* et al. [47.171] asked subjects to rate the degree of congruency between nonaromatized creamy custard

and each of seven aromas (vanilla, lemon, strawberry, chocolate, buttery, rubbery and lavender). The creamy custard showed high congruency scores with vanilla and buttery aromas, but it produced low congruency with rubbery, chocolate and lavender aromas. Overall, in the presence of creamy custard, congruent odors (vanilla and buttery) were preferred, whereas incongruent odors (rubbery and chocolate) were not appreciated. That is, this study demonstrated that a texture cue can enhance pleasantness of its congruent odors.

47.7.2 Effects of Viscosity and Hardness

It is generally observed that increasing viscosity results in a decrease in perceived intensity of retronasal odor (flavor) in various liquid matrices: for example, juice [47.172], coffee [47.172] and thickened flavor solutions [47.173–175].

In semi-solid and solid matrices, many studies have emphasized the effect of hardness (or firmness) on flavor intensity. Overall, earlier research has shown that perceived flavor intensity decreases with increasing hardness of semi-solid and solid matrices such as gels [47.24, 176–180], custard [47.24], milk [47.181] and candy [47.182].

The modulatory effects of viscosity and hardness on the perceived odor intensity can be explained by 1) physicochemical interaction of volatiles in the sample matrix and 2) tactile, cue-induced selective attention. Firstly, physicochemical properties, such as air/sample partition, diffusion coefficients and chemical bindings of the samples may influence odor intensity [47.182, 183]. For varying viscosity or hardness of the samples, structuring agents such as hydrocolloids and gelatine were used in previous studies. These structuring agents interact with volatiles of the sample, resulting in variations in the amount and the rate of odor release [47.176, 180, 182–184]. In this way, as a certain sample is composed of higher concentration of structuring agents (gelatine), the structuring agents of the sample may entrap more volatiles in the matrix, thereby reducing perceived odor intensity. However, this idea seems insufficient to explain relationships between viscosity/hardness and odor intensity because 1) structuring agents do not bind all kinds of volatiles [47.178, 182] and 2) concentration of the structuring agents was not linearly related to the perceived intensity of odor, as well as to the amount of odor release [47.178, 182]. When the amount of the odors released in the in vivo condition was compared among the samples with varying hardness/viscosity, the amount of odor/flavor release from the samples was not different, while perceived intensity of the odor/flavor was decreased [47.185, 186]. Another plausible explanation for the modulatory effect of viscosity/hardness on the perceived odor intensity is the tactile cue-induced selective attention. Oral behaviors (force, frequency and duration of biting, chewing and swallowing) vary depending on the first perception of sample texture in the mouth [47.182, 186, 187]. For example, a hard cracker needs greater biting force and longer chewing duration than a soft cracker, which may lead consumers to pay attention to the tactile cue more than aroma/flavor cue. As previously mentioned, consumers' olfactory performance may decrease (decreases in odor intensity and discrimination) when they are highly attentive to other sensory cues or tasks [47.99, 109, 142, 188]. In this way, it can be thought that certain tactile cues may be more distinctive (e.g., very hard or very viscous), which may induce more attention to the tactile cue, thereby reducing perceived odor/flavor intensity in the hard or viscous sample [47.183, 187].

47.8 Conclusion

In this chapter, the cross-modal integration between olfactory and other sensory cues was reviewed. In that odors are frequently experienced with accompanying other sensory cues such as visual, gustatory, auditory, trigeminal and/or tactile stimulation, olfactory perception should not only be understood as the result from a single sensory input, but also within the framework of multisensory interaction.

This chapter shows that *congruency* between bimodal cues plays a major role in modulating the cross-modal integration of odorous cues with visual, gustatory, auditory, trigeminal, or tactile cues. Furthermore, the modulatory effect of congruency on olfactory perception is affected by many factors including odor delivery route (orthonasal and retronasal pathways), selective attention to specific sensory cue, experience (associative learning), cultural background, type of a given task (analytical versus synthetic perception) and characteristics (hedonic tone and intensity) of a given stimulus.

Part F Human B

Part F Human Body Odor, Chemo-Communication and Behavioral Implications

Humans predominantly live in environments and with habits that minimize exposure to their own physiological smell. The human habit of applying measures for body hygiene, as well as scenting themselves, their clothes and their homes, can be traced back to early civilization. On the other hand, science provides increasing evidence that human beings not only each possess a unique olfactory signature, making it easy for relatives to (subconsciously) assign them to their company, but that many influencing factors can modify these smells. Amongst others, dietary habits, hormonal variations or diseases may change the smell signature of an individual. Such changes might be recognized by others and initiate specific responses, even if these recognition and response patterns follow unconscious mechanisms. Accordingly, humans not only communicate via spoken words, body language or other acoustic or visual signs (e.g., gestures), but also via chemostimuli. Close relationships in social human behavior, such as in partnerships or parent–infant relationships, are influenced by olfactory cues, which strengthen or even weaken the social bonds between individuals. The underlying biochemical and physiological processes in body odor generation and smell evolution throughout the human lifespan are complex, as are the influencing factors, and are either endogenous or exogenous to the human body. Thus, it is important to keep in mind that the major part of our organism represents a complex microbial assembly, and the outer surface of our body is also far from sterile but is rather inhabited by myriad microorganisms. Depending on the species composition of this flora and their respective numbers, these microorganisms may cleave precursors of smell substances in characteristic ways, further adding another dimension to our individual smell signature. Changes in this microcosm, e.g., due to infections, can then be quickly recognized by others, which leads to changes in their behavioral responses, and potentially leads to social distancing and exclusion. In view of these considerations, future research on diagnostics and medico-physiological prediction will surely be of great benefit if both the influencing factors as well as the changes in individual body odor signatures are better understood, and adequate tools are developed or adapted to monitor these changes instrumentally.

48. Analysis and Chemistry of Human Odors

Christian Starkenmann

The analysis of volatile organic compounds (VOCs) is now accessible to almost any laboratory using gas chromatography coupled to mass spectrometry (GC-MS). With mass spectrum libraries now being well populated with thousands of molecules, structure elucidation is no longer a hurdle in most cases. Two-dimensional GC-MS and high-resolution MS systems facilitate the interpretation and accuracy of VOCs analysis (Chap. 17). Sample preparation techniques have also significantly improved. VOCs extraction can be performed using polymer absorbents, but the drawback is that the equilibrium of VOCs between the matrix and the polymer may reflect an analytical profile that does not correspond to reality. This chapter focuses on the common VOCs profiles in body odors, human urine odors and fecal odors. Analytical strategies are discussed. These VOCs are classified by chemical functionalities and their importance to the smell is discussed in detail.

48.1 Human Sweat

The human body is covered by eccrine and sebaceous glands having an important role for thermoregulation, skin protection, and other beneficial functions. Their distribution is not the same on the whole body; this will influence the quality of the skin microbiota. The skin bacteria will transform the lipids from sebaceous glands or amino acids from eccrine glands in short-chain carboxylic acids. Ammonia and lactic acid are also emitted by all body parts [48.1]. Personal habits, hygiene, disease, and living conditions can alter the overall body odor [48.2]. From the gland distribution, their densities on the human body and the understanding of different body part microflora, we can postulate that an odor mapping of different body parts is possible [48.3]. But the typical human sweat odor that we can smell in exercise room or in public transportation is only produced by apocrine glands and bacteria.

The apocrine glands are present massively in underarm regions but we can also find them in ears wax, eyes, nipple, and in pubis area (Fig. 48.1). These glands become active only at puberty; they excrete a complex juice containing some compounds which are unique to humans. The human smell is unique, except in those people who have a recessive ABCC11 gene variant, in which case the apocrine glands are inactive (Chap. 49). Under stress, the apocrine glands are stimulated which generate stronger underarm malodors.

48.1.1 Analysis of Human Axillary Odors

Since 1953, it has been known that fresh, sterile axillary sweat is odorless and that bacteria transform water-soluble chemical precursors to smelly volatile organic compounds (VOCs) [48.4]. Very soon after this discovery, in 1963, a description of the use of antibacterial substances to prevent the formation of malodor was published [48.5].

Sample preparation is critical for unbiased analysis. In early studies, sweat was collected by using a grooved rubber brush that was mechanically rotated in the axillary vault. Apparently, this procedure was *moderately discomforting* [48.5]. The smell was described as putrid and was due to microbial degradation of the stratum corneum from the eroded skin; therefore, it can be concluded that this procedure did not lead to the recovery of a representative human axillary smell. Furthermore, most studies on human body odors were performed on worn T-shirts or cotton-wool pads worn in the armpit region for 5–7 days and extracted with an organic solvent [48.6, 7] (Fig. 48.2a), allowing plenty of time for the microflora to perform an abundance of transformations and for chemical reactions to occur. The solvent extraction of these T-shirts generated background contamination, originating from fabrics mainly, as well as a loss of trace sulfur compounds by irreversible trapping on fabrics. This was an important limitation. To further avoid using solvent extractions, an individual sat or lie down in a glass box and the headspace was collected as it passed through the cabin in a gas stream [48.8] (Fig. 48.2b). From these studies, over 300–400 individual chemicals were detected, among which 135 were identified, but it could not be demonstrated that any of these were relevant for axillary odors [48.9]. Other devices for in-vivo underarm VOCs analysis by confining the underarm emanation with a polyethylene form are described without giving clear answers of which VOCs are responsible for the underarm malodor [48.8] (Fig. 48.2c). A stir bar sorptive extraction in connection with thermal desorption gas chromatograph-mass spectrometry (GC-MS) was also used to analyze the body fluids of 197 adults. A total of 373 compounds were selected for individual discrimination, such as methyl-*N*-methylanthranilate, α-ionone and other compounds [48.10]; however, these were not representative of the authentic human axillary smell but of an overall human emanation. In other words a subject who smokes or who comes back from a French fries place will smell differently from a subject just having a shower and wearing new clean cloths. Trained dogs may choose between these molecules to build an olfactive image used to track a subject.

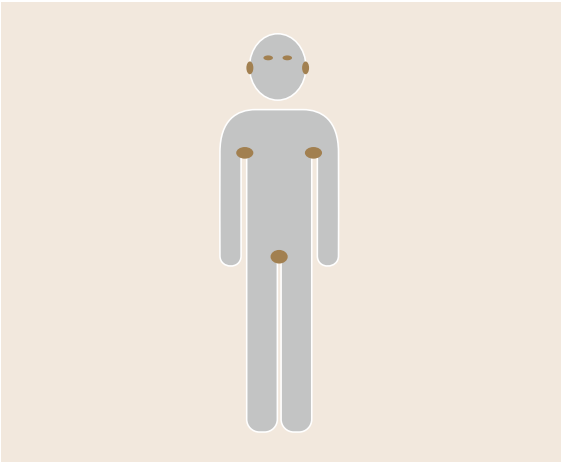

Fig. 48.1 Distribution of apocrine glands *in brown* on the whole human body (after [48.1])

The controversy about which are the most relevant compounds that cause axillary odors was mainly due to the sampling methodology [48.11, 12]. Now the role of skin microbiota in the production of body odors is better understood, mainly due to a founded understanding of the biochemistry of nonvolatile precursors, which will be explained in the following [48.13, 14].

48.1.2 Carboxylic Acids

The structure of (*E*)-3-methyl-2-hexenoic acid **1** was elucidated for the first time in the sweat of patients with schizophrenia; by 1969, researchers reported a concentration of 0.1 μg/ml of this acid in axillary sweat [48.15]. The occurrence of (*Z*)-3-methyl-2-hexenoic acid **2**, which represents 10% of the (*E*)-**1** isomer, and a possible difference in the *E*/*Z* ratio between men and women was discussed [48.16]. (*R*/*S*)-3-Hydroxy-3-methyl-hexanoic acid **3** was mentioned for the first time in 1975 as anticonvulsant [48.17], but the clear analytical occurrence of **3** in fermented human axillary sweat was reported in 2003 [48.18].

The understanding of organic acids excreted in axillary sweat occurred in two phases. The first phase involved the collection of axillary sweat on T-shirts or cotton pads sewn onto T-shirts (Fig. 48.2a), followed by solvent extractions. The second phase was based on the understanding of the biochemical pathways.

During the first phase, the major acid **1** was discovered as well as the straight chain aliphatic acids **4**–**7** and the branched acids in C2 **8**–**12**, C3 **13**, and C4 positions **14**–**18**. The occurrence of 7-octenoic acid **18** and other terminally unsaturated homologs **19** [48.19] were also observed. In this first phase, the background noise was important due to the contaminants extracted from

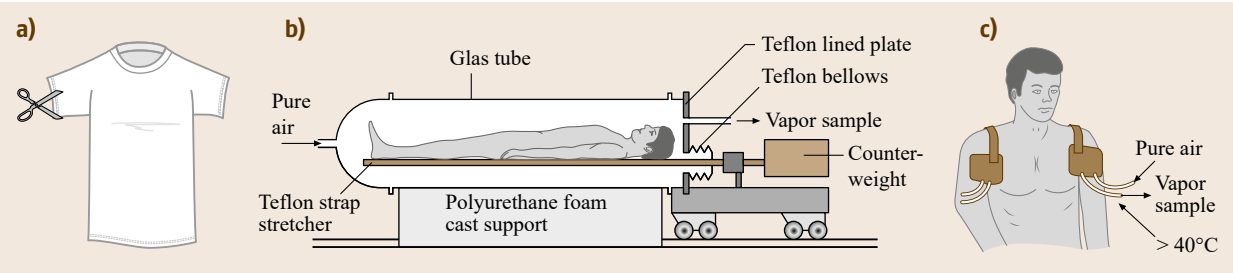

Fig. 48.2 **(a)** Many underarm malodor samplings were performed on T-shirts by solvent extraction of the underarm regions; **(b)** and **(c)** are two examples of headspace sampling devices described by *Dravnieks* et al. [48.8], reprinted with permission

the T-shirts. An example is given in Fig. 48.3, where we can see the background noise in the blank and the differences of excreted acids by individuals. Even if this study was performed only on four subjects some very interesting conclusions were made. The subjects A and D demonstrated a consistent acid profile. The four subjects presented differences in relative acid concentrations, for example the subject A produced about 30% of **1** and his T-shirts were described having the most human sweat smell and the T-shirt of the subject Joe was the less typical, it smelled more like dirty, rancid, therefore the acid profile influences the body odor.

The second phase focused on understanding the biological pathways in the formation of the acids. The sterile sweat does not smell and it is constituted only of nonvolatile water-soluble compounds. The analysis of sterile sweat led to the discovery of N^{α}-3-hydroxy-3-methylhexanoyl-L-glutamine and N^{α}-3-methyl-2-hexenoyl-L-glutamine [48.18]. The odorless sterile sweat is transformed by bacterial enzymes into odorous volatile compounds. From *Corynebacterium striatum* Ax20, present in the axilla region, it was possible to characterize a metal-dependent dipeptidase, N^{α}-acylglutamine aminoacylase. This enzyme cleaves the amide bond between the acid moiety and the glutamine. The structural gene of this enzyme was cloned for heterologous expression of a functional enzyme in *Escherichia coli* [48.18, 20]. Thanks to the availability of the enzymes, it was possible to incubate the sterile sweat and to discover a range of new hydroxy acids and unsaturated acids like **16**, **22–32** (Fig. 48.4) [48.21]. The relative abundance of acids confirmed that in fermented sweat, the major acid is **3** [48.21]. The acids **16**, **22–32**, **36–38** were present in much lower concentration compared to **3**, signifying that their contribution to the overall smell is minor. The ratio of **20** and **21** in sterile sweat, collected from 25 women and 24 men over a period of 3 years, was 10 : 1 [48.22, 23].

When odorous sweat was analyzed without knowing the precursor biochemistry, compound **3** was not

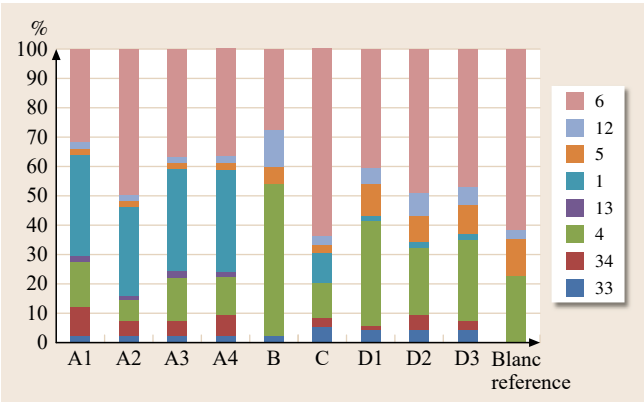

Fig. 48.3 Acids extracted from T-shirts. Cotton T-shirts, previously washed with unperfumed detergent and extracted with ethanol and chloroform were worn by volunteers in a sports club during 2 h exercise. The underarm T-shirt areas were cut. After acid base extraction, methylation with diazomethane, and clean-up via a Likens–Nickerson extraction, the GC-FID peak area of the acids were normalized to 100

discovered. Possible explanations could be a bad elution pattern of **3** on GC [48.24], or compound **3** is not stable on the GC injector port. It can be dehydrated or undergo a retro aldol reaction, leading to the formation of 2-pentanone and acetic acid. This was not verified, as synthetic **3** is stable in the injector port up to 280 °C. Another explanation could come from the bacteria. In vitro incubation of a mixture of synthetic **20** and **21** with *C. striatum* DSM 20668 produced only a mixture of **1** and **2**, whereas **20** remained in solution. Compounds **20** and **21** have different kinetics: **3** is better degraded by microorganisms further down and is more polar compared with **1** and **2**. In addition, its analytical recovery can be predicted to be less favorable; overall, this may explain why **3** was not discovered until 2003 by *Natsch* et al. [48.18].

Chiral-GC analyses revealed **3** to be a 72 : 28 mixture of the (*S*)/(*R*)-isomers. A difference in smell was described between *R*-**3** and *S*-**3** enantiomers, with *S*-**3**

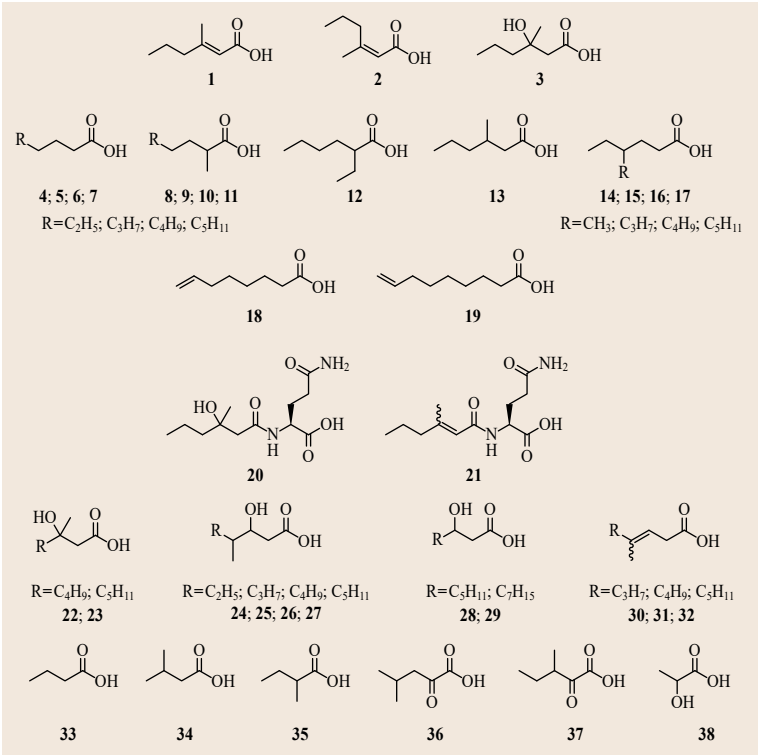

Fig. 48.4 Carboxylic acids detected in human axillary sweat

being described as more spicy (Table 48.1). The spicy odor descriptor was associated with cumin (*Cuminum cyminum*) seed odor or white *Piper nigrum*, even though these spices do not contain these exact same compounds, and the *R*-**3** enantiomer was described as weak animalic.

48.1.3 Sulfur Compounds

All of the investigators in the field of axillary malodors, in the year 2000, suspected that sulfur compounds also had an important role in axillary malodors. Unfortunately, these compounds are not easy to isolate for two reasons: they occur in very low concentration and free thiols stick to surfaces such as cotton T-shirts or metals. For the acids, one grain of table sugar would be enough to make an Olympic swimming pool smelling. For the sulfur compound, this grain of sugar would be enough to make 100 Olympic swimming pool smelling.

The discovery of thiol odorants in sweat occurred also in two phases in our laboratory. A perfumer noticed that clary sage (*Salvia sclarea* L.) (Fig. 48.5a) and *Ruta chalepensis* L. (Fig. 48.5b) in full blossom elicit a peculiar repulsive olfactory signal, somewhat reminiscent of human axillary perspiration [48.26, 27]. The sulfur compounds of the plant, refined in a 15 g fraction, were obtained from the distillation of 300 kg of clary sage. The sulfur compounds were concentrated by affinity chromatography. Then the chemical structures of most potent sulfur compounds were elucidated by gas chromatography coupled to mass spectrometry and an olfaction port (GC-MS-O). Both flower extracts contained many sulfur compounds, such as 3-sulfanyl hexan-1-ol **39** and 1-methoxyhexane-3-thiol **40**. Chiral analysis demonstrated that *S*-**40** has sulfury, alliaceous notes and evoked the smell of human axillary perspiration. *R*-**40** smelled sulfury, herbaceous and onion-like, but the principal sulfur compound detected by -olfactometry (GC-MS-O) in sweat extracts did not correspond to any of the sulfur compounds discovered previously in *R. chalepensis* L. or *S. sclarea* L. (Fig. 48.5) [48.26, 27].

For this reason, we decided to collect enough human sterile sweat for incubation. An exercise room equipped with steady bicycles and a sauna was installed in the basement of our research center. Volunteers were asked to exercise during at least 45 min plus 15 min sauna. The underarm area was scrubbed with a plastic cup, filtered on sterile filter and frozen. An average male gave 12 ml per session and females 2 ml per session (Fig. 48.6). The sweat pool used for the discovery of the sulfur compounds and other analyses represented 191 h of male efforts and 113 h of female efforts to

Table 48.1 Odor thresholds of sweat odorant compounds (after [48.23, 25–27])

Organic carboxylic acid	Abbreviation	Odor detection threshold (ng/l air)
3-Methyl butanoic acid	**34**	0.2
(*E*/*Z*)-3-Methyl-2-hexenoic acid	**1** and **2**	0.1
(*E*)-3-Methyl-2-hexenoic acid	**1**	0.7
(*Z*)-3-Methyl-2-hexenoic acid	**2**	0.7
(*R*/*S*)-3-Hydroxy-3-methyl hexanoic acid	**3**	0.2
(*S*)-3-Hydroxy-3-methyl hexanoic acid	*S*-**3**	0.08
(*R*)-3-Hydroxy-3-methyl hexanoic acid	*R*-**3**	0.2
(*R*/*S*)-4-Ethyl-octanoic acid	(*R*/*S*)-**16**	0.1
(*S*)-1-Methoxyhexane-3-thiol	*S*-**40**	4×10^{-5}
(*R*)-1-Methoxyhexane-3-thiol	*R*-**40**	1.09×10^{-3}
(*R*/*S*)-1-Methoxyhexane-3-thiol	(*R*/*S*)-**40**	3.6×10^{-4}
(*R*/*S*)-3-Methyl-3-sulfanyl hexan-1-ol	(*R*/*S*)-**41**	2×10^{-3}

give, respectively, about 2.5 l of male sweat and 0.2 l of female sweat. Additionally, we cultivated underarm bacteria and then incubated each colony with the sterile sweat. We first discovered that the more intense sulfury odor came from sweat incubated with one specific bacterial strain of the cultivated underarm bacteria, namely *Staphylococcus haemolyticus*. Then the incubation was repeated on 300 ml of sterile male sweat and finally after purifications and concentrations, the structure of 3-methyl-3-sulfanyl hexan-1-ol **41** (transpirol) was elucidated. This compound was discovered simultaneously by three groups [48.28–30]. In the same fraction, the compound **39** and the odorant 2-methyl-3-sulfanyl pentan-1-ol **42** (Fig. 48.7), the key odorants of fresh onion [48.31] were detected.

As it became evident that the identified substances are extremely odor potent but still low in concentration, the odor-detection thresholds of these volatile sulfur compounds were measured in air by olfactometry [48.25, 32, 33]. Thereby, the threshold of *S*-**40** at 0.04×10^{-3} ng/l air is 25 times lower than that of *R*-**39** (1.09×10^{-3} ng/l air). The racemic thiol (*R*/*S*)-**40** has an odor threshold of 0.36×10^{-3} ng/l air [48.23, 25]. The odor detection threshold of racemic transpirol **41** was measured at 2×10^{-6} µg/l air. Also, women seemed to be slightly more sensitive compared with men, as

Gervason). **(b)** Picture of *Ruta chalapensis* L. took in Chinque Terre (Italy) and **(c)** Human underarm. Chemical structures of compounds **39** and **40** discovered in these flowers, and in human **39**, **41**, and **42** were discovered

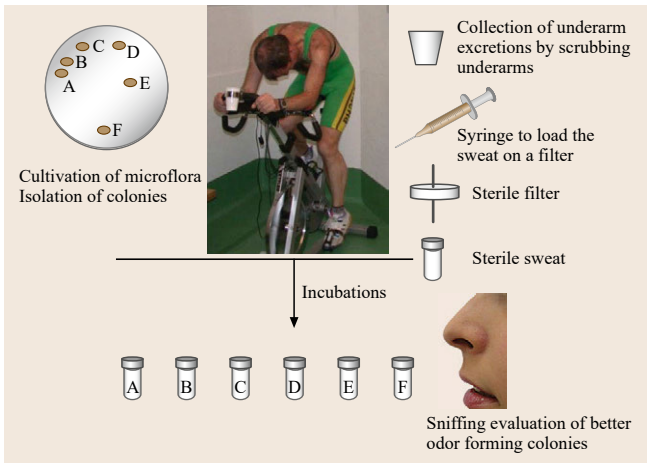

Fig. 48.6 Analytical approach to understand the biochemistry of underarm malodor formation. The microflora was analyzed. The odorless sterile sweat was incubated with isolated underarm bacteria colonies and the most efficient odor forming bacteria were detected by sniffing the fermented sweat (after [48.22])

shown by the values measured for 15 male subjects and 15 female subjects, but this needs further investigations to be confirmed (Table 48.1) [48.23].

All living organisms have biological systems to protect them against aggressive chemical substances. A tripeptide, constituted of the γ-glutamic, cysteine, and glycine amino acids, named glutathione **43** reacts with free radicals or any xenobiotics to prevent them from damaging the cell functions. The glutathione is an important scavenger for the living cells. From an un-

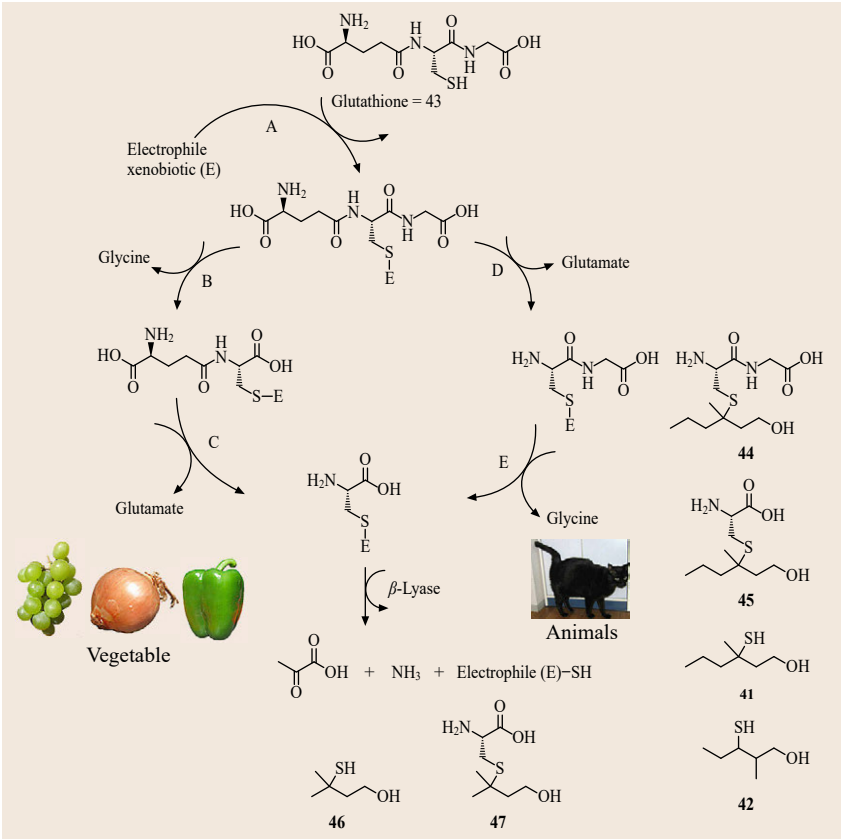

Fig. 48.7 Glutathione detoxification pathway. The glutathione free thiol is nucleophilic. Its main role is trapping the free radicals. In the case of human body odors and in plants-like *Alliaceous* sp. the soft nucleophilicity of the sulfur atome reacts with α,β-unsaturated carbonyls. Then enzymatic reactions can cleave the peptidic bond to release the glutamine or to release the glycine. The final step is the excretion of the cysteine-*S*-conjugate. In *Alliaceous* sp. most of the cysteine conjugates are stored under sulfoxide and cleaved when plant cells are disrupted. In human urine they are excreted under mercapturate (*N*-acetyl-cysteine-*S*-conjugate), which are good biomarkers of exposure to pollutants

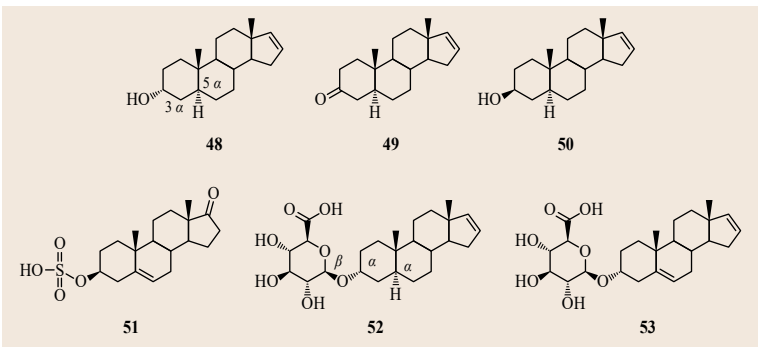

Fig. 48.8 Major odorous steroids and their respective precursors found in axillary sweat (after [48.34])

derstanding of glutathione **43** detoxification pathways (Fig. 48.7) [48.35, 36], the corresponding cysteine-*S*-conjugate **45** was the obvious candidate as being the precursor of sulfur compounds. The sterile sweat was then fractionated and a small portion of the fraction (only 1/10) was sacrificed for incubation with *S. haemolyticus* in order to identify by smelling which fraction was the odorless precursor. This fraction was fractionated further until it was possible to detect relevant masses by LC-MS-MS. This approach led to the discovery of 1-[(2-hydroxyethyl)-1-methylbutyl]-(L)-cysteinylglycine (cys-gly-*S*-transpirol) **44** [48.22]. The biochemistry of **41** in humans is close to 3-methyl-3-sulfanyl-butan-1-ol **46** found in domestic cats (*Felis domesticus*) and in bobcats (*Lynx rufus*) [48.37, 38]. The precursor is a cysteine-*S*-conjugate (2-methyl-3-hydroxy-butyl-*S*-cysteine) **47**.

48.1.4 Steroids

In 1944, Prelog and Ruzicka isolated 5α-androst-16-en-3α-ol (α-androstenol) **48** from 181 kg of hog

testes [48.39]. It was described as having a musk-like odor. When the alcohol was oxidized to 5α-androst-16-en-3-one (androstenone) **49**, the odor was described as being stronger and like *vessels which had been used for storing urine for prolonged periods* [48.40]. The perception of androstenone **49** can be offensive, pleasant, or odorless, depending on the individual and possibly hormonal state [48.41–43]. Compared with α-androstenol **48**, β-androstenol **50** is noticeably weaker in odor [48.44]. Androstenone **49** is a pig pheromone that was also found in the human armpit [48.45, 46]. The apocrine glands become active at puberty, and so these odorous steroids were intensively studied because of their possible role in human communication [48.7, 47–49]. α-Androstenol **48**, but not androstenone **49**, was detected in human male axillary sweat [48.6]. α-Androstenol was previously detected in human urine [48.50]. Because androstenone is a boar sex pheromone, an abundant literature focused on the importance of androstenone in axillary sweat, but to our knowledge, no solid documented work proved its occurrence in sterile sweat. However, *Bird* and *Gower* demonstrated the occurrence of androstenone in one subject [48.46], and *Claus* and *Alsing* confirmed the occurrence of androstenone after 24 h of collection on pads placed in the axillary region, via radioimmunoassay [48.7]. They estimated the production as being 14 ng/h per armpit. During the numerous incubations and analysis of sterile sweat in our laboratory, it became clear that androstenone **49** is not present in sterile sweat and that it seems to be the result of the oxidation of α/β-androstenol **48**, **50**. Here, it is especially interesting to note that some of our subjects had very efficient microflora to cause this oxidation while others did barely transform the substance [48.34].

The apocrine glands excrete water-soluble derivatives of odorants in sweat that are themselves odorless. For example, most of the steroids are excreted as sulfate derivatives such as 3β-hydroxyl androst-5-en-17-one (DHEA) sulfate **51** found in the range of 2–90 µg/ml in axillary sweat [48.34]. The precursor of α-androstenol is α-androstenol-β-glucuronide **52**, as in human urine [48.50], and in sterile sweat we measured α-androstenol-β-glucuronide **52** at 0.2 µg/ml for men and 0.08 µg/ml for women [48.34, 50]. If 5α-androst-5,16-dien-3α-ol β-glucuronide **53** is present in sterile sweat, the concentration is below 0.02 µg/ml (< 20 ppb) (Fig. 48.8).

When *Gilbert* and *Wysoski* [48.51] issued a questionnaire called *The Smell Survey* (1987), they obtained 26 200 replies and found that androstenone posed a greater identification and detection problem compared with other odors and that 70% of women could smell it, whereas only 63% men could [48.51]. Based on this observation, the genetic basis of variation in odor perception between individuals at the human receptor OR7D4 was studied, along with associated interindividual genetic variations; the main finding of this comparison was that genotypic variation in OR7D4 correlates with the perception of α-androstenone [48.52, 53].

In conclusion, apocrine glands start functioning when humans become adults. They excrete acids **1**–**3** that have a structure that is unique to humans. Thiol **41** is also unique to humans. The biochemistry associated with **46** in cats is similar and the unusual amino acid **47** was considered as a semiochemical in cats, but no proof of its action as a pheromone has yet been demonstrated [48.53]. Androstenone **49**, a pig pheromone, is also excreted by humans, primarily as α-androstenol **48** under the β-glucuronide conjugate **52**, and is then oxidized in androstenone **49**. This excretion starts at puberty. Together, these facts suggest that compounds **1**–**3**, **41** unique to human and **48**, **49** are odorant signaling compounds of humans.

48.2 Volatile Organic Compounds of Human Urine

The smell of urine is recognized by everyone, especially when the urine is not very fresh any more. However, the smell of fresh urine is mainly due to highly volatile compounds such as methyl mercaptan and amino compounds that result from the degradation of urea. More substantive molecules are later formed to produce the smell of stale urine. In relation to this process, we now better understand the role of microorganisms and chemical reactions that bring about these odors and their associated aversive responses in humans. The smell of felids urine was reported to be caused mainly by sulfur compounds **46** [48.54], which is not the case for human.

48.2.1 Analysis of Human Urine Odors

Everyone has at some time experienced the typical odor of stale urine downtown, in remote places or around train stations. In contrast to this, fresh urine has little odor. Moreover, dietary influences can modify the smell of urine; the most obvious case being the typical sulfury odor of urine after someone has eaten asparagus [48.55–57]. The modulation of urine odor by diet has been documented [48.58–60]. Most of the studies on the specific VOC composition of urine have been carried out in relation to urinary tract infections [48.61] and on changes in urine odor related to a specific

disease [48.62–66]. Other studies on the volatile and odorous fraction of human urine and their conjugates were performed to obtain insights into common excretion processes [48.63, 67].

However, also the common nuisances associated with urinary smell attract researcher's interest, not only because of their scientific craziness but also with the real goal of improving the quality of our everyday life. To understand the smell of urine in a latrine, to develop tools against such nuisances, investigators need to design an aging protocol from healthy subjects. However, few options are possible: collecting odors on site, boiling urine to mimic-aged urine during water evaporation in an open-air environment, or aging urine with microorganisms.

Fresh urine has a faint odor described as ammonia, floral, and sweet, but even if variations are noticeable, the overall odor descriptor is still *urine*. In this context, it is interesting to note that the term *urine* as descriptor for smell is more often used by perfumers than by flavorists, and not necessarily in a negatively associated context. When looking at the individual constituents of urinary smell, the ammonia-like odor quality is due to the presence of trimethyl amine [48.65, 66], which has a lower odor threshold than ammonia itself which is also related to pH effects: a water solution of NH_4OH at pH 7–8 is odorless, but at the same pH, a solution of Et_3N at 1 mg/l has an odor.

A boiled urine organic extract smells like urine but has a more syrupy, medicinal, and cooked-food type of odor, resulting from Maillard-type degradation products (Chap. 5) such as pyrazines, sugar degradation products such as maltol (3-hydroxy-2-methyl-4(4*H*)-pyranone), furaneol (4-hydroxy-2,5-dimethyl-3(2*H*)-furanone), and methyl nussol (2-hydroxy-3,4-dimethyl-2-cyclopenten-1-one). The occurrence of odorant molecules thermally generated was observed by GC-MS-O (Chap. 17) [48.67].

In comparison to that, a fermented urine organic extract smells like authentic stale urine, is acrid, and is more representative of stale urine than boiled urine, an odor that is noticeable when urinals are dirty. To obtain this sample, we left sterile fresh urine in the open air for 5 days during the summer. The urine was spontaneously contaminated by bacteria. From this aged urine, 73 bacteria colony isolates were incubated separately with sterile urine. Only 13 colonies produced a repulsive strong urine odor, from which five odor-generating bacteria were identified: *Morganella morganii*, *Escherichia fergusonii*, *Enterococcus faecalis*, *Citrobacter koseri*, and *Streptococcus agalactiae*. When sterile urine was incubated with *M. morganii*, the pH rose to 9 and the fishy odor due to ammonia, trimethyl amine and dimethyl disulfide was repulsive [48.67].

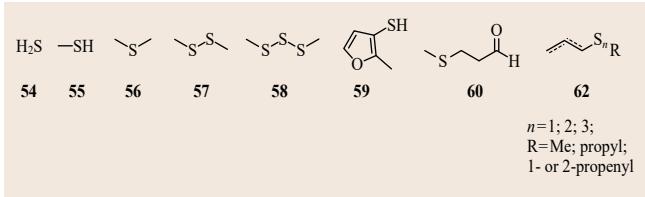

Fig. 48.9 Common sulfur compounds in urine and feces originating from food

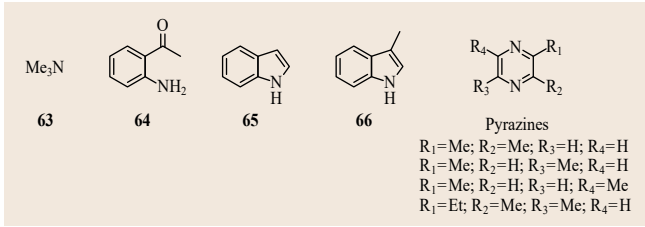

Fig. 48.10 Nitrogen-containing compounds in urine and feces

In the following, the respective compounds being pronounced in aged urine will be addressed in more detail.

48.2.2 Carboxylic Acids

The carboxylic acids present in fresh and aged urine do not contribute to its smell [48.68–71]. When we used gas chromatography-olfactometry (GC-O), an odor in the background reminiscent of sweat triggered our curiosity, and after a specific acid–base extraction and analysis, we confirmed the occurrence of traces of **3**. The acid **16**, main odorant compound of the goat, was always well detected by GC-O and it may contribute to the odor descriptor *animal*.

48.2.3 Sulfur Compounds

Hydrogen sulfide **54** does not seem to be reported in urine, but methyl mercaptan **55** is a key odorant. Dimethyl sulfide **56**, dimethyl disulfide **57**, smelling like garlic and rubber and dimethyl trisulfide **58**, smelling more sewage-like, are the other important contributors to urinary smell. 2-Methyl-3-sulfanyl furane **59**, a strong meaty odor, coming mainly from flavored food, was detected in all GC-O analyses of urine extracts; 3-(methylthio)-propanal (methional) **60**, the Strecker aldehyde of methionine, which smells of boiled potatoes, was detected in fermented urine by all panelists during GC-O evaluation [48.67] and is a potent odorant in urine.

When a urine donor eats garlic or onion, 1-propenyl, 2-propenyl mercaptan, or the corresponding polysulfides **62** are detected in the analysis and

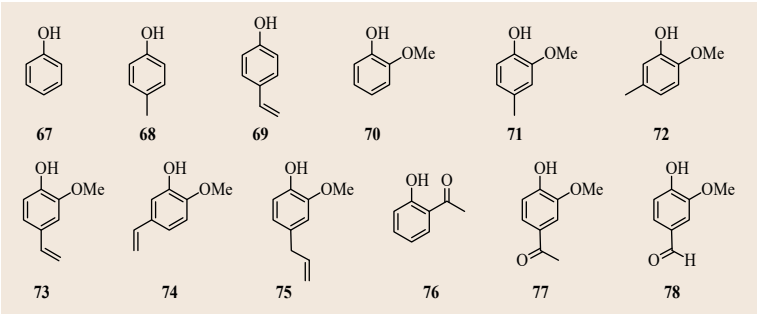

Fig. 48.11 Phenolic compounds in urine, feces, and in pit latrine sludge

can influence the onion-like, sulfury smell of urine (Fig. 48.9).

48.2.4 Nitrogen-Containing Compounds

Amino compounds are affected by a low pH. An ammonia solution at pH < 9 is odorless as its concentration in the headspace (air above the solution) is very low because it is present in protonated form. Trimethyl amine **63** is also affected by the pH but to less extent, because it is more hydrophobic due to the carbons attached to the nitrogen. Trimethyl amine is a very important odor contributor to urine smell and its odor threshold is thousand time lower compared to ammonia, but its odor is more fishy. 2-Aminoacetophenone **64** has a floral tonality, a smell-like Concorde grape, that was clearly detected by GC-O, having a nasal impact factor (NIF) above 50% [48.67]. For a representative odor of fresh, aged, or boiled urine, indole **65** is an important contributor. Indole has a pleasant odor and a good jasmine perfume cannot be made without using indole. But indole in the presence of other compounds can be associated to a malodor. The skatole **66** present in urine [48.60, 64] is too fecal, has a mothball-like odor, and its concentration is too low to be a typical impact odorant for urine. Boiled urine contains many pyrazine derivatives, originating from the condensation of ammonia from dicarbonyl compounds that stem from sugar degradation products [48.60]. The occurrence of pyrazine itself in urine has rarely been reported (Fig. 48.10) [48.70–74].

48.2.5 Phenols

In fresh urine, phenol derivatives are present, and their concentration and impact on the smell of urine even increases over time because of the action of enzymes originating from microorganisms. The core substance phenol **67** itself has a medicinal or ink-like smell [48.60, 62, 72]. The most important contributor to the smell of urine, however, is *para*-cresol **68**, which smells horse-stable-like and fecal. 4-Vinyl-phenol **69** was also identified in fresh urine and its odor is reminiscent of urine, leather. Apart from that, the concentration of the smoky-smelling guaiacol **70** increased when fresh urine was incubated with the bacteria *Citrobacter koseri* [48.67]. Also, the methyl guaiacols **71**,**72** smell smoky, with the clove-like, smoky tonality, and contribute together with the spicy smell of 4- and 5-vinyl guaiacol **73**, **74** or 4-allyl-2-methoxyphenol (eugenol) **75** to the smell of urine [48.61, 67]. 2-Acetylphenol **76** was detected in fresh and boiled urine (NIF = 75%), and its smell was described as old urine, representing the same odor impression as elicited by vanilloketone **77**. These compounds are impressive in terms of overwhelming odor impression when they elute from the column in GC-O analysis (NIF > 75%), but in water at 1% and pH 7, their odor impact are weak. Apart from that, vanillin **78** also contributes to the sweet smell of urine in some cases (Fig. 48.11).

48.2.6 Miscellaneous Odorant Compounds

The number of volatile organic odorant compounds in urine is higher compared to volatile compounds in fecal material. Diacetyl **79** contributes to the buttery smell of urine [48.61, 69, 71]. 2-Phenylethanol **80** is also an important contributor to honey and to the floral smell of urine; it is formed after aging with microorganisms [48.67]. Other compounds that have an impact on urine odor are also common in food, including 2*H*-chromen-2-one (coumarin) **81**, 3-hydroxy-4,5-dimethyl-2(5*H*)furanone (sotolone) **82**, and 4-hydroxy-2,5-dimethyl-3(2*H*)-furanone (furaneol) **83** [48.61, 69, 71].

Monoterpenes present in urine commonly do not contribute to its smell, nor do ketones and many other compounds that often occur in urine and are linked to food, such as (+-)-3-methyl-6-(prop-1-en-2-yl)cyclohex-2-enone isopiperitenone **84** and menthol **85** (Fig. 48.12).

α-Androstenol **48** is excreted in the conjugated form as α-androstenol-β-glucuronide [48.50] and is responsible for stale urine odor after cleavage [48.44,

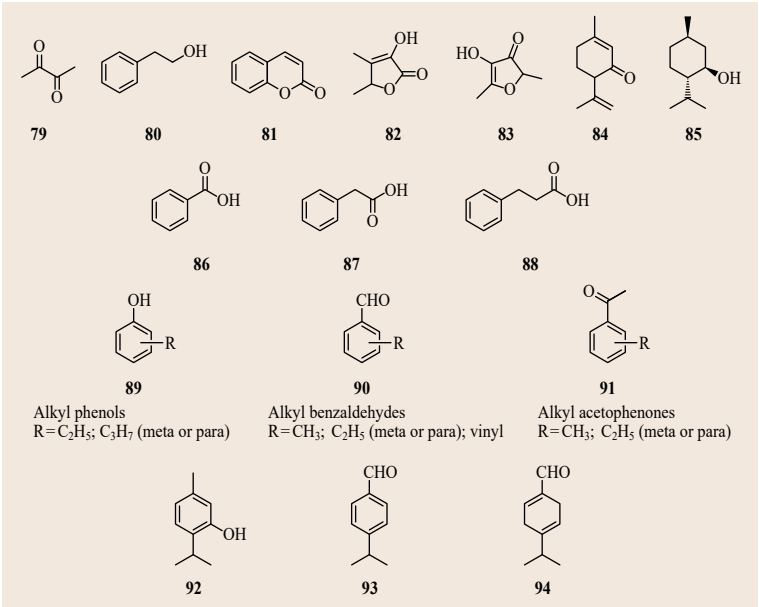

Fig. 48.12 Miscellaneous structures of compounds found in urine or in fecal material

71]. It is then oxidized to androstenone, described as having a urine smell [48.72]. *Streptococcus agalactiae* contains an efficient glucuronidase to liberate α-androstenol **48**, as well as menthol [48.65]. On the other hand, α-androstenol is not liberated during boiling of urine, as apparently the glucuronide conjugate is too stable under heat treatment [48.67].

In conclusion, the smell of urine is influenced by microflora and in the early stage of urine degradation, the pH increases and the smell of ammonia dominates, mainly due to the presence of trimethyl amine. After a few hours, the pH slowly returns to neutral and then more substantive molecules like *para*-cresol, indole, androstenol, and its conversion product androstenone, change the fresh urine smell into stale urine. Overall, the smell of urine is a more complex system compared with axillary body odors, or fecal odors. This is predominantly due to the fact that urinary excretion of odorants and volatiles is strongly linked to primary elimination pathways of exogenic and endogenic compounds from the food, and the smell of feces originates from further microbial biodegradation of fibers, sugars, and proteins, basic food constituents, as will be discussed in the following.

48.3 Volatile Organic Compounds in Human Feces and Pit Latrines

Understanding the smell of feces is not a new topic: the archives show that by the 19th century, scientists already had a good idea of which compounds are important to the smell of feces [48.78]. In medieval times, fecal smells were obviously a commonly tolerated and integral part of everyday life, for example, in the early cities with excretions having been simply deposed of in the streets. Nowadays, the smell of feces, as well as the analysis of the respective odor compounds currently gains momentum as modern humans increasingly less tolerate such human emissions. The fecal smell is rated as repulsive, but with regard to its molecular composition it is relatively simple, especially when being compared with that of urine. The importance of single constituents, such as acids, sulfur compounds, and nitrogen-containing compounds such as indole, skatole, and phenolic compounds are discussed in the following.

48.3.1 Analysis of Fecal Odors

The analyses of volatile compounds in human feces were mainly done to understand the relation between the gut microbiota and the food intake. Few methods were developed to understand the composition of malodorous compounds in human feces and the main motivations were not obvious to understand. The most pertinent analyses were performed on the headspace analysis using a tenax trap. In one case, the odor was sucked during the stool expulsion using a pump in

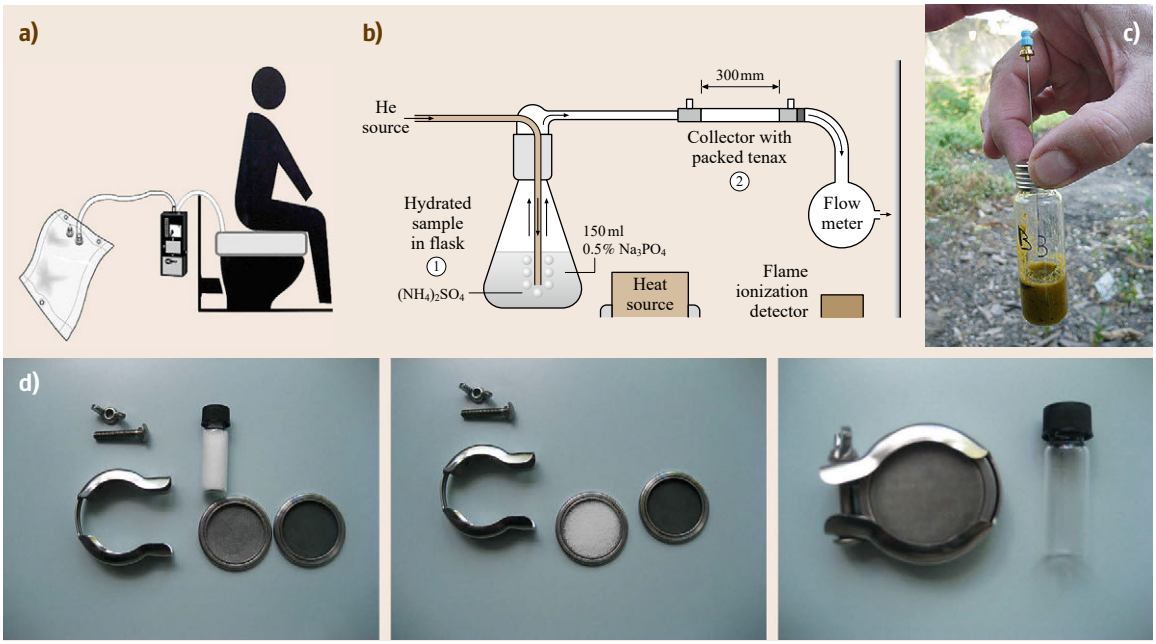

Fig. 48.13a–d Analytical devices used for sampling the smell of fecal malodor. **(a)** To analyze immediate odor, adapted from [48.75]. **(b)** Example of dynamic headspace sampling (after [48.76]). **(c)** Example of SPME pit latrine sludge sampling [48.77]. **(d)** Device used to analyze pit latrine odors on site overnight [48.77] ((**c**) and (**d**) reprinted with permission from [48.77]. Copyright (2013) American Chemical Society)

a sampling bag and then the gas phase from the bag was pushed onto a tenax trap [48.75] (Fig. 48.13a). More commonly, the stool was placed in an Erlenmeyer flask and a gentle air flux was used to push the headspace in a tenax trap [48.76] (Fig. 48.13b). Analyzing a single stool by direct extraction is challenging because after a few days, even with centrifugation, it is difficult to eliminate and discard the fine residual suspension. Acidification of the suspension, in the presence of an organic solvent, can form a stable gel which poses another obstacle to the extraction of volatiles from such samples. Headspace analysis is a good alternative, but method validation must be carefully designed [48.79–85]. The fecal sludge from African pit latrine was analyzed by SPME using internal standards (Fig. 48.13c) [48.77]. The limitation was the stability of some compounds on the fiber. The dynamic headspace using tenax cartridges is a good alternative to SPME, but due to the breakthrough volume, we must choose if to trap highly volatile compounds or to trap heavier compounds. This means that pumping pit latrine headspace during a short period of time, about 1 h, methyl mercaptan is well detected but indole and scatole are not detected. The benefit of using static headspace is that we can leave the device on site overnight and it can be hidden easily in the ventilation port of the pit latrine. During our African pit latrine analysis, we used an organic polymer (Porapak Q), which was conditioned in our lab and dispatched in many small glass flasks. On site the polymer was loaded on a filter commonly used for filtration in organic chemistry. The disc was exposed to the headspace and then the polymer was loaded back in the flask to be shipped back in ice-cooled pack to the lab (Fig. 48.13d) [48.77]. The solvent extraction of the polymer allowed to obtain an extract which can be smelled and injected multiples times, but highly volatile or unstable compounds like methyl mercaptan **55** are lost.

48.3.2 Carboxylic Acids

Short-chain fatty acids are major products of microbial oligosaccharide breakdown in the large intestine, a pathway that leads not only to the formation of products that supply the intestinal cells with energy but also goes along with the generation of smelly compounds. The extent of formation of individual acids in relation to the metabolism of these oligosaccharides or arabinoxylans from maize, rice, and wheat has been investigated in vitro and in vivo [48.86, 87]. Thereby, acetic acid, propionic acid, and butyric acid **33** are the most abundant acids. Isotope labeling studies using [$U^{13}C6$] glucose were used to show that $^{13}C_2$ and

$^{13}C_4$ acids are the major labeled butyrate species produced from glucose fermentation via [^{13}C2] acetate-acetyl coenzyme A as the intermediate [48.88, 89].

Specifically, butyric acid is an important contributor to fecal odors. The odor threshold of butyric acid in air is $< 0.1\,\mu g/l$, but in water or sludge, pH influences its partitioning in air. Overall, the impact of all organic acids becomes less important at neutral pH. Furthermore, the composition or the ratio between acid concentrations also plays a role in the resulting odor profile. For example, stool with a ratio of **33** and **34** of 2 : 1 will be significantly different from that with a ratio of 10 : 1. Other acids contribute to fecal smell, for example, benzoic acid **86**, phenylacetic acid **87** (odor threshold $1\,\mu g/l$), and 3-phenylpropionic acid **88**. It is also known that people with diarrhea produce stools that consist mainly of acids, which explains the vomit odor. Over time, stool smells less and less of rancid cheese and vomit; this can be explained by the faster bacterial metabolism of the acids compared with the slower bacterial catabolism of phenolic compounds [48.77].

48.3.3 Sulfur Compounds

H_2S **54** and methyl mercaptan **55** are primarily responsible for the odors associated with bad breath, feces, flatulence, and sewage. Dimethyl sulfide **56**, dimethyl disulfide **57** and dimethyl trisulfide **58** are the second most important contributors to an eggy, sewage, cabbage smell [48.86]. The sulfur atom originates from proteins and the consumption of vegetables, such as onion or garlic. The consumption of albumin as present in eggs increases the formation of methyl mercaptan [48.87]. Fermentation in anaerobic conditions and nutritional substrates that originate from waste both favor the formation of sulfur compounds, such as **54** and **55**, to produce typical sewage, egg-like odors [48.86, 88–92].

48.3.4 Nitrogen-Containing Compounds

In 1878, a Swiss doctor from Bern hospital, *Brieger* [48.78], distilled 50 kg of feces from healthy men. He chose only those patients who were in hospital after an accident and did not suffer from any other diseases. In the course of these investigations, he discovered skatole **66** and described its contribution to the odor of feces. He also mentioned the occurrence of butyric acid **33**, branched C-5 acids, phenol **67**, and indole **65**. As in the case of urine, the analysis of fecal odor was at this time primarily conducted in the medical sciences as a diagnostic tool for the detection of specific diseases.

The first GC-MS-O analysis on human feces was performed in 1984 [48.93]. About 25 g of fecal material was placed in an Erlenmeyer flask suspended in an Na_3PO_4 buffer and $(NH_4)_2SO_4$ and then stored for 24 h before dynamic headspace sampling was performed and the odorants trapped in a Tenax collector trap (Fig. 48.13b) [48.76, 93]. The Tenax absorbent was then thermally desorbed on GC-flame ionization detection (FID) coupled to an olfaction port or to a GC-MS. The pH was not displayed, but the solution must have had a pH > 8. These conditions favored the analysis of nitrogen compounds, which are not strongly protonated at this pH. Indole **65** and skatole **66** were well detected and were described as being mothball and napthalene-like, but not considered as being important to the foul odor of feces. The fishy odor, characteristic of volatile amines, was also not detected, and the author concluded that trimethylamine was not important for fecal odors [48.93]. These observations are still valid today and have been confirmed by recent investigations on this topic.

48.3.5 Phenols

The major phenolic odorants in fecal material are para-cresol and also to some extent meta-cresol. Phenol is also always detected, but its bandage smell is not a typical attribute for fecal smell. Ethyl and propyl phenols in meta and para positions **89** (Fig. 48.12) are always detected by GC-O and twist the fecal smell into one that is more barnyard like and outdoor associated. Although guaiacol **70** can be present, it was not detected in a single stool and can be ruled out as a contributor to human fecal odor (Fig. 48.12) [48.77].

In conclusion, the stool odor is mainly due to short chain fatty acids, *p*-cresol, sulfur compounds, indole, and skatole. The odor profile is simpler compared to urine because these compounds result from proteins and fibers and not from detoxifications pathways, with soluble molecules of odorant molecules excreted in urine. Only in extreme situations when the subject eats heavily flavored food, terpenes can be detected in fecal material.

48.3.6 Miscellaneous Odorant Compounds

Benzaldehydes and substituted benzaldehydes with methyl, ethyl, or vinyl residues **90** and acetophenone derivatives **91** may contribute to the fecal smell to a lesser extent and were frequently detected by GC-O. Thymol **92** was smelled and identified in stools from India, as well as 4-isopropylbenzaldehyde (cuminaldehyde) **93**, 1,4-*para*-menthadien-7-al (phellandrenal) **94**, and vinylguaiacol **73**. They were more abundant than

para-cresol **68**, and the smell was spicy and rancid, atypical of fecal material. This observation reflects a rich spicy food that affects the smell of Indian stools (Fig. 48.12) [48.83].

48.4 Conclusions

The human axillary sweat has a unique odor due to the occurrence of compounds **1**, **2**, **3**, **41**, not found yet in any other natural species. This is the signature of human adult smell. The urine smell is mainly due to trimethyl amine, ammonia, dimethyl disulfide, indole, and skatole. But in urine, many other organic compounds originating from food are excreted in soluble form like glucuronide or sulfate form. The α-androstenol **48** is an important contributor to the stale urine odor as well as its oxidation product **49**; **48** is also found in underarm regions and it is excreted by apocrine glands, when they become active at the puberty. The fecal material smell is mainly due to the acids **33**, **34**, **35**, phenol **67**, para cresol **68**, plus indole **65** and skatole **66**. The type of the food intake plays an important role in fecal smell. Eating garlic, onion, or cabbage will produces a lot of powerful volatile sulfur compounds.

The microflora is very important to generate malodor, cleaving the chemical bond between the soluble part of the molecule to the hydrophobic part, for example, the glucuronide of α-androstenol **48**, the glutamine conjugate of the acids **1**–**3** or cysteine-glycine conjugate of the sulfur compounds like **41**. The beauty of nature is the capacity of modulating the generation of odors; if the apocrine glands are very active to excrete the α-androstenol glucuronide **52**, the microflora must include bacteria producing the right β-glucuronidase enzyme to release the odorant molecule. Understanding this chemistry is very important to develop strategies to prevent the malodor formation without disturbing the microflora. What was said for the gut microflora, as *Zimmer* reported [48.94]:

> *For a century, doctors have waged war against bacteria, using antibiotics as their weapons. But that relationship is changing as scientists become more familiar with the 100 trillion microbes that call us home – collectively known as the microbiome,*

is also valid for the skin microflora.

49. Biochemistry and Genetics of Human Axilla Odor

Andreas Natsch

Human axilla odors are only formed once skin secretions come into contact with the skin microflora. Axilla odors are thus a product of an intricate interplay between skin bacteria and axillary gland secretions. The bacterial populations in the axilla are dominated by *Staphylococci* and *Corynebacteria*. The magnitude of odor formation is associated with the population density of *Corynebacteria* on the skin of human panelists.

In recent years, amino-acid conjugates were identified as the key secreted odorant precursors: Different odorant acids are secreted as glutamine conjugates, whereas sulfur volatiles arise from the bacterial degradation of conjugates related to glutathione. Specific enzymes were identified in *Corynebacteria* cleaving these amino-acid conjugates and thus releasing the odors.

Based on this molecular understanding, questions on the evolutionary significance of these odors could be asked. The pattern of secreted odor precursors appears to be stable within an individual and it is genetically determined as was shown in a twin study. Based on behavioral studies, an association between axilla odors and the human leukocyte antigen (HLA) genotype had been proposed, but the chemical nature of potential HLA-associated body odors remained enigmatic. A family study on siblings with identical HLA-genes could not identify a link between genetically inherited patterns of glutamine conjugates and HLA-types.

Axilla odors are largely absent in a significant fraction of the human population in the Far East. This has been associated with a single nucleotide polymorphism (SNP) in the *ABCC11* gene. Indeed, human subjects lacking a functional ABCC11 allele are not able to secrete the amino-acid conjugates of the key odorants, which confirm the relevance of these biochemical mechanisms of odor formation identified in the last decade.

49.1 Importance of Bacteria in Odor Formation

The human axilla is covered by a particularly dense array of secretory glands. These mainly belong to two types: eccrine glands secrete an aqueous solution, containing salts, and water soluble components such as lactic acid and amino acids. Apocrine channels associated with the hair follicles secrete a more hydrophobic mixture containing fats, steroids, and proteins belonging to the lipocalin family. Lipocalins are small proteins binding a variety of hydrophobic ligands. They include the major urinary proteins (MUP) in mice, which

bind odorants in mouse urine, as well as odor binding proteins (OBP) in humans and other vertebrates, which can bind to a variety of lipids and odorants. The major lipocalin in human sweat is apolipoprotein D. In addition to the two major types of glands mentioned above, apoeccrine glands were discussed as a third type with a high abundance in the axillary region [49.1]. The secretions provided by all these glands serve as ideal growth medium for a number of bacterial species – combined with the partial occlusion provided by the anatomy of the axilla and the dense coverage by hair (which delay water evaporation and thus help to provide a moist environment), the axilla is an almost perfect habitat for bacterial colonization. It was therefore early recognized that the density of the bacterial flora is particularly high within the axillary region [49.2] and that this bacterial habitat is strongly differing from the dry surface of most other skin sites. This was recently summarized in the statement [49.3]:

> *The moist underarms lie a short distance from smooth dry forearms, but these two niches are likely as ecologically dissimilar as rainforests are to deserts.*

In parallel to the observation of a high bacterial population density in the axilla, it was shown that there is a direct association between bacteria and body odor formation. Fresh apocrine secretions were found to be odorless, but they developed the typical pungent axilla odor if contacted with skin bacteria [49.4]. This initial study sets the scene to search for the mechanisms of body odor formation, which could only be understood by focusing on both the skin microflora and the axilla secretions to finally understand the interplay between both contributors.

49.2 Specific Odor-Forming Bacterial Populations Colonizing the Axilla

In early studies, the bacterial population was investigated by culture-based methods. Human panellists were tested both for strength of odor formation and the presence and abundance of specific bacterial species. This approach led to the conclusion, that the two main genera in the axilla are *Staphylococci* and *Corynebacteria*, and that odor formation is particularly associated with the population density of lipophilic *Corynebacteria* [49.2, 5]. In these pioneering studies, it was not only shown that there is a correlation between density of *Corynebacteria* and odor formation, but the authors did also directly incubate bacteria with apocrine secretions and could show that only *Corynebacteria* were able to release the odors. This conclusion was later confirmed by a detailed correlation analysis between odor intensity and abundance of specific bacterial groups, and again the strongest association was observed between population density of *Corynebacteria* and odor formation [49.6]. More recent studies did not focus on odor formation, but generated a global inventory of bacterial species present at different skin sites. These studies applied more advanced culture-independent molecular methods and high throughput sequencing of the deoxyribonucleic acid (DNA) coding for 16s-RNA (ribonucleic acid). Among nine human panelists, the populations on seven were found to be dominated by *Staphylococci* and *Corynebacteria* by these culture-independent techniques whereas the remaining two carried a population dominated by β-proteobacteria [49.3]. *Propionibacteria* were also found to be present in significant densities in some panelists. A similar result was found in a study on 16s-RNA sequences of pooled samples from five panelists [49.7]. A study on three panelists also indicated a population dominated by *Staphylococci*, with *Corynebacteria*, and *Propionibacteria* as the next most abundant genera [49.8]. Similarly, in a further recent study *Staphylococci*, *Corynebacteria* and *Propionibacteria* were found as forming the typical axilla flora, in this case additionally a high number of sequences clustering with *Streptococci* was found [49.9]. Overall these recent studies using the latest high throughput sequencing technologies confirmed the taxonomic view reached with culture based methods 30 years earlier and added some more details on the interindividual bacterial diversity. However, they have not added further information on the importance of different bacterial populations for odor formation as they only provided an inventory of sequences and putative species but asked no functional questions: Therefore, the *Corynebacteria* remain the prime suspect.

49.3 Specific Odorant Precursors Secreted in the Human Axilla

Given the knowledge on the bacterial populations and their importance in odor formation, for a long time the key missing link was what kind of constituents in the gland secretions are transformed by bacterial ac-

tion into the odorant principles. Significant progress was made in this area in the last decade by the use of liquid chromatography-mass spectrometry (LC-MS) technologies – but next to this analytical tool, the studies successfully isolating odor-precursors had to combine the chemical analysis with targeted degradation (by hydrolysis or bacteriolysis) of the precursors, followed by sensorial analysis.

49.3.1 Precursors for Acids

Two key, structurally closely related, odorant acids were described as typical body odorants in acidic fractions of sweat: 3-methyl-2-hexenoic acid (3M2H) [49.10] and 3-hydroxy-3-methyl-hexanoic acid (HMHA) [49.11]. The quest for a potential precursor for 3M2H started early. In a pioneering study, it was shown that this compound is bound to a water-soluble precursor and can be liberated therefrom both by hydrolysis catalyzed by NaOH or by bacteriolysis using corynebacterial isolates [49.12]. Due to the high protein content in apocrine secretions, it was proposed that 3M2H is likely to be bound to proteins, either by a covalent bond or by noncovalent associations. Following these early studies, evidence for the latter hypothesis was presented showing that there appears to be a noncovalent linkage between apolipoprotein D and 3M2H [49.13]. However, no hypothesis could be presented, how *Corynebacteria* then would dissociate these noncovalent associations to release the odorants. A covalent linkage to the terminal glutamine of apolipoprotein D was more recently proposed [49.14], but the relevance of this observation was questioned, since with this 1 : 1 association between the small acid and the large protein, an extremely high level of apolipoprotein D would be needed to explain the high observed amounts of odorant acids which can be released from axilla samples [49.15].

Using size exclusion chromatography in combination with LC-MS, hydrolysis of sweat fractions and sensorial analysis it was later shown that axilla secretions contain large amounts of glutamine conjugates, in which the acids 3M2H and HMHA are covalently attached to the N_α-atom of glutamine (Fig. 49.1) [49.11]. This observation was confirmed by an independent laboratory quantifying the HMHA-Gln conjugate in a longitudinal study for 3 years on 49 volunteers [49.16]. Male axilla sweat samples were shown to contain on average 794 µg of the HMHA-Gln conjugate, whereas female samples contained 365 µg. Based on all available evidence, these glutamine conjugates appear to be the key precursors for odorant acids, and an alternative proposal for odorant acid formation was recently abandoned [49.15, 17].

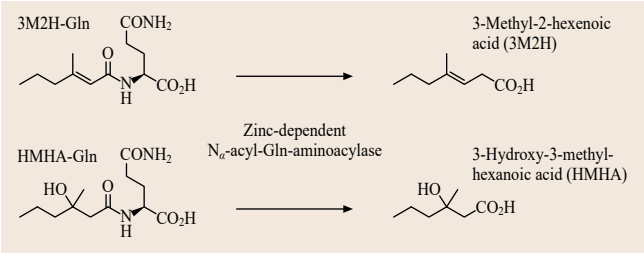

Fig. 49.1 The structure of the precursors for the two key odorant acids and the enzymatic activity in *Corynebacterium Ax20* performing the precursor cleavage

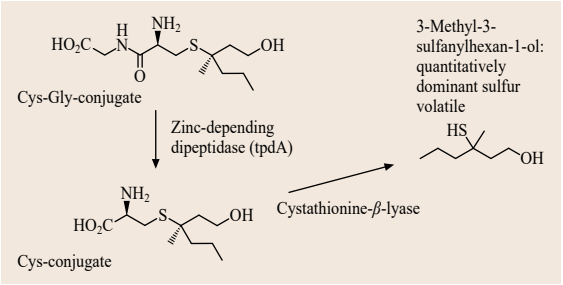

Fig. 49.2 The structure of the key precursor for odorant sulfanylalkanols and the two enzymes isolated from *Corynebacterium Ax20* involved in odorant release

49.3.2 Precursors for Sulfanylalkanols

Next to the acids, sulfanylalkanols were identified as key contributors to body odors by three laboratories in the same year [49.18–20], see for a detailed review in this volume (Chap. 48). Originally we proposed that the sulfanylalkanols are secreted as cysteine conjugates based on the finding that (i) *Corynebacteria* isolated from the axilla can release the odorants from such cysteine conjugates, and that (ii) a cystathionine-β-lyase from a strain of *Corynebacterium* can release the odorants from both the synthetic cysteine conjugates and from authentic sweat. However, it was later shown that the quantitatively dominating precursor is a cysteine-glycine conjugate (Fig. 49.2) [49.21]. This finding was confirmed by our laboratory [49.22] and later in population studies [49.16, 23]. A minor level of the originally proposed cysteine conjugate was then also analytically detected [49.22], although it is not clear whether this compound is directly secreted by the glands or whether it is an intermediate formed on the skin by the bacterial peptidase activity.

49.3.3 Precursors for Steroids

The odorant steroids androstenol and androstenone had been identified as the first human axilla odor-

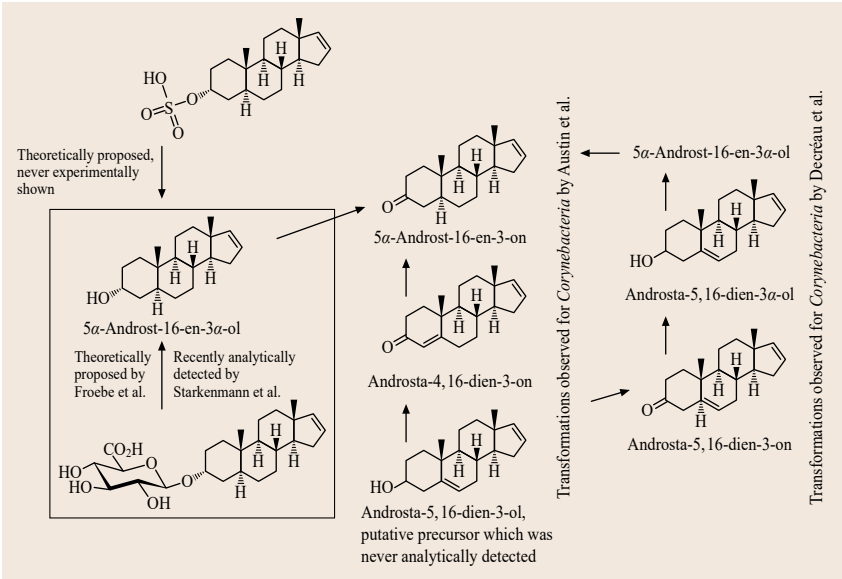

Fig. 49.3 The structure of the proposed precursors for odorant steroids and the associated biotransformation reactions

ants [49.24, 25], following their description as key odorants and pheromones in the pig. However, the analytically detectable levels are extremely low in human sweat and it was recently proposed that their contribution to axilla odor is much less than was originally believed [49.15]. At the same time, there is much less analytical information on secreted precursors for these steroids.

Based on analogy with the soluble, transported forms of other steroids in the human body, it was proposed that androstenol could be secreted as sulfate or glucuronide conjugate [49.26], although such precursors were not analytically detected in sweat when this hypothesis was first presented. Indeed, cleavage of some synthetic steroid sulfates by isolates of *Corynebacteria* was later shown [49.27], but the sulfate conjugates could never be detected in sweat. Only very recently it could be shown, that sweat contains the glucuronide conjugate of androstenol (Chap. 48).

An alternative hypothesis proposed the formation of the odorant steroids from other nonodorant steroids (which are not conjugated to a carrier molecule) [49.28, 29]. Evidence for a number of steroid oxidations and reductions by axilla bacteria was indeed presented [49.29, 30] – but these studies did not detect analytically the potential odorless precursor androsta-5,16-dien-3-ol in the axilla secretions, which then would be transformed to the odorant principles by the proposed mechanisms. These alternative pathways are summarized in Fig. 49.3. They appear currently rather unlikely.

49.4 Malodor Releasing Enzymes in Axilla Bacteria and Corresponding Genes

Although the importance of bacteria and the contribution of specific taxonomic groups to odour formation had long been known, the quest to identify odor-releasing enzymes could only start once the odor-precursors were analytically identified and synthetic samples of these compounds could be prepared. Using such synthetic references, we could identify particular bacterial strains with the ability to cleave the conjugates. A highly odor forming strain, *Corynebacterium* sp. Ax20 [49.11] was selected as model organism. Based on recent sequence analysis of the DNA coding for 16s ribosomal RNA, it is most closely related to *Corynebacterium glaucum* [49.15].

49.4.1 Acid Releasing Enzyme

The first focus was to explain the release of the most dominant odorants, the carboxylic acids. Using classical biochemical tools, a single enzyme from Ax20 involved in cleavage of the glutamine conjugates was purified to homogeneity and then used for amino acid sequence analysis. The corresponding gene could be cloned and expressed in *Escherichia coli* [49.11]. This recombinant enzyme, biochemically speaking it is an N_{α}-acyl-glutamine aminoacylase, did cleave both the synthetic precursors and it released the acids from axilla secretions [49.31], thus verifying its role in odor re-

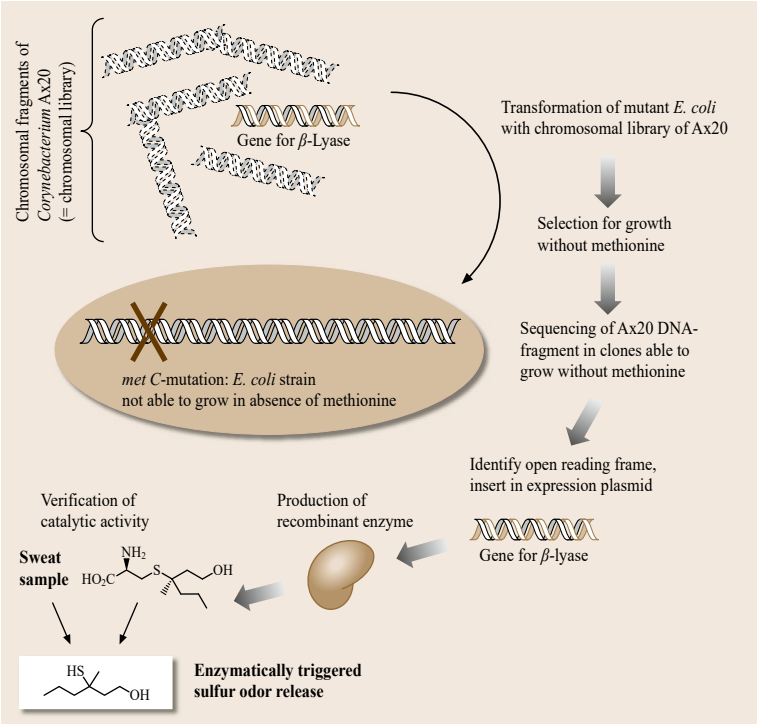

Fig. 49.4 The experimental approach to isolate the β-lyase gene from Ax20 and verification of its involvement in release of odorant sulfanylalkanols from cysteine conjugates

lease (Fig. 49.1). This enzyme was also coined AMRE (axillary malodor releasing enzyme) [49.32]. It has a very high specificity for the glutamine residue in the substrate, not accepting other amino acid residues. Thus it has a high specificity to the glutamine conjugates secreted in the axilla. At the same time, it has a high tolerance to different acyl-side chains. As discussed in the following, there are indeed many different acyl-glutamine conjugates present in the axilla, but no conjugates with other amino acids were found. Thus, the substrate specificity of this enzyme (high specificity for Gln, but not acyl part of the substrate) is perfectly adapted to the available substrates, and presents a fascinating example of coevolution of the skin bacteria with the human host. A direct evolutionary benefit for the bacteria would then be the utilization of the released glutamine as a nutrient source.

49.4.2 Enzymes Releasing Sulfanylalkanols

Based on the assumption that sulfanylalkanols might be linked to cysteine in the secreted form, cysteine conjugates were first synthesized. They are indeed cleaved by the same bacterial isolate Ax20. Thioethers of cysteine are often cleaved by cystathionine-β-lyases, which are encoded in many bacteria by the *metC* gene. The corresponding enzyme could therefore be cloned from Ax20 by a genetic approach instead of the tedious classical biochemical approach of enzyme purification: Chromosomal fragments of Ax20 complementing *E. coli* *metC* mutants were isolated. These fragments contained a common open reading frame, which was expressed in *E. coli* and the recombinant protein was purified. This experimental approach is schematically depicted in Fig. 49.4.

This enzyme was then shown to cleave both synthetic cysteine conjugates and it was able to release sulfanylalkanols from sweat (Fig. 49.4) [49.18]. A phylogenetically related cystathionine-β-lyase, which is also able to release the sulfanylalkanols from cysteine conjugates, was later cloned from *Corynebacterium jeikeium* K411 [49.15], showing that this enzymatic activity is present in several species of *Corynebacteria*. In the latter bacterial isolate, a detailed analysis of the regulatory mechanisms was also made, and a repressor protein was cloned, supressing the expression of the β-lyase gene in the presence of high methionine concentrations [49.33]. This indicates that the primary biological function of this enzyme is still in the biosynthesis of methionine (rather than in the cleavage of cysteine conjugates, which is a secondary function), and that its production is regulated by the bacterial need for methionine. On the other hand, detailed analysis of *Staphylococcus hemolyticus* led to the cloning of a *metC* gene, again coding for a cystathionine-β-lyase. However, this enzyme had an extremely low

activity on the cysteine- and on the Cys-Gly conjugates and it did not release odors from native sweat. It was therefore concluded that this enzyme is not the key enzyme for odor release in this bacterial strain or that the concerted action of several enzymes is needed [49.34].

Upon the report that the key precursor for sulfanylalkanols is as a Cys-Gly conjugate rather than a simple cysteine conjugate, the question arose whether this new compound could be cleaved by the same β-lyase from Ax20, but this was not the case. Indeed, complete enzyme extracts of Ax20 were able to release the odor from the Cys-Gly conjugate, but this ability was lost as soon as the extracts were fractionated, pointing to the involvement of at least two enzymes. Indeed, if all individual fractions of the bacterial lysate were complemented with the recombinant β-lyase, only then a fraction was identified which was able to release the odor from the Cys-Gly conjugate. This indicated that a second enzyme is needed to first release the Gly-residue. This conclusion proved correct and led to the isolation, by classical purification and activity assays, of a novel dipeptidase named *tpdA* which cleaved the glycine from the Cys-Gly conjugate. This enzyme then generates the substrate for the previously identified β-lyases and the sequential action of both enzymes is needed for odor release [49.22]. These findings are summarized in Fig. 49.2.

49.4.3 Formation of Steroids

As regarding the formation and transformation of odorant steroids, so far no enzyme was isolated and characterized in axilla bacteria, which would catalyze the hypothetical routes summarized in Fig. 49.3. Thus, to advance this field it would now be necessary to study the glucuronidase activity in axilla bacteria to verify the cleavage of the recently identified odor precursor. Currently, however, there are no reports in the literature on this highly interesting topic.

49.5 Fingerprints of Released Odors in Human Individuals

There are three key, quantitatively most dominant, odor precursors identified so far, as summarized in Figs. 49.1 and 49.2. These could be identified in all human individuals in the longitudinal study cited earlier [49.16]. However – human individuals have different odors, and only three chemicals cannot account for this interindividual variability. With the availability of the recombinant enzymes, it became possible to look in more detail into the volatiles released from native sweat, and it could be shown that a broad variety of different acids can be released by the same N_α-acyl-glutamine aminoacylase [49.31]. The variability of the pattern of these different acids was then studied in more detail. One key question to ask was whether the odors are inherited and stable in an individual, thus giving each person his/her specific odorprint. This could best be addressed with a twin study. Pairs of genetically identical twins contributed sweat samples, which were then treated with the aminoacylase and the released odor pattern was analyzed with a comprehensive 2-D (two-dimensional) gas chromatographic method. With this approach, an influence of the micro-

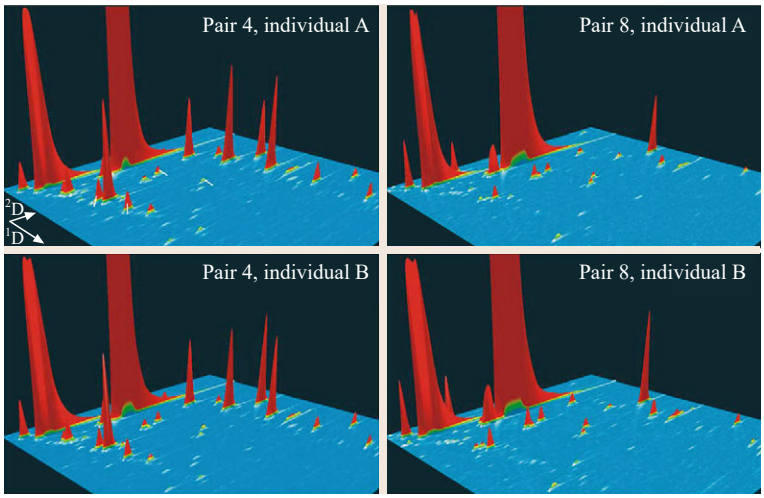

Fig. 49.5 The pattern of carboxylic acids in two pairs of monozygotic twins. The acids were released from sweat samples by the bacterial N_α-acyl-glutamine aminoacylase and analyzed in the form of their methyl esters by comprehensive two-dimensional GC (after [49.35])

bial population could be excluded, as the fingerprints generated from the released pattern of odor precursors were actually evaluated. Indeed it could be shown that monozygotic twins had highly similar patterns of acid precursors, and that these patterns were stable within individuals between different days and between the samples from the left and the right axilla, but there was a high variability between nonrelated individuals (Fig. 49.5). No standardization of the diet was needed in order to observe these stable odorprints, indicating that diet has a minor impact on these typical axilla odors. This study showed for the first time genetically inherited, individual-specific odor patterns in human beings at the analytical level [49.35], although inherited odors in twins were shown before in sensorial studies [49.36]. It is known that apocrine glands, and hence body odor, only form with puberty [49.1], but currently there is no information whether the body odor then changes with age or hormonal changes such as the menopause.

49.6 Effect of the Human Leukocyte Antigen (HLA) on Precursor Release?

In mice, urine odors appear to be influenced by genes in the major histocompatibility locus (MHC). Urine samples from mice with different MHC-genotypes can be discriminated by trained mice [49.37]. This seems to have important implications for mate selection, parent-progeny recognition [49.38] and inbreeding avoidance [49.39]. Later, evidence for human leukocyte antigen (HLA) associated body odors were also reported in humans [49.40] (HLA is the human pendant of the MHC). However, a more recent study did not replicate the same findings [49.41]. Nevertheless, we wondered whether the genetically inherited patterns of odorant acid precursors identified in twins could be associated with an individual's HLA-genotype. Therefore, families with four siblings of identical sex were recruited and tested for both HLA-genotype and pattern of released acids in the sweat. Siblings have a 25% chance of exhibiting the same HLA-genotype, and thus in these larger families many pairs with identical HLA-genotype could be identified, which, given the high diversity in the human HLA region, is rare in the general population. Again, individuals had similar patterns of released acids if sampled on different days, thus verifying the stable patterns of acid precursors. However, whether two siblings shared none, one or two HLA-haplotypes had no significant effect on the similarity in their odor patterns (Fig. 49.6). Thus we could not show a clear effect of the HLA-genotype on patterns of odorant acid secretion [49.42]. On the other hand, these acids were the most likely known candidates for such an HLA-dependent effect for the following reasons:

1. In mice, the HLA-dependent signal could be isolated from urine in the acidic organic fraction [49.43].
2. This fraction contained no MHC-specific acids, but an MHC-dependent pattern of common acids.
3. The acids are the only human odorants previously shown to have a both a high diversity and an individual specific, genetically inherited pattern. Given the negative results in this study, the open question remains, whether other, genetically and HLA-determined odorants can be isolated from human body secretions, or whether potential HLA-associated body odors in humans remain a myth as their chemical nature cannot be resolved by current analytical means.

In a very recent report, a new potential HLA-dependent odorant principle in human body odor was proposed. Based on the earlier findings in mice that synthetic peptides with specific motifs binding to the MHC receptor can trigger a response in mouse olfactory neurons [49.44], it was hypothesized that humans may also perceive nonapeptides, which are known as HLA-ligands. Such synthetic peptides were thus tested both in a behavioral study and in a neuroimaging study. Statistically, significantly different results were obtained

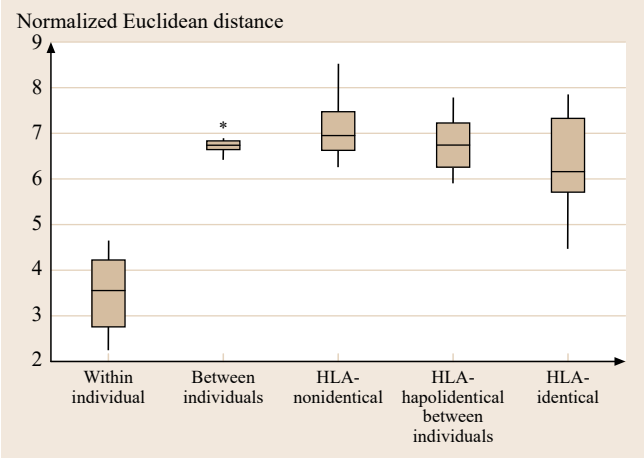

Fig. 49.6 Similarity between odorprints obtained from pairs of unrelated individuals or siblings sharing one or two HLA-haplotypes (after [49.42])

in both approaches depending on the receiver's HLA-genotype, which led to the conclusion that such HLA-binding peptides indeed are the HLA-dependent body odorants in human body secretions [49.45]. However, the study left many questions unanswered, as neither there was analytical verification of the HLA-dependent presence of such peptides in sweat nor evidence for conscious detection by human panellists – all parameters firmly established for the human body odorants described earlier. Finally, the question how nonvolatile nonapeptides may reach the human olfactory epithelium remained unanswered for the time being [49.46].

49.7 Ethnic Effects on Odor Formation and the ABCC11 Polymorphism

There is little analytical evidence whether body odors are affected by ethnic origin. However, there is one exception. A significant fraction of the population in the Far East is known to produce dry and white earwax, as opposed to the yellow and wet earwax dominant in the remaining global population. Individuals with the *dry and white* phenotype were reported not to have the typical axilla odors [49.47, 48]. This phenotype could be linked to a single nucleotide polymorphism (SNP) in the gene coding for the efflux pump protein ABCC11 [49.49]. We thus wondered whether this SNP does equally affect secretion of odor precursors, as it does affect the formation of the yellow earwax phenotype. Panelists with ethnic origin in the Far East were thus typed for their ABCC11 genotype and their axilla secretions were sampled and analyzed with LC-MS for the content of the odor precursors [49.23]. A 100% association between a functional allele of the *ABCC11* gene and the presence of the odorant precursors depicted in Figs. 49.1 and 49.2 could be shown, suggesting that this efflux protein is directly involved in secretion of these precursors in the apocrine glands. Moreover, this strong association between an odorant phenotype and the ability to secrete these odorant precursors gives a very clear indication that the findings from the biochemical and sensorial analysis reviewed earlier are relevant, as the odorant genotype and phenotype are closely linked to the presence of these precursors. In addition, also the amount of a number of steroids is affected by the ABCC11 phenotype. However, these steroids were detected with specific antibodies, and the analytical evidence for the exact structures of these analytes is therefore less strong as compared to results obtained for the odor precursors by mass spectrometry.

It may also be worth to look at the evolutionary context of this SNP. Based on detailed analysis, it was concluded that it is present as a specific extended haplotype in all individuals [49.49], that is, there are other, completely linked SNP's in close proximity of this mutation. This indicates that (i) the mutation is relatively young in human evolution, as no crossing over took place between these linked SNPs and (ii) this mutation occurred only once and all carriers have inherited this same allele from this single mutation event. Given the fact that the allele frequency reached close to 100% in several human populations, one has to speculate that there was a strong positive selection pressure for the dominant recessive, ABCC11-negative phenotype (Fig. 49.7). Whether there was a positive, odor-dependent selection for this nonodorant phenotype in partner choice, or whether the ABCC11-negative phenotype contributed another, positively selected advantage is a challenging question.

49.8 Outlook: Toward More Specific Deodorants

The detailed biochemical studies do have practical implications, as it is now possible to develop specific chemicals targeting any of the three key malodor releasing enzymes described in this chapter. Whereas classical underarm products attempt to reduce secretion of sweat (antiperspirant mode of action) or to reduce the growth of the bacterial flora on the skin (deodorant mode of action), it has now become possible to try a more specific intervention by targeting the enzymes. One class of such molecules was developed in our laboratory – based on the finding that the N_α-acyl-glutamine aminoacylase has a high specificity for Gln, but a high tolerance for the acyl-part of the substrate, we designed conjugates, which upon bacterial action release a fragrant molecule instead of a malodorant molecule. Such alternative substrates were tested in in vitro studies, and shown to reduce malodor release in bacterial incubations by competitive inhibition of the enzyme [49.32]. One substrate was then further taken into a series of clinical tests in deodorant formulations not containing classical deodorant principles. Interestingly, this substrate did reduce malodor formation in vivo, and this effect was most

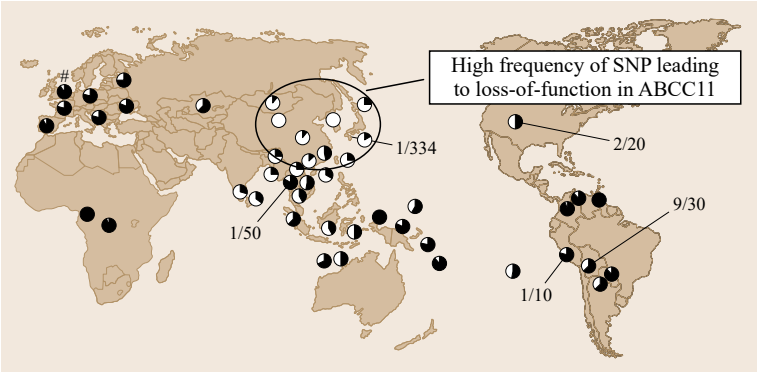

Fig. 49.7 Global frequency of the 538G ⇒ A allele in the *ABCC11* gene in the human population. Gray indicates frequency of the mutated allele. Individuals carrying this loss-of-function mutation on both chromosomes have completely lost the ability to secrete the odor precursors listed in Figs. 49.1 and 49.2, whereas these compounds are detectable in all individuals carrying one or two of the functional G-allele (after [49.49])

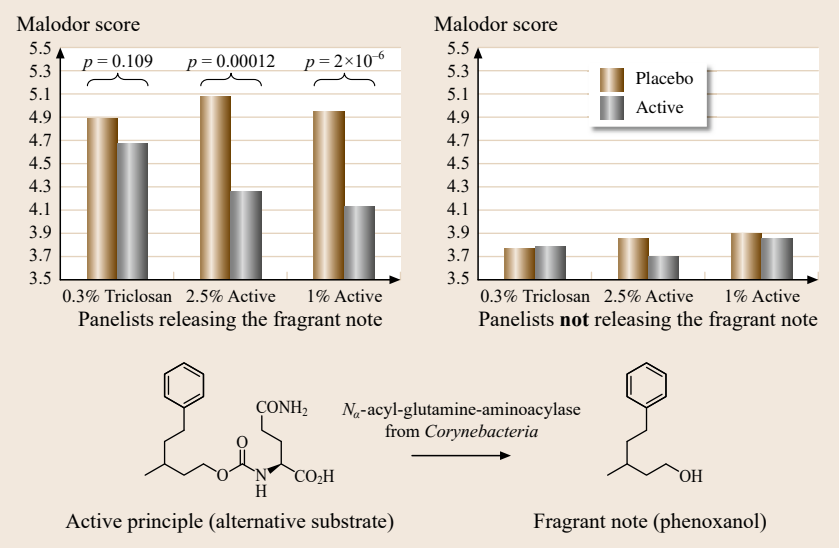

Fig. 49.8 In vivo test of an alternative substrate targeting the N_α-acyl-glutamine aminoacylase (after [49.50])

prominent on individuals with high malodor scores – notably these were also the panellists having high N_α-acyl-glutamine aminoacylase activity as determined by a noticeable release of the fragrant principle from the alternative substrate in vivo [49.50] (Fig. 49.8). Shown in the figure are malodor scores 8 h after application of deodorants containing either the classical principle Triclosan or the new active shown below. Panelist results were separated for those on whom the fragrant note could be perceived by the assessors and those who did not release the fragrant note. The odor level was low in the *negative panelists* putatively not carrying a bacterial population with high aminoacylase activity (right panel). At the same time no further malodor reduction could be observed in these panelists, but a clear effect was noted on individuals with high odor and carrying a bacterial flora able to cleave the substrate (left panel). Next to the ABCC11 study described earlier, this observation further substantiates the relevance of the biochemical routes to odor discovered before: Strength of odor is clearly linked to the presence of bacteria able to cleave Gln conjugates. Thus, both the basic genetic study and the applied deodorant research yielded further in vivo proof of the biochemical work performed earlier.

50. Individual Variation in Body Odor

Jan Havlíček, Jitka Fialová, S. Craig Roberts

Humans produce numerous volatile compounds from different areas of the body, either as a direct result of metabolic processes or indirectly via metabolism of resident microflora. Body odors vary between individuals, partly due to genetic differences, but odors of the same individual also vary across time due to environmental influences. We discuss how at least part of the genetic influence appears to be related to certain personality characteristics and to sexual orientation. We then review the current state of the art in terms of intraindividual variation, including effects of intrinsic factors, such as hormonal influences on body odor and environmental factors, namely effects of diet and certain diseases. Some of these changes can be perceived by other individuals and might therefore provide social cues of current motivational, nutritional, and health status. Finally, we discuss how specific odor profiles associated with certain infectious diseases and metabolic disorders can be used as a cheap and efficient medical screening tool.

In common with other animals, humans constantly produce a cloud of volatile chemicals which can potentially be perceived by others. The majority of these compounds are direct by-products of body metabolism or products of the metabolism of either commensal or pathogenic microflora. Human body odors are emitted from various areas of the body notably from the mouth, the anogenital region, the scalp, and the axillae. In healthy adults, axillary odor appears to be the most distinctive, due to a relatively high concentration of both eccrine and apocrine glands in this area. Interestingly, most compounds in fresh apocrine sweat are odorless and these are converted to odoriferous molecules by the action of the residential bacterial microflora (Chap. 48). Body odor appears to be individually specific and relatively stable [50.1], perhaps due to genetic influences. This is supported by three lines of evidence:

1. Body odor of monozygotic twins show high resemblance [50.2].
2. Unacquainted individuals can match relatives (e.g., offspring and parents) based solely on body odor [50.3].
3. People show odor preferences associated with the genes of the major histocompatibility complex [50.4].

Further, people can identify others based on their body odor (for details of this kind of evidence, see Chap. 51). Apart from genetic influences, there are also numerous intrinsic and extrinsic factors shaping individual variation in human body odor. Here, we first review two factors contributing to interindividual odor variation, namely personality factors and sexual orientation. We then turn our attention to intrinsic factors of intraindividual variation in body odor, namely hormonal influence (emotion-related fluctuations in body odor are reviewed elsewhere; see Chap. 49), and to environmental factors, such as effects of diet and disease.

50.1 Personality

People tend to spontaneously attribute a range of psychological characteristics to others based simply on their appearance or on *thin slices* of their behavior. At least in some characteristics, such attributions are to some extent accurate; that is, they correlate with the target's personality profile. These attributions have been described as having a *kernel of truth* [50.5, 6]. Although less well-known, body odor could also contribute to such attributions based on first impression, as some personality traits are correlated with social perception of body odor. For example, women in the fertile phase of their menstrual cycle find the axillary odor of relatively dominant men more attractive [50.7], and in a series of studies it was recently shown that strangers can accurately attribute levels of neuroticism and dominance in others based solely on their axillary odor with women showing more accurate judgments compared to men [50.8, 9]. Furthermore, prepubertal children can accurately judge neuroticism [50.10]. The precise mechanism responsible for the association between personality traits and axillary odor quality is not well understood. In the case of dominance, both traits may be underpinned by levels of testosterone. The picture might be more complex in the case of neuroticism, but a potential indication lies in the observation that some emotional states (anxiety) have impact on odor quality and in turn affect other people exposed to such odors [50.11, 12]; as neurotic individuals tend to be more frequently distressed, this might also affect their body odor.

50.2 Sexual Orientation

The effects of one's sexual orientation extend beyond the sex of preferred romantic partners. There is robust evidence that it also influences various psychological (e.g., verbal fluency [50.13]) and morphological characteristics (e.g., second to fourth digit ratio, which is considered a marker of prenatal exposure to testosterone [50.14]), perhaps due to shared biological machinery, such as prenatal exposure to the level of androgens [50.15]. Several studies have consequently tested whether sexual orientation also has an impact on the quality of body odor, although results of these studies are somewhat inconsistent. In one study, odor samples taken from both heterosexual and homosexual men and women were judged for pleasantness by groups of heterosexual and homosexual men and women. There was a complex pattern of significant between group differences, although one relatively consistent pattern emerged: All groups except homosexual men showed lower preference for the odor of homosexual men [50.16]. In contrast, another study, which tested only the preferences of heterosexual women, reported that they found the odor of homosexual men more, not less, appealing than those of heterosexual men [50.17]. We therefore await further research before being able to draw sharp conclusions on this fascinating topic. Furthermore, the underlying mechanism linking sexual orientation and the quality of body odor is currently unknown.

50.3 Hormonal Influences

The endocrine system controls a very wide range of physiological processes and contributes to the motivation systems. Hormonal action can thus also influence body odor quality, either as a by-product of hormonal metabolism or by metabolism of the affected tissue. Furthermore, hormonal action might also target the apocrine glands in order to directly communicate motivational state to other individuals. The main focus of research on endocrine influences on body odor has been on steroid hormones.

In women, for example, there is relatively robust evidence showing that attractiveness of axillary body odor rated by men varies across the menstrual cycle, peaking in the follicular phase when the probability of conception is highest [50.18, 19]. No such changes are observed in women using hormonal contraception, suggesting that this effect is steroid hormone dependent [50.20], presumably as a result of changing amounts or ratios of estrogen and progesterone. One early study also found significantly higher pleasantness of vaginal odor in the follicular phase of the cycle [50.21]. Although the magnitude of these cyclic changes is substantially lower than the differences in odor attractiveness among individual women [50.22], they are nonetheless perceivable and might play a role in coordinating sexual activity. In line with this idea,

men exposed to women's axillary odors collected during the fertile phase of the cycle experience elevated levels of testosterone [50.23, 24] although another study was not able to replicate this effect [50.25]. Similar increases in testosterone and cortisol are invoked by vulvar odor collected in the women's fertile phase [50.26]. In a series of follow-up studies, it was found that exposure to fertile phase axillary odors specifically activates mating-related concepts in men (e.g., generating more sexually tinged words), increases their judgments of women's sexual arousal, and leads to more risky decisions (assessed by a computerized blackjack card game) [50.23]. Furthermore, women seem to be similarly reactive to fertility-related odors as they showed increased testosterone levels after exposure, although this is presumably a consequence of intrasexual competition rather than attraction [50.27].

One might also expect changes in body odor related to pregnancy, based on the specific hormonal profiles which occur during this time. This includes elevated levels of human chorionic gonadotropin during the first trimester and continuously rising levels of progesterone and estrogens during the course of pregnancy. In one study, several specific compounds were detected in axillary and areolar samples taken from pregnant women. Some of these were also found in lactating women after delivery, but not in a control group of nonpregnant women. Two of the identified chemicals, 1-dodecanol and oxybis octane, showed systematic fluctuations during the pregnancy [50.28]. Furthermore, changes in breath volatiles of pregnant women have been found using an electronic nose, although no specific compounds related to pregnancy were identified [50.29]. These analytical results are also supported by subjective ratings, such that men rate axillary odor of women in the second trimester as most pleasant [50.30]. Finally, several studies on attractiveness of human body odor to mosquitoes showed higher bite rates in pregnant women [50.31–33]. Interestingly, the attractiveness of body odors to mosquitoes appears to be affected by levels of short-chain fatty acids, and this might explain higher bite rates observed in pregnant women [50.34].

In contrast, investigations into potential links between the quality of body odor and levels of other hormones present more inconsistent results. In one study, it was found that attractiveness of axillary body odor is positively associated with cortisol levels but not with testosterone [50.35]. Another study, based on a larger sample of both odor donors and raters, showed that males whose odor samples were judged as attractive show higher levels of testosterone but not cortisol [50.36]. Finally, one more study found a negative association with cortisol levels [50.37]. Thus, clearly it is currently difficult to draw any robust conclusions on relationships between these steroid hormones and odor, and further investigations of potentially modulating factors responsible for these inconsistent findings are required.

50.4 Diet

Some authors consider diet as the most salient environmental factor shaping our body odor as humans consume a high variety of aromatic foods [50.38]. Several volatile compounds may subsequently emanate in breath odor. Further, some components of the diet might produce volatile compounds only after being metabolized by the digestive system. As volatile molecules are relatively small, they can pass through the epithelium and be distributed across the body via the blood stream. In this way, they can consequently affect axillary odor or odor of urine and feces. The studies on effect of diet are summarized in Table 50.1.

Evidence from animal studies indicates that diet might be a potent modulator of body odor and that in some species, females can use odor cues to assess the quality of potential mates by the quantity and quality of ingested food. *Pierce* and *Ferkin* [50.49] investigated the effect of food deprivation on odor of female meadow voles (*Microtus pennsylvanicus*). It was shown that the odor of starving animals was less attractive compared to individuals fed *ad libitum*. This effect disappeared 48 h after re-feeding. The crucial factor for nutrition appears to be not only the availability of food, but also its quality, such as the amount of dietary protein. It was found that both male and female meadow voles preferred the odor of opposite-sex individuals on a high-protein diet, and spent the least time investigating the odor of individuals on a low protein diet [50.50]. Similarly, attractiveness of urine odor was positively linked to high quality food in guinea pigs (*Cavia porcellus*) [50.51]. In an analogous manner, red-backed salamander (*Plethodon cinereus*) females assess territory quality by examination of male fecal pellets and prefer pellets from individuals fed on high-quality food [50.52]. Other social interactions might be affected by diet as well. For instance, in spiny mouse (*Acomys cahirinus*) pups, preferences are formed early in life, and they subsequently prefer the odor of females fed on the same diet as their mothers [50.53].

The effect of diet on human body odor was first demonstrated in twin studies. Humans were able to discriminate the hand odors of monozygotic twins on

Table 50.1 Summary of studies on effect of diet on human bodily odors

Authors	Food	Odor source	Odor quality/hedonicity	Volatile compound(s)
Fialová et al. [50.39]	Garlic	Axilla	↑ Attractiveness, pleasantness, ↓ intensity	
Hauser et al. [50.40]	*Amba* (mango, saffron, curry)	Skin, amniotic fluid	Foul, curry	
Hauser et al. [50.40]	*Khilba* (fenugreek)	Skin	Fenugreek	
Hauser et al. [50.40]	*Shug* (cumin, garlic, salt, oil, pepper)	Skin	Cumin	
Havlíček and *Lenochova* [50.41]	Red meat	Axilla	↑ Attractiveness, pleasantness, ↓ intensity	
Korman et al. [50.42]	*Hilbe* (fenugreek)	Skin, urine	Maple syrup	3-hydroxy-4,5-dimethyl-2(5H)-furanone (sotolone)
Lefèvre et al. [50.43]	Beer	Skin	↑ Attractiveness to malarial mosquitoes *(Anopheles gambiae)*	
Pelchat et al. [50.44]	Asparagus	Urine	Sulfurous, cooked cabbage	Methanethiol, carbon disulfide, dimethyl disulfide, dimethyl sulfide, dimethyl sulfone, dimethyl trisulfide, S-methyl-2-propenthioate
Suarez et al. [50.45]	Pinto beans, lactulose	Flatus	Rotten eggs, decomposing vegetables, sweet	Hydrogen sulfide, methanethiol, dimethyl sulfide, hydrogen sulfide
Suarez et al. [50.46]	Garlic	Breath	Garlic	Hydrogen sulfide, methanethiol, allyl mercaptan, allyl methyl sulfide, allyl methyl disulfide, allyl disulfide
Tamaki et al. [50.47]	Garlic	Breath	Garlic	Methanethiol, dimethyl sulfide, allylthiol, allyl methyl sulfide, dimethyl disulfide, methyl propyl sulfide, diallyl disulfide, 3-(allylthio) propionic acid
Yalcin et al. [50.48]	Fenugreek	Skin, urine	Maple syrup	3-hydroxy-4,5-dimethyl-2(5H)-furanone (sotolone)

a different diet, but their performance was not higher than chance when assessing odor of twins on the same diet [50.54]. This task appears to be too difficult even for trained dogs. They successfully discriminated between the odors of both dizygotic and monozygotic twins on different diets, but not the odors of monozygotic twins on the same diet [50.55].

Perhaps predictably, the main source of bodily odors that is affected by diet is breath odor. Breath malodor could have a profound impact on everyday social interactions [50.56] as numerous volatiles emanate from consumed food due to mastication and digestive processes in both the oral cavity and the stomach. Nevertheless, only some parts of the diet produce specific odor profiles. Garlic odor would be a representative example. It has been demonstrated that the typical garlic odor in breath is more intense after ingestion of raw garlic compared to cooked garlic [50.47]. The characteristic odor consists of distinctive sulfur-containing compounds (allicin, mono-, di- and trisulfides, ajoene, and vinyldithiines). Moreover, this odor lasts for several hours even despite oral hygiene, especially due to the unique derivation of allyl methyl sulfide from the gut. Thus, *garlic breath* initially originates from the mouth and subsequently from the gut [50.46].

Another source of bodily odors originates from digestive processes. Action of bacteria on endogenous sources produces gases within the digestive system [50.57]. These eventually emerge as flatus that consists of both nonodorous compounds, such as oxygen,

Fig. 50.1 An odor sample rating session (courtesy of J. Fialová)

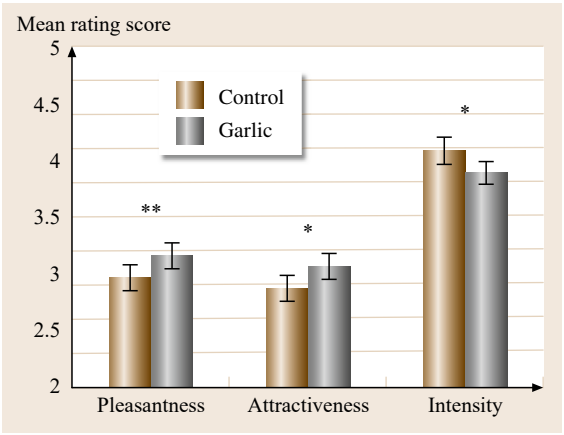

Fig. 50.2 Mean ratings (± SE) of 16 pairs of axillary odors on pleasantness, attractiveness, and intensity in the experimental (*garlic*) condition (*gray bar*) and control (*non-garlic*) condition (*brown bars*) by 40 women. Ratings were on 7-point scale (e.g., 1 – very unpleasant and 7 – very pleasant). *Asterisks* indicate level of significance in paired *t*-tests. $^{*}p < 0.05$ level; $^{**}p < 0.01$ level (after *Fialová* et al. [50.39])

nitrogen, carbon dioxide, hydrogen and methane, and odorous ones containing sulfur, the production of which could be affected by dietary habits [50.45]. Higher levels of sulfur occur in some breads, dried fruits, brassicas and soy flour. A study where flatulence was increased in participants due to consumption of pinto beans and lactulose found that flatus malodor correlates with the concentration of hydrogen sulfide (reminiscent of rotten eggs) and methanethiol (decomposing vegetables) [50.58]. Similarly, urine of people who have recently eaten asparagus has an unusual sulfurous odor similar to cooked cabbage [50.44].

Several case studies show that the mother's diet might also affect the body odor of the newborn baby. For instance, in one case, a newborn baby had body odor and urine that smelled of maple syrup. The baby was therefore suspected of having maple syrup syndrome, but subsequent laboratory tests did not confirm this diagnosis. It was subsequently discovered that, prior to delivery, the mother ate fenugreek-spiced food which was responsible for this distinctive odor [50.42, 48]. The *maple syrup* odor that appears after fenugreek consumption was recently analyzed and several compounds which could be responsible for the distinctive odor were found in human sweat [50.59]. The same odor may also be detected exuding from the mother's skin and may be transmitted to the infant via the mother's breast milk [50.42]. In other cases, the mother consumed *shug* (a dish containing cumin, garlic, salt, oil, and pepper) and her baby consequently smelled of cumin. In a similar way, a newborn baby and its amniotic fluid was found to be yellowish, with an odor reminiscent of curry, after the mother ate *amba*, which consists of mango, saffron, and curry [50.40].

The evidence on the effects of the diet on axillary odor is comparatively limited. One study [50.41] investigated whether consumption of red meat affects human body odor, because people from some predominantly vegetarian cultures say that people who eat meat smell bad because of it. The results of the study showed that the axillary odor of individuals on a nonmeat diet was perceived as more attractive, more pleasant, and less intense than the odor of the same individuals on a diet containing meat (at least one meat dish daily for 2 weeks). These results might appear counterintuitive, as meat consumption is thought to play a significant role in human evolution, and because they might be at odds with studies on effects of high protein diets in rodents (see above). The explanation may be that the amounts of meat consumed in contemporary populations, and in Havlicek and Lenochova's experiment, may be higher than would normally be experienced in traditional or ancestral societies. In this way, body odor changes after consumption of relatively large quantities of meat could in fact resemble a metabolic disorder [50.41]. Another surprising finding resulted from a series of studies that examined the effects of garlic consumption on axillary odor. Samples of body odor from the same individuals were obtained in both an experimental

(high garlic consumption) and control condition. Axillary odor of the participants after ingesting garlic was perceived as more attractive, more pleasant, and less intense (Fig. 50.1). In contrast to the effects of garlic on breath odor, the positive influence on axillary odor might be explained by longer term health benefits of garlic consumption, including antioxidant action and antibacterial activity [50.39] (Fig. 50.2).

Interestingly, dietary effects might also affect attractiveness of human body odor to blood sucking insects. *Lefèvre* et al. [50.43] found that beer consumption increases human odor attractiveness to malarial mosquitoes (*Anopheles gambiae*). Exposure to the body odor of participants who consumed beer caused an increase in mosquito activation (take-off and up-wind flight) and orientation (flying toward volunteers' odors).

50.5 Diseases and Disorders

The profile of volatile compounds found in human body odor can be affected by health and disease. This was recognized by ancient medical authorities, such as Hippocrates, Galen, and Ibn Sina, who advocated the use of olfaction in medical diagnostics. Recent technological advances and availability of highly sensitive techniques like gas chromatography-mass spectrometry (GC-MS) makes volatile compounds an increasingly significant part of early disease diagnostics. Generally, such changes in body odor might be either a result of altered metabolism and/or more direct effects of infectious agents. For this reason, metabolic disorders and infectious diseases are reviewed separately in the following paragraphs, where we present some representative examples of the effects of disease on body odor (Table 50.2).

50.5.1 Metabolic Disorders

The main cause of metabolic disorders is deficiency in enzymes or transport systems. Such deficiencies frequently lead to the accumulation of specific metabolites and in some disorders, to its further conversion to other compounds. If these are volatile, the metabolite or its products may lead to a characteristic odor profile in affected individuals. These metabolic disorders are often a consequence of simple Mendelian inheritance.

Isovaleric Acidemia

The disorder is caused by a deficiency of the isovaleryl-CoA dehydrogenase, which is involved in leucine metabolism. Due to the disorder, isovaleric acid accumulates in the tissues and leads to serious ketoacidosis which may subsequently result in coma [50.83]. Patients with isovaleric acidemia produce high levels of isovaleric acid in body fluids and urine, which is characterized by the distinctive odor of sweaty feet [50.64].

Maple Syrup Urine Disease

This is an autosomal recessive inherited disorder caused by deficiency in the enzyme 2-oxo acids dehydrogenase complex, which results in the accumulation of branched-chain amino acids, such as leucine in tissues and body fluids [50.84]. If not recognized early after birth and treated by a branched-chain amino-acid-free diet, the disorder can result in mental retardation. Body odor and urine odor of affected individuals smell relatively pleasant, resembling maple syrup. The compound responsible for the odor appears to be sotolone (3-hydroxy-4,5-dimethyl-2(5H)-furanone) [50.63].

Phenylketonuria

This disorder is caused by a recessive mutation in a gene coding for phenylalanine hydroxylase. The enzyme is expressed in liver tissue where it converts the amino acid phenylalanine into tyrosine. Due to the phenylalanine hydroxylase deficiency, the phenylalanine is converted to phenylpyruvic acid and phenylacetate which are excreted in sweat and urine. The phenylacetate gives affected individuals a musty odor, resembling sweaty lockers [50.61].

Trimethylaminuria

The disorder is characterized by a deficiency of the flavin containing monooxygenase 3 which converts trimethylamine to trimethylamine *N*-oxide. Trimethylamine is produced by gut bacteria from choline rich food, such as eggs or legumes. In unaffected individuals, most of the odorous trimethylamine is converted in hepatic tissue to odorless trimethylamine *N*-oxide. However, in people suffering from trimethylaminuria, trimethylamine emanates from their breath, sweat, and urine, with an odor which resembles that of decaying fish [50.60].

Diabetes

An example of a metabolic disorder with an etiology involving multigenetic as well as environmental factors (e.g., dietary habits) is diabetes. Type I diabetes is characterized by insufficient secretion of insulin, and the lack of insulin leads to an increase in the level of ketones including acetone in the blood. As a consequence, people suffering from diabetes with elevated

Table 50.2 Summary of studies on disease-related body odors

Authors	Disease/Disorder (Pathogenic agent)	Pathology/Symptoms	Odor source	Odor quality	Volatile compound(s)
Metabolic disorders					
Chalmers et al. [50.60]	Trimethylaminuria	↓ Flavin monooxygenase 3	Breath, sweat, urine	Decaying fish	Trimethylamine
Cone [50.61]	Phenylketonuria	↓ Phenylalanine hydroxylase	Sweat, urine	Musty, wolf-like, barny, sweaty locker-room towels	Phenylpyruvic acid
Laffel [50.62]	Diabetes	↓ Insulin secretion	Breath	Sweet	Ketones (acetone)
Podebrad et al. [50.63]	Maple syrup urine disease	↓ 2-oxo acids dehydrogenase	Skin, urine	Relatively pleasant, maple syrup like	3-Hydroxy-4,5-dimethyl-2(5*H*)-furanone (sotolone)
Tanaka et al. [50.64]	Isovaleric acidemia	↓ Isovaleryl-CoA dehydrogenase	Urine	Sweaty feet	↑ Isovaleric acid and its derivatives
Infectious diseases					
Anderson et al. [50.65] *Landers* et al. [50.66] *Wolrath* et al. [50.67]	Bacterial vaginosis (Gram-negative bacteria *Gardnerella vaginalis, Mycoplasma)*	Abnormal vaginal discharge (color, consistency, amount), itching, burning, dysuria	Vagina	Cheesy, fishy, foul	Trimethylamine
Finlay et al. [50.68]	Skin ulcers *(Bacteroides, Propionibacterium)*	Cutaneous lesions	Skin	Offensive, foul	
Garner et al. [50.69]	Cholera *(Vibrio cholera)*	Watery diarrhoea, vomiting, dehydration	Feces	Sweetish	Dimethyl disulfide, *p*-menth-1-en-8-ol
Honig et al. [50.70]	Scarlet fever *(Streptococcus pyogenes)*	Red-colored rash on the body, sore throat and fever	Skin, breath	Foul	
Liddell [50.71]	Typhoid fever *(Salmonella typhi)*	High fever, drenching sweat, gastroenteritis	Skin	Baked brown bread	

Table 50.2 (continued)

Authors	Disease/Disorder (Pathogenic agent)	Pathology/Symptoms	Odor source	Odor quality	Volatile compound(s)
Phillips et al. [50.72], *Syhre* and *Chambers* [50.73] *Syhre* et al. [50.74]	Tuberculosis *(Mycobacterium tuberculosis)*	Cough, chess pain, weight loss, fever, night sweats	Breath	Foul	Methyl nicotinate, methyl phenylacetate, methyl *p*-anisate, *o*-phenylanisole, cyclohexane, benzene derivatives, decane, heptane
Shirasu and *Touhara* [50.75]	Diphtheria *(Corynebacterium diphtheriae)*	Sore throat, fever, difficulty breathing	Breath	Sweetish, putrid	
Tumors					
Jobu et al. [50.76]	Bladder		Urine		Ethylbenzene, nonanoyl chloride, dodecanal, (*Z*)-2-nonenal, 5-dimethyl-3(2*H*)-isoxazolone
Phillips et al. [50.77]	Lung		Breath		Alkanes, alkane and benzene derivatives, isoprene, benzene
Phillips et al. [50.78]	Breast		Breath		2-propanol, 2,3-dihydro-1-phenyl-4(1*H*)-quinazolinone, 1-phenyl-ethanone, heptanal, isopropyl myristate
Psychiatric disorders					
DiNatale et al. [50.79] *Phillips* et al. [50.80] *Phillips* et al. [50.81], *Smith* et al. [50.82]	Schizophrenia	Hallucinations, delusions, cognitive deficit	Breath	Peculiar, unpleasant	*Trans*-3-methyl-2-hexenoic acid, carbon disulfide, pentane

ketones produce acetone from their breath, which gives off a characteristic sweet smell [50.62].

50.5.2 Infectious Diseases

The pathogenic activity of many infectious agents also produces various volatile compounds which are emitted from skin, breath, sweat, vaginal fluid, urine, and feces. In contrast to odor-producing metabolic disorders, which are frequently characterized by specific volatile molecules with distinctive odor as we have just described, effects on odor of patients with infectious diseases are more complex and therefore more challenging to characterise. This can be attributed to three main reasons:

1. Bacteria of one strain/species may metabolize different substrates producing a complex mixture of volatiles.
2. Different bacteria overlap in the specific volatiles they produce.
3. Some diseases are frequently characterized by multiple infections which may lead to less characteristic odor.

Several infections of the digestive system are characterized by distinctive fecal odor. This involves infection by *Vibrio cholerae* which causes acute watery diarrhoea with a distinctive sweetish odor. The volatile compounds responsible for the odor were identified as p-meth-1-en-8-ol and dimethyl disulfide [50.69].

Infections of the respiratory system frequently affect breath odor. For instance, people suffering from lung tuberculosis, caused by infection with *Mycobacterium tuberculosis*, are reported to have foul breath odor. A specific mixture of volatile compounds was reported from the breath of infected patients, with a similar volatile profile found in in vitro cultures [50.73]. The biomarkers of tuberculosis infection were proposed to be nicotinic acid, cyclohexane and some benzene derivatives [50.72, 74]. Similarly, individuals infected with *Corynebacterium diphtheriae* are characterized by sweetish and putrid breath odor, resulting from effects of the diphtheria-causing bacteria on the upper respiratory system, generating other symptoms including sore throat and swollen tonsils [50.75].

The vagina is a major source of body odor in adult women. It is rich in residential microflora which play a part in odor production. Changes in vaginal odor might reflect infection by pathological agents and it is frequently used by gynecologists in differential diagnostics [50.65]. For instance, bacterial vaginosis is frequently accompanied by a cheesy or fishy odor which is caused by the production of highly odorous trimethylamine [50.67]. Women diagnosed for an infection by the protist *Trichomonas vaginalis* also frequently complain about malodor [50.66].

Perhaps most common are changes in skin odor caused by infections. These may derive from infection in other parts of the body, such as infection of the intestinal tract by *Salmonella typhi*, the agent of typhoid fever. People suffering from typhoid fever are said to smell like baked bread [50.71]. Infections directly affecting the skin include scarlet fever caused by *Streptococcus pyogenes*. The disease manifests in the form of a rash, strawberry-colored tongue, and fever, but patients also emit a distinctive foul odor from their skin and breath [50.70]. An offensive smell is also associated with anaerobic infections (e.g., by *Bacteroides*, *Propionibacterium*) which cause skin ulcers. Patients often complain about the strong smell which can be significantly reduced by cutaneous application of metranidazol [50.68].

50.5.3 Tumors

Oncological disorders are characterized by abnormal cell growth, mostly caused by mutations in genes (or epigenetic factors) controlling for cellular growth and division. However, neoplasia might be caused by various genes and further development depends on affected tissue. Nevertheless, affected cells might show specific metabolic changes, partly attributable to oxidative stress, and production of distinctive patterns of volatile molecules. Recently, there has been increased interest in the analysis of various substances in patients with different carcinomas. Air exhaled by individuals with lung cancer form a specific pattern of volatile molecules including alkanes, alkane derivatives, and benzene derivatives [50.77]. Similarly, people diagnosed with breast cancer emanate a specific profile of volatiles in their breath. Five biomarkers for breast cancer have been detected including 2-propanol, heptanal, and isopropyl myristate [50.78]. In addition, the urine of people suffering from bladder cancer and prostate cancer has been analyzed. Volatile metabolites reported to be related to bladder cancer include dodecanal, 2-nonenal, and ethylbenzene [50.76]. The specific odor profile associated with several carcinomas has been confirmed by studies using dogs as cancer detectors. Dogs can be trained to differentiate between breath or urine odor samples taken from people suffering from lung, bladder, and prostate cancer [50.85].

50.5.4 Psychiatric Disorders

For a long time, it has been noted by psychiatric hospital personnel that certain psychiatric conditions can be as-

sociated with a peculiar odor. Schizophrenia, in particular, has attracted most attention. Early studies claimed to identify *trans*-3-methyl-2-hexenoic acid as a reliable marker of schizophrenia-associated odor [50.82]. These results were subsequently questioned [50.86], but a further study found that schizophrenic patients may indeed show elevated levels of this compound [50.79]. More recently, analysis of breath volatiles indicates that compounds like carbon disulfide, pentane, and several other volatiles might be associated with schizophrenia [50.80, 81]. Interestingly, other patients treated with neuroleptics did not share the same pattern of volatiles. This suggests that compounds associated with schizophrenia are not a by-product of the medical treatment, although further studies are needed.

There is accumulating evidence showing that some affective states, such as anxiety, influence axillary body odor (for review see [50.11]). One may therefore speculate whether some affective disorders (e.g., major depression) are also associated with changes in the body odor. To our knowledge, there has not yet been a systematic investigation on this subject.

50.6 Conclusion

Seen from various perspectives, human body odor is a highly complex biological system. First, it consists of several sources, such as the axillae, skin, mouth, feet, anogenital region, and the scalp. Each of these sources is characterized by sets of dozens or even hundreds of different volatile compounds. Second, most of the volatile compounds are not directly produced by the human body, but mainly result either from residential or pathogenic bacterial metabolic activity. Third, each human is characterized by an individual odor profile, which is partly due to the genetic influences. This profile is relatively stable across the life span and contributes to individual olfactory identity and may affect social interactions. On the other hand, individual body odor can also be altered by various intrinsic and extrinsic factors.

The main aim of this chapter was to review selected factors contributing to the inter- and intraindividual variation in body odor. We first focused on differences in body odor associated with between-individual differences in personality and sexual orientation (other sources of variation include factors, such as genotype at the major histocompatibility complex (Chap. 49). We then described within-individual changes in body odor due to hormonal influences, in which odor seems to be intimately associated with hormonal fluctuations, although it must be said that most research has focused on steroid hormones, such as estrogens or testosterone. It is noteworthy that other humans can perceive hormone-related changes in body odor and that odor might therefore provide important social cues, perhaps especially those relevant to reproduction, such as actual or potential fertility. Nevertheless, most of the chemicals responsible for hormone-related effects are currently not identified and await further investigation.

One of the major influences on body odor quality is considered to be diet, which contains numerous aromatic chemicals of mainly plant origin. As expected, various volatiles consumed in the diet affect breath and fecal odor. However, some compounds might also be emitted from the skin surface, or can influence body odor indirectly via several possible mechanisms, including oxidative metabolism, nutritional status, and antibacterial action. The effect of diet might also show an idiosyncratic pattern as a result of the interaction between digested food and individual genetic make-up. Unfortunately, these interactions are currently poorly understood.

Finally, various disorders and diseases are characterized by specific odors which are often used in clinical diagnostics or may be at least increasingly utilized in the future as a diagnostic mean. This is pronounced in the case of inherited metabolic disorders which often results in the production of unusual volatiles or their metabolites. Several carcinomas, such as lung or bladder cancer, are also known to be associated with changes in produced volatiles, and these can be used in early screening. More complex odor profiles are associated with some infectious diseases. The potential for using these changes in screening looks likely to increase in the near future.

51. Processing of Human Body Odors

Valentina Parma, Amy R. Gordon, Cinzia Cecchetto, Annachiara Cavazzana, Johan N. Lundström, Mats J. Olsson

Human chemosensory signals are able to transmit a wide range of social information to conspecifics. Resulting from the interaction of several genetic and physiological processes (e.g., metabolic, immune, nervous), each individual produces a unique odor signature. The central processing of such chemosignals by conspecifics modifies physiological, behavioral, and psychological responses. To illuminate the importance of this mode of communication, we describe how humans produce, decode, and respond to warning chemosignals. Behavioral evidence highlighting the cognitive and emotional consequences of body odor communication will be discussed. Special attention will be devoted to the current understanding of human body odor neural processing. After an overview on the topic, we discuss the role that social chemosignals may have in our everyday life in health and disease.

Social communication is a central aspect in the life of animals and human beings alike. Despite the considerable research conducted on the topic of how social information is communicated among humans [51.1], the multisensory character of such communication has often been misrepresented. In humans, most of the literature is characterized by evidence originating from the visual and auditory modalities, uncovering how facial expressions or body postures as well as linguistic features (e.g., prosody) affect social communication [51.2]. Although olfaction is widely used across species for social communication [51.3], little attention has been given to chemosensory communication in humans. This is even more surprising in light of the intrinsic and unique advantages of this form of communication. For instance, chemosignals can easily escape

the restrictions imposed by physical and time barriers where chemical molecules are able to freely disperse in air or water, and thus can be transported over long distances and remain a signal for several days. According to the physical features of the molecules, in particular volatility, chemical communication can outlast the presence of the sender (low volatile molecules) or quickly dissolve and facilitate the transmission of messages in a rapid time scale (highly volatile molecules) [51.4]. Among the far senses, olfaction remains functional when vision and audition are unavailable (e.g., in the dark, in noisy environments) and even when multiple chemosensory stimulations are simultaneously present. As an example, despite the efforts of western cultures to mask body odors with fragrances [51.5], chemosensory communication is still possible [51.6].

Aside from this ability of chemosignals to travel in space and time, and to persist within sensory overloaded environments, chemosensory communication is rather effortless for senders, as suggested by the low amount of energy required to produce and release a chemosignal [51.3]. The energy investment necessary during decoding is also limited, as suggested by the fact that receivers often elaborate the message outside of their conscious awareness [51.7–9].

This series of advantages is further strengthened by the specificity of the communication. Chemosignals transmit detailed social information related to both stable and transient states. Chemosignal communication successfully conveys information regarding personal identity [51.10–14], kins [51.15–17], partners [51.11, 12, 18], relatives [51.15, 17, 19, 20] and friends [51.15]. Furthermore, age [51.21], gender [51.21, 22], and personal predispositions [51.23] can be gleaned via human chemosignals. In addition, humans transmit information of transient states such as health status [51.24], sexual availability [51.25] and emotions [51.26–39] through chemosignals. This cumulative evidence suggests that the olfactory modality is a reliable medium through which social communication can occur among humans.

In the following sections, we will first briefly present the rationale for the terminology that we will be using throughout the chapter. Second, we will discuss the often mentioned, though questionable, concept of humans as microsmatic individuals, trying to review the basis for this belief, and the consequences for research and interpretation of data. Third, we will review how human chemosignals are produced and which are the experimental methods used during collection. Fourth, we will discuss the effects of chemosignal communication in recipients with special attention to central neural processing. Because such neural underpinnings are still incomplete and/or unaccounted for, we will advance speculative, yet fact-based, arguments in the hope of stimulating future discussion and research. Fifth, among all types of olfactory-mediated information, we will focus on the transmission of chemosignals promoting harm avoidance, for the critical survival benefits they serve. Please note that when using the word *signal* throughout the text we do not differentiate whether the signal is beneficial to the sender or not. Finally, challenges in the field as well as outstanding questions that warrant further investigations will be emphasized.

51.1 The Microsmatic Fallacy

Over the years, among both laymen and scientists, the concept of humans being microsmatic animals has wrongfully taken ground (Chap. 32). The term *microsmatic*, used in reference to primates and then extended to humans, traces back to *Turner* [51.40] who described animal species with differential olfactory skills ranging from acute in macrosmatic animals, such as dogs, to those without an olfactory system, i. e., anosmatic animals such as dolphins. Many authors have then characterized primates and humans as microsmatic in light of the concomitant increased emphasis on their use of vision [51.41–43] and based on morphological aspects. Often highlighted is the fact that the relative size of the olfactory epithelium and the olfactory bulb is reduced in primates as compared to other species [51.44, 45]. A direct comparison with vision has been gathered by the investigation of olfactory skills in nocturnal primates, who – unable to rely on visual cues – show a greater portion of peripheral and central structures dedicated to the main olfactory system as compared to diurnal primates [51.46]. Such morphological approach, coupled with direct comparisons between vision and olfaction, has rendered the erroneous conclusion that animals primarily relying on vision exhibit a poor sense of smell. This notion has been extended to humans by Pierre Paul Broca, best known for his discovery of the speech processing area subsequently named after him. On the basis of the available measures of the relative sizes of the olfactory system and estimates of the centrality of olfaction in daily life, *Broca* and *Pozzi* [51.47] suggested that humans (as other mammals) were microsmatic. Data collected using more accurate techniques in the subsequent years deemed this classification system rather obsolete. *Keverne* [51.48–50] challenged the

concept that microsmia can be explained on the basis of a reduced number of olfactory receptors alone. Each receptor is part of a combinatorial code that can respond to different odors and even a limited number of receptors can therefore form many distinct patterns [51.51]. With respect to genetics, the biggest part of the human genome is dedicated to olfaction, with its approximately 400 olfactory receptors [51.52]. Besides functional genes, modern techniques have revealed that the number of pseudo-olfactory genes is higher in humans as compared to other species, macrosmatic included [51.53–55]. This notion, often used as an argument for human microsmia, does not, however, take into account the new discoveries that these *non-coding* regions have an essential role in gene regulation and ribonucleic acid (RNA) transcription [51.56]. The jury is still out on whether having more pseudogenes is advantageous or not.

Additionally, direct correlations between olfactory structures' morphology (e.g., anatomical size), the percentage of expressed olfactory genes, and olfactory performance cannot be found in either humans or other species investigated [51.57–61]. Direct behavioral testing of the human sense of smell also repeatedly contradicts the microsmia concept where humans have been demonstrated to possess a superbly keen sense of smell [51.62, 63], as confirmed by studies assessing detection thresholds and discrimination performance [51.58–60]. For example, ethyl mercaptan (or ethanethiol), an additive used to make odorless gases (such as propane) perceivable, can be detected by untrained humans at concentrations less than 1 ppb (part per billion) and perhaps as low as 0.2 ppb [51.64]. This ability was directly translated to a real-life example by *Yeshurun* and *Sobel* [51.65]: Humans can discriminate between two olympic-size swimming pools, of which only one contains three drops of ethyl mercaptan. Provided that the chemosensory message is of sufficient relevance, it appears that humans are able to detect very subtle olfactory cues [51.57].

A final testament towards the notion that odors indeed are important to us is the fact that a large portion of western countries' commercial interests revolves around the cosmetic, fragrance, and food industries. Capitalizing on the emotional advantages of odors to evoke memories and emotional transfer (Chap. 39), the fragrance industry has in 2015 a projected annual global sales revenue of approximately 29 billions US dollars [51.66], almost equivalent to the gross domestic product (GDP) of Paraguay in 2014 at USD market prices.

Altogether, these facts indicate that humans have a sense of smell that cannot be considered functionally microsmatic. Indeed, *Zelano* and *Sobel* [51.63] have even suggested that humans constitute an ideal model to study the olfactory system, providing access to introspective information that would be otherwise inaccessible in animals.

In the next sections we will provide evidence that human behavior – and in particular social behavior – cannot be fully understood without having a good knowledge of olfactory functioning.

51.2 Human Chemosignals

Chemosignals in social communication often comprise complex molecular mixtures, some of which are volatile and produce an odor [51.3]. These chemicals are interpreted as a signal actively conveying information from a sender and potentially influencing the behavior of receivers, rather than a cue, a passive biological trait that provides an observer with information [51.67]. In light of the still unresolved debate on whether human chemosignals transmitting social information should enter the domain of pheromones [51.3, 68], we will use the terms chemosensory signals, social chemosignals or body odors interchangeably in the present chapter (Chap. 52). Such signals are produced by the human body, making an individual the sender of a message. They are made of chemicals, part of which are characterized by odorous substances and contain socially relevant information. These chemical messages can be transmitted to a human receiver, who decodes the message and uses that information to adjust his/her responses in the environment.

51.3 How do Human Senders Produce Chemosignals?

Several systems across the human body can produce volatile odorous chemosignals with communicative potential. Here, we briefly present known chemical pathways that have been suggested to be involved in communicating social information in humans. For a more detailed overview of the chemical composition and production of human body odors, please see Chap. 49.

51.3.1 The Axillary Glandular System

The majority of studies on human body odors to date have been conducted using axillary secretions with a few noticeable exceptions [51.69–75]. Besides the increase in experimental feasibility, the biological reason for such over-representation is that the glandular system contained in the axillary area contributes consistent secretions.

Most of the social communication mentioned in the literature is thought to derive from the activity of apocrine glands, found in the ano-genital and underarm areas or its specialized variations, among which we can count mammary glands (producing milk), ciliary glands in the eyelids (Moll's gland, responsible for lacrimal secretions), and ceruminous glands (which produce ear wax) [51.76]. The number of apocrine glands changes in relationship with the specific area of the body in which they are retrieved. However, the number of glands seems to be unrelated to the ability to produce signals with socially relevant information. The areas of the cutaneous gland system, in which the number of apocrine glands are most prolific, are the axillae [51.76]. Besides apocrine glands, the axillary skin contains eccrine, apoeccrine, and sebaceous glands. In light of this diversity, the glandular system of the axillary region constitutes a specific habitat, differing from most other body parts, because it harbors hair follicles with sebaceous glands and a high density of sweat glands [51.77].

Apocrine glands, inactive before puberty, increase in size under hormonal influence and begin functioning [51.78]. Their secretions are characterized by milky odorless solutions, consisting of electrolytes, steroids, proteins, vitamins, and a variety of lipid compounds [51.71, 73–75]. The activity of apocrine sweat glands is pronounced during eustressing and distressing situations and reduced during emotionally neutral physical exercise [51.79].

Eccrine glands are located throughout the body, with only a few exceptions [51.76]. In the armpit areas, they coexist with apocrine glands. The clear secretion produced by eccrine glands is thinner as compared to that of apocrine glands, mainly consisting of water and electrolytes, derived from blood plasma, and sodium chloride [51.76]. The amount of sweat depends on the number of functional glands and the size of the surface opening. Neural and hormonal mechanisms are responsible for the total volume of secretions. When all of the eccrine sweat glands are working at maximum capacity, the rate of perspiration for a human being may exceed 3 l/h [51.80].

Apoeccrine glands, comprising up to 50% of all axillary glands, share features of both apocrine and eccrine glands, as the name suggests. They produce watery secretions, in higher quantity as compared to both apocrine and eccrine glands, thus playing a primary role in axillary sweating [51.81].

Sebaceous glands are responsible for the discharge of an oily, waxy substance called sebum, mainly involved in the waterproofing and lubrication of the human skin [51.82].

Altogether, these glands contribute with their activity to the production of water-based secretions, involved in thermoregulation processes and skin protection [51.77, 83]. Such secretions are initially near odorless and the characteristic sweat odor is the product of the incubation with the bacteria residing in the armpit area [51.84–88].

51.3.2 The Axillary Microbiome

The moist environment created by the glandular secretions in the axillary areas represents a moderately diverse ecological niche hosting specifically adapted organisms establishing a distinct microbial profile [51.89]. The presence of hair follicles and sebum creates a rather occluded environment in which nutrients are readily available at a temperature that facilitates bacterial colonization [51.85]. The dominant resident flora is composed of Corynebacterium, Staphylococcus, Streptococcus and b-Proteobacteria [51.85, 89–93]. Combined, this flora is responsible for the microbial biotransformation of the nutrients secreted in the human axilla [51.94, 95]. Specifically, the axillary Corynebacteria and cocci (e.g., *Staphylococcus epidermidis*) are largely responsible for the production of odorous substances, such as androgen steroids [51.96] and aliphatic acids (e.g., isovaleric acid [51.97]). Furthermore, they contribute to the conversion of weakly odorous steroids (androstadienone) into more intensely smelling androstenes with urineous and musky notes (androstenone and androstenol, respectively [51.98, 99]).

Even though it is well established that the microbial activity is responsible for body-odor formation, the active metabolic processes are still unknown [51.100]. Obtaining axillary meta-transcriptomics is necessary to identify how endogenous characteristics (e.g., sex, age, handedness, ethnicity, and individual host factors) in combination with exogenous features (use of cosmetics, detergents, etc.) contribute to the definition of individual chemosignals, opening up a better understanding of body odors in a personalized manner.

51.3.3 What is in a Chemosignal?

The combination of a personalized axillary microbiome [51.100] and both exogenous and endogenous

factors of the donor (or sender of the chemical message) interacts to form a unique production that constitutes the individuals body odor; an end product that lies behind the notion that each individual possess an *odor print* [51.22, 101] (Chap. 50). (The term *odor print* should not be confused with the newly coined term *olfactory fingerprint* [51.102]; the former relates to a biomarker for identification of an individual and the latter is related to the characterization of an individual's olfactory perception.)

The high chemical variability needed to allow such a large degree of individualization does not necessarily rely on different chemical compounds to form this signature. Rather, it seems like a greater dependence is put on a differential quantitative composition of similar compounds, thus creating a complex code consisting of both chemical components and magnitudes of each individual component present [51.103]. Four classes of chemical compounds have been consistently associated with the characteristic sweaty odor of axillary secretions [51.104]: unsaturated or hydroxylated branched fatty acids, thio-alcohols, short chain fatty acids, and volatile steroids. For a more specific overview of the chemical composition, please refer to Chap. 49.

Additional variability in the production of axillary body odor is associated with sexual dimorphism, which strictly interacts with genetic makeup, the endocrine system, the immune system, microflora peculiarities, and diet. Men and women show dynamic structural and functional differences at the level of the glandular system. As alluded to above, during puberty, apocrine glands grow and mature [51.105], eccrine glands' production increases [51.106–108] and the axillary microbiome augments and differentiates across genders [51.109–111]. This results in substantial differences in the olfactory profiles of axillary sweat in men and women, such as different concentrations of fatty acids (e.g., 3M2H), isomers (e.g., Z-isomer), thiol and acid precursors [51.86, 95], as well as androgen steroids in male odor samples as compared to women [51.99, 112]. Furthermore, differences in the genetic makeup alter the olfactory characteristics of the body odor. Here, we bring forth the examples of the impact of a gene (ABCC11) and of a gene cluster: The major histocompatibility complex (MHC), or in humans, the human leukocyte antigen (HLA) system. The ABCC11 gene, in its homozygous variant, is expressed by the apocrine glands and produces a very mild body odor [51.113] as an effect of a reduced production of odoriferous molecules [51.114]. MHC/HLA are the main determinants of immunological individuality and may contribute to the uniqueness of each *odor print* [51.115, 116]. For instance, as well demonstrated by transplant studies, different polymorphisms of the MHC/HLA between donor and receiver increase organ rejection rates. This rate is reduced when the similarity of the MHC/HLA is high, as among relatives [51.117].

Odor variability is also influenced by ecological factors, such as the health status [51.24, 118] and diet features [51.119]. Indirect evidence of a change in the composition of body odor is gathered from the analysis of odor preferences in the recipients. Activating the innate immune system in healthy individuals via injection of lipopolysaccharide results in more aversive body odors as compared to controls within a few hours [51.24]. Analogously, red meat consumption seems to have a negative impact on perceived body odor hedonicity [51.120].

All in all, a combination of endogenous as well as exogenous factors within the sender dynamically impacts the activity of the glandular system and of the axillary microbiome, determining unique and complex olfactory outcomes of the body odor production. Such olfactory signatures are complex messages containing information of social relevance, reflecting the activity of all the systems of the senders specifically involved in the production of the body odor. Signature odors contain information about particular individuals and, as a result of the processing of such information, they modulate the activity of different systems in the perceiver, prominently, his/her perception, physiological and neurophysiological state and behavior. Also, the outcomes promoted by olfactory signatures reflect the high variability that characterizes body odor production, creating a complex and dynamic multivariate pattern of changes in the recipient.

51.4 Human Axillary Chemosignals for Experimental Purposes

Recent data suggest that humans spontaneously sample chemical signals from their own body parts that have been in close proximity with an unknown individual using what could be considered an intuitive sampling method. Individuals sniff their hand more often in the period following a handshake with a conspecific relative to a similar timeframe lacking such contact [51.121]. However, in an experimental setup where temporal presentation is of importance, more controlled sampling methodologies, as those reviewed in the following paragraphs, are usually implemented. Unfortunately, even though different sampling methods

may have significant impact on the obtained results, the field still lacks a clear methodological systematization of the way odor stimuli are collected meaning that direct comparisons between individual studies are, at best, difficult.

We have characterized the methodological steps of sampling and preserving body odors by extending the framework proposed by *Lenochova* et al. [51.122]. Each of these steps can influence the quality of the donated chemosignals, and – by extension – the experimental measures of interest:

1. The restrictions placed on body odor donors
2. The medium of sampling
3. The type of sampling
4. The time of the day and length of sampling, to
5. Sample storage.

51.4.1 Restrictions on Body Odor Donors

Common lifestyle restrictions related to hygienic, dietary, and behavioral concerns are applied before and/or during body odor sampling. The stringency of such restrictions varies greatly across studies and research groups, but the rationale is always a reduction in the variability due to external factors of the body odor samples. Such external factors can be either removed (e.g., fragrance-containing body products, foods and drinks, etc.) or standardized (e.g., all donors are provided with the same odor-free products). As any contact of an exogenous material with the sampling area can be a source of contamination, it is nearly impossible to collect uncontaminated samples outside of the strictest laboratory settings. Therefore, standardization of inevitable contamination sources can be a valuable approach, provided that the experimental design is compatible (e.g., planned contrasts).

Hygienic restrictions combat the many fragranced products often applied to body odor sampling areas and to the materials that come into contact with those areas. Products (e.g., deodorants, antiperspirants, perfumes, etc.) usually applied to sampling areas, often the underarm or vicinities (e.g., trunk, face, hands) are often eliminated. Any materials that will contact sampling areas (e.g., clothes, bedding), are often selected with regard to minimizing contamination by exogenous chemicals. To address the variability of shower products, donors can be provided with a standard, odor-free body wash, shampoo [51.21], and – in some cases – deodorant. Hygiene restrictions are usually implemented before the sampling period starts and can last from a minimum of 1–2 days to as long as 10 days (especially in cases in which chemical analyses are performed [51.123]) presampling. Restriction involving armpit shaving has only rarely been taken into account. Experimental evidence suggests that, even though odor preference increases for unshaved relative to shaved armpits [51.124], such differences are minimal and, when present, transient [51.125].

Dietary restrictions, the most commonly implemented type of restriction, include the elimination of a collection of food items that, when metabolized, leave detectable traces in bodily fluids. A few examples are garlic, fruits, and asparagus [51.126–128]; however, many other reports on this topic are either anecdotal or subjectively ascertained by the experimenters, and there is a lack of controlled studies in this area. Alcohol consumption is commonly eliminated during presampling and sampling periods despite the fact that the effects of alcohol on the perception of body odor is still lacking. To date, one of the few controlled studies of how diet modulates skin secretions comes from a study investigating the olfactory traces of a diet rich in red meat [51.120].

Behavioral restrictions are a catch-all category of nonhygienic and nondietary regulations aimed at eliminating exogenous contamination. Sporadic or social smoking as well as second-hand smoking is often eliminated due to its strong contamination potential. Levels of physical exercise and exposure to highly emotional situations are often regulated, especially in studies examining the emotional chemosignals. Sexual intercourse and sharing a bed with another person and/or pet are also commonly prohibited during presampling and sampling periods of nighttime-collection studies. For female donors, hormone-based contraception and menstrual phase are commonly recorded – if not actively controlled for – to detect or avoid their effects on body odor perception [51.129, 130].

The most common means of ascertaining the usability of each sample is to have a small (e.g., two to three) panel of trained people determine the presence of uncontaminated body odor. While chemical analysis (e.g., gas chromatography-mass spectrometry) would provide a means of detecting and quantifying a priori-defined contaminants, obstacles of cost and practicality concerns often make this impossible.

51.4.2 Medium of Sampling

T-shirts alone, or cotton pads sewn into the armpit area of the T-shirt [51.131], are the most common means by which to collect body odor samples from the axillary areas. The T-shirts, with or without pads, are usually worn directly on the bare skin and are subsequently removed and subjected to olfactory ratings or additional analyses [51.13]. If the underarm area or cotton pad is not cut and separated from the rest of the T-

shirt, the ratings can be confounded by odors originating from extra-axillary areas, such as the torso [51.130]. The variability introduced by T-shirts can be counteracted by laundering each with the same odor-free detergent shortly before use and storing each in a similar manner until use. If the T-shirts are worn during the day without compensative strategies or are worn at any time with clothes laundered with a nonstandard or fragranced detergent, the odor variability of the sweat sample significantly increases. Prepared properly, T-shirts can serve as shields to external chemicals for cotton pads sewn to the T-shirt or anchored by other means to the underarm area. Cotton pads have also been used in isolation and fixed to the axillae with surgical tape [51.16, 130, 132]. This facilitates the adherence of the sampling medium to the collection area and maintains its position throughout the sampling period.

The large variability in sampling mediums and procedures has generated an equally wide array of criticisms. One common concern is with the use of tape as a means of securing pads to the underarm area, as the compounds found in the tape material and its adhesives pose a risk for contamination. Another concern is with the use of cotton as a sampling medium, which can trap the sulfurous compounds of axillary odors [51.133], removing the sulfurous compounds from the odor signature, when the collection is performed with cotton pads and/or T-shirts [51.95]. These concerns and others like it are important in that any sampling method that systematically alters body odor collection prevents studies from assessing the odor signature in its entirety. However, these concerns must also be balanced by feasibility considerations. In the case of cotton as a sampling medium, finding an alternative that simultaneously enables sample collection in situations mimicking day-to-day life and preserves the sample's sulfurous compounds has been very challenging. Furthermore, sulfurous compounds have been identified at very low concentrations; their detection required the collection of hundreds of milliliters of sweat in glass vials while participants were exercising in a sauna [51.95]. It seems therefore that although perceivable using a perceptual smell test – such as that performed by most behavioral and neuroimaging experiments – these molecules, by their own chemical nature, tend to disappear when extracted from a cotton medium and when chemically quantified in isolation. The chemical and physical considerations of the odorants, the materials and form of sampling media, as well as potential interactions are all questions ripe for systematic evaluations within future studies.

51.4.3 Type of Sampling

An additional factor that is seldom factored into experimental designs as a source of experimental variation is the direct comparison of different activities performed during collection. Recent research on the emotional effects of body odor communication raises this issue. Some experimenters used video clips with specific emotional content (e.g., horror clips for fear/anxiety, splatter video for disgust, cheerful videos for happiness [51.26–28]) to induce a vicarious experience of a transient emotional state. Other experimenters prefer more ecologically relevant conditions and collect emotional chemosignals of acute stress responses at an important examination [51.134], during a first-time skydiving event [51.33], or during a high-ropes course experience [51.30]. As a control condition for emotionally induced axillary secretions, groups have used sweat collected from participants at rest or during performance of aerobic or anaerobic physical exercise. The use of physical exercise might be experimentally problematic due to the increase in secretions originating from the eccrine glands (as opposed to the apocrine glands), which serve to cool the body during exercise. Published evidence from chemical analyses characterizing the differences between these control conditions is lacking [51.135].

51.4.4 Time of the Day and Length of Sampling

Various studies sample body odors at different times of the day – some daytime, others nighttime, and still others, both. Considering the differences in level of activity in many systems (skin microbiome, metabolic, immune, autonomic, and central nervous) during wakefulness and sleep [51.136], it is possible that such differences are reflected in the sampled body odors. However, no experimental evidence contrasting daytime and nighttime collection has been published. Furthermore, regardless of sampling time (of day), body odor samples can be affected by the length of the collection. Large disparities in collection duration have been reported across studies, ranging from 20 min [51.26] to 7 nights [51.11]. Considering sampling time and duration in conjunction, samples collected during the day for longer periods of time are likely to be more emotionally variable and more likely to include a greater variety of exogenous, contaminant compounds that nighttime samples do not share. Despite limitations in the control over activities performed by daytime donors, our own experience is that daytime-collected samples are more intense. Aside from the interference of night-

mares and other emotionally vivid dreams, nighttime-collected samples are considered less variable due to the decreased variability in participants' emotional and physical states and greater control over sampling conditions. To reach supra-threshold detection levels, multiple-night sampling periods or highly controlled daytime samplings are often used. One method of characterizing sample quantity is to weigh the pads used during collection and compare this weight to unused pads [51.26–28]. This method is particularly useful to determine the presence of chemosignals collection over short sampling periods. These differences in sampling time of day and length might lead not only to differences in the intensity of the chemosignals but also to differences in the co-varying odor pleasantness [51.132, 137, 138].

51.4.5 Sample Storage

Post-collection methodologies are another critical variable affecting the preservation of body odor samples. After sampling, bacteria transferred to the sampling medium will continue metabolizing the sample, thereby continually altering the chemical substrate over time. In an effort to limit this confound, some groups use freshly collected samples for each rating session [51.132, 139–141]. This approach prevents us from studying longitudinal effects of specific olfactory signatures. The most commonly used storage method is freezing [51.21, 142–144], though, like so many other aspects of sampling methodology, there is a great degree of variability; across studies and research groups, samples are frozen at variable temperatures in different types of containers for a variable amount of time and are thawed (and re-frozen for re-use) a variable number of times in different types of containers. A study conducted by *Lenochova* et al. suggests that freezing at −32 °C, the lowest temperature achievable with a regular freezer, for relatively long periods of time (up to four months was assessed) and repeated freeze-thaw cycles do not affect perceptual ratings of body odor samples [51.122]. However, the freezing temperature is relevant in maintaining the integrity of a chemosignal, as it is for other types of bodily secretions. Storing milk at temperatures around −20 °C resulted in degradation after a few months of storage, whereas conserving the samples at −80 °C did not change the chemical profile of the milk [51.145, 146]. Other parameters, such as whether the thawing is done within the storage container (e.g., a ziplock bag) or within a delivery container (e.g., a glass or plastic jar), are still untested. It is important that future studies consider the absorptiveness and permeability of the storage and delivery containers to limit both the loss of volatiles as well as the acquisition of exogenous contamination.

Finally, it is important to note that the aforementioned experiments assessed the effects of these freezing parameters only on the perceptual characteristics of the body odor stimuli, not on whether the chemical structure or composition, and therefore the chemosignals themselves, may have been altered. Moreover, it is not clear what the link is between perceptual ratings and chemosensory signal strength.

51.5 Central Processing of Human Chemosignals

Ever since the first olfactory neuroimaging study was published over 20 years ago [51.147], a plethora of studies have demonstrated the involvement of a range of brain areas in the processing of olfactory stimuli. Areas consistently reported as involved in processing of common odors are the piriform cortex, amygdala, entorhinal cortex, hippocampus, hypothalamus, thalamus, orbitofrontal cortex, and the insula [51.148]. For a detailed overview of the cerebral processing of olfactory stimuli, please see Chap. 38.

Stimuli with ecological relevance presented in other sensory modalities, such as vision [51.149–151] and audition [51.152], are processed via dedicated brain pathways outside of the main sensory system. The range of behavioral studies presented above supports the claim that human chemosignals are salient carriers of information about other individuals, along the same lines as visual and auditory stimuli. Empirical validation of this claim has been corroborated by a study by *Lundström* et al. [51.131]. To assess whether human body odors are subjected to non-olfactory processing recruiting a separate network from common odors, *Lundström* et al. [51.131] exposed recipients to different body odors as well as to a fake body odor, namely a mixture of common odorants (including cumin oil, anise oil, and indole) with perceptual characteristics similar to real social chemosignals. Direct comparisons of neural processing between the two perceptually similar stimuli, real and fake body odors, demonstrated that real body odors selectively activate a neural network located predominantly outside the main olfactory system and composed of the occipital cortex, the angular gyrus, and the anterior and posterior cingulate cortex (Fig. 51.1).

51.5.1 Occipital Cortex

The occipital gyrus is an area located within the primary visual cortex, responsible for the processing of visual information. Activations at the level of the occipital gyrus following exposure of body odors suggest that this area has a multimodal character. Indeed, rather than activating at the presentation of purely visual stimuli, it responds to the social relevance of the stimuli presented in different modalities [51.153]. It has previously been demonstrated that olfactory cues are able to activate visual processing areas in the absence of visual stimulation [51.154–158] and that emotional highly relevant stimuli induce increased activations in the primary visual cortex [51.159]. In the study by *Lundström* et al. [51.131] activations in primary visual areas are retrieved from participants who were not able to distinguish between real and fake body odors. This is in line with the fact that activations in the occipital cortex are commonly found in olfactory neuroimaging studies [51.145–149], and it suggests that the observed activity is not completely attributable to the social content of chemosignals. In other words, olfactory stimuli – independent of their social value – activate this visual area. Therefore, this finding has been interpreted as indicative of a preparedness mechanism [51.131]. An odor (as well as an image), whether ecologically relevant or not, indicates the presence of an object in the immediate vicinity and may trigger the visual system to be prepared for the entrance of a stimulus in the visual field, therefore requiring special attention.

51.5.2 Angular Gyrus

Located in the posterior part of the inferior parietal lobule, the angular gyrus activates in response to information related to the human body. Indeed, the functional role of the angular gyrus has been associated with a variety of tasks, including those involving social cognition [51.160] and multisensory integration if we also include the overlapping area of the intraparietal sulcus. Please refer to Fig. 51.1 [51.161]. Overall, recent meta-analytic evidence suggests that the angular gyrus is involved in the processing of concepts during tasks in which the simultaneous interface of perception/recognition and action is required [51.160]. Specifically, lesions at the level of this area alter (or fully impair) the ability to interpret the perception of one's and other individuals' bodies [51.162–165] and evidence indicates the angular gyrus serves as a cross-modal hub in which converging multisensory information is combined and integrated, including that relating to body

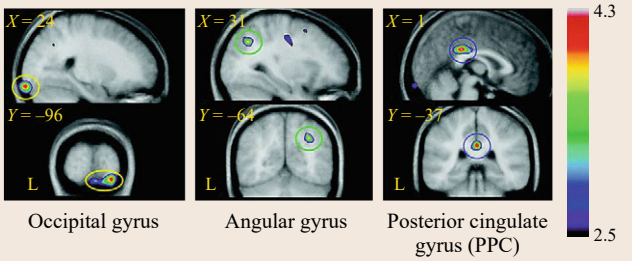

Fig. 51.1 Comparing the group-averaged regional cerebral blood flow (rCBF) responses to the processing of body odors versus fake body odors produced the depicted statistical parametric maps of *t* values thresholded at 2.5 superimposed on group-averaged anatomical magnetic resonance imaging (MRI). The *top panels* show a lateral view and the *lower panels* show a coronal view of the same areas. Coordinates refer to the center of activation and slice expressed according to the Montreal Neurological Institute (MNI) world coordinates system. From left to right, the *colored circles* mark an increased rCBF response in the right occipital cortex (*yellow*), in the left angular gyrus (*green*) and in the posterior cingulate cortex (*blue*) (after [51.131])

representations [51.165]. Given its multisensory nature, the role of the angular gyrus in the chemosensory context cannot be appreciated in isolation and requires the simultaneous account of the contribution of the connected regions.

51.5.3 Anterior and Posterior Cingulate Cortex

Smelling a body odor in contrast to common odors increases activity in both the anterior cingulate cortex (ACC) and the posterior cingulate cortex (PCC), which have been linked to the implementation of attentional, mnestic templates [51.166–168], emotion regulation [51.169, 170] and regulation of emotional actions [51.171, 172], respectively. Moreover, a recent meta-analysis identified ACC and PCC as critically involved in self-reflective processes [51.173]. PCC elaborates not only self-relevant information, but it is also included in the evaluation and decision-making process of whether a certain stimulus is applicable to the self, therefore in line with autobiographical memories [51.173]. In contrast, the ACC activity underpins the emotional aspects of the processing of self-relevant information [51.174] and it is involved in the comparison with other-reflective processes, to indicate self-specificity [51.173].

Although a definite mechanism of body odor communication has not been established, it may be that body odors, in contrast with common odors, receive

a preferential processing in virtue of their signal value [51.131]. Seen from an evolutionary perspective, signals carrying important information, such as those related to threats, might have been selected by evolutionary pressure to receive preferential processing (i. e., emotional and attentional prioritization).

51.6 Human Chemosignals of Harm Avoidance

Besides general differences in the neural processing of common and body odors, the body odor literature has focused on the characterization of the neural underpinnings of different messages with social relevance. These specific areas of social communication via chemosignals can be distinguished in two macro areas: chemosignals related to reproduction and chemosignals involved in harm avoidance. We will refer to the excellent review by *Lübke* and *Pause* [51.104] in reference to an analysis on the chemosignals of reproduction and we will here focus our attention on the chemosignals sustaining harm avoidance.

Harm avoidance is an umbrella term used to refer to all adjustments made in response to stressful events, involving demanding environments and/or dangerous individuals [51.90]. Stress is a response based on fight, flight, or tend-and-befriend behaviors, that occurs following the perturbation of an organism's homeostasis [51.175]. If stress requires severe adjustments over long periods of time, such as in the case of chronic stress, the organism faces collapse and eventually death [51.176]. Given the life-threatening power of stress, it is not surprising that mechanisms of harm avoidance have been favored during evolution and are presently used by the vast majority of animal species [51.3] as well as by plants [51.177]. Chemosensory signals have all the characteristics to act as efficient warning signals, as overviewed in the introduction of this chapter. Below, we will review chemosensory harm avoidance mechanisms, including strategies capitalizing on self-other recognition, discrimination among different types of *others* and transient harm-related signals.

51.6.1 Self-Other Recognition

The first step to identify what is safe and what is potentially harmful is the recognition of something different from oneself. Disposing of a system able to differentiate self from others might capitalize on the decoding of social information related to threat, including that coming from body odors. A self-reference mechanism, such as that used by rodents and referred to as the *armpit effect* [51.178], is supposed to be at the basis of the ability of people to identify their own body odor by sniffing [51.179]. However, *Pause* et al. [51.180] could not reveal a similar pattern of results when testing males and females with self and non-self odors. In the authors' words, the low accuracy in the identification performance might be a result of the low odor concentration. Alternatively, it might indicate that the ability to discriminate between subtle body odors does not necessarily involve conscious processing [51.131].

51.6.2 Different Types of Others: From Kin to Strangers

Recognizing whether a signal is similar or different to oneself is a binary decision. However, what is *other* can be categorized in many different ways. Other can be a kin, with whom the receiver shares genetic features; the individual can be a friend, with no genetic relationships with the donor of the chemosignal, yet familiar due to exposure to that individual; or the individual can be a stranger, with no genetic or learned connections and, given the lack of additional information besides the odor, considered potentially dangerous.

Recognition of kin via chemosignals is an important mechanism that is manifested very early in life. In virtue of the pre-post birth continuity of the chemosensory experience [51.69], body odors are supposedly the first signals used to prevent the occurrence of stress situations. In situations of high vulnerability, such as early in life when a newborn is totally dependent on maternal care to survive [51.181], olfactory cues from the mother and the newborn become the basis of parent–infant interactions, and they constitute a foundation of the development of the parent-child relationship and secure attachment [51.182, 183]. Besides the ability of newborns to recognize and prefer the odor of their mother's amniotic fluid and breast body odor, mothers – who have an active role in the protection of their offspring from stress and harm – are able to discriminate and prefer the odor of their own baby [51.139, 184, 185].

However, as mentioned above, experience has an impact on the processing of human social chemosignals. Evidence to this claim is suggested by *Lundström* et al. [51.131], who asked their participants to smell the odor of highly familiar individuals such as long-time friends. Interestingly, duration of friendship – which correlates with the neural activity in the right occipitotemporal cortex – did not increase the identification rate

or the confidence in the recognition of the kin's body odors, supporting the notion that social chemosignal communication is primarily mediated by nonconscious processes. This view of a specific reaction to familiar body odors and their relationship with the duration of friendship suggests that exposure to a specific body odor in the context of long-lasting positive experiences will specifically impact the social chemosignal communication. In the study the odors of some sisters were also included [51.131]. When compared to friends, no differences in the identification of body odors were found, suggesting a complex interplay between learned and genetic cues. This would be in line with evidence found in mice, for whom a common odor (e.g., peppermint odor) can produce the same social behavior as a kin's odor (i. e., maternal odor), when previously associated with care and protection [51.181].

How is chemosignal communication modulated by the origin of the body odor? Such highly relevant stimuli seem to embed a threatening message, as suggested by the perceptual ratings collected in the *Lundström* et al. study [51.131]. Body odors were rated as being more intense and less pleasant when rated by individuals to whom these donors were a stranger to than when the very same odors were presented as the body odors of kins, indicating that the relationship to the rater, and not the chemical composition of the odor, was responsible for the perceptual differences found across conditions.

51.6.3 Transient Harm-Related Chemosignals: Behavioral Evidence

Besides stable traits, more transient information related to harmful situations can be communicated via body odors. For instance, *Shirasu* and *Touhara* [51.118] reviewed a number of infectious diseases as well as metabolic disorders, toxins and poisons that had been associated with either a volatile organic compound and/or a more or less specific odor label. *Olsson* et al. [51.24] have recently demonstrated that healthy individuals use chemosensory cues to evaluate the health status of individuals in their surroundings. Indeed, the body odor of senders undergoing an innate immune response induced by a lipopolysaccharide injection is rated as more intense, unpleasant and unhealthy (in other words, aversive) than that of individuals exposed to a placebo. This finding, in line with the idea that perceived disgust promotes avoidance behavior [51.28], suggests that olfaction plays an important role in reducing the risk of contagion, thereby maintaining an individual in good health. This is in line with the idea that behavioral avoidance is a first-line defense against disease; which of course is more cost efficient than to involve the organism's immune system.

Other types of situational danger can also be communicated via chemosignals. When an individual faces the need to implement a fight or flight response, and therefore experiences a stress situation, it is of value for potential conspecifics in the surrounding to be warned that a critical event is occuring. A series of studies have recently explored the chemosensory communication of stress by using axillary sweat samples. Stress is a complex response characterized by an increase in physiological arousal associated with the experience of a variety of emotions, ranging from those related to eustress (e.g., excitement and surprise) to those coupled with distress (e.g., fear and disgust) [51.186]. The literature on chemosensory communication of stress includes chemosignals collected within a wide range of situations, potentially affecting the quantity and the quality of the axillary sweat samples donated. The less intense stress sampling conditions consist of a person watching movies with a predominant emotional character and vicariously experiencing the situation visualized, while the body odor sampling occurs. Although this method induces relatively weak stress responses, the advantage is in providing a rather precise characterization of the emotions experienced by the donor, and that can be mediated to recipients via chemosignals, of anxiety and disgust [51.27, 28, 37, 187] (for positive accounts see [51.26]). In an attempt to keep the emotional specificity of the body odor donation stable and to specifically focus on the collection of chemosignals in highly anxious situations – thus, increasing the intensity of the signal – *Pause* et al. [51.134, 188] collected the body odor from donors waiting for an examination needed to complete their academic degree. Other groups increased the intensity of the stress response at the expense of emotional specificity by collecting body odors in extreme conditions, such as a first-time parachute jump [51.31] and high-rope courses [51.30, 38]. These chemosignals were subsequently presented to receivers and the effects of the exposure were quantified. It was reliably demonstrated across studies that chemosensory sweat stimuli are difficult to detect perceptually [51.33, 134, 188] and as a result, participants have difficulties in reliably verbally reporting the emotions experienced by sweat donors during collection [51.31, 32, 37, 187]. However, there is mounting evidence suggesting that adults, and in particular women, are more accurate than chance in identifying the emotion of the donor during collection [51.37, 187], in visually evaluating facial expressions on the basis of the chemosensory prime [51.32], and in discriminating between emotional expressions especially when body odor samples from donors experiencing fear are the target [51.31]. Altogether these data suggest that the effects of chemosensory stress signals are largely

unknown to the perceiver and that perceptual acuity mechanisms specific for social information are at play. Indeed, detection of safety signals (e.g., positive emotions, [51.38, 134]) is reduced in favor of an increased prevalence of detecting threatening stimuli [51.31, 32]. This is in line with the idea that body odors originating from fearful individuals, in virtue of the highly relevant message they convey, receive prioritized processing [51.189, 190]. Indeed, anxiety chemosignals, but not emotionally neutral body odors, affect the acoustic startle reflex [51.36], an evoked preattentive reflex modulated by the affective and relevance value of the stimulus [51.191].

Further, the association between a neutral body odor and a threatening situation can facilitate the processing of body odors. *Alho* et al. [51.192] tested the idea that an offender, in parallel to eyewitness lineup identification tests, could be identified by their odor alone. Participants could do this fairly well. It was also demonstrated that when the encoding of a body odor is associated with the simultaneous presentation of threatening information (e.g., authentic and arousing videos of criminal activities), they were subsequently identified well above chance in body odors lineup tests and considerably better as compared to the body odors associated with neutral videos. In other words, a body odor of a threatening stranger was remembered significantly better than a nonthreatening stranger.

So far, the evidence suggests that the responses to threatening body odors are in line with the elicitation of the automatic, and rather nonconscious, responses to fearful stimuli [51.193]. In contrast with this view, *Chen* et al. [51.35] found that smelling threatening body odor stimuli increased the response time and response accuracy of participants in processing words with fearful content in a word association task. This finding, interpreted as the ability of body odors to modulate cognitive processes, could be seen as counterintuitive. In contrast to carefully deliberated, but not timely reactions, rapid and automatic reactions to threatening situations are thought to increase the chances of survival. In other words, the promotion of mechanisms facilitating fast detection of threat, possibly high in false positives, would maximize survival rates as compared to a precise and slow processing. Threatening stimuli commonly enhance speed (that is, lower reaction times) at the cost of accuracy, as previously demonstrated for fearful multimodal stimuli [51.189, 194–196]. Because few studies have investigated the trade-off between speed and accuracy in response to threatening body odors, it is too early to say whether the detection of these chemosignals is governed by other processing principles than visual signals of threat.

Besides the cognitive consequences of body odor communication, emotional information processing is also affected. Evidence suggests that threatening body odors are sufficient to induce – particularly in female receivers [51.31] – a reflection of the emotional state of the sender [51.28, 197]. This is particularly true for fear-related odors, which have been demonstrated to quickly establish (and maintain) synchrony between sender and receiver. Sweat samples, produced with the involvement of the sympathetic-adrenal medullary system contain a distinctive signature (not yet chemically specified), which triggers in receivers fearful facial expressions (i. e., co-contraction of corrugator supercilii and medial frontalis muscle) and vigilant behavior (faster reaction times when classifying facial expressions) [51.27].

Emotional synchronization also occurs in the presence of chemosignals of disgust [51.28]. Indeed, a body odor from a person experiencing disgust while watching a disgusting movie will induce in the recipient an experience of disgust, revealed via the analysis of sniff patterns and facial electromyogram [51.198]. As demonstrated by *de Groot* et al. [51.28], the chemosignal communication of different forms of harm is specific and therefore can be discriminated. On the one hand, fear chemosignals generate a fearful facial expression and promote sensory acquisition (increased sniff magnitude and eye scanning); on the other hand, disgust chemosignals evoke a disgusted facial expression and sensory rejection (decreased sniff magnitude, target-detection sensitivity, and eye scanning) [51.28].

One of the theories mainly used to explain the transmission effects from sender to receiver via chemosignals involves the idea of emotional contagion, a basic mechanism promoting coordinated thoughts and actions, mutual understanding, and interpersonal closeness [51.199, 200]. However, as demonstrated in other types of social interactions [51.201], the simple emulation of a social percept is not the only possible adaptive response. Indeed, complementary states can be triggered. Emotional complementarity occurs when one person's emotions evoke different (yet corresponding) emotions in others. A classic example is the fact that a person's distress triggers compassion in another [51.202]. In the domain of social chemosignals of harm avoidance, emotional complementarity can acquire different meanings. Let's imagine the example of an individual who donates his/her body odor while involving in an act of aggression, characterized by anger. Rather than the implementation of an emotional contagion mechanism, i. e., the social chemosignal triggers anger feelings in the recipient, it is also plausible that a fear reaction is experienced by the recipient. This

would be in line with the fact that angry expressions are perceived as threatening [51.203, 204] and are known to trigger adaptive actions in the observers [51.205]. Future research extending the limited knowledge of chemosignals of aggression, now mostly performed with indirect measures (e.g., competitiveness, dominance, [51.23, 206]) or limited to one odorous compound (e.g., androstenone) and not to a more complex odor signature [51.4], will shed further light on the issue.

51.7 Central Processing of Human Chemosignals Involved in Harm Avoidance

Behavioral and psychophysiological data suggest that chemosignals involved in harm avoidance can be preferentially processed. To further characterize this idea, the neural underpinnings of such body odor communication are explored below.

51.7.1 Self Body Odor Activates Areas in the Self–Other Recognition System

Lundström et al. [51.15] uncovered the neural mechanism of human self-recognition mediated by chemosignals, in line with the *armpit effect* [51.178]. They compared the body odor of oneself to the odor of a known friendly person and did not find any difference in cerebral activity. They suggested that humans, as had been suggested for rodents, use their own body odor as a template to assess the identity of another individual [51.178]. Further support to this interpretation seems to come from the neural underpinnings elicited by body odors when contrasted with common odors. As suggested, the PCC processes emotional stimuli via interaction with the ACC using *self* as reference frame [51.173]. Furthermore, the activity in the angular gyrus can be put in the context of self-referential space. Indeed, patients with an epileptic focus in the angular gyrus are known to report out-of-body experiences or perceptual distortions of other people's bodies [51.164, 165]. The self-reference matching mechanism is in line with results from studies using chemosensory event-related potentials, a temporally specific technique based on the averaged epochs of the electroencephalogram occurring in association with the presentation of chemosensory stimuli [51.180, 207]. These studies reveal that the human brain is able to discriminate between body odors coming from different sources, irrespective of conscious awareness of such differences. Specifically, the odor originating from oneself can be discriminated and processed faster as compared to the odor originating from someone else [51.180]. Further evidence reveals that more neural resources are required to process the body odors more similar to oneself (e.g., with similar HLA) [51.207], indicating a preferential neural processing for self-matching chemosignals. The lack of conscious awareness, present in both the behavioral and neural correlates of chemosignal self-other recognition [51.15, 18], might be explained by a unique anatomical feature of the olfactory system. Olfaction is the only sense characterized by the lack of a mandatory thalamic relay, meaning that the olfactory receptors project directly to the olfactory bulb and primary olfactory cortical areas [51.208]. Given that thalamic processing has been implied in conscious awareness [51.209], it seems likely that the contribution of this structure to the olfactory percept might make it more weakly associated with conscious processing. However, the thalamic involvement in conscious and unconscious olfactory perception has not yet been fully clarified [51.210].

51.7.2 The Neural Encoding of Familiarity in Someone Else's Body Odor

The first chance to use odors to recognize others comes as early as in utero [51.69]. The evidence on the behavioral preference of infants for their mother's odors and for parents of their baby's odor is also reflected at the neural level. Indeed, the odor of the mother and the child are both subjected to preferential processing, a strategy that in evolutionary terms facilitates the survival of the individual and of the species. Mothers exposed to the body odor of newborns, including their own infant, show selective activation of the thalamus [51.211] and of the orbitofrontal cortex [51.212]. Interestingly, the orbitofrontal cortex is activated in both mothers and nulliparous women when smelling body odors originating from men [51.212]. Moreover, as demonstrated by *Lundström* et al. [51.211], both mothers and nulliparous women respond with neuronal activity within the reward system to the exposure to unfamiliar baby odors. The authors interpret this finding in light of evolutionary theories suggesting that the general ability of infant chemosensory cues to prime affection in adult women serves the purpose to motivate them to care for the infant, i. e., an indication of attachment mechanisms at play [51.213]. Although untested, the fact that fathers are also able to identify

the odor of their infant's amniotic fluid and judge it as qualitatively similar to their infant's and mother's body odor [51.214], suggests that fathers too can present specific neural pathways elaborating body odors.

The individual learning history seems to modulate signal processing, especially in brain areas with social roles [51.215]. Smelling a friend [51.15] activates, among other areas, the occipital cortex including posterior parts of the retrosplenial cortex, previously involved in the processing of familiar faces and voices [51.216]. Furthermore, the duration of friendship – an indirect index of the familiarity of the body odor – significantly correlates with increased regional cerebral blood flow in the extrastriate body area, a region implicated in the multimodal processing of information related to the human body [51.217, 218]. In other words, the more familiar the smell of the body odor, the greater the neuronal involvement to process body-related information [51.15].

With respect to unknown individuals, *Lundström* et al. [51.15] demonstrated that smelling a stranger's body odor evokes cortical activations (i. e., inferior frontal gyrus and amygdala) similar to those described in response to viewing negative stimuli [51.219–221], including masked fearful faces [51.220]. This supports the idea that a body odor never encountered before is treated like any other highly relevant (and potentially dangerous) stimuli [51.222] and differently from perceptually comparable common odors.

In line with the idea that the strangers' body odors conveys a threat sociochemosignal is the activation of the insula, implicated in the processing of unpleasant chemosensory stimuli [51.223] as well as in the recognition of fearful and disgusting objects [51.150]. The simultaneous activation of amygdala and insula, two highly interconnected areas [51.224], suggests that the body odor of a stranger induces separate, yet related, activations of fear and disgust [51.222]. This reaction is not, however, specific to body odors, but is shared with all novel and suddenly presented stimuli [51.225].

In addition, the body odor of a stranger elicits activations at the level of the supplementary motor area and, right below threshold of significance, of the premotor area [51.15]. These structures are known to be part of a hierarchical executive network involved in the adaptation and optimization of motor behaviors [51.226]. The involvement of such a network suggests that the body odor of a stranger by communicating fear or disgust information prepares the recipient to react to the potential presence of an unknown individual in the vicinity. Such motor preparation involves fight or flight responses: basic reactions critically involved in the survival process of the individual.

51.7.3 Threatening Body Odors and Their Neural Correlates

In line with the idea of a preferential processing of chemosignals indicating threat or harm, smelling the body odor collected in anxious situations increased neuronal processing from medial frontal brain areas (P3 amplitude) [51.188]. This effect was more pronounced in women than in men, which is in accordance with the findings that females show a processing advantage for social emotional stimuli [51.227] and for perceptually weak threatening stimuli [51.228]. Preferential processing can also be inferred by the allocation of early attentional resources to threatening stimuli [51.229] and to ambiguous stimuli (e.g., neutral facial expressions [51.29]).

Studies conducted with body odor samples collected from individuals experiencing anxiety activate brain areas involved in the processing of social emotional stimuli (fusiform gyrus), and in the regulation of empathic feelings (insula, precuneus, cingulate cortex; [51.33]). This evidence is used in support of the idea that fear-related chemosignals produce emotional contagions [51.28], and increase the level of situational anxiety [51.30] in the receivers.

When the sweat presented in the scanner comes from individuals experiencing high levels of stress, it being eustress or distress, such as in the case of the parachute jump [51.31], activations were mainly demonstrated within the amygdala, a center encoding the relevance of a situation and stimulus, in a nonspecific fashion. This is indeed related to a negative affect compatible with fear. The amygdala has long been known to process negative emotional stimuli [51.150, 220, 221] including threat [51.230], although nonselectively [51.231]. In mice, the amygdala has been specifically identified as the main processing center of threat-related endogenous odors [51.232]. This might be taken as an indication of the fact that the amygdala should also be involved in the detection of threat-related olfactory stimuli in humans and not in the processing of fear itself [51.230]. As suggested by *Pause* et al. [51.188], amygdala activations are more pronounced in women than in men [51.233], indicating that stress-related chemosensory cues are more relevant to women.

However, not all evidence points towards a preferential processing of threatening human chemosignals. Indeed, the cognitive modulation induced by smelling threatening body odors suggests that smelling anxiety chemosignals makes the receiver more accurate and less fast in using that information [51.31, 32, 35], thus raising the issue of intermodal differences in the processing

of threatening stimuli. If, on the one hand, threatening visual and auditory stimuli are processed fast [51.195, 196], this is not in accordance with how the olfactory system generally works. Indeed, chemosensory stimuli take longer to be processed as compared to visual or auditory stimuli [51.234]. Furthermore, the estimated time difference between the onsets of the first perceptual and the first cognitive processing is approximately 200 ms in vision, and it is approximately doubled for olfactory stimuli [51.235, 236]. This evidence highlights a downside of olfaction as a warning signal: early detection of alarming olfactory stimuli might be delayed by the slower central processing that olfactory signals undergo. Nevertheless, the possibility of using such mechanisms in critical conditions (e.g., in the absence of visual and auditory functioning, at a distance), makes the olfactory warning system a good addition to the survival kit mechanisms, by allowing chemosensory stimuli to shape the slower and more deliberate processing rather than the initial and more rapid detection phase [51.35].

Interestingly, none of the published functional neuroimaging studies including threat-related body odors in their paradigms has reported activations at the level of the primary or secondary olfactory cortices [51.15, 31, 33]. When extending the search including studies incorporating body odors of any sort [51.15, 34], only one of the two remaining experiments reveals activations at the level of the lateral orbitofrontal cortex. *Zhou* and *Chen* [51.32] recorded increased neural activity in that structure when participants were smelling the body odors sampled from donors watching erotic videos. Because the activation of the lateral orbitofrontal cortex is determined in *Zhou* and *Chen* [51.34] by contrasting body odors with a common odor (phenylethyl alcohol (PEA)) but a similar activation is also obtained when discriminating odorants within a mixture [51.228], whether the lateral orbitofrontal cortex activity is a clear demonstration of differential body odor processing still remains to be determined. What can be safely concluded though is that five neuroimaging studies, which have included different types of body odors and were performed by independent laboratories, have not been able to report activations located within the olfactory areas even though participants are presented with clearly perceivable odors. This phenomenon can have a series of explanations, for which direct experimental proof is still lacking. It is possible that the conscious perception of body odors is too transient to be detected at the level of the olfactory cortices, possibly due to the high susceptibility to habituation of such areas [51.237, 238] and activity is therefore only demonstrated in less habituating areas of the social brain [51.239]. If this were to be true, non-endogenous control odors (i. e., the fake body odors), should have not generated clear activations in olfactory cortices [51.15, 18]. One might also claim that the lack of olfactory activations depends on the neuroimaging analyses applied, which only correct for false positive errors but do not account for false negative errors. Therefore, lack of significant activity in a neuroimaging study cannot be taken as evidence for the hypothesis that a specific area is not involved in a task. However, if the lack of activation in olfactory cortices is due to cognitive processing, no differences should be found between real and fake body odors [51.131]. Finally, it is unlikely that five independent neuroimaging studies would produce five sets of results with similar false negative errors.

51.8 A Clinical Perspective on Human Chemosignals

The research on how a social message is transmitted from a sender to a receiver through body odors has mostly been conducted on healthy human participants. However, health and mental issues modify brain processing and experience [51.240] (Chap. 50). Given the social relevance of body odor communication, differences in the processing of such signals according to baseline social skills are expected. Only a few studies have empirically tested this assumption and demonstrated that socially skilled versus socially unfit individuals use body odor information differently. For instance, emotional competence facilitates the identification of familiar body odors [51.32] and highly sociable and assertive individuals process body odors within the central nervous reward system, as well as in structures involved in social cognition and in synchronization processes (inferior frontal gyrus) [51.241]. In other words, higher social emotional competence facilitates the transmission of socioemotional messages via chemosignals. This powerful feature of chemosensory stimuli, along with the automatic processing of these stimuli, might offer an opportunity for individuals with reduced social skills. This hypothesis has been tested in a group of children with autism spectrum disorders (ASD), a series of disorders known for their core deficits in social information processing [51.242]. When exposed to their mother's body odor, high-functioning children with ASD can readily start and conclude basic social actions [51.243, 244]. With specific reference to harm avoidance, individuals with high social anxiety quickly elaborate the

presence of body odors of anxiety, yet subsequent attentional processing is blocked, possibly reflecting a mechanism of perceptual defense [51.188]. Furthermore, individuals with high social anxiety show greater startle responses under the exposure of chemosignals of anxiety as compared to neutral chemosignals [51.245] and respond with heightened sensitivity to such chemosensory contextual information [51.229].

Recent studies in rodents indicate that a single receptor is involved in the transmission of warning chemosignals and, when blocked, the warning signal (predator odor) loses its threatening power [51.246]. Should a similar mechanism be proved in humans, it could be used as a therapeutic strategy for patients suffering from social anxiety.

Overall, these results show that socioemotional skills and human communication mediated via chemosignals are intrinsically interwoven. In light of the ability to sensitively detect, accurately process, and show appropriate responses based on relevant chemosensory social information, it is plausible that chemosignal communication critically contributes to the formation and maintenance of social groups [51.247], an essential condition for human evolution.

51.9 Conclusions

The evidence reviewed in this chapter suggests that humans do use chemosignals as a form of social communication [51.248]. A chemosensory signal conveying a social message is generated by the coactivation of the systems maintaining the homeostasis in the sending individual. In healthy individuals, genetics, the immune system, metabolism, hormones, and the autonomic and central nervous systems work in concert to determine the chemical composition of body secretions. With respect to the axillary sweat, such systems affect the apocrine and apoeccrine secretions. These secretions will be converted by the resident flora into a joint result. Such a chemosignal, conveyed from the sender to the receiver via airborne molecules, carries a variety of information, among which is that promoting survival. Suggested to date are chemosignals can communicate self-other information (e.g., kin recognition), emotional messages (e.g., chemosignals of anxiety), and those that inform the receiver about the presence of potential threats in the environment (presence of an unknown or sick individual). As noted by *Lübke* and *Pause* [51.104], the receiver's responses constitute the only unspecific step in the social chemosignal communication process, as outlined here. This would be in line with the need of receivers to adaptively respond to the presence of situations challenging survival. In the case of danger perceived through different sensory modalities, the same type of fight, flight, or tend-and-befriend responses would be required to handle the threat. Importantly, receivers can implement those responses without conscious awareness of having smelled the chemosignal [51.131].

With respect to methodology, researchers have not yet agreed upon guidelines for body odor collection, reducing the comparability across databases. In this respect, it is worth noting that the choice of the experimental control conditions is of primary importance. To avoid confounders in the perceivers' responses, secretions from the same glands should be sampled across conditions. Stringent control conditions can separately account for several significant factors and it is advisable to include common odors to reveal further distinctions and similarities across olfactory functional subsystems. However, the extensive time required to collect usable body odors, as well as the fast central habituation to olfactory stimuli [51.237], constrains the number of olfactory conditions and trials possibly included in one experimental session.

Delivery techniques have also been one of the major causes limiting the exploration of the field. Indeed, olfactometers – dedicated computer-controlled delivery systems, with rapid onset-offset stimulus release – are machines not widely commercialized and relatively expensive. Nevertheless, they are necessary for the study of the temporal dynamics and the neural underpinnings of body odor communication.

With regards to the neural bases of social chemosignal communication, future efforts should focus on increasing our knowledge of the neural bases of social chemosignal communication and further our understanding of the functional separation between pathways processing common and body odors. Furthermore, the neural underpinnings of chemosignals with different emotional characterizations should be included to assess emotion-specific dissociations. This would open the discussion on the communication strategies used by emotional chemosignals.

Finally, a better understanding of how social aspects of life are transmitted through chemosensory stimuli can provide additional insights on clinical populations struggling with social information processing (e.g., ASD, schizophrenia, social phobia).

52. Human Chemosensory Communication

Bettina M. Pause

Social communication refers to a basic human need, and findings accumulate that show humans communicate numerous kinds of social information via chemosignals. Briefly, it will be introduced which chemicals are conveyed through body fluids and which sensory systems are considered to process social chemosignals. Then, it will be shown that pheromones in humans have not yet been discovered. Studies on putative pheromones in humans often are performed disregarding the biological underpinnings of chemical communication and seem randomly to investigate volatile substances without any theoretical background. However, evidence will be provided that human chemosensory communication has been well demonstrated, using natural body fluids (e.g., sweat) as the source of chemosignals. Humans can decode information about the immunogenetic profile and the level of sexual hormones from volatiles released from the sweat of other individuals. These chemical signals are considered to affect mate choice. However, the signal extraction also depends on the sexual orientation of the perceiver. Furthermore, the recognition of kin and mother-infant communication comprise the release and decoding of chemosignals. Both phenomena are important prerequisites for the formation of social bonding and harm protection. Finally, the communication of stress and anxiety in humans will be presented as an example of a chemical transmission of emotional states. At the end of the chapter it will be questioned whether chemosensory communication is a skill, protective for certain mental disorders.

52.1 Interindividual Communication

52.1.1 Social Communication

Like most mammals, humans are inherently social in nature. Social isolation and loneliness are major risk factors for mortality in humans [52.1, 2]. The impact of social isolation on health in humans is comparable to the effects of high blood pressure, obesity or smoking [52.3, p. 5]. Social exclusion leads to a decline in cognitive performance and decrements in intelligent thought [52.4] and is processed in the human brain similarly to physical pain [52.5–7]. In socially isolated adult mice, myelination of oligodendrocytes in the prefrontal cortex (PFC) is impaired [52.8]. Therefore, avoiding loneliness seems to be a basic drive in humans and group living might have been mandatory for phylogenetic survival. In fact, the social brain

hypothesis postulates that predation risk (through outgroup members or predator animals) was the ultimate cause for group living in primates [52.9]. Social complexity, in turn (e.g., group size, grooming clique size, the frequency of coalitions, and the prevalence of social play) might have been the main promoter of the neocortex size of anthropoid primates [52.10]. Social enrichment requires the development of behavioral flexibility, which in turn is essential for the formation of stable social bonds. In anthropoid primates, relationships involve a form of bonding that is found elsewhere in reproductive pair bonds only. Thus, the formation of long-term friendships is unique to humans and other anthropoid primates and inherently linked to our neocortex size.

In line with the consideration that the processing of complex social information requires larger brains is the discovery of specialized neural networks responsible for the processing of social information [52.11]. It has been demonstrated that the perception of other humans' facial expressions is different from the perception of common visual objects (fusiform face area, [52.12, 13]), and that memory for faces is specialized, holistic, and hippocampus-independent [52.14]. Moreover, social touch is probably also processed as a unique social signal [52.15, 16]. Finally, social feelings like empathy require the processing in specialized neuronal relays, different from common nonsocial feelings [52.17].

52.1.2 Chemosensory Communication

Successful social communication is based upon the release and processing of sensory signals, including speech, touch, biological motion, facial expressions and chemosensory signals. Among these, chemosensory communication is the least understood, which is usually justified by referring to the fact that some other species might have a keener olfactory sense than humans. However, just recently, it could be demonstrated that within the human species the olfactory sense might have a higher resolution than the visual or auditory sense [52.18]. Humans are able to distinguish up to seven million colors and about 340 000 tonnes, however, they are able to discriminate at least one trillion (10^{12}) odors. Thus, the chemical sense in humans is by far keener than the visual or auditory sense.

As compared to the other senses, chemosensory communication has several advantages [52.19]. Chemosensory signals can be used in darkness, and can easily cross barriers. Depending on the volatility of the molecules, chemosensory signals can be transmitted across very long distances. In contrast, low volatile molecules can keep the information for conspecifics at the place of release, while the sender has already disappeared [52.20]. Furthermore, as social chemical signals are usually based on a specific mixture of molecules, the potential number of social signals is extremely high.

Due to these advantages in communicating via chemosignals, high-resolution olfaction might have developed in mammals about 200 million years ago. Especially, the use of the olfactory sense in darkness might have been of special importance to early mammals, which were probably nocturnal animals in order to avoid to be eaten by early carnivores (dinosaurs) [52.21]. The improved ability to analyze and process the complex olfactory environment is considered the ultimate force for driving the encephalization of the unique mammalian brain (as assessed by X-ray computed tomography of fossil mammalian skulls) [52.22, p. 957]:

> *... at its start, the brain in the ancestral mammal differed from even its closest extinct relatives specifically in its degree of high-resolution olfaction, as it exploited a world of information dominated to an unprecedented degree by odors and scents.*

Surprisingly, the final encephalization phase in *Homo sapiens* can be explained in a similar way: Based on three-dimensional geometric morphometric analyses of the endobasicranial shape, it was reported that as compared to *H. neanderthalensis*, modern humans show larger olfactory bulbs, a relatively wider orbitofrontal cortex and increased temporal lobe poles [52.23]. According to the authors, evolution may have favored olfaction-related neuronal circuits in *H. sapiens* because chemosensory skills were of special importance for the development of optimum social strategies (e.g., in communicating emotions or messages related to reproduction), which in turn supported the survival of the modern human. Thus, in human chemosensory communication, the two main promoters of brain size seem to be included (social and chemosensory signals).

In the following, findings related to human chemosensory communication will be reviewed. The term *pheromone* will be avoided, as there is no general consensus on its meaning [52.19, 24]. Instead, the rather neutral term *body odor signal*, or *chemosignal* will be preferred. A signal can be defined as a stimulus that is produced and released by a sender and carries a message to a receiver. In contrast to a pure stimulus, which may or may not carry relevant information, a social signal always conveys specific information between two individuals.

52.2 Release of Chemical Substances in Humans

Since a number of excellent reviews have already summarized the potential sources of social chemosignals in humans (Chap. 51; [52.19, 24, 25]), here the current state of knowledge will be summarized briefly only.

Social chemosignals in humans are generally considered to be volatile, however exceptions might be possible [52.26]. The source of volatile molecules is body fluid of any kind ([52.27]; e.g., sweat, urine, vaginal secretions, sperm, and lacrimal fluid). In humans, most research focused on the secretions of apocrine and apoeccrine sweat glands in the axillae [52.28]. Four kinds of substances contribute significantly to the typical armpit smell. The first class comprises unsaturated or hydroxylated branched fatty acids, such as (*E*)-3-methyl-2-hexenoic acid (3M2H), which constitute the dominant, characteristic axillary odor [52.29]. 3M2H is carried to the skin surface by apocrine secretion odor-binding proteins and then liberated by axillary bacteria [52.30]. The second class of major odor constituents are thio-alcohols (sulfanylalkanols), such as 3-methyl-3-sulfanylhexan-1-ol (3M3SH), molecules with a high volatility and very low olfactory thresholds [52.31–33]. The third class of substances includes short-chain fatty acids, such as propionic, butanoic acid, and isovaleric acid [52.34]. Isovaleric acid is liberated by micrococci and gram-negative bacteria and might contribute to a sweat-like odor [52.35].

The fourth group of compounds are androgen steroids representing a musk or urine-like odor [52.34], such as 5α-androst-16-en-3-one (androstenone), 5$\alpha(\beta)$-androst-16-en-3α-ol (androstenol), and 4,16-androstadien-3-one (androstadienone). In the human testis as well as in the human axillae, androstenol is metabolized from androstenone, which in turn is metabolized from androstadienone [52.36]. As odorless testosterone occurs in apocrine secretions, androgen steroids (16-androstenes) might originate from testosterone metabolism. However, axillary bacteria, such as aerobic coryneform, convert testosterone directly only to dihydrotestosterone, androstanedione and androstenedione, but not to 16-androstenes. Therefore, the metabolism of odorous androgen steroids is considered to be rather complex and to involve numerous interconversions [52.37]. In females, the source of 16-androstenes are probably the adrenals and ovaries [52.34]. The amount of 16-androstenes in apocrine sweat varies considerably between individuals [52.38]. Nevertheless, androstenone and androstenol occur in larger concentrations in males than in females [52.34, 39].

In summary, the individual mixture of compounds within axillary sweat is determined by a) the amount of single molecules that are released by the apocrine and apoeccrine glands, which in turn partly depends on the formation of hormones (e.g., in the gonads and adrenals) as precursors, b) the composition of the axillary flora, responsible for metabolizing odorless precursor molecules to odorous molecules (e.g., 16-androstenes), c) the availability of carrier proteins for the transport of long chain fatty acids (e.g., 3M2H), and d) a specific variant in the ABCC11 gene [52.40]. Individuals who are homozygous for the single-nucleotide polymorphism (SNP) 538G→A of gene ABCC11 have significantly less of the acidic axillary odor [52.41]. The ABCC11 protein is expressed and localized in apocrine sweat glands and seems to be involved in the formation of glutamine precursors to axillary odors.

52.3 Perception of Social Chemosignals in Humans

As several chapters of this handbook are describing the perceptual systems in humans for environmental chemicals in detail, here I will briefly focus on whether social chemical signals are likely to be processed via a non-olfactory system.

Four different systems should be considered when looking for a chemosensory organ responsible for the transduction of social chemosignals: the primary olfactory system, the trigeminal system, the grueneberg ganglion (GG) cells, and the trace amine-associated receptors (TAARs). Whereas the former two systems are rather nonspecific systems, processing volatile chemicals either as smelling (olfactory system) or as cool, pungent or irritant (trigeminal system), the latter two systems might specifically process social chemosignals. The vomeronasal organ (VNO) has no proven function in adult humans.

Even though sweat contains a number of substances that could activate the trigeminal system (fatty acids, lactic acids, and uric acids), complex social chemosignals (body odor) seem not to be processed predominantly by the trigeminal system [52.42, 43].

However, the olfactory system is most probably involved in the processing of body odors. The main olfactory system can be subdivided into the level of the sensory neuron, the olfactory bulb and the olfactory

cortex. Each olfactory sensory neuron (OSN) is considered to express only one type of olfactory receptor that is highly specific for certain molecular features, but also tolerant of others [52.44]. The main olfactory bulb is the first relay station in the olfactory pathway, where axons of the sensory neurons form synapses with the dendrites of secondary neurons (mitral and tufted cells) and interneurons (periglomerular cells) within structures called glomeruli. From the olfactory bulb olfactory information is transmitted to the structures of the primary olfactory cortex (anterior olfactory nucleus, piriform cortex, olfactory tubercle, entorhinal cortex, amygdala) [52.45–47]. Neurogenesis is a central feature of the olfactory system [52.48–50]. The OSNs are in constant turnover through local progenitor cells. Also, neurogenesis occurs continuously in two brain regions of adult mammals, the subventricular zone (SVZ) of the lateral ventricles and the subgranular zone (SGZ) of the hippocampus. Neurons born in the SVZ migrate into the olfactory bulb, whereas neurons born in the SGZ migrate into the dentate gyrus.

Specific OSNs and bulbar glomeruli mediate innate responses to biologically significant odors (spoiled food and predator odor) in mice [52.51]. In addition, the avoidance response to predator (fox) odor in mice requires constant neurogenesis of SGZ and SVZ neurons [52.52]. This neurogenesis seems also to be required for intraspecies chemical communication, since sex-specific responses that are olfaction-dependent and innately programmed (e.g., male-to-male aggression, female pregnancy and nursing behavior) are severely impaired in mice lacking neurogenesis [52.52].

Another chemosensory system, the GG, has been observed in a variety of mammals (including rodents, carnivores, and humans) and might specifically be involved in social chemosensory perception. In mice, the GG is located at the tip of the nose, close to the entry of the naris. The sensory neurons' axons project to a special set of glomeruli – the necklace glomeruli – in the main olfactory bulb [52.53], which are distinct from the glomeruli typically innervated by OSNs. In mice, GG receptors are sensitive to alarm pheromones, released by stressed conspecifics [52.54]. Just recently, it could be shown that mice GGs also respond to predator odor, an odor representing similar chemical features as the mouse alarm pheromone [52.54]. The authors conclude that the GGs might represent a chemosensory subsystem for the processing of danger.

TAARs have been detected within the mouse [52.55] and human olfactory epithelium [52.56, 57], but have also been described to be expressed on GG cells [52.58]. In mice, TAARs respond to predator odor and to volatile amines, released from urine of conspecifics and trigger avoidance-related motor behavior [52.59]. Therefore, TAARs might also process significant social signals in humans.

In a number of vertebrates, including mammals, the VNO is involved in the detection of social chemosignals [52.60]. In the 1990s one working group reported activation of the human VNO through a number of so-called *vomeropherins* [52.61–63]. These substances (e.g., androstadienone, estratetraenol, estratetraenyl acetate, and pregnadienedione) were reported to change mood as well as the endocrine and physiological status in a sex-specific manner. Due to these publications it was stated that pheromones do exist in humans [52.64], and numerous researchers started to investigate possible pheromonal effects of these substances in humans. However, it could not be confirmed by others that the human VNO is a functional sensory organ. The search for a VNO in humans has been revealed that there are no sensory cells, no functioning receptors, no connections to the brain, and no accessory olfactory bulb, at which a vomeronasal nerve would terminate [52.19, 25, 65, 66]. One single VNO receptor gene has been discovered to be expressed within the human olfactory epithelium [52.67], but its functional significance is strongly questioned [52.19]. However, the VNO is not necessary for social communication in mammals and some effects of social chemosignals on the behavior and physiology of conspecifics have been shown to rely on the main olfactory system instead [52.68, 69]. Moreover, as the VNO also processes nonsocial odors [52.70], its function still remains to be understood [52.71]. The main problem remaining until today is the fact that *vomeropherins* are still investigated, even though they have never been proven to stimulate a pheromone-detecting organ.

In summary, it seems likely that social chemosignals are at least partly processed in specialized neuronal systems, similar to social signals of other modalities. Promising candidates for the processing of social chemosignals are GG cells and TAARs.

52.4 Chemosensory Communication via Single Molecules

In 1959 the term *pheromone* was introduced to increase the understanding of insect communication [52.72]. Since then, pheromones were often considered to be monomolecular substances, and to release a stereotyped behavior or physiology in conspecifics. However, intensive research has meanwhile demonstrated that across phyla, including insects, pheromones are usually molecular mixtures and rather seldom a single substance [52.19]. Therefore, it is difficult to comprehend that just in humans single molecules should act as pheromones. Nevertheless, numerous papers on putative human pheromones were published. Below, those studies will be summarized, which are exemplary for the enormous inconsistency in results and conclusions.

52.4.1 Substances Related to Male Body Fluids

In males, the substances that have been intensively studied for their pheromonal effects are 16-androstenes, especially androstenone, androstenol and their precursor androstadienone. The search for male pheromones can be divided into two phases. During the 1970s and 1980s, research focused on androstenone and androstenol. Since the end of the 1990s most studies investigated whether androstadienone exerted pheromone-like effects.

Androstenone and Androstenol

Androstenone is a powerful chemical signal in the pig. When a boar is sexually aroused or aggressive it produces odorous saliva, including a mixture of steroid compounds. Androstenone is a main component of this mixture and its odor is attractive to sows and induces the mating stance (lordosis) in estrous female pigs [52.73, 74]. As androstenone was also detected in body fluids of human males [52.34], quite suddenly, numerous studies investigated whether androstenone has also pheromone-like effects in humans. Maybe the most popular study, made known to the public by the yellow press, investigated whether females prefer androstenone sprayed seats in a dentist's waiting room [52.75]. In this study, androstenone was applied to a specific chair in three different concentrations, and it was observed whether males or females preferred the treated chair in comparison to an untreated chair. According to the study, females preferred the seat sprayed with the high and the low androstenone concentration, and men avoided the seat treated with the high concentration. Despite its popularity in the public, many aspects of the study's methods have been criticized [52.76]. Especially, the appearance of the behavioral effect in association with the low and the high concentration but not with the intermediate concentration, strongly argues against a biological effect. Furthermore, it was suggested [52.76] that possible effects of androstenone on overt behavior might rather be due to a common odor effect than to a pheromone effect. In fact, the authors of the original study themselves questioned a direct effect of social chemical stimuli on behavior [52.77]. Instead, they declared that behavioral effects of odors always depend on the context of the odor exposure as well as on the odor meaning, which is acquired through the individual learning history.

Apart from behavioral observations, the mood during androstenone exposure was investigated. However, contrary to the expectations, androstenone exposure led females to describe themselves [52.78] and others (males and females; [52.79]) as less sexy, and led males to describe themselves and other males as less sexy [52.79]. The odor of androstenone itself is perceived as unattractive and unpleasant in women, however, during midcycle, around ovulation, the smell of androstenone becomes more neutral, but is not perceived as emotionally positive [52.80]. In the human brain, androstenone is processed like nonsocial odors (rose) in the (orbito-) frontal cortex [52.81].

Two studies investigated whether androstenol had an effect on social behavior. The first study [52.82] indicated that men avoid restroom stalls that are sprayed with androstenol. However, in this study, women's choices were not affected by androstenol. In the other study [52.83], the participants were asked to wear an androstenol sprayed necklace for 17 h, and were later on asked to recall their social contacts. Here, the female participants reported to have experienced intensified contacts with males (according to number of contacts, the emotional depth of the contact, and the contact duration). However, males' social contacts were not affected by androstenol exposure.

While the two studies on androstenol effects on human behavior revealed mutually incompatible results, similar incongruities cast a cloud over androstenol-related mood studies. One study suggests that females exposed to androstenol feel more submissive during the ovulatory phase of their cycle (the effect was significant for the beginning and end of ovulation time, but not for the core of ovulation time, as compared to 12 measurements during the menstrual cycle; [52.84]). However, the ratings on four other mood scales (like sexy/unsexy) were not affected by androstenol. Later on, and even though androstenol was presented to females within an erotic context (reading of an erotic text passage), this effect could not be confirmed [52.85]. In this study, an-

drostenol exposure had no effect on any of nine mood measures. This result is in accordance with a more recent study, which also could not confirm any effect of androstenol on mood (positive and negative mood, and alertness) either in women or in men [52.86].

Apart from behavioral and mood measurements, it was investigated whether androstenol has an impact on the perception of other males and females [52.79]. Smelling androstenol, men rated other males, but not females, as more sexy, and themselves as less sexy, and females rated other males as less sexually attractive.

Even though the reported findings on androstenol are highly inconsistent, a recent study [52.87] reformulated possible pheromonal effects of androstenol, as it is supposed to activate hypothalamic structures in females. In this study, androstenol was presented in crystalline form, thus its concentration exceeded the physiological concentration of androstenol in sweat by far.

In sum, both, androstenone and androstenol do not show any consistent effects on human behavior or mood. The study results are extremely contradictory, suggesting that significant findings appear by chance. As most studies suffer from an insufficient correction of the statistical alpha error, it is to be expected that from time to time some of the measured variables show statistically significant results (see the section on methodological suggestions). The accidental nature of the studies' results becomes obvious, integrating their outcome: Females dislike the odor of androstenone, and while exposed to it, they describe themselves and others as less sexy. However, in very low or very high concentrations, they seem to (unconsciously) approach this odor. Exposed to androstenol, females seem to describe males to be less sexy but are considered to get in contact with men more often. Men, on the other hand, are supposed to describe other males as more sexually attractive while smelling androstenol, but seem to avoid restroom stalls smelling like androstenol.

Accordingly, studies on single molecules like androstenone and androstenol, which are claimed to exert a pheromone-like effect in humans, have strongly been criticized [52.25, 88, 89]. Importantly, it has been stated that chemical communication in humans is affected by experience, culture, and the social and nonsocial context. In 1995 *Kirk-Smith* stated that [52.90]:

> *The experiments [on androstenone and androstenol] form an inconsistent pattern and thus provide little basis for concluding that human males produce odors directly analogous to the sexual attractants of other species.*

In fact, during the 1990s, the interest in possible pheromonal properties of androstenone and androstenol strongly disappeared. However, the run on human pheromones started again, since it was reported that single molecules activate the human VNO [52.61]. These molecules are androstadienone (putative male pheromone), estratetraenol and estratetraenyl acetate (putative female pheromones).

Androstadienone

Aiming to find a sexual attractant in humans, the effects of androstadienone on mood, physiology, and behavior have been studied extensively. However, as with androstenone and androstenol, the effects of androstadienone are highly contradictory across studies.

A number of studies investigated possible mood effects of androstadienone. According to *Jacob* and *McClintock* [52.91], androstadienone increased positive mood in females, but did not change negative mood or alertness. However, according to *Lundström* et al. [52.92] females felt more focused after androstadienone exposure, but did not show general mood changes. Several other studies could not find any mood effects in women after the mere exposure to androstadienone [52.93–97, 97, 98]. In males, only one study suggested that androstadienone perception decreases positive mood [52.91]; most studies, however, observed no effects of androstadienone exposure in men [52.94, 96, 97].

According to the aforementioned studies it seems obvious that simple androstadienone exposure exerts no (predictable) mood effect, either in men or in women. Therefore, some authors suggested that an appropriate context might be necessary for valid mood effects to occur. Thus, it was suggested that androstadienone should affect mood whenever presented by a tester of the opposite sex (in heterosexual participants). According to these studies, androstadienone increased positive mood in females, but only in the presence of a male tester [52.94, 95]. However, whereas some authors found these effects to only occur directly after odor exposure (6 min, [52.91, 94]), other authors report such effects even about 30 min after odor exposure [52.92, 95]. In men, no effects of androstadienone on mood were observable, either in the presence of a male or a female tester [52.94].

In another experimental context, participants were asked to view an erotic movie, while smelling androstadienone [52.98]. Here, it was reported that after androstadienone exposure, females' mood became more positive and females felt more sexually aroused. In a similar study with a comparable context movie, androstadienone increased the feeling of being sexually aroused in female participants [52.97]. However, positive and negative mood was not changed by androstadionone. Instead, viewing the same erotic movie,

the perception of androstadione also increased sexual arousal in male participants [52.97].

Summarizing the studies on mood effects of androstadienone, no consistent result emerges from the different studies. It remains unclear whether in females, androstadienone exerts effects on its own or only in a social or in an erotic context. It further remains unclear whether it has any effects at all, or effects on positive or on negative mood or on alertness and arousal. Finally, it is not clear whether androstadienone decreases positive mood or increases sexual arousal in males.

In addition to mood, a number of studies investigated whether androstadienone affects physiological arousal (assessed by measuring the activity of the autonomic nervous system) in men and women. Unfortunately, similar to the mood studies, the indicator of the autonomic arousal strongly varied between studies. Accordingly, some studies suggested that the exposure to androstadienone in the presence of an opposite sex tester affects physiological arousal, whereas others suggested that a specific erotic context is necessary for these effects to occur. According to *Jacob* et al. [52.94], androstadienone increased the activity of the autonomic nervous system in women (reduced the skin temperature and increased the skin conductance) in the presence of a male tester. Similar results were reported by *Lundström* and *Olsson* ([52.95], autonomic arousal as measured by finger pulse and skin temperature) and by *Bensafi* et al. ([52.96], combining eight physiological parameters to a physiological arousal index: skin conductance response, electrocardiogram, finger pulse, ear pulse, blood pressure, skin temperature, abdominal respiration, and thoracic respiration). However, another study reported null effects of androstadienone exposure, even when presented by an opposite sex tester ([52.97], separate testing of seven autonomic nervous system parameters). In this study a decrease in the physiological arousal level (increase in skin temperature) in women was observed, when administering androstadienone in an erotic context (erotic movie).

In addition, some studies tested whether the autonomic nervous system of males is affected by androstadienone exposure: Androstadienone decreased the activity of the autonomic nervous system in men (increased the skin temperature), independent of the tester's sex [52.94]. Similar results were reported by *Bensafi* et al. [52.96], calculating a physiological arousal index. However, again, in a third study, effects on the physiology of males did only occur when androstadienone was presented in an erotic context [52.97].

Only a few studies investigated whether androstadienone affects the endocrine system of the perceiver. *Wyart* et al. [52.98] presented androstadienone to females by a male tester and in the context of erotic video clips. These authors could show that the increase in activity of the autonomic nervous system after stimulus exposure was associated with an increase of the stress hormone cortisol. However, this effect was not confirmed in males by a more recent study [52.99]. Here, androstadienone, presented during a social interaction, did not change the cortisol level in men.

In summary, some studies suggest an increase while some suggest a decrease in physiological arousal in women after exposure to androstadienone. In addition, one study indicates the release of stress hormones (cortisol) in females smelling androstadienone. These effects sometimes occur in the presence of a male tester, and sometimes they can only be observed in an erotic context. In males, androstadienone exposure seems to decrease physiological arousal, however, the necessary context conditions for this effect are not specified.

Another area of research on androstadienone is related to possible effects on social perception. It was observed that androstadienone did not affect attractiveness ratings of male faces (on pictures) in females [52.95], and furthermore that androstadienone did not alter attention to male and female faces in male and female participants [52.93]. Albeit androstadienone seems not to change face perception, its perception might inherently be linked to the perception of males (and not of females). Accordingly, dynamic point-light displays reflecting walkers of ambiguous sex are categorized as more male-like by females exposed to androstadienone as compared to females smelling a control solution [52.100].

To the knowledge of the author, two studies assessed whether androstadienone directly affects social behavior in humans. *Saxton* et al. [52.101] reported that females chose males more often during a speed-dating event in order to meet again, when exposed to androstadienone as compared to water exposure. However, the selection rate was increased only in one out of three studies, and did not exceed the selection rate in females exposed to clove oil. In an economic exchange context, males who were exposed to androstadienone offered more and asked for less money than males exposed to a control substance (dry yeast), thus behaving more generously while being exposed to androstadienone [52.99].

Multiple brain clusters have been observed to be activated by androstadienone. Brain areas related to emotion processing (prefrontal cortex, cingulate cortex, amygdala and hypothalamus), to attentional systems (visual cortex, parietal cortex, thalamus, basal ganglia, premotor cortex, cerebellum), and to the olfactory system (inferior temporal lobe, hippocampus, amyg-

dala, thalamus) seem to process androstadienone in females [52.102]. However, as androstadienone was diluted in clove oil and smelled similar to the control (clove oil without androstadienone), it is rather puzzling that the test solution activated attentional and olfactory systems in a different way than the control solution. In the same year, another working group presented the same substance in much higher concentrations (in crystalline form) and found far less areas to be involved in androstadienone processing in females (hypothalamus), and no significant activations in males [52.103]. As androstadienone perception was compared to the perception of pure air, it is surprising that no other brain regions, responsible for attentional feature processing, were significantly activated. Later on, a study from the same working group compared androstadienone activations with brain activations evoked by neutral, positive, and negative odors [52.104]. Here, two large brain clusters (within the lateral prefrontal cortex and superior temporal cortex) discussed to be related to social cognition were observed to process androstadienone in females. Summarizing, the results revealed by functional brain imaging studies are again highly inconsistent. Furthermore, the validity of these studies is highly questioned, comparing the effects of androstadienone, as a substance that cannot be perceived chemosensorily but activates large brain areas [52.102] and as a substance that has a distinct smell on its own but activates either very small subcortical, or large neocortical brain areas [52.103, 104].

52.4.2 Substances Related to Female Body Fluids

Female Copulins

Since the late 1960s molecules deriving from female body fluids, functioning as chemical attractants, have been searched for. A possible candidate was the so-called *copulin*, which seemed to derive from vaginal secretions from female rhesus monkeys. It was reported that these secretions stimulate male sexual interest and behavior (mounting and ejaculation, [52.105]) and consist out of five acids: acetic, propionic, isobutyric, butyric, isovaleric and isocaproic acid [52.106]. Similar mixtures of these short-chain fatty acids have later been reported to occur also in human vaginal secretions [52.107]. Consequently, it has been speculated whether these copulins have an impact on human sexual intercourse [52.108]. However, it became evident later on that all experiments demonstrating behavioral effects of copulins were based on the data obtained from only six rhesus monkeys, which were preselected as positive responders. In addition, two of these monkeys contributed to more than 50% of the data [52.109]. Accordingly, in a series of well-controlled experiments conducted in an independent laboratory, neither the odor of vaginal secretions of rhesus monkeys nor the supposed mixture of fatty acids had any effects on the behavior of male rhesus monkeys [52.110]. The critique on the experiments on copulins in primates and humans was overtly stated in the early reviews on pheromones [52.88, 111, 112] and the interest of the scientific community in these female chemical attractants strongly declined during the 1970s. Only once, some time later, a single study examined chemosensory effects of short-chain fatty acids on social behavior in men and women and found no effect [52.83].

Estratetraenol and Estratetraenyl Acetate

The second wave of publications on single molecules released by female body fluids that should act as chemical attractants on males was related to the estrogen-related molecules estratetraenol and estratetraenyl acetate, both of which were considered to activate the human VNO and to be pure pheromones since the appearance of the publications of *Monti-Bloch* and *Grosser* in the early 1990s [52.61, 62]. However, only estratetraenol has been reported to be detectable in human body fluids, namely in the urine of pregnant females in the third trimester [52.113].

In a first study [52.91], mood was assessed on 14 different scales, which were combined into three mood dimensions via factor analysis (positive-stimulated mood, alertness, negative-confused mood). Estratetraenol affected mood only immediately after exposure (6 min), but not 2, 4, and 9 h after initial exposure. During the first mood measurement, females experienced a stronger positive mood than males, while exposed to estratetraenol. However, negative mood and alertness were not affected by estratetraenol. In the second study [52.94] mood was assessed on 17 different scales, which were reduced to three main mood dimension through factor analysis (alertness, bipolar mood, relaxed/open). The ratings were obtained prior to and after (6 min) exposure to estratetraenol, masked by clove oil. In addition, it was analyzed whether the sex of the tester modulates the effects of estratetraenol. However, estratetraenol did not affect mood in either condition. In the same study [52.94], it was also investigated whether estratetraenol has an impact on the activity of the autonomic nervous system. In men, estratetraenol increased palmar skin temperature and the skin conductance level; however, this was independent of the sex of the tester. In women, the skin conductance level increased through estratetraenol exposure in the presence of a male tester. Women's hand temperature was not affected by estratetraenol exposure in either context.

In a later study [52.96] two mood dimensions (positive mood, negative mood) were extracted from 16 emotional descriptors and mood was measured four times after estratetraenol exposure (10, 20, 30, 40 min after exposure). However, estratetraenol did not affect positive or negative mood or sexual arousal, neither in men or in women, regardless of the time point of measurement. In addition, the activity of the autonomic nervous system was measured via eight parameters (skin conductance response, electrocardiogram, finger pulse, ear pulse, blood pressure, skin temperature, abdominal respiration, and thoracic respiration) and the digitized data were separated into four measurements, paralleling the mood ratings. Perception of estratetraenol did not affect any of the physiological measures, at either time-point, neither in men or in women. A second study of the same working group [52.97] used the same methods in stimulus administration and data recording (except for not measuring blood pressure), but presented estratetraenol in three different contexts (during the presentation of either a happy, or a sad, or a sexually arousing movie). Estratetraenol did not affect any of the physiological parameters in either context, neither in males or females, and did also not affect positive or negative mood, but increased sexual arousal in males and females in the erotic context.

A subsequent study [52.114] used a design similar to *Jacob* et al. [52.94], but focused on the effects of estratetraenol in males and increased the number of study participants ($N = 21$ males in: [52.94]; $N = 80$ males in: [52.114]). In this study, mood (positive and negative mood, extracted by factor analysis from eight descriptors) and physiological arousal (skin conductance level, heart rate) were tested in the presence of a male or a female tester, 20 min after stimulus exposure. Estratetraenol had no effect on the physiological parameters but increased negative mood in the presence of a female tester and decreased negative mood in the presence of a male tester.

Brain activations through estratetraenol exposure were investigated in a PET experiment [52.103]. Pure, unsolved, estratetraenol in crystalline form was presented and its perceptual qualities were rated to be similar to those of androstadienone, with no rating differences between the sexes. Estratetraenol activated parts of the olfactory cortex in both sexes (amygdala, piriform and insular cortex, significantly in females and as a trend in males). In addition, only in males, the hypothalamus was activated through the smelling of estratetraenol. As the hypothalamus releases hormones that activate the development of sexual hormones, it was concluded that estratetraenol has *pheromone*-like effects in males.

One study investigated the brain response to estratetraenyl acetate in eight male volunteers by means of fMRI analysis [52.115]. Estratetraenyl acetate was diluted in mineral oil and presented in a high and a low concentration. As the low concentration was detected at chance level, it was concluded that it was perceived below the threshold level. However, largely independent of the concentration, estratetraenyl acetate induced activation within the anterior medial thalamus and the inferior frontal gyrus.

Summarizing the studies on estrogen-related compounds, there are no consistent effects among studies. Mood effects of estratetraenol were observed in two studies [52.91, 114], but could not be confirmed by three other studies [52.94, 96, 97]. In addition, the observed mood effects are not consistent with a hypothesis of estrateraenol being attractive for males: the observation that estratetraenol induces a decrease of positive mood in males, relative to females [52.91] would rather indicate that males avoid the signal. Furthermore, the finding that estratetraenol increases negative mood in males, especially when a female (tester) is present [52.114] indicates that stimulus avoidance in males will be even stronger if females are around.

Furthermore, it is not clear whether estratetraenol has an effect on arousal and alertness. Two studies could not find effects of estratetraenol on self-reported arousal [52.91, 94], similar to three studies that could not find effects of estratetraenol on physiological indicators of arousal [52.96, 97, 114]. However, one study [52.94] indicated an increase in sympathetic activity in males and females.

One study reported that estratetraenol exposure increased the self-reported sexual arousal [52.97]. However, as this effect was similar in male and female perceivers, its ecological relevance is strongly questionable. According to this study males and females were equally attracted by female *pheromones*.

The brain imaging studies do not illuminate a straight summary of the findings either. In the PET study [52.103], estratetraenol was presented in very high (pharmacological) concentrations, exceeding the physiological concentration range by far. The fMRI study on estratetraenyl acetate [52.115] found effects of subliminal (unconscious) perception on the attentional gating system (thalamus). However, attentional systems, per definition, depend on conscious stimulus processing and are inherently related to alertness, response selection and limited processing capacity [52.116, 117], and the thalamus is the main relay for these attention-related processes [52.118]. Thus, it seems to be impossible for subliminal stimuli to require neuronal capacity that is usually associated with conscious stimulus processing.

52.4.3 Methodological Suggestions

The studies on androstenes as male pheromones and estratetraenol as a female pheromone did not reveal any consistent results. This is due to a number of methodological flaws, which are related to:

1. A misunderstanding of the biological underpinnings of chemical communications in humans and animals
2. A misunderstanding of experimental and statistical methods, and
3. Missing theories that could explain the results.

These three areas of deficient research strategies will be outlined in detail.

Biological Underpinnings of Chemical Communication

The message conveyed through chemical signals always depends on the concentration of the chemical substance(s), and is usually valid only within a certain time frame. Moreover, in general, molecule mixtures, but not single substances, build up the signal and it is to be expected that the message conveyed by the chemical(s) varies with the internal and the external context.

Concentration of the Chemical Signal. Going back to the time of Paracelsus (1493–1541), a general law was stated that the effect of all substances always depends on their concentration (*dosis sola facit venenum*, the dose [alone] makes the poison). Thus, it has been known for 500 years that the effect of environmental substances on human body (receptor) cells is inherently contingent on their concentration. In this sense, all kinds of chemical communication in animals discovered so far are considered to be concentration dependent [52.19]. As an example, ants respond to almost all volatile compounds released by other ants with an alarm response, if the concentration of these compounds is high enough [52.119]. In the nematode and in the termite, the meaning of the chemical signal produced by conspecifics changes with the concentration [52.19, p. 54]. In mammals, the concentration range of the efficiency of the rabbit mammary pheromone has been found to be very narrow [52.120]: newborn rabbits only respond with head searching and oral seizing behavior to the mammary pheromone in a very tight concentration range. However, despite this basic principle, which seems to be valid across all physiological systems, the research on the efficacy of single substances in humans seems not at all to care about the definition of an efficient concentration range. Axillary hair of men contains on average about 200 pmol androstadienone and human plasma androstadienone has been found in concentrations of about 50 ng/100 ml [52.34, 38]. Studies investigating pheromonal effects of androstadienone in humans often used either 250 µmol [52.91–95, 101, 102], 500 µmol [52.100], 6250 µmol [52.121], or used androstadienone in its crystal form (200 mg in [52.103]; 50 mg in [52.96, 97]; 30 mg in [52.98, 99]). Thus, across studies, the concentrations investigated exceed the concentrations in human body fluids by about one million (10^6) and more. Therefore, it is highly unlikely that in any of these studies ecologically valid pheromone effects were described.

Duration of Signal Effectiveness. The longevity of chemical signals mainly depends on their volatility and molecular weight. The higher the volatility of a single molecule within a mixture used as a signal, the faster the diffusion rate and the faster the decay of the signal. Depending on the meaning of the message, signal molecules have different effect durations. Alarm pheromones, used to inform conspecifics about potential harm, are often highly volatile in order to spread the message immediately across long distances. Sex pheromones are often composed of larger molecules, allowing a higher specificity. Marking or trail pheromones often show a very low volatility and can last for months or years [52.19]. Furthermore, in complex body fluids (e.g., human urine), small molecules (< 250 D) responsible for signal formation (e.g., related to identity), are constantly rebuild from larger molecules [52.20]. Thus, a chemical signal can change its message over time. However, a possible effect duration time of androstadienone is not known and different effect times are reported (examples of effect peak latency: within a few seconds [52.103], within less than 20 min [52.91, 94], within 20 to 40 min [52.95, 96, 121], within one to two hours [52.101, 102]). As long as there is no agreement about the time frame of the expected effects of androstadienone, it is highly unlikely that reliable effects will be confirmed.

Single Molecules or Molecule Mixtures. *Doty* [52.24] and *Wyatt* [52.19] point to the fact that most (mammalian) pheromones are multicomponent mixtures. Signals based on mixtures of volatile molecules can be extremely diverse and can be specific for certain messages and species. However, signals based on only one molecule may have the strong disadvantage of being redundant as they could be used for different messages and different species. Androstenone, androstenol and androstadienone are produced in the boar testis [52.122], and all induce the mating stance in female pigs in estrus [52.123]. If these substances were equally effective in female pigs as in female humans,

female pigs should also be attracted by human males and female humans should be attracted by male pigs. These preposterous conclusions are critically put to the tip of the iceberg by *Doty* [52.24], concluding that human birth rates should be higher in areas with pig farms, if androstenes equally act as pheromones in pigs and humans [52.24, p. 141].

External and Internal Context. For a while now, there seems to be mutual agreement in pheromone research that the meaning of a social signal varies with its context. Accordingly, in various studies the putative pheromones were presented by an opposite-sex experimenter, e.g., [52.94, 95, 98, 121]. Furthermore, erotic movies [52.97] and speed-dating encounters [52.101] were introduced as context conditions for pheromone effects. However, in accordance with *Pause* [52.76] not only the external, but also the internal context of the signal perceiver should be considered when investigating chemical communication in humans.

The internal context is related to the motivational and endocrine status of the perceiver. It is well known that the motivational status of the perceiver affects the perception of food cues [52.124] and of social signals [52.125]. More specifically, in females the neuronal processing of erotic stimuli varies with the level of sexual hormones [52.126, 127] and it has also been suggested that the sensitivity to androstadienone might vary with the reproductive state in females [52.128]. Thus, an appropriate context should increase the likelihood of evoking an appropriate response in the perceiver. This is possible whenever the physiological system of the perceiver is primed for optimal stimulus processing and stimulus response.

Finally, it should be considered that the response to 16-androstenes could be affected by the amount of experience with the substance [52.129, 130]. After repeated exposure to androstenone or androstadienone, formerly anosmic subjects become sensitized and are able to smell the substance. The sensitization process is due to peripheral [52.131] as well as to central neuronal plasticity [52.132]. After being sensitized, the hedonic profile of the odor changes [52.133]. Therefore, it is assumed that an altered behavioral response could follow the changed emotional valence of the odor.

One Receptor for Different Androstenes. 4,16-androstadienone is the precursor of 5α-androstenone, and both appear in different human body fluids, including sweat [52.38]. Humans have about 400 functional olfactory receptor genes [52.134], each of them expressing receptors highly sensitive to a single or very few ligands. It has been shown that one single human olfactory receptor (OR7D4, as compared to 334 other human odor receptors) is highly sensitive to androstenone and androstadienone [52.135]. Perception of androstenone and androstadienone varies with two allelic variants (RT and WM) at the OR7D4 locus. Individuals homozygously carrying the RT allele are more sensitive to androstenone and androstadienone and judge the odors as rather unpleasant, whereas individuals homozygously encoding the WM allele are much less sensitive to both substances and find them less unpleasant. As both substances are processed via the same receptor and as the perceptional qualities of both substances depend on the same allelic variations, it remains a mystery why only one of these substances is called to be a putative pheromone (androstadienone), while the other (androstenone) is not [52.136].

Experimental and Statistical Methods

Most pheromone studies are conducted on the basis of an experimental design. In experimental designs the number of independent variables is not restricted, however, as long as the experimenter choses to use univariate statistical tests (such as t-tests, or ANOVAs), the number of dependend variables should not exceed one. Using more than one dependend variable will lead to an inflation of the alpha error. For example, if it is investigated whether a putative pheromone affects mood through four different and independent mood scales the empirical alpha error increases from 0.05 to 0.19; if 40 independent tests were carried out, the experimentwise error rate would even exceed to an alpha equaling 0.87. Thus, as long as the dependend variables are not introduced with a specific hypothesis each, a so-called Bonferoni correction is necessary. However, a number of pheromone studies did not follow this advice and thus the reported results reached the significance level more or less accidentally (androstenol: [52.83, 84]; androstenone: [52.75, 78, 79]; androstadienone: [52.92, 97]; estratetraenol: [52.97]).

In addition to the methodological problems regarding the alpha-error inflation, the mood studies on adrostadienone suffer from an inherent methodological flaw regarding the mood scales. Instead of using reliable and validated measurements to assess mood (e.g., by questionnaires or mood scales), in almost all studies a different number of items of different scales and questionnaires were merged and regrouped with different statistical analyses (e.g., factor analysis or cluster analysis). Hereby, studies investigated different mood dimensions that only occurred in single studies (e.g., [52.91]: positive-stimulated mood, alertness, negative-confused mood, extracted from 14 mood items by factor analysis; [52.94]: alertness, bipolar mood, relaxed/open extracted from 17 mood items by factor analysis; [52.96]: two mood dimensions – pos-

itive mood and negative mood – extracted from 16 emotional descriptors by principal component analysis; [52.121]: three mood dimensions – positive mood, high aroused negative mood and low aroused negative mood – extracted from 16 emotional descriptors by principal component analysis; [52.95]: two mood dimensions – positive mood and negative mood extracted from ten emotional descriptors by cluster analysis). The validity and reliability of these mood dimensions were never assessed, and studies are not comparable.

Theoretical Background

Studies on putative pheromones in humans were never based on a theory that could account for the reason why single substances (such as androstenes and estratetraenol) should affect mood, physiology and behavior in humans. As outlined above (Sect. 52.4.1, *Androstenone and Androstenol*) the interest in androstenone obviously results from the observation that it was effective as a sex pheromone in female pigs. It took 20 to 30 years until it became obvious that androstenone does not induce the mating stance in women [52.25, 76, 77, 89, 90, 137]. Due to the never-validated results that androstadienone and estratetraenol activate the (nonexistent) VNO, a second wave of studies on human pheromones was published. However, even though it became evident that adult humans do not possess a functional VNO [52.25, 65, 66], pheromone research remained active. However, 16-androstenes could have either no function in human chemosensory communication or a very different function from being a sex pheromone. For example, 16-androstenes could convey information about the sex of the sender or about the testosterone level of the sender.

In the search for a theory that could explain how and why androstene-related molecules should affect human behavior, it is necessary to specify the conditions of androstene production. In animals, the production and secretion of androstenone are tightly linked to the level of circulating testosterone [52.138–140]. Similarly, in humans, axillary androstenone is detected in larger quantities in men than in women [52.141], and its source seems to be mainly located in the testis [52.34, 36]. Thus, a link between androstenone and testosterone in humans seems as likely as it is in animals. High testosterone levels in men seem to be related to certain personality styles (traits), like aggression, dominance and competitiveness [52.142–145]. Thus, if 16-androstenes vary with endogenous testosterone, they could function as social warning signals [52.76], and activate withdrawal instead of approach behavior. It has recently been shown that men with a higher testosterone level are more sensitive to androstenone and dislike its odor [52.146]. The authors relate this finding to the possibility that androstenone might signal the readiness for competition in men. Moreover, the odor of androstenone is also disliked by women with higher estradiol levels. Thus, also in fertile women androstenone seems to induce escape-related behavior. However, this theory would comprise the assumption that specific messages can be conveyed via single molecules.

As stated above (Sect. 52.4.3 *Biological Underpinnings of Chemical Communication*), specific social chemosignals usually require multicomponent signals. If androstenes carry significant social information, it could be expected that these substances carry relatively redundant, nonspecific information, for example about the sex of the substance releaser. Two publications point to the possibility that androstenes might carry information specific for the male sex. In the first study [52.147], females with a specific anosmia to androstenone were successfully sensitized to androstenone and brain potentials (chemosensory event-related potentials, CSERPs) in response to male and female (self-related) sweat samples were recorded before and after sensitization. The CSERPs showed a general decrease in amplitude from the first to the second session, except for the sensitized females in response to male sweat samples. It was concluded that androstenone might carry specific information about the person's sex [52.147, p. 136]. These conclusions are similar to those of a recent study on androstadienone [52.100]. In this study, dynamic point-light displays reflecting walkers of ambiguous sex were to categorize. They were judged as more male-like by females exposed androstadienone as compared to females smelling a control solution. Thus, being part of a molecule mixture, 16-androstenes could add the information about the sex of the sender (maybe indirectly via being associated with the testosterone level) to more specific information, conveyed by other substances.

52.5 Chemosensory Communication via Complex Body Fluids

In the following, studies will be reviewed that used natural, complex body fluids as stimulus. Most often, axillary sweat was presented above or below the olfactory sensory threshold. In these studies, the characteristics of stimulus production were systematically varied and thereby the transmitted information. Thus,

instead of focusing on chemical characteristics of the signal, these studies focused on the specific kind of information, chemically transmitted and the related effects in the perceiver. In accordance with *Lübke* and *Pause* [52.148] and *Stevenson* [52.149], the two main areas of chemical communication in humans investigated so far can be divided into one area related to reproduction and one area related to harm avoidance.

52.5.1 Chemical Communication Related to Reproduction

Human Mate Choice and Sexuality

The major histocompatibility complex (MHC) is a highly polymorphic gene complex, encoding cell-bound glycoproteins that regulate T cell activity. Thereby the MHC creates histocompatibility or self-identification for the immune system. It has been shown in several vertebrate species that the individual MHC-type is associated to an individual body odor profile, which can be used to chemosensorily discriminate between conspecifics. Fertile individuals prefer the body odors of partners with a relatively dissimilar MHC type to their own [52.150, 151]. It has been proposed that this differential mating helps to maintain the high MHC polymorphism within species. A high MHC polymorphism enables the species members to resist a broader array of pathogens, which is crucial for survival.

In reference to the immunological function of the MHC in humans, it is called human leucocyte antigen (HLA). Humans exert body odor preferences for HLA-dissimilar individuals, but also preferentially select partners who possess a relatively different HLA type [52.152, 153]. CSERP analyses revealed that body odors of donors with a similar HLA type to the perceiver are processed faster and activate more neuronal resources than body odors of donors with a dissimilar HLA type to the perceiver [52.154]. This result suggests that the behavioral impact of chemosensory signals related to HLA similarity might be stronger than of signals related to HLA dissimilarity. Hereby, inbreeding avoidance could be successfully achieved if MHC similarity is transmitted as a signal activating avoidance behavior. Therefore, in humans, HLA-related signals seem to be associated with a negative selection bias in mating behavior [52.155]. Recently, fMRI indicated that peptides ligands that selectively bind to allelic variants of the perceiver's HLA system are processed within the right middle frontal cortex [52.156–158].

Endocrine Status of Sexual Hormones

In general, the body odor of women changes with the endocrine status of sexual hormones. Men judge female axillary and vaginal odors as most pleasant and most sexy around ovulation [52.159, 160]. Some authors discuss these results as pointing toward human female ovulation not being completely concealed, and thus body odors contributing to successful reproduction.

One study indirectly investigated whether an increase in the level of sexual hormones in men can be detected chemosensorily by the female brain [52.161]. Axillary sweat was collected from men while watching erotic videos. Brain imaging in female participants revealed that the sex-related sweat, as compared to axillary sweat collected during an emotionally neutral situation, was primarily processed within the orbitofrontal and the fusiform cortex and the hypothalamus. The activation of the hypothalamus and the orbitofrontal cortex could be related to the processing of the emotional significance of the stimuli, whereas activation of the fusiform cortex could be related to the social nature of the stimuli.

Another area of research in human chemosensory communication is related to the phenomenon of menstrual synchrony. Women living or spending time together show a synchronized menstrual cycle [52.162]. This phenomenon seems to be due to the communication of menstrual cycle-related chemosignals [52.163]: Whereas odorless axillary sweat samples of women in the follicular cycle phase shorten the menstrual cycle of the female recipients, chemical signals derived from sweat samples of women in the ovulatory cycle phase lengthen the menstrual cycle phase of the signal receivers. This study was the first to show that the endocrine status in humans is prone to effects of human chemosignals. However, the evolutionary significance of synchronized menstrual cycles in women is still debated [52.164, 165].

Sexual Orientation

Sexual orientation is conveyed between individuals through visual [52.166–168] and auditory social signals [52.169], and sexual orientation affects the response to these signals, as has been shown with visual social signals [52.170]. It is well known that the sex of individuals can be transmitted chemosensorily [52.171, 172]. In addition, chemosensory communication of sex varies with the sexual orientation of sender and perceiver: depending on their sexual orientation, men and women display specific patterns of preferences for body odors obtained from homosexual and heterosexual men and women [52.173, 174]. These preferences may be based on divergent central nervous responses to these body odors. According to CSERP analyses [52.175], individuals showed comparably faster processing of body odors derived from individuals constituting potential partners (e.g., gay male body odor presented to other gay men). Moreover, especially homosexual in-

dividuals' responses to body odors of individuals not constituting potential partners (heterosexual male body odor presented to gay men) showed a striking similarity to responses to body odors from HLA-similar individuals [52.154]. Thus, body odors from *incompatible* individuals in regard to sexual orientation might also function as social warning signals.

52.5.2 Chemical Communication Related to Harm Avoidance

Kin Recognition

Kin recognition is most important for structuring social relations in many diverse species [52.176]. In order to promote inclusive fitness, which can be understood as the successful transmission of one's own and relatives' genes to the next generation, pro-social behavior is favored among family members [52.177]. However, unrelated individuals, like out-group members, are more easily perceived as aversive [52.178] and more easily attacked [52.179]. In primates, being around related individuals (and friends) as in-group members is probably the most important strategy in order to avoid predation from out-group members or non-primates [52.9].

Numerous studies have shown that kin can be communicated chemosensorily: Newborns are able to chemosensorily identify their mothers, mothers and fathers are able to chemosensorily identify their children, siblings recognize each other by smell, and unrelated individuals are able to match family members by smell [52.180, 181]. The chemosensory transmission of kinship can be observed in noncohabiting individuals [52.182], and rats are even able to differentiate the degree of human relatedness through olfactory cues [52.183]. So far, one brain imaging study investigated whether body odor of kin is processed differently from body odor of non-kin [52.184]. The regional cerebral blood flow was higher in the frontotemporal junction, the insula and the dorsomedial prefrontal cortex during kin recognition. The activation of the dorsomedial prefrontal cortex is discussed to be related to self-referent stimulus processing during kin recognition [52.184, 185].

In line with the ability to recognize kin through olfactory cues, humans can also differentiate self from non-self via chemosignals [52.186]. Chemosensory information about the self facilitates self-face recognition in a reaction time task [52.187] and is processed faster than non-self information by the human brain [52.147]. According to the coemergence hypothesis, self-recognition and advanced expressions of empathy appear together in both individual development and phylogeny [52.188].

Mother–Infant Communication

The survival of a newborn is fully dependent on protection through adults, usually its mother. The protection covers all needs of the newborn, especially food (milk) delivery. Through a number of studies it has been demonstrated that newborns are able to detect their mother's odor in breast skin, milk odor, and axillary odor [52.181, 189]. Infants show preferential orienting towards their mother's breast odor as early as ten minutes after birth [52.190].

Importantly, smelling their mother's odor, newborns adjust their behavior. Two-week old sleeping infants exhibit sucking movements when presented with breast odors of lactating females [52.191]. Moreover, maternal breast odors elicit directional crawling in newborns [52.192]. Breast odors of lactating women further modulate breast- and bottle-fed newborn infants' arousal state. Crying babies calm down when they are presented with night gowns worn by their own mother or unfamiliar mothers [52.193]. The maternal body odor also affects social perception in infants: In the context of their mother's body odor, four-month-old infants look significantly longer at human eyes than in the context of a nonsocial odor [52.194].

Mothers, on the other hand, are equally able to recognize their offspring's unique body odor [52.195]. Even women who had only limited contact with their infant prior to testing recognize their infants' body odor [52.196, 197]. Moreover, infant chemosensory signals seem to prime affection in adult women in order to motivate them to care for infants: When exposed to body odors of unfamiliar newborns, primiparous and nulliparous women likewise respond with neuronal activity within the reward system [52.198]. However, only mothers, in contrast to nulliparous women, show activity of the orbitofrontal cortex in response to infant odors [52.199]. This result might reflect the attraction of mothers to infant odors.

Communication of Stress and Anxiety

Stress refers to a disturbance of the homeostasis of body systems [52.200] and thus to an imbalance of physiological messenger systems (e.g., neurotransmitters, neuropeptides, hormones, cytokines, etc.). The consequences of chronic stress will include the collapse of organ functions and in the long run inevitably cause the organism's death [52.201]. Thus, stress protection is among the most important prerequisites for ontogenetic survival. One highly efficient stress protection mechanism is a fast spread of information regarding a potential harm among all potentially affected group members. The stress signal should be distributed in a fast manner, should inform conspecifics about the

specific features of the potential danger, should be efficient during day and night time, and at best, stay at the place of potential danger until all group members are informed. Chemosensory signals fulfill all of these criteria regarding powerful warning signals. Thus, it is not surprising that chemosensory alarm signals evolved in the vast majority of species of the animal kingdom [52.19]. Resembling the originally stressed animals, the perceivers show increased motor activity and immediately escape from areas with high signal strength [52.202–204]. In addition, the perception of chemosensory alarm signals leads to the activation of physiological stress systems in mammals [52.205, 206].

Recently, a number of studies confirmed the phenomenon of chemosensory stress communication in humans. In these studies, axillary sweat was sampled from individuals experiencing stress-related emotions and afterwards the effects of sweat perception were measured. In some studies [52.207, 208] the sweat donors were exposed to extreme stress conditions (e.g., first-time skydiving or exercising on a high rope course). Such conditions induce strong physiological arousal in the sweat donors and activate a diverse set of physiological systems related to a mixture of different positive (e.g., surprise, joy) and negative emotions (e.g., disgust, fear). In other studies, emotion-inducing movies (related to happiness, anxiety, or disgust) were presented and thus the induced feelings were relatively weak but rather emotion-specific [52.209–211]. Another approach was realized by sampling sweat from university students while waiting for their final examination in order to obtain their academic degree [52.212, 213]. According to self-ratings, the sweat donors experienced anxiety, but no other emotion, and their physiological stress level (cortisol) was increased. This procedure induces a specific and relatively strong emotion. In the following, the nonspecific term *stress* will be used to describe effects observed in different studies. The more specific term *anxiety* will only be applied to studies that investigated this specific emotion.

Humans have difficulties in identifying the emotions of sweat donors [52.207, 209, 210, 214] and it has been reported that the chemosensory sweat stimuli were hard to detect in comparison to room air [52.212, 213, 215]. Therefore, the effects of stress related chemosignals seem to occur predominately without conscious experience.

Three effector systems have been described consistently across studies: First, in the context of chemosensory stress signals social perception is sensitively tuned to detect signals related to harm or danger. In detail, the perceptual acuity for social safety signals (happy faces) is reduced [52.208, 212] and the perceptual acuity and attention allocation for social threat signals (fearful and angry faces) is increased [52.207, 214, 216]. Moreover, alertness to indifferent social signals (ambiguous and neutral facial expressions) with no clear meaning is enhanced [52.217].

The second system that changes in the context of chemosensory stress signals is the motor system. Humans respond with an augmented startle reflex to sudden loud tones, in the context of chemosensory anxiety signals [52.218, 219]. This resembles the motor response of rats to startling noise in the context of chemosensory alarm signals of stressed conspecifics [52.220, 221]. As the startle reflex is an indicator of the activation of motor systems related to withdrawal behavior, it can be concluded that motor systems related to signal avoidance are automatically primed through the perception of stress-related chemosignals of conspecifics.

The third system that changes its activity in the context of chemosensory stress signals is the human brain: A study based on chemosensory event-related potentials (CSERPs) showed that the processing of almost odorless chemosensory anxiety signals requires enhanced neuronal energy (P3 amplitude) originating from medial frontal brain areas [52.213]. In a first brain imaging study it was shown that sweat samples collected during the experience of anxiety activate brain areas involved in the processing of social emotional stimuli (fusiform gyrus), and in the regulation of empathic feelings (insula, precuneus, cingulate cortex; [52.215]). It was concluded that the physiological adjustments in response to chemosensory anxiety signals seem to be mainly related to an automatic contagion of the feeling. The emotional contagion hypothesis is confirmed by the findings that fear chemosignals generate fearful facial expressions [52.211] and induce increased state anxiety [52.222] in the perceivers. In contrast to the anxiety study, stress-related sweat (from first-time skydivers) was mainly processed within the amygdala [52.207]. It is reasonable to assume that the perception of stress-related chemosignals does not activate emotion- and empathy-specific neuronal networks, but only less specific structures (like the amygdala), which prime nonspecific autonomic adjustments.

Thus, in summary, emotional states that are caused by potential threat or danger and associated with feelings of stress, fear or anxiety activate the release of chemosensory signals. These signals are processed in brain areas related to social fear perception and emotional contagion, prime withdrawal behavior and tune visual social perception to sensitively detect harm.

52.6 Outlook

The studies on human chemosensory communication using natural body fluids as stimulus reveal that many different kinds of information are transmitted via chemosignals. It has been outlined that the domains of chemosensory communication are related to phylogenetic (reproduction-related behavior) and ontogenetic (harm avoidance) survival. Therefore, chemosensory communication in humans touches social behavior with a high biological significance. Here, it is proposed that we are just beginning to understand human chemosensory communication, and that many areas of chemical communication are still to be discovered. For example, besides stress and anxiety, other emotions might be transmitted between individuals. The communication of such emotional states should support the fitness of the species. First results show that social dominance is communicated between humans [52.11]. Like in other mammals, the transmission of the signals might help to maintain group hierarchy and reduce the likelihood of status conflicts between group members. Another area of information transmitted via chemical signals is related to health and age. So far it has been shown that body odor contains information about an individual's diet [52.223] and age [52.224]. In rats, body odors transmit information about illness-associated states [52.225]. As dogs are able to detect particular diseases in humans by smell [52.226] it is to be expected that humans also chemosensorily communicate their health states.

Furthermore, the science of chemical communication in humans may help to understand and even cure mental diseases that are related to disturbances in social communication. It has been shown that patients with panic disorder show an intensified processing of chemosensory stress signals in the inferior frontal gyrus [52.227] and that individuals with social anxiety show an enhanced processing of and response to chemosensory anxiety signals [52.213, 216, 218]. As social phobia is a powerful risk factor for subsequent depressive illness and substance abuse [52.228], the explanation of its pathogenesis is of special importance. For the behavioral therapy of social anxiety it may be crucial to know that social anxiety is associated with an increased sensitivity to chemosensory threat signals. Autism is another disorder with severe impairment of social communication. Children with autism spectrum disorder show reduced motor imitation skills, which might be an indicator of a dysfunctional mirror neuron system. Just recently it could be demonstrated that the imitation of the action of others is strongly improved in autistic children exposed to their mother's odor [52.229, 230]. Thus, the implementation of body odors into psychotherapy will enhance social behavior among autistic individuals.

On the other hand, individuals with a high social intelligence might use social chemosignals highly effectively in order to adapt successfully to their social environment. In line with this consideration, individuals scoring high in social openness (being highly sociable and assertive, being able to initiate and maintain social contacts) process body odors within their brain reward systems (caudate nucleus, [52.231]). Furthermore, emotionally highly competent individuals, presumably also tending to be socially skilled, outperform less emotionally adept individuals in identifying familiar persons by their body odor [52.214]. In the beginning of this chapter it was highlighted that the development of long-term friendships between same- and different-sex anthropoid primates (including humans) was crucial for the increase of the neocortex. First data are published, indicating that chemosensation might in fact play a role in human friendship bonds, as friends share more similar olfactory receptor genes than expected by chance [52.232]. On average, two individuals have functional differences at over 30% of their odorant receptor alleles, resulting in a unique olfactory percept in each individual [52.233]. Thus, friends might experience the smelling (social) environment more alike than strangers.

Acknowledgments. The author would like to thank Sabine Schlösser and Katrin Lübke for their help in editing the manuscript.

Part G Odors in

Part G Odors in Language, Culture and Design

Mankind learned to communicate immediate hedonic ratings of smells early on in the evolutionary process, using one of the oldest communication tools in the animal kingdom, i. e., facial expressions and species-specific mimics. Detection and discrimination of smells was an important strategy in survival, often with a binary differentiation of smells into *good* or *bad*, and these primary attributions could be clearly expressed, for example, by cringing. Over the course of evolution a more detailed communication of smells developed, for example, with humans pointing out to each other that they recognized the smell of specific food such as mushrooms. They maybe wanted to talk about spices, or they traced the path of specific animals not only via their footprints but also via their smell signatures. Nowadays, people might appear to be losing the competence of talking about smells, as they are no longer required to trace objects, living organisms, or food via their sense of smell. Verbal differentiation of smells, e.g., of spices, tends to be lost with less active involvement in food preparation and increasing consumption of ready-made meals, although global travel has expanded the diversified exposure to 'exotic' foods like never before. On the other hand, our modern world encounters an ever growing number of new materials and products that are, at times, associated with odorous substances that have never been encountered by human mankind before. Why these new substances are able to activate receptors, if only due to cross-reactions with established receptors, and false triggering of smell responses that were originally not created for the purpose of detecting these modern molecules, is a mere academic discussion. In any case, it may happen that smell impressions are generated in the course of such interactions and that they can barely be named, as natural analogs with which they may be associated seldom exist. In view of this, one might even consider inventing novel expressions for describing such smells, keeping in mind that the evolution of language is, in any case, a process that was only adapted to preexisting smell impressions.

Apart from the creation of language in relation to smell, creative processes can also relate to the generation of novel smell compositions, as is constantly undertaken in perfumery. This creative process is related to cultural premises, streamlines of fashion, and the zeitgeist in general. Humans use smells as an additional dimension to express themselves and their intentions in specific situations. Accordingly, it is a logical consequence that people try to induce specific attitudes using smells, to create expectations and feelings, and to leverage specific behavior, e.g., of consumers by the use of smell. Current research is, therefore, striving to monitor and predict such influencing effects on humans in specific scenarios, environments, and situations of life. In any case, the awareness of smell as another important sensory dimension in our everyday life is constantly increasing. Humans no longer only strive to optimize and control the temperature, humidity, sound and light, or visual appearance of their living, working, and leisure environments, but to also adapt the smell properties in a way that has a beneficial impact on their well-being and their attitude to life.

53. Odor Descriptions from a Language Perspective

Jeannette Nuessli Guth, Maren Runte

Talking about food is essential in our life. We love certain products, others are disgusting. While eating and drinking, we might express spontaneously our perceptions that foods have triggered. The range of reactions include nonverbal behavior, changing our facial expressions and bodily movements, verbal statements of liking and disliking including emotional and evaluative judgements, as well as analytical and neutral or objective descriptions. Our evaluation starts off with the perception of visual stimuli and volatile compounds eliciting an olfactory impression to the perception of various sensory modalities during breakdown of the food including taste, retronasal aroma and texture, as well as trigeminal impressions. As human beings, we use our senses to judge the quality of food. However, it is not always straightforward to verbalize what is perceived for all sensory impressions. Olfactory impressions are known to be difficult to describe. This chapter elaborates on language for odor descriptions from a language perspective with focus on the German and English or translated vocabularies. Culture and language are closely connected and shape the way we talk about olfactory impressions. Insights are given into vocabularies of people who are trained in describing food products and in everyday language, principally, what we experience in daily life when we are confronted with sensory stimuli.

Ein Tisch ist ein Tisch/A Table is a Table
Short story by Peter Bichsel, Swiss Writer, 1995

Naming objects helps us in daily life to communicate with the people around us. We understand each other when talking about a table, for example. The short story of Peter Bichsel illustrates how an old man has lost his connection to the outside world, when he started to name objects differently; *Bed* he called *picture*, *table carpet*, or *newspaper bed*. It is evident that he was not understood anymore nor could he follow any conversation in the world around him. What seems so obvious for these objects might not be so clear for odor perception. How do we name the odor of many objects in our world around us? How do we verbalize our perceptions? What kind of strategies does language have to support communication? Is there a universally valid concept of how we describe olfactory impressions?

Description of odors is not a trivial issue. In everyday situations or even in an experimental setting with untrained subjects many individuals feel speechless. They know what they smell, it is familiar, but they cannot name it verbally. Giving the solution is like a relief. Verbalization of sensory perceptions, especially taste and odor, is therefore a challenging process.

From a physiological perspective, perception of various signals like the different single components of foods ingested, the smell of perfumes, or visual cues of objects can be attributed to the reaction on specific receptor cells; clearly distinguishing the perception of

taste from other sensory modalities. However, the way of processing of all these signals in the brain is not fully clear. The integration of sensory signals and the subsequent verbalization in sensory analysis as well as in everyday life might need an interdisciplinary approach to better understand the perception of different sensory modalities and how we create meaning of terms in talking about our perceptions as human beings.

The difficulty of verbalization of sensory perceptions, especially odor descriptions is a common assumption as it matches everyday experience within the field of sensory and consumer science. As we often do not distinguish when talking about our perception in the mouth, flavor is used as an overall description for what we perceive while eating and drinking. According to *Small* [53.1], it is a multimodal sensory experience including the gustatory, retronasal olfactory, and oral-somatosensory signals. *Shepard* [53.2] introduced *retronasal smell* in his paper as term to avoid the double meaning of taste and a part of flavor. In sensory analysis, the definition of flavor is important as sensory panelists are trained in recognizing as well as verbalizing their perception of different sensory signals. However, this might only be true for communities speaking English or other Western languages for which lexica of sensory terms exist. Crossing cultural and language borders and investigating less known communities might reveal a totally different picture. In Jahai, a language spoken on the Malay Peninsula, people could name smell impressions as easily as colors whereas English speakers had difficulties naming odors [53.3]. A similar investigation was conducted with Maniq speakers (hunter-gatherers in Southern Thailand). The study showed that in Maniq odors can be encoded [53.4]. This underlines the fact that the chosen language plays a crucial role in how we verbalize our perceptions.

In our approach to investigate the verbalization of odors, we focus on how language deals with the descriptions of perceptions and what strategies might be used in communication to verbalize perceptions. Our experience focuses on the German language. Comparisons are mostly with terms in English as most publications list mainly English terms or terms translated into English. However, comparing Western languages, some of the concepts might be similar.

From a language perspective, the vocabulary of odor belongs to the subvocabularies of (the German) language, the size and specifics of which are hitherto little known. Although, odor is, in everyday life, in perfumeries, wine or coffee, valued and also described. However, untrained subjects find it difficult to describe odors with appropriate words: How is it possible to adequately capture in words the odor of commonplace smells like strawberries, coffee, or vanilla? And what is actually odor in understanding of untrained people? As the term *taste* in language comprises more than only the mere physiological understanding of taste limited to basic tastes, what about odor? Is the same true for this sensory modality? To address these questions focus is on German and English.

To actually learn about flavor terms in language, a linguistic perspective might add another piece to the understanding of flavor perception and in particular to odor descriptions. The objective of our language data survey for the compilation and description of the German odor vocabulary was to reveal an everyday concept of *odor*. In everyday life, we clearly understand more by odor; in everyday odor descriptions we do not confine ourselves to purely physiologically perceptible impressions, when we speak about odor, we frequently say something about the intensity – neutral, intensive or obtrusive, or of the pleasantness of the odor, good or bad.

But it is not only the extended concept of odor that leads to the everyday vocabulary of odor being relatively extensive and complex – smelling is frequently connected to emotional experiences and memories – but also appraisals, good or bad, and emotional descriptions must be counted among the odor terms.

With the example of the German language, we will elaborate on odor terms. We would like to illustrate the differences between the concept of odor in sensory science and the everyday concept. Furthermore, it is of interest to look at spoken versus written language. In spoken language, we might have more strength in describing our perceptions as nonverbal gestures or the exchange with communication partners might help picturing our efforts of verbalization. Also, the connection to the expert or specialized language in sensory analysis is made. In the following, the terms *specialized language* or *expert language* are both used when referring to the language of people trained in sensory analysis, i. e., in describing sensory perceptions professionally. Profiling of food for product development purposes is a standard procedure whereby the development of the appropriate vocabulary is a crucial step. An extended vocabulary taking into account all aspects of flavor perception helps to build a bridge to the consumer, for example, in advertisement.

The interdisciplinary approach to combine language and sensory science started off with a project on sensory semantics with focus on the consumer aspects of freshness [53.5]. A thorough investigation of taste and specific products was conducted in collaboration with different universities in Switzerland from disciplines in food and sensory science and linguistics.

53.1 Comparison of Odor Terms Used by Experts and in Everyday Language

Descriptions of sensory perception are used in both professional environment and in everyday life. As there are substantial differences of the objectives and in the way how language is used for these two groups, this chapter covers different aspects of expert and everyday language.

53.1.1 Sensory Vocabulary of the Specialized Language

In sensory science, well-established methods exist for the description of food products as well as for the measurement of intensities for the various descriptors, words used to analytically describe perceptions in sensory analysis. Trained people use their senses to evaluate and describe food products in an analytical way, without naming of hedonic, emotional, or evaluative judgements.

The typical approach in sensory analysis is to recruit people based on their sensory acuity as well as their communication skills and ability to describe sensory sensation besides availability and personality. An example of such a procedure is given in the document 8586 of the International Organization for Standardization (ISO). A part of the screening procedure is the description of odors. The ISO norms differentiate between ortho- and retronasal sample presentation. In the first example, samples are presented as smelling strips or small bottles that can be sniffed. In the latter case, aqueous solutions are ingested and evaluated. Olfactory materials include substances like benzaldehyde, menthol, and eugenol and are presented with the most common name associated with the odor being in the present case bitter almond or cherry, peppermint, and clove. Selected assessors are then trained in detection and recognition as well as in using scales for measuring the sensory sensations of interest. In principle, this is the procedure for all sensory sensations, not only for odor. However, based on the speciality of the panel, the focus can vary. It can be of interest to train assessors for a certain product category. From this perspective, they become experts in describing and measuring the sensory sensations of this specific category.

A continuous monitoring process on the performance of single assessors during an evaluation session by including replicate samples or in the long term over a period of several weeks or months guarantees the quality of the results. Within this process of generating profiling data, sensory descriptions and intensities of the sensory sensations measured by the assessors, the development of a vocabulary or lexicon is an important step. In most cases, the panel starts from a pre-existing list of terms for the description. For many products or product categories, separate lexica as a source of descriptors or terms for describing sensory sensations are published, as apparently, no universally valid lexicon exists. Selected examples of recently published sensory lexica on a broad variety of food are given in the references [53.6–17] For all lexica is common that panelists are trained extensively and are confronted with a large set of products for term generation. In many cases, the initial list of descriptors usually embraces a larger variety of terms, which are reduced in panel discussions to a list that includes terms that are nonredundant and are considered to be discriminative for the purpose of product description.

It is not surprising that lexica principally exist for specific products only as the terms for descriptions need a context to be fully understood by the assessors. Definitions of terms and reference substances might only be appropriate for the product chosen and not universally valid with the exception of taste references for sweet, sour, or salty. Thus, the expert assessors are trained in describing and measuring their perceptions with the help of definitions and references in a reproducible and consistent way.

It is indeed an artificial situation in which human beings are trained in using a custom-made language for the specific purpose within sensory science. In most instances, this custom-made language is valid and understood within the community that has developed the language, mostly the panel, that is, the group of assessors.

To illustrate what type of terms and the versatility of odor descriptions are present in the domain of sensory science, the above cited references of 12 publications and 13 product categories for sensory lexica [53.6–17] were taken as the basis for odor term evaluation. All the publications chosen are in English whether or not the original language of descriptor development was English or another language except for the study on Kimchi [53.8]. Translation of descriptors is a critical issue, which is however not addressed in the evaluation of the terms.

In total, over 200 terms were extracted, including words listed multiple times. Overall, from the terms the following observations can be made:

- $\approx$ 170 Different terms or word combinations were listed.
- $\approx$ 140 Terms were single words like fruity, caramel. rancid, in contrast to word combinations, colloca-

tions (cooked lemon juice, cut grass, canned tomato, fresh citrus etc.).
- About 60% of the terms name an object like peach, tobacco, chocolate, bacon, dried plum, spiced tea, or thyme.
- Twelve terms mentioned chemical substances like diacetyl, sulfur dioxide, carvone, eugenol, or ethyl acetate.

Table 53.1 shows the terms found multiple times with their definition and references if available. Some authors present only the descriptors [53.1, 15]. The list includes only terms that were identical and they were *citrus, fruity, fermented, green, molasses*, and *woody*. For citrus, molasses and woody and to a lesser degree for green the definitions are comparable. Citrus is always related to citrus fruits and green to grass or vegetables whereas in the case of fruity and fermented the definitions vary more. References strongly depend on the product category investigated and/or the cultural background. This becomes evident if a panel group is investigating an unfamiliar product and needs to gain experience first. This shows the example of a US panel that started with the sensory evaluation of Kimchi. In the process of lexicon development, the panel traveled to South Korea to refine the lexicon for this product category and to test actual samples [53.8]. As Kimchi might gain more global attention according to the authors, the awareness for the product outside Asia might increase and as a consequence increase the experience of consumers with the product.

It has to be noted that the examples are more or less common products and include results of the classical sensory science approach. In other domains like wine, expert language might be linked to less accurate evaluation and thus, the word lists would be more extensive including not only sensory descriptors. *Lehrer* [53.18], for example, differentiates between two types of experts for wine evaluation, the ones with scientific ambition and those who are in wine trade, sommeliers, or wine writers.

What can be extracted from these observations for expert language in general and with respect to odor terms:

- Sensory scientists elaborate comprehensive lists of terms for a specific product category that differentiate between products when the terms are used for intensity evaluation.
- Panel discussions make sure that all members evaluating the products know what the terms mean. In order to facilitate this process, definitions are elaborated and references are presented to the panel members so that they can taste or smell this reference and match their perception with the term given.
- The definitions alone often advise of associations. The reader of the definition has to know the object of the association by either experience during daily life or by evaluation of the reference.
- Considering odor terms, in particular, most of the terms name an object and not the sensory impression involved. Occasionally, names of chemical structures are given. Especially for experts in the aroma analytics domain, people are trained in linking a sensory perception to a distinct chemical substance and naming it which as such is not the description of the sensory perception either.
- Single terms naming objects are often not sufficient to precisely describe a perception. Fruits change their aromatics during ripening and during processing (cooking), resulting in terms like cooked plum, dried tomato, overripe fruit or processed berry juice. Other terms relating to a certain state of the products are rancid butter, spiced tea or dark chocolate.
- Word creations with the expression – *like* were hardly listed (hay-like, wine-like). This is more common for everyday language when talking about sensory perceptions (Sect. 53.2.2).

A curiosity is the term *other* that was mentioned in reference [53.16] as the *aromatic associated with noncitrus fruit*. The word has no relationship to sensory perceptions and can only be understood by the panel using the term.

Overall, in expert language, pure odor terms are limited in the (English) language. Most of the terms with its definition and references are applicable for the product category investigated. *Miller* et al. [53.19] made an attempt to characterize the descriptor *nutty* as an example for different food categories like nuts, grains, or beans. They could reveal five concepts for the term nutty as there are nutty-beany, nutty-buttery, nutty-grain-like, nutty-woody, and overall nutty including definitions and references for different intensities for measuring on a scale for sensory evaluation. The references, however, are quite specific for the United States and might not be so easily transferable to other countries. Although there might not be a fully developed vocabulary for expressing olfactory perception in English or German and other languages, people are still able to exchange their perceptions by the help of naming objects or physical references. Interestingly, there are cultures having limits in their language to express another sensory perception, and that is color. In languages, such as Umpila, spoken in Cape York Peninsula, Australia, or Kilivila, spoken in the Trobriand Islands of Papua New Guinea, color terms are limited in the range black–white–red. Similarly as to odor descriptions, the speakers of these languages have to find other strategies by naming objects, e.g. it is like a banana or a flower [53.20].

Table 53.1 Examples of sensory descriptors and their descriptions and references

Odor term	Definition	Reference	Literature
Citrus	Aromatic associated with general impression of citrus fruits	–	*Lawless* et al. [53.6]
	Aromatics associated with freshly squeezed orange or lemon juice	Freshly squeezed orange and lemon juice	*Bett-Garber* and *Lea* [53.9]
	Aroma associated to citrus as lemon, orange, mandarin	Natural products placed in sensory tasting glasses	*Monteiro* et al. [53.11]
Fruity	The aromatic associated with a mixture of nonspecific fruits: Berries, apples/Pears, tropical, melons, but usually not citrus fruits	No reference	*Lawless* et al. [53.6]
	–	1″ slice each of chopped Granny Smith and Fuji apples	*Haug* et al. [53.7]
	Aroma associated to tree fruits like peach, apple, apricot, plum	Natural products placed in sensory tasting glasses	*Monteiro* et al. [53.11]
	Aromatic blend which is sweet and/or sour reminiscent of a variety of different fruits	Welch white grape juice	*Cherdchu* et al. [53.12]
	An aroma blend which is sweet and reminiscent of a variety of different fruits. When possible, specific fruits were described.	–	*Suwonsichon* et al. [53.15]
	Odor/aroma characteristic of fresh olives, either ripe or unripe	Extra virgin olive oil from Aloreña variety	*Galán-Soldevilla* et al. [53.13]
	Aromatic associated with Fruity Pebbles cereals	Post-brand Fruity Pebbles	*Leksrisomong* et al. [53.16]
Fermented	The aroma of over-ripe fruit, slightly fermenting sugarcane juice	Mango juice fermented with yeast	*Smyth* et al. [53.8]
	Aromatics associated with fermented fruits, vegetables	Juice of sauerkraut, 1 part juice to 2 parts water	*Bett-Garber* and *Lea* [53.9]
	Sweet, overripe, rotten, musty. Sweet, slightly brown, overripe aromatics assoicated with fermented fruits, vegetables, or grains; can have a yeasty note	Great lakes sun dried tomato	*Cherdchu* et al. [53.12]
	A combination of aromatics that are sweet, slightly brown, overripe and somewhat sour	Blackberry WONF 3RA654	*Suwonsichon* et al. [53.15]
	Combination of sour aromatics associated with somewhat fermented diary/cheesy notes that may include green vegetaton, such as sauerkraut, soured hay or composed grass	Frank's Quality Kraut	*Leksrisomong* et al. [53.16]
Green	Aromatic characteristic of freshly cut leaves, grass, or green vegetables		*Lawless* et al. [53.6]
	A green aroma associated with fresh stems, also pear kins or watermelon rind	*cis*-3-Hexen-1-ol, floral stems, tomato stems, watermelond rind	*Bett-Garber* and *Lea* [53.9]
	Sharp slightly pungent aromatics associated with green plant/vegetable matter, such as asparagus, Brussels sprout, celery, spinach, etc.	Dried seaweed (kelp)	*Cherdchu* et al. [53.12]
	Odor/aroma characteristic of newly cut grass	1 drop of *cis*-3-hexen-1-ol in 50 ml of water or newly cut grass	*Galán-Soldevilla* et al. [53.13]
	Slightly sour aromatics, commonly assoicated with underripe fruit (astingent)	Green Granny Smith (without peel)	*Suwonsichon* et al. [53.15]

Table 53.1 (continued)

Odor term	Definition	Reference	Literature
Molasses	–	1/2 tsp. unsulfured molasses (exact product given)	*Haug* et al. [53.7]
	Dark caramel top notes, which may include slightly sharp, acrid, sulfur like of molasses notes characters	Grandma's molasses	*Cherdchu* et al. [53.12]
Woody	The flat, dark, dry, musty aromatics associated with the bark of a tree.	Oil of cedar wood	*Suwonsichon* et al. [53.15]
	Aroma associated to barrels, wood	Maceration of 1.0 g/l of french oak chips, medium toast, in ethanol (19% v/v)	*Monteiro* et al. [53.11]
	Flat, dark dry aromatics associated with the bark of a tree or wood by-products	Popsicle stick 4-Ethylguaiacol	
	Odor/aroma characteristic of wood	Wood shaving in 60 ml flask	*Galán-Soldevilla* et al. [53.13]

Looking at the sensory science literature, various methods for measuring the intensity of predefined descriptors exists. *Lawless* and *Civille* [53.21] give a summary of the most important methods and outlined in a review on how to develop lexica, that is, standardized vocabularies for the purpose of sensory analyses, and as they write to *facilitate communication across diverse audiences*. According to their view published, lexica might help to standardize the sensory language across panels, companies, or even countries. Consistency in sensory descriptions of products therefore seems to be a need as business is more and more globalized. The authors outline the procedure for collecting terms, generating definitions as well as to find the appropriate references and validation of the lexicon. From a language perspective, this approach is somehow an imposition that works well in small groups like panels. For expert language sensory lexicon development might foster communication; however, it is actually an open question whether this would be the case for nonexperts.

Giboreau and coworkers [53.22] concentrated on how to define descriptors for sensory evaluation using an integrative approach. The principal goal of the descriptor definitions, as it is the common approach in sensory science, is to minimize any ambivalence in the meaning for descriptors within a panel, but it additionally would also help to support users of the results or translations of descriptors according to the authors. Also, more subject instead of object centered definitions as it is the case for many sensory lexica might be advantageous.

It will be interesting whether within the discipline of sensory science, it will be possible to find a language that measures sensory sensations across geographical and cultural borders. As published for commonly unknown languages, simple translation of terms is not possible [53.23]. Concepts of perceptions might not be congruent as culture, type of language, and experiences in a society influence the importance of naming specific olfactory impressions. An example of frequent odor terms in Jahai, which must be classified as verbs, is given in reference [53.23]. The verbs listed cannot be translated with simple English terms. They are related mostly to unpleasant odor impressions, such as urine, blood, feces, and rotten meat. Pleasant terms are linked to sweets, cooked food, or flowers. This might reflect that cultural imprint to a certain extent is the case for all cultures and languages.

53.1.2 Comparison to Terms in Everyday Language

Language of experts or standardized language is somehow an artificial world. As outlined in Sect. 53.1.1, all precautions are taken to standardize which terms are taken for a specific sensory perception. The objective is to be able to measure the properties of food or nonfood products sensorially with a small number of people which makes it necessary to train them extensively for such a task.

This is in contrast to what we experience in everyday life. Depending on our personal experiences, our cultural background and language we might express our perceptions in a not necessarily comparable way. However, language in the written and spoken form allows elucidating our perceptions.

Urdapilleta et al. [53.24] conducted a study for the collection of odor descriptions for floral scents. They asked university students with no experience in sensory descriptions to describe the odors, which were

presented to the participants on paper strips. The participants were given the task to describe the odors as well as what they made them think of and what terms would characterize them. As a result, the terms were classified whether they were sensory terms, personal memories, intensity, hedonic expressions, or other characteristics. Not surprisingly, only 18.6% of the terms referred to sensory perception. Most of the terms, 52.8%, referred to objects. That is actually comparable to expert language. Hedonic expressions with 17.1% are common for novices in sensory descriptions as perception of food or perfume, for example, are strongly linked to liking and disliking in a first step and not especially a neutral and analytical description of the sensory stimulus.

In the domain of food, a speciality in everyday language are conversations about wine; although nowadays products like coffee and chocolate, for example, are also promoted with an elaborated language. The domain of wine offers even a more versatile language that might not only be a sensory description of the product. *Lehrer*, for example, has investigated the American language for wine [53.18]. She noted that wine language only has few pure odor terms including, for example, fragrant and perfumed. Most of the odor related terms include the name of objects like blackberry or asparagus as is the case also for the sensory lexica. Nonsensory descriptions of wine comprise evaluative terms as *balanced* or *complex* or body language as *muscular*, *brawny*, *lean* or *sleek*, words not necessarily related to odor perception in wine.

Odor descriptions of nonexperts for sensory descriptions focus also mainly on naming objects. However, the vocabulary is enriched with hedonic expressions, metaphors, intensity description and to a lesser extent with personal experiences.

The method of data collection influences the outcome, the terms listed. From a semantic perspective, two approaches are possible. The first one is an *onomasiological* approach by starting off with tasting products and then collecting terms for descriptions as well as discussing them. The second approach is called *semasiological* whereby the starting point are words, and discussions should elucidate their meaning [53.25]. To provide insights into this methodology, experimental data is presented for the German language in the following section. Furthermore, the investigation of written and spoken language is of interest as conversations allow us to better understand the strategies on how we create meaning in the exchange between partners whereas in written language creating meaning is limited to a single person.

53.2 Odor Terms in Everyday Language

The basic principles of odor terms are built up on the vocabulary of what is called taste in the German language. Since taste and odor are closely related in language as the physiological differentiation for human beings in everyday life are not of importance some insights are given on taste terms (Sect. 53.2.1). In the literature, this is described as taste–smell confusion [53.26]. Also, the duality of the olfactory sense as *Rozin* [53.26] describes it might impact what we consider as olfactory impression. Volatile compounds are either perceived orthonasally with the object being at a distance or retronasally, the situation where the object is actually ingested in the mouth.

The principles were elaborated for the German language; however, they might be applicable similarly to the English or other Western languages, but definitely not universally.

A critical note is added here to the issue of translation. Attempts have been made to publish multilanguage vocabularies. Examples are the ISO norm 5492, listing sensory vocabulary with definitions, or the special multilingual lexicon with focus on textural terms which was published as polyglot list [53.27]. The one-to-one listing of terms is critical as not for all words translation is simple without giving a context. Concepts in different languages are not necessarily congruent, especially for polysemous words, terms with several different meanings. This has been shown for *fresh* as an example [53.5].

53.2.1 Basic Taste Terms

The German taste vocabulary was collected in collaboration between linguists and sensory scientists. Different procedures (Sect. 53.2.2) were combined to collect and to confirm the terms by which taste perceptions in everyday language can be described. The result was a collection of 1000 taste terms, but also other strategies for describing taste were identified and analyzed [53.25]. Figure 53.1 shows the most important taste terms of the German language (results in English translation).

53.2.2 The Odor Terms in German Language: Data Collection

To show a concrete example of how data on language data can be compiled, our approach to investigate the

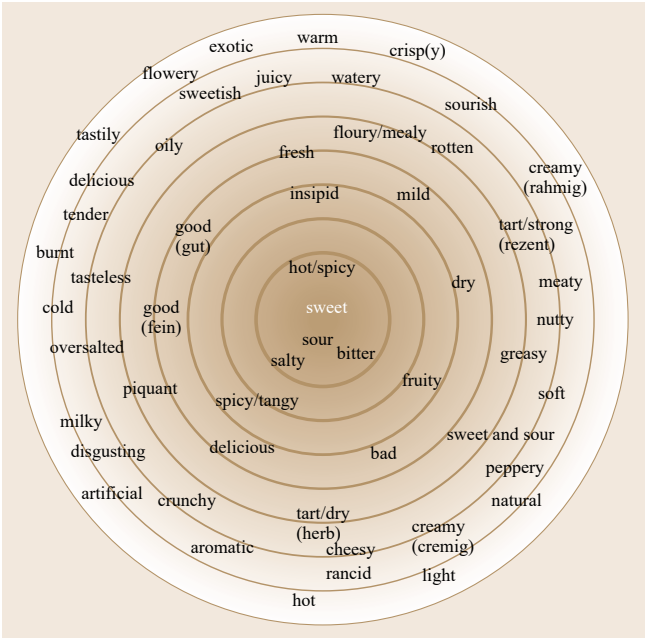

Fig. 53.1 The central taste terms of the German language translated into English

German odor vocabulary which combines three procedures is presented here:

1. The first part included the extraction of odor terms in different general monolingual dictionaries of German: Different dictionaries were screened to find all adjectives which were used to describe odor. The critical part of the extraction was that the words were used in at least one version in connection with *Geruch* or *riechen* (*odor* or *smell*, noun, and verb). These words had to be explicitly mentioned within the description of meaning or the examples.
2. The second part comprised the evaluation of the largest written language corpus of the German language called the *German Reference Corpus* (DeReKo), developed and maintained by the Institut für Deutsche Sprache (IDS, Institute for the German Language) in Mannheim. It was searched with identical criteria for odor terms.
   By using current research tools such as COSMAS II, it was also possible to detect and verify odor terms which at first glance were rather untypical, such as *grün* (green) usually mentioned in connection with oil, a descriptor quite common in sensory lexica (Sect. 53.1.1, Table 53.1), *neu* (*new*), usually in connection with new machines and cars or *warm* (*warm*), usually in connection with animals, especially horses. Additionally, it is possible to state in which way and with what frequency odor terms are used in connection with the words *odor* or *smell*.
3. The third part included the collection of odor terms actively listed by test persons using the so-called *Basic Odor Term Test* (BOTT) similar to the *Basic Taste Term Test* presented in Sect. 53.2.3.

Based on the results of the three procedures, the odor vocabulary of the German language was compiled.

The evaluation of different dictionaries resulted in (only) 44 odor terms and by searching the corpus the odor vocabulary could be completed with additional 290 terms. Finally, the BOTT revealed 451 odor terms which were actively listed by test persons. After revision of the results of the combined approach about 600 different terms were identified, which are actually used in the German language to describe odor.

It is worthwhile noting that only 125 terms were mentioned in both corpus research and in the BOTT, and therefore, the terms are used with a certain frequency. This rather limited intersection could be an indication that the actual use is either not documented in dictionaries or that the use of specific terms is reduced to certain situations, in written communication.

Furthermore, the third part with the BOTT provided illustrative information about the structure and inward lexical relationships of the odor vocabulary.

53.2.3 The Basic Odor Term Test (BOTT)

The number of terms is only partial information for a comprehensive understanding of the odor vocabulary. Structural characteristics can provide important insights about a certain sub-vocabulary, the information on how central or peripheral in terms of usage a certain word is. In order to identify those words which form the central odor vocabulary of the German language, the method of the BOTT is presented to differentiate between central and less central odor terms.

The Method of the Basic Odor Term Test

In accordance with the color term test by *Morgan* and *Corbett* [53.28] and the *Basic Taste Term Test* (BTTT), 213 students of ETH Zurich, Switzerland, were invited to write down as many words as possible with which the odor of foodstuffs or beverages can be described within a limited time frame. In order to determine the number of terms listed per minute they were instructed to draw a line under the already written words after each minute.

Additionally, data on age, gender, and the region in which they have grown up was collected. Both, number of mentions and time of mention played a decisive role in the evaluation.

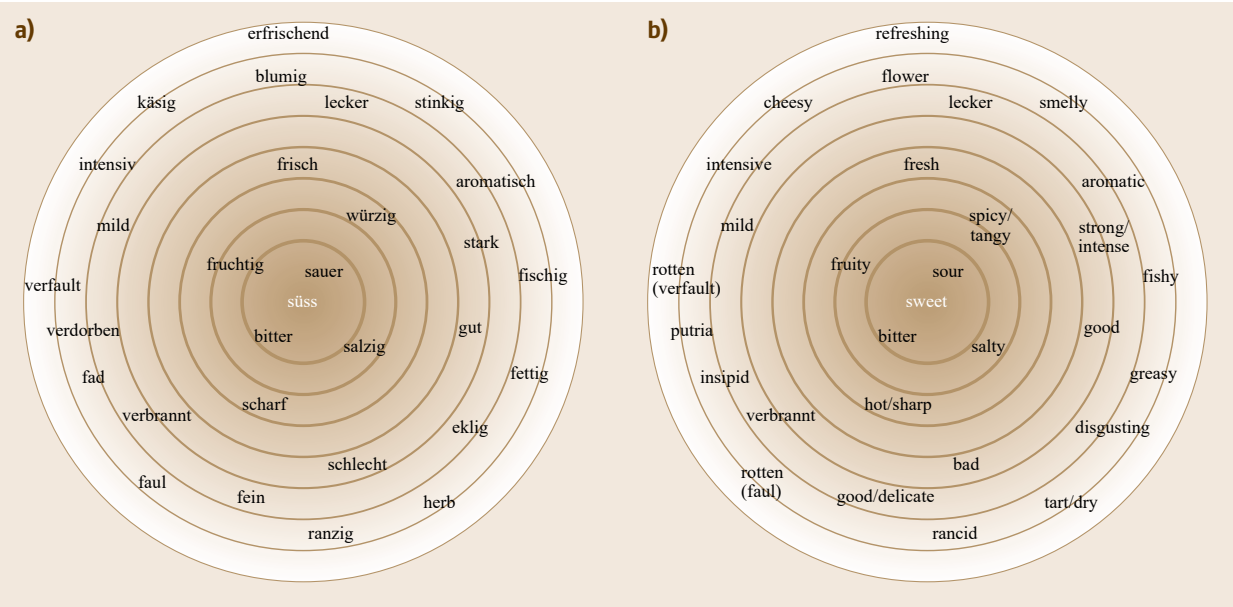

Fig. 53.2a,b The 30 most central odor terms of the German language **(a)** and their approximate translation into English **(b)**

Results of the BOTT

The evaluation of the frequency of each term and the time when a term was listed during the BOTT helped to sort the odor terms collected by the dictionary and corpus research approach according to their relevance. In total, 451 terms were listed. These results for the German odor terms are visualized in Fig. 53.2. Figure 53.2a shows the original results in German and Fig. 53.2b the approximate translation into English. Again, it has to be noted that translation of terms is critical. Especially word-by-word translations without context have to be handled with care as the meaning might not be fully captured. Furthermore, the results are valid for the German language and might be only partially applicable to the English language.

In Fig. 53.2, the position of the odor terms is indicated within the circles according to their frequency of mention with the central terms in the graph being the ones listed as the 30 most frequent odor terms.

Based on this evaluation, the following observations are especially interesting:

- *Süss* (*sweet*) is mentioned very often as well as at the very beginning of the BOTT – normally in the first minute – while all other central odor terms are mentioned later (Table 53.2). *Süss* must therefore be considered as the central odor term of the German language although it is a taste descriptor from a physiological point of view.
  The finding that *süss* seems to be the central odor (Fig. 53.2) and the central taste term (Fig. 53.1) of the German language, demonstrates the proximity between odor and taste. It also supports the fact that in everyday life no clear distinction is made between taste and odor perception [53.26].
- Therefore, it is not surprising that also other taste terms are found to be central to the odor vocabulary in the German language. They include basic taste terms in the following order: *Süss* (*sweet*), *sauer* (*sour*), *bitter* (*bitter*), and *salzig* (*salty*) (Table 53.3). The term *umami* for the fifth basic taste is not mentioned. This supports the confusion of taste and odor. Apparently, it is not important how human beings perceive a sensory stimulus, but the quality is, whether it is sweet or sour for example.
- Another interesting point is the evaluation of the perception. Positive and negative evaluation seem to be very important for the description: *Gut* (*good*), *schlecht* (*bad*), *fein* (*good*, *delicious*), and *lecker* (*delicious*) are found among the terms most frequently mentioned.
- Negative terms for the description of unpleasant odors are listed very early. Examples include *verbrannt* (*burned*), *ranzig* (*rancid*), *stinkig* (*smelly*), or *verfault* (*rotten*).
- Furthermore, intensity of odor perception is important. Terms like *fad* (*flavorless*, *insipid*), *mild* (*mild*), *intensiv* (*intensive*) or *stark* (*strong*) show the significance of intensity descriptions.
- 10.2% of the odor terms indicate the end of a – positive or negative – food processing step. They

Table 53.2 Listing of the 10 most important odor terms during the first minute of the BOTT

Odor term	Translation	Frequency of mention (%)
Süss	Sweet	78.9
Sauer	Sour	58.2
Bitter	Bitter	41.8
Salzig	Salty	37.6
Fruchtig	Fruity	26.8
Scharf	Hot/sharp	26.3
Würzig	Spicy/tangy	22.5
Frisch	Fresh	17.4
Gut	Good	13.6
Fein	Good/delicate	12.7

Table 53.3 The 20 most central odor terms of the German language

Odor term (original word)	Translation	Frequency of mention (%)
Süss	Sweet	85.0
Sauer	Sour	69.5
Bitter	Bitter	61.5
Salzig	Salty	57.3
Fruchtig	Fruity	54.9
Würzig	Spicy/tangy	51.2
Frisch	Fresh	46.0
Scharf	Hot/sharp	44.6
Gut	Good	30.5
Schlecht	Bad	27.2
Mild	Mild	23.9
Verbrannt	Burnt	22.5
Stark	Strong/intense	21.1
Fein	Good/delicate	20.2
Lecker	Delicious	20.2
Verdorben	Rotten	18.8
Fettig	Greasy/oily	18.3
Blumig	Flowery	17.4
Faul	Rotten	16.9
Herb	Tart/dry	16.9

include terms like *verbrannt* (*burned*) or *gepökelt* (*cured*, *salted*).

- A few terms make reference to different times of the year like *weihnachtlich* (*christmas(s)y*), *herbstlich* (*autumnal*), *sommerlich* (*summerly*). In this context, specific events (Christmas) seem to be inextricably linked to different odors (*zimtig*, *like cinnamon*).
- As the food we eat is more and more globalized, it is not surprising that reference is made to specific food experiences. This becomes evident with terms like *thailändisch* (*Thai*), *orientalisch* (*oriental*), or *amerikanisch* (*American*).
- The German language has various means to mark the lexical origin (e.g., the suffixes *-ig* and – *artig*, for example *zitronig*, *zitronenartig* (like lemon) or intensity of odors (the suffix *-lich*, which expresses a lower intensity). An example is *süsslich* (sweetish). It is therefore possible to adapt the term of an object into an adjective and by this actually generating a sensory odor descriptor. This is the case for 20.8% of the odor terms.

The evaluation of these results gives insight into the size and structure of the German odor vocabulary, which apparently is rather small with 451 terms in comparison to the vocabulary of taste terms as shown in the BTTT (Sect. 53.2.3) with 836 terms. Although the number of different odor perceptions from a physiological perspective is less limited than the perception of taste, the number of adjectives used for describing odors in language seems indeed to be limited.

Two explanations are conceivable for this finding. First, there are many other ways to describe odor (Sect. 53.3), the use of adjectives is not the only option. For example, phrases can be used that express a comparison including an object as *der Geruch erinnert mich an* (*The smell reminds me of*) or *das/es riecht wie* (*it smells like*). The latter example was found 300 times in the IDS corpus.

On the other hand, the BOTT reveals that many adjectives are listed that can be derived from a noun indicating a reference or an object, such as *beerig* (like berry) or *knoblauchig* (like garlic). These references can thus be described in German by ad hoc formations which are not frequently used.

As mentioned at the beginning of this chapter, the 600 odor terms collected by various procedures have only a small intersection of 125 terms. A possible explanation could be that the terms are used in different language varieties like active versus passive or written versus oral language use.

The terms found by corpus search are used in written communication. In contrast, the terms collected with the BOTT include many ad hoc formations and taste terms. The latter could be an indication that the test persons in such an analytical experimental situation do not distinguish between taste and odor. Furthermore, it might not be of relevance in daily life to do that.

As for the study of *Urdapilleta* et al. [53.24], especially naming objects occurred when collecting odor descriptors. However, the language approach has been carried out without real tasting of samples. Interestingly, the absence of a product for tasting during the task limits the variety of terms listed.

53.2.4 Odor Terms in Written Language

Evaluation of corpus data yields information on written language. This is in contrast to listing terms as in the BOTT. Consequently, differences in the list of terms

are found. Interestingly, they include terms that are often not used anymore or they belong to the language of a special group. At first, exalted terms are mentioned. An exalted word only found in the corpus data is *balsamisch* (*balmy*). Another interesting observation is that terms are used by special groups, such as educated people or experts. An example of a term used by educated people is *ominös* (*ominous*). Even terms from expert language, such as *campherartig* (*like camphor*) are included in dictionaries and used in written language, but they are rare in everyday life.

53.2.5 Odor Terms in Spoken Language

Spoken language has the advantage of being more flexible and to adapt to specific situations [53.29]. The BOTT has shown that not only lexicalized odor terms, but also terms that show a correspondent definition in dictionaries, are used. In order to be able to capture the complexity of odor perceptions and describe them to others, words, which are used in a quite different context as, for example, *hässlich* (ugly) or *grün* (green), as well as numerous ad-hoc formations, adjectives that are derivated from nouns by the suffix *-ig* like *holzig* (like wood), *erdig* (earthy), *zitronig* (like lemon), and *schokoladig* (chocolatey).

As another way of capturing spoken language data, focus group discussions are an interesting method. In our research, we could observe that in focus groups discussions the participants often use ad hoc formations to describe a specific taste. Likewise, the participants often agree after a longer discussion on a term, which includes what has been described previously. This is an analogy to the sensory panel discussions with trained assessors, in which the development of lexica is conducted in a similar way.

53.3 Strategies to Describe Odor Perceptions in Everyday Language

Based on vocabularies of people trained in describing sensory perceptions and of those being untrained, it becomes clear that pure odor description terms are not numerous. It is therefore of interest to look at the strategies language offers to express our perceptions. From corpus data and evaluation of dictionaries, some aspects were already mentioned. They include naming objects, hedonic, and intensity descriptions. In daily life conversations communication partners seldom describe an odor with sensory descriptors. It is therefore necessary to investigate the strategies that are used in discussions or conversations to describe individual perceptions to better understand the means in the German language for the description of odor perception.

In the following subsections, we want to show that the description of sensory perceptions may vary between giving a single word, discussing a term in contrast to others (word fields) or to narrative sequences.

Language data was collected by conducting focus groups discussions. Several product categories were chosen and participants were selected based on gender, age, and mother tongue (native speakers of German). Focus groups are group discussions with a limited number of participants; the moderation is limited to the activation of the conversation, so that a free discussion can develop in a relatively relaxed and informal atmosphere. In contrast to focus groups in market research, all conversations were fully transcribed based on the video- and audio-recordings including detailed information on how people were talking. This includes also nonverbal reactions and interjections like *pfui* (ugh) or *igitt* (yuck). Therefore, the results of focus group discussions can help to reveal underlying strategies in communication.

In the following, we illustrate findings with concrete language examples. They are presented in the original transcript as well as in a translated version. Emphases are highlighted by capitalization, breaks in different lengths by brackets, a short break by (.), (–) and (–) indicate medium breaks.

53.3.1 Word Fields

In most cases, a simple term is not sufficient for odor description; more than one (odor) term is needed to convey the individual perception of a person talking to the others. This is demonstrated by the delimitation of a word (and semantic clarification) within a word field (Table 53.4).

Table 53.4 is an extract of a focus group discussion with women about yoghurt. The participant Mia first attempts to describe the odor of a yoghurt sample by the term *faulig* (rotten), but is unsure herself, if this term is correct. Zoe agrees, but uses for clarification the semantically similar term *sour*, which is finally adopted by Mia as appropriate – *sour* is *okay* in conjunction with milk products.

53.3.2 Images/Scenarios

A further strategy can be observed in the focus group conversations. The participants frequently rea-

Table 53.4 Linguistic transcript for illustrating the concept of a word field based on focus group data with women and yoghurt as product example

German	English
Mia: ich glaub er RIECHT auch nicht beSONders; ich find wenn man (.) wenn man JOghurt aufmacht- und er RIECHT irgendwie stark nach- ((bewegt Hände mit gespreizten Fingern))- was: weiss nicht so (—)- ja nicht FAUlig IST ja es nicht;	Mia: I think it SMELLS not particularly well I think when (.) when you open a yoghurt cup and it has a strong SMELL like ((moving hands with fingers spread)) what: I don't know (—)- well it is not really ROTTen
Zoe: Ja EINmal dieses SÄUerliche	Zoe: Well for a start this is kind of SOUrish
Mia: Ja (–) ja- aber so SAUer ist ja mmh in verbindung mit MILCH oKEY weil es gibt ja auch so verschiedene KÄse die ziemlich heftig RIEchen; und aber das ist dann so diese EIgenart das ist oKEE	Mia: Yes (–) yes- but so well in connection with MILK sour is okay because there are also so many different CHEEses that smell pretty intensive and but that is then this peculiarity that is okAY

German	English
Tina: Und WIE SCHMECKT es dann (.) wenn es KÜNSTLICH schmeckt (–)? was macht dieser (.) KÜNSTLICHE GESCHMACK aus (2.45)	Tina: And HOW does it TASTE like (.) if it tastes ARTIFICIAL (–)? what makes this (.)TASTE ARTIFICIAL (2.45)
Rolf: Hat auch VIEL mit GERUCH zu tun und wenn der GESCHMACK so n bisschen is wie DAS (—), wenn man ne TÜTE aufmacht, und es riecht nach PLASTIK, dann (—) hat man oft SCHON- den GESCHMACK so: Auch auf der ZUNGE-	Rolf: It has a LOT to do with ODOR and if the TASTE is a little bit like THAT (—), when you open a BAG, and it smells like PLASTIC, then (—) one often has ALREADY- the TASTE on the TONGUE-

son using references to concrete situations or describe possible or actual experiences with different products. For these verbalization strategies the participants sketch action scenarios, pictures and scenes by means of which they contextualize odor terms and thereby concretize their vague meanings at the same time.

Table 53.5 is an extract of a focus group discussion with women about bread. The participant Ida uses the image of fungi in the forest to describe the

odor of a particular type of bread, because an appropriate word for the odor is missing. Joy finally tries to put the description in one word – *erdig* (earthy). It has to be especially noted that Ida illustrates not only by using a picture but supports her description by gestures.

53.3.3 Prototypical References

Prototypical references are of great relevance for the description of odor terms. They can specify the meaning of odor terms and give an indication of the specific contexts in which the terms occur in everyday language use.

It was observed that prototypical references are an important strategy for the clarification of odor terms, as also generally for the verbalization of taste [53.25] and odor perceptions.

Table 53.6 is an extract of a focus group discussion with men about the taste terms *artificial* and *natural*. To describe what constitutes an artificial flavor, the participant Rolf first makes a comment on artificial odor, at which he gives the scent of a plastic bag as reference for artificial odor.

53.4 Conclusion

Investigations on how we talk about odor perceptions reveal interesting features of language and by this, our ability to verbalize them even if language is limited to specific terms. It is clear that the type of method used for this kind of investigation influences the outcome. Our focus was on different language-based approaches.

Depending on the language investigated, the number of terms to precisely describe or other strategies to capture our perception can vary. Furthermore, there are differences between people. Training, for example, in verbalizing perceptions as it is done in sensory analysis might influence the way terms or strategies in language are used. Research on the German language demonstrated that for this specific language, the odor vocabulary is limited. There are differences in vocabularies between different groups of people whether they are trained or not. However, the lack of clearly defined terms is evident for all groups. The most prominent feature for describing odor is probably the fact that objects are named or ad-hoc formations occur.

In comparison to the taste vocabulary comprising approximately 1000 terms, the German odor vocabulary which consists of 600 terms is rather small. For this fact, two explanations can be given. First, the taste vocabulary also includes other perceptions as taste in physiological sense (Fig. 53.3). Texture terms (crunchy, creamy), description of mouth feel (dry), indication of temperature (warm, cold) or hedonic descriptions are all taste terms from a language perspective. A second reason could be that other constructions are used like the phrase *that smells like*, as the naming of a reference is more conventional than the use of an odor adjective.

Figure 53.3 shows an illustration of the type of terms used for odor as well as for taste perception in the German language and how they are connected in everyday language. It is clear that there is a certain overlap as we often do not distinguish between the perceptions of different sensory modalities as it is known for the confusion of taste and smell [53.26].

Overall, it can be concluded that language offers versatile strategies to express our sensory perception even though we might not have precise terms for them as the clear description of basic taste like salty or sweet. Furthermore, in communication we can understand each other although we might use vague descriptions. Verbalizing sensory perceptions, something very personal happening in our body, might not be a major issue in daily life. However, understanding how language is used to verbalize sensory perceptions supports the professional approach to describe sensory perceptions.

54. The Scent Creation Process

Elise Sarrazin

The scent creation process consists in creating an original and attractive combination of fragrance ingredients. As the great perfumer Jean Carles said in 1961 *perfumery is an art, not a science*. Perfume creation indeed is far from easy and results from an extensive work of olfactory training and memorizing. Moreover, various parameters now have to be taken into account to develop a new fragrance. Technical aspects, such as performance, stability, as well as regulation and toxicology induce new issues that perfumers have to consider during the creation process. Perfume creation is thus at the crossroads of creativity and technology, art and science.

54.1 The Role of Perfumer, Between Craftsman and Artist

54.1.1 A Brief History of Perfumery

Ancient Perfumery

The word perfume derives from the Latin *per fumum*, meaning *through smoke*. Perfume is a mixture of fragrant essential oils or aroma compounds, fixatives, and solvents used to bring a pleasant scent. The art of making perfumes began in ancient Egypt and was later developed by the Romans and the Persians (Fig. 54.1). In these civilizations, perfume was rare and mainly used during religious rituals, as attested by ancient texts and archeologicals digs. Then, between the eighth and the fourteenth centuries, the Arabs significantly improved perfumery by developing steam distillation for plant extraction.

Perfumery was introduced in Europe during the fourteenth century by Crusaders who came back from the Holy Land. The use of perfume then spread throughout Europe among the aristocracy and the first modern perfume, consisting of scented oils blended in an alcohol solution, was created in Hungary in 1370, at a command of Queen Elizabeth of Hungary. During Italian Renaissance, the art of perfumery prospered in Europe and Venice became the capital of perfumes. Later on in the sixteenth century, Catherine de' Medici introduced Italian refinements in France. France was already known for its fragrant extracts made from flowers cultivated in the region of Grasse, and gradually became the European center of perfume and cosmetic manufacture.

Modern Perfumery

At the end of the nineteenth century, the various limitations of natural ingredients, as well as the need of a broader palette encouraged perfumers to introduce synthetic compounds already identified in nature, such as vanillin or coumarin. Since then, modern perfumery began. During the twentieth century, the increasing use of synthetic compounds in fragrance compositions made chemical industry essential for perfumery creation. As the perfumer's palette was significantly extended, the use of perfumes was popularized and lost its elitism as explained by *Elisabeth de Feydeau* [54.1]. Perfumery became a global industry, and numerous small local companies merged or were absorbed by bigger corporations. As a result, between 2008 and 2012, five fragrance manufacturers held 60% of the fragrance market: Givaudan (Switzerland), Firmenich (Switzerland), IFF (USA), Symrise (Germany), and Takasago (Japan), according to Leffingwell and Associates [54.2]. In this globalized context, only three luxury houses have been preserving their own perfume creations internally: Chanel, Guerlain, and the Patou-Rochas group.

New Trends

These days, to reinforce the status of perfume as a luxury product, several brands have chosen to hire a master perfumer as observed by *Elisabeth de Feydeau* [54.1]. In 2004, Hermès hired the perfumer Jean-Claude Ellena as director of perfume design and Christine Nagel joined him in 2014. Following the same strategy, LVMH Group recruited François Demachy in 2006 as head of the Fragrance Creation of Christian Dior, and in 2011 Jacques Cavallier-Belletrud was chosen to create the first perfume for Louis Vuitton.

Another trend recently appeared: the alternative perfumery or *niche* perfumery [54.1]. This tendency is drifted by discreet brands, such as L'Artisan Parfumeur, Diptyque, Serge Lutens, or The Different Company, and aims at repositioning perfume as a luxury product through highly selective advertising and retailing.

Fig. 54.1 Fragrance flasks from the Gallo-Roman Era (Daoud – Fotolia.com)

Due to historical know-how, Europe, and the United States to a lesser extent, preserves a major role in perfume design and trade. According to the International Fragrance Association (IFRA), today there are globally less than 900 perfumers and 60–70% of the perfumers reside in Europe. Moreover, perfume creation is mainly localized in two cities: Paris and New York.

54.1.2 What is a Perfumer?

A perfumer is an expert in scents, who composes fragrant creations. He aims at bringing not only pleasure and well-being, but also at achieving the desired effects that suit the application use. When perfumers are asked about their sources of inspiration, answers are countless. Depending on their own experience and their personal feelings during the creation process, perfumers do not always follow the same approach to develop a new fragrance. Some perfumers are interested in specific materials they want to glorify, or are inspired by olfactory families they are fond of. Others try to translate intimate olfactory feelings into fragrances. Music, literature, or painting can also inspire perfumers. However, first and foremost, the creation of a scent takes place in the mind. *Yet this concept* is paradoxically *neither an idea, nor an image, but a smell*, as the perfumer Jacques Polge, director of the Chanel perfume laboratories since 1978 observed [54.3]. In the same manner, *Jean-Claude Ellena* said *I am the only person who can conjure the smell [I am creating] mentally* [54.4].

Therefore, perfume creation is first an intellectual approach. This idea may look surprising for newcomers, and a French research team recently studied perfumers' brain to get new insights into perfumer know-how. They demonstrated that intense olfactory training led to a reorganization of key olfactory and memory regions, and increased gray matter volumes in the corresponding brain areas [54.5]. As a consequence, the authors showed that perfumers are able to imagine an odor clearly enough to *smell* it, even though it is physically absent, which is hardly possible for the general population [54.6]. Moreover, the authors demonstrated that greater the level of expertise, less key brain regions (right primary piriform cortex, left orbitofrontal cortex, and left hippocampus) are activated. Olfactory expertise even appeared to counteract the effect of aging as gray matter volumes increased with years of practice, whereas these volumes decreased with age in naive subjects. These results demonstrated the astonishing plasticity of human brain and the essential role of olfactory training to become familiar with fragrance ingredients, and also to mentally learn odors. Taking into account these recent results, one can better appreciate

perfumer work and the need of a highly specific olfactory training.

54.1.3 How to Become a Perfumer?

Jean Carles said *the perfumer's only tool is his nose* [54.7], and it is commonly thought that perfumers are endowed with an exceptional sense of smell. A good nose indeed is a major criterion and aspiring perfumers have to pass various olfactory tests during their application program. However according to Jean Carles, *no "nose" can be said to be better than another* and *anyone may acquire a highly developed sense of smell, as this is merely a matter of practice* [54.7]. Olfactory training is thus the first step to become a perfumer. Olfactory training consists in studying and memorizing hundreds of natural and synthetic materials used in perfumery. This training also implies learning which odorants work well together to create harmonious combinations. Due to the extensive variety of fragrance materials, olfactory training must be rigorous and intense. For many perfumers, daily training is not only necessary, but indispensable [54.4, 7]. Odorant learning is thus based on a substantial personal work. According to IFRA, to qualify as a perfumer requires more than 7 years training.

Industry Schools

Since there are few official courses for perfumery in the world, perfumery can be a difficult industry to break into. Remembering his own start, when he felt lost in front of the hundreds of odoriferous materials, Jean Carles founded the first Perfumery School in 1946 in Grasse. This school was part of the Roure company and was aimed at training the future in-house perfumers according to the method he developed and which now bears his name. Later on, in 1992, when Roure merged with Givaudan, the Perfumery School became the Givaudan Perfumery School. Many great perfumers, such as Jacques Polge (from Chanel), Jean-Claude Ellena (from Hermès), or Thierry Wasser (from Guerlain) started in this industry school and this institute can claim to have trained the perfumers responsible for approximately one third of the fragrances on the market today [54.8].

Now, all the major fragrance companies possess their own in-house perfumery training programs. Internal training programs are generally planned for an average length of 4 years to allow future employees to learn the various raw materials used in perfumery, as well as the techniques of fragrance formulation, and technical aspects of the work of perfumer. Afterward, students become Junior Perfumers and complete their instruction under the mentorship of a Senior Perfumer. Industry in-house programs are highly selective: they attract hundreds of applicants from all over the world and from various backgrounds, but only a few aspiring perfumers are qualified each year and there is no guarantee of a position afterward. Jean Guichard, the director of the Givaudan Perfumery School, indicated that only three students out of 200 candidates were selected in 2011 [54.1]. He added that the applicant culture is now a major criterion as fragrance companies aim at suiting local olfactory tastes.

Independent Schools

Besides industry schools, several university programs have been created to train would-be perfumers. The most famous independent school of perfumery is based in Versailles (France) and is called ISIPCA (Institut Supérieur de la Parfumerie, de la Cosmétique et de l'Aromatique Alimentaire). This school was founded by perfumer Jean-Jacques Guerlain in 1970. ISIPCA is now internationally recognized for its expertise in the field of perfumery, as well as cosmetics and flavors, and proposes a wide range of education programs, from undergraduate to graduate degrees. Most of these programs are proposed in the context of day-release contracts with perfume companies. In addition, ICATS (International Centre for Aroma Trade Studies), which is part of the University of Plymouth (UK), offers flexible quality learning to professional and aspiring professionals in the Aroma Trades, Perfumery, and Flavor industries. This school provides distance learning on a global basis leading to the IFEAT (International Federation of Essential Oils and Aroma Trades) Diploma. Besides these well-known schools, the École Supérieure du Parfum which is based in Paris (France) has recently launched a new scholar program. It consists of four full years of teaching, interspersed with two internship periods, followed by a fifth year dedicated to work placements and final year projects. Courses in perfumery techniques are also offered by the Grasse Institute of Perfumery situated in Grasse (France) and the Perfumery Art School based in London (UK). Both programs are planned for one year and combine courses given by confirmed perfumers and practical work.

Like industry schools, independent schools are highly selective. Less than 20 students out of the hundreds of candidates are selected every year by each school. Finally, out of all the schools, less than a dozen students will become perfumers. The other graduates will find jobs as cosmeticians, evaluators, marketing assistants, quality controllers, production managers, and the like [54.8].

54.2 Perfumery is an Art

54.2.1 Perfumer's Palette

As *Jean-Claude Ellena* said, *The art of perfumery is closely associated with chemistry* [54.8]. Perfumer's palette indeed is composed of various materials and has been continuously evolving with scientific discoveries in the field of chemistry. Generally, the materials used by the perfumer are categorized in three families: natural ingredients, synthetic substances, and bases (Fig. 54.2).

Natural Ingredients

Natural ingredients are obtained from natural raw materials using various extraction techniques. They consist of essential oils, concretes, resinoids, absolutes, or butters, depending on the amount of waxes in the extracted product. The most frequently used techniques are steam distillation, solvent extraction (using generally ethanol or hexane), supercritical fluid extraction, fractionation, and expression. Natural raw materials are essentially plants and various parts of the plant are used to obtain fragrance ingredients: flowers, buds, fruits, leaves, barks, woods, resins, gums, seeds, roots, and lichens. As an example, rose and jasmine extracts result from the treatment of fresh petals, whereas iris butter is obtained from the distillation of dry matured rhizomes, and geranium essential oil comes from the distillation of fresh leaves (Figs. 54.3, and 54.4). The chemicals responsible for the typical odor of natural extracts are secondary metabolites of the plant, such as terpenes, norisoprenoids, or fatty acid derivatives. Natural extract composition can thus be deeply modified depending not only on the botanic variety used, but also on the origin of the plant. Moreover, different parts of a same plant can be extracted, leading to different olfactory materials. The steam distillation of cinnamon bark leads to an essential oil rich in cinnamic aldehyde, whereas the distillation of cinnamon leaves results in an essential oil rich in eugenol [54.9].

Fig. 54.2 Fragrant ingredients composing perfumer's palette (monropic – Fotolia.com)

Animalic fragrance materials, such as civet, castoreum, or ambergris, were traditionally used as fixatives. However, they all have been replaced by chemical reconstitutions. One exception is beeswax absolute that is still used for perfume creation.

Despite their historical use in perfumery and their unique olfactory complexity, natural ingredients present several major limitations. First, the cost of natural ingredients can be highly prohibitive. Indeed, due to poor extraction yields, some natural ingredients, such as rose or jasmine absolutes, are hardly reachable for daily applications. Table 54.1 illustrates this constraint show-

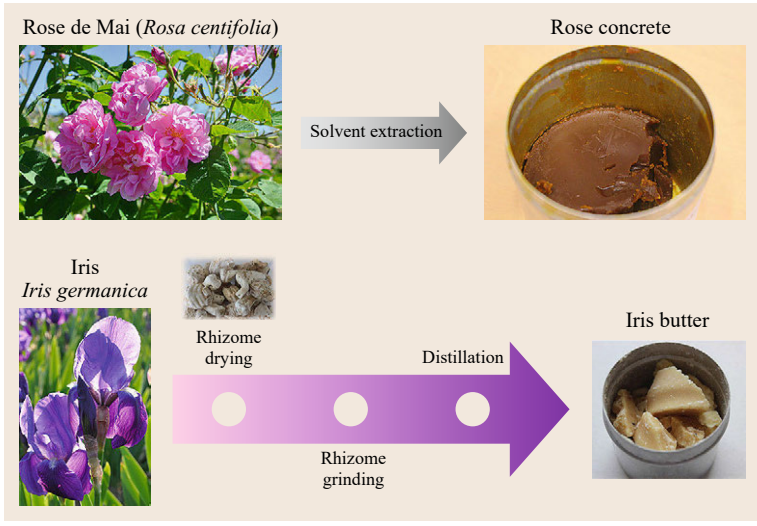

Fig. 54.3 From natural botanic sources to perfumer's ingredients. Two examples: rose de mai and iris (courtesy of Jean-François Vieille)

Fig. 54.4 Geranium leaves and flowers (*Pelargonium graveolens*). Geranium essential oil is obtained from hydrodistillation of fresh leaves (courtesy of Jean-François Vieille)

ing the quantities needed to obtain natural ingredients from various botanical sources [54.10, 11]. Moreover, even today, the scents of some plants, such as lily of the valley (*Convallaria majalis*), frangipani (*Plumeria acutifolia*), heliotrope (*Heliotropum arborescens*), or honeysuckle (*Lonicera caprifolium*), remain hardly extractible because of the lack of raw materials, or poor extraction yields. Finally, natural extracts are hardly reminiscent of the real natural scents as the use of heat and harsh solvents often distort the odor of the raw materials. All these constraints encourage the use of synthetic alternatives, especially for functional perfumery compositions.

Synthetic Ingredients

When modern perfumery began at the end of the nineteenth century, most of the synthetic ingredients used in perfumery were identical in structure to natural odorants. Later on, improvements in organic synthesis led to a significant extension of perfumer palette and offered new perspectives of creation. Table 54.2 lists the main synthetic ingredients introduced in perfumery since 1960 and gives examples of perfumes created with them [54.1]. As Ernest Beaux, the creator of Chanel N°5, used to say *a worthy creation must contain a new material* and *one has to rely on chemists to find new aroma chemicals creating new, original notes*. Therefore, scientists are continuously searching for new synthetic materials. According to IFRA, the fragrance industry invests up to 18% of its total annual revenues in research and development, especially to discover new molecules and patent them. These innovative ingredients are known as *captives* and are crucial to provide newness and originality to perfumers' palette. However, the search for new scent ingredients often comes as a result of serendipity. As an example, every year, over 2000 new molecules are developed by Givaudan researchers, but only three or four per year are selected for launch, after scent evaluation, synthesis studies, and testing [54.12]. Like the best natural ingredients, the best synthetics are extremely expensive. Consequently, captives are generally dedicated to fine fragrances in a first time, and their use is extended to a wider range of products in a second time.

Bases

The third class of fragrance ingredients corresponds to bases. Bases, also known as accords, are simple formulae that provide a premade fragrant blend that can be incorporated as a component on its own in the full perfume formula [54.13]. Bases are olfactory interpretations that are used to bring specific olfactory facettes, such as leathery, fruity, or flowery notes. Bases present several advantages for perfumers. First, they make easier the use of powerful ingredients that are difficult to directly add at very low levels in compositions. They also represent an alternative to the use of materials of animal origin that are no longer available. Moreover, bases widen perfumer palette with olfactory reconstitutions of flowers or fruits whose scent cannot be extracted. Bases can sometimes be better scent approximations of the flower scent than the corresponding natural extract, especially when perfumers aim at bringing the odor of fresh flowers.

Table 54.1 Quantities needed to obtain natural extracts from several botanical sources [54.10, 11]

Product	Extract	Origin	Botanic variety	Quantity needed to obtain 1 kg extract
Mandarin	Oil	Italy	*Citrus reticulata*	1350 kg fruits
Neroli	Oil	Tunisia	*Citrus aurantium*	1000 kg flowers
Jasmine	Absolute	Egypt	*Jasminum grandiflorum* L.	400 kg flowers
Rose	Oil	Bulgaria	*Rosa damascena*	4500 kg flowers
Rose	Absolute	Turkey	*Rosa damascena*	700 kg flowers
Rose de mai	Concrete	France	*Rosa centifolia*	400 kg flowers
Iris	Absolute	Italy	*Iris pallida*	2000 kg roots
Patchouli	Oil	Indonesia	*Pogostemon cablin* (Blanco)	50 kg leaves
Vetiver	Oil	Haiti	*Vetiveria zizanoides* L.	250 kg roots
Ylang ylang	Oil	Comores	*Cananga odorata*	50 kg flowers

Table 54.2 Main synthetic compounds introduced in the perfumers' palette during the last 50 years (after [54.1])

Year	Event	Attributed to	Applications in perfumery
1957–1962	Methyl dihydrojasmonate (MDJ) or Hedione	Firmenich	*Eau Sauvage* (Dior, 1966)
1961	Z11	Firmenich	*Bulgari pour homme* (Bulgari, 1995)
1962	Vertofix	IFF	*N° 19* (Chanel, 1970) *Silence* (Jacomo, 2004)
1964	Lyral	IFF	*Fidji* (Guy Laroche, 1966) *Parfum d'été* (Kenzo, 1992)
1965	Galaxolide	IFF	*Jovan Musk* (Jovan, 1974) *Trésor* (Lancôme, 1990)

54.2.2 Ingredient Classification: Top, Middle, and Base Notes

In order to make the learning of fragrance materials easier, Jean Carles developed a method where ingredients are divided into three categories according to their volatility and tenacity [54.7, 8, 13]. These three categories are known as top notes, middle notes and base notes. Table 54.3 presents three categories of volatile notes and gives examples of odorous materials. Top notes (or head notes) are highly volatile products that lack tenacity. They represent the first 15 min or so of evaporation. Middle notes (or heart notes) present an intermediate volatility and tenacity and last for several hours. Base notes (or end bottom notes) are characterized by a low volatility and a high tenacity and can last for days on a blotter (Fig. 54.5). As explained by *Jean Carles* in 1962, *base note compounds generally give off a rather unpleasant smell when freshly deposited on a paper strip, but the scent given off after the subsequent stages of evaporation is excellent* [54.7]. Base notes thus need to be improved by materials with high and intermediate volatility to impart to the perfume composition an attractive odor on opening the bottle. Consequently, perfume is an optimized equilibrium between top, middle, and base notes. According to Calkin and Jellinek, the balance between the three categories of materials should be 15–25% top notes, 30–40% middle notes, and 45–55% base notes [54.13].

Nevertheless, the concept of top, middle, and base notes mainly aims at guiding students and cannot restrict fragrance creation. Indeed, odorant classification depends mostly on the ingredient blend. As an example, clove essential oil is generally listed as a middle note ingredient but has also some top note character. On the contrary, neroli essential oil, considered as top note material, can also impart some middle note character. In addition, the balance between top, middle and base notes can vary depending on the perfume application. A fine fragrance for instance is formulated to have a distinctive *sillage* to persist even hours after application, whereas a shower gel aims at bringing immediate freshness and blooming. Therefore, one should only remember that a well-constructed perfume must have notes that blend well and run into each other successfully as the perfume evaporates with the fragrance theme apparent at every stage [54.7, 13].

Table 54.3 Odorant classification based on volatility and substantivity [54.7, 8, 13]

Top notes	
Citrus	Orange essential oil, lemon essential oil, mandarin essential oil, grapefruit essential oil, bergamot essential oil, lime essential oil, petitgrain essential oil
Herbal	Pine essential oil, rosemary essential oil, basil essential oil, oregano essential oil, tarragon essential oil
Aldehydic	Decanal, undecanal, 2-methyl undecanal, dodecanal
Marine/ozone	Calone, Ozonal, Algol
Green	Galbanum essential oil, *cis*-3-hexenol, and its esters, coriander essential oil
Fruit	Black currant absolute, isoamyl acetate, ethyl caproate, ethyl butyrate
Middle notes	
Floral	Rose (rose essential oil, odors of hyacinth, lily of the valley): phenylethyl alcohol and geraniol White flowers (orange flower absolute, jasmine absolute, tuberose absolute): methyl anthranilate and indole Yellow flowers (osmanthus absolute, cassia absolute, odor of freesia): beta ionone Exotic or spiced flowers (ylang-ylang essential oil, odors of carnation, lilies): benzyl salicylate and eugenol Anise flowers (mimosa absolute, odors of lilac, wisteria): anisic aldehyde or heliotropin
Spice	Cool spices: pepper essential oil, cardamom essential oil, nutmeg essential oil, pink pepper essential oil Hot spices: cinnamon essential oil, clove essential oil, pimento essential oil
Base notes	
Wood	Cedarwood essential oil, sandalwood essential oil, patchouli essential oil, vetiver essential oil, agarwood absolute, oak moss absolute
Animal	Civet, synthetic musks, castoreum absolute, birch tree essential oil
Amber	Ambergris, labdanum absolute, myrrh, cistus essential oil
Vanillic	Tonka absolute, vanillin, ethylvanillin, ethylmaltol, benzoin resinoid

54.2.3 Perfume Classification – Olfactory Families

Just like in all artistic disciplines, students first learn raw materials and then pursue their apprenticeship with the copying of perfumery models. They learn olfactory families, as well as the perfumes that are particularly characteristic of their era. According to *Jean-Claude Ellena*, *all this imitation drives home the importance of the interactions between materials, the role of fragrance's total construction, and the detail* [54.8].

The most famous fragrance classification was developed in 1984 by the Société Française de Parfumerie (SFP) and is based on seven olfactory families [54.1, 8, 10]:

- *Citrus* or *Hesperides* defines fragrances reminiscent of citrus. This family consisted historically in Eaux de Cologne. Later on, around 1960, it was widened with the introduction of synthetic compounds reminiscent of citrus that present higher tenacity than naturals.
- *Floral* corresponds to fragrances dominated by a scent of a particular flower or combining several flower scents.
- *Fougère*, meaning fern in French, corresponds to compositions made from a combination of lavender, geranium, coumarin, and oak moss. This family emerged in 1884 with *Fougère Royale* by Houbigant.
- *Chypre* defines fragrances based on an olfactory accord of oak moss, cistus labdanum, patchouli, and bergamot. This class of fragrances was named after

Fig. 54.5 Fragrance flasks and paperstrips used for sensory evaluation (rdnzl – Fotolia.com)

a perfume created by François Coty in 1917, *Chypre* being the French translation of Cyprus.

- *Woody* fragrances are mainly dominated by woody scents. Some woody notes are opulent, such as sandalwood and patchouli, while other scents are dryer like cedarwood and vetiver.
- *Amber* or *Oriental* represents a large fragrance class structured around three main notes: amber notes, like vanilla, tonka bean, and balsams, spicy notes reminiscent of clove and cinnamon, and woody notes with patchouli and sandalwood.
- *Leather* fragrances are composed of scents of honey, tobacco, wood, and wood tars.

Each olfactory family is divided into several subfamilies depending on the additional accords of the compositions. Since new fragrance materials are introduced every year, fragrance subfamilies evolve continually. As an example, the introduction of Calone 1951 by Pfizer in 1966 resulted in the rising of the *Aquatic/Oceanic/ozone* subfamily, which defines fragrances reminiscent of the ocean. In the same manner, in the early 1990s the introduction of Ethylmaltol in perfumer's palette launched the trend of the *Gourmand* accord reminiscent of sweet delights.

Recently, the fragrance-dedicated website Osmoz proposed a new classification that considers the increasing number and diversity of men's fragrances. Indeed, as observed by Elisabeth de Feydeau, in 2007 men's fragrances represented one third of fragrance launches, whereas this market only started around 1930 [54.1]. Osmoz classification is based on eight major families: four families are dedicated to women's fragrances (*Citrus*, *Floral, Chypre*, and *Oriental*), and the four other correspond to men's fragrances (*Citrus*, *Aromatic*, *Woody*, and *Oriental*). *Aromatic* defines fragrance accords based on one or more aromatic herbs, such as clary sage or rosemary.

54.2.4 How do Perfumers Work on a Creation?

According to IFRA, fragrance is a blend of 50 to 250 raw materials drawn from a palette of up to 3000 available ingredients. In front of the hundreds of fragrance materials and compositions, perfumers are constantly seeking for new olfactory sensations. As already explained, scent creation is first an intellectual work, which is designed according to the perfumer's personality, in agreement with the context of the project, that is, the name of the future fragrance, the bottling, or the consumer target.

Once a perfumer has an idea – or a smell – in mind, creation process begins. Fragrance formula consists of a list of ingredients in specified quantities. The creation process is iterative: a first formula is made and evaluated on a smelling strip then the formula is adjusted and reevaluated, etc., [54.10]. For every trial, the overall evaporation profile is considered in order to assess gradual changes from the volatile top-notes to the most retained base-notes. Creation process can last from a couple of weeks to several years, so the perfumer needs to persevere to succeed in creating the best formula. Finally, as Jean-Jacques Guerlain said, *after much groping in the dark the perfume begins to resemble the image which I had forged abstractly in my mind* [54.3]. Christopher Sheldrake, Perfumer and Director R&D Perfumes, Chanel, added that *a fragrance is successfully completed when it smells obvious; when the perception of the fragrance is coherent with objectives researched; when the aesthetic appreciation of the fragrance replies convincingly to one's expectation* [54.14].

Fragrance is thus a personal work that depends on its designer and many perfumers consider scent creation as an art, such as painting, or music. The great perfumer Edmond Roudnitska, who created *Eau Sauvage* (Christian Dior), was the first to defend this idea. Besides his well-known creations, he collaborated with the philosopher Etienne Souriau to demonstrate the artistic nature of fragrance creation (Fig. 54.6) [54.15]. For Edmond Roudnitska, learning is as essential to appreciate perfume creation, as it is to appreciate music. He added that *taste evolves chiefly with the acquisition of learning, with the knowledge of facts and of aesthetic accomplishments, which makes it possible to analyze them and to provoke instructive comparisons*. Today, Christophe Laudamiel (from IFF) defends the same idea. According to him, perfume is an everlasting quest for beauty: perfume translates the intimate character of its creator,

Fig. 54.6 Perfume is an everlasting quest for beauty that can be seen as an artistic creation (ra2 studio – Fotolia.com)

and is designed to inspire not only sensory pleasure, but also emotions [54.16].

Nevertheless, as the fragrance industry evolves, the perfumer's work also changes. Many fragrances are now created by a perfumer team and no longer signed by only one nose as it used to be traditionally. Cosigning is recent and opinions disagree on this creation method. According to Olivier Cresp (from Firmenich), working on a creation with another perfumer is perfect [54.17]. For him, during the creation process, a perfumer sometimes needs help or advice and it is useful to share these issues with another perfumer. On the contrary, *Jean-Claude Ellena* declares that *even if the exchange is beneficial, the accumulation of ideas is an utter negation of any creative process* [54.4].

Moreover, despite their personal investment in perfume creation, perfumers generally work on several creation projects at the same time. Most of the designers need to move from one project to another to get new ideas and avoid creator's blocking [54.4, 14, 17].

54.3 Perfumery is a Science

Creating a fragrance requires a specific know-how which is based on an intensive olfactory training. However, the perfumer also has to take into account technical parameters, such as performance, stability, and regulation, to create the blend that best suits to the context.

54.3.1 Physicochemical Parameters Used to Define Fragrance Ingredients

Several physicochemical values are available to describe sensory performance of fragrance ingredients. These physicochemical data, and especially saturated vapor pressure and $\log P_{o/w}$, are useful for selecting ingredients [54.8, 10, 13]. Saturated vapor pressure refers to the equilibrium pressure exerted by a substance in a closed system at a specified temperature. As can be seen in Table 54.4, the vapor pressure of ambrettolide is below 0.01 hPa at 25 °C, making it a product with low volatility that lasts over time, whereas prenyl acetate has a high vapor pressure of 2.53 hPa (at 25 °C) and therefore fades in less than a minute [54.18].

In addition, as perfume composition aims at sticking to final application, it is important to consider the partition of the material between aqueous and organic phase. This property is given by $\log P_{o/w}$, also known as partition coefficient. Higher values of $\log P_{o/w}$ indicate higher hydrophobicity of the substance, and thus higher affinity for any alternative surface in comparison with water. As can be seen in Table 54.4, ambrettolide is much more hydrophobic than prenyl acetate and thus has a better affinity for skin, hair, or clothes than prenyl acetate [54.18].

Actually, saturated vapor pressure, as well as $\log P_{o/w}$, express material physicochemical behavior that perfumers used to learn empirically. Since perfume is a mixture of various materials, these data cannot predict the behavior of the materials in the final product.

54.3.2 Volatility, Tenacity, and Substantivity

Fragrances must be volatile to be perceived. Volatility of an odorant is determined by two main factors: its molecular weight and its polarity. Generally, molecules with fewer than eight carbon atoms in their structure are too volatile to be used in perfume creation [54.13]. On the contrary, compounds that comprise more than 18 carbon atoms are usually not volatile enough to reach the olfactory receptors in the nose. Volatility is also affected by the ability of odorant to form nonbonded interactions, and thus by the nature of its functional groups. As explained by *Charles Sell*, *the more polar a molecule is, the more easily will it form electrostatic bonds, such as hydrogen bonds, to other molecules around it, whether they are other fragrance molecules, cellulose (paper strips), or proteins (skin, hair)* [54.13].

In addition to volatility, perfumers have to consider fragrance ingredient tenacity. Tenacity, also known as substantivity, defines perfume long lastingness, and is empirically measured as the duration the fragrance remains detectable on a blotter [54.8]. Tenacity depends mainly on the volatility of the fragrance components [54.13].

Table 54.4 Comparison of physicochemical values of two fragrance materials [54.18]

Compounds	Structure	Olfactory description	Saturated vapor pressure (hPa)	$\log P_{o/w}$	Substantivity
Ambrettolide		Musk	< 0.01	6.510	> 48 h
Prenyl acetate		Fruity, floral, pear	2.53	1.650	< 3 h

54.3.3 Sensory Thresholds

The olfactory perception threshold is defined as the lowest concentration at which a perfume ingredient can be perceived, whereas the olfactory recognition threshold represents the lowest level at which a perfume ingredient is identified in odor terms. Clearly, the olfactory perception threshold is important in perfumery since it gives information about the olfactory strength of odorants, and consequently of the acceptable level range in a composition. As an example, the olfactory perception threshold of vanillin is 0.02 ng/l, which means that vanillin is perceptible even in highly diluted form [54.8]. By contrast, the perception threshold of isoamyl acetate is 95 ng/l, so this compound becomes quickly undetectable once diluted [54.8].

54.3.4 Radiance, Bloom, and Sillage

Charles Sell defined *radiance* as *the ability of a perfume or perfume ingredient to fill space* [54.13]. One of the best examples of radiant materials is methyl dihydrojasmonate, also known as Hedione. When this material is smelt from a perfumer's blotter, it does not seem to have a high olfactory impact, but if the blotter is left in a room, its floral odor is easily perceptible by anyone entering the room. Two properties are essential in making a material radiant: volatility and sensory threshold. Indeed, the perfume material must be poorly volatile not to evaporate too quickly, and it must have a very low perception threshold to be immediately detected.

Another important parameter is *bloom* which is defined by *Charles Sell* as *the ability of a fragrance to perfume a room when the fragrance is introduced, not directly as an oil or aerosol, but in a product, such as a soap* [54.13]. One should distinguish *dry bloom* that corresponds to the fragrance effect of a dry bar of soap left in a room, from *wet bloom* that defines the fragrance effect in the room when the soap is in use. Bloom is a main feature for functional products, such as body care and home care products.

Finally, *sillage* is the phenomenon of a scent trail being left by a person. Sillage is a property that is highly evaluated in the creation of fine fragrances [54.14].

54.3.5 Influence of the Application Matrix

Fragrance results from the blend of various materials that can react together or with the matrix used [54.10, 13]. In the case of fine fragrance, the product base is aqueous ethanol that is relatively perfume friendly. However, some applications, such as soaps or deodorants, are more aggressive media. In any case, the fragrance has to subsist through manufacture, distribution and storage. Consequently, the perfumer must learn to design fragrances that will be stable in the product and not interfere with its active ingredients.

The most important parameter the perfumer has to take into account during the creation process is pH [54.10, 13]. Indeed, perfumers have to design fragrances for products with pH values ranging from one end of the scale to the other. Fine fragrances are characterized by neutral pH, whereas the composition of functional products generally induces acidic or alkaline conditions. In these harsher media, various chemical reactions are readily observed, such as acetalization, ester hydrolysis and aldolization, and restrain perfumer's palette. As explained by *Charles Sell*, *while all fragrance ingredients are stable enough to be used in neutral conditions, only* 65% *of the palette can be used by the perfumer creating a fragrance for an antiperspirant,* 45% *in a laundry powder,* 25% *in an acid lavatory cleaner, and mere* 5% *in a dish wash powder* [54.13].

Besides pH matrix, the perfumer has to consider the presence of oxidizing or reducing agents that can induce undesired chemical reactions. The designer has also to take into account the presence of surfactants, opacifiers, or dyes [54.10, 13]. These latter compounds induce loss of available fragrance ingredients because of adsorption onto or into the active compounds and thus lower fragrance intensity.

54.3.6 Sensory Performance

Fragrances are created in order to bring a pleasing odor, but the hedonic dimension of a perfume is highly subjective. To ensure success of fragrance creations, various sensory studies can be performed before launching a new product. Historically, sensory studies focused on the bipolar hedonic valence dimension, that is, the propensity of an odor to be liked, or on the contrary disliked. However, this methodology can only predict the success of a product and cannot explain hedonic responses. To get new insights, various researches have been performed during the last 20 years especially to measure emotional and behavioral responses to odor. Indeed, odors can elicit innumerable emotions because of direct connection between the brain limbic system, which is the center of emotions, and the olfactory system.

Generally, emotional response is categorized according to six basic emotions: anger, disgust, fear, happiness, sadness, and surprise [54.19]. However, this classification hardly fits the emotions linked to olfactory experience. Recently, researchers from the Swiss Centre of Affective Sciences demonstrated that feelings induced by odors are structured around a small group of dimensions that reflect the role of olfaction in well-

being, social interaction, danger prevention, arousal and relaxation sensations, and conscious recollection of emotional memories [54.20]. With this concept, these authors developed the Geneva Emotion and Odor Scale (GEOS), which is based on six dimensions: sensuality, relaxation, pleasant feeling, refreshment, sensory pleasure, and unpleasant feeling [54.21]. Through collaboration with Firmenich, the authors extended their study to other regions and developed a global verbalization tool called ScentMove, which is adapted to commercial and development needs and aimed at better discriminating fragrance products focusing on emotions [54.22].

Using a similar strategy, IFF focused its research on mood. Indeed, pleasant odors are likely to induce positive moods, whereas unpleasant odors tend to induce negative moods [54.23]. In order to measure both subjective and physiological effects of aromas and fragrances on emotions, IFF has developed a self-report method called Mood Mapping [54.24]. This method is based on eight mood categories: happy, relaxed, sensuous, stimulated, irritated, stressed, depressed, and apathic. For each sample, the panelists are asked to pick a mood category that best matches the aroma of the sample. In the same context, Takasago developed a method for measuring the emotional response to olfactory stimuli [54.25]. This method requires the use of magnetic resonance imaging to assess the ability of fragrance sample to elicit a reward through the dopaminergic pathway. Applying this method, they were able to assay the sedative or energizing effects of odors for various applications. More generally, all the leading fragrance companies now integrate the importance of emotions in the development of new fragrance products.

54.3.7 Stability

During storage, the quality of the final product evolves: the fragrance evolves and the matrix also changes. Therefore, the physical and chemical characteristics of the final product need to be checked to ensure the absence of significant changes over time before the product reaches the market place. Stability tests consist in monitoring any changes in the fragrance odor once in the product matrix and in the final packaging, as well as any changes in the product aspect, over a period of accelerated storage at different conditions. Accelerated test theory is largely based on the Arrhenius rate equation: for every 10 °C increase in temperature, the rate of the reaction doubles. Consequently, a 12 month-aging at 20 °C equals a 12 week aging at 40 °C, or a 6 week aging at 50 °C, or a 3 week aging at 60 °C. In practice, fragrance companies test all their products at 0–4 °C, 20 or 25 °C, and 37 °C, for 12 weeks as a minimum standard [54.13]. These conditions are usually more severe than real conditions to ensure good stability.

Moreover, depending on the product packaging, additional stability tests can be performed. First, humidity tests can be carried out for products that are likely to be packed in permeable materials, such as paper or cardboard. Humidity tests commonly consist in monitoring any changes over high-humidity conditions, that is, 37 °C/70% relative humidity or 40 °C/80% relative humidity [54.10].

Light testing is also commonly performed for products that will be exposed to daylight or strong sunlight. Light tests are carried out using a Xenon arc lamp that emits UV light in the 300–800 nm wavelength range, with a 400 or 1000 W burner fitted. In these conditions, a 6 h exposure to the 1000 W lamps is sufficient to monitor any changes that are likely to occur in about 3 months of daylight testing [54.13]. However, light testing presents a severe limitation. Indeed, the temperature inside the UV cabinet can be drastically high despite the presence of a cooling fan, resulting in a temperature artifact in testing conditions.

In practice, fragrance ingredients are storage tested before the introduction to the perfumer's palette and their stability performances are collected in in-house databases to guide perfumers in picking out the optimal odorants for the product application [54.13].

54.3.8 Safety and Toxicology Issues

Around 1960, the fragrance industry established a self-regulatory system that involves the two major international fragrance organizations: the Research Institute for Fragrance Materials (RIFM) and the International Fragrance Association (IFRA).

RIFM was formed as a nonprofit corporation in 1966 and represents the international scientific authority for the safe use of fragrance materials. The RIFM database of flavor and fragrance materials is the largest available worldwide, classifying more than 5000 materials. RIFM has settled several science programs to cover all the aspects of fragrance safety. Its research is supported by more than 60 companies that consist of fragrance manufacturers and consumer product manufacturers. Moreover, its activities are reviewed by an independent Expert Panel, which provides strategic guidance, determines scientific study design and interprets results for relevance to human health and environmental protection.

IFRA was established in 1973 and represents over 100 fragrance manufacturers in 15 countries. Its members account for 90% of the global production volume. IFRA is registered in Switzerland and has its operational center in Brussels, Belgium. IFRA board is

composed of six active members that are Firmenich, Givaudan, IFF, Robertet, Symrise, and Takasago. IFRA is responsible for issuing and up-dating the Code of Practice which sets standards for good manufacturing practice within the industry, quality control, labeling and advertising. This code also sets limits or even prohibits the use of certain ingredients. The Code of Practice is updated according to the conclusions of the RIFM Expert Panel. Currently, the IFRA safety program contains 186 Standards, which restrict, or prohibit, the use of selected fragrance materials.

In addition to these two international organizations, the European Commission acts as a major actor in fragrance regulation. Indeed, fragrance industry is now global and changes in European regulation directly impact international market by restricting the perfumer's palette. More precisely, the 7th amendment to the European Cosmetic Directive 76/768/EEC has highlighted 26 fragrance materials identified as potential skin sensitizers by the Scientific Committee for Consumer Safety (SCCS). As a consequence, since March 2005 the presence of these compounds has to be indicated in the list of ingredients on the cosmetic label in Europe. This labeling is triggered if there is equal or above 10 ppm of any one of these materials present in a leave-on cosmetic product, and if the level in a rinse off cosmetic product is equal or above 100 ppm [54.10]. As most of these ingredients were commonly used in perfumery before 2005, the 7th amendment to the European Cosmetic Directive 76/768/EEC induced numerous modifications of the ingredient list labeling or reformulations depending on the companies' strategy.

54.4 New Challenges in Scent Creation

Perfumery evolves in the course of scientific discoveries. In the same time, customer demand changes generating new challenges for fragrance creation. Several new trends are detailed in this paragraph.

54.4.1 Environmental Issues

During the last two decades, consumer interest for environmental issues has been growing, especially focusing on sustainability. Ecological and ethical awareness has resulted in modifications of perfumers' palette. First, there has been an increasing demand for natural ingredients with full traceability. IFF-LMR Naturals was one of the pioneers of this approach as it uses to contract directly with farmers from all over the world to guarantee full traceability and sustainability of its products. As an example, in 2010 IFF-LMR renewed decade-long contracts with Burgundy farmers to ensure the production of blackcurrant bud absolute. Now, this strategy has spread in line with fair trade, and several fragrance manufacturers have developed partnerships with local farmers to ensure sustainable sourcing of natural ingredients of strategic importance, such as vetiver, vanilla, ylang-ylang, tonka bean, and patchouli. Through these partnerships, farming communities benefit from a guaranteed minimum price and regular technical support in order to improve harvesting and manufacturing processes. In this context, a partnership was developed in 2009 between Chanel, Robertet, and Serei no Nengone (SNN) to ensure sustainable production of sandalwood oil in New Caledonia [54.14]. In addition, customer concern for organic crops has resulted in an increasing demand for organic-certified natural ingredients. This rising interest induced new challenges in analytical research, especially to assay pesticide residues in natural ingredients.

Sustainability issues also concern synthetic substances. Indeed, various researches are currently performed to get new insights into substance biodegradability, as well as to integrate green chemistry into manufacturing processes. Green chemistry designs products and processes that reduce waste, limit the use of solvents, promote biodegradability, and improve energy efficiency.

54.4.2 New Regulation Issues

In June 2012, the Scientific Committee on Consumer Safety of the European Commission adopted a new opinion on fragrance allergens in cosmetic products (SCCS/1459/11). This opinion updated the list of fragrance allergens that the consumer should be made aware of when they are present in cosmetic products (European Cosmetic Directive 76/768/CEE). It identified among fragrance ingredients some allergens established in humans for which a maximum limit of concentration in the cosmetic product should be fixed. It also indicated that three fragrance allergens (HICC, atranol, and chloroatranol) should not be used in cosmetics. After a public consultation of the different stakeholders, the Cosmetic regulation will be amended accordingly.

54.4.3 New Fragrance Applications

These days, the best perfumer's challenges consist in exploring new sensory territories. Some of them are detailed in this paragraph.

Scent Branding

Various companies now aim at strengthening their brand identity and enhancing customer well being. With this goal, several brands have already adopted an olfactory signature. Olfactory signature, also known as scent branding, defines an ambient fragrance exclusively designed for a brand and diffused in its establishments. Fashion and beauty brands were the first to adopt a fragrant ambiance. But, this trend is now followed by numerous hotels and spas, as well as spirits and food brands. First results have demonstrated that fragrant ambiance can improve customer well-being, resulting in an enhanced time spent in the establishment. Olfactory marketing thus opens up a wide range of new opportunities for fragrance creation.

Medical Support

According to *Jacques Polge*, *Olfaction is the most vital and the most animal of our five senses: if one loses the sense of smell, he loses taste for life* [54.1]. However, the sense of smell used to be poorly regarded by the medical staff. As olfaction is now recognized as a powerful elicitor of emotions, it also begins to be considered for medical support. Indeed, odors can evoke autobiographical memories that are emotionally intense and long forgotten, and even more effective than cues from other sensory modalities [54.26]. Since 2000s, several medical projects have been performed using olfaction as a re-education tool for patients with neurological disorders. As an example, a medical program was launched in 2001 by the team of Pr Brussel at Raymond-Poincaré Hospital (Garches, France) and IFF to help brain-injured patients to recover memory and improve their quality of life. In this context, IFF provided olfactory kits containing reconstitutions of daily odors in order to train patients and to increase their olfactory sensitivity [54.27]. This re-education experiment was a success, and since then the Raymond-Poincaré Hospital has launched several re-education programs in collaboration with speech therapists and nutritionists. *Hummel* et al. confirmed the effects of olfactory training on patients with olfactory loss, and verified the amazing plasticity of human brain even after severe injury [54.28]. More recently, patients with Parkinson's disease performed olfactory training and this training was demonstrated to significantly increase their olfactory capability, and thus their quality of life [54.29].

54.5 Conclusion

Today scent creation process requires not only creativity, but also technical understanding of molecular interactions in the final product, as well as in contact with skin, and environment. These constraints are challenging for perfumers and force them to develop ingeniousness to design original products. Besides these limitations, perfumers have to interpret customer desires. Indeed, perfumers have to be aware of all the emerging trends and tastes to propose creations that anticipate customer needs. In a sense, perfume reflects our civilization. Its use has been evolving throughout the centuries, from a religious gift, to a medicine and since the nineteenth century as an hygiene and beauty product. Even now, despite industry globalization, perfume preferences vary from one region to another one, and perfumers have to understand these cultural contrasts.

Perfumers generally agree that there is no key for success in perfume creation. However, some qualities seem to be essential to become a perfumer: creativity, curiosity, open-mind, perseverance, and obviously an excellent memory.

Acknowledgments. I would like to acknowledge Christopher Sheldrake, Perfumer and Director R&D Perfumes, Chanel. I am grateful to Gaëlle Madiot, Nathalie David, Carol Surot, and Michèle Elbaz for fruitful discussions during the redaction of this paper. I also thank Elisabeth de Feydeau who authorized me to use her data. Finally, I would like to acknowledge Jean-François Vieille who accepted me to use his pictures.

55. Odor in Immersive Environments

Manfred Dangelmaier, Roland Blach

Immersive environments provide a computer-generated virtual reality for their users. They are applied in various fields such as engineering, marketing and sales, education and training, therapy or entertainment. Besides the dominant visual aspects or acoustic perception, olfactory perception can be one of the addressed senses in such a multimodal experience. The purpose is to immerse the user in a virtual scene in order to support decision making and design processes as well as learning. While odor can fulfill several functions in human–computer interaction there is currently no big market for computer-controlled scenting devices. Such devices should provide at least a subset of the functions of scent synthesis, dispensing, diffusion/ventilation, neutralization and exhaustion. Immersive environments in addition have to provide an interactive realtime experience and need to be controlled in synchronization with the other experiences and the scene context. This requires the integration of the olfactory simulation with the scene graph. Simple event-driven control models can be used as well as more complex fluid dynamics models to achieve a credible experience. Repeated attempts in previous decades to introduce scenting devices into mass markets for entertainment such as cinema and games were not successful. A more likely development path is the development in the aroma application industries, for example wearable devices for dispensing and dosing scent and aromas.

55.1 Defining Immersive Environments

Immersion means a sense of presence in a virtual environment. Virtual environments are generated in computers (Fig. 55.1). They appear for instance as computer games for entertainment, but are also used in serious applications such as education, decision making in product development, production planning or in purchasing decisions. The opposite of a virtual environment is a physical environment. An immersive environment is thus a virtual computer-generated environment, which allows the user to feel like they are there. This implies that immersive environments provide a realtime experience and that the user can interact with it.

Immersive environments go beyond simple windows as known from graphical user interfaces in daily work with workstations, mobiles and wearable computers. This is typically achieved by a selection from the following set of measures [55.1]:

- Spatial representations are used. A digital world in three dimensions is modelled.
- Stereoscopic displays allow for spatial vision.

Fig. 55.1 Virtual computer-generated environment (Victor Brigola)

Fig. 55.2 Head-mounted display (courtesy of Fraunhofer IAO, University of Stuttgart IAT)

- The user is surrounded by displays, which can be either head-mounted (Fig. 55.2) or positioned in the environment (Figs. 55.3–55.4).
- Eye or head tracking is used to allow for natural motion in the virtual world.
- The user can navigate and manipulate the virtual environment with spatial interaction devices [55.2].
- A multimodal experience is provided. That means that additional senses are addressed. Sounds, motion, haptic clues (Fig. 55.5), odor or taste [55.3, 4] etc., are added to the virtual environment. This means the olfactory sense is one of the perceptual modalities used to create immersive environments.

55.2 Virtual Reality

An immersive environment provides virtual reality [55.5] to its user. It avoids the need for physical presence in the physical environment or even the need for an existing physical environment. Good reasons for using virtual environments and realities are seen in Table 55.1.

A virtual reality (VR) is never an exact reproduction of a physical reality. It always differs for several reasons:

- VR differs from reality in substance.
- VR provides models of a reality and contains modeling errors.
- VR is perceived through imperfect human–machine interfaces with restricted performance and reproduction acuity.
- VR is typically a simplification or idealization of a reality.

Therefore it is not helpful and inefficient in most cases to follow an ideal concept of VR as a perfect reproduction of a physical reality. It is better to understand VR as a sufficient representation of a reality for a specific purpose. Imperfections may be intended, for example in artwork [55.6]. Frequently they are not desired but accepted by users [55.7]. Furthermore a cognitive immersion or adaptation effect occurs in the course of an immersive experience – the virtual reality becomes the present reality for the user.

Following this paradigm it is helpful to add odor to VR where it is crucial for the purpose of the application. Designing a shop interior with VR requires fragrances in VR in case aromatization is part of the proposed shop experience. For example in case a museum wants to present a virtual medieval town to its visitors following an experiential archeology approach, it should consider odor as an option for the virtual environment.

Odor in VR requires an appropriate dispensing device (Chap. 58). In case scene-dependent change of odor is required, a computer-controllable dispenser is needed as well as an appropriate controllable evacuation or neutralization device.

Table 55.1 Reasons for using virtual environments

Reason	Example
Physical environment does not exist anymore	Archeology
The physical environment does not yet exist	Architectural planning, product development
The environment is not physical in its nature	Games, abstract information spaces
The physical environment is not accessible or physical presence is too risky	Expedition to Mars, training environments for hazards
The physical realization is too expensive or takes too long	Construction of prototypes

55.2.1 Augmented Reality

In contrast to VR, where a virtual model of a reality is in the focus of consideration, *augmented reality* (AR) denotes the introduction of virtual elements in a physical perception space (Fig. 55.6). Visual virtual elements can be models of physical objects, abstract spatial information, or two-dimensional graphical components.

Unlike VR, AR is always related to the present spatial situation of the user and depends therefore on the situation. It is a situational context-related technology. AR can use a stationary device in the rare cases that it is only related to one specific location. Mostly, however, AR has to rely on mobile or wearable devices.

Examples are sightseeing information virtually added to physical landmarks, navigation information superimposed in the field of vision, personalized location-dependent advertisements presented in a shop-window, furniture from a catalog virtually positioned in an existing living room, or a virtual temple superimposed over an ancient ruin.

AR uses either the natural perception of the human and adds information through a wearable device or it uses video camera images and augments those with additional information. One category of AR applications uses commodity smart phones or tablets to augment their camera live videos with additional information.

Like in VR spatial representation is crucial for AR. In addition spatial relation plays an important role. Augmenting a word processor screen with correction information is not considered as AR. Labeling a tower in a city skyline with its height is however accepted to be named AR. In order to place augmenting informa-

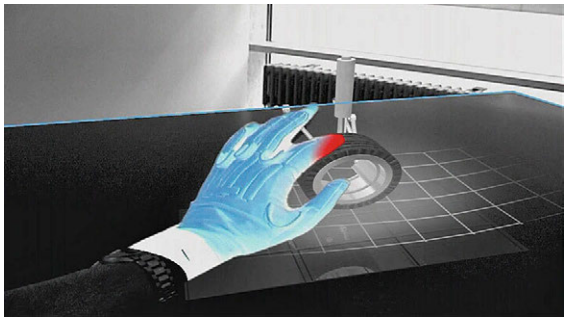

Fig. 55.6 Augmented reality in engineering workspaces (courtesy of Fraunhofer IAT, University of Stuttgart IAO)

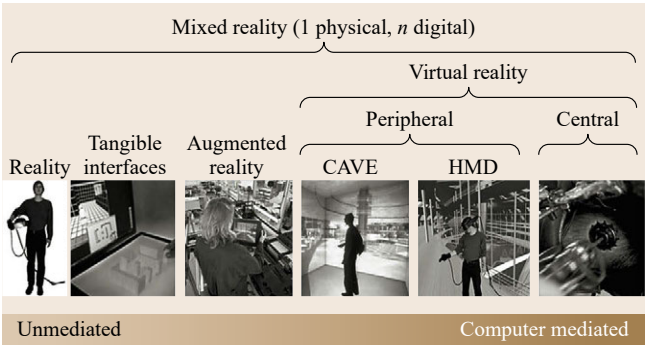

Fig. 55.7 Mixed reality – between unmediated physical reality and computer-mediated virtual reality (after [55.8], courtesy of Fraunhofer IAO, University of Stuttgart IAT)

tion correctly, positioning virtual objects correctly in an observed reality is a key technology for AR.

Using odor in AR is more difficult than in VR. AR is frequently applied in the public space. Released fragrances can be disturbing for persons in the environment and appear as pollution. Wearable devices with integrated dispensing devices could be an option to avoid this. Devices for that purpose are however not yet available. On the other hand situational perfuming using wearable devices could be considered as a contribution to the augmented reality of the future.

55.2.2 Mixed Reality

Mixed reality is an extension of the concept of virtual reality. It denotes a mixture of physical and virtual computer-generated elements in a perception space [55.9]. Augmented reality is hence mixed reality. But mixed reality is not necessarily augmented reality. Mixed reality (MR) is a more precise expression for many VR applications. As soon as the user perceives herself or himself as part of the scene, for example when experiencing architecture or playing games, MR is a more precise denomination than VR. When seated in a virtual scene the user needs a physical seat or chair and VR becomes MR. Perceptible hardware in a virtual scene always means mixed reality (Fig. 55.7).

Applying odor in immersive environments representing a marketplace by commercial devices as used in scent marketing would be considered as MR. In the case where the odor is computer-generated and provided by a universal computer-controlled scent output device it would be considered as VR.

55.3 Multimodality in Immersive Environments

Multimodality is one of the characteristics of immersive environments. Frequently the visual mode dominates the virtual experience and other modalities are neglected. In particular this is the case in many visually based decision support applications in design, architecture and engineering disciplines. In simulation and entertainment applications however, the auditory and haptic modes become important and are addressed. Games and simulations typically utilize sound and proprietary haptic interfaces to improve the experience. The senses to be addressed include the well-known five senses:

- Visual perception
- Auditory perception
- Olfactory perception
- Gustatory perception
- Tactile perception.

Four further modes of perception are relevant including:

- Thermoception
- Nociception
- Equilibroception
- Proprioception.

All modalities are relevant for and used in immersive environments with the exception of nociception, which is usually neglected in nonmedical applications due to ethical reasons.

Nambu et al. [55.10] showed in an experiment that modalities are not independent. They found that olfactory perception is changed by visual cues. They could even achieve olfactory perception by pure visual stimuli.

The multimodal nature of human perception may also lead to simulation sickness in immersive environments. Such a phenomenon occurs among users depending on predisposition as well as on the simulated motions. Simulation sickness arises by reason of conflicts between stimuli and user experience – in particular if perceived motion clues are not in line with previous user experience. A well-known example is missing or imperfect representation of acceleration cues in simulated driving. Impaired breathing air quality and disagreeable olfactory stimuli are supposed to contribute to simulation sickness.

55.4 Functional Aspects of Odor in Human–Computer Interaction

Odor is yet not widely used in human–computer interaction and in immersive environments [55.11]. This is due to the fact that odor is not a means of voluntary communication in humans. But humans perceive and respond to odor, so there are functional aspects of odor, which can be addressed in human–computer interaction as shown in Table 55.2.

As odor depends on chemical substances in the breathing air it is not suited for quick interaction tasks. The substance has to be dispensed and needs time to be transported through convection, diffusion and inhalation to the olfactory receptors. In case the odor needs to be changed the previous substance has to be removed from the inhalation zone or neutralized chemically and to be exchanged by another one. Furthermore the perception of odor has a spatial component, which is determined both by the presence of the aroma and the perception of the airflow [55.12, 13]. The following technical functions are relevant:

- Synthesis
- Dispensing
- Diffusion and ventilation
- Neutralization (chemical decomposition)
- Exhaustion.

A computer-controlled scenting device has to cover at least a subset of these functions and requires also a computer interface.

Table 55.2 Functions of odor in human–computer interaction

Function	Examples
Output of odor as a main purpose of the computer system	Smart wearable perfume dispensers Room ambience control
Feedback in working with odor	Computer-assisted synthesis of fragrances
Odor as part of a simulated experience	Training of firefighters
Improvement of the sense of presence in immersive environments	Virtual service scape engineering for a bakery
Triggering emotional responses	Affective computing
Support of memorization	Ambient assisted living for dementia patients
Nonurgent warnings and notification	Announcing coffee breaks

55.5 System Design

55.5.1 Hardware for Odor Exposure

Hardware for creating scents can be classified according to different variables. Important ones are:

- Affected space
- Fragrance creation
- Physical principle of dispensing (particle release to airflow, vaporization)
- Physical principle of removal (diffusion and ambient convection, exhaustion, neutralization)
- Control of fragrance release.

The affected space can be firstly the personal body space, which can be addressed by head-mounted or otherwise wearable devices. In this case the scent releasing system moves with the user. Secondly the same personal space can be addressed by stationary devices. This includes seat-mounted devices in a cinema or scent-generators mounted at a workstation. Thirdly the affected space can be of room size or partial room size as it is intended with most ambient scenting systems applied today and as it is needed for stereoscopic projection rooms (CAVEs) (Fig. 55.4).

Fragrance or scent creation can take place inside the scent generating system or outside. In the latter case fragrances and scents are prefabricated and only released by the scenting device. In the first case the fragrance is mixed from component substances inside the scenting device directly on site, which allows for much higher variety and flexibility but leads to less sensory fidelity.

The physical principles of dispensing the substances include vaporization from a liquid solution by heat or airflow, Venturi mixing and others. Heat might cause chemical reactions and impact the fragrance.

Overall, there are several ways to remove the scent. The easiest is to use dilution by diffusion and ambient convection. This does not require technical measures. Technical system-integrated solutions comprise exhaustion and chemical neutralization by decomposition of the molecules or by binding odorous molecules to others. The latter method requires neutralizing substances such as cyclodextrins as used in household odor eliminators.

The control of the scent can be achieved manually by switching on and off the dispenser. Closed-loop controllers would for instance control the concentration of

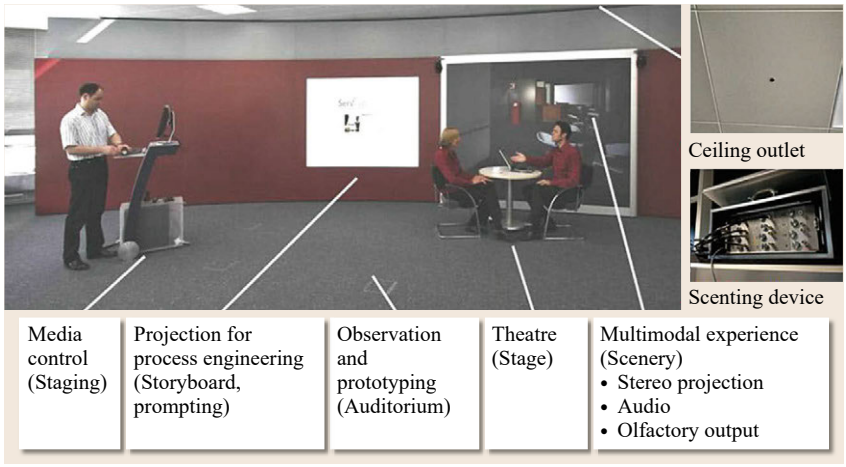

Fig. 55.8 Immersive system for service engineering with scenting device (courtesy of Fraunhofer IAO, University of Stuttgart IAT)

the fragrance in the air. Computer interfaces are the most flexible way to control scents and are targeted for universal use in virtual environments.

There is a limited range of scenting devices on the market. The mainstream can be characterized as single-scent dispensing devices for prefabricated scents. Some products on the market also support chemical neutralization by catalytic decomposition. This can either be implemented as an alternative to scenting or as an additional function.

Most of the devices on the market do not have computer interfaces to allow for software control, which makes them useless for computer-created and controlled immersive environments.

An example of a mixed reality system with a computer-controllable scent output device is shown in Fig. 55.8. The scenting device dispenses up to five different prefabricated scents. These are released from a ceiling outlet. The room is equipped with an air conditioning system to provide ventilation. Furthermore, neutralizing substances can be dispensed by a separate system.

Programmable scenting devices like Smell-O-Vision [55.14] were invented around 1960. The scent experience was designed for cinemas. The system used containers of prefabricated scents ordered in a belt in sequence of appearance. The release was controlled by signals encoded in the film roll. The scents were delivered through pipes at the seats of the audience. The film Scent of a Mystery was produced for this system.

This idea was recently taken up by a Japanese group of researchers from Tokyo applying it to computer or TV screens [55.15]. By controlling the airflow in front of the screen a two-dimensionally distributed localized scent experience is achieved. Most of their research in olfactory displays goes in the direction of supporting spatial perception of odor [55.12, 13, 15].

The first decade of the new millennium saw new start-up companies in the field of computer-controlled scent output trying to commercialize devices. Israel-based Scentcom [55.16] claimed to have developed a technology and proposed applications in games, home movies, toys, military simulation and training, mobile devices and for warnings in motor vehicles. Most of these initiatives and start-up companies failed. Like Scentcom some of them followed the approach of composing odors from a limited set of base aromas. AromaJet [55.17] planned to use 16 ingredients to synthesize scents. But to date commodity computer-controlled multi-scent devices for personal computing or entertainment are not available.

55.5.2 Software and Integration Aspects

Immersive environments have to provide an interactive realtime experience of a virtual, computer-generated reality for its user. This requires software corresponding to these needs. The software must deliver, together with the hardware, a consistent user experience over all modalities. In particular the sensory modalities have to be synchronized. Because olfactory perception is related with time lags due to the physical nature of diffusion and convection the synchronization of scents with the other modalities is not time critical. Acceptable time lags depend on the scene and are typically in the magnitude of seconds. Hardware pipe dead times have to be taken into account as well.

Immersive environments are frequently built on a scene graph representing the structure of the represented scene. Nodes in such a graph represent the objects in the scene. In case of an immersive environment with scent output olfactory properties could be assigned to those objects and will thus become part of the scene graph.

Objects associated with a certain odor could be spaces or rooms. When the user is inside a space or room, the corresponding odor could be released. When the user changes his space the odor of the new space has to be displayed. Another approach would be to assign smell to physical objects in the scene. When the user approaches the object in the virtual space, the corresponding odor will be released from the scent output system. When the user moves away from the object the scent output is reduced or stopped. A certain ventilation of the room is required in these cases to ensure vanishing odors when the user moves in the scene.

These models do not match physics very well. A more complex system would model fluid dynamics and odor transmission in the virtual world on the one hand and in the physical world of the immersive system on the other hand. It will try to match the physical world with the virtual world. The used fluid dynamic computation can vary from calculating simple one-dimensional transportation models up to solving full spatial fluid dynamics models. However, as complex fluid dynamics models cannot be solved in realtime a compromise is necessary.

The disadvantage of this forward control approach is the lack of feedbacks from the physical world. This could lead to a divergence between calculation and reality. Odor sensors with a control algorithm could be used to implement a closed control-loop to overcome this issue.

55.6 Applications

Immersive environments are widely in use in different fields like engineering, architecture, marketing and sales, eduction and training as well as entertainment and even in therapy. Many of them are multimodal. But only in rare cases are olfactory displays applied. The following paragraphs will focus on applications with odor. So it will rather show potentials for the future than productive settings of the present.

55.6.1 Computerized Scenting and Therapy

Immersive environments are usually expected to include computer graphics plus other sensory modalities. In this sense computerized scenting is a border case of a virtual environment or mixed reality. The scent does not originate from the natural physical environment and is not dispensed manually by its user but is generated by the computer and a scent output device thus augmenting the physical environment.

Wearable computer-controlled perfuming or ambient scenting devices belong to this class of application. They are expected to appear in the future either as an evolvement of the products of the traditional aroma industry or as an additional function of the increasing market in wearable devices for sports and lifestyle.

Chen proposes combining virtual reality therapy with aromatherapy approaches [55.11]. One specific suggestion is to apply scents as stimuli in VR-supported therapy of phobia.

55.6.2 Engineering

User-centered product development has become an important approach in product design and development. Human factor engineering includes more physically oriented ergonomics and hardware- and software-related usability aspects but also the aspect of user experience. Instead of focusing on the design of a physical product this approach aims at designing an experience for the user. This paradigm is supported by the view that products are not mainly hardware and software but provide services to their users. Products can also be pure services, where no physical product is provided at all.

This also means that product engineering becomes experience engineering. In digital or virtual engineering immersive environments are used to provide an experience of the product before a physical prototype or mock-up exists. This experience is used for evaluation purposes involving end users and other stakeholders in the product lifecycle.

An example of an immersive experience engineering system is shown in Fig. 55.8. A stereoscopic projection wall is used to provide a visual immersive scene of a service environment for service engineering purposes [55.18, 19]. The laboratory is also equipped with an audio system and an accenting device to allow for a multimodal experience.

Another example for the aroma industry is use-context-sensitive decision making for aroma products. The context of use is displayed visually or audio-visually and scents are presented in parallel. The decision makers experience the product in the use context and decide context-aware.

Odor is frequently considered as a component of the product and the user experience. This holds true not only for cosmetic products, food or coffee but also for more technical products like cars, where the odor is even used for branding. In these cases odor has to be an integral part of experience engineering. In consequence

it needs to be implemented in immersive environments for holistic experience engineering.

A special case of experience engineering is product customization. The customer is involved in the design of the product and has degrees of freedom in selecting among a finite number of options or even a range of product parameters. This results in a high number of combinations and requires production on demand.

This can also be applied to product-related aromas. In these cases the customer needs a feedback on his/her choice, which again results in the need for computer-generated aromas. The World Wide Web and a web browser are frequently used for mass customization. Due to a lack of commodity scent output devices for computers this is not possible for scent customization. Therefore special devices have to be provided at the point of sale.

55.6.3 Marketing and Sales

Scent marketing has gained importance during the last decades. Scent is used in supporting the sales process by:

- Providing a positive shopping experience
- Advertising the product with its own odor (billboard scenting)
- Establishing a brand (scent branding).

Frequently natural scents are used. A typical example is baking at the point of sales in the bakery. If this is inappropriate, for example for packed convenience food stores, scenting devices at the point of sale can be applied. They also allow for a better control of intensity of the odor. In cases where the experience varies over time a computer-controlled immersive environment could be applied. This can be the case if several user experiences are related to a product, or a product story needs to be told, or if several products or product variants shall be displayed in sequence. A typical and comparably simple setup would include a visual display presenting video sequences and a synchronized scenting device.

55.6.4 Education and Training

Immersive environments allow for the creation of a sense of presence for education and training purposes. In particular an immersive simulator is a valuable tool where highly automated decisions and behavior have to be acquired. This holds particularly true if the situations are dangerous or hard to reproduce.

In a more uncritical situation a programmable scenting device could be applied for training sensory analysis. A multimodal immersive system could be used to train scent recognition, design or selection in a sensory context.

In more complex situations scents are also relevant, for example in medical education and training or in chemical and fire hazard and military training.

Immersive environments with scent output can also be applied in virtual experimental history approaches to generate historical experiences for research and educational purposes.

55.6.5 Entertainment

Audio-visual entertainment is developing towards more immersive experiences. Stereoscopic devices are used in movie theaters as well as in home entertainment and games. While scent as an supplementing modality for audio-visual experiences in entertainment for the masses such as movies, TV and games has been a topic of research and start-up enterprises for decades, it has not yet been possible to establish such a technology for the masses.

Even custom-built multimodal theaters, presenting so-called four-dimensional (4-D) programs, rather focus on kinesthetic and tactile enhancements and use smell only sparingly.

55.6.6 Conclusion

In conclusion, there is a lack of immersive environments using odor. The application of odor suffers from the nonexistent market of computer-controllable scent output devices. Although there were several attempts during the last decades to introduce scenting devices into mass markets for entertainment purposes such as cinema, TV and games, there was no success. A more likely path to such devices might be the developments in the aroma application industries. Wearable devices for dispensing and dosing scent and aromas could be point in the right direction.

56. Odor in Marketing

Nathalie Nibbe, Ulrich R. Orth

Marketers are increasingly using scent for differentiating, enhancing, and promoting products, and services. The spreading commercial use of scent, however, stands in contrast to a limited and fragmented body of knowledge on how people as consumers perceive and respond to olfactory stimulation. To facilitate a better understanding of opportunities and limitations to the commercial use of scent, this chapter reviews the state of research in the psychology, consumer behavior, and marketing literature. Extant studies examine scent as a primary product attribute, a secondary product attribute, an agent for promotional efforts, and as an ambient cue. Organized in six major sections, the chapter starts with a discussion of effective characteristics and the human processing of scent. A comprehensive review of consumer responses to scent follows. Section 56.4 adopts a multimodal perspective to illustrate how scent interacts with other sensory modalities to influence consumers as multisensory beings. Section 56.5 highlights individual and situational factors that can enhance or mute olfactory effects. The chapter concludes with a discussion of ethical aspects and outlines avenues for future research that may prove beneficial to both researchers and practitioners.

56.1 Using Scent for Marketing

In a world where consumers encounter countless choices, marketers are trying to find new ways for their offers to stand out, appeal to, and ultimately persuade shoppers. One option that is attracting more and more attention is to deliver more complete and holistic sensory experiences. For example, engaging multiple senses aids brands in being perceived as more distinctive and successful [56.1], and getting better remembered [56.2]; it also increases the attractiveness of retail environments to visitors [56.3], and enhances the overall persuasiveness of marketing communication [56.4]. While vision can be considered the key modality in consumer perception and processing of offers [56.5, 6] – engaging additional senses can enhance the overall consumer response, leading to more favorable affect [56.7], cognition [56.8], behavior [56.9], and memory [56.2, 8–10]. This capacity for triggering more positive consumer response is particularly evident with the sense of smell due to its unique properties [56.11]. Scent marketing, defined as *using scents to set a mood, promote products or position a brand* [56.12], has thus attracted the attention of both researchers and practitioners.

Morrin [56.3] classifies the use of scent in marketing products and services into four categories:

1. Scent as a primary, product attribute
2. A secondary product attribute
3. Part of a promotional effort
4. Ambient scent.

Scent is considered a *primary product attribute* when it represents the major driver of consumer purchase, such as the fragrance in perfumes or deodor-

ants [56.13]. In those cases, scent provides key information about the product, such as a deodorant's freshness or an after-shave's soothing quality. In contrast, scent is considered a *secondary product attribute* when the product's primary attributes are not scent related. In those cases, scent is used for differentiation, distinguishing the product from alternative options. For example, some people can tell the Nivea crème apart from other brands even when blindfolded because they recognize the brand's unique scent [56.14]. In the third category, scent is being used in *advertisements and sales promotion*. For example, in 2006, advertisers attached scented paper stripes to *Got Milk* billboards promoting dairy products to commuters at various bus stations in San Francisco. The stripes emitted the scent of freshly baked cookies to entice consumers. Similarly, in 2012, McCain launched an integrated marketing communications campaign involving scent to promote a baked potato product to shoppers in Great Britain. After pressing a button on a bulging 3-D-baked potato, consumers could smell the product and receive a money-off coupon for their purchase [56.15]. McCain also used other measures including automatic scent dispensers that released the smell of baked potatoes in the frozen-food aisles of supermarket every time someone passed by and specially fitted taxis with huge three-dimensional (3-D) potatoes on their roof driving through cities in the United Kingdom. Perhaps the most common use of scent in marketing is its diffusion as an *ambient cue*, a scent that cannot readily be attributed to a particular object but is present in the environment. Ambient scent is widely used in many kinds of environments ranging from hotel lobbies to retail outlets, casinos, airlines, and hospitals [56.16]. Pioneering the commercial use of ambient scent in the 1990s, Singapore Airlines had an aroma specifically designed for its fit with the airline's corporate image to be used on the hot towels served before takeoff and landing as well as in the flight attendants' perfume [56.1].

Using scent for marketing to consumers in a psychologically sophisticated manner provides challenges that do not necessarily follow all the rules of other types of (sensory) marketing. Olfactory marketing has distinct combinations of properties and mechanisms that lead to unique patterns of psychological responses and therefore demand out-of-the-ordinary attention to a variety of issues. This chapter advances the understanding of scent in marketing by bringing olfaction, consumer psychology, and marketing communications together to further business practices and research. Readers will learn some of the latest insights in the areas of:

1. Effective properties of scent (specific drivers of consumer response)
2. Effects attributable to scent (the range of consumer reactions to scent)
3. Interactive effects with information obtained through other sensory modalities
4. The contingency of effects upon individual and situational factors.

This chapter further summarizes and refines what we know about marketing and consumer psychology in relation to scent; it includes a comprehensive review, innovative conceptual frameworks, and empirical studies. We trace the work of scholars who can be characterized as pioneers in the field. Our review is selective and not exhaustive. Our intention is to illustrate how the training, creativity, and motivation of notable researchers provided a significant part of the foundation of this field as we know it today and as it is reflected by the sections in this article. The chapter's sections are structured as follows. First, a discussion of effective characteristics and the human processing of smell is presented. Then a detailed review of odor effects on consumers follows. Given that in the marketplace consumers are usually not exposed to scent only but additionally to information obtained through other senses, the third section sheds light on the interaction of scent with other sensory input. The fourth section offers evidence for what individual and situational factors enhance or attenuate scent effects. Finally, ethical aspects and promising avenues for future research are discussed.

56.2 Effective Characteristics and Processing of Scent

56.2.1 Effective Properties

In psychology and the cognitive sciences, perception is the process of acquiring, interpreting, selecting, and organizing sensory information [56.17]. What, exactly, is it that makes people react to scent, specifically, what are its effective properties? Research points to four properties that trigger consumer response to scent: character, pleasantness, familiarity, and intensity.

Relying on six to ten million receptors located in the olfactory epithelium [56.18], the human nose does relatively well in detecting and discriminating the *character* of between 2000 and 4000 different scents [56.19]. Untrained people are not good, though, when it comes to

identifying and characterizing scents [56.20]. For example, when asked to name the scent of at least half of the scented household items used daily, consumers fail [56.21–23]. The rate of success improves when the familiarity of the scent increases [56.24], but, very commonly, people experience a feeling of recognition and familiarity while being unable to voice a verbal description or assign a semantic label (the *tip-of-the-nose* phenomenon) [56.24]. This difficulty in naming a scent is thought to derive from a variety of reasons. One reason could be that in our evolutionary past naming an odor has not been essential for survival. It is usually enough to detect a scent and discriminate it [56.25]. A different reason might be that in everyday life odors most frequently occur within a context. It has thus been argued that the weak performance in odor naming tasks is due to a lack of context [56.26]. A third reason for the lacking ability to name scents may lie with the relatively weak semantic link between an odor and its name. It is conceivable that the areas of the brain responsible for processing words are located apart from the olfactory processing areas, at least further than for other sensory modalities [56.27]. In addition, odor processing and language processing engage identical cortical resources [56.28]. Therefore, simultaneous processing of language and olfaction leads to a competition for processing resources, hereby making it difficult to name odors [56.20]. Some of these limitations, however, may be overcome as people can be trained to enhance their ability to name and describe odors more accurately [56.29].

A scent's *pleasantness* is sometimes viewed as a property almost as important as its character [56.30] because people routinely and quickly establish if they like an odor or not. Past consumer research even suggests that odors are primarily perceived in terms of their pleasantness or unpleasantness, the individually and positively evaluated stimulation of the olfactory senses [56.31]. Beyond pleasantness, individuals perceive and respond to a scent's *familiarity* and *intensity*. While the evaluation of pleasantness and familiarity is often highly correlated (familiar scents are evaluated as more pleasant and vice versa) [56.32], the relationship between pleasantness and intensity is more complex [56.33]. Familiar odors are better liked than unfamiliar odors; also, pleasant odors are often found to be more familiar. In comparison, the relationship between odor intensity and pleasantness often can be characterized as an inverted-U function, depending on the specific scent. A perfume smells pleasant, as intensity increases, but only up to a point. Beyond that point the scent intensity becomes so strong as to be evaluated as unpleasant. Yet, with some scents, the relationship between intensity and pleasantness may be linear rather than bell shaped. Whereas a light fish odor may be acceptable, the evaluation may become continually more unpleasant as intensity increases [56.11].

The issue whether hedonic differentiation in human perception of odors is innate or learned is still under discussion. Support for the claim that hedonic discrimination is innate derives from research on taste perception which suggests that this mechanism is mostly hardwired [56.34]. However, there is also evidence for the associative learning theory [56.27]. According to this theory, one item (a scent) becomes connected to another (the judgment of pleasantness) as a function of an individual's past experience [56.35]. Supporters of the associative learning theory claim that newborns lack any odor preferences. Over a life time, odors occur bound to experiences and emotions, and hedonic responses are developed [56.30]. Therefore, the hedonic perception should depend on individual experiences.

56.2.2 Scent Processing

Given that other chapters are dedicated exclusively to the human processing of scent, we just briefly highlight a few issues with unique relevance for marketing. First, scent is special in that some scholars consider it the slowest sense when it comes to information processing [56.11]. Second, different from all other sensory inputs, olfactory information is relayed directly to the amygdala-hippocampal complex without any mediators in between. Input obtained through all other senses is routed first to the thalamus [56.11], which then relays the information to higher cortical areas. Further relevant to scent processing is the close proximity of the olfactory nerve and the amygdala (which are only about two synapses apart) and the hippocampus (three synapses) [56.11]. The amygdala is critical for processing of emotion and emotional memory [56.36, 37], and plays a key role in classical conditioning [56.38], and associative learning [56.39]. The hippocampus is a key player in short- and long-term memory and is involved in a variety of declarative memory functions [56.11]. Furthermore, the hippocampus is where most of the cross-modal integration takes place, that is, the combination of information obtained through two or more sensory modalities [56.40–42]. Finally, there is evidence pointing to olfaction and emotion as being intimately connected during neuro-evolution [56.43]. Both brain areas involved in the processing of scent, amygdala and hippocampus, evolved from a tissue that was formerly olfactory cortex, thus indicating that structures now dedicated primarily to emotion and associative learning were previously exclusively dedicated to scent processing.

Taken together, the unique ways of human olfactory information processing suggest that no other sense has such an instantaneous and explicit connection to the brain areas related to emotion, memory, and learning. This special processing combined with the large number of options available in influencing effective properties of scent is perhaps the major reason for scents holding appeal to marketing.

56.3 Consumer Response to Scent

Using scent for marketing products and services is an emerging idea. Not all effects are fully understood yet and some aspects are still heatedly debated [56.44]. The following sections detail specific consumer responses to scent, including changes in affective states, evaluative judgment, intention, behavior, and memory, and offer some integrative models.

56.3.1 Change in Affective States

Human affective states include both emotions and moods [56.45]. Marketing researchers commonly differentiate both concepts along the dimensions intensity, durability, and reference [56.46]. Moods are less intense, longer lasting, and largely unintentional in that they occur in the absence of a reference object. Emotions, in contrast, are more intense, short-term, and object-related, and incorporate some element of cognitive processing; in other words, emotions are *moderately mediated* by cognition [56.47]. In line with the dispositional theory of moods [56.45] and the affect-as-information paradigm [56.48] affective states are recognized for their role in impacting consumer behavior.

Among the most frequently discussed responses to scent are shifts in consumer mood and general affect [56.31, 49–52], often measured in terms of the *pleasure* and *arousal* dimensions of the PAD (pleasure – arousal – dominance) scale developed by *Mehrabian* and *Russell* [56.53]. Reported outcomes are not consistent, though. Reviewing twenty-two studies on ambient scent in retailing and consumer services, *Bone* and *Ellen* [56.44] found large variance in effects evidenced by more than 200 different consumer reactions; only three studies, however, demonstrated a significant effect of an ambient scent's presence on consumer mood. Other studies similarly failed to provide corroborating evidence [56.9, 54, 55], providing little to no support for what popular press repeatedly refers to as the myth of seducing shoppers through ambient scent [56.4, 12]. Strong negative evidence is further provided through *Chebat* and *Michon*'s study as shoppers' positive mood was completely unrelated to ambient scent and pleasure did not mediate the effects of ambient scent on behavior. It was therefore concluded that effects initially attributed to ambient scent may, in fact, be due to an interaction between scent and other factors rather than exposure to scent only [56.56–58]. Consistent with this interpretation, *Orth* and *Bourrain* [56.7] showed that the pleasantness of an ambient scent enhances the influence of consumer affective states (mood) on behavior, thereby stimulating exploratory tendencies, such as the exploration of unfamiliar offers and consumer acquisition of radically new offers.

Contrasting the lack of evidence in shopping contexts, the direct influence of scent on mood has been one of the major principles in aromatherapy; some fragrances even trigger physiological reactions (change in heart rate) in close correspondence with shifting moods [56.59]. Experimental (but not field) studies have generated corroborating evidence. For example, when completing a mood questionnaire in a room scented either with lavender and lemon (pleasant scents) or dimethyl sulfide (unpleasant scent), panelists in the pleasantly scented condition reported significantly more positive moods than did panelists in the unpleasantly scented condition [56.51]. In line with this finding, women seated in a dentist's waiting area exhibited more positive moods when the room was scented with an orange aroma than when it was not scented [56.60]. Contrasting the majority of retailing studies, *Doucé* and *Janssens* [56.61] found a positive effect on consumer mood (greater pleasure and higher arousal) when an upscale clothing store was scented with a minty lemon aroma. The authors emphasize, however, that their results likely trace back to their examination of high-involvement products (prestigious clothing) rather than the low-involvement products studied in previous research (school supplies, decor items, toiletry, and household cleaning products).

In summary, changes in affective states do not always emerge clearly from studies trying to link scent to mood. Although some studies have been conducted in realistic settings, such as a casino [56.62], a fashion store [56.61], or a shopping mall [56.56], most research has been conducted in artificial laboratory situations [56.9, 63] with differences in findings suggesting that effects may depend on additional individual or situational factors. We will revisit this issue later when discussing conditions and moderators of consumer response to scent.

56.3.2 Evaluative Judgments

Conveying meaning to consumers is one of the central objectives in marketing. To convey meaning (such as a product's quality, a brand's personality, or a store's price level) retailers, servicescape and brand managers around the globe employ a variety of visual, haptic, auditory, and olfactory cues. Quality is important because it represents the cognitive evaluation of an offer's intrinsic core benefit [56.64]. At times when this functional benefit is difficult to judge consumers employ extrinsic cues, including scent to infer quality [56.65]. Brand personality is important because it systematically captures and categorizes facets of brands in terms of generalizable symbolic benefits [56.66], enabling consumers to express themselves [56.67], and assisting managers in differentiating offers [56.68]. Companies that succeed in conveying a certain meaning, therefore enjoy advantages in terms of heightened consumer attention [56.69], better recognition [56.70], more favorable behavioral intentions [56.65, 71–73], extra advantageous positioning [56.74–76], and superior financial performance [56.77]. Although marketers – in principle – recognize the potential of conveying meaning through scent, the literature investigating this topic is still limited, with the majority of studies focusing on scent as a secondary product attribute, and only a few studies examining ambient scent.

Focusing on *scent as a secondary product attribute*, research on evaluative responses has commonly examined effects on consumer judgment of product attributes and overall quality [56.44]. Pioneering research in this field, *Laird* [56.78] instructed housewives to rate the quality of panty hoses in a home use test. Three of the hoses were lightly scented (aromas of flowers and fruits), the fourth was not. Regardless of the specific scent, study participants rated the scented hoses significantly better in terms of quality (as more durable, pearly sheen, and stronger); an effect that extended to higher preference. In addition, differences between the scents emerged as half of the participants preferred the panty scented with a narcissus scent. Examining the question whether or not a scent has to fit the product to elicit positive evaluation, *Bone* and *Jantrania* [56.8] found that consumers, in fact, evaluated a product more favorable if they judged a scent to be appropriate. Nevertheless, a broad range of key product attributes were uniformly rated more positive when the product was scented rather than unscented, regardless of whether the scent was deemed appropriate or not.

Examining consumer response to *ambient scents*, researchers selected scents according to their affective charge (pleasant, unpleasant) for use in a laboratory setting. The scents were diffused in a room designed to resemble a one-stop shopping outlet for students with merchandise consisting primarily of household items and school supplies. Adding a scent significantly improved visitor ratings of merchandise quality compared to the no-scent condition [56.54]. This finding was later replicated in a field study where the presence of a pleasant scent improved the consumer perception of an actual shopping mall and increased the amount of money spent by shoppers [56.56]. Merging research on ambient scent with studies of scent as a secondary product attribute, and extending the focus to brands, *Morrin* and *Ratneshwar* [56.55] requested members of a consumer panel to rate familiar and unfamiliar brand names in the presence of select ambient scents. The findings indicate that consumers evaluated the brands more positively when a pleasant scent was present.

Taken together extant research substantiates scent's ability to influence consumer evaluative judgments related to products, brands, and shopping environments. Differences in researchers' focus on effective scent properties (presence, valence, aroma), contexts (products, brands, environments), and dependent variables (overall quality, specific attributes) render it difficult, though, to deduct broad conclusions or infer general guidelines. In addition, making study participants aware of scents, an approach employed in several of the studies (respondents explicitly submitted scores on scent properties), may generate exaggerated or skewed findings [56.79].

56.3.3 Memories

Recent research highlights evoking involuntary autobiographical memories as a possible mechanism for successfully marketing to consumers [56.80]. Involuntary memories, one of Ebbinghaus's three basic kinds of memory, are memories of personal experiences that come to mind spontaneously – that is with no preceding attempt at retrieval [56.81]. Different than voluntary recall (deliberately retrieving memories), the activation of involuntary memories involves little executive control [56.82] as implicit memories are brought to mind automatically by a variety of cues including scent [56.83, 84] (Chap. 42). When implicit memory becomes accessible, the resulting experience shares many of the properties of the original experience. It is vivid, accompanied by subjective feelings and physiological changes, and commandeers attention, thought, and behavior [56.82].

Due to their unique processing, scents are considered superior to other sensory input in evoking vivid and complex memories [56.41, 85]. Implicit memories triggered by olfactory cues are usually highly personal, consist of fewer cognitions, and are accom-

panied by strong affective charges [56.86]. In comparison to autobiographical memories evoked by visual cues, scent-evoked memories trace back farther into one's past [56.87], and are accompanied by more and stronger feelings [56.85]. Integrating research on atmospherics with autobiographical memories, *Orth* and *Bourrain* [56.7] investigated the influence of scent-evoked nostalgic memories on consumer exploratory behavior in a laboratory environment scented with natural and manmade odors. The findings indicate that ambient scent evokes nostalgic memories, which in turn positively influence consumer sensation seeking with downstream effects extending onto exploratory tendencies, namely risk taking, variety seeking, and curiosity-motivated behaviors.

Most of marketing and consumer research studies have concentrated on examining scent as a secondary product attribute and as a means to promote brands. Scenting *products* with an appropriate scent can enhance individuals' memory for information about the product as well as associated attributes [56.88]. For example, when consumers were presented with a pencil, either scented with a common scent (pine), an uncommon scent (tea tree), or unscented, they remembered the information included on the uncommonly scented pencil best after a period of two weeks had passed [56.89]. Because the information on the commonly scented pencil was also remembered better than the information on the unscented one, the researchers concluded that scenting products improves consumer remembering of product information, regardless of the specific aroma.

Accompanying an *advertisement* with a pleasant and appropriate scent (diffusing rose or sandalwood aroma during a commercial promotion of a spa in a movie theatre) enhanced consumer recall of attributes (unaided as well as aided) compared to a no-scent condition [56.90]. Similarly, when seated in a room with an ambient scent, consumers recalled unfamiliar brand names better when the scent was pleasant rather than in an unscented condition. Further analysis suggested that this finding relates to a scent's pleasantness increasing attention as consumers spent more time evaluating the offer.

The literature discussed advocates that both ambient and product-related scents influence consumers' memories and behavior. Specific effects, however, hinge on the individual recollection of and personalized meaning attached to scent-evoked memories.

56.3.4 Behavior and Intention

One of the key effects of olfactory stimuli is their directive function. Ambient scents alert the organism to the existence of agents in the air, to check their quality for the guidance of behavior on the basis of previous encounters, to avoid or approach certain states [56.91]. This capacity of scents to heighten awareness is thought to be the primary cause for people's basic approach and avoidance responses [56.54]. Given that perceiving odors requires little, if any cognitive effort [56.31], no conscious attempt is required for fundamental behavioral responses, such as taking a deeper breath when a pleasant scent is present or holding the breath in the presence of an unpleasant scent [56.92].

The literature holds ample evidence for ambient scent's influence on consumer behavior. Behavioral responses assessed by researchers center on approach-avoidance, with specific measures including the length of a person's stay in an environment, spending, and behavioral intention. For example, in the presence of a pleasant and congruent scent, the amount of time consumers spent in a store increased in comparison to an incongruent pleasant scent condition [56.93]. This finding similarly holds for restaurants, where a pleasant lavender ambient scent related to consumers staying for a longer time, and spending a larger amount of money [56.94]. In casinos, diffusing an ambient scent increased the amount of gambling [56.62]. More recent findings, however, suggest that ambient scent can exert divergent effects depending on what type of shopping behavior is examined [56.95]. While ambient chocolate scent facilitates general approach behavior and increases the amount of money patrons spend in a bookstore, it also leads to less goal-directed behavior. Specifically, positive effects of the chocolate scent occur only when the product is thematically congruent with the scent. Accordingly, the sale of congruent books (e.g., cooking or baking guides) increased, whereas the sale of incongruent books decreased. Further support for the possibly important role of congruence stems from *Fiore* et al.'s [56.96] study testing the effect of ambient scent on consumer response to a product display. The findings indicate that consumers exhibited a significantly higher purchase intention and were willing to pay a higher price when the scent was both pleasant *and* congruent with the product displayed compared with a no-scent condition and a pleasant-scent-only condition.

In sum, the presence of an (pleasant) ambient scent impacts consumer behavior in terms of the time spent in the environment and the amount of money spent. Yet, some scholars caution that empirical evidence does not always support these outcomes [56.97]. Particularly, the psychological mechanisms of the reported effects on approach-avoidance behavior are not well understood and need further investigation [56.55].

56.4 Cross-Modal Effects

Our previous discussion of olfactory effects indicates that scent can impact consumer responses in a variety of ways. Readers should note, however, that the majority of studies have either examined scent in laboratory experiments (with other sensory input considered a distorting factor to be minimized) or have examined consumer response to scent in field studies that did not account for variation in other sensory input. These approaches do not fully reflect the reality of consumers experiencing the world through all of their five senses; in the marketplace individual judgments about a store, its products, and even its personnel, are driven by a concert of smells encountered, things heard, objects touched, taste experienced, and the products seen [56.17]. It is therefore imperative to consider cross-modal effects involving scent.

Humans are equipped with five basic senses (their olfactory, auditory, tactile, gustatory, and visual systems) with each modality providing sensory information about the environment. Although, overall, vision is considered the most informative and olfaction a less informative modality [56.5], the relative importance of each modality depends on the individual situation. For example, olfaction is more functional in providing information about a product being clean and safe [56.6], and a lack of olfactory input negatively impacts consumers' product experience [56.98]. In many cases (such as with the color and scent of food), specific product properties need to co-occur to signal safe use. This association in input received through two or more sensory modalities, termed *cross-modal correspondence* [56.99], is still an emerging area in research on consumer behavior. While the initial studies in this area have focused more narrowly on the interaction of two sensory modalities, such as color and scent [56.100–102] or music and scent [56.103, 104], a few studies have started examining multisensory effects in marketing contexts, such as interactive effects of scent and touch on product evaluation [56.89] or effect of scent and vision on memory for a product [56.89]. The next sections discuss noteworthy cross-modal effect studies in more detail.

56.4.1 Olfaction and Vision

Many sensory studies converge on the finding that the sense of vision dominates the other senses, as is the case in the interaction between visual and olfactory stimuli. Although there is large variance in effective properties for both, scent and vision research has mainly focused on the interaction of scent aroma and object color. Two streams of research relate to (1) color cues influencing scent perception and (2) visual and olfactory cues jointly influencing the individual evaluation of and response to products.

Although the influence of one sensory modality (vision) on another modality's (scent) input is not a straightforward marketing issue, much research has been dedicated to how colors affect scent perception, yielding some important insights for marketing [56.105]. For example, when fragrant liquids are colored appropriately rather than inappropriately (cherry-scented liquid that is colored red versus green), humans are more likely to identify the scent correctly [56.106]. This finding holds not only with abstract stimuli, but also extends to consumer products, as wine experts use descriptors that are typical for red wine for describing a white wine when it is colored red [56.107]. According to *Demattè* et al. [56.100, 105] the dominance of the sense of vision over olfaction is so strong that people are biased by color even when explicitly instructed to ignore visual cues. For example, when asked to identify scents and ignore visual cues (color) presented jointly with the olfactory cue, participants' responses were biased in that their identification of scents depended on the color. This biasing effect of color not only applies to scent identification [56.108], but also extends to the individual judgment of scent intensity [56.102] as visual lightness and odor intensity appear to correlate.

Investigating possible causes for the biasing capacity of vision, researchers posit that the interaction of color and scent takes place at the perceptual level [56.108]. Functional magnetic resonance imaging corroborates this view, indicating that the brain regions activated for processing pairings of scent and color vary as a function of the perceived congruence of these pairings [56.109]. Labeled a *perceptual illusion* [56.110–112], the concept reflects the fact that – following sensory input – a higher level of information processing (at the semantic level) relates to divergent olfactory perception. Further adding to the evidence of vision–scent congruence effects at the semantic level, individuals evaluated an identical scent as more pleasant when it was labeled positively (*cheddar cheese*) rather than negatively (*body odor*). In the latter case, the scent was also rated as more intense [56.113].

Putting the semantic congruence between vision and olfaction to practice, fragrance producers carefully match the colors of the vessel to the liquid, and design elaborate color schemes for packages and advertisements to better inform shoppers about their fragrance [56.99]. Package color has been identified as an especially effective tool for steering shopper ex-

pectations regarding levels of scent intensity (high: dark red; low: pastel green), sweetness (high: dark red; low: pastel green), and freshness (high: pastel green; low: dark red) [56.114]. Joining these findings with insights that the consumer perception of a deodorant's scent depends on the color of the package, it is therefore thought that people perceive the package and the content not separately but as a single integrated whole [56.99].

56.4.2 Olfaction and Other Sensory Input

Much less research has focused on the interaction of scent with other sensory input besides vision. A few studies have examined the cross-modal interaction of scent with auditory input (obtained through the sense of hearing) and haptic input (obtained through the sense of touch). As with the sense of vision, most studies focus on very basic relationships between sensory properties; only few examine outcomes more directly related to marketing.

Paralleling the previously discussed congruence effects between color and scent, a similar phenomenon has been established for the interaction between scent and auditory pitch. Qualitatively different odors correspond with different levels of pitch and sound volume. Fruity scents, for example, relate to higher pitch [56.103, 104], and the volume of a sound is positively associated with the perceived concentration of a scent [56.115]. More directly relevant to marketing environments, congruence in music and scent (their stimulating quality) leads visitors to rate an environment significantly more positive, with effects further extending to approach and impulse buying behavior, and an increase in satisfaction [56.116]. *Spangenberg* et al. [56.117] attribute this finding to the moderation effect of background music. In their study, consumer evaluations of the store were more favorable when the scent was congruent with the music (Christmas scent – Christmas music). Combining an identical scent with incongruent music (Christmas scent – non-Christmas music), however, leads to less favorable evaluation. Overall, carefully combining music and ambient scent may lead to an enhanced shopping experience and more profitable retail. Again, stimulus semantic congruence appears to be the key.

Regarding the cross-modal interaction of olfactory and haptic stimuli, only a few studies exist. Initial findings hint at the existence of a cross-modal link between scent and haptic similar to the previously discussed interaction effects of scent involving color and music [56.118]. Presenting a soft versus rough piece of cloth jointly with either a lemon or animalistic scent yielded softness ratings that varied significantly depending on the scent (were higher for the lemon scent). While this outcome was obtained using explicit measures (psychometric scales), a subsequent experiment confirmed that this effect also held when associations were assessed implicitly (using an implicit association test; [56.119]). Adding different scents to a shampoo yielded a significant effect of scent on the perception of haptic dimensions as participants – when washing their hair with the shampoo – evaluated both the fluid and their hair as softer. Similarly, using different scents influenced a product's haptic characteristic such as thickness [56.120]. Further strong evidence for scent's capacity to affect haptics stems from the research by *Krishna* et al. [56.10]. Scenting a cold versus a hot gel pack with a *hot* (pumpkin cinnamon) versus *cold* (sea-island cotton) scent elicited more positive evaluations of the gel pack with consumers when the scent matched the temperature. Perhaps even more important, participants evaluated the packs as more effective and faster in treating pain (sea-island-scented cold pack) and in warming one's hands (pumpkin-cinnamon-scented hot pack). Summarizing empirical studies on bimodal interactions involving scent yields that a major driver of consumer response is the semantic congruence between olfactory input and sensory information obtained through other modalities.

56.5 Moderators

Researchers and practitioners alike often seek to better understand what the conditions are for enhancing or attenuating (possibly even cancelling) effects of scent on consumer response. Addressing the corresponding question of *when*, moderation studies provide answers by generating insights into conditional values of moderator variables. While the preceding sections have implicitly referred to moderator variables (semantic congruence), the following paragraphs provide a more structured overview of salient variables in terms of conditions for scent to exert an effect.

56.5.1 Congruence

A recurring issue in studying how scent influences consumer behavior is the possibility that effects may depend on the congruence of the scent with other stimuli [56.8, 116, 117]. Of the many theoretical accounts

put forward to explain consumer response to scent, the vast majority acknowledges that responses may be moderated by the congruence between a scent and the product, the category, the shopping theme, or input received through another sensory modality. Congruence here is defined as the degree of fit or match among salient properties of two or more stimuli [56.10].

Product congruence effects were reported in *Bone* and *Jantrania*'s [56.8] study where a sunscreen lotion scented with a coconut aroma received more positive evaluations of product beliefs and attitude than the same lotion with a lemon scent. Similarly, consumers found a household-cleaning product combined with a lemon scent more appealing than one with a coconut scent. In both studies, approach behavior toward the product was enhanced by a higher product-scent congruence.

Regarding *congruence with other sensory input* music has received much of the attention in research with results indicating that congruence between music and scent leads to more positive evaluation of the shopping environment, an enhanced shopping experience, a higher level of approach behavior and more impulsive shopping in a mall. For example, studies on retail atmospherics indicate that when ambient scent and background music match in terms of arousing quality (high/high or low/low; [56.116]) or their consistency with a holiday (Christmas music-Christmas scent; [56.117]), consumers experience increased pleasure, evaluate the store more positively, and ultimately exhibit approach behavior.

A special case of congruence exists when consumers explicitly assess the fit in terms of semantic associations among stimulus properties [56.10]. Because of mutual associations with the experience, individuals assign sensory stimuli a semantic meaning; congruent associations then lead to a more positive evaluation of products and enhance the perception of this semantic meaning. Semantic congruence research is distinct in that it changes the focus from the perceptional to the cognitive processing level. A prominent example is *Krishna* et al.'s [56.10] testing of feminine versus masculine scents in combination with rough versus soft paper. The semantic congruence (assessed in terms of roughness–softness) moderated effects of the bimodal sensory input. In all, cue congruence appears to be a key concept in understanding consumer response to scent.

56.5.2 Individual Differences

There are a number of individual differences relating to both the perception and impact of scent. Individual differences include not only demographic variables (age, gender) but also chronic tendencies (personality traits) and situationally activated and less stable individual states (mood).

Regarding scent perception, a substantial body of evidence advocates that people differ in their ability to smell, that is, in their capacity to detect and identify olfactory input [56.121]. This individual difference traces back, in part, to differences in people's genetic information. In addition, prominent environmental factors, such as smoking habits and age affect the human ability to smell. Smoking has a negative impact as it reduces the number and sensitivity of receptors available for receiving scent molecules [56.122]. Similarly, aging has a negative impact as – over one's life span – receptors become dysfunctional or die [56.123]. Gender, in contrast, has no major effect; women and men appear equally capable of detecting and identifying olfactory input [56.124].

Regarding the impact of scent, age may have an effect as an ambient scent impacts individual spending during a shopping trip with young people but not with older people [56.125]. Adopting a more holistic perspective, *Davies* et al. [56.126] stipulate that the way in which an ambient scent is perceived depends on the objectively present ambient scent and the acuity of the consumers, which is influenced by individual characteristics, such as age and gender. This view is consistent with [56.60] finding of gender differences in mood shifts with men (no change) and women (mood shift) seated in a dentist's waiting area scented with an orange fragrance.

56.6 Ethical Aspects

Ethics generally distinguishes between the *right* or *good* and the *wrong* or *bad* [56.127]. The following paragraphs are intended to alert readers to a few of the challenges and pitfalls involved in (a) using scent for marketing purposes (marketing ethics) and (b) conducting research on consumer response to scent (ethics in consumer research).

Questions of *marketing ethics* arise when companies come to market with products aimed at consumers. Given the imperative of operating at a profit, commercial marketing activities can raise ethical questions [56.128]. Resolving these issues then depends on the perspective taken, especially whether one adopts a more deontological or teleological view-

point [56.129]. Quite commonly, resolving issues of marketing ethics also involves governmental regulation. Critical voices have expressed very specific concerns about marketers employing scent for misguidance, deception, and manipulation of the consumer. For example, it has been argued that using scent for enhancing the consumer perception of product quality [56.8] meets the standards of misguidance and deception because the product appears to be of better quality than it would ordinarily be (without scent). Another common application involves dispensing a *new car* fragrance in a used car to stimulate the perception of newness and possibly raise consumers' willingness to pay. Regarding marketing's use of ambient scent, it could be argued that the effects established could trick consumers into actions (spontaneous buying, exaggerated spending) they would not take if the scent was absent [56.130].

Issues of *ethics in consumer research*, by contrast, arise when researchers pursue self-interested goals possibly at odds with the needs of those either undergoing or sponsoring their study. These issues give rise to the requirement to protect *subjects* (consumers) against potentially harmful research practices and to preserve the integrity of findings intended to contribute to our knowledge. In many societies, there is a consensus that respondents are entitled to anonymity, peace of mind, candor, and freedom of choice; conversely, they agree that research practices deemed hurtful, deceptive, or treacherous should be outlawed [56.131]. Most prominent with scent are possible risks to health or well-being. Some fragrances are outright toxic [56.132] or carcinogenic [56.130], others have been identified as a major cause of allergies [56.133]. Given increasing numbers of people sensitive to scent, even mild reactions, such as headaches and asthma attacks [56.134] need to be considered when conducting research on human response to scent.

Responding to calls for state or federal governmental regulation, a number of national and international systems have been put into place including guidelines intended to regulate the identification and labeling of allergens in fragrances used in or on products. In addition to regulation, industry associations, such as the International Fragrance Association, have issued a detailed code of good practice for their member companies. Most regulations focus on making consumers aware of possibly harmful ingredients. However, testing over 700 products marketed to consumers in Germany for 26 supposedly (according to Article 10.1 of the 7th Amendment, Guideline 2003/15/EC) allergenic fragrances, *Klaschka* [56.135] found about half of all cosmetics, washing, and cleansing products contained at least one mandatory label ingredient, and 14% contained strong allergens. To date, consumers are still buying these products; the effect of companies voluntarily labeling their products to decrease the number of allergenic substances seems small.

56.7 Future Research

While the previous sections illustrate that much progress has been made toward a better understanding of how and when scent impacts consumer behavior, significant gaps in our knowledge still exist. From our perspective, there are at least three promising avenues for generating potentially valuable future insights: improving methods, advancing analytics, and adopting a more holistic perspective.

In spite of the variance in scent properties, marketing contexts, and consumer response variables investigated, the studies reviewed mostly rely on a single *method*, namely, the explicit assessment of constructs through psychometric rating scales. While widely applied, those scales are not without limitations in terms of design, analysis, and interpretation [56.136]. To overcome some of the limitations inherent to explicit measures (scale-based surveys or experiments), a few studies have started to rely on implicit association tests [56.119] and functional resonance imaging [56.109] to capture automatic thought and nonconscious responses. With the help of advanced or integrated techniques, applied to study effects of scent used for marketing, a more revealing view into the *black box* of the individual consumer should be feasible.

Benefitting from recent advances in the social sciences, marketing research has made great strides in terms of more sophisticated and powerful *analytics* in the past decade. For example, ever faster high-performance processors allow *big data* processing, computing large numbers of variables for large numbers of cases (consumers) in reasonably short periods of time [56.137]. Concluding that an analysis that focuses on answering only either *how* or *when* is inferior to one that examines both [56.138] researchers further developed methods, such as conditional process modeling to better quantify and simultaneously test hypotheses about how (through mediator variables) and when (conditional values of moderator variables) an independent variable influences a dependent variable [56.139]. It is plausible that the strength of the hypothesized indirect (mediation) effect is conditional on the value of specific moderators, or what has been termed conditional indi-

rect effects [56.140], alternatively known as moderated mediation. Collectively, many of the studies on scent in marketing suggest an indirect effects model, whereby the relationship between scent and consumer response (approach avoidance or intention to purchase) is transmitted by a mediator (a shift in affect or evaluative judgment), and is contingent upon a moderator (individual shopping goals, age, or gender). Given shortcomings identified for initial approaches [56.141], it is suggested that conditional process modeling yields far more complete results than do formal significance tests or bootstrapping alone [56.138, 141]. The application of these novel methods and analytical tools may therefore require practitioners and researchers to rethink how scent functions with consumers for more effectively market products and services.

Adopting a more holistic perspective naturally follows from establishing cross-modal effects of sensory input and further integrates sensory with marketing research. Past marketing and consumer research has concentrated on classical means of communicating products and brands (through advertising) including visual aspects. Marketing scholars considered vision the major source of consumer beliefs [56.142], but largely ignored the potential contribution offered by sensory science. More recently, however, researchers have started to embrace the concept of experiential marketing positing that a more holistic perspective may be appropriate for fully understanding consumer interaction with products [56.8], brands [56.9], or service environments. While the resulting multifaceted view of visual, tactile, olfactory, auditory, and taste input is deemed to possess greater explanatory power, new methods and analytics necessary for assessing the relationship between numerous variables are just recently becoming available (Chap. 47).

56.8 Conclusion

This chapter covered a lot of ground. Yet, it has barely begun to capture the number and diversity of phenomena directly or indirectly attributable to scent's use in marketing. Readers will inevitably identify many important areas of research, in consumer behavior, and related areas, that have been omitted here for the sake of brevity. As new research frameworks and controversies develop, updates, revisions, and extensions to the perspectives discussed here will become necessary in the coming years. We hope that the current chapter stimulates excitement and discussion about employing scent for marketing, and readers will contribute to the discipline through their own teaching, research, and practice. Scent marketing truly is an interdisciplinary field, and we are pleased to have the opportunity to provide these viewpoints.

57. Sensual Perception in Architecture

Katinka Temme

From the five senses (according to Aristotle), the sense that first comes to mind when thinking about space is the visual sense. Indeed, much of spatial experience is derived from vision. In this article, it is postulated that an equal consideration of all senses however can lead to a refined architectural design method and designed space.

In particular, spiritual spaces offer often an experience beyond the visual. The space reception is thus multisensory; influenced by such factors as incense, darkness, coldness, and awe. All those stimuli constitute an intense, dense architectural atmosphere. If such an overlay of senses is possible, is it also possible to void a space of its stimuli? A study at the University of Applied Sciences in Augsburg came to the conclusion that a *neutral space* is impossible to design. Senses are essential to the human being and as soon as a space is emptied of this quality, its abstraction is perceived as nonhuman (*mad-house*) and thus as a negative space. Thus, the creation a positively perceived space was aimed for: one in which a majority of users feel welcomed at and comfortable in. This architectural answer can be utilized for test laboratories to avoid the potential negative perception by the sixth sense: that of anxiety when entering a testing environment.

From a chemist's or sensory scientist's point of view, the most important factor in an olfactory test room would probably be its functionality – for example odorous inertness, convenience in sample preparation and presentation as well as flexibility. These premises are strongly reflected in norms and settings of common sensory testing rooms that are precisely described in, for example, DIN EN ISO 8589:2014-10 [57.1]. Such test rooms are designed to allow for group discussions between panelists or to provide privacy in terms of isolated cabin-like booths, providing sinks for drinking water supply and to offer the possibility to spit out samples in case the samples need to be tasted. The rooms or booths may further comprise touchpads or computer workstations where panelists are supposed to record the data of their ranking. Light might be adjusted, for example with red light illumination to ensure that the color of samples does not falsify the rating results. A typical floor plan and a representative sensory panelist group discussion are shown in Fig. 57.1 and 57.2.

All in all, however, it becomes evident that such a testing room is not really related to real-life situations of everyday odor experience, and, moreover, does not fulfill the requirements of a scenic environment that is designed for providing a space for experiencing, enjoying or even celebrating smells.

Moreover, as soon as we add a psychologist's perspective on smell perception in a building or spatial surrounding, the prerequisites for such a room become much more complex. We know that multisensory integration and emotions can influence the perception of an odor subconsciously (Chaps. 40, 47). For a completely unbiased olfactory evaluation, it would hence be ideal if neither emotions nor other senses than the olfactory sense were triggered specifically, consequently perceiving the test environment as completely neutral. This raises the question what defines *neutral* in con-

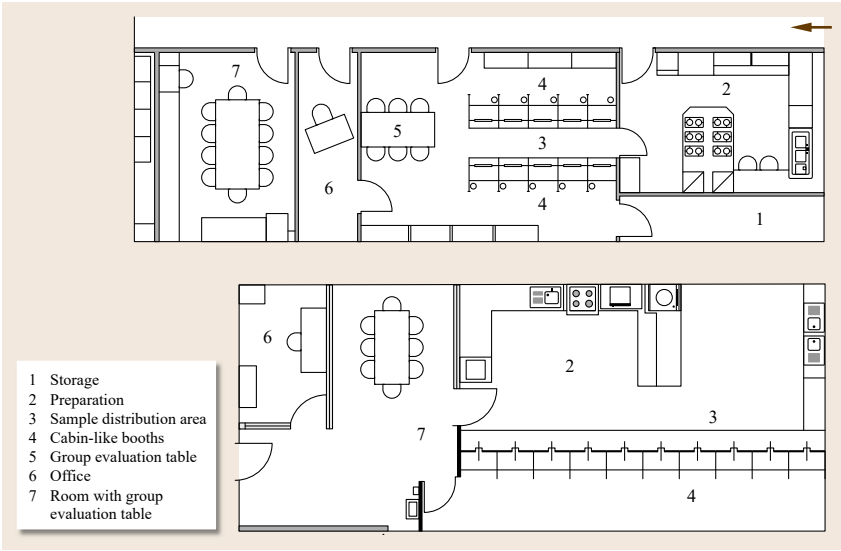

Fig. 57.1 Floor plan of a sensory testing room according to DIN EN ISO 8589:2014-10

Fig. 57.2 Expert panelist group discussion of presented smells (courtesy of Fraunhofer IVV) ◄

trast to a *sense-filled* space and whether it is possible to design an olfactory test setting that is *neutral*. This article deals with the question of how to design space for a sense such as odor and in what manner spatial experience is related to sensual perception and experience. It postulates that any successful design has to consider both the context of the building as well as the whole human body with its senses as valuable design perimeters.

57.1 Space and Limits of Space

Thinking about architectural design, one ultimately has to inquire into the architectural definitions of *space* and what constitutes or forms space. Space is defined on one hand by its limits indicating the architectural dimensions of the allocated space such as height, width, and depth. The porosity of those spatial borders evident in openings such as windows, doors, and skylights is essential as it allows light to penetrate space and accentuate the edges further. However, an enormous impact on the experience of space has to do with its sensual qualities evoked by its atmosphere and materiality. A wooden log cabin of small size might seem more intimate than a white tiled room of equivalent dimensions. These perceptions relate on one hand to the visual perception but it can be assumed that all other senses play a crucial role in identifying a spatial atmosphere as well.

Dom Hans van der Laan defines *architectonic space* as something experienced physically, sensually, and mindfully. Among the several definitions of *space* in relation to architecture there are fundamentally three tendencies: one that defines the object character of real, built space; one that deals with the experience of space as a complex situation; as well as one that, in a combination of the two previous positions, deals with the conceptual design or idea of space [57.2].

57.2 *Sensual* Space

In Japanese architecture, the empty room is the center of the Shinto shrine called *jinja* in which people perform religious duty. The graphic designer *Kenya Hara* points out in his book *White* [57.3], that this *jinja* space is homonymous to white (*shiroi*) and thus called *shiro* or *yashiro*. The design principle is that of an embracement of void. Placed along the cardinal points, four wooden pillars are erected on the ground, connected at their tips by a straw rope. That is the archetypal shrine. The space is simply regulated by a rope and the four pillar-points and contains nothing. In essence, because the space contains nothing, it has the enormous potential that *something* may enter; in a way like a sheet of white paper, waiting to be filled. The definition of a sacred space, such as a shrine as described by Hara, also appears in the land-pacifying ceremony known as *jichinsai*, in which offerings of produce and sake are placed on an altar within the sacred space. Note the four bamboo pillars and the straw rope, attached with ritual white sheets of paper. Although sake has no color (which reflects the *nothingness* of space), it has a light perfumed scent. In that sense, the void is rich and potent and this design principle is essential to Japanese aesthetics – symbolizing simplicity and subtlety (Fig. 57.3).

A similar approach towards spiritual space is evident in Western/Christian culture: spiritual space design is, in terms of decoration, very minimal. Contemplation, meditation, oneness with God is sought and objects superfluous or irritating are usually avoided. Religious buildings erected prior to the Middle Ages, in especially during the Romanesque Period (1000- about 1200) are still fine examples of sheer-walled environs, void of content other than faith, for example the Abbaye du Thoronet (Fig. 57.4). The abbey, erected between 1160 and 1190 is one of the *three provencal sisters*, famous Cistercian monasteries. The church is a Romanesque basilica with barrel vault above the central nave, yet without windows in the clerestory. The abundance of architectural sculptures leads to further formal clarity, order and minimal ideal space.

It is interesting that although visual or acoustic influences are minimized, odor on the other hand is widely used. Flower decorations, perfumed oils, incense sticks (in Buddhism, Shintoism and Hinduism) and burnt incense (in Catholic congregations) are symbols of respect towards the deity and heaven (see also Chap. 4). Incense is supposed to be the *scent of god*: as the incense smokes towards the sky, so does the prayer of the faithful servant of God [57.4] as described in the following psalm:

> *Psalm 141: "Come to Me Quickly! [1]A Psalm of David. O LORD, I call upon You; hasten to me! Give ear to my voice when I call to You! [2]May my prayer be counted as incense before You; The lifting up of my hands as the evening offering. [3]Set a guard, O LORD, over my mouth; Keep watch over the door of my lips. . . . ".*

In Egypt and Mesopotamia, incense may be purificatory, apotropaic, propitiatory, or mediatory [57.5] (Fig. 57.5).

Gustatory elements such as wine or harder liquor are rather common, be it the red wine for the Lord's Supper in the Catholic faith or the pox liquor, consumed in Mexican highland churches for an intense intoxicated state of mind, ready to embark on a journey to the *beyond* [57.6].

That being said, in order to find the ideal of an empty or neutral space in order to insert a function,

Fig. 57.3 Ritual space allocation at a *jichinsai* (land-pacifying ceremony when erecting a new building); photo by Sugimata Yasushi

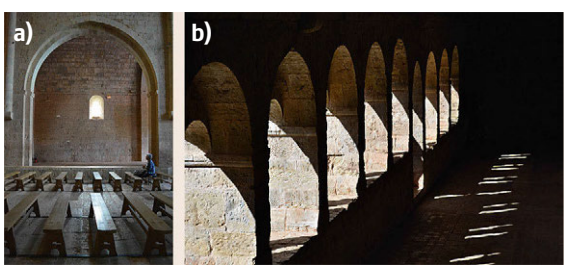

Fig. 57.4 Abbaye du Thoronet

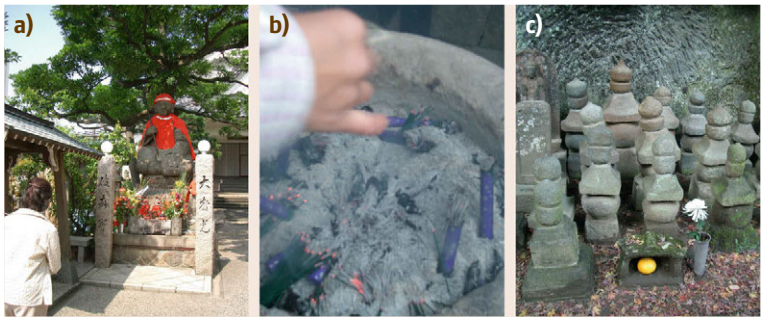

Fig. 57.5 Flowers (**a**), incense (**b**), and fruit (**c**) at spiritual places in Japan

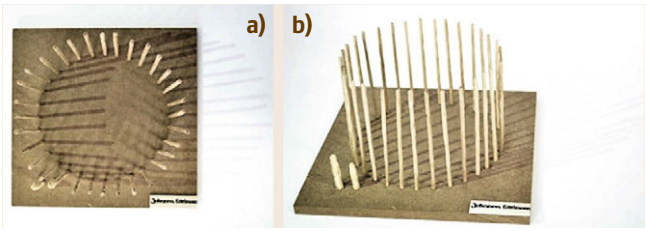

Fig. 57.6a,b Johanna Edelmann's neutral space is formed by wooden columns only; similar to the Japanese *jinja*

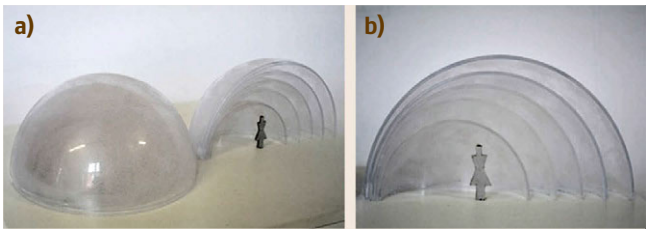

Fig. 57.7a,b Brigitte Kastner's neutral space is formed by dome shapes made of a glass-ricepaper sandwich creating thus a semi-transparent shell

such as an olfactoric laboratory, I conducted a series of design experiments in the summer semester 2014 at the University of Applied Sciences Augsburg. It was clear that the architectural space had to have more solid boundaries than those of a *jinja*. The idea of a void or emptiness had to accept the functional requirement: a space with little connotation in which test persons could concentrate on one sense.

57.2.1 The Search for *Neutral/Sense-Less* Space

The first experiment started with an analysis of *neutral space*. A freestanding pavilion not exceeding 30 m^2 in floor area had to be conceived including a mindful selection of material and dimensions of building members. The leading design question was whether or not it is possible to create space without qualities, a room void of any character, the zero-box with no emotional or sensual stimuli (Fig. 57.6–57.10).

It was very soon clear that a neutral built space does not and cannot exist. Even if we use non-colors such as white or black, and even if we use characterless materials such as a coating with no joints or surfaces, the space still triggers an emotional response. The less character it is given, the creepier the atmosphere. One student even showed an image of a psychiatric ward. The absence of sound, touch and smell makes us insane. The resulting design question was hence: *How minimal can space be without being irritatingly void?* Rather than further minimizing the qualities and atmosphere of space, the students investigated *positive* and *negative* associations regarding space. For example, most people would associate wood or warmer colors with a positive space; tiles and plastic as well as grayish colors with something negative. Concrete can be experienced as *brutal*, but as soon as the casting form with its wooden surface details the concrete with a more human scale, concrete can also appear as beautiful and positive.

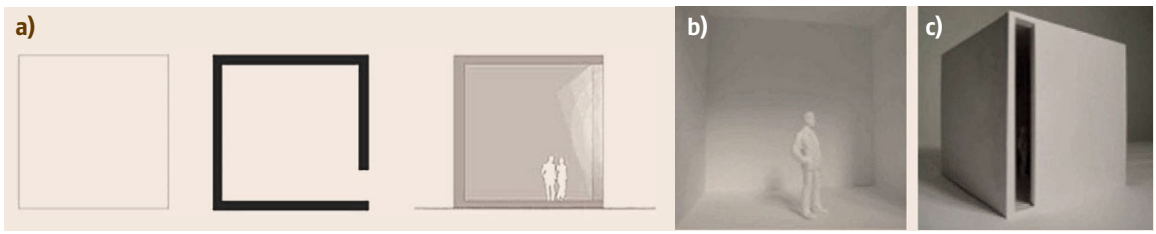

Fig. 57.8a–c Christoph Stegner considered the square to be the most *neutral* geometric form

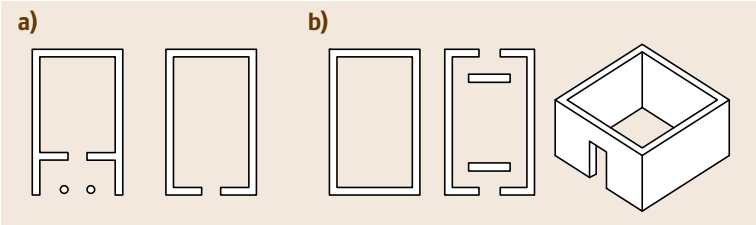

Fig. 57.9a,b Wolfgang Kramer analyzed **(a)** the ancient Greek *megaron* and *cella* spaces as neutral containers and **(b)** developed them further into the *white cube*, commonly considered best for art display

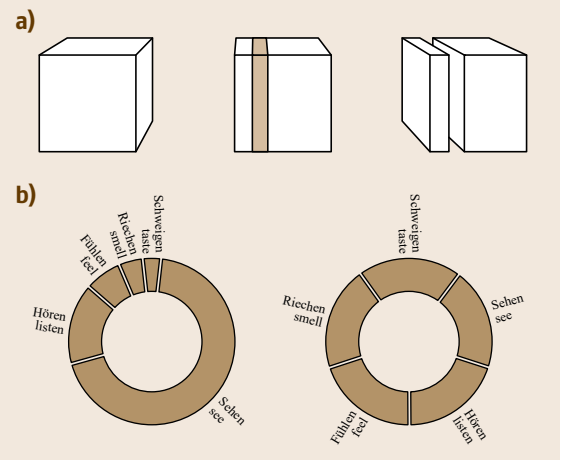

Fig. 57.10 **(a)** Marius Prechtl dissected the *perfect cube* to make the neutral space accessible. **(b)** His aim is to architecturally trigger all senses equally and cross-stimulate yet create harmony out of the sensory balance

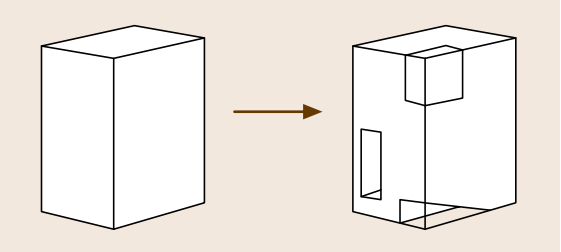

Fig. 57.11 Design task: sculpting a sensual space out of a given volume

In summary, it can be said that it is not possible to create a space void of emotion and atmosphere. Space immediately triggers our mind and memory to relate our body and soul to the architectural space. The more we try to empty space of character, the more frightened and negative its perception is. Rather than a *neutral* space, the ideal surrounding for a laboratory seems to be a space that makes most people feel comfortable; a positively filled room rather than an empty box, the living room or salon versus the lab cage.

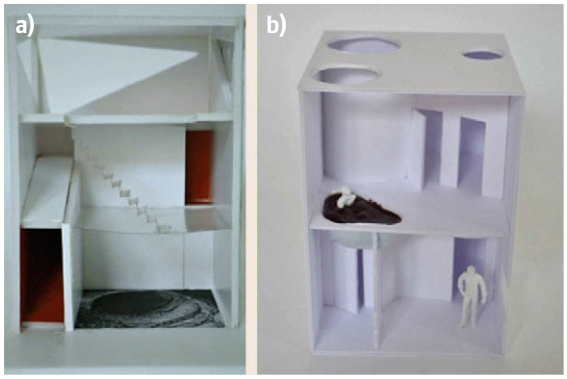

Fig. 57.12 **(a)** Sixth sense demonstrating several spaces of fear: a steep slope, a fragile glass stair across a seemingly large abyss, a narrow dark room. **(b)** The smell of the cocoa bath on the upper floor seductively leads through the building

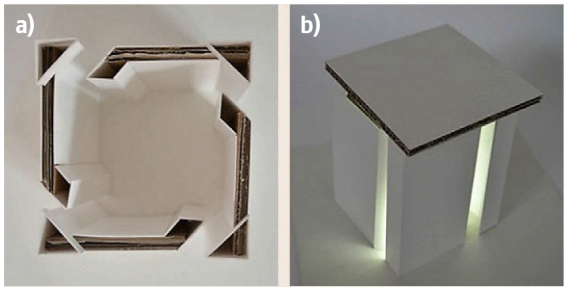

Fig. 57.13a,b The visual sense rarely resulted in successful designs

57.2.2 The Search for *Sense-Filled* Space

For the second experiment, first semester students had to each pick one sense and develop an architectural envelope for it. The ground floor area of 5×5 m as well as 7 m height was a given parameter to create a coherent volume in order to focus on the specific interventions. Together with the five classical senses (according to Aristotle), acoustics, optics, haptics, gustatorics and olfactorics, the sixth sense was added as a choice (Fig. 57.11–57.17).

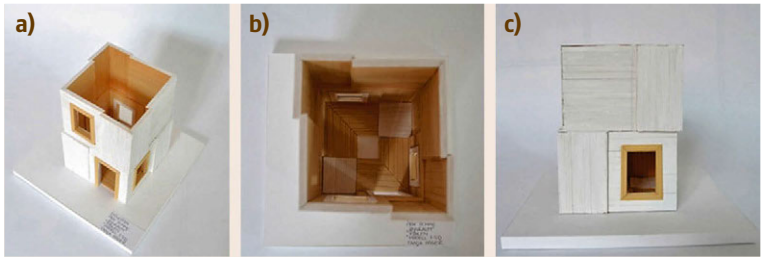

Fig. 57.14a–c Haptics and optics are combined and create a very intriguing sensual space

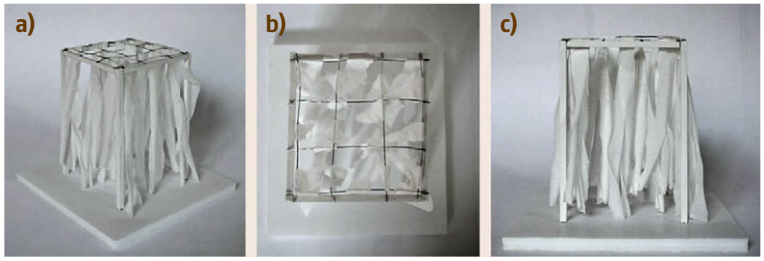

Fig. 57.15a–c A fresh breeze of air causes this building to enchant the visitor, its soft strips of fabric softly waving in space: a very poetic approach to a space that deserves to be touched and explored very physically

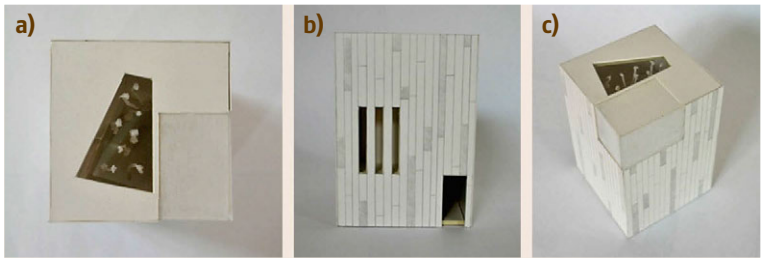

Fig. 57.16a–c Olfactoric sense: Small strips of light and the inserted atrium with skylight are the only means of light; the only guidance through space is the smell of trees and earth

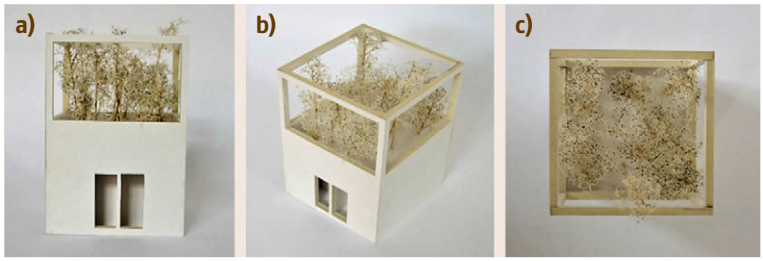

Fig. 57.17a–c This design visually hinted at the presence of trees. Once inside other, rather underrated senses are triggered: the smell of trees, the sound of earth beneath one's feet, the touch of the bare concrete wall, the taste of wet earth and the feeling of being somewhere very *rooted*

Each sense had to characterize the space and enable a focus on the specific sensual atmosphere: How does space sound? How can silence be built? How to concentrate on sound only? What do I see? How do I perceive? Is there too much visual stimuli so that I do not see the essence of the space? What is the smell of a space? When does odor turn to smell? Is it possible to sense materials differently if I approach them first by smell, by touch, by view? How does space smell? Can I taste a room? Can I trigger memories of a space by smell or taste? Does odor leave a trace on my tongue to *multi-sense* space? How do I move around space and can I be guided in my movements by smell in a space? What are the limits of space, of me in that space and of my perception of that space?

In regard to the sense-filled space, the students initially preferred to deal with the visual aspect. It seems that the supremacy of the eyes as a means of perception eased this decision. We are surrounded by visual stimuli. Our eyes are in constant demand, not just due to the increase of electronic gadgets such as smartphones, and tablets, but also the increased rapidity of cuts and sequences in film, media and advertising. In the end, many students failed to create a successful space for the visual senses. Most architectural spaces were overloaded or simply too blunt. It was not clear that the building had something specific about it (Fig. 57.13).

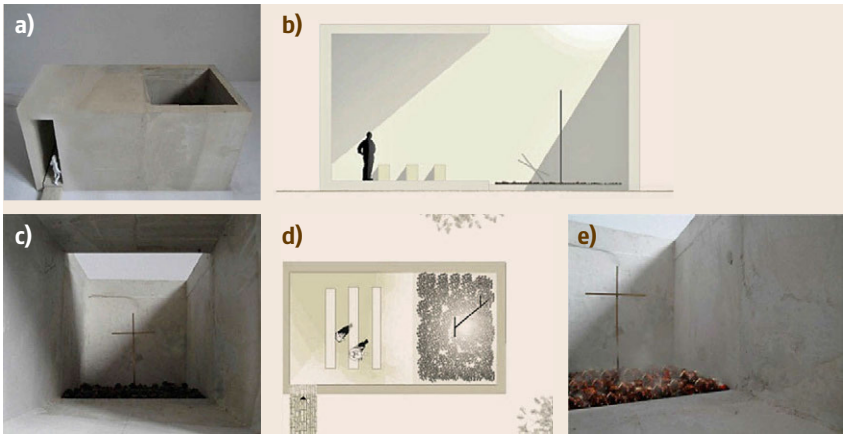

Fig. 57.18a–e Christoph Stegner composes a solemn space surrounded by concrete walls that show the wooden surface of the formworks. The altar is illuminated by the skylight and sensually connects the visitor to the outside surroundings. At the floor, pine cones are burned and not only cause an acoustic stimuli (shrinking under the influence of fire) but also an olfactoric one (the smell of burnt pine) as well as the visual sensation of slowly evaporating fumes

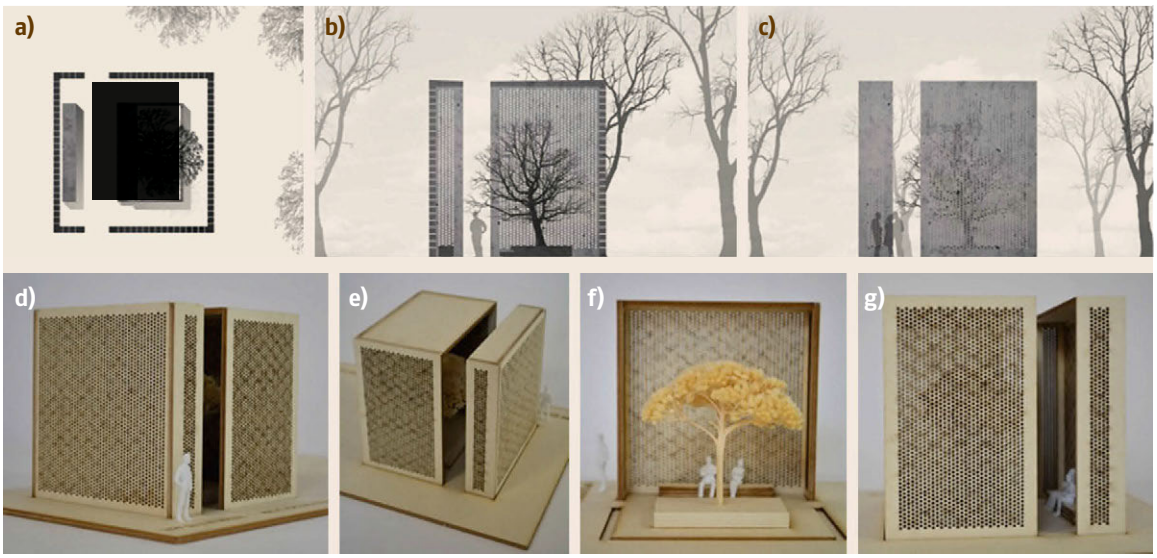

Fig. 57.19a–g Marius Prechtl balances all senses by a porous outer wall that allows light, sound and smell to penetrate through. Inside the sliced open cube, one can rest on a wooden bench (haptic stimuli) and reflect on the cherry tree that not only blossoms (visual and olfactoric stimuli) but also invites one to harvest (gustatoric stimuli) while listening to the wind and birds in the surrounding forest (acoustic stimuli). The overall atmosphere results in reconnecting all senses and ultimately body, mind and soul

The eyes are even in such dominance that perception with other senses almost has to be forced. Most students even doubted that space can be perceived by nose or mouth, and only on second thought did the acoustic and haptic perception appear as feasible. Thus, for all other senses but the visual, the buildings were rather successful. The difficulty of the design task challenged the students to think outside the box and to approach the design problem creatively and in a visionary, uncommon way (Figs. 57.14 and 57.15).

It was interesting that the students immediately wanted to deactivate the visual sense in order to activate touch or sound. In almost all cases, acoustic and haptic spaces were spaces without light in order to concentrate on the ears and hands (Fig. 57.16).

It can be noted that as soon as space had to deal with taste, odor and the sixth sense, two distinct design approaches occurred: those that *erased* all other senses to concentrate on a single sense and those that enabled all other senses to create a multisensory, complex sensual perception (Fig. 57.17). Reduction requires discipline so that the one conceptual idea can clearly be recognized and experienced in space. A multisensory and thus potentially multidimensional approach to space allows a more relaxed design and perception and is thus more suitable for everyday functions.

57.2.3 The Search for *Sense-Filled* Space; Multiple Senses

In a similar exercise, Master (fourth and fifth year) and Bachelor (third year) architecture students were given the same task yet without dimensional limitations. Rather than focusing on one sense alone, they were asked to design a *space for the senses*. In this combinatory experiment that also started with research into *neutral* space, the students were able to combine poetic architectural elements with the sensual experience (Figs. 57.18 and 57.19). It can only be assumed that it is indeed impossible to shut off any sense and that by nature, the whole body with all its senses has to be taken into consideration for any valuable and reflective, sensitive and sensual architecture.

57.3 Sensual Perception as a Design Method in Architecture

Although it seems very natural to utilize our own body and our senses to design and experience space, the lack of homogeneously distributed sensual awareness is indeed surprising. Little has been researched or written about the connection between sensual and spatial perception. In terms of odor, we know and can test how building materials evaporate toxins but it is unknown what positive odor does to the human mind and body. We know how to measure what potentially makes us sick, but we have not even started to research what sensual stimuli in the built environment make us happy. We know that color in the built environment might have a positive effect, however with the vague notion that this is perceived quite subjectively. While one might prefer a blue-colored room, another is infuriated by its coldness.

In regard to multisensory perception, we know even less. It can be assumed that one positive trigger might lessen the impact of another. However, there has been no further research into this cross-stimulating, at least not in the construction industry. We can only assume that the negative stimuli of a protruding smell might be weakened by a positive stimuli of a smooth touch for example. The result of such research could offer manufacturers and designers an enormous design potential. Cross-combining sensual stimuli might not only generate new products and material choices. The awareness of how *sensitive* each user is might additionally help to customize any design much further to clients' demands than to just please aesthetic (= visual) requirements.

Considering the need to investigate into that matter, it also has to be pointed out that both designers and users still lack this knowledge. Thus, not only the test person in a lab that has to focus on one specific sense is challenged, but also the architects of such a lab. When architects design space, they start with general dimensions, then continue to think about materiality and light, but most decisions taken stem from visual (or functional or budget) considerations. We render a designed space in 3-D, showing how it *looks* but never how it smells, feels or sounds. The other senses are rather relevant when it deals with eliminating those: avoiding hazardous building materials that evaporate an irritating smell, installing soundproof windows or non-slippery floor surfaces. Although clients place the same emphasis on the visual appearance (when talking about design objects, one usually refers to *the look* of things), in the end they do experience the designed spaces with the whole body and should be educated about those parameters in the design process.

Reducing ourselves to only one sense, we as well limit the spatial experience. While we allow our eyes to bathe in an intense arrangement of stimuli, all other senses are blocked or unused. Rarely, there are buildings (and architects) that emphasize senses other than the visual. Our memory might remind us that the smell of the bakery at the corner of our childhood home was compelling and the sound of rain and thunder is certainly something everybody can emotionally refer to. The sound of old wooden flooring, the smell of freshly mowed grass – there are many odor-triggered memories in relation to space and literature is full of those references. Rarely are senses, other than the visual, utilized as a design method or considered as valuable design parameters by architects; however there are few exceptions.

Peter Zumthor for example, a Swiss architect who designed the Thermal Baths in Vals, literally composed the baths as sensually rich spaces. Concerts take place in the thermal bath and due to the dimensions of each bath hall, the sound can be perceived very differently. Light shafts, openings in the massive gneiss stone walls (sometimes just slits, sometimes real openings to enter through), the temperature and mineral content of the bathwater all act as notes in the composition. Even time is taken into consideration as a design element. The mineral content of the water will change the appearance of the stone over time, the salt crystals will cover the joints and change the smooth appearance of the wall as well as the increasing patina on the brass mountings and fixtures. The vapor of the hot water bath perme-

ates through the walls and gives an optical hint to itself: a very clever design approach to signage in buildings. The stone floors are executed in a way so that not only the *pad-pad* of the wet feet can be heard but the imprint of the soles leaves also a visible dark mark on the floor. Those sensual perceptions all work, because as soon as one enters the space, the overall poetic becomes evident. The materials are strong in their appearance, solid like the surrounding rocks and mountains of the Vals valley but also simple in their expression. The spatial configuration is clear and the space laid out is easy to identify in. As the function of a thermal bath already suggests that of a relaxing space, a space to *let go*, sensual perception soon takes over from the mind-driven approach.

It can be assumed that a mindful concept for any space can be measured with the following design specifications: A material choice that makes sense and contextualizes the building within its surroundings (in architecture commonly called *genius loci*), a clear allocation of functions and division of rooms graspable by human scale, and a spatial quality that allows the mind to step back and allow us to perceive space with our whole body and senses.

57.4 The Ideal Laboratory

As a final experiment, Bachelor students were given the task to design a *sensual lab*. They could use their neutral and sense-filled experiments as a research base but had to develop the projects from rather abstract spatial experiments to a real architectural design with spaces for sanitary installations and technical systems, doors and windows, and the potential to be easily adaptable, moveable and extendable.

In order to approach the design task, students started focusing on the single cell first: the testing space. For the guest user (the tested person), a series of questions evolved: How do I enter the room? How do I experience the threshold between the *normal* exterior world and the *lab* space? Do I feel supervised (consciously or unconsciously) and *tested*? How and where do I interact with the lab personnel? How do I leave the testing space? Is there a rest area, allowing me to take a breath before exiting back to the *real* world? Can I see the *outside* while being inside? Do I have a chance to relax or is the spatial arrangement comparable to that of a conveyer belt?

For the main user (the testing person), the main questions were: How do I encounter the guest? Where do we meet, greet, chat and test? How can I operate my tools and machines? Where do I gather my results? How can I change the test surroundings? How much flexibility do I have with the test settings: Can I test more than one person, can I change the appearance, size, atmosphere or technical setting of a room by myself? And most importantly: Can I make sure that the guest is able to focus on the given task and is not irritated (positively or negatively) by the spatial surroundings?

While we did not go into detail about the technical limitations to any test setting, the students had to be aware that there are several possibilities to emit odor into the test cell. It was also clear, that there had to be a way to measure the responses from the tested person and that this already negatively influenced the emotional state of mind. It was also clear that too much flexibility in an architectural sense (removable wall panels and such) could easily lead to an *experimental atmosphere* further increasing the *lab* experience in a negative way.

In result, many designs came up with a pavilion like space (Fig. 57.20): a glass-surrounded building for which the roof is only supported by slender columns. Test labs, machine and sanitary rooms are inserted as *freestanding boxes* into the space so that anybody can wander around freely and always with a visual connection to the landscape surrounding the building (Fig. 57.20).

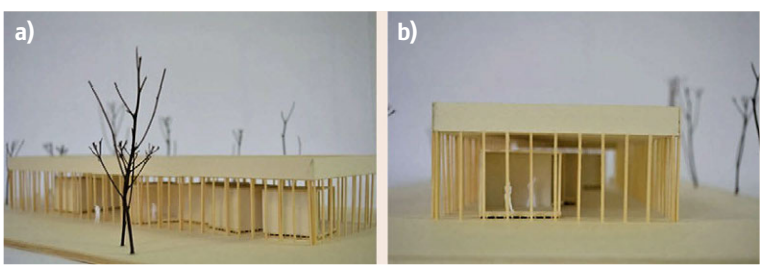

Fig. 57.20a,b A grid of columns lifts the roof above the ground and allows for a series of freestanding *lab boxes* to be freely arranged underneath and within the thermal and architectural enclosure

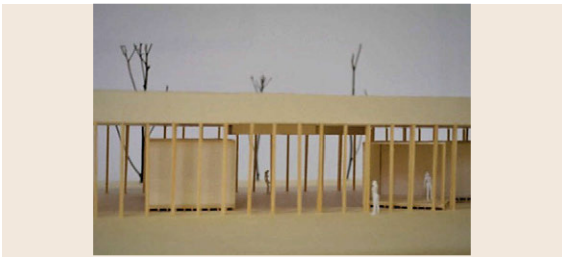

Fig. 57.21 The façade is structured by a row of columns. The inner core is flexible; technical installations are at floor level and in wall panels so that each lab module connects and disconnects as needed

Lounge-like areas for reading are randomly dispersed as well as tea kitchens and information counters. The overall atmosphere is that of an open, welcoming space, set in nature. The random placement of solid labs versus the overall open floor plan intensifies the transparent appearance, something not only felt physically but also psychologically: rather then entering the unknown, everything is evidently displayed. Lab personnel walking around interacting with the tested persons is normal and enhances the easy-going atmosphere of the space.

Due to this simple allocation, much focus can be given to the *freestanding boxes* (Fig. 57.22). The technical installations are either placed in the floor or the ceiling (less ideal) so that one can hook up easily and directly from the floor or indirectly through the walls. The placement of walls in a grid (in accordance to the placement of the structural columns) means that each wall can easily be extended within the structural grid to extend or limit the room size. Two functions or more can be joined without problems by simply taking out or inserting a wall panel (Fig. 57.23).

The above described combination of a fixed overall structural and architectural setting on one hand and that of a flexible lab system on the other hand is the most successful result. It combines the ease of a welcoming, living-room like space with the pragmatic and highly demanding technical requirements of a lab.

An architectural setting in which the architecture steps back in intensity and allows for an open, welcoming character in an almost democratic manner of a free plan is potentially the best answer to creating a lab space of the future: a lab that not only allows a positive emotional approach by the tested user but also by the testing user and is thus a lab that facilitates communications. In a way and looking back to Kenya Hara's observations to the void but potent shrine space, the ideal lab is a space that is defined by subtle architectural elements but has enormous potential for the functions to come.

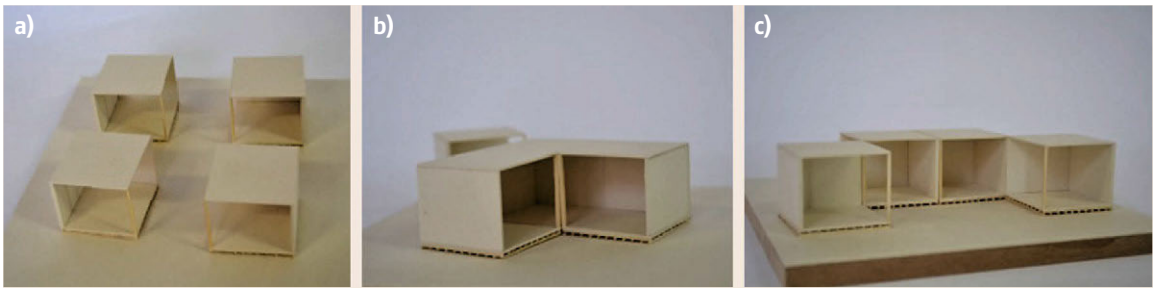

Fig. 57.22a–c Layout and combinations of lab modules

Fig. 57.23a–c Lab module details, showing the flexible wall panel if two or more modules have to be combined. The floor is composed of a *Euro Palett* and can easily be transported by a forklift

58. Microdosing of Scents

Martin Richter

Microdosing systems based on micropumps, which are applied nearby the nose, will enable the change of scent impressions of human nose at every breath several times a minute. Due to the small dosing volume the scent impression can be detected only once, and no other person in the room can smell the scent. With that, for the first time scent scenarios become possible, analogous to *picture scenarios* (movies) and *sound scenarios* (music). Such vision of scent scenarios can be combined with audio and video for applications in the movie, games, and music industry. The technology could also enable new applications for other branches like training of tasters (wine, food) or training tools for sense of smell for kids or adults.

To realize this vision, both small and cost-efficient micropumps as well as a tight reservoir technology with small dead volume to provide scent molecules to be dosed are required. This chapter is discussing the *dosing chain* of scent from the reservoir to the nose, the dynamics of single-breath scent dosing as well as the state of the art of microdosing systems and micropumps.

58.1 Microdosing of Scent

The nose can be considered as a biodetection system for specific molecules, residing in a defined space in front of the nose. To smell a scent impression, the molecules have to be sucked into the nose by a breath intake. Depending on the type of the scent, just a few molecules can be enough for such a scent impression.

A conventional air freshener usually has a high dosing rate in order to fill the whole room with scent molecules. To replace this odor by another one, it would not be sufficient to dose other molecules into the room; this new odor impression would superimpose to the previous one, resulting in an unwanted mixed odor. For the pure smell of this new odor, the complete air in the whole room has to be removed and exchanged. Such a complete change of scent within short time is very difficult to achieve using conventional dosing technologies.

Novel technologies have been developed during the past years to dose small amounts of liquids or gases in a defined way. These technologies can not only handle small volumes of gas, but they are also very small in size and energy efficient. These new microdosing technologies can be mounted near the nose in portable, battery-driven systems.

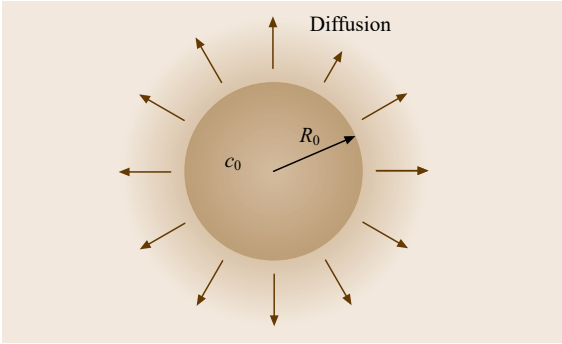

Fig. 58.1 Diffusion of a scent cloud in the air

Each single micro-dosed scent impression ideally disappears by diffusion after onebreath intake. This allows scents to be varied over a short time, enabling scent scenarios with different scents.

Air and sound can spread in space very quickly and disappear without any residuals. This can be technically exploited for providing *picture scenarios* (movies) or *sound scenarios* (music). Both audio and video are multibillion dollar markets, providing our eyes and ears with quickly changing pictures and sounds.

Together with these new microdosing devices, a completely new *scent scenario* technology for odors can be realized. The frequency of changing scents is defined only by the frequency of breath intake of human beings. For an adult this frequency is 12–15 breath intakes per minute [58.1]. With a microdosing technology, mounted near the nose and including several scent reservoirs, it is possible to realize a scent scenario with 15 different scent impressions in 1 min. Such scent scenarios can be combined with audio and video for applications in the movie and music industry. The technology could also enable new applications for other branches like training of tasters (wine, food) or training tools for sense of smell for kids or adults.

58.1.1 Transport Mechanisms for Scent Molecules

The transport mechanisms for scent molecules are diffusion and convection.

Diffusion

If there is a gradient in concentration, molecules travel from higher to lower concentration by diffusion. This mechanism is isotropic.

We consider a spheric scent cloud with radius R_0 with concentration of scent molecules c_0, which is surrounded by air without any scent molecules (Fig. 58.1).

The concentration $c(r,t)$, which depends on radius r and time t, is spreading by diffusion according to Fick's law [58.2, 3].

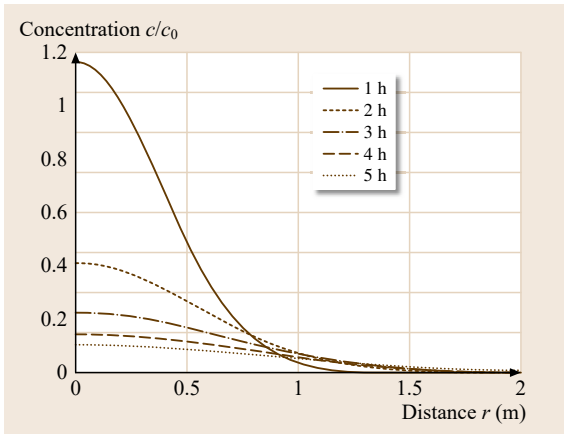

Fig. 58.2 Concentration profiles for diffusion of air as a function of radius r for different times from 1 to5 h

$$\mathbf{j} = -D\nabla c\,, \qquad \text{(1. Fick's law)}$$

$$\frac{\partial c}{\partial t} = D\nabla^2 c\,. \qquad \text{(2. Fick's law)}$$

Combining both equations and solving them gives the solution for the time- and radius-dependent concentration $c(r,t)$

$$c(r,t) = \frac{1}{8}N_0(\pi Dt)^{-\frac{3}{2}}\mathrm{e}^{-\frac{r^2}{4Dt}}\,. \qquad (58.1)$$

The constant N_0 describes the total amount of scent, which can be verified by integrating over the total space

$$\int_0^\infty \frac{c}{N_0}4\pi r^2\mathrm{d}r = \int_0^\infty \frac{1}{8}(\pi Dt)^{-\frac{3}{2}}\mathrm{e}^{-\frac{r^2}{4Dt}}4\pi r^2\mathrm{d}r$$

$$= \sqrt{\frac{1}{Dt}}\sqrt{Dt} = 1\,.$$

D is the coefficient of diffusion of the scent molecules (referring to ambient air). The unit of D is $[\mathrm{m}^2/\mathrm{s}]$. For diffusion of air in air (self-diffusion) D amounts to $D = 2\times10^{-5}\,\mathrm{m}^2/\mathrm{s}$. Molecules with higher atomic weight (e.g., scent molecules) normally have a smaller coefficient of diffusion D. The concentration is Gauss-shaped according to Fig. 58.2, in a space of 2 m around the source for a time up to 5 h.

At a given distance r_1, the concentration grows up to a maximum at the time t_1 and will fall down afterwards until all molecules are spread over the (infinite) room. This time t_1 of the local concentration maximum at distance r_1 can be calculated using the root of the

derivative of (58.1). to be

$$t_1 = \frac{r_1^2}{6D} .$$

In the air, the maximum concentration at a distance of 0.1 mm from the scent source is reached within 0.83 s, at a distance of 10 mm within 83 s, and at a distance of 1 m from the source that time amounts to 8333 s or 2.3 h, respectively.

These results show that diffusion is (for distances above around 1 mm) a very slow process. Only in the direct surrounding of the scent source diffusion is fast. Due to this fact, diffusion is not suitable for scent transportation over longer distances.

The amplitude $c(r_1)$ of the concentration maximum at r_1 amounts to

$$c(r_1) = \frac{1}{8} N_0 \left(\pi \frac{r_1^2}{6}\right)^{-\frac{3}{2}} \mathrm{e}^{-\frac{3}{2}} = \frac{1}{8} \left(\frac{\mathrm{e}\pi}{6}\right)^{-\frac{3}{2}} \frac{N_0}{r_1^3} .$$

The maximum of concentration is decreasing with the third power of the distance to the source.

Convection

If there is a pressure gradient, molecules flow from higher to lower pressure. Very small pressure gradients are sufficient to move air. Wind is one example for convection. In nature, air pressure drop of less than 1 kPa generates wind. Additionally, a temperature gradient in the air (by a heat source) generates a thermal convection flow, the heated air has a lower density and moves upward due to buoyancy. Moving bodies like human beings, opening a door, or a rotating fan generate convection, too. This is why transportation of scent molecules over larger distances in a short time is originated by convection, instead of diffusion.

Breathing is an example for this effect, an underpressure is generated in the lung, by sucking in the air, together with scent molecules. To complete the breath cycle, the used air is pushed out of the lung by an overpressure.

The volume of a typical breath comprises around a half liter of air. By sucking in the air the volume is taken from an almost spherical-shape region (here defined as volume V_1, Fig. 58.3). During exhalation the air is accelerated by the over-pressure in the lung and blows out in a directed flow due to the nozzle effect of the nose. One can verify this by putting the hand a few centimeter in front of the own nose for one breath cycle: During breath intake, there is no or just a little flow feeling, while during exhalation one can feel the air stream flowing out through the nozzle of the nose.

Due to this asymmetric flow, the nose sucks in *fresh air* during the next breath intake, instead of inhaling the

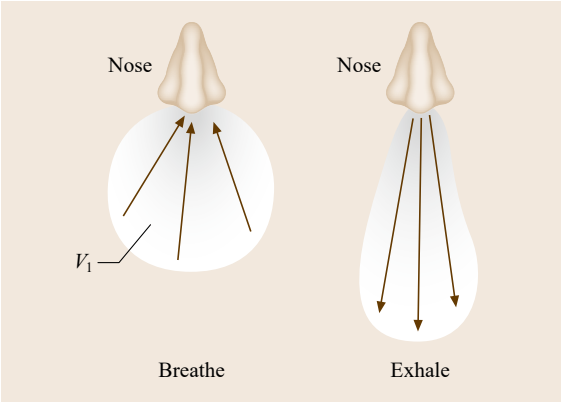

Fig. 58.3 Cycle of inhaling and exhaling as an example for convective transport. The breath is taken from the volume V_1

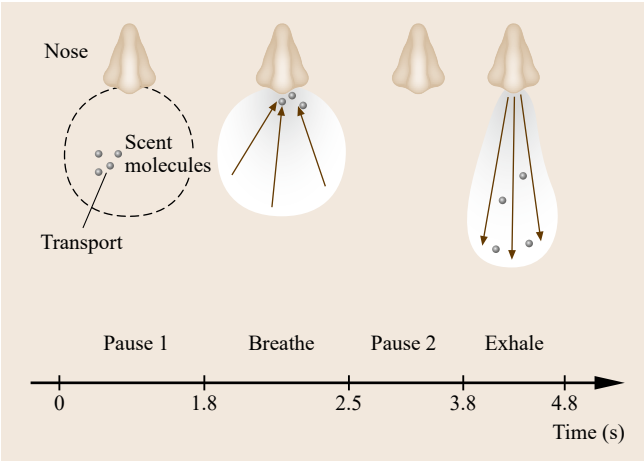

Fig. 58.4 Scent impression during one breathing cycle

air of the previous breath cycle. It is evident that this is very important for every human being in order to get sufficient oxygen from every breath cycle.

This cannot be exploited only for oxygen, but also for scent molecules.

The whole breathing cycle consists of

$$\text{inhale} \Rightarrow \text{pause}_1 \Rightarrow \text{exhale} \Rightarrow \text{pause}_2 \Rightarrow \text{inhale etc.}$$

To get a scent impression, scent molecules have to be transported to the volume V_1 (Fig. 58.4).

A microdosing unit, which can deliver a very small amount of different scent molecules into the volume V_1 in front of the nose, enables scent scenarios. At every breath stroke a different scent impression can be delivered.

After exhaling, the most scent molecules *type coffee* are transported out of the breath volume V_1. During

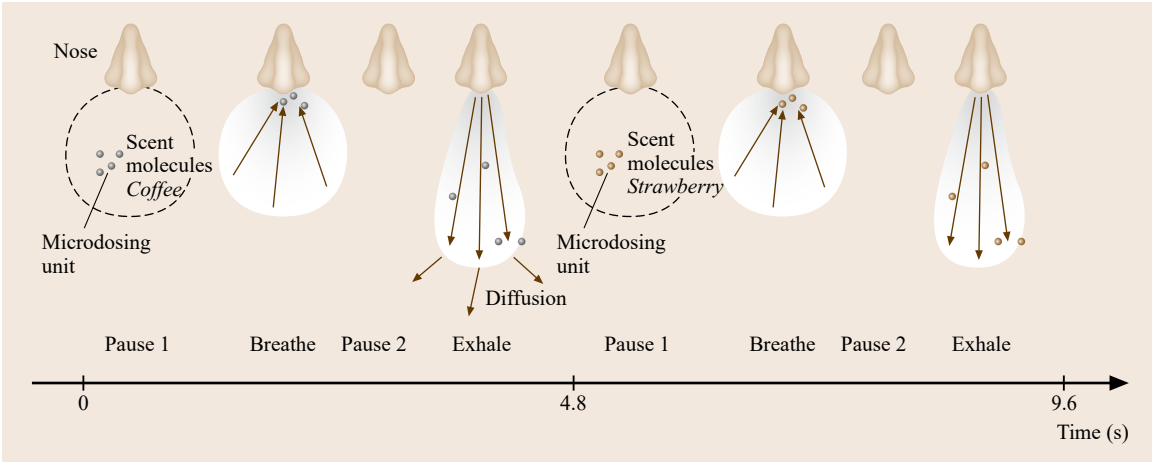

Fig. 58.5 Scent scenario, a microdosing unit delivers different scent molecules at different breath cycles to the nose. At the beginning of the first breath cycle (for example) coffee scent is dosed to the volume V_1, at the beginning of the second breath cycle strawberry scent is dosed to V_1

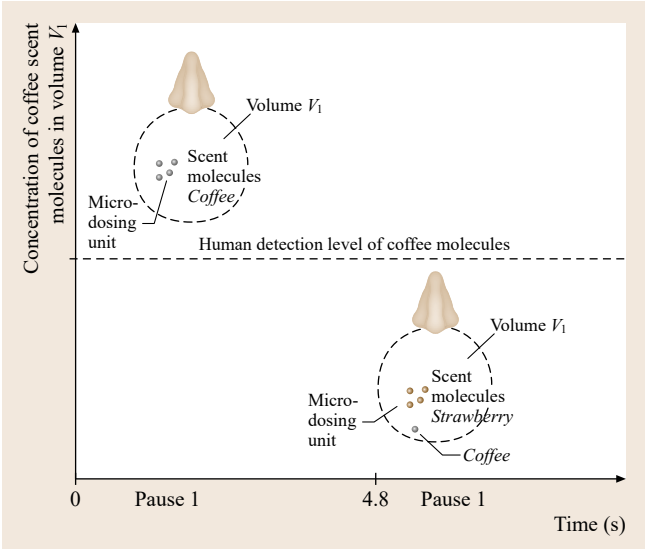

Fig. 58.6 Concentration of coffee scent molecules in volume V_1 at the beginning of both breathing cycles: Coffee can be olfactorily recognized only within one breath cycle

pause 1 of the next cycle, the molecules disappear by convection and diffusion. Just a few molecules of the coffee odor remain in the volume V_1. For that, the concentration of coffee scent molecules within the volume V_1 at the start of the second breath cycle is much lower and beyond the human recognition threshold compared to the start of the first breath cycle. The coffee scent impression is present just for one breath cycle. At the next breath cycle another scent (e.g., *strawberry*) can be dosed to V_1 by the microdosing unit (Fig. 58.5). As a result, the person would smell coffee in the first breath intake, and strawberry in the second, without smelling the previous coffee odor.

The dosing volume of the scent is adjusted to create such a concentration, which the nose will detect the scent after the delivery, and after exhaling and diffusion the concentration descends beyond the detection limit of the nose. This is illustrated in Fig. 58.6.

In principle, at every breath stroke a different scent impression could be delivered by the microdosing unit. Together with audio and video scenarios this enables a new dimension for consumer applications, such as scent memory games and training tools for the human nose.

Due to the dosing volume, low enough for only the user of the microdosing unit to get a scent impression at one breath, the other persons in the same room will not be able to detect this scent: Due to diffusion the concentration of the scent molecules is far beyond the detection level of other persons except the user. This enables micro-scent dosing units to be used also in public locations without bothering other people.

58.2 Generating Scent Molecules

To olfactorily detect a scent molecule, it has to be liberated into the air phase. Scent molecules, which are concentrated in a liquid or solid phase, can be released into the air by different mechanisms:

- Outgassing of a solid or liquid
- Evaporation of a liquid
- Nebulizing of a liquid.

58.2.1 Scent Reservoir

Pleasant scents like from flowers or perfumes, as well as unpleasant scents like those emanating from excrements, can be detected by the nose due to the fact that the scent molecules move first from a liquid or solid phase into the air. If the scent source is surrounded by a fixed volume (e.g., the gas volume in the colon, or the atmosphere in a closed fuel tank), within a certain time an equilibrium concentration builds up, meaning that the number of molecules, which exit the solid or liquid phase within a certain period of time, is the same as the number of molecules, which travel back by condensation to the liquid or solid phase. If the gas volume is continuously exchanged and the scent molecules constantly leave to the ambient air, the scent reservoir is depleted. The smell of a new car vanishes within a few years, as well as the scent of a new wooden chair, or a new carpet.

To realize a microdosing unit for scent, a scent source, a defined gas volume around the scent source to store the scent in a defined concentration, and a delivery unit to transport a small volume from this store into the volume V_1 in front of the nose are required. To ensure a defined number of scent molecules to be dosed to volume V_1 in order to give a scent impression just above the human recognition threshold for this particular scent, the concentration of scent molecules of the gas in the scent reservoir has to be known. During the time between two scent-dosing events (a multiple of a breathing cycle), the scent reservoir has to return to its original concentration. With that, during that time the same number of molecules which have been dosed before has to be emitted by the solid or liquid scent reservoir.

Given is a reservoir (volume V_0, temperature T_0) with a scent sample (solid or liquid) which has been completely purged at the time $t = t_0$. No scent molecule is in the reservoir at t_0. Assumed that the reservoir is airtight again after purging, what is the time-dependent concentration in the reservoir? (Figs. 58.7 and 58.8)

58.2.2 Resaturating of the Volume in the Reservoir with Scent Molecules

The calculation of the transient behaviour of the saturation of a closed and purged reservoir volume with scent molecules is very complex. Evaporation and condensation parameters depend on the type of the molecule, on temperature and pressure. Also the concentration distribution in the gaseous volume has to be taken into account.

Even for water, the substance which is very well known, this cannot be calculated easily. If a bottle with dry air is filled half with water and closed at the time $t = 0$, the humidity in air as a function of time cannot be easily calculated. The humidity concentration is not only a function of time, but also has a space distribution. The concentration of humidity is higher directly over the water level than higher above it. If diffusion would be the only mechanism to transport the humidity in the reservoir, the time to achieve equilibrium would be very long, as shown in Fig. 58.2.

However, it can be stated that even in a closed reservoir convection takes place: The evaporation of the water needs energy, which influences the temperature slightly, changing the density, leading to convection flow, leading to a uniform humidity within the air over the water.

Based on this, for scent reservoirs it can be assumed that due to convection flow a uniform concentration is everywhere in the space above the reservoir at a specific point of time.

Using this assumption, a very simplified model can be derived for calculating the time-dependent concentration of scent molecules after purging: Assuming a constant temperature and a constant free liquid or solid surface of the scent source, the number of molecules which move from liquid (or solid) to air is a constant α

$$\left.\frac{\mathrm{d}N}{\mathrm{d}t}\right|_{\text{liquid}\,\rightarrow\,\text{air}} = \alpha\,.$$

The inverse process of condensation is proportional to the number of scent molecules N in the air

$$\left.\frac{\mathrm{d}N}{\mathrm{d}t}\right|_{\text{air}\,\rightarrow\,\text{liquid}} = -\beta N\,,$$

and β is the condensation probability of one gaseous molecule to enter the liquid phase during the next time

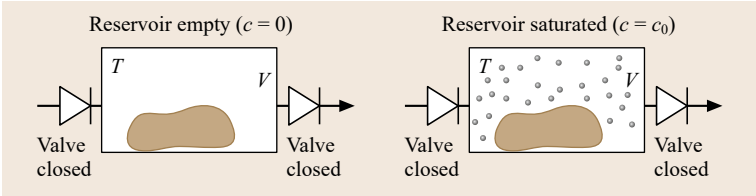

Fig. 58.7 Re-saturating of the reservoir with scent molecules after purging

step. Both the evaporation coefficient α and the condensation coefficient β are directly proportional to the free surface A between liquid or solid scent source and the air in the reservoir.

The net flow is given by the differential equation

$$\frac{\mathrm{d}N}{\mathrm{d}t} = \left.\frac{\mathrm{d}N}{\mathrm{d}t}\right|_{\text{liquid}\to\text{air}} + \left.\frac{\mathrm{d}N}{\mathrm{d}t}\right|_{\text{air}\to\text{liquid}} = \alpha - \beta N \,.$$

The solution of this differential equation is

$$N(t) = \frac{\alpha}{\beta}(1 - \mathrm{e}^{-\beta t}) \,.$$

Dividing by volume V_0 of the reservoir gives the time-dependent concentration $c(t)$ of scent molecules in the headspace

$$c(t) = \frac{\alpha}{V_0\beta}(1 - \mathrm{e}^{-\beta t}) \,.$$

The concentration is following an exponential law. Within a typical time constant τ

$$\tau = \frac{1}{\beta}$$

the headspace with a volume V_0 will be saturated with scent molecules to a concentration c_0. The time constant is inversely proportional to the condensation coefficient β

$$c_0 = \frac{\alpha}{V_0\beta} \,.$$

Figure 58.8 shows the time-dependent concentration.

The parameters α and β depend on the molecule properties, on pressure and temperature, as well as on the surface O of the liquid or solid scent source within the reservoir (Fig. 58.8).

$$c(t) = c_0(1 - \mathrm{e}^{\frac{t}{\tau}}) \,.$$

Assuming an ideal gas

$$pV = NkT \,.$$

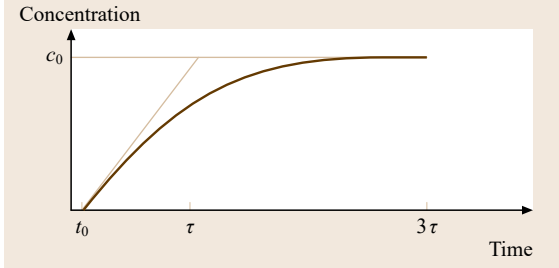

Fig. 58.8 Refilling the headspace: Time-dependent concentration of the scent

The equilibrium concentration c_0 can be described by the saturated partial pressure p_s

$$c_0 = \frac{N}{V} = \frac{p_s}{kT} \,.$$

The saturated concentration c_0 is proportional to the saturated vapor pressure p_s, which can be calculated from the equation of Clausius–Clapeyron. Assuming that the volume of the evaporated gas is much larger compared to the volume of the liquid, the saturated vapor pressure p_s can be integrated from

$$p_s(T) = p_0\mathrm{e}^{-\frac{Q_n}{RT}} \,.$$

With that, the time-dependent concentration would be

$$c(t) = \frac{p_0}{kT}\mathrm{e}^{-\frac{Q_n}{RT}}(1 - \mathrm{e}^{\frac{t}{\tau}}) \,.$$

The molar evaporation heat (or enthalpy of vaporization) Q_n has to be known for the particular odor material to quantify this equation. Q_n also depends slightly on temperature. From all materials, the material best investigated is (odorless) water.

After a time of 3 τ more than 99% of the saturated concentration has been achieved.

58.2.3 Recognition Threshold and Detection Threshold

The *odor detection threshold (ODT)* can be defined as the concentration of scent molecules which is necessary to smell a scent impression (*there is something smelling*), whereas the *odor recognition threshold*

(ORT) can be defined as the concentration of scent molecules which is necessary to identify the scent impression. The ODT concentration is about a factor of 100 lower than the ORT [58.4].

These odor thresholds of different fragrances for human beings can vary in a broad range: The human nose is very sensitive to odors such as hydrogen sulfide (rotten egg) or skatole (C_9H_9N, excrement). For these scents the ODT is only 10^7 molecule/ml air, whereas geraniol ($C_{10}H_{18}O$, essence of roses) the odor detection level is a factor of 10 million higher (10^{14} molecules/ml air) [58.4, p. 155].

This different sensitivity of the human nose to different fragrances has consequences to the microdosing systems: Assuming ideal gas behaviour of gaseous fragrances, in 1 mol (22.4 l) there are 6×10^{23} molecules of a gaseous fragrance. With that, the odor detection level of 10^7 molecules (e.g., to smell rotten eggs or excrements) correspond to a gaseous volume of

$$V_{\text{odor}} = \frac{22.4\,\text{l}\times 10^7\times 1000}{6\times10^{23}} = 3.7\times10^{-13}\,\text{l} = 0.37\,\text{pl}\,.$$

The odor volume $V_{\text{odor}} = 0.37$ pl (picoliter) corresponds to a cube with side length of 7.2 µm. To detect essence of roses (10^{14} molecules/ml air) the odor detection level would correspond to a gas volume of $V_{\text{odor}} = 3.7$ µl (cube with side length 1.5 mm). This means that even for odors with high detection levels the volumes of scent molecules are very small. These detection levels are values for trained people. The detection level of untrained people can be higher.

58.3 Microdosing Systems: Concepts

The microdosing chain according to Fig. 58.9 consists of a micropump or microfan for transporting the odor molecules from a headspace inside a reservoir to the volume in front of the nose. Two check valves at inlet and outlet of the reservoir avoid incorrect dosing when the pump is switched off.

If the micropump is arranged before the reservoir (left side of Fig. 58.10), it will not be contaminated with the odor. This might be the preferred solution if the reservoir has to be exchanged for another scent type. However, the dosing accuracy of the left arrangement is lower compared to the situation, where the micropump is between the reservoir and the nose: The micropump has to achieve a certain over-pressure for opening the check valves, which increases the dosed volume. The arrangement on the right hand side can deliver very small gaseous volumes of pure odor molecules and might be the preferred solution, if very small amounts of the sample are to be dosed.

Normally, a fan can achieve only a very small backpressure of a few pascal (Pa). Using a fan, instead of a micropump, is only possible, if on the one hand the check valves are replaced by active valves, and on the other hand there are huge cross-sections. Furthermore, no pressure drop along the flow path has to occure.

In other cases, a micropump that can achieve a certain back pressure is needed.

The micropump would be the key component for realizing small microdosing technologies according to Fig. 58.10. It must be able to handle small amounts of gases, and in some applications the micropump itself has to be very small and energy efficient.

58.3.1 Micropumps

During the past 25 years, many different types of micropumps have been developed. Actuation principles like electromagnetic, piezoelectric, osmotic, magneto-hydrodynamic, thermopneumatic, electrostatic or electro hydrodynamic and more have been investigated. For gaseous scent dosing, the displacement of the gas, followed by transportation through valves, is required. Some of the actuation principles mentioned above cannot be applied for pumping air (osmotic, electro-hydrodynamic, magneto-hydrodynamic), as these principles need the properties of a liquid for actuation. The stroke of electrostatic actuation is too small to compress gas to a sufficient compression ratio. Ther-

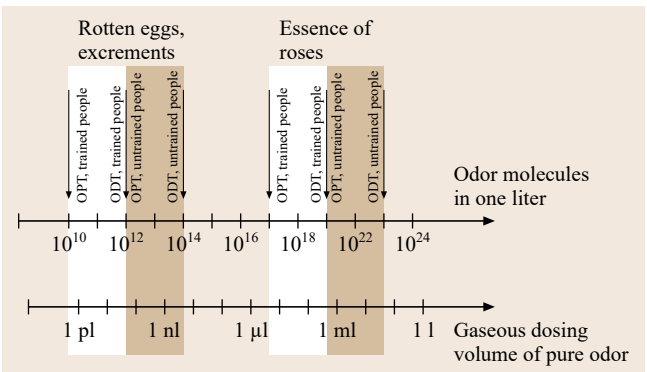

Fig. 58.9 Low ORT *(light green)* and ODT *(dark grey)* for human beings for two different odors, for untrained people. The *bottom axis* shows the corresponding gas volume of the odor for an ideal gas

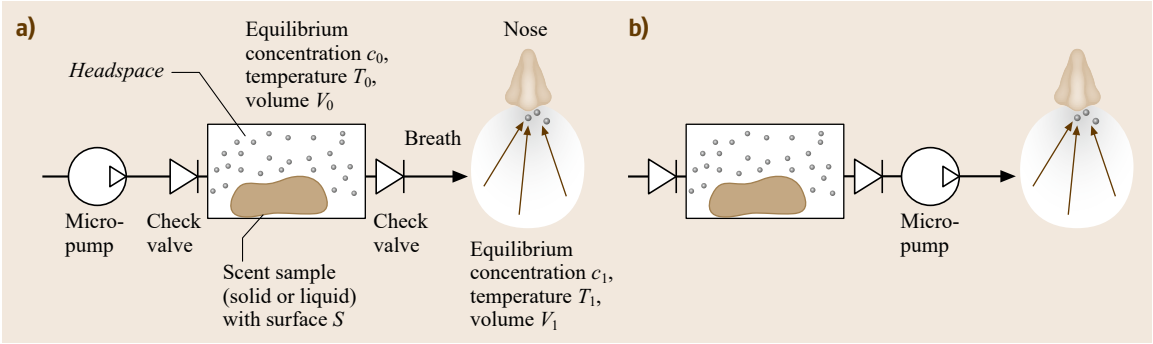

Fig. 58.10a,b Microdosing chain for scent molecules: **(a)** pump is arranged before scent reservoir, **(b)** pump is between the scent reservoir and the nose

mopneumatic actuation exerts higher strokes but huge energy consumption and low pump frequencies are associated drawbacks.

For these reasons, especially piezoelectrically driven micropumps seem suitable for the purpose:

- The most common type is the *microdiaphragm pump with passive check valves* (Fig. 58.11): A piezoceramics mounted on a diaphragm forms the actuation unit and borders the upper part of the pump chamber. Two passive check valves are arranged beyond the pump chamber, directing the flow as inlet and outlet valve. Upon application of a negative voltage the diaphragm expands the pump chamber, leading to a negative pressure, which sucks the gas through the inlet valve into the pump chamber (supply mode, Fig. 58.11b). When a positive voltage is applied at the piezo, the diaphragm moves down, compressing the pump chamber. The corresponding over pressure opens the outlet valve and pushes the stroke volume out of the pump chamber into the outlet (pump mode, Fig. 58.11c), completing the pump cycle. After that, a new pump cycle can start.
- Another common type is a *quasi peristaltic micropump*: Here three piezoceramics are glued onto a diaphragm forming a pump chamber and two active valves: Actuating the piezo in a phase-shifted way, the fluid (liquid or gas) can be transported from the inlet valve via the pump chamber to the outlet valve. Due to the symmetric arrangement, this pump type can operate in a bidirectional way (Fig. 58.14).

These pump principles have been realized with different technologies:

- Silicon micropumps
- Plastic micropumps
- Metal micropumps.

Silicon Micropumps

Debiotech S.A. (Switzerland) has a long experience in developing silicon microdiaphragm pumps for medical applications, especially for the therapy of diabetes. For medical applications, the *nanopump* with a chip size of $10 \times 6\,\mathrm{mm}^2$ has been developed [58.5, 6]. It is optimized for low flow; a dosing rate of 2.5 ml/h can be delivered with an accuracy better than 5%.

Different types of piezo-driven silicon microdiaphragm pumps have been developed at Fraunhofer EMFT within the past 24 years (Fig. 58.11d). Most types have a chip size of $7 \times 7 \times 1\,\mathrm{mm}^3$. One type is optimized for high flow rate (max. air flow rate 40 ml/min, liquid flow rate 5 ml/min, air back pressure 5 kPa, liquid back pressure 50 kPa). Another type has been developed for low flow rate and high pressure (max. air flow rate 0.5 ml/min, liquid flow rate 0.2 ml/min, air back pressure 90 kPa, liquid back pressure 600 kPa) [58.7].

The micropumps are manufactured by silicon micromachining (Fig. 58.12): Three monocrystalline silicon wafers (100 oriented) are structured by double-sided lithography and etched by silicon wet etching (using potassium hydroxide solution KOH). Two wafers form the valve unit, and the third one the actuation diaphragm. The connection between the structured wafer layers is realized by silicon fusion bond (Fig. 58.13). This bonding technology needs very smooth surfaces (roughness lower than 0.3 nm) and very high temperatures (up to 1100 °C) to perform a direct silicon–silicon bond between the wafer layers. Silicon fusion bond provides two benefits: There is no bonding layer, which might be attacked by the fluid to be pumped, and without a bonding layer the vertical pump design parameters (especially pump chamber height) are well defined.

An important design rule for a micropump to achieve a high compression ratio (defined as ratio

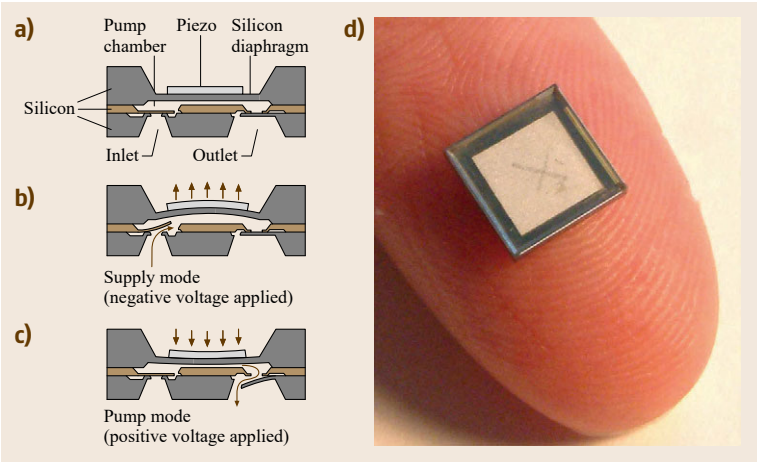

Fig. 58.11a–d Schematic view to a micropump **(a)** with piezoactuator and passive check valves. The pump cycle consists of supply mode **(b)** and pump mode **(c)**. **(d)** A micropump chip (size $7 \times 7 \times 1\,\mathrm{mm}^3$) placed on a fingertip (courtesy of Fraunhofer EMFT)

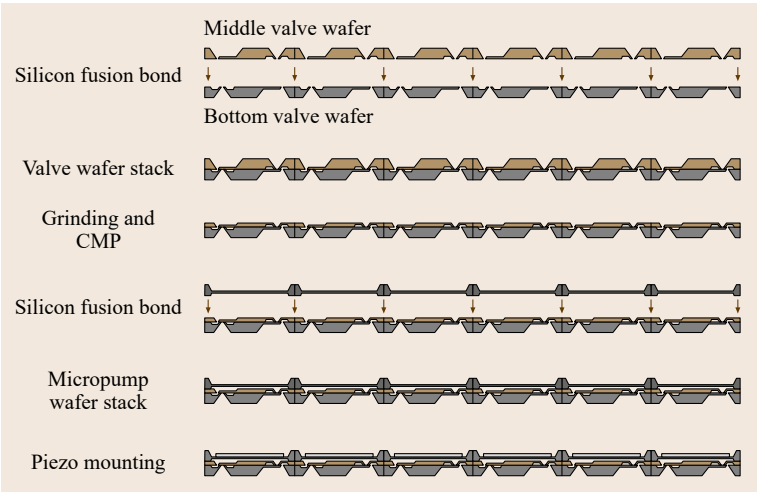

Fig. 58.12 Process flow of micropump manufacturing by silicon micromachining

between stroke volume and dead volume), which is needed to pump gas, is to reduce the dead volume. For silicon pumps as shown in Fig. 58.12 the middle valve wafer is thinned by a grinding process, followed by a CMP (chemical mechanical polishing) process step to enable the second silicon fusion wafer bond to complete the silicon wafer stack.

Plastic Micropumps

One general problem using plastic parts in microdosing systems for scent is the adsorption of scent molecules to plastic materials. For that, the use of plastic materials is only recommended if the micropump will not be used to deliver different scent molecules. Furthermore there is the problem of corrosion induced by some scent molecules for many plastic materials.

Since 2008, Bartels Mikrotechnik has established the serial production of a plastic micropump [58.8]. To improve the bubble tolerance, two micropumps are assembled in series in one housing. This micropump can achieve flow rates up to 7 ml/min (water) and 18 ml/min (gas), and maximum back pressures of 60 kPa (water) and 10 kPa (gas). The energy consumption of the pump including the driver is less than 200 mW. The size (without the driver unit) is $30 \times 15 \times 3.8\,\mathrm{mm}^3$, the weight 2 g.

Micro Jet (Taiwan) offers a series of different piezo-driven microdiaphragm pumps made of plastics [58.9]. The flow rate of the micropump PS31U (dimensions $34.5 \times 34.5 \times 12.3\,\mathrm{mm}^3$) is up to 100 ml/min (liquids) and back pressures up to 35 kPa. The gas flow micropump GS51C (dimensions $53.5 \times 53.5 \times 14.5\,\mathrm{mm}^3$) achieves air flow rate of 200 ml/min and back pressure of 5 kPa.

At Fraunhofer EMFT, a three-chamber plastic micropump has been developed in cooperation with RKT GmbH [58.10]. It consists of an injection-molded plastic body, a metal diaphragm glued onto the metal body,

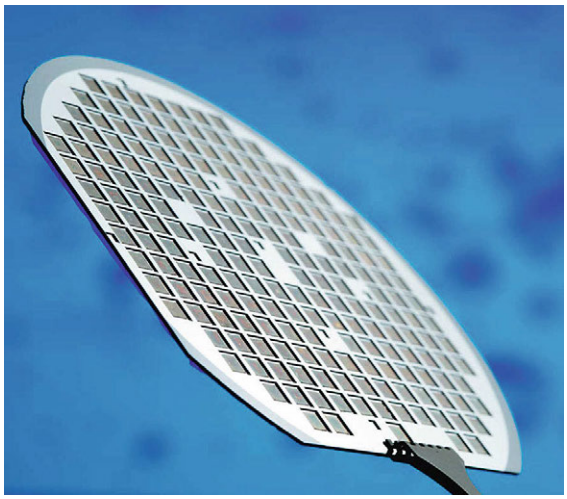

Fig. 58.13 Micropump wafer stack with mounted piezos and 190 micropumps (each $7 \times 7\,\mathrm{mm}^2$) (courtesy of Fraunhofer EMFT)

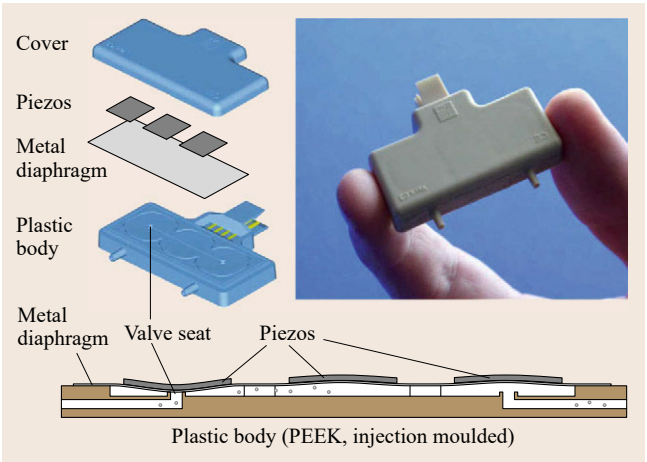

Fig. 58.14 Plastic micropump with three piezoactuation units (quasi peristaltic operation) (courtesy of Fraunhofer EMFT)

and three piezoceramics glued onto the metal foil. The middle piezo is for the actuation of the stroke volume, whereas the outer two piezos can open and close a valve seat each. The pump can operate bidirectionally (Fig. 58.14).

This pump can achieve flow rate of 3 ml/min (Fig. 58.15, *left*) with water and 30 ml/min with air (Fig. 58.15, *right*).

Multimaterial Micropump

Together with Fraunhofer EMFT, RKT GmbH and PI Ceramics Paritec GmbH have developed a multimaterial micropump (Fig. 58.16). This pump has a steel actuation diaphragm driven by a piezo and a plastic body with silicon check valves integrated by hot embossing. This pump has been developed for high performance [58.11], and has diameter of 30 mm, thickness of 4 mm, and can achieve flow rates up to 150 ml/min with water and 350 ml/min with air, respectively.

Figure 58.17 shows the performance of the multimaterial micropump with a double-layer piezo. Due to its outstanding performance, this micropump can be considered as a benchmark for this class of micropumps. On the other hand, due to the combination of several materials (silicon, metal, plastic), this micropump has a limited potential for low cost manufacturing.

Metal Micropumps

Kikuchi Seisakusho Co., Ltd. has developed a piezo-driven microdiaphragm pump made of metal foils [58.12]. The size of the metal pump is $7 \times 7 \times 1.6\,\mathrm{mm}^3$, max. flow rate, 3.5 ml/min, max. back pressure (liquids) of 90 kPa. This micropump can be considered as the currently smallest metal micropump worldwide.

For high-flow applications, Fraunhofer EMFT has developed a micropump consisting of steel foils (Fig. 58.18). A cross-section of the parts of this micropump is shown in Fig. 58.19, in order to explain the laser welding technology used for joining the metal foils together.

The diameter of the micropump µP303 is $d =$ 25.6 mm, the thickness of the actuation diaphragm 100 µm, the thickness of the piezo 200 µm [58.13]. The pump achieves a back pressure of 20 kPa (Fig. 58.20).

58.3.2 Evaporation

The transition of odor molecules from the liquid to gaseous phase can be enforced by heating up the liquid above the boiling point. Scent molecules evaporate and can be transported, for example, by a fan to the human nose. One example is the *Sniffman* scent dispenser [58.14]: Driven by a piezoactuator a small droplet is jetted to a heater plate and evaporated (Fig. 58.21). After that, the scent molecules are transported by a fan through an outlet to the human nose.

The droplet-generation mechanism is similar to a piezo-driven ink jet printer: The pump chamber has to be primed completely with liquid scent without gas bubbles. The actuated piezo generates a pressure wave, which travels to a nozzle, generating a droplet with a very small volume of about 50 pl. This dosing principle is similar to other dosing dispensers, for example, from microdrop [58.15] and Gesim [58.16].

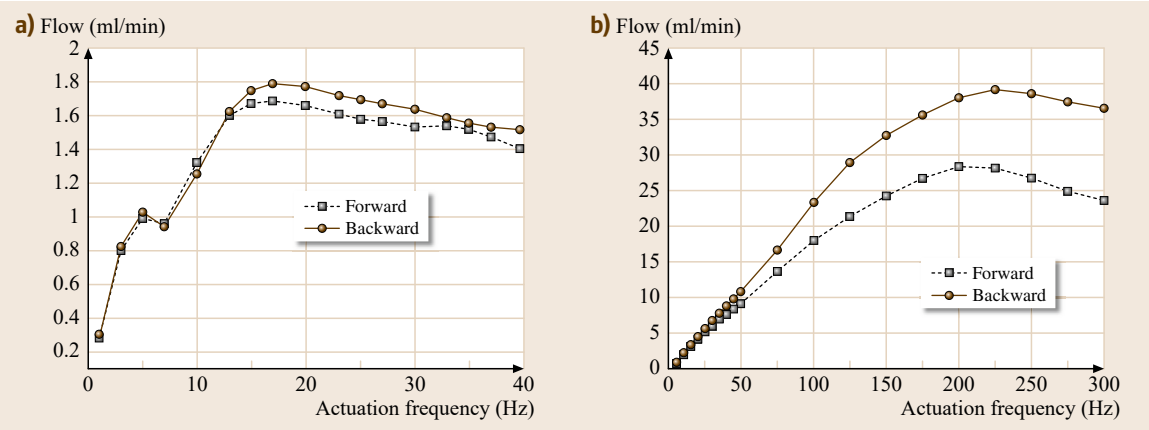

Fig. 58.15a,b Frequency-dependent flow characteristic of the quasi peristaltic plastic pump for water **(a)** and air **(b)**

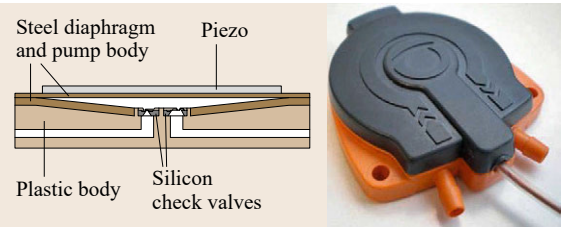

Fig. 58.16 Multimaterial micropump micro-run from Paritec (courtesy of Fraunhofer EMFT)

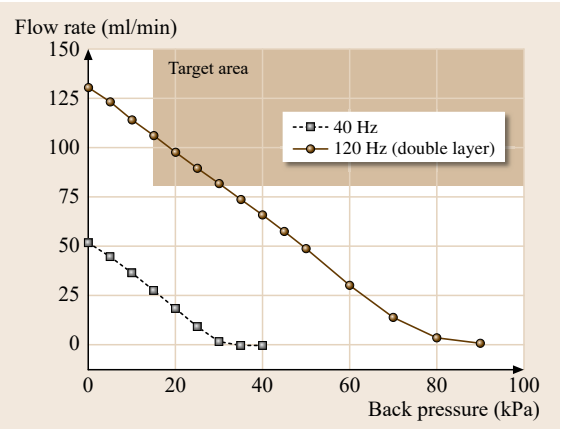

Fig. 58.17 Back-pressure-dependent flow rate of the micro-run micropump with water

Very high droplet frequencies of more than 1000 Hz can be achieved.

Drawbacks of the Sniffman principle are unwanted odors due to the open reservoir at the filling port, and bubbles inside the pump chamber resulting in a malfunction of the jetter (no bubble tolerance). The lack of bubble tolerance is a general drawback of this *ink jet* method of droplet generation.

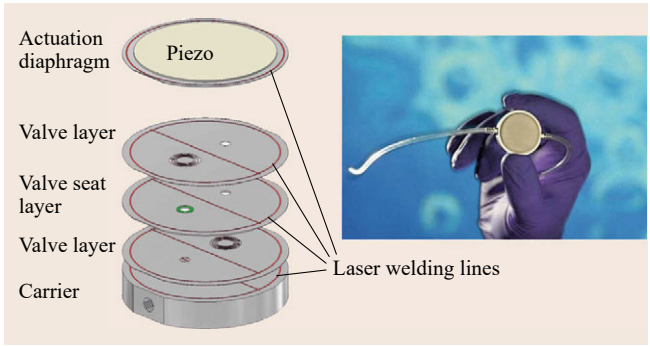

Fig. 58.18 Metal micropump consisting of steel foils structured by laser cutting and joined together by laser welding

58.3.3 Integrated Scent Microdosing System

Another approach for realizing an integrated scent dosing system has been developed at Fraunhofer EMFT. A nanoliter micropump delivers a small amount of liquid scent from a reservoir to a heater chamber. The heater is activated and evaporates the scent. An air micropump with high flow rate pushes the evaporated scent through a micro nozzle (Fig. 58.22). Prototypes of the system have been realized (Fig. 58.23).

Drawbacks of the evaporation method are on the one hand the energy consumption of the heater, and on the other hand the possible unwanted recondensation of gaseous scent at cold walls inside or at the scent dosing device. Furthermore, the heating energy has to be specifically optimized for every type of liquid scent.

58.3.4 Free Jet Dispenser Based on Volume Displacement

There is another jet technology with a different jet generation principle: The actuator can be designed to

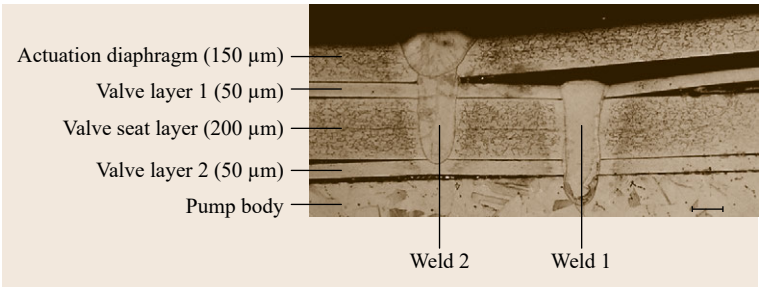

Fig. 58.19 Cross-section of the metal micropump with the weld grooves from laser welding. The thickness of the four steel layers is 450 µm, together with the piezo thickness of 300 µm the active thickness of the micropump (without body) is less than 1 mm

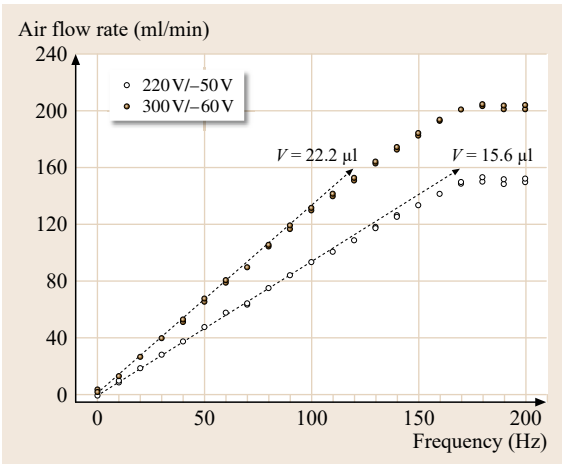

Fig. 58.20 Air flow rate of the Fraunhofer EMFT metal micropump, depending on the operation frequency, at two different actuation voltages (no back pressure)

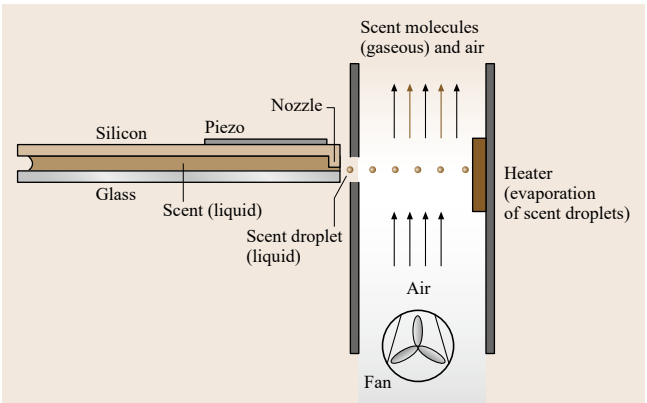

Fig. 58.21 Principle of the *Sniffman* scent dispenser

generate not only a pressure wave, but also to displace a stroke volume in the pump chamber, resulting in a jet ejection outside the nozzle. The dosing volume of that jet ejection is about 50 nl and thus three orders of magnitude larger than in the ink jet technology. An example of this dosing principle is the pipe-jet from Biofluidix, Germany [58.17].

This jetter has a better bubble tolerance compared to the ink jet principle; however the refilling frequency of the pump chamber is limited by the surface forces: During the refilling of the chamber, the surface forces of the liquid at the nozzle have to be at flow stop to avoid sucking in air through the nozzle. That is why, depending on the surface force and the nozzle diameter, a jetting frequency of max. 100 Hz can be achieved.

One possibility to increase the jetting frequency is the combination of a micropump with a nozzle [58.18]. The check valves of the micropump enable a very quick refilling (Fig. 58.24). With that, several 100 Hz of jetting frequency can be achieved. Furthermore, this jetter with integrated micropump is self-priming and bubble tolerant.

58.3.5 Nebulizers

Beside the headspace concept (evaporation or outgassing), the scent molecules can also be nebulized. With this technology, small droplets are generated. Using microactuators, especially piezo ultrasonic nebulizers driven at several hundred kilohertz are used. The liquid (e.g., perfume) is in contact with a metal diaphragm driven by a piezo, and an aerosol is generated which can be transported to the nose. Depending on the piezo frequency, the droplet size has a certain distribution and can vary between submicrometer and some tenths of micrometer.

Recent developments for medical inhalers use a metal diaphragm, which is perforated by laser drilling with a defined hole diameter forming a metal sieve. Around the metal sieve a ring piezoceramics is glued. Beyond the sieve, the drug is in contact with the holes of the sieve. After actuation of the piezo with an actuation voltage with an ultrasonic frequency, the sieve vibrates generating a fog of drug droplets above the sieve. The diameter of the droplets have a sharp size distribution according to the diameter of the holes. The size of the droplets define their ability to be inhaled into the human lung: while droplets with a diameter of 3 µm and below can be deeply inhaled, diameters of 15 µm stay outside. This is why the inhaler eFlow from Pari has a metal

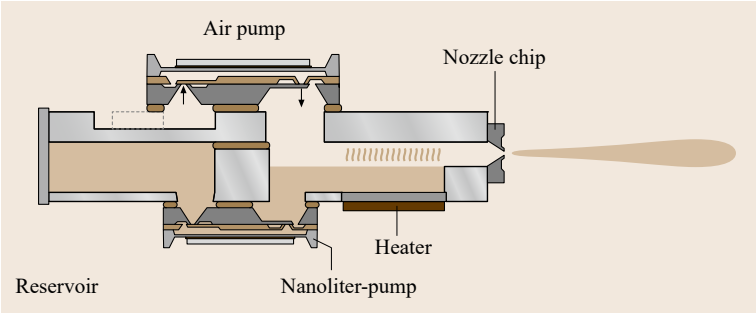

Fig. 58.22 Microdosing system for scent, developed by Fraunhofer EMFT

diaphragm with 3 µm nozzles. In contrast to medical applications, scent droplets shall not be inhaled into the lung in order to prevent potential health damage by the scent.

Dispensing scent by nebulizers has two drawbacks:

- It must be ensured that the liquid droplets of the scent do not harm the user. Thus the diameter of the droplets generated by the nebulizer technology must be large enough so that they cannot be inhaled into the lung.
- Due to the large aerosol diameters, the consumption of scent is much higher compared to evaporation or outgassing. This means that a larger amount of scent is needed for the same scent impression. Next, the big scent droplets contaminate the environment around the user, resulting to an unwanted permanent odor.

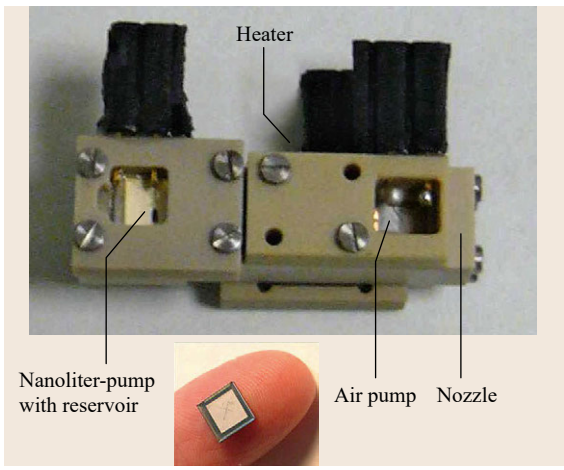

Fig. 58.23 Demonstrator of microdosing system (after [58.19], courtesy of Fraunhofer EMFT)

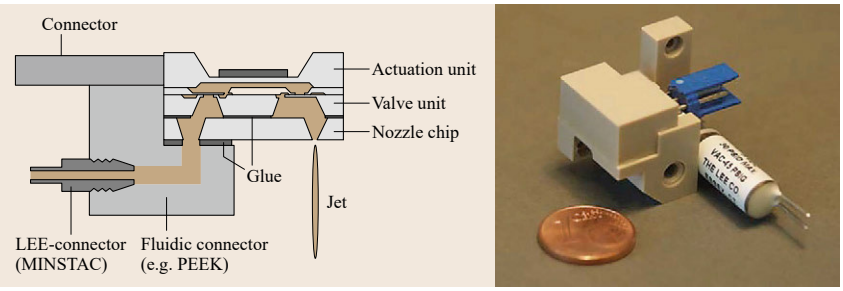

Fig. 58.24 Principle and prototype of a jet dispenser with integrated valves (after [58.18], courtesy of Fraunhofer EMFT)

58.4 New Applications for Microdosing of Scent

Dosing of small volumes of scent molecules enables new features: due to the small dosing volumes:

- The change of the scent impression within short time (even between two breath cycles) becomes possible.
- The concentration of scent molecules is so small that only the user of the dosing unit and not the person right beside can smell the scent.

The application scenarios behind these technologies are mostly not yet realized. In this chapter new potential applications are discussed.

58.4.1 New and Accurate Olfactometers

The accurate dosing of gaseous scent samples can be used to deliver scent in a defined way, in order to improve the accuracy of conventional olfactometers. Transferring the scent to a carrier gas (normally air) by bubbling the air through a scent liquid (state of the art of olfactometers, Fig. 58.25a) is not very accurate nor defined. A more accurate way would be to sample the scent from the headspace of a scent liquid by a micropump (Fig. 58.25b) in a defined way, and dose this to the carrier gas stream. Knowing the concentration of scent molecules of the headspace, the concentration of scent in the carrier stream can be adjusted precisely.

The micropump type μP001FW from Fraunhofer EMFT has a stroke volume of 250 nl, a flow rate of 15 μl/min at 1 Hz operation frequency, and a max. flow rate of 40 ml/min. This allows the concentration to be adjusted in a wide range of more than 3 orders of magnitudes. To ensure a high dosing accuracy, it is important to realize a small dead volume in the micropump and its housing and fluidic tubings between headspace and carrier stream.

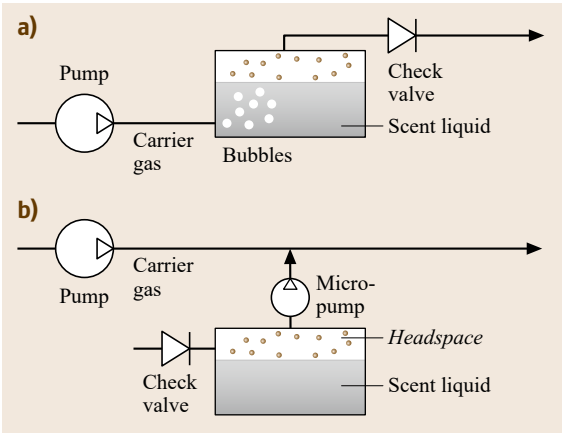

Fig. 58.25a,b Fluidic schematics of a conventional olfactometer **(a)** and a new olfactometer **(b)** using a micropump to deliver scent to a carrier stream

58.4.2 Training of Sniffer Dogs with Microdosing Units

Dogs can be trained to find people after earthquakes or avalanches; they can detect illegal drugs or explosives at airports or stations or can help to find and remove mines in mine-contaminated areas. Currently, it takes approximately 4 months to train a sniffer dog in a dog school. Microdosing units mounted at the dog's muzzle can help to train sniffer dogs more quickly and precisely.

Medical Application: Early Detection of Lung Cancer (LC) by Micropump-Trained Sniffer Dogs

The vision behind this idea is to establish a noninvasive analysis of exhaled breath of patients as a new tool for early in vitro diagnosis of lung cancer.

Early diagnosis is essential to improve the prognosis and healing rate of the patient. However, up to now, there is no established method for lung cancer screening. For lung cancer, the 1 year survival rate in UK is 29.4%, falling to 7.8% after 5 years. Lung cancer is rarely curable at late stages. However, if lung cancer is found in an early stage (currently often only by chance), according to the American Cancer Society (ACS) the survival rate is much higher at 47% (instead below 10% for all stages).

Current methods for diagnosis of lung cancer are x-ray detection and bronchoscopy. However, the random diagnosis of early lung cancer (stage 1) by x-ray detection is difficult. Round focals from 5 to 10 mm can easily be overlooked. The new diagnostics approach using sniffer dogs could be a major step forward to detect lung cancer in an early stage.

For lung cancer detection from breath samples using diagnostic sensor devices, such as electrochemical sensors or pattern recognition sensors, no clear target has been identified yet. Animals' noses are an alternative to detect biomarkers for lung cancer. Here, multidisciplinary scientific and technological knowledge from diverse fields is needed to improve and establish *living sensors* for clinical applications. Prospective clinical trials have convincingly shown that animals' noses (especially sniffer dogs) have the potential to detect lung cancer from patient's breath [58.6, 20]. To establish the diagnostic capabilities of sniffer dogs,

new multidisciplinary methods have to be developed to quantify and scale the training of dogs regarding organic compound targeting in the patient's breath.

It can be hypothesized from that work that there are organic compounds transported with the human breath with the potential to act as biomarkers for LC. A quantitative reference of the relevant biomarker amount could be established with the help of technical sensors analysing the breath samples. That would allow the quantification of the sensitivity of a dog's nose for this purpose.

In a previous prospective clinical trial conventionally trained sniffer dogs were used to discriminate breath samples of lung cancer patients and healthy individuals: In 220 patients lung cancer was detected with 71% sensitivity and 93% specificity. With that, the presence of lung cancer specific organic compounds in the breath of patients was hypothesized. Comparing these results with established multimodal diagnostic capabilities, it is apparent that dogs can detect lung cancer better than conventional diagnostic tools.

However, one big drawback using dogs for lung cancer diagnosis is the missing acceptance of an animal nose as a lung cancer sensor both for physicians and for patients. The diagnosis of a life-threatening cancer disease currently cannot be based on a not verifiable animal decision. Additionally, medical industry, especially big and expensive diagnostic analysis tool producers, state that there are approved and validated methods, which can be traced back to an objective calibration standard. For sniffer dogs there is a lack of traceability.

Up to date training methods of dogs are the same as 100 years ago: A toy is contaminated with the target scent and hidden. The dog searches for that hidden toy. He will get a reward if he finds the hidden toy. It is not possible to measure during the training how much target molecules arrive at the dog's nose. Accordingly, up to now, it is very difficult to introduce a *scaling method* for the dog. In order to increase the acceptance of diagnosis by dogs, there is an urgent need to train dogs in a way that enables every dog's nose to be calibrated by the dog's trainer to the breath sample and the organic compound which is representative for lung cancer.

Microdosing systems could be a breakthrough in solving this problem: A micropump with a connected reservoir of patient's breath sample can be mounted onto the muzzle of the dog. The dosing system is so small that it does not disturb the dog. The dog's trainer can activate the microdosing system and deliver tiny amounts of breath sample directly to the snout of the dog (Fig. 58.26).

A tiny remote-controlled microdosing system to be mounted on a dog's muzzle will be used to train the

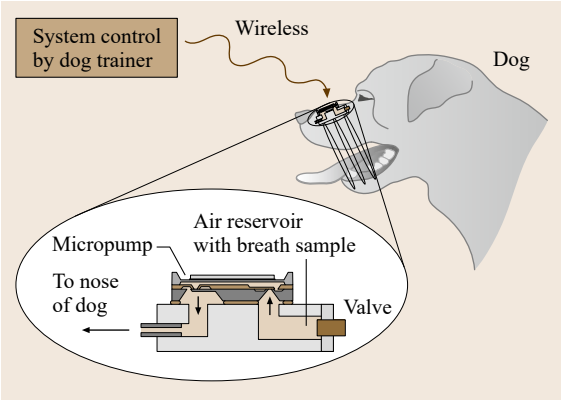

Fig. 58.26 Concept of dog training with microdosing systems

dogs at dog school Lisar and to sample patient's breath. Fraunhofer EMFT and Lisar have jointly developed a demonstrator of a microdosing system including a micropump, electronics, a reservoir, and a check valve (Fig. 58.27) and successfully tested the system at the dog school Lisar (proof of concept).

With this microdosing tool, dogs can be trained much faster (4 weeks instead of 4 months). On the other hand, the dogs can be trained to a lower detection level, and dogs can be calibrated to a defined concentration.

Especially for lung cancer detection, if the patient's breath is stored in the reservoir, the dog trainer can repeat the dosing several times to ensure the response of the dog. The dog trainer can also mount the same microdosing system to another dog to ensure the feedback of the first dog.

These microdosing tools can thus help to establish sniffer dogs for medical diagnostics.

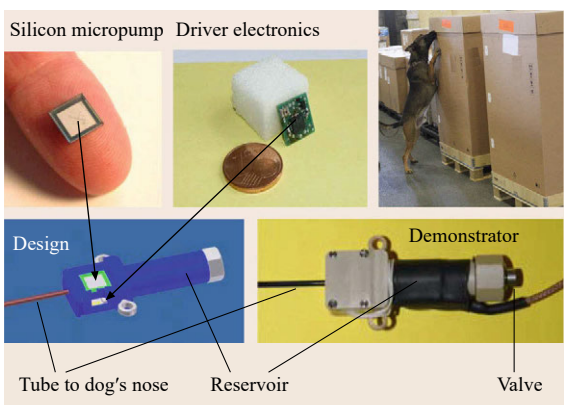

Fig. 58.27 Demonstrator of microdosing system for dog training (courtesy of Fraunhofer EMFT and dog school Lisar)

58.4.3 Scent in Cars

Peugeot and Citroen offered controllable scent sticks already 10 years ago; currently the models Peugeot 308 or Citroen DS3 Cabrio have scent-dispensing technologies. The acceptance on the market has been limited in the past, but the situation is currently changing, due to the car market increase in Asia [58.21]. Recently, the S-Class Mercedes started to offer scent-dosing technology [58.22]. Other car manufacturers now begin to work on own solutions for scent dosing in the car.

The scent delivery technology is similar to the headspace concept of Fig. 58.25: The scent cartridge generates a headspace scent atmosphere in a closed volume. To release the scent, a flap valve, driven by a stepper motor, is opened and closed (Fig. 58.28). When the flap is open, the air stream of the car's air conditioning takes the scent headspace and transports it inside the car [58.23].

58.4.4 Scent for Games

Scent scenarios can be combined with video and audio for games. For this, a headset with integrated multiple scent-dosing systems (e.g., 32 different scents) driven by battery-powered programmable electronics is needed. The game software can control the dosing unit in the headset wirelessly (e.g., via bluetooth), enabling scent scenarios for the user depending on the current game event.

To play different games, disposable scent cartridges can be exchanged and mounted nearby the nose (e.g., at to mouthpiece of a headset). The scent cartridge of a video game related to formula 1 race (scent of tunnel, forest, breaks, fuel, . . .) has different scents than a game to train memory and to learn to distinguish flowers, or an adventure game to explore an old castle.

58.4.5 Scent for *Point of Sales*

Another future application field for microdosing units is scent dosing at *point of sales* in super markets or shopping malls. One of the pioneers in this field is Airplay [58.24]. The buying decision of many goods is supported by scent impressions (drugstore articles, fruits, juice, etc.) a customer can choose the product at a user interface panel, and beside the product information at the monitor the scent-dosing unit delivers a scent impression of the selected product to the customer. Once the customer makes the buying decision, he gets a light signal helping him to find the product quickly.

Another future possibility of scent microdosing is the replacement of room scenting in shopping malls (which fills the whole room) with customer-specific scenting. Different customers might prefer specific scent impressions. Depending on the customer, a specific scent can be delivered, and this scent can be replaced by another fragrance for the next customer. Here, a technology similar to the car scent dosing technology is needed.

58.4.6 Scent in Mobile Phone Applications

During the last decade, several attempts to integrate scent to mobile phones have been made. Motorola submitted an invention for scent delivery in portable electronic devices in January 2003 (US 20040203412 A1), whereas in 2004 Samsung patented a mobile phone with scent delivery function [58.25]. In 2005, Hyundai launched the mp 280 perfume cell phone, with a user-refillable scent reservoir [58.26]. In 2007, a mobile phone from Sony Ericsson (SO703i) entered the market with scent delivery function. In 2008, isi and Convisual developed a scent function for mobile phones [58.27]. Here, a scent can be released by a scent cartridge with different liquid reservoirs. Recently, Scentee (Tokyo) developed a scent dosing module, which can be adapted at the headphone port of the mobile phone [58.28]. Every scent capsule has a capacitance for 100 bursts, the user can select between various scents.

There are many challenges to be solved for integration of scent delivery functions in mobile phone applications: On the one hand it is difficult to miniaturize both the delivery technology and the scent reservoirs, especially, if more than one scent is to be delivered. On the other hand, the energy consumption of the delivery technology has to be low to meet the mobile phone requirements. Next the scent reservoirs have to be tightly

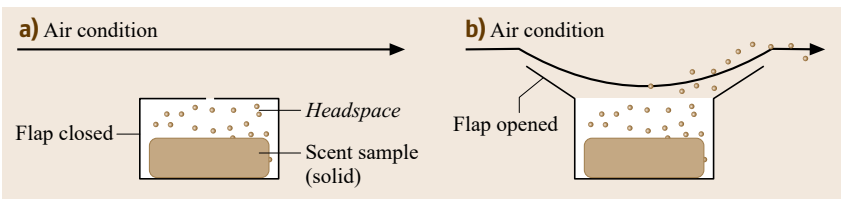

Fig. 58.28a,b Principle of scent dosing unit in automotive (after [58.23]): **(a)** closed; **(b)** open

closed, when the delivery function is off. And last but not least, the scent reservoir has to be changeable by the user if it is empty, and all parts have to be very cost-efficient.

One possibility is to provide *scent cards* with different liquid or solid scent materials attached on the card. There is a heater for each reservoir, which can be controlled by system electronics. To release the specific scent, the heater which is located nearby the scent material is activated. This method does not need mechanical parts like pumps or valves. Drawbacks are high energy consumption for the heaters, and false scents due to untight reservoirs, as well as condensation of scent vapor on the mobile phone.

To overcome these drawbacks, miniaturized and cost-efficient micropumps, microfans, and microvalve technologies are needed. Micropumps and microvalves made of silicon seem to have the highest potential to meet these miniaturization and cost requirements in the future.

58.5 Conclusions

Micro dosing of scent is a new and emerging field enabling many new applications. Delivery systems for very small volumes of one or several different scent pulses in close proximity to the human nose are needed to realize this vision. Considering all scent delivery technologies, micropump-based systems appear to be most suitable. Very small micropump arrays, which are mounted nearby the nose (e.g., at the mouthpiece of a headset), will deliver very small volumes of scent which can be sniffed just once by the person. This technology enables the perception of *scent scenarios* analogous to *picture scenarios* (movies) or *sound scenarios* (music) for human beings.

About the Authors

Artin Arshamian

Karolinska Institutet
Department of Clinical Neuroscience
Stockholm, Sweden

Radboud University
Centre for Language Studies, and Donders Institute for Brain, Cognition, and Behaviour
Nijmegen, The Netherlands
artin.arshamian@ki.se

Chapter E.42

Artin Arshamian earned his PhD at Stockholm University and is currently a postdoctoral fellow jointly at Karolinska Insitutet, Stockholm, and Radboud University, the Donders Institute for Brain, Cognition and Behaviour in Nijmegen, the Netherlands.

Anat Arzi

The Weizmann Institute of Science
Department of Neurobiology
Rehovot, Israel
anat.arzi@weizmann.ac.il

Chapter E.45

Anat Arzi is a postdoctoral fellow studying the interaction between olfaction and sleep at the Department of Neurobiology at the Weizmann Institute of Science, Israel. She completed her PhD and MSc in Neurobiology at the Weizmann Institute of Science and her BSc at the Hebrew University of Jerusalem.

Jinhe Bai

U.S. Dept. of Agriculture – Agricultural Research Service
US Horticultural Research Laboratory
Fort Pierce, USA
jinhe.bai@ars.usda.gov

Chapter B.9

Jinhe Bai received his PhD from Osaka Prefecture University. He worked at the Northwest A&F University Yangling, Osaka EPA, Oregon State University, and the Produce Safety and Quality and Horticultural Research Laboratories in the US. Now at the US Horticultural Research Laboratory, he works on flavor chemistry of fruits and vegetables, focusing on flavor and quality changes occurring during postharvest storage and processing.

Nicolas Baldovini

Université de Nice-Sophia Antipolis
Institut de Chimie de Nice, UMR 7272 CNRS
Nice, France
baldovin@unice.fr

Chapter A.3

Nicolas Baldovini received his PhD from the University of Corsica. After postdoctoral work at the University Louis Pasteur in Strasbourg and the University of Tokyo he was appointed Assistant Professor at the Université de Nice-Sophia Antipolis. His research interests are focused on the analytical and synthetic chemistry of odorants, mainly on the analysis of natural raw materials and structure–odor relationships.

Elisabeth Baldwin

U.S. Dept. of Agriculture – Agricultural Research Service
US Horticultural Research Laboratory
Fort Pierce, USA
liz.baldwin@ars.usda.gov

Chapter B.9

Dr Baldwin received her PhD in Horticulture from the University of Florida. She worked for the USDA-ARS for 26 years and is Research Leader of the Citrus and Other Subtropical Products Unit at the US Horticultural Research Laboratory. She works in the area of postharvest fruit physiology and food science, with emphasis in applied and basic problems related to fresh or processed fruit product storage, ripening, and flavor.

Jonathan Beauchamp

Fraunhofer Institute for Process Engineering and Packaging (IVV)
Freising, Germany
jonathan.beauchamp@ivv.fraunhofer.de

Chapter C.18

Jonathan holds a MSc degree in Physics and a PhD in Environmental Physics. He is currently Senior Scientist and Deputy Head of the Department of Sensory Analytics at Fraunhofer IVV in Freising, where his research interests focus on olfactory detection and perception of aromas, as well as the temporal development and release of volatiles from food.

Ofir Benjamin

Tel Hai College
Food Science Department
Upper Galilee, Israel
ofirbe@telhai.ac.il

Chapter B.14

Ofir Benjamin received his PhD from Otago University at Dunedin. Part of his PhD studies took place at Fraunhofer Institute in Germany. His thesis involved research on flavor release from emulsion under oral conditions using novel methods to mimic the mouth conditions. He is currently working at the Food Science Department at Tel Hai College and MIGAL Research Institute in Israel, focusing on sensory aspects of food and dairy science.

Carlo Bicchi

University of Torino
Dept. of Drug Science and Technology
Torino, Italy
carlo.bicchi@unito.it

Chapter C.19

Carlo Bicchi has been Full Professor of Pharmaceutical Biology at the Faculty of Pharmacy of the University of Turin since 1990. His main field of research is the development of analytical technologies for biologically active secondary metabolites in vegetable matrices. Carlo Bicchi is a member of the scientific boards of several international symposia and of the editorial or advisory boards of international journals.

Roland Blach

Fraunhofer Institute for Industrial Engineering IAO
Stuttgart, Germany
roland.blach@iao.fraunhofer.de

Chapter G.55

Roland Blach is the Head of the virtual environments group at Fraunhofer IAO. He is an architect of VR system lightning and has participated in many industrial and research projects. He was involved in the technical management of the European INTUITION Network of Excellence on VR/AR Technology. He also coordinated STREP IMVIS on multiuser display technology.

Sanne Boesveldt

Wageningen University
Division of Human Nutrition
Wageningen, The Netherlands
sanne.boesveldt@wur.nl

Chapter E.44

Sanne Boesveldt received her MSc in Biomedical Sciences/Neurobiology from VU University and obtained her PhD studying olfactory dysfunction in Parkinson's disease by means of psychophysical and neuroimaging techniques. After a postdoctoral position at the Monell Chemical Senses Center she moved back to The Netherlands and has since been an Assistant Professor in Sensory Science and Eating Behavior in the Division of Human Nutrition at Wageningen University.

Heinz Breer

University of Hohenheim
Institute of Physiology
Stuttgart, Germany
breer@uni-hohenheim.de

Chapter D.27

Heinz Breer studied biology and chemistry at the University Münster. He worked as a scientist at the Max-Planck-Institute for Biophysical Chemistry in Göttingen, at the University Osnabrück, and at the Albert-Einstein-College in New York. He has been Full Professor of Physiology at the University of Hohenheim since 1987. His fields of studies are the chemical senses, in particular olfaction and gustation in vertebrates and insects.

Andrea Burdack-Freitag

Fraunhofer Institute for Building Physics
Department Building Chemistry, Building Biology, Hygiene
Valley, Germany
andrea.burdack-freitag@ibp.fraunhofer.de

Chapter C.26

Andrea Burdack-Freitag studied chemistry and nutritional science and obtained her PhD in Flavor Chemistry at the Technical University Munich. She has been a Research Scientist with the Fraunhofer Institute for Building Physics at Holzkirchen since 2005, investigating off-odors of construction products and technical materials for indoor and automotive use by sensorial and chemical analytical methods.

Cecilia Cagliero

University of Torino
Dept. of Drug Science and Technology
Torino, Italy
cecilia.cagliero@unito.it

Chapter C.19

Cecilia Cagliero received her MSc and PhD in Pharmaceutical Chemistry and Technology at the University of Turin. She has been Assistant Professor in Pharmaceutical Biology at the University of Turin since December 2011. Her main field of research is enantioselective GC development and applications and advanced HPLC techniques in the natural products fields.

Annachiara Cavazzana

Monell Chemical Senses Center
Philadelphia, USA
acavazzana@monell.org

Chapter F.51

Annachiara Cavazzana is a PhD student at the University of Padova, Italy, in the Experimental and Clinical Psychobiology program. Her research mostly focuses on the influence of multisensory stimuli on behavior and neural processing.

Cinzia Cecchetto

Monell Chemical Senses Center
Philadelphia, USA
ccecchet@sissa.it

Chapter F.51

Cinzia Cecchetto is a PhD student at the International School of Advanced Studies (ISAS-SISSA), Trieste (Italy) in the Neuroscience and Society Lab. Her research is focused on how perceptual and cognitive stimuli impact on social behaviors.

Pierre Chatelain

ChemCom SA
Brussels, Belgium
pch@chemcom.be

Chapter C.22

Pierre Chatelain holds a PhD in Biophysics and a PhD in Biochemistry. He has 30 years of experience in several pharmaceutical companies (Sanofi, UCB). He has a proven track record with more than 150 scientific publications and patents on new chemical entities, mode of action of drugs, high throughput screening (HTS). He joined Chemcom in 2006 as Chief Scientific Officer.

Sung-Tong Chin

Imperial College London
Department of Surgery and Cancer
London, UK
s.chin@imperial.ac.uk

Chapter C.17

Sung-Tong Chin was awarded his PhD from Monash University and began his post-doctoral fellowship in the School of Chemistry, Monash University, Australia, in 2013. His current research interests mainly involve the development of multidimensional gas chromatography systems, incorporation of olfactometry with MDGC, and profiling of complex mixtures using MDGC coupled with tandem mass spectrometry technology.

Norbert Christoph

Bavarian Health and Food Safety Authority (LGL)
Würzburg, Germany
norbert.christoph@lgl.bayern.de

Chapter C.20

Dr Norbert Christoph studied Food Chemistry at the Technical University of Karlsruhe. He received his PhD in Flavor Chemistry and Sensory Analysis in 1994 from the Technical University of Munich-Weihenstephan. He has been employed at the Bavarian Health and Food Safety Authority (LGL) since 1995. The focus of his work is applied research, official control and authentication of wines, spirits, and fruit juices using 2H-NMR stable isotope analysis.

Géraldine Coppin

Yale University
The John B. Pierce Laboratory
New Haven, USA
geraldine.coppin@yale.edu

Chapter E.40

Géraldine Coppin studied Psychology at the University of Lille 3 and obtained her PhD in Psychology and Affective Sciences from the University of Geneva. Géraldine has been a postdoctoral fellow at the John B. Pierce Laboratory, Yale University and at the Max Planck Institute for Neurological Research in Cologne. She investigates the behavioral and cerebral correlates of flavor nutrient conditioning in humans using psychological methods and fMRI.

Chiara Cordero

University of Torino
Dept. of Drug Science and Technology
Torino, Italy
chiara.cordero@unito.it

Chapter C.19

Chiara Cordero received her MSc and PhD in Pharmaceutical Chemistry from the University of Turin. She has been Assistant Professor of Food Chemistry at the University of Turin since November 2001. In 2008, she was awarded with the Leslie S. Ettre Award for her work in the field of capillary gas chromatography applied to food characterization.

Michael Czerny

Frauenhofer Institute for Process Engineering and Packaging
Freising, Germany
michael.czerny@ivv.fraunhofer.de

Chapter B.16

Michael Czerny studied Food Chemistry at the Friedrich-Alexander University of Erlangen-Nürnberg. After obtaining his PhD on coffee aroma from the Technical University Munich he was a researcher at the German Research Center for Food Chemistry. He has been a Senior Scientist at the Fraunhofer Institute for Process Engineering and Packaging since 2007. Besides food aroma, off-odors of packaging are in his field of activity.

Manfred Dangelmaier

Fraunhofer Institute for Industrial Engineering IAO
Stuttgart, Germany
manfred.dangelmaier@iao.fraunhofer.de

Chapter G.55

Manfred Dangelmaier received his doctoral degree from the University of Stuttgart. He has been Director of Business Area Engineering Systems of Fraunhofer IAO, including the units Virtual Environments, Visual Technologies, Digital Engineering, and Human Factors Engineering. He is currently working in the fields of ergonomics, human–machine interaction and virtual engineering, and teaches Virtual Engineering at the University of Stuttgart and the Technical University of Cluj.

Philippe Darriet

Bordeaux University
Institute of Vine and Wine Sciences
Villenave d'Ornon, France
philippe.darriet@u-bordeaux.fr

Chapter B.8

Philippe Darriet is Professor of Enology at the Institute of Vine and Wine Sciences (ISVV), University of Bordeaux. His PhD thesis (1993) was on enology and his Habilitation thesis (2002) was on wine aroma chemistry. Philippe Darriet's research activities are mainly the characterization of volatile compounds and the study of chemical, biochemical, and microbiological aspects related to the release of their chemical reactivity during the ageing process.

Sylvain Delplanque

University of Geneva
Swiss Center for Affective Sciences
Geneva, Switzerland
sylvain.delplanque@unige.ch

Chapter E.40

Sylvain Delplanque studied Human Physiology and Psychophyiology at the University of Lille I, completed postgraduate studies in Neuropsychology and Cognitive Neuroscience, and in 2004 received a PhD in Cognitive Sciences from the University Pierre et Marie Curie (Paris). He then joined the Swiss Center for Affective Sciences at the University of Geneva as a postdoctoral scholar. Sylvain Delplanque is a Senior Researcher at the Swiss Center for Affective Sciences.

Richard L. Doty

University of Pennsylvania
Perelman School of Medicine
Philadelphia, USA
doty@mail.med.upenn.edu

Chapter C.23

Richard L. Doty is the Director of the University of Pennsylvania's Smell and Taste Center. Dr Doty received his BSc in Psychology from Colorado State University, his MA from California State University, San Jose, in conjunction with NASA, and his PhD from Michigan State University, East Lansing. He received postdoctoral fellowship training at the University of California, Berkeley, and the University of Pennsylvania, Philadelphia.

Michael Dresel

AB InBev Belgium n.v.
Leuven, Belgium
michael.dresel@hotmail.de

Chapter B.7

Michael Dresel studied Food Chemistry and wrote his PhD thesis at the Technical University Munich on the hard resin of hops and completed a short exchange program at the Oregon State University on pharmacological properties of hop-derived compounds. Afterwards he started to work in Belgium as a postdoctoral fellow at the Faculty of Engineering Technology (KU Leuven), before joining AB InBev in 2015 as a Product & Process Development Specialist in Europe. His research focuses on sensory- and bio-active compounds of hops and beer.

Graham Ellis

Givaudan International SA
Regulatory Affairs and Product Safety
Vernier, Switzerland
graham.ellis@givaudan.com

Chapter D.36

Graham Ellis studied Chemistry at the Universtity of Wales, Cardiff, and Toxicology at Birmingham Universtity. He worked at Unilever Safety Assurance and Environmental Centre and is now Head of Global Toxicology for the fragrance division of Givaudan and responsible for Regulatory Affairs and Product Safety for EAME with a specific focus on fragrance allergy.

Karl-Heinz Engel

Technical University of Munich
Chair of General Food Technology
Freising-Weihenstephan, Germany
k.h.engel@wzw.tum.de

Chapter B.15

Karl-Heinz Engel is Professor at the Technical University of Munich, Germany, and holds the Chair of General Food Technology. His research activities comprise analysis of flavor compounds (sulfur-containing volatiles, enantiospecific analysis), metabolite profiling of crops (rice, barley), and analysis of novel foods (phytosteryl/-stanyl esters). He has been involved in the safety assessment of flavorings by the European Food Safety Authority (EFSA).

Graham T. Eyres

University of Otago
Department of Food Science
Dunedin, New Zealand
graham.eyres@otago.ac.nz

Chapter C.17

Graham Eyres completed a PhD in Food Science at the University of Otago, focusing on the identification of aroma compounds in hop essential oils. In the Sensory and Consumer Science group at CSIRO, his research focused on flavor release during consumption and the impact on sensory perception. The focus of his current research is to understand the physicochemical factors that influence perception of flavor.

Jitka Fialová

Charles University
Faculty of Science
Prague, Czech Republic

National Institute of Mental Health
Klecany, Czech Republic
jitka.fialova@nudz.cz

Chapter F.50

Jitka Fialová is currently a PhD student at Charles University in Prague. She is working as a junior researcher at the National Institute of Mental Health, Czech Republic. Her research focuses on human chemical communication and environmental factors affecting human body odor.

Jean-Jacques Filippi

Université de Nice-Sophia Antipolis
Institut de Chimie de Nice, UMR 7272
CNRS
Nice, France
jfilippi@unice.fr

Chapter A.3

Jean-Jacques Filippi studied Natural Product Chemistry at the University of Corsica and obtained his PhD from the Université de Nice-Sophia Antipolis. After postdoctoral research at the University of Hohenheim on prebiotic chemistry, he became Assistant Professor at LCMBA. His scientific interests focus on analytical chemistry, particularly the identification of odor impact molecules in extracts of the flavor and fragrance industry.

Jörg Fleischer

University of Hohenheim
Institute of Physiology
Stuttgart, Germany
joergf@uni-hohenheim.de

Chapter D.27

Joerg Fleischer received his PhD in Biology from the University of Hohenheim. He did his postdoctoral work at the University of Hohenheim in the laboratory of Heinz Breer. Working as a Private Lecturer and Scientific Collaborator at the University of Hohenheim, his primary research interest is chemo- and thermosensory neurons in the Grueneberg ganglion.

Johannes Frasnelli

Université du Québec à Trois-Rivières
Department of Anatomy
Trois-Rivières, Canada
johannes.a.frasnelli@uqtr.ca

Chapter E.46

Johannes Frasnelli received a MD from University of Vienna Medical School in 2001 and a habilitation diploma from Technical University of Dresden. After several fellowships at McGill University, University of Montreal and the Monell Chemical Senses Center in Philadelphia, PA, he is now a Professor of Anatomy at the University of Quebec in Trois-Rivieres and works on the neuro-anatomical fundamentals of chemosensory perception.

Jessica Freiherr

RWTH Aachen University
Diagnostic and Interventional
Neutoradiology
Aachen, Germany
jfreiherr@ukaachen.de

Chapter E.38

Jessica Freiherr studied Nutritional Science at Friedrich-Schiller-University Jena and received her PhD in Neuroscience from LMU Munich. After a postdoctoral visit at the Monell Chemical Senses Center in Philadelphia, she became Assistant Professor in Neuroscience of Chemosensation at RWTH Aachen University. Additionally, she leads the MultiSense Research Group at Fraunhofer IVV in Freising.

Eric Frérot

Firmenich SA
Analytical Innovation Corp. R&D
Geneva, Switzerland
eric.frerot@firmenich.com

Chapter B.11

Eric Frerot received his PhD in Organic Chemistry from the University of Montpellier II. After a postdoctoral visit at the Institute of Organic Chemistry in Lausanne with Professor Pierre Vogel, he joined Firmenich, a Swiss family-owned flavor and fragrances company. He is currently working on flavor chemistry, trying to find new taste and aroma ingredients in natural products.

Kristina Friedland

Friedrich-Alexander-Universität
Erlangen-Nürnberg
Department of Chemistry and Pharmacy
Erlangen, Germany
kristina.leuner@fau.de

Chapter D.34

Kristina Friedland received her PhD in Pharmacology from Goethe University, Frankfurt. After working in Frankfurt and later in the Department of Neurobiology at the University of Alabama in Birmingham, she became Professor of Molecular and Clinical Pharmacy at Friedrich-Alexander-Universität of Erlangen-Nürnberg. Her research focuses on the involvement of TRPC channels in the pathophysiology of CNS disorders and on natural compounds that activate TRPC channels.

Marcus A. Glomb

Martin-Luther University
Halle-Wittenberg
Institute of Chemistry
Halle, Germany
marcus.glomb@chemie.uni-halle.de

Chapter A.5

Marcus A. Glomb received his PhD from the University of Stuttgart. After appointments in the pharmaceutical and food industry, he worked at Case Western Reserve University in Cleveland. He habilitated at the Technical University of Berlin and is now a Full Professor of Food Chemistry at Martin-Luther-University Halle-Wittenberg. His major subjects are enzymatic and non-enzymatic browning reactions and identification and characterization of novel food ingredients.

Amy R. Gordon

Karolinska Institutet
Department of Clinical Neuroscience
Stockholm, Sweden
amy.gordon@ki.se

Chapter F.51

Amy R. Gordon is a graduate student in Clinical Neuroscience at Karolinska Institutet, Stockholm, Sweden. Her research interests are centered on social chemosignals and the multimodal nature of social interaction.

Brian Guthrie

Cargill Inc.
Global Food Reserach
Wayzata, USA
brian_guthrie@cargill.com

Chapter C.21

Brian Guthrie has been working in the food and ingredients industry with responsibilities spanning from knowledge building, utilizing fundamental science, to formulation and product development. He has also worked extensively in food sensory science, from studies on the cellular events of olfaction and gustatory signal transduction to developing an understanding of consumer preference.

Ute Habel

Uniklinik RWTH Aachen
Department of Psychiatry, Psychotherapy and Psychosomatics
Aachen, Germany
uhabel@ukaachen.de

Chapter E.39

Ute Habel is a Professor of Neuropsychological Gender Studies in the Department of Psychiatry, Psychotherapy, and Psychosomatics at RWTH Aachen University. Her research focus lies on neurobiological correlates of emotion and cognition, including olfactory functions and their interactions. She focuses on gender differences in healthy individuals and psychiatric patients. Furthermore, she investigates effects of psychotherapeutic interventions and hormonal influences on behavior and cerebral activation.

Ilana S. Hairston

Academic College of Tel Aviv Yaffo
Department of Behavioral Sciences
Tel Aviv, Israel
ilanahai@mta.ac.il

Chapter E.45

Ilana S. Hairston is a Senior Lecturer at the Academic College of Tel Aviv – Jaffa, Israel, with expertise in sleep research. She completed her PhD in Neuroscience at Stanford University and postdoctoral training at UCSF and UC Berkeley. Prior to moving to Israel, she was an Assistant Professor in Psychiatry, at the University of Michigan.

Christian Harteneck (deceased)

Chapter D.34

Hanns Hatt

Ruhr-University Bochum
Department of Cell Physiology
Bochum, Germany
hanns.hatt@ruhr-uni-bochum.de

Chapter D.33

Professor Hanns Hatt is Head of the Department of Cell Physiology at the Ruhr-University Bochum. He received his PhD in Biology in 1976 and his MD in 1981 from the University of Munich, Germany. His research focuses on the characterization of the effect of odors at the cellular and molecular level in humans and higher vertebrates.

Heike Hauschildt

Olfasense GmbH
Kiel, Germany
hhauschildt@olfasense.com

Chapter C.25

Dr Heike Hauschildt studied Meteorology and Oceanography at the University Kiel. She obtained her Diploma in Meteorology and her PhD at the Geomar in Kiel. Since 2006 she has been working in the field of odor measurement at Odournet GmbH. She is Team Leader of the Environmental Section and Head of the Measurement Laboratory.

Jan Havlíček

Charles University
Faculty of Science
Prague, Czech Republic
jhavlicek@natur.cuni.cz

Chapter F.50

Jan Havlíček received his PhD from Charles University in Prague in 2004 and has been working there since then. His work focuses on factors affecting the quality of human body odor, human chemical communication, and the evolution of human sexuality.

Anja Heinlein

Friedrich-Alexander-Universität
Erlangen-Nürnberg
Department of Chemistry and Pharmacy
Erlangen, Germany
anja.heinlein@fau.de

Chapter C.26

Anja Heinlein is a state-certified food chemist, who received her degree from Friedrich-Alexander-Universität of Erlangen-Nürnberg and the Bavarian Health and Food Safety Authority. She was awarded her PhD from FAU in 2014, which was supported by the German National Academic Foundation, for her research on pharmacokinetics of odorants. She is currently working with the Chemical and Veterinary Investigatory Office in Freiburg.

Thomas Hummel

TU Dresden
Smell & Taste Clinic, Department of Otorhinolaryngology
Dresden, Germany
thummel@mail.zih.tu-dresden.de

Chapters D.31, E.47

Dr Hummel received his medical education in at the Friedrich-Alexander University of Erlangen-Nürnberg, where he also participated in a special program on pharmacology and toxicology. He worked in the Department of Pharmacology at the University of Iowa and was Assistant Professor in the Department of Otorhinolaryngology of the University of Pennsylvania, before joining TU Dresden where he works at an olfactory/gustatory dysfunction clinic.

Cornell Kärnekull

Stockholm University
Department of Psychology
Stockholm, Sweden
stina.cornell.karnekull@psychology.su.se

Chapter E.42

Stina Cornell Kärnekull is a doctoral student at the Department of Psychology, Stockholm University, Sweden.

Gerhard Krammer

Symrise AG
Holzminden, Germany
gerhard.krammer@symrise.com

Chapter C.20

Dr Gerhard Krammer studied Food Chemistry at the Julius Maximilians University of Würzburg. He completed his PhD studies in 1992 in the field of glycosides and flavor precursors in plants and fruits. In the course of his career Dr Krammer has held various positions in flavor research, quality control and regulations and is currently leading the research and technology development program at Symrise Flavors on a global level.

Basile N. Landis

Universtiy of Geneva Medical School and
Geneva University Hospitals
Department of Otorhinolaryngology
Geneva, Switzerland
basile.landis@hcuge.ch

Chapter D.31

Basile Landis went to Medical School in Zurich and Geneva and is an ear, nose, and throat specialist. He is currently Head of the Rhinology-Olfactology Unit, University Hospital of Geneva. In addition to studying in Geneva (Silvain Lacroix), he was trained in Dresden (Thomas Hummel) and Bern (Marco Caversaccio). His activities are patient care, nasal surgery and research, as well as clinical work-ups for chemosensory disorders.

Maria Larsson

Stockholm University
Department of Psychology
Stockholm, Sweden
marlar@psychology.su.se

Chapter E.42

Maria Larsson is the Chair of Perception and Psychophysics and Director of Gösta Ekman Laboratory, Department of Psychology, Stockholm University, Sweden. She is the Principal Investigator of the large research program *Our unique sense of smell* running 2015–2020, funded by the Swedish Foundation for Humanities and Social Sciences.

Matthias Laska

Linköping University
IFM Biology
Linköping, Sweden
malas@ifm.liu.se

Chapter D.32

Matthias Laska is Professor of Zoology at Linköping University, Sweden. He received his doctoral degree in 1988 from the University of Bonn, Germany. His research interests include odor structure–activity relationships, correlations between chemosensory performance and neuroanatomical or genetic features, olfactory-guided behavior in mammals, and studies of lateralized behavior.

Erica Liberto

University of Torino
Dept. of Drug Science and Technology
Torino, Italy
erica.liberto@unito.it

Chapter C.19

Erica Liberto obtained her MSc and PhD in Pharmaceutical Chemistry and Technology at the Turin University. She has been Assistant Professor in Food Chemistry at the University of Turin since November 2006. Her main field of research is exhaustive studies on the volatile fraction of food and advanced statistical methods.

Johan N. Lundström

Karolinska Institutet
Department of Clinical Neuroscience
Stockholm, Sweden
johan.lundstrom@ki.se

Chapters E.39, E.41, F.51

Johan N. Lundström is an Associate Professor at Karolinska Institutet and at the Monell Chemical Senses Center. Using a range of functional neuroimaging and behavioral approaches, his group specializes in the neuronal processing of human chemosensation and multisensory integration. He has authored more than 50 original publications on the topic.

Simona Manescu

Université de Montréal
Department of Psychology
Montréal, Canada
simona.manuescu@umontreal.ca

Chapter E.46

Simona Manescu received her BSc in Psychology from Concordia University in 2010. She is presently completing her PhD in Clinical Neuropsychology at Montreal University in Canada. She is currently researching the impact of vision loss on the olfactory abilities in blind individuals.

Bettina Mannebeck

Olfasense GmbH
Kiel, Germany
bmannebeck@olfasense.com

Chapter C.25

Bettina Mannebeck obtained a degree in Civil Engineering at Luebeck University of Applied Sciences. Since 1996 she has been working in the field of odor measurement at Odournet GmbH, where she is Managing Director and Deputy Head of the Measurement Laboratory. She has designed, implemented, and evaluated odor projects in different fields of odor emission and impact, and in the area of product and material testing.

Dietmar Mannebeck

Olfasense GmbH
Kiel, Germany
dmannebeck@olfasense.com

Chapter C.24

Dietmar Mannebeck is a worldwide leading product developer of olfactometer and sampling equipment for environmental odor measurements. His professional experience of 29 years includes hundreds of odor-related studies and consulting projects of various industry sectors worldwide. He is member of several standardization working groups of CEN, VDI, and DIN for odor-related regulations and appointed Technical Auditor of the German accreditation body DAkkS.

Philip J. Marriott

Monash University
Australian Centre for Research on
Separation Science
Victoria, Australia
philip.marriott@monash.edu

Chapter C.17

Philip Marriott received his PhD from LaTrobe University, Victoria, Australia in 1980, followed by postdoctoral research at the University of Bristol, UK. He commenced his academic career in chemistry at the National University of Singapore, returning to Australia to RMIT University, and is now Professor at Monash University. His work is primarily in high resolution, multidimensional and comprehensive two-dimensional gas chromatography, and mass spectrometry, for a broad array of applications.

Florian Mayer

Fraunhofer Institute for Building Physics
Department Building Chemistry,
Building Biology, Hygiene
Valley, Germany
florian.mayer@ibp.fraunhofer.de

Chapter C.26

Florian Mayer studied Food Chemistry at the Ludwig-Maximilians-University Munich. He graduated with a PhD in Flavor Chemistry from the German Research Center for Food Chemistry and did postdoctoral work with the Western Regional Research Center of the United States Department of Agriculture. He has been a Scientist with the Fraunhofer Institute for Building Physics, Holzkirchen, Germany, since 2002, investigating odorous emissions from materials.

Andreas Natsch

Givaudan Schweiz AG
Biosciences
Duebendorf, Switzerland
andreas.natsch@givaudan.com

Chapters D.36, F.49

Andreas Natsch received his PhD in Environmental Microbiology from the Swiss Federal Institute of Technology. After studies at the Spanish National Centre for Biotechnology in Madrid, he moved to the Research Department of the fragrance manufacturer Givaudan. In this role, he elucidated the key enzymatic steps involved in human body odor formation and investigated the biological activities of fragrance materials.

Nathalie Nibbe

Olfasense GmbH
Fraunhoferstrasse 13
Kiel, Germany
nnibbe@olfasense.com

Chapter G.56

Nathalie Nibbe received her PhD from Christian-Albrechts University, Kiel, in 2014 for her work on the interaction of vision and olfaction in marketing. She has been an employee of Odournet GmbH since 2010 and specializes in odor sensory evaluation of products and materials.

Johannes Niebler

Friedrich-Alexander-Universität
Erlangen-Nürnberg
Department of Chemistry and Pharmacy
Erlangen, Germany
johannes.niebler@fau.de

Chapter A.4

Johannes Niebler studied Food Chemistry at the Friedrich-Alexander-Universität of Erlangen-Nürnberg. In his diploma thesis, he worked on the synthesis of thio derivatives of terpenes in the group of Prof Balaban at Aix-Marseille University in France. He received an academic scholarship from the Cusanuswerk for both his undergraduate and graduate studies. His current research focuses on frankincense odor chemistry, odor analytics, and pyrolysis methods.

Jeannette Nuessli Guth

ETH Zurich
Dept. of Health Sciences and Technology
Zurich, Switzerland
jnuessli@ethz.ch

Chapter G.53

Jeannette Nuessli Guth is a Food Scientist by training and received her doctoral degree from ETH Zurich, Switzerland. She carried out her postdoctoral studies at INRA in France. At present, she is responsible for research and education in Sensory Science at ETH Zurich, Switzerland. Her current areas of research include sensory language and emotions in sensory science.

Mats J. Olsson

Karolinska Institutet
Department of Clinical Neuroscience
Stockholm, Sweden
mats.j.olsson@ki.se

Chapter F.51

Mats J. Olsson is Professor at the Karolinska Institutet. His research focuses on olfactory psychophysics, perception, cognition and communication primarily using behavioral approaches.

Ulrich R. Orth

Kiel University
A&F Marketing – Consumer Psychology
Kiel, Germany
uorth@ae.uni-kiel.de

Chapter G.56

Ulrich R. Orth is a Professor of Marketing and A&F Marketing - Consumer Psychology at Christian-Albrechts-University (CAU), Kiel, Germany. He received his doctorate and habilitation degrees from Munich University of Technology and worked at Mendel University and Oregon State University. His research focuses on consumer behavior and psychology-related topics such as design, consumer-brand relations, and cross-cultural issues.

Jane K. Parker

University of Reading
The Flavour Center
Reading, UK
j.k.parker@rdg.ac.uk

Chapter B.10

Jane K. Parker is a Physical-Organic Chemist and received her PhD from Cambridge University. After having worked in both the chemical and the flavor industry, she moved to the University of Reading to train as a Flavor Chemist. She is a Senior Research Fellow at the University of Reading and Founder and Director of The Flavour Centre, the University's interface between flavor research and the food industry.

Valentina Parma

Monell Chemical Senses Center
Philadelphia, USA
vparma@monell.org

Chapters E.41, F.51

Valentina Parma is a postdoctoral fellow at the Monell Chemical Senses Center, Philadelphia. Her research activity and recent publications have been focused towards the study of olfactory processing and the effect of odors on typical and atypical human behaviors.

Bettina M. Pause

University of Düsseldorf
Department of Experimental Psychology
Düsseldorf, Germany
bettina.pause@hhu.de

Chapter F.52

Bettina M. Pause is Professor of Biological and Social Psychology at the University of Düsseldorf. She uses chemosensory stimuli as a methodological approach for understanding phylogenetically ancient emotions. Her applied research interests are related to deviant emotional processes, as manifested in diverse psychological disorders. She was awarded the Prize for Outstanding Science by the Heinrich–Heine–Universität in Düsseldorf in 2009.

Ofer Perl

The Weizmann Institute of Science
Department of Neurobiology
Rehovot, Israel
ofer.perl@weizmann.ac.il

Chapter E.45

Ofer Perl studied Life Sciences at the Hebrew University of Jerusalem. During his graduate studies in the group headed by Prof Noam Sobel at the Weizmann Institute of Science, he discovered his interest in the influences of odors during sleep in both health and disease. He is currently pursuing his PhD in the same group, investigating the roles of sniffing in human cognitive functions.

Magali Philippeau

ChemCom SA
Brussels, Belgium
mph@chemcom.be

Chapter C.22

Magali Philippeau obtained a MSc in Biotechnology from ENSTBB. She worked with Novartis and in the Laboratory of Histology, Neuroanatomy, and Neuropathology at the Free University of Brussels. In 2004, she joined Chemcom. She leads the high throughput screening department that is active in deorphanizing olfactory receptors, identifying antagonists or enhancers, and in achieving structure–activity relationship studies for receptors of industrial interest.

Wilhelm Pickenhagen

Chavannes-des-Bois, Switzerland
pickenhagen@bluewin.ch

Chapter 1

Wilhelm Pickenhagen received his PhD from the University of Paris. After postdoctoral studies at MIT, he became a Research Chemist and then Department Head at the Research Division, and later Vice President General-Manager for Flavor Technology at Firmenich. He has also worked with PPP Geneva SA and Dragoco AG (now Symrise AG) and is Lecturer and Honorary Professor at the University of Göttingen and at the University of Versailles-St. Quentin.

Anne Plotto

U.S. Dept. of Agriculture – Agricultural Research Service
US Horticultural Research Laboratory
Fort Pierce, USA
anne.plotto@ars.usda.gov

Chapter B.9

Anne Plotto has a degree in Agricultural Engineering from Montpellier Sup Agro and a PhD in Horticulture and Plant Physiology from Oregon State University. She has worked towards improving eating quality of fruit by using horticultural practices. Her current research at the US Horticultural Research Laboratoryin Fort Pierce focuses on flavor analysis and sensory evaluation of fruit and fruit products.

Alexandre Pons

Bordeaux University
Institute of Vine and Wine Sciences
Villenave d'Ornon, France

Seguin Moreau Cooperage
Cognac, France
alexandre.pons@u-bordeaux.fr

Chapter B.8

Alexandre Pons studied Chemistry, Physics, and Enology at the University of Bordeaux. In 2006 he obtained his PhD in Enology in the group of Professor D. Dubourdieu, where he worked on the identification of volatile compounds associated with the organoleptic quality of wines and oak wood. In 2007, his work on the study of the flavor of prematurely aged white wines was awarded the Great Prize of the Amorim Academy.

Christina Regenbogen

Uniklinik RWTH Aachen
Department of Psychiatry, Psychotherapy and Psychosomatics
Aachen, Germany
cregenbogen@ukaachen.de

Chapter E.39

Christina Regenbogen obtained her PhD at RWTH Aachen University, where she studied emotion processing and empathy in healthy individuals, and patients with schizophrenia and depression. She works at Karolinska Institutet, where she is responsible for designing, running, and analyzing studies that share common ground on finding out how huamns deal with multisensory input that reaches them via nose, eyes, and ears.

Gary Reineccius

University of Minnesota
Department of Food Science and Nutrition
Saint Paul, USA
greinecc@umn.edu

Chapter B.12

Gary Reineccius received his PhD from Penn State University. He has been employed at the University of Minnesota since then, except for sabbatical leaves spent at Fritzsche Dodge and Olcott (New York), Nestle (Switzerland), and Robertet S.A. (France). His area of research is food flavors, most notably, their encapsulation and controlled release.

Martin Richter

Fraunhofer Research Institution for
Modular Solid State Technologies EMFT
Munich, Germany
martin.richter@emft.fraunhofer.de

Chapter G.58

Martin Richter studied Physics at the Technical University of Munich. He received his PhD in Electrical Engineering for work in the field of microfluidic systems. He managed several research projects in the field of microdosing systems, and since 2000 he has been responsible for the Department of Micromechanics, Actuators, and Fluidics at Fraunhofer EMFT in Munich. He focuses on micropumps and microdosing systems.

S. Craig Roberts

University of Stirling
Division of Psychology
Stirling, UK
craig.roberts@stir.ac.uk

Chapter F.50

S. Craig Roberts holds a Personal Chair at the University of Stirling. His early research was in mammalian chemical communication and behavioral ecology, but he now studies human behavior within an evolutionary framework, particularly mechanisms involved in social communication and mate choice.

Philippe Rombaux

University of Louvain – Brussels
Department of Otorhinolaryngology,
Cliniques Universitaires Saint Luc
Woluwe-Saint-Lambert, Belgium
philippe.rombaux@uclouvain.be

Chapter D.31

Philippe Rombaux is Head of the Dept. or Otorhinolaryngolgy at the University of Louvain in Brussels. His principal interest is medical and surgical rhinology with a special focus on the chemosensory perception. He developed with his collaborators a Smell and Taste Center where all the common techniques to measure the chemosensory function in the clinic are performed such as psychophysic, electrophysiology and imagery.

Patrizia Rubiolo

University of Torino
Dept. of Drug Science and Technology
Torino, Italy
patrizia.rubiolo@unito.it

Chapter C.19

Patrizia Rubiolo studied Pharmacy at the University of Turin and spent research periods at the Laboratory of Medicinal Chemistry and Microbiology of the University of Antwerp and the Institute of Organic Chemistry of TU Berlin. She joined the faculty of the University of Turin in 1993 and has held a full professorship since 2011. Her research is directed to exhaustive studies of biologically active fractions from plants.

Maren Runte

ZHAW Zurich University of Applied Sciences
School of Applied Linguistics
Winterthur, Switzerland
maren.runte@zhaw.ch

Chapter G.53

Maren Runte received her M.A. degree in Linguistics from Ruhr-University Bochum and her doctoral degree in Linguistics from University Duisburg-Essen, Germany. Since 2009 she is Lecturer at ZHAW School of Applied Linguistics, Switzerland. Her research interests include lexicography, semantics and communication for special purposes.

Michael Rychlik

Technical University of Munich
ZIEL Research Center for Nutrition and
Food Sciences
Freising, Germany
michael.rychlik@tum.de

Chapter D.29

Michael Rychlik is the Head of Analytical Food Chemistry and the R&D Division of the Bioanalytics Department at the Technical University of Munich (TUM). He graduated in Food Chemistry from the University of Kaiserslautern and he was appointed Full Professor at TUM in 2010. His group has been working for 15 years in the field of developing analytical methods for bioactive food components, such as odorants.

Christian Salles

Université Bourgogne Franche-Comté
(UBFC)
Centre for Taste and Feeding Behavior
Dijon, France
christian.salles@dijon.inra.fr

Chapter B.14

Christian Salles is a Senior Scientist in Food Science with a PhD in Agronomic Sciences. He joined the National Institute of Agricultural Research in 1990 and leads a research group at the Centre for Taste and Feeding Behavior in Dijon. His main research field is flavor release and perception during chewing of foods.

David Sander

University of Geneva
Swiss Center for Affective Sciences
Geneva, Switzerland
david.sander@unige.ch

Chapter E.40

David Sander studied Mathematics and Psychology at the University René Descartes (Paris, France), and received a PhD in Cognitive Sciences from the University Louis Lumière (Lyon, France). In 2002, he joined the Department of Psychology at the University of Geneva (Switzerland). He is now Full Professor in this Department where he directs the Laboratory for the Study of Emotion Elicitation and Expression. In 2012, he was appointed Director of the Swiss Center for Affective Sciences, and of the National Center of Competence in Research (NCCR) in Affective Sciences. He is mainly interested in the mechanisms involved in emotion elicitation, and how these mechanisms modulate attention, memory, and decision-making.

Elise Sarrazin

Surenes, France
elise.sarrazin.marechal@gmail.com

Chapter G.54

Elise Sarrazin received her PhD in Analytical Chemistry from the Faculty of Enology of the University of Bordeaux, France, in 2007. She carried out her postdoctoral work at Firmenich R&D Department in Geneva. She then joined the University of Nice as Assistant Professor. She is currently working for a leading fragrance company in Paris. Her work is focused on fragrance chemistry, especially on fragrance raw materials.

Benoist Schaal

University of Burgundy
Centre of Taste and Feeding Behaviour
Dijon, France
benoist.schaal@u-bourgogne.fr

Chapter E.43

Benoist Schaal is Director of Research at the National Center for Scientific Research (CNRS) at the Center for Smell, Taste, and Food Science in Dijon, France.

Antje Schellenberg

Bavarian Health and Food Safety
Authority (LGL)
Oberschleissheim, Germany
antje.schellenberg@lgl.bayern.de

Chapter C.20

Dr Antje Schellenberg studied Food Chemistry at the Technical University of Munich. She completed her PhD studies in Flavor Chemistry at the Technical University of Munich in 2002. Afterwards she was responsible for stability analysis of drugs in a pharmaceutical laboratory until 2007. Since 2007 she has been employed at the Bavarian Health and Food Safety Authority and is responsible for stabile isotope analysis.

Boris Schilling

Givaudan Schweiz AG
Fragrance S&T – Biosciences
Duebendorf, Switzerland
boris.schilling@givaudan.com

Chapter D.28

Boris Schilling studied Biochemistry and Molecular Biology and received his PhD from the University of Zurich, Switzerland, in 1994. He continued his education with postdoctoral training at Harvard Medical School in Boston, before joining Givaudan as a biochemist and biotechnologist. He is currently heading the biosciences platform in the Fragrance Science and Technology organization of Givaudan.

Han-Seok Seo

University of Arkansas
Dept. of Food Science
Fayetteville, USA
hanseok@uark.edu

Chapter E.47

Han-Seok Seo studied Food Science in Korea, before his training to become an Otorhinolaryngologist at TU Dresden's Smell and Taste Clinic. Since 2012 he has been Assistant Professor at the University of Arkansas in the Department of Food Science. His research interests are chemosensory perception, contextual influences on taste and smell perception, and the relationship between emotion and olfaction.

Janina Seubert

Karolinska Institutet
Department of Clinical Neuroscience
Stockholm, Sweden
janina.seubert@ki.se

Chapter E.39

Janina Seubert completed her postdoctoral training in Human Chemosensation at the Monell Chemical Senses Center in Philadelphia. At Karolinska Institutet, her research goal is to understand the unique informational value carried by olfactory perception in humans, and how it adaptively complements other sensory modalities during interactions with the environment.

Anne-Marie Seuvre

University of Burgundy/Agrosup Dijon
UMR PAM Food Processing and Microbiology
Dijon, France
anne-marie.seuvre@u-bourgogne.fr

Chapter B.13

After receiving her MSc in Industrial Biotechnology from the University of Technology of Compiègne, Anne-Marie Seuvre obtained her PhD in Macromolecular Physico-Chemistry and Solution Chemistry. She received her habilitation in 2007. She is currently an Associate Professor at the University of Burgundy, where she teaches biological physico-chemistry in the food industry section.

Barbara Sgorbini

University of Torino
Dept. of Drug Science and Technology
Torino, Italy
barbara.sgorbini@unito.it

Chapter C.19

Barbara Sgorbini received her MSc in Pharmaceutical Chemistry and Technology from the University of Turin. Dr Sgorbini has been Assistant Professor of Pharmaceutical Biology at the University of Turin since November 2006. Her main field of research is the development of new solvent-free sample preparation techniques and analysis of natural products of vegetable origin.

Noam Sobel

The Weizmann Institute of Science
Department of Neurobiology
Rehovot, Israel
noam.sobel@weizmann.ac.il

Chapter E.45

Noam completed a PhD in Neuroscience at Stanford University (1999) and a postdoctoral fellowship at Caltech (2000), before taking the position of Assistant (2001) and later Associate (2005) Professor of Neuroscience at UC Berkeley. In 2007, Noam moved back to Israel, where he took the position of Professor of Neurobiology at the Weizmann Institute. Noam's lab studies human olfaction.

Veronika Somoza

University of Vienna
Department of Nutritional and Physiological Chemistry
Wien, Austria
veronika.somoza@univie.ac.at

Chapter D.35

Veronika Somoza graduated from the University of Giessen and received her *venia legendi* for Food Sciences from the University of Kiel. She was Vice Chair at the German Research Centre for Food Chemistry before she accepted a tenured professorship at the University of Madison. Currently, she is Head of the Department of Nutritional and Physiological Chemistry at the University of Vienna.

Marc Spehr

RWTH Aachen University
Dept. of Chemosensation
Aachen, Germany
m.spehr@sensorik.rwth-aachen.de

Chapter D.30

Marc Spehr received his PhD from Ruhr-University Bochum in 2002. After a postdoctoral position at the University of Maryland, School of Medicine in Baltimore, he was appointed Independent Research Group Leader at Ruhr-University Bochum. In 2009, Marc Spehr was appointed a Lichtenberg-Professor in Chemosensation at RWTH Aachen University. He works on signaling mechanisms in mouse chemodetection and the physiological basis of spermatogenesis.

Christian Starkenmann

Firmenich SA
Geneva, Switzerland
christian.starkenmann@firmenich.com

Chapter F.48

Christian Starkenmann received his PhD in Organic Chemistry from Geneva University, Switzerland, in 1990. He currently works as Distinguished Scientist at Firmenich S.A. in flavor and fragrances research and development. His main focus is the understanding of food flavors, the modulation of taste perception via mouth microflora, and also the study of malodor formation in the environment.

Jörg Strotmann

University of Hohenheim
Institute of Physiology
Stuttgart, Germany
strotman@uni-hohenheim.de

Chapter D.27

Jörg Strotmann studied Biology at the University of Osnabrück and received his diploma in 1989. He obtained his PhD in 1992 from the University of Hohenheim in Stuttgart. From 1995–1996 he engaged in postdoctoral work at Rockefeller University in the Department of Developmental Biology and Neurogenetics. He has been Associate Professor in the Institute of Physiology in Hohenheim since 2005.

Katinka Temme

University of Applied Sciences Augsburg
Faculty of Architecture and Civil Engineering
Augsburg, Germany
katinka.temme@hs-augsburg.de

Chapter G.57

Katinka Temme studied Architecture at the University of Karlsruhe and at Arizona State University. After several years in various international architectural firms and after teaching experience at the University of Darmstadt and the Bauhaus-University Weimar, Katinka has held the Chair for Analog Architecture and Design at the University of Applied Sciences in Augsburg, Germany, since 2013. She collaborates with Daniel Reisch in their architectural think tank studio3architekten.

Michael Thiel

Sana-Klinikum Remscheid GmbH
Academical Teaching Hospital of the University of Cologne
Remscheid, Germany
michael.thiel@sana.de

Chapter D.37

Michael Thiel is a pediatrician at Sana-Hospital Remscheid specialized in neonatology as well as in naturopathy. He started his scientific work as Vice Director of the Pediatric Department at the University of Witten/Herdecke in the field of integrative pediatrics, with focus on the evaluation of complementary and alternative medicine in neonatology.

Alex Veithen

ChemCom SA
Brussels, Belgium
ave@chemcom.be

Chapter C.22

Alex Veithen obtained degrees in Biology at the University of Louvain and in Cell Biology at the de Duve Institute. After postdoctoral work at the Pasteur Institute of Lille, he joined ChemCom. He works on functional assay development for olfactory and taste receptors and also manages structure–activity relationship studies for agonists and antagonists of olfactory receptors.

Sophie Veitinger

Ruhr-University Bochum
Department of Cell Physiology
Bochum, Germany
herlisb6@rub.de

Chapter D.33

Dr Sophie Veitinger studied Biology at Ruhr-University Bochum, Germany. During her PhD she focused on the male reproductive system, and one of her interests was olfactory receptor signaling in human sperm. Currently, she is engaged in postdoctoral work in the Department of Cell Physiology at Ruhr-University Bochum and concentrates on the ectopic expression of olfactory receptors in human skin and sperm.

Andrée Voilley

University of Burgundy/Agrosup Dijon
UMR PAM Food Processing and Microbiology
Dijon, France
andree.voilley@u-bourgogne.fr

Chapter B.13

Emeritus Professor and Doctor of Science since 1986, Andrée Voilley has always taught and researched in the same field. She was part of the research group Food Science and Engineering at the University of Burgundy. Her area of expertise extends to physico-chemical properties of small molecules (especially mass transfer of aroma compounds) at the interfaces in complex food systems.

Jessica Walker

University of Vienna
Department of Nutritional and Physiological Chemistry
Wien, Austria
jessica.walker@univie.ac.at

Chapter D.35

Jessica Walker graduated in Food Chemistry and Toxicology and completed her dissertation at the Technical University of Kaiserslautern in 2008. She worked in the Department of Food Science at the University of Madison. Currently, she investigates the anti-inflammatory impact of food constituents on models of periodontal and systemic inflammation as a Research Assistant at the University of Vienna, Austria.

Donald Wilson

NYU Scool of Medicine
Department of Child and Adolescent Psychiatry
New York, USA
donald.wilson@nyumc.org

Chapter E.41

Donald A. Wilson is Professor at the Nathan Kline Institute and NYU School of Medicine. He is interested in how the mammalian brain processes and remembers information. Using electrophysiological, behavioral, genetic, neuroanatomical, and pharmacological approaches his group explores the neurobiology of memory and the role of experience in sensory system function.

Matthias Wüst

University of Bonn
Institute of Nutritional and Food Sciences
Bonn, Germany
matthias.wuest@uni-bonn.de

Chapter A.2

Matthias Wüst received his PhD in Food Chemistry. After postdoctoral studies at Washington State University, he joined the Institute of Food Chemistry of the Goethe University Frankfurt. In 2003, he was appointed Professor of Food Chemistry at the University of Applied Sciences Western Switzerland. He has been Full Professor of Bioanalytics/Food Chemistry at the University of Bonn since 2009.

Chahan Yeretzian

ZHAW Zurich University of Applied Sciences
Institute of Chemistry and Biotechnology
Wädenswil, Switzerland
yere@zhaw.ch

Chapter B.6

Chahan Yeretzian received his PhD in Chemistry from the University of Bern. He has worked at the University of California, Los Angeles and the Technical University of Munich and has held positions at Nestlé. In 2008 he joined the Zurich University of Applied Sciences, were he is Head of the Center for Analytical and Physical Chemistry. He is currently a board member of the Specialty Coffee Associations of Europe.

Wiebke Zander

Cargill GmbH
Hamburg, Germany
wiebke_zander@cargill.com

Chapter C.20

Dr Wiebke Zander studied Chemistry at Leibniz University of Hannover and finished her diploma in 2008. For her PhD she studied natural product chemistry. She was Research Assistant in the group Microbial Drugs in Braunschweig before taking up a position at the Analytical Research Center of Symrise AG in Holzminden, where she was responsible for preparation and structure elucidation. She has been Laboratory Manager at Cargill GmbH, Hamburg, since 2015.

Erika Zardin

Fraunhofer Institute for Process Engineering and Packaging (IVV)
Freising, Germany
erika.zardin@ivv.fraunhofer.de

Chapter C.18

Dr Erika Zardin has a background in Environmental Sciences (MSc, University of Venice, 2004) and Analytical Chemistry (PhD, University of Western Australia, 2011). She worked as a Research Scientist on the chemical analysis of volatile aroma compounds and is currently a Business Field Manager in sensory processes and technologies; both positions being at the Fraunhofer Institute for Process Engineering and Packaging IVV in Freising (Germany).
