Preface

We are delighted to deliver a second, expanded, and brought up to date edition of the *Handbook of Computational Chemistry*. It is apparent that this fast-growing research area requires constant updates. The second edition of our book provides the reader with current, key references to both methodologies and the results of the computational chemistry studies. We selected various focus areas to be covered by the handbook, and this selection is a subjective choice of the editors since due to a vast number of studies published every year, only the most representative examples of applications could be incorporated in the five volumes of this edition.

An amazing transformation of chemistry from an exclusively experimental science to one with theoretical foundations started in the early twentieth century, when principles of quantum mechanics had been established. The most notable progress has been accomplished during the last 50 years during which time it has advanced through noticeable developments and applications of computational methods. This transformation has its roots in both theoretical breakthroughs (Heisenberg's 1925 and Schrodinger's 1926 first papers on quantum mechanics) and the development of the first computer – Electronic Numerical Integrator and Computer (ENIAC) – built in 1943 for the US Department of the Army. However, it took about 20 years after the creation of the ENIAC computers to deliver computational chemistry techniques to the scientific community. Such early methods, being semiempirical in nature, do rely on the large number of experimental parameters. Disappointedly, though such an approach unites experimental chemistry origins with new theoretical approaches, it proves to produce in various cases artificial computational results, and it also lacks reliable parameters for some elements. The next successful chapter for computational chemistry started in the 1970s with applications of nonempirical ab initio methods. The first ab initio computer code popular among non theoreticians – GAUSSIAN 70 – was developed in the 1970s by John A. Pople's group. It initiated a computational chemistry revolution that fired up in the 1980s when supercomputers became accessible to the general scientific community. Also during this period, density functional theory approaches gained a prominent position among efficient computational methods. The vital role of computational chemistry in many research areas was convincingly acknowledged in 1998 when the chemical and physical community celebrated the Nobel Prize that was awarded to two leading

computational experts. It was not by chance that Walter Kohn and John A. Pople were recognized by the Nobel Committee for their contributions to the development of efficient computational methods for quantum chemistry.

Over the past years, different methods of theoretical chemistry were successfully transformed into useful tools that could be applied in diverse areas of research, science, and technology. Owing to the fundamental methodological developments and continuous impressive progress in computational technologies in the last quarter of the twentieth century, several fast and user-friendly programs were developed and made accessible to a wide community of scientists. These near-automatic computer codes are evidence of how methods of theoretical chemistry could be applied as both diagnostic and predictive research tools which support efforts or even guide the direction of traditional experimental approaches. The user-friendly features of commercial codes combined with efficient visualization methods make them accessible to researchers with almost no educational background. Generally, only a limited knowledge and a little formal experience in theoretical chemistry are required to use such programs and to obtain some numerical data. This might cause unexpected outcomes. Most of the methods of theoretical (quantum) chemistry have a limited range of applications, and their use by an inexperienced amateur who performs computational studies without understanding such constraint may lead to serious problems and mistakes. Moreover, a variety of methods of different qualities exist, and a user without a good background in theoretical chemistry may feel lost at the choices from usually rich menus of available programs.

The multivolume *Handbook of Computational Chemistry* is primarily intended as a guide to help navigate among different computational methods currently in use. In order to accomplish this goal, it provides a compact description of the basis of computational chemistry along with many examples of applications of these methods in various areas. The handbook is designed for researchers who are just being introduced into computational methods, as well as for those who are searching for the best choice for a solution to a specific problem involving theoretical approaches.

The first two volumes briefly describe different methods used in computational chemistry without going into exhaustive details of theory. Basic assumptions common to the majority of computational methods based on either quantum or statistical mechanics are outlined. Particular attention is paid to the limits of their applicability. Importantly, this volume also establishes definitions of various acronyms and terminologies used in the area of computational chemistry.

Since we assumed that the readers of this book are interested in applications of computational methods, a broad range of the most important applications of computational chemistry is provided. The applications include descriptions of standard chemical calculations for model molecules under various conditions. The handbook provides information on prediction of various molecular properties as well as investigations of chemical reactions.

There are two classes of species, biomolecules and nanomaterials, that are of a vital interest not only to chemists but also to physicists, biologists, and material scientists. Two volumes are devoted to description of specific computational

methods that are designed to investigate such species. Numerous examples of applications as well as descriptions of specific research problems and their solutions for various types of biomolecules and nanoparticles are given in volumes 3 and 4 of the handbook. The reviewed topics will attract the attention of all those who are already working or planning to start research involving computational approaches.

The fifth volume, an entirely new addition to the second edition, is devoted to the cheminformatics – both a description of techniques and discussion of applications. This is an important enhancement of the current *Handbook of Computational Chemistry* since the techniques of cheminformatics are vital tools of many computational chemists, those in research laboratories and, especially, those working in industry. Techniques developed allow storage, indexing, search, and comparing of information on chemical compounds. Such information could be used in the well-known quantitative structure-property (activity) relationship (QSPR/QSAR) studies for the prediction of specific property/activity of compounds of interest. QSAR techniques have been successfully applied for over 50 years in the pharmaceutical industry, and at the beginning of this century they were also adopted to investigate properties, biological activities, and toxicity of a new, unique class of compounds – nanomaterials.

We welcome all comments and suggestions related to the current version of the handbook as well as recommendations for possible revisions in the future. Many of the suggestions obtained from the readers of the first edition of the handbook have been applied to improve the second edition, and we are grateful for all inputs and comments. Such feedback and active participation help us to focus on areas that are important for the majority of our readers and improve the context of the book.

The Editors

Contents

Volume 1

Part I Theory and Methodology	1
<i>Anna Kaczmarek-Kedziera and Heribert Reis</i>	
1 Computational Chemistry: From the Hydrogen Molecule to Nanostructures	3
Lucjan Piela	
2 Molecular Mechanics: Principles, History, and Current Status	21
Valeri Poltev	
3 The Position of the Clamped Nuclei Electronic Hamiltonian in Quantum Mechanics	69
Brian Sutcliffe and R. Guy Woolley	
4 Remarks on Wave Function Theory and Methods	123
Dariusz Kędziera and Anna Kaczmarek-Kedziera	
5 Adiabatic, Born-Oppenheimer, and Non-adiabatic Approaches	173
Monika Stanke	
6 Directions for Use of Density Functional Theory: A Short Instruction Manual for Chemists	225
Heiko Jacobsen and Luigi Cavallo	
7 Introduction to Response Theory	269
Thomas Bondo Pedersen	
8 Intermolecular Interactions	295
Alston J. Misquitta	
9 Molecular Dynamics Simulation: From “Ab Initio” to “Coarse Grained”	337
Chris Lorenz and Nikos L. Doltsinis	

10	Statistical Mechanics of Force-Induced Transitions of Biopolymers	397
	Sanjay Kumar	
Part II Applications of Computational Methods to Model Systems		
	421	
<i>Anna Kaczmarek-Kedziera and Heribert Reis</i>		
11	Molecular Structure and Vibrational Spectra	423
	Jon Baker	
12	Molecular Electric, Magnetic, and Optical Properties	497
	Michał Jaszuński, Antonio Rizzo, and Kenneth Ruud	
13	Weak Intermolecular Interactions: A Supermolecular Approach	593
	Mark Waller and Stefan Grimme	
14	Chemical Reactions: Thermochemical Calculations	621
	John D. Watts	
15	Calculation of Excited States: Molecular Photophysics and Photochemistry on Display	639
	Luis Serrano-Andrés and Juan José Serrano-Pérez	
16	Solvent Effects in Quantum Chemistry	727
	Gerald Monard and Jean-Louis Rivail	
17	Solvent Effects on Molecular Electric Properties	741
	Miroslav Medved', Šimon Budzák, Wojciech Bartkowiak, and Heribert Reis	
18	Auxiliary Density Functional Theory: From Molecules to Nanostructures	795
	Patrizia Calaminici, Aurelio Alvarez-Ibarra, Domingo Cruz-Olvera, Victor-Daniel Domínguez-Soria, Roberto Flores-Moreno, Gabriel U. Gamboa, Gerald Geudtner, Annick Goursot, Daniel Mejía-Rodríguez, Dennis R. Salahub, Bernardo Zuniga-Gutierrez, and Andreas M. Köster	
19	Guide to Programs for Nonrelativistic Quantum Chemistry Calculations	861
	Tao Zeng and Mariusz Klobukowski	
20	Relativistic Methods in Computational Quantum Chemistry	885
	Paweł Tecmer, Katharina Boguslawski, and Dariusz Kędziera	
21	Time-Dependent Density Functional Theory: A Tool to Explore Excited States	927
	Daniel Escudero, Adèle D. Laurent, and Denis Jacquemin

Abstract

Quantum chemical calculations rely on a few fortunate circumstances like usually small relativistic and negligible electrodynamic (QED) corrections and large nuclei-to-electron mass ratio. The fast progress in computer technology revolutionized theoretical chemistry and gave birth to computational chemistry. The computational quantum chemistry provides for experimentalists the ready-to-use tools of new kind offering powerful insight into molecular internal structure and dynamics. It is important for the computational chemistry to elaborate methods, which look at molecule in a multiscale way, which provide first of all its global and synthetic description such as shape and charge distribution, and compare this description with those for other molecules. Only such a picture can free researchers from seeing molecules as a series of case-by-case studies. Chemistry represents a science of analogies and similarities, and

3

computational chemistry should provide tools for seeing this. This is especially useful for the supramolecular chemistry, which allow chemists to planify and study intermolecular interactions. Some of them, involving concave and convex moieties, represent molecular recognition, which assures a perfect fitting of the two molecular shapes. A sequence of molecular recognitions often leads to self-assembling and self-organization, typical to nanostructures.

Exceptional Status of Chemistry

Contemporary science fails to explain the largest-scale phenomena taking place in the Universe, such as speeding up the galaxies (supposedly due to the undefined “black energy”) and the nature of the lion share of Universe’s matter (also unknown “dark matter;” estimated roughly as about 90 % of the existing matter).

Quantum chemistry is in by far better position, which may be regarded even as exceptional in the whole domain of sciences. The chemical phenomena are explainable by contemporary theories down to individual molecules (which represent the subject of quantum chemistry). It turned out, by comparing theory and experiment, that the solution to the Schrödinger equation (Schrödinger 1926) offers in most cases a quantitatively correct picture. Only molecules with very heavy atoms, due to the relativistic effects becoming important, need to be treated in a special way based on the Dirac theory (Dirac 1928). This involves an approximate Hamiltonian in the form of sum of Dirac Hamiltonians for individual electrons and the electron-electron interactions in the form of the (nonrelativistic) Coulomb terms, a common and computational successful practice ignoring, however, the resulting resonance character of all the eigenvalues (Brown and Ravenhall 1951; Pestka et al. 2008). When, very rarely, a higher accuracy is needed, one may eventually include the quantum electrodynamics (QED) corrections, a procedure currently far for routine application, but still feasible for very small systems (Łach et al. 2004).

This success of computational quantum chemistry is based on a few quite fortunate circumstances (for references, see, e.g., Piela 2014):

- Atoms and molecules are built of only two kinds of particles: nuclei and electrons.
- The constituents of atoms and molecules are treated routinely as point charges. Although nuclei have nonzero size (electrons are regarded as point-like particles), the size is so small that its influence is much below chemical accuracy (Łach et al. 2004).
- The QED corrections are much smaller than energy changes in chemical phenomena (like 1:10,000,000) and may be safely neglected in most applications (Łach et al. 2004).
- The nuclei are thousand times heavier than electrons, and therefore, except some special situations, they move thousand times slower than electrons. This makes possible to solve the Schrödinger equation for electrons, assuming that the nuclei do not move, i.e., their positions are fixed in space (“clamped nuclei”).

This concept is usually presented within the so-called adiabatic approximation. In this approximation, the motion of the nuclei is considered in the next step, in which the electronic energy (precalculated for any position of the nuclei), together with a usually small diagonal correction for coupling the nuclei-electron motion, plays the role of the potential energy surface (PES). The total wave function is assumed to be a product of the electronic wave function and of the function describing the motion of the nuclei. The commonly used Born-Oppenheimer (BO) (1927) approximation is less accurate than the adiabatic one, because it neglects the abovementioned diagonal correction, making the PES independent of nuclear masses. Using the PES concept, one may introduce the crucial idea of the spatial structure of molecule, defined as those positions of the nuclei that assure a minimum of the PES. This concept may be traced back to Hund (1927). Moreover, this structure corresponds to a certain ground-state electron density distribution that exhibits atomic cores, atom-atom bonds, and atomic lone pairs.

It is generally believed that the exact analytical solution to the Schrödinger equation for any atom (except the hydrogen-like atom) or molecule is not possible. Instead, some reasonable approximate solutions can be obtained, practically always involving calculation of a large number of molecular integrals, and some algebraic manipulations on matrices built of these integrals. The reason for this is efficiency of what is known as the algebraic approximation (“algebraization”) of the Schrödinger equation. The algebraization is achieved by postulating a certain finite basis set of functions $\{\Phi_i\}_{i=1}^{i=M}$ and expanding the unknown wave function as a linear combination of the Φ_i 's with unknown expansion coefficients. Such an expansion can be encountered in the one-electron case (e.g., linear combination of atomic orbitals, LCAO, introduced by Bloch (1928)) and/or in the many-electron case, e.g., the total wave function expansion in Slater determinants, related to configurations (Slater 1930), or in the explicitly correlated many-electron functions (Hylleraas 1929). It is assumed for good-quality calculations (arguments are as a rule of numerical character only) that a finite M chosen is large enough to produce sufficient accuracy, with respect to what would be with $M = \infty$ (exact solution). The abovementioned integrals appear, because, after the expansion is inserted into the Schrödinger equation, one makes the scalar products (they represent the integrals, which should be easy to calculate) of the expansion with $\Phi_1, \Phi_2 \dots \Phi_M$, consecutively. In this way the task of finding the wave function by solving the Schrödinger equation is converted into an algebraic problem of finding the expansion coefficients, usually by solving some matrix equation. It remains to take care of the choice of the basis set $\{\Phi_i\}_{i=1}^{i=M}$. The choice represents a technical problem, but unfortunately it contains a lot of arbitrariness and, at the same time, is one of the most important factors influencing cost and quality of the computed approximate solution. Application of functions Φ_i based on the Gaussian-type one-electron orbitals (GTO) (Boys et al. 1956) provides a low cost/quality ratio, and this fact is considered as one of the most important factors, which made the contemporary computational chemistry efficient.

Algebraization involves as a rule a large M and therefore the whole procedure requires fast computing facilities.¹ These facilities changed over time, from very modest manual mechanical calculators at the beginning of the twentieth century to what we consider *now* as powerful supercomputers. Almost immediately after formulation of quantum mechanics in 1926, Douglas Hartree published several papers (Hartree 1927) presenting his manual calculator-based solutions for atoms of rubidium and chlorine. However amazing it looks now, these were self-consistent *ab initio*² computations.

In 1927 Walter Heitler and Fritz Wolfgang London clarified the origin of the covalent chemical bond (Heitler and London 1927), the concept crucial for chemistry. The authors demonstrated, in numerical calculations, that the nature of the covalent chemical bond in H_2 is of quantum character, because the (semiquantitatively) correct description of H_2 emerged only after inclusion the exchange of electrons 1 and 2 between the nuclei in the formula $a(1)b(2)$ (a, b are the 1s atomic orbitals centered on nucleus a and nucleus b , respectively) resulting in the wave function $a(1)b(2) + a(2)b(1)$. Thus, taking into account also the contribution of Hund, 1927 is therefore the year of birth of computational chemistry.

Perhaps the most outstanding manual calculator computations were performed in 1933 by Hubert James and Albert Coolidge for the hydrogen molecule (James and Coolidge 1933). This variational result has been the best one in the literature over the period of 27 years.

The 1950s mark the beginning of a new era – the time of *programmable* computers. Apparently, just another tool for number crunching became available. In fact, however, the idea of programming made a revolution because:

- It liberated humans from tedious manual calculations.
- It offered large speed of computation, incomparable to that of any manual calculator.
- The new data storage tools soon became of massive character.
- It resulted in more and more efficient programs, based on earlier versions (like staying “on the shoulders of the giants”), offering possibilities to calculate dozens of molecular properties.
- These programs and data soon became transportable, and also they could be copied and diffused worldwide.
- It allowed the dispersed, parallel, and remote calculations.
- It resulted in the new branch of chemistry: computational chemistry.³

¹Computational chemistry contributed significantly to applied mathematics, because new methods had to be invented in order to treat the algebraic problems of the previously unknown scale (like for M of the order of billions); see, e.g., reference Roos (1972).

²That is, derived from the first principles of the (nonrelativistic) quantum mechanics

³It is difficult to define what computational chemistry is. Obviously, whatever involves calculations in chemistry might be treated as part of it. This, however, sounds like a pure banality. The same is with the idea that computational chemistry means chemistry, which uses computers.

- It allowed performing calculations by anyone, even not trained in chemistry, quantum chemistry, mathematics, etc.

These achievements appeared gradually in the chemical practice. The first ab initio Hartree-Fock calculations (based on the ideas of Douglas Hartree (1927) and Vladimir Fock (1930)) on programmable computer for diatomic molecules have been performed at the Massachusetts Institute of Technology in 1956, using basis set of Slater-type orbitals. The first calculations with Gaussian-type orbitals have been carried out by Boys and coworkers also in 1956. An unprecedented spectroscopic accuracy has been obtained for the hydrogen molecule in 1960 by Kołos and Roothaan. In the early 1970s began the era of gigantic programs offering computation of many physical quantities at various levels of approximation.

We currently live in this era with computational possibilities growing exponentially (the notorious “Moore law” of doubling the computer power every 2 years).⁴ This enormous progress revolutionized our civilization in a very short time. The revolution in computational quantum chemistry changed chemistry in general, because computations became feasible for molecules of interest for experimental chemists. The progress has been accompanied by achievements in theory, however mainly of the character related to computational needs. Nowadays fair accuracy computations are possible for molecules composed of several hundreds of atoms, spectroscopic accuracy is achievable for molecules with a dozen of atoms, while the QED calculations can be performed for the smallest molecules only (few atoms). In many instances, we now reach the stage, when computing a molecular property is faster, less expensive, and more informative than to measure it.

A Hypothetical Perfect Computer

Suppose we have at our disposal a computer, which is able to solve the Schrödinger equation exactly for any system and in negligible time.⁵ Thus, we have free access to the absolute detailed picture of any molecule. This means we may predict with high accuracy and confidence the value of any property of any molecule. We might be tempted to say that being able to give such predictions is the ultimate goal of science: *We know everything about our system. If you want to know more about the world, take other molecules and just compute, you will know.*

It is questionable whether this problem needs any solution at all. If yes, the author sticks to the opinion that computational chemistry means quantitative description of chemical phenomena at the molecular/atomic level.

⁴The speed as well as the capacity of computer’s memory increased about 100 billion times over the period of 40 years. This means that what now takes an hour of computations would require in 1960 about 10,000 years of computing.

⁵In addition, we assume the computer is so clever that it automatically rejects those solutions, which are not square integrable or do not satisfy the requirements of symmetry for fermions and bosons. Thus, all nonphysical solutions are rejected.

Let us consider a system composed of 6 carbon nuclei, 6 protons, and 42 electrons. Suppose we want to know the geometry of the system for the ground state. Our computer answers that it does not know what we mean by the term “geometry.” We are forced to be more precise now and say that we are interested in the carbon-carbon (CC) and carbon-hydrogen (CH) distances. The computer answers that it is possible to compute only the *mean* distances and provides them together with the proton-proton, carbon-electron, proton-electron, and electron-electron distances, because it treats all the particles on equal footing basis. We look at the CC and CH distances and see that they are much larger than we expected for the CC and CH bonds in benzene. The reason is, that in our perfect wave function, the permutational symmetry is correctly included. This means that the average carbon-proton distance takes into account *all* carbons and *all* protons, the same with other distances. To deduce more, we may ask for computing other quantities like angles, involving three nuclei. Here too we will be confronted with numbers including averaging over identical particles. These difficulties do not necessarily mean that the molecule has no spatial structure at all, although this can also happen. The numbers produced would be extremely difficult to translate into a useful 3D picture even for quite small molecules, not speaking about such a floppy molecule as a protein.

In many cases we would obtain a 3D picture we did not expect. This is because many molecular structures, we are familiar with, represent higher-energy metastable electronic states (isomers). This is the case in our example. When solving the time-dependent Schrödinger equation, we are confronted with this problem. Let us use as a starting wave function the one corresponding to the benzene molecule. In time evolution, we will stay probably with a similar geometry for a long time. However, there is a chance that after a long period, the wave function changes to that corresponding to three interacting acetylene molecules (3 times HCCH). The Born-Oppenheimer optimized ground electronic state corresponds to the benzene [-230.703 a.u. in the Hartree-Fock approximation for the 6-311-G(d) basis set]. The three isolated acetylene molecules (in the same approximation) have the energy -230.453 a.u. and the molecule (also with the same formula C_6H_6) $H_3C-C \equiv C-C \equiv C-CH_3$ -230.592 a.u. Thus, the benzene molecule seems to be a stable ground state, while the three acetylenes and the diacetylene are metastable states within the same ground electronic state of the system. All the three physically observed realizations of the system $6C + 6H$ are separated by barriers, and this is the reason why they are observable.

What is, therefore, the most stable electronic ground state corresponding to the flask of benzene? This is a quite different question, which pertains to systems larger than a single molecule. If we multiply the number of atoms in a single molecule of benzene by a natural number N , we are confronted with new possibilities of combining atoms into molecules, not necessary of the same kind and possibly larger than C_6H_6 . For a large N , we are practically unable to find all the possibilities. In some cases, when based on chemical intuition and limiting to simple molecules, we may guess particular solutions. For example, to lower the energy for the flask of benzene, we may allow formation of the methane molecules and the graphite

(the most stable form of carbon). Therefore, the flask of benzene represents a metastable state.

Suppose we wish to know the dipole moment of, say, the HCl molecule, the quantity that tells us important information about the charge distribution. We look up the computer output and we do not find anything about dipole moment. The reason is that all molecules have the same dipole moment in any of their stationary state Ψ , and this dipole moment equals to zero; see, e.g., reference Piela (2014), p. 735. Indeed, the dipole moment is calculated as the mean value of the dipole moment operator, i.e., $\boldsymbol{\mu} = \langle \Psi | \hat{\boldsymbol{\mu}} | \Psi \rangle = \langle \Psi | (\sum_i q_i \mathbf{r}_i) | \Psi \rangle$; index i runs over all electrons and nuclei. This integral can be calculated very easily: the integrand is antisymmetric with respect to inversion and therefore $\boldsymbol{\mu} = \mathbf{0}$. Let us stress that our conclusion pertains to the *total* wave function, which has to reflect the space invariance with respect to inversion, leading to the zero dipole moment. If one applied the transformation $\mathbf{r} \rightarrow -\mathbf{r}$ only to some particles in the molecule (e.g., electrons), and not to the other ones (e.g., the nuclei), then the wave function will show no parity (it would be neither symmetric nor antisymmetric). We do this in the adiabatic or Born-Oppenheimer approximation, where the electronic wave function depends on the electronic coordinates only. This explains why the integral $\boldsymbol{\mu} = \langle \Psi | \hat{\boldsymbol{\mu}} | \Psi \rangle_e$ (the integration is over electronic coordinates only) does not equal to zero for some molecules (which we call polar ones). Thus, to calculate the dipole moment, we have to use the adiabatic or the Born-Oppenheimer approximation.

Now we decide to quit the perfect computer and the perfect picture of the molecule it produces, because the computer output looks like almost useless, paradoxically because it is “too exact,” similarly as a map of a terrain with the scale 1:1. We desperately need an approximation (a model), which will tell us the most important features of the molecule under consideration. This is why we introduce the Born-Oppenheimer approximation. Its first consequence is the molecular geometry, this one which leads to a minimum of the electronic energy. There is a problem though that usually we have many such minima of different energy, each minimum corresponding to its own electronic density distribution. Any such distribution corresponds to some particular chemical bond pattern.⁶ In most cases the user of computers does not even think of these minima, because he performs the calculations for a predefined configuration of the nuclei and forces the system (usually not being aware of it) to stay in its vicinity. This is especially severe for large molecules, such as proteins. They have an astronomic number of stable conformations,⁷ but often we take one of them and perform the calculations for this one. It is even difficult to say that we select this one, because we rarely even consider the other conformations. In this situation, we usually take as the starting point a crystal structure conformation (we *believe* in its relevance).

⁶Bond patterns are the same for different conformers.

⁷For a dipeptide, one has something like ten energy minima, counting only the backbone conformations (and not counting the side-chain conformations for simplicity). For very small protein of, say, a hundred amino acids, the number of conformations is therefore of the order of 10^{100} , a very large number exceeding the estimated number of atoms in the Universe.

Moreover, usually one starts calculations by setting a starting electronic density distribution. The choice of this density distribution may influence the final electronic density and the final geometry of the molecule. In routine computations, one guesses the starting density according to the starting nuclear configuration chosen. This may look as a reasonable choice, except when small deformation of the nuclear framework leads to large changes in the electronic density.

In conclusion, in practice computer gives the solution, which is close to what the computing person considers as “reasonable” and sets as the starting point.

Does Predicting Mean Understanding

The existing commercial programs allow us to make calculations for molecules, treating each molecule as a new task, as if every molecule represented a new world, which has nothing to do with other molecules. We might not be satisfied with such a picture. We might be curious:

- Whether, living in the 3D space, the system has or has not a certain shape (“geometry”)
- If yes, why the shape is of this particular kind
- If the shape is fairly rigid or rather flexible
- If it is reasonable to assign the system some external surface
- If there are some characteristic substructures in the system
- How these substructures interact one another interact
- How they influence the calculated global properties, etc.
- If the same substructures are present in other molecules
- If the presence of the same substructures does determine similar properties

It is of fundamental importance for chemistry that we do not study particular cases, case by case, but derive some general rules. Strictly speaking these rules are false for, because of approximations made, they are valid to some extent only. However, despite this, they enable chemists to operate, to understand, and to be efficient. If we relied uniquely on exact solutions of the Schrödinger equation, there would be no chemistry at all, and people would lose the power of rationalizing this branch of science, in particular to design syntheses of new molecules. Chemists rely on molecular spatial structure (nuclear framework), on the concepts of valence electrons, chemical bonds, electronic lone pairs, etc. All these notions have no rigorous definition, but they still are of great importance describing a *model* of molecule. A chemist predicts that two OH bonds have similar properties, wherever they are. Moreover, chemists are able to predict differences in the OH bonds by considering what the neighboring atoms are in each case. It is of fundamental importance in chemistry that a group of atoms with a certain bond pattern (functional group) represents an entity that behaves similarly, when present in different molecules.

We have at our disposal various scales at which we can look at details of the molecule under study. In the crudest approach, we may treat the molecule as a point mass, which contributes to the gas pressure. Next we might become interested in

the shape of the molecule, and we may approximate it first as a rigid rotator and get an estimation of rotational levels we can expect. Then we may leave the rigid body model and allow the atoms of the molecule to vibrate about their equilibrium positions. In such a case, we need to know the corresponding force constants. This requires either to choose the structural formula (chemical bond pattern) of the molecule together with taking the corresponding empirical force constants or to apply the normal mode analysis, first solving the Schrödinger equation in the Born-Oppenheimer approximation (we have a wide choice of the methods of solution). In the first case, we obtain an estimation of the vibrational levels; in the second, we get more reliable vibrational analysis, especially for larger atomic orbital expansions. If we wish we may consider anharmonicity of vibrations.⁸

At the same time, we obtain the electronic density distribution from the wave function Ψ for N electrons⁹

$$\rho(\mathbf{r}) = N \sum_{\sigma_1=\frac{1}{2}}^{\frac{1}{2}} \int d\tau_2 d\tau_3 \dots d\tau_N |\Psi(\mathbf{r}, \sigma_1, \mathbf{r}_2, \sigma_2, \dots, \mathbf{r}_N, \sigma_N)|^2.$$

According to the Hellmann-Feynman theorem (Hellmann 1937; Feynman 1939) ρ is sufficient to compute the forces acting on the nuclei. We may compare the resulting ρ calculated at different levels of approximation. The density distribution ρ can be analyzed in the way known as Bader analysis (Bader 1994). First, we find all the critical points, in which $\nabla\rho = 0$. Then, one analyzes the nature of each critical point by diagonalizing the Hessian matrix calculated at the point¹⁰:

- If the three eigenvalues are negative, the critical point corresponds to a maximum of ρ .
- If two are negative and one positive, the critical point corresponds to a covalent bond.

⁸The low-frequency vibrations may be used as indicators to look at possible instabilities of the molecule, such as dissociation channels, formation of new bonds, etc. Moving all atoms, first according to a low-frequency normal mode vibration and continuing the atomic displacements according to the maximum gradient decrease, we may find the saddle point and then, sliding down, detect the products of a reaction channel.

⁹The integration of $|\Psi|^2$ is over the coordinates (*space and spin ones*) of all the electrons except one (in our case the electron 1 with the coordinates \mathbf{r}, σ_1) and in addition the summation over its spin coordinate (σ_1). As a result one obtains a function of the position of the electron 1 in space: $\rho(\mathbf{r})$. The wave function Ψ is antisymmetric with respect to exchange of the coordinates of any two electrons, and, therefore, $|\Psi|^2$ is symmetric with respect to such an exchange. Hence, the definition of ρ is independent of the label of the electron we do not integrate over. According to this definition, ρ represents nothing else but the density of the electron cloud carrying N electrons and is proportional to the probability density of finding an electron at position \mathbf{r} .

¹⁰Strictly speaking the nuclear attractors do not represent critical points, because of the cusp condition (Kato 1957). This worry represents rather a pure theoretical problem, when, what is a common practice, one uses Gaussian atomic orbitals as the basis set.

- If one is negative and two positive, the critical point corresponds to a center of an atomic ring.
- If all three are positive, the critical point corresponds to an atomic cavity.

The chemical bond critical points correspond to *some* pairs of atoms, and there are other pairs of atoms, which do not form bonds.¹¹ The Bader analysis enables chemists to see molecules in a synthetic way, nearly independent of the level of theory that has been used to describe it, focusing on the ensemble of critical points. We may compare this density with the density of other molecules, similar to our one, to look whether one can see some local similarities. We may continue this, getting a more and more detailed picture down to the almost exact solution of the Schrödinger equation.

It is important in chemistry to follow such way, because at its beginning as well as at its end, we know very little about chemistry. We learn chemistry traveling along the way.

Orbital Model

The wave function for identical fermions has to be antisymmetric with respect to exchange of coordinates (space and spin ones) of any two of them. This means that two electrons having the same spin coordinate cannot occupy the same position in space. Since wave functions are continuous, this means that electrons of the same spin coordinate avoid each other (“Fermi hole” or “exchange hole”). This Pauli exclusion principle does not pertain to two electrons of opposite spin. However, electrons repel one another (Coulombic force) at any finite distance, i.e., they have to avoid one another because of their charge (“Coulomb hole” or “correlation hole”). It turned out (references in Piela (2014), p. 710) that the Fermi hole is by far more important than the Coulomb hole. A high-quality wave function has to reflect the Fermi and the Coulomb holes. The corresponding mathematical expression should have the antisymmetrization operator in front, and this will take care of the Pauli principle (and introduce a Fermi hole). Besides this, it should have some parameters or mathematical structure controlling somehow the distance between any pair of electrons (this will introduce the Coulomb repulsion). Since the Fermi hole is much more important, it is reasonable to consider first a wave function that takes care of the Fermi hole only. The simplest way to take the Fermi hole into account is the orbital model (approximation). Within the orbital model, the most advanced is the Hartree-Fock method. In this method, the Fermi hole is taken into account by construction (antisymmetrizer). The Coulomb hole is not present, because the Coulomb interaction is calculated through averaging the positions of the electrons.

¹¹Although this is only after assuming a reasonable threshold as a criterion. This is a common situation in chemistry – strictly speaking there is no such thing as chemical bond in a polyatomic molecule.

The orbital model is incorrect (i.e., represents an approximation), because it neglects the Coulomb hole. Due to its simplicity, it gains, however, enormous scientific power, because:

- It allows to see the electronic structure as contributions of individual electrons, with their own “wave functions,” i.e., orbitals, mutually orthogonal, with a definite mathematical form, symmetry, energy (“orbital energy levels”), etc.
- We take the Pauli exclusion principle into account by not allowing occupations of an orbital by more than two electrons (if two, then of the opposite spin coordinates). The occupation of all orbital levels is known as the all-important orbital diagram.
- The orbital energy may be interpreted as the energy needed to remove an electron from the orbital (assuming that all the orbitals do not change during the removing, Koopmans theorem (Koopmans 1933/1934)).
- Molecular electron excitations may be often identified with changing the electron occupancy in the orbital diagram.
- We may even consider electronic correlation (still incorporating a concept of the Coulomb hole) either by allowing different orbitals for electrons of different spin or considering a wave function expansion composed of electron diagrams with various occupations.
- One may trace the molecular perturbations to changes in the orbital diagram.
- One may describe chemical reactions as a continuous change from a starting to a final molecular diagram. Theory and computational experience bring some rules, like that only those orbitals of the molecular constituents mix, which have similar orbital energies and have the same symmetry. This leads to important symmetry selection rules for chemical reactions (Woodward and Hoffmann 1965; Fukui and Fujimoto 1968) and for optical excitations (Cotton 1990).
- The orbital model provides a set of fundamental keywords, which create a chemical vocabulary – a tool to communicate among chemists (including quantum chemists). This language and the numerical experience supported by theory create a kind of quantum mechanical intuition coupled to experiment, which allows to compare molecules, to classify them, and to predict their properties in a descriptive way. A majority of theoretical terms in general chemistry stem from the orbital theory.

Molecular Surface

Many ideas of chemistry, although extremely helpful and sometimes indispensable, are more or less arbitrary. The all-important concept of molecular surface belongs to this class. The molecular surface, also representing a kind of synthetic view of molecule, can be defined in several distinct ways, like:

- The isosurface corresponding to a given electron density contour.
- The isosurface corresponding to a given interaction energy with an atom like helium atom.

- The surface (van der Waals surface) of the sum of the van der Waals spheres of all the atoms of the molecule, with the van der Waals radii assigned (by an empirical consensus).
- The accessible surface area (Lee and Richards 1971) is the area of the solvent accessible surface (SAS) that corresponds to rolling a ball representing a water molecule (its radius usually taken as 1.4 Å) over the van der Waals surface, i.e., extending the latter by the radius of the water molecule.

At any of these definitions, some molecules may possess multiple surfaces (external and internal), due to possible cavities. It is true that each of the definitions leads to a different surface. However, the role of such a molecular surface is in fact to define the molecular shape, and the resulting shapes do not differ much. In the all-important intermolecular interactions, the *overall* molecular shape belongs to primary and synthetic characteristics of the molecules involved and often decides about the strength of the interaction.

The molecular shape is a function of the quantum mechanical state of the molecule. The most important in chemistry and physics are the low-energy lying states, in most cases the conformational states separated by some rather low energy barriers and all corresponding to the ground electronic state. How to find these lowest-energy states among myriads of others (their number sometimes of the order of 10^{100}) represents a very serious problem of chemistry (Piela 2002). The most promising way is to use the concept of pseudoatoms (like united atoms), the appropriate force field, and the Monte Carlo approach to overcome the energy barriers (Koliński and Skolnick 2004).

Molecular Recognition

The interaction energy of two molecules in the vacuum is dominated by several physically distinct contributions (Jeziorski and Kołos 1977). The first two result from the first-order perturbation theory: the electrostatic interaction energy and the valence repulsion energy. The electrostatic interaction represents a Coulomb interaction of the two molecular charge distributions, which are identical (“frozen”) to those corresponding to the noninteracting molecules. The valence repulsion, a consequence of the Pauli exclusion principle, increases very strongly (exponentially) with shortening of the intermolecular distance, when the two molecular charge distributions begin to overlap. In the second order, one has the induction interaction (an electrostatic effect of relaxing the charge distribution) and the dispersion interaction (the intermolecular electron-electron Coulomb correlation effect) with some small electron-exchange corrections of these quantities.

Among these effects the most important are the electrostatic interaction and the valence repulsion. The first one is of the most long-range character and represents the only interaction that may change the sign (attraction or repulsion) upon rotation of one of the molecules by 180° (large anisotropy). This means the electrostatic interaction usually predefines to a large extent the mutual orientation

of the approaching molecules. The two molecules when approaching just try to fit electrostatically one another. This electrostatic fitting may be lost by an ill fitting of the inappropriate shapes of the molecules (which results in an excessive valence repulsion energy; this is why this effect may be critically important) or may be enhanced by a perfect fitting of the shapes over a large contact area of the interacting molecules (molecular recognition). The induction and dispersion interactions always represent attraction and have much smaller anisotropy. This is why in most cases they do not decide about the resulting structure, while always enhancing its stability.

The molecular surface plays a role of determining a no-access zone for other molecules or atoms. A violation of the zone's border is possible, but at a large energy price (valence repulsion). In addition to this repulsive effect, there is an energy gain or expense for approaching the molecular surface at a given surface point. This is related to the (long-range) electrostatic potential created by the charge distribution of the molecule. The electrostatic potential represents the interaction energy (attraction or repulsion) of the unit charge $+1$ a.u. with the electrostatic field created by the molecule. The sign and the absolute value of the electrostatic potential calculated at each point of the molecular surface represent an important information about accessibility of this part of the molecular surface by other molecules (with their own surface and their own electrostatic potential calculated on it). A large area of the molecule-molecule contact (fitting) together with the opposite signs of the corresponding electrostatic potentials (over the contact area) means a perfect fitting: of the shapes and of the electrostatic characteristics. Thus, the molecular surface "colored" by the electrostatic potential provides an essential (and synthetic) information about the ability of the molecule to interact with the other ones.

The above described contributions are responsible for some specific interactions like: the ubiquitous hydrogen bonds, the coordination interaction (interaction of the lone electron pair of the electron donor with an empty orbital of the electron acceptor), and, in aqueous solutions, the hydrophobic effect (hydrocarbon, or "fatty," residues having tendency to keep together in water). The hydrogen bond is dominated by the electrostatic energy, the coordination interaction (e.g., the coordination of a positive ion by a crown ether of suitable size) by the electrostatic attraction and the valence repulsion, and the hydrophobic effect by the hydrogen bond network of the liquid water. These three types of intermolecular interaction determine the majority of the appearing supramolecular structures, typically of the size of nanometers.

In the case of two interacting molecules, the resulting molecular recognition is characterized by one of the following scenarios differing by the role played by molecular flexibility of the interacting moieties:

- Keylock (both molecules are rigid and fit together just because the complementary molecular shapes in their ground conformational states)
- Template (a higher-energy conformation of a flexible molecule makes a perfect fit with the ground conformational state of a rigid molecule, the latter serving as a template)

- Hand glove (two flexible molecules do not fit one another unless they acquire some particular higher-energy conformational states)

In the two last cases, the expense of the necessary conformational excitation is more than compensated by the resulting interaction energy of the two moieties.

Rules of the Nanoscale

Note that all three types of the molecular recognition stem from the same general principle that a molecule with a convex surface (guest) may find a perfect fitting with a certain molecule with a concave surface (host). This phenomenon, which may now look even trivial, has been discovered as late as in the 1960s of the twentieth century. The very reason of why it was so late is that chemists had to learn how to synthesize large molecules and only such molecules can have a concave surface. Another reason is that the progress in organic chemistry has been limited in the past by the possibilities of computational chemistry, which finally enabled chemists to plan the complex molecular geometries and check whether they fit as expected.

This convex-concave paradigm represents a basis of the molecular self-assembling and self-organization. This type of interaction has some unique features, which make possible precise human operation in the nanoscale by planning the molecules to be synthesized using the tools of computational chemistry:

- A convex molecule of a particular shape may fit a *specific* concave one, much more precisely than two convex molecules are able to do (*molecular recognition*). This may be used to get a sure and direct contact of some particular functional groups to make a particular chemical reaction to proceed with a high reaction yield.
- Many interatomic contacts distributed over a *large convex-concave contact area* may assure a sufficiently strong intermolecular binding.
- A concave reactant (“host”) means also preventing some potential and unwanted reactants (“guest molecules”) to enter the cavity, just because these molecules do not recognize each other (a large energy penalty by the valence repulsion, a result of ill fitting).
- A sufficiently weak intermolecular binding in order to allow for an easy reorganization of the complex, if needed.
- Leaving the reaction cavity by the products, because they may have not enough space there.

Power of Computer Experiments

In experiments we always see quantities averaged over all molecules in the specimen, all orientations allowed, all states available for a given temperature, etc. In some experiments, we are able to specify the external conditions in such a way

as to receive the signal from molecules in a given state. Even in such a case, the results are averaged over molecular vibrations, which introduce (usually quite small) uncertainty for the positions of the nuclei, close to the minimum of the electronic energy (in the adiabatic or Born-Oppenheimer approximations).

This means that in almost all cases, the experimenters investigate molecules close to the minimum of the electronic energy (minimum of PES). What happens to the electronic structure for other configurations of the nuclei is a natural question, sometimes of great importance (e.g., for chemical reactions). Only computational chemistry opens the way to see what would happen to the energy and to the electronic density distribution if:

- Some internuclear distances increased, even to infinity (dissociation).
- Some internuclear distances shortened, and the shortening may correspond even to collapsing the nuclei into a united nucleus, or approaching two atoms which in the minimum of PES form or do not form a chemical bond. This allows us to investigate what happens to the molecule under a gigantic pressure.
- Some nuclei changed their mass or charge (beyond what one knows from experiment).
- We apply to the system an electric field, whose character is whatever we imagine as appropriate. Sometimes such a field may mimic the influence of charge distributions in neighboring molecules.

This makes from computational chemistry a quite unique tool allowing to give the answer about the energy and electronic density distribution (bond pattern) for any system and for any deformation of the system we imagine. This powerful feature can be used not only to see, what happens for a particular experimental situation, but also what would happen if we were able to set the conditions much beyond any imaginable experiment. This uniqueness is probably the most exciting feature of computational chemistry for it carries us to discoveries everyday.

Concluding Remarks

What counts in computational chemistry is looking at molecules at various scales (using various models) and comparing the results for different molecules. If one could only obtain an exact picture of the molecule without comparing the results for other molecules, we would be left with no chemistry. The power of chemistry comes from analogies and similarities, as well as from trends rather than from the ability of predicting properties. Such ability is certainly important for being efficient in any particular case, but predicting by computation does not mean understanding. We need computers with their impressive speed, capacity, and possibility to give us precise predictions, but also we need a language to speak about the computations, a model which simplifies the reality, but allows us to understand what we are playing with in chemistry.

Acknowledgements The author is very indebted to Professor Leszek Z. Stolarczyk, for joy to be with him, discussing all exciting aspects of chemistry, science, and beyond, a part of them included in the present paper.

Abstract

A short survey of the general principles and selected applications of molecular mechanics (MM) is presented. The origin of molecular mechanics and its evolution is followed starting from “pre-computer” and the first computer-aided estimations of the structure and potential energy of simple molecular systems to the modern force fields and software for the computations of large biomolecules and their complexes. Analysis of the current state of physicochemical study of biological processes suggests that MM simulations based on empirical force fields have an ever-increasing impact on understanding the structure and functions of biomolecules. The problem of “classic mechanics” description of essentially quantum properties and processes is considered. Various approaches to a selection of force field mathematical expressions and parameters are reviewed. The relation between MM simplicity and “physical nature” of the properties and events is examined. Quantum chemistry contributions to MM description of complex molecular systems and MM contribution to quantum mechanics computations of such systems are considered.

Introduction

Molecular mechanics (MM) deals with the classical (“mechanistic,” i.e., via Newtonian mechanics) description of molecular and supramolecular systems. The simplified assumptions and approximations enable one to use MM for wide applications to various systems, starting from simple low-molecular-weight molecules (such as numerous hydrocarbons) to large biomolecular complexes (such as those of proteins, nucleic acids, and membrane fragments) or material assemblies of many thousands of atoms. During a period a bit longer than a half of a century, the number of publications using this approach roused by many orders of magnitude. It was rather easy to follow nearly all the works related to MM calculations in the 1960s and in the early 1970s of the last century (and the author of this chapter tried to do so); today it is very difficult to follow all the papers related to the MM approach even in the rather restricted area of application (e.g., to biopolymer structure and function). Thus it is impossible to consider all the applications of MM in a short survey, and the choice of the material for this chapter is “a matter of taste” of the author who refers readers to other monographs and chapters for a more general description of the modern state and/or selected aspects of extended applications of MM; for general references see, e.g., monographs (Lewars 2011; Allinger 2010; Ramachandran et al. 2008; Cramer 2004; Leach 2001). We will follow the evolution of MM from the first “precomputer” and early computer-aided (i.e., before the era of personal computers) works to modern complex simulations impossible without supercomputers.

The MM method is used now not only in theoretical and computational works but also as a part of experimental studies (e.g., many X-ray and NMR-derived structures of proteins, nucleic acids, and their complexes with other molecules deposited in

Protein Data Bank (Berman et al. 2003) and Nucleic Acid Data Bank (Berman et al. 1992) are the results of MM refinements). The MM-like semiempirical terms are widely used now in some quantum mechanics-based studies. The systematic inclusion of such terms started from the addition of the dispersion term to the standard density functional theory computations, for creating the so-called DFT-D method (see, e.g., Grimme 2004; Antony and Grimme 2006; Jurecka et al. 2007, and references herein for the first DFT-D results). Recent developments and applications of different DFT-D methods (DFT-D2, DFT-D3) demonstrated their predictive power for biomolecular systems (see, e.g., Grimme 2011; Brandenburg and Grimme 2014). Since the beginning of this millennium, MM-like terms are frequently included into so-called enhanced semiempirical quantum mechanics methods (see, e.g., Yilmazer and Korth (2015) for a recent review). Both dispersion (D) and hydrogen-bond (H) correction terms are used in such methods usually referred to as SQM-DH methods.

The rapid extension of MM simulations is a result of development of new branches of natural science related to molecular biology with its numerous applications, to directed synthesis of new substances with desirable properties (including new drugs and new materials for the industry), and many other areas of so-called nanoscience. The MM simulations enable one to perform a preliminary selection of the compounds with desirable properties before experimental testing, and even before chemical synthesis itself. Sometimes it is impossible to rationalize completely experimental results without the construction of atom-level mechanistic model. In many cases, the model cannot be derived from experimental data only, e.g., the accuracy of X-ray diffraction patterns for biopolymer fragments is not sufficient for the extraction of precise atom coordinates due to a complexity of the system and inherent irregularities of atom positions (e.g., delocalization of water molecules). In other cases, the complex molecular system cannot be characterized by a single three-dimensional structure but by a set of conformations. MM simulations enable one to construct habitual atom-level molecular models of sufficiently complex systems favorable from energy viewpoint. These models can be visualized by computer graphics programs and are ready to use for further investigations and refinements (e.g., by quantum mechanics methods or by new experimental approaches).

Foundations and General Scheme of Molecular Mechanics. Atoms as Elementary Units of the Matter

The modern MM can be considered as an extension of simple atom and bond representation of molecules and their complexes in classical chemistry. In the beginning of the 1950s, scaled paper images and hand-made primitive models of atoms and bonds from wood and wire enabled subtle scientists to construct the first successful models of proteins and DNA. The pioneering papers of Nobel Prize authors can be mentioned in this relation (Pauling et al. 1951; Watson and

Crick 1953). Stick, ball-and-stick, and space-filling plastic models as well as their computer images are widely used until now for both teaching and investigation.

General Expression and Terms of Molecular System Energy

The MM approach is a generalization and quantitative representation of these models via mathematical expressions. A set of such expressions together with numerical coefficients is usually referred to as the force field; the MM method itself is frequently referred to as the force field method. Rigid balls of computer graphics or plastic (metal, wood, etc.) models are replaced by “soft” ones, and hard sticks are replaced by springs. “Hard Sphere” approximation can be considered as simplified (in many cases oversimplified) MM approach. Nevertheless, very important results were obtained via this approximation in the middle of the last century; we will mention some of them below.

The modern MM method and most of force fields mathematical expressions are the results of the efforts of many researchers for nearly half a century, trials and errors of both well-known and widely cited authors, as well as of those who contributed to specific parts of nonbonded energy computations for a selected class of molecules. In this section, we will describe general scheme and the main common assumptions of the MM method leaving any references to specific papers and contributions of the researchers for next sections. The main subject of this survey is rather simple MM scheme suggesting that the systems (molecules or their complexes) consist of atoms, each atom being simulated as a single point particle. Most computations for biologically important molecules use the so-called Class 1 model. More complicated schemes considering additional centers of interactions, additional terms, and more exact expressions (so-called Class 2 and Class 3 MM models) will be mentioned briefly. Molecular mechanics describes molecules in terms of “bonded atoms” (atoms in molecule), their positions are distorted from some idealized (equilibrium) geometry due to nonbonded interactions with the atoms of the same molecule and of other molecules. The MM approach implicitly uses the starting approximation for both classical and quantum computational chemistry schemes, namely, Born–Oppenheimer approximation. MM does not include electrons explicitly, but different configurations of electron shells of the same chemical element’s atoms are implicitly considered in force field parameters. Some authors consider not only atoms but lone pairs of electrons, chemical bonds, and other points in a molecule as centers of interactions. We will mention such “extension” of Class 1 models below.

The first principal approximation of MM method is the additivity for several levels of calculations, namely, the additivity of energy terms responsible for the contributions of different physical nature, and the additivity of contributions of the atoms. The simple (“minimalist”) representation of the potential energy of a molecule or molecular complex as a function of atom coordinates, R , can be represented by a sum of four main terms each term being a sum of many contributions (Eq. 1).

$$\Delta E(\mathbf{R}) = \sum E_b + \sum E_a + \sum E_t + \sum E_{nb} \quad (1)$$

The summing up in the terms is over all the chemical bonds (the first term), valence angles (the second term), torsion angles (the third term), and all pairs of atoms nonbonded to each other or to common third atom (the last term). The energy terms depend on mutual positions of atoms and on the adjustable constants (parameters); the parameters are suggested to be transferable between atoms and molecules of the same type. The transferability of the force field parameters is the second important assumption of MM, and the number of atom types of the same chemical element depends on particular force field.

Intramolecular Contributions to Molecular System Energy

The first and the second terms (sums of Eq. 1) refer to the energy changes due to variations of bond lengths, stretching (Eq. 2), and bond angles, bending (Eq. 3). These terms are usually modeled as harmonic potentials centered on equilibrium values of bond lengths and bond angles, respectively, i.e., “simple Hooke’s law” dependences are used.

$$E_{b_i} = k b_i (l_i - l_i^0)^2 \quad (2)$$

$$E_{a_i} = k a_i (\alpha_i - \alpha_i^0)^2 \quad (3)$$

In these equations, l_i and α_i , the current values of bond lengths and angles; parameters l_i^0 and α_i^0 , equilibrium values for bond lengths and angles; $k b_i$ and $k a_i$, stretch and bend force constants, respectively. These adjustable parameters depend on types of atoms forming the bond or the valence angle. Some force fields may also contain cubic and higher-order contributions to these terms, or sometimes more flexible Morse potential can be used instead, as well as “cross terms” can be included to account for correlations between stretch and bend components. In the latter case, the terms depending on both bond length and angle variations are added. The third sum of the expression (Eq. 1) refers to the changes of torsion energy; it is responsible for interactions of electron shells of two atoms A and D (and of two bonds A–B and C–D) which are connected through an intermediate chemical bond B–C.

$$E_{t_i} = k t_i (1 + \cos (n_i \phi_i - \delta_i)) \quad (4)$$

This periodic function (integer n_i being the periodicity) contains the current value ϕ_i of the angle i of the rotation around B–C chemical bond (the angle between the two planes defined by atoms A, B, and C and by B, C, and D) and three parameters ($k t_i$, n_i , and δ_i ; n_i is multiplicity and δ_i is the phase angle) for each type of torsion (for each combination of four neighbor atoms of the molecule). These parameters can be estimated from experimental data on the structure and properties of the

molecule considered and of related molecules, then they (as well as I_i^0 , α_i^0 , kb_i , and ka_i of Eqs. 2 and 3) should be adjusted by trial computations. Many force fields include terms responsible for “improper” torsions or out-of-plane bending, i.e., terms related to four atoms not forming consecutive chemical bonds, which function as correction factors for out-of-plane deviations (for example, they can be used to keep aromatic rings planar). These terms can be expressed via harmonic potentials like those for bond stretching and valence angle bending. Cross terms depending on both torsion angle and bond length or valence angle are added in some force fields. Three terms mentioned above are positive for practically all states of all the molecular systems (or equal to zero when the term corresponds to equilibrium state for contributed bond, angle or torsion).

Intermolecular and Nonbonded Intramolecular Interactions

The last sum of Eq. 1 refers to so-called nonbonded interactions, E_{nb} , of all the atom pairs not bonding to each other or to the same third atom, Eq. 5. Each atom-atom term is usually represented by a sum of electrostatic, Coulomb (the first term of Eq. 5), and van der Waals (the second and the third terms of Eq. 5) interactions.

$$E_{ij}(r_{ij}) = Kq_iq_j/r_{ij} - A_{ij}/r_{ij}^6 + B_{ij}/r_{ij}^{12} \quad (5)$$

This equation contains r_{ij} , the current distance between i and j atoms; q_i and q_j , effective atom charges; A_{ij} and B_{ij} , adjustable parameters responsible for dispersion (London) attraction and short-range repulsion interactions respectively. The atomic charges are usually derived using calculations via various quantum chemistry methods, effective dielectric constant implicitly accounting for surrounding can be used (this value may be distant dependent). The A_{ij} and B_{ij} coefficient can be preliminarily estimated via equilibrium inter-atomic distance and energy values at equilibrium for neutral pairs of atoms (ρ_{ij} and ϵ_{ij} respectively) and followed by the adjustment to reference experimental data. Most of the early force fields used for description of van der Waals interactions are Buckingham (6-exp) potential instead of Lennard-Jones (6-12) potential in Eq. 5. The total expression for nonbonded interaction term are usually referred to as (1-6-12) or (1-6-exp) potential relating to the dependency of the terms on the inter-atom distance. The Buckingham potential is more flexible (it has three adjustable parameters instead of two for 6-12 potentials for each atom pair type) and has more physics justifications for the range of experimentally observed distances (due to exponential dependence of electron wave functions on the distance from nuclei), but it is less convenient for computations. It has a maximum at short distance and then trend to negative infinite value. Majority of the modern force fields utilize 6-12 expressions for description of van der Waals interactions, the total atom-atom potential being referred to as 1-6-12 one. Some force fields substitute 6-12 potential by 10-12 one for the interactions of hydrogen atoms of hydrogen bonds in order to describe more sharp distance dependence in the most important area of energy minimum corresponding to H-bond formation (referred

to as 1-10-12 potential). More complex expressions (including those dependent on the angles between two straight lines connecting three atoms of H-bond) were used for H-bond description in some early potential sets. The nonbonded terms of the intramolecular energy related to 1-4 interactions (i.e., the interactions between atoms in a molecule separated by three chemical bonds) are frequently accounted for with a coefficient less than 1 (1-4 scaling) as these interactions are already included into torsion term (Eq. 4). To reduce the number of adjustable A_{ij} and B_{ij} parameters of Lennard-Jones potential (and corresponding parameters of other potentials), the combination rules for equilibrium inter-atom distance, ρ , and minimal energy values, ϵ , for pairs of different atoms are usually applied.

$$\rho_{ij} = \rho_i + \rho_j; \epsilon_{ij} = (\epsilon_i \epsilon_j)^{1/2} \quad (6)$$

Some force fields apply the combination rules directly to the coefficients of van der Waals terms.

The calculations of potential energy via Eq. 1 are used to search for local energy minima (mutual atom positions corresponding to possible stable configurations), to construct and analyze multidimensional potential energy surfaces (PES), to follow trajectory of movement (in MD, molecular dynamics simulations), or to study averaged thermodynamic and geometry characteristics (via MC, Monte Carlo sampling) of the systems. Description of MD and MC methods is beyond the survey, while some results of these applications of MM method will be mentioned briefly.

General Remarks on Molecular Mechanics, Its Accuracy, and Applicability

The first computer (and all “precomputer”) applications of mechanistic approach to molecule conformations and interactions ignored certain energy terms (e.g., stretching, bending, torsion, or electrostatic ones). Some modern works can ignore certain terms as well in order to reduce the number of variables of energy function, e.g., considering bond lengths as constants (their changes in many cases are very small and have no influence on energy and geometry of minimal energy structures). The simplest one of such approaches considers bond lengths and valence angles as constants, ignores torsion energy (the contributions of the first three terms of Eq. 1 being zeros), and utilizes “hard sphere approach” to nonbonded interactions. This approach is a mathematical representation of plastic (or wood, iron, etc.) space filling mechanic models or their computer images. The configurations are forbidden when any two nonbonded atoms are closer to each other than a sum of van der Waals radii (these configurations have infinite positive energy), all other being allowed (with zero energy). Already this oversimplified approach enables one to obtain some important results, e.g., to reject certain configurations and even a possibility to synthesize the molecule with inevitable too close positions of nonbonded atoms. The first “Ramachandran maps” for proteins (which will be discussed in the next section) have demonstrated allowed and forbidden regions on two-dimensional plots of the

fragment of polypeptide chain. These maps were subsequently improved using more realistic MM functions or quantum mechanics calculations.

Most modern MM computations include additional terms besides those already mentioned. These terms refer to direct imposition of experimental data (e.g., NMR-derived restrains on inter-atom distances or global characteristics of the macromolecule) and to description of specific quantum effects not accounting for by standard MM force field formulae.

The complexity of mathematical expressions and the number of parameters depend on the systems considered. The problem of “which atoms pertain to the same type and which ones are of different types” is considered by the authors of specific force field and software depending on the tasks and computer resources. The atom type may depend not only on the chemical element and electron shell configuration but on neighbor atoms and on the structure of the whole molecular fragment (e.g., the carbons of six-member and five-member aromatic rings having the same three bonded atoms may be considered as pertaining to different atom types). The more broad the applications that are planned for the force field, the greater the number of atom types that should be involved and the more complex force field formulae that should be constructed. The first works which dealt with the tasks related to specific systems (e.g., the conformations of saturated hydrocarbons or peptide fragments) usually contained a few parameters; the modern force fields may contain thousands of parameters (in spite of use of combination rules mentioned above). The mathematical forms of the equations and numbers of atom types and adjustable parameters represent a compromise between the simplicity (for elaboration and for use) and the accuracy of the results obtained.

Various physical considerations can be used for preliminary estimation of mathematical expressions and parameter values (rather simplified considerations were used in Eqs. 2, 3, 4, and 5). It is important to emphasize that neither dependences nor values of parameters can be “derived” (directly calculated) from universal principles or measured by any experimental method. The stretch and bend constants (of Eqs. 2 and 3) can be evaluated using infrared spectra; equilibrium bond lengths and valence angles can be estimated from X-ray data for crystals of simple molecules. The A_{ij} coefficients of the attraction part of van der Waals interactions can be evaluated (and really were calculated and used without refinement in the first MM works) via approximate formulae for dispersion interactions; however, their exact values for a certain class of systems should be adjusted by comparison with experimental data or with the most exact quantum chemistry results after trial computations for reference set of related systems. The same is valid for other terms and their parameters. Some parameters have rather simple physical meaning and restricted areas of possible values (e.g., equilibrium distances between bonded and nonbonded atoms or barriers to rotation about the bonds); other parameters have only approximate relation to physical values (atom charges, B_{ij} coefficients of Lennard-Jones potential). As all the parameters are adjustable ones, only the values of total energy and the equilibrium geometry of the molecular system can be compared with experimental data, and consequently have the strict physical meaning, not the individual contributions or the values of the individual parameters.

As various force fields utilize different reference sets of data, the individual parameters are not transferable between different force fields even in cases where they use the same mathematical expressions. Different force fields may result in the nearly equal energy and geometry of local minima configurations but rather different values of the individual term contributions. Thus individual terms of the energy may have very approximate physical interpretation, although in some cases it is interesting to evaluate the certain energy contributions and to follow their changes for different molecular complexes and different configurations (and many researchers include these evaluations to their publications).

It is worth mentioning that preliminary consideration of MM scheme has resulted already in some doubts and objections. Generally speaking, the classical description of the essentially quantum molecular systems cannot be exact and full. Most of the terms in Eqs. 2, 3, 4, and 5 refer to the first approximation or to the first term of expansion of the corresponding interaction energy. The atoms are not points, they have dipole and quadrupole moments (not only charges), and charge distribution in a molecule is continuous. The polarization or electron delocalization interactions are not considered in the classical “minimalist” MM approach, and the contributions of three-body and four-body interactions can be essential ones. Many attempts have been undertaken to overcome these inherent difficulties of the MM method as well as to justify the assumptions and simplifications; we will consider some of these attempts below. Few remarks for justification of the main principles of MM method are described here.

The possibility of consideration of atoms as elementary subunits of the molecular systems is a consequence of Born-Oppenheimer or adiabatic approximation (“separation” of electron and nuclear movements); all the quantum chemistry approaches start from this assumption. The additivity (or linear combination) is a common approach to a construction of complex functions for a physics-based description of the systems of various levels of complexity (cf. orbital approximation, MO LCAO approximation, basis sets of wave functions, and some other approximations in quantum mechanics). The final justification of the method is good correlation of the results of its applications with the available experimental data and a possibility to predict the characteristics of molecular systems before experimental data become available. It can be achieved after careful parameter adjustment and proper use of the force field in the area of its validity. The contributions not considered explicitly in the force field formulae are included implicitly into parameter values of the energy terms considered.

A Bit of History: The “Precomputer” and Early Computer-Aided MM Calculations

The quantitative estimations of molecular properties via simple atom level mechanics representations originate from the communications of Hill (1946, 1948), Westheimer and Mayer (1946), and Barton (1948, 1950). All these papers refer to conformations of organic molecules. It is interesting to mention that mathematical

expression of potential energy suggested in the pioneering work of Hill (1946) contains common for all the modern force fields stretch and bend components (Eqs. 2 and 3 of previous section) as well as the Lennard-Jones terms of nonbonded interaction energy. Westheimer and Mayer (1946) suggested the use of exponential term for description of steric repulsion. The first calculations for selected conformations of rather simple (“medium size”) molecules, such as diphenil derivatives in paper (Westheimer and Mayer 1946), cis-decalin and steroids in the papers of Barton (1948, 1950) were performed manually or using desk calculators. Some researchers constructed “hand-made” models of steel or wood (e.g., of cyclic saturated hydrocarbons in the papers of Allinger (1959)) for careful measurements of geometry parameters. The importance of quantitative estimations of nonbonded interactions for considerations of three-dimensional structure of organic molecules was emphasized starting from the first mechanical considerations, which was clearly shown by Bartell in 1960. He illustrated the preference of “soft sphere” over “hard sphere” approach to the analysis of hydrocarbon structure and suggested one of the first (6-12) parameters for hydrocarbons (Bartell 1960). As mentioned above, rather approximate calculations clearly demonstrated the utility of MM approach to the problems of organic chemistry as well as the need for further extensive computations and searching for more reliable parameters. We will refer to all these quantitative theoretical considerations of molecular properties as MM, not depending on the use of this term by the authors or on the method of estimation of different types of interactions.

Rapid expansion of MM method starting from the 1960s was provoked by an introduction of computers into all the branches of natural science. In this section, we will briefly consider some examples of the first computer-aided applications of MM method to three research areas, namely, the physical organic chemistry (these works can be considered as a continuation of the “precomputer” papers mentioned above), the structure and properties of molecular crystals, and the interactions and conformations of biopolymers.

First MM Applications to Three-Dimensional Structure and Thermodynamics of Organic Molecules

The first paper on computer study of organic molecule conformations was related to saturated hydrocarbons by Hendrickson (Hendrickson 1961). The angle bending, torsion, and (6-exp) van der Waals contributions to the conformation energy were taken into account, while constant values were assigned to bond lengths. The computer calculations of cyclo-alkanes containing 5, 6, and 7 carbon atoms enabled him to consider various conformers and to reproduce and rationalize the experimental data. During the 1960s and the beginning of the 1970s such computations were performed by several groups of investigators. Hendrickson (1962, 1973, and references herein), Allinger et al. (1971), and Allinger and Sprague (1973) extended MM approach to more complex hydrocarbons including those with delocalized electronic systems. Allinger’s computations took into account bond stretching in

addition to terms used by Hendrickson. Wiberg (1965) was the first researcher who suggested use of the Cartesian coordinates of atoms (instead of “internal coordinates,” i.e., bond lengths, bond angles, torsions) for nonbonded (“strain”) energy minimization. Such approach enables researchers to use the same scheme and the same software to study completely different systems. Most modern MM programs use such an approach. The electrostatic term has not been included in the papers mentioned in this paragraph as hydrocarbons are nonpolar molecules; it was introduced later when more broad sets of molecules became to be considered.

The most important results of early MM computations of organic compounds can be illustrated by Engler et al.’s paper (1973) titled “Critical Evaluation of Molecular Mechanics.” The calculations for various hydrocarbons have been performed using two rather different force fields, their own and that of Allinger et al. (1971). The two force fields have substantially different parameters as different sets of experimental characteristics were used for parameter adjustment. It results in significant difference of separate terms of the energy, which may vary by several times or even be positive for one force field and negative for another one. Nevertheless, total energies and relative values for various conformations calculated by two force fields are rather close to each other for most of the compounds considered. Two phrases of the paper’s abstract can be considered as characteristics of the whole situation with the MM approach for that time: “Most of the available data are reproduced with an accuracy rivaling that achieved by the experimental methods” and “The molecular mechanics method, in principle, must be considered to be competitive with experimental determination of the structures and enthalpies of molecules.”

Since the abovementioned publications, the theoretical conformational analysis using MM force fields has become an inherent part of physical studies of organic molecules. It became clear that in spite of difficulties with the parameter choice, the MM calculations are not only a useful tool to rationalize experimental observations, to reproduce and to predict the structure and energy characteristics of “medium size” organic molecules with experimental accuracy, but they can also help in elaboration of pathways of chemical synthesis. Different mathematical expressions and parameters transform into *force fields*, i.e., to complete and verified sets of the formulae and constants and ready-to-use computer programs. One of the first such force fields and programs was MM1 program based on the paper by Allinger and Sprague (1973), which then was followed by MM2, MM3, and MM4 force fields and software for broad class of organic molecules. The inclusion of new atom types and new terms of energy as well as parameter refinement continued till last years, and we will discuss these program sets in the next sections together with other modern force fields and software.

The Role of Molecular Crystal Study on the First Steps of Molecular Mechanics

The first publications on MM approach to molecule conformations mentioned above deal with *intramolecular* interactions. The first works on such approach to

intermolecular interactions belong to one of the pioneers and founders of MM, A. I. Kitaigorodsky (other spellings, Kitaigorodskii, Kitajgorodskij, Kitaygorodsky), though he (and all the researchers at that time) did not use the term “Molecular Mechanics.” Nearly at the same period (the 1950s) as Hill and Westheimer, usually mentioned as initiators of MM approach, he suggested to consider mechanical models of molecular systems quantitatively via mathematical expressions. In the 1950s, he foresaw the applications of the method to various problems of physics and physical chemistry of organic and biological molecules, including the problems of crystal structure, adsorption, and conformational transitions. We refer to the most frequently cited works of Kitaigorodsky (1960, 1961, 1973). Kitaigorodsky used structure and thermodynamic data on the crystals of organic molecules for adjustment of parameters of atom-atom potential functions for calculations of non-bonded interaction energy. This term of the total energy is dominant for molecular crystals. The method of atom-atom potentials was suggested as a generalization of the “principle of close packing” of molecules in molecular crystals he discovered earlier; his book (Kitaigorodski 1959) describing this principle is still widely cited. Later he demonstrated that this principle is a consequence of more general atom-atom approach to potential energy of molecular crystals. Kitaigorodsky was the first researcher who suggested to consider the interactions of nonbonded atoms in a molecule and of such atoms of different molecules via the same mathematical expressions and parameters (applications of MM approach to biopolymers would be impossible without this suggestion). The studies of molecular crystals via MM approach enabled one to derive potential functions for nonbonded interactions and to test the fidelity and accuracy of the approach itself using extensive sets of available quantitative data on structure and energy of molecular crystals.

Some energy terms were ignored in the first MM works on conformations of organic molecules, but it was impossible to predict a priori what types of contributions to intramolecular interactions energy (sums in Eq. 1) can be reasonably neglected for specific types of molecules. Considering crystal structure of nearly rigid molecules (e.g., aromatic rings) it is possible to ignore (at least in the first approximation) all the terms but the last one in Eq. 1. This assumption is just a consequence of examination of the geometry of series of related molecules in crystals (e.g., aromatic hydrocarbons consisting six-atom rings); all of them have nearly equal values of bond lengths and angles not depending on molecular complexity and the type of crystal packing. For hydrocarbons, it is possible (again at least for the initial studies) to ignore electrostatic contributions as well (the molecules have no dipole moment, and all the estimations of atom charges result in small values, less than 0.1 of electron charge). Kitaigorodsky suggested step-by-step selection of potential functions starting from molecules of nearly neutral atoms of two types (hydrocarbons) and introducing next atom types one-by-one for selecting next parameters. His pioneering works on molecular crystals were followed by more extensive computations of other authors. Some of these works were inspired by his ideas and followed his methodology (e.g., first papers of Williams (1966, 1967)), other researchers performed computations using different expressions for nonbonded potentials and additional terms of the energy (e.g., Lifson and Warshel

1968; Warshel and Lifson 1970). The common set of (6-exp) parameters for C...C, C...H, and H...H intermolecular interactions was obtained by Williams (1967) from energy and structure calculations for crystals of both aromatic and aliphatic hydrocarbons. Warshel and Lifson (1970) derived “consistent force field” parameters for description of both intermolecular and intramolecular interactions in crystals. This set contains both parameters for van der Waals interactions and other terms of energy mentioned in the previous section. Mason and coauthors (e.g., Craig et al. 1965; Rae and Mason 1968; Mason 1969) used combined approach to calculations of intermolecular interactions in crystals, namely, repulsive terms were calculated at atom-atom level, while attractive ones were considered on bond-bond level. Such approach and other changes of simple atom-atom scheme are not convenient for computations, and we would like to cite a phrase from Mason’s paper comparing his and Kitaigorodsky’s methods: “Although the representation of the attractive potential by spherically symmetric atom-atom interactions cannot be justified theoretically, it has been outstandingly successful in predicting the properties of crystals” (Mason 1969). The calculations for molecular crystals became a part of the selection and test of the parameters during elaboration of nearly all modern force fields. Later MM calculations for molecular crystals enable researchers to examine the approximations accepted in force field elaboration and to derive force field versions with additional terms of energy (including polarization and atom centers, e.g., Williams and Weller (1983)).

Molecular Mechanics on the First Steps of Molecular Biology: Molecular Mechanics and Protein Physics

Development of molecular biology and biophysics in the 1960s required a quantitative consideration of the conformations and interactions of proteins, nucleic acids, and biomolecules in general. The problems of biological importance were to rationalize the structure and conformational properties of the proteins and nucleic acids, namely, to understand the contributions of the subunits and to construct the models of the most favorable and biologically important conformations of the fragments. We already mentioned in previous section that the first successful models of regular structures of proteins and DNA duplex have been constructed using “hand-made” fragments of paper, wood, wire in the beginning of the 1950s. For understanding, explanation, and prediction of molecular level mechanisms of biopolymer functions, it was necessary to work out the method of quantitative simulation of the three-dimensional structure and properties of biomolecules. The first molecular mechanics considerations of biopolymer fragments were performed in 1960s. We will follow briefly such studies for proteins in a few paragraphs below.

The general problems on proteins which can be in principle solved via MM simulations are (1) the construction of three-dimensional structure of the macromolecule and prediction of the pathways of “protein folding” using restricted experimental data (ideally, the primary structure only); (2) the refinement of experimental structure (X-ray diffraction patterns usually do not supply us with information sufficient

for precise atom coordinate assignment). The whole problem of the proteins functioning cannot be solved via MM only as chemical reactions are beyond the MM approach. Changes in electronic structure in processes that involve bond-breaking and bond-forming, charge transfer, and/or electronic excitation require quantum mechanics considerations. Nevertheless, MM approach is useful for the problems of enzyme-substrate complex formation and of molecular recognition which are crucial for the protein functions.

First of all, two important results on protein structure obtained before classical MM computations should be mentioned. The atom-level structures of α -helical and β -sheet fragments of polypeptide chains have been designed by Linus Pauling and Robert Corey in 1951 using “hand-made” models of wood (Pauling and Corey 1951; Pauling et al. 1951). Such regular structures are the intrinsic parts of the majority of the proteins. The success in the construction of these first models of the regular protein fragments (as well as of the DNA duplex) primarily depended on correct subunits geometry and a potential to predict the correct scheme of hydrogen-bond formation, all other contributions to intramolecular interactions being of secondary importance. The regular structures imply H-bond formation between N-H donors and C=O acceptors of the peptide groups of the same chain for α -helix, and of other chain or of distant parts of the same chain for β -sheet. As it was pointed in more than half of century (Eisenberg 2003), “In major respects, the Pauling-Corey-Branson models were astoundingly correct, including bond lengths that were not surpassed in accuracy for >40 years.”

The second important “precomputer” result refers to construction via hard-sphere models of two-dimensional map for possible (and impossible) conformations of the dipeptide unit, the so-called Ramachandran plot (Ramachandran et al. 1963). The polypeptide backbone consists of repeating peptide group connected via C_α atoms, the latter being connected to hydrogen atom and amino-acid residue (the first atom of the residue is designated as C_β atom). The peptide group is practically planar, and the only single bonds in the peptide chain are those between C_α atom and two neighbor peptide groups (C_α -N-H of one group, the torsion angle for rotation about this bond is designated as Φ , and C_α -C=O of the next group, the torsion angle for rotation about this bond is designated as Ψ). Using mathematical expressions for atom coordinates suggesting fixed bond lengths and bond angles, Ramachandran et al. (1963) have constructed the two-dimensional Φ - Ψ maps with two sets of van der Waals atom radii, “normally allowed” and “outer limit,” i.e., normal and shortened radii. The main part of the maps for all the amino-acid residues except glycyl corresponds to the conformations forbidden due to shorten atom-atom contacts, while α -helix and β -sheet fall into the allowed regions. For glycyl residue, the allowed regions were considerably more extended. It took about half a year to construct these maps using a desk calculator (Ramachandran 1990); later such maps were computationally constructed using various force fields and quantum mechanics methods; superposition of Φ - Ψ combinations corresponding to experimentally or computationally constructed three-dimensional structure of proteins and peptides on the Ramachandran plot helped to check and rationalize the protein models nearly for half a century. The consideration of dependence

of Ramachandran plot on amino acid residue via hard sphere approach enables Leach et al. (1966a) to evaluate semi-quantitatively the parts of two-dimensional map corresponding to allowed conformations for different amino-acid residues (from about 50 % of all conceivable conformations for glycyl to only 5 % for valyl). The evaluation of steric restrictions emphasizes their important role as a determinant in protein conformation; the consideration of α -helices demonstrated that the preference of the right-handed ones in comparison to left-handed helices is due essentially to interactions of the C_{β} atom of the side chains with atoms in adjacent peptide units of the backbone (Leach et al. 1966b). The “hard sphere” approach was applied to search for allowed conformations of cyclic oligopeptides, for example (Némethy and Scheraga 1965).

The main conclusion of the “hard sphere” works was that steric effects are one of the most important factors in determining polypeptide conformations. “Many conformations of a polypeptide can be classed as energetically unfavorable without consideration of other kinds of interactions; however, the method breaks down to the extent that it cannot discriminate between those conformations which are sterically allowed . . . The contribution that this method has made is that more than half of all the conceivable polypeptide conformations are now known to be ruled out by steric criteria alone” (Scott and Scheraga 1966a). Nearly at the same time (the middle of 1960s) as abovementioned hard sphere considerations of peptides, the first applications of MM formulae to protein structure were started using “soft atoms,” and the first parameters of potential functions suitable for peptide subunits calculations were suggested. The first such works were published by three groups of researchers, namely, those of De Santis and Liquori (De Santis et al. 1965), Flory (Brant and Flory 1965), and Scheraga (Scott and Scheraga 1966a). All these works were preceded by the publications of the authors related to synthetic polymers. The bond lengths, valence angles, and planar peptide group in all the early studies of polypeptides were fixed.

De Santis et al. (1963) have carried out the calculations of van der Waals term of the energy using different potentials for regular conformations of linear polymers as functions of torsion angles of monomer units. The deepest minima of the conformational diagrams were found very near to the experimental structures, as obtained by X-ray fiber diffraction methods, for a series of polymers investigated including polyethylene, poly(tetrafluoroethylene), poly(oxy-methylene), and polyisobutylene. When the calculations were extended to the polypeptides (polyglycine, poly-L-alanine, and poly-L-proline), good agreement with the experiments was obtained as well (De Santis et al. 1965). After nearly 30 years De Santis wrote “While other contributions to the conformational energy are included in the calculations, the dominant role of the van der Waals interactions remains well established as the main determinant of the conformational stability of macromolecules” (De Santis 1992).

Brant and Flory (1965) have carried out the calculations on peptide unit energy in which they included torsion potentials, van der Waals (6-exp) interactions, and dipole-dipole interactions between the permanent dipole moments of near-neighbor peptide groups. The conformational energies were used by Brant and Flory

in statistical mechanical calculations of the mean-square unperturbed end-to-end distance of various polypeptide chains. They concluded that it was necessary to include the electrostatic interactions in the energy calculations to obtain agreement between the calculated and experimentally determined chain dimensions and thus that these interactions are important in determining polypeptide conformations.

The first publication of Scheraga's group related to "soft atoms" MM simulations related to proteins (on helical structures of polyglycine and poly-L-alanine (Scott and Scheraga 1966a)) included besides contributions considered in paper of Brant and Flory (1965) explicit accounting of hydrogen bonds and interactions of atom charges of peptide group. Rather complex expression for dipole-dipole energy of interactions between peptide groups used by Brant and Flory (1965) was substituted by Coulomb atom-atom terms, and (6-exp) expressions for van der Waals interactions were substituted in this paper and subsequent publications by (6-12) potentials, but additional complicated expression for description of hydrogen bond energy was added. The method and parameters for calculation of torsion and van der Waals energies were earlier developed by Scott and Scheraga (1966b) for normal hydrocarbons and polyethylene. It is interesting to note that both groups of authors (those of Flory and of Scheraga) applied without further refinement approximate Slater-Kirkwood equation for calculation of coefficient for attractive term of van der Waals energy (the coefficients were expressed via polarizabilities and effective numbers of electrons of the interacting atoms) and van der Waals radii for calculation of repulsion term parameters. Approximate character of such parameters is evident, but rather good agreement with experimental results was obtained in the both publications (Brant and Flory 1965; Scott and Scheraga 1966a). The existence of polyglycine and poly-L-alanine regular α -helices was rationalized as a consequence of favorable both H-bond and van der Waals interactions, while helices of other possible types (ω and 3_{10}) lie in relatively high-energy regions, and for isolated helices these structures have been excluded (Scott and Scheraga 1966a).

The abovementioned calculations of Scheraga et al. on protein simulations were followed by a series of publications related to both improvements of the method (both parameter adjustments and new term additions) and of simplifications of computations. Such changes in the methods enable them to obtain preliminary results on peptides of up to 20 amino acid residues already in 1967 (Gibson and Scheraga 1967a, b). The improvements of the method refer to enlarging the equilibrium radii of atoms, assigning partial charges to each atom (but neglecting the electrostatic contribution when the atoms are not close together), and introduction of orientation-dependent term for H-bond description instead of complicated formulae of the previous paper (Scott and Scheraga 1966a). The simplified account for solvent contribution to the energy has been included considering the effect of removing the nearest neighbor to peptide water molecules (Gibson and Scheraga 1967a). The simplification of the model refers to introducing "extended atom," i.e., CH, CH₂, and CH₃ groups were considered as the single atom to reduce the number of atom-atom interactions that had to be computed (this approach was used later in many force fields and such potential functions are commonly referred to as "united atom" potentials, we will discuss this simplification below). Scheraga's group prolongs

the improvement of the parameters and the method continuously till recent years. We will discuss these studies below, now we will mention some improvements performed in the first half of the 1970s. The most important improvements refer to description of H-bond potential by (10-12) expression (McGuire et al. 1972) (some other force fields adopted such dependence for description of interaction between hydrogen atom capable to participate in H-bond and atom-acceptor of H-bond), to calculation of partial charges via semiempirical CNDO/2 method (Yan et al. 1970), and to adjustment of repulsion part of van der Waals interactions to crystal data for extensive set of molecules including amino acid crystals (Momany et al. 1974, 1975). The results of the crystal calculations led to an internally self-consistent set of interatomic potential energies for interactions between all types of atoms found in polypeptides (ECEPP force field (Momany et al. 1975)). The bond lengths and bond angles were obtained from a survey of the crystal structures and were considered as fixed for each of amino acid residue (Scheraga's force fields differ in this feature from most other widely used force fields). The preliminary set of potential functions they used to refine X-ray structures of some proteins, e.g., lysozyme (Warne and Scheraga 1974), α -lactalbumin (Rasse et al. 1974), and rubredoxin (Warne et al. 1974).

We will not consider details of these papers; instead we will mention the first publication on MM refinement of X-ray protein structure of Levitt and Lifson (1969). The refinements of protein structures (myoglobin and lysozyme) have been performed via two steps by minimization of the energy function containing all the MM terms and an additional term describing deviation of the atom coordinates from their values obtained from X-ray diffraction studies (penalty function). Three energy terms (corresponding bond stretching, bond angle bending, and torsion potentials) supplemented by penalty functions were used at the first step. At the second step nonbonded and hydrogen-bonded interactions were included, and penalty functions were omitted. The authors mention that energy function parameters are preliminary ones, intended for protein simulation in aqueous solution, differed significantly from those of Scheraga and subject to further improvement. The refined structures were close to X-ray diffraction ones and do not contain short atom-atom contacts or unusual bond lengths and valence angles. Starting from rough model coordinates, the method minimizes the assumed total potential energy of the protein molecule to give a refined conformation (Levitt and Lifson 1969).

Molecular Mechanics on the First Steps of the Biophysics of Nucleic Acids

The problems related to MM approach to nucleic acid structure and functions differ in some aspects from those for proteins. The main computational tasks for the 1960s in the area of nucleic acids were to rationalize the structure of native and modified DNA duplexes, t-RNAs, synthetic polynucleotides, i.e., to understand the contribution of the subunits (the bases, sugars, ionized phosphate groups, counter-

ions, and surrounding water) to three-dimensional structure, and to evaluate the contributions of interactions of different physical nature to structure and functions of nucleic acids. The extensive applications of MM approach to nucleic acids were started a few years after those for proteins. The same is true for the adjustment of MM parameters for calculations of nucleic acids. Such a situation can be explained by “special role” of DNA in cells as a heredity material as well as by expectations of “specific” forces between the bases as conjugated molecules with delocalized electron system. Many researchers considered the electron exchange via H-bonds in base pairs and exchange interactions between stacked bases as the crucial contributions to nucleic acid functioning. It took some years before pioneers of quantum mechanics approach to biochemical problems would write: “The possible contributions of resonance energy stabilization through electronic delocalization across the hydrogen bond for horizontal interactions and of overlapping of their π -electronic cloud or of charge-transfer complexation for the vertical interactions appear to be of much smaller order the magnitude than the stabilization increments due to van der Waals-London forces” (Pullman and Pullman 1968).

The author of this survey was the first researcher since the application of MM formulae in 1966 to consider the interactions of nucleic acid subunits. We will now briefly follow the route of investigations of nucleic acid interactions to “classic” MM approach. The first quantitative estimation of interactions of bases in DNA duplex via formulae of intermolecular interactions was performed by De Voë and Tinoco (1962). They used so-called molecule dipole approximation, i.e., permanent and induced electric point dipoles were placed into the center of each base. The energy of interaction between two paired or stacked bases was suggested to be a sum of the interactions of permanent dipoles (Coulomb electrostatic interactions), permanent dipole-induced dipole (polarization interactions), and of induced dipoles (London dispersion interaction). Such an approximation does not enable them to obtain even qualitatively correct results (e.g., the energy of interaction between the bases in Watson-Crick A:T pair was positive), but the computational problem of evaluation of interaction energy changes on the formation of the specific nucleic acid conformation has been defined in this chapter. That is why it is cited in hundreds of publications during nearly a half of century, many of them (including those of the author of this survey) were inspired by the paper of De Voë and Tinoco (1962). Shortly it became clear that such an approximation is invalid for this system not depending on dipole location as well as after replacement of point dipoles by “real” ones, i.e., by dipoles of definite size. Bradley et al. (1964) suggested that the main contribution into base-base interaction energy is of Coulomb electrostatic nature, which can be calculated in “monopole approximation.” The point charges were calculated via semiempirical methods of quantum chemistry and placed on each atom of the bases. This paper was followed by the papers of Nash and Bradley related to calculations of base-base interactions. One of their papers should be mentioned in relation to the general progress and development of MM approach. Starting from various mutual in-plane positions for all the combinations of RNA bases, the calculations and search for minima of electrostatic energy was performed (Nash and Bradley 1966). Van der Waals energy was taken into account

in “hard sphere” approximation, i.e., any non-hydrogen atom pair should not be closer than sum of van der Waals radii. As a result of the calculations, 27 energy minima were obtained which have two or more short N-H...O or N-H...N contacts (with N...N or N...O distances about 3 Å) corresponding to nearly linear or bifurcated hydrogen bonds. The results enable Nash and Bradley to rationalize the available up-to-date experimental data on base crystals data as well as base-base complex formation in solutions and polynucleotides. It appears that the observed base pairings with two H-bonds in crystals always correspond to one of the computed geometries of lowest energy (Nash and Bradley 1966). It is important to emphasize that Bradley et al. (1964) “monopole” approach to calculations of the base interaction was the first attempt to consider the electrostatic energy in the framework of the modern MM scheme. The abovementioned calculations of Scheraga’s group with inclusion of point charges of peptide group were started 2 years after the Bradley’s publication.

The subsequent studies on the quantitative evaluation of the interactions and three-dimensional structure of nucleic acid fragments were continued via two routes. One of the approaches suggested construction of MM force field parametrized to nucleic acids interactions; another approach implied calculations using more rigorous physics concepts and molecular characteristics in a hope to understand physical nature of interactions. The first works on this way were performed by Pullman’s group and referred to interactions of the bases in fixed positions (e.g., Pullman et al. 1966). Considering the energy of interactions as a sum of electrostatic, polarization, and dispersion terms, two approximations were applied, “dipole” and “monopole”. The monopole approximation was applied to electrostatic energy only (following Bradley et al. 1964), while two other terms were really calculated in molecular dipole approximation. This approach was later augmented by inclusion of the short range repulsion term and representation of the molecule as a set of “many-centered multipole distributions obtained from ab initio SCF calculations (charges, dipoles, and quadrupoles located on the atoms and the middles of segments joining pairs of atoms)” (Langlet et al. 1981). We will not consider subsequent progress on this way of nucleic acid computations as new schemes (e.g., Gresh et al. 1986 and references herein) do not correspond to the MM approach. Nevertheless, it is worth to mention that the sophisticated schemes of base-base computations had no advantage for rationalization and prediction of experimental results in comparison to “standard” MM scheme reviewed in the next paragraph.

In the middle of the 1960s, the author of this survey proposed the first atom-atom scheme and numerical parameters for the calculation of interactions of nucleic acid bases (the terms “force field” and “molecular mechanics” were not widely used in those years). This scheme had three source points, namely, idea of De Voe and Tinoco (1962) on quantitative estimations of interactions of nucleic acid subunits, “monopole” approximation of Bradley et al. (1964) for electrostatic interactions of the bases, and Kitaygorodsky (1961) atom-atom approach to calculations of van der Waals interactions in molecular crystals. At that time, there was no “MM-like” calculation scheme suitable for quantitative considerations of nucleic acid

interactions and structure. We refer here only to later papers summarizing some preliminary adjustments and applications of the approach (Poltev and Sukhorukov 1970; Poltev and Shulyupina 1986). When calculating the interactions of nucleic acid bases or other conjugated heterocyclic molecules the only term $\sum E_{nb}$ of Eq. 1 was considered, corresponding to all the pair-wise interactions of atoms not pertaining to the same molecule. The bond lengths and valence angles were fixed and corresponded to averaged experimental geometry for each of the bases (like those for amino-acid residues and peptide backbone in Scheraga's force field (Momany et al. 1975)). The atom-atom terms contained electrostatic, London attraction, and short-range repulsion contributions. This scheme was the first one assigning different parameters of van der Waals terms to the atoms of the same chemical element but different electron shell configuration (e.g., aromatic and aliphatic carbons, pyridine and pyrrol nitrogens, keto and enol oxygens). These parameters were preliminarily evaluated from approximate London formulae (for A_{ij} coefficient of Eq. 5) and enlarged van der Waals radii of atoms (for B_{ij} coefficient of Eq. 5 or corresponded values for the firstly used 6-exp potentials). The final values of the parameters were selected after step-by-step calculations and comparison with experimental data for crystals containing the atoms of some types only (starting from graphite, then aromatic hydrocarbons, pyrazine, benzoquinone, purine, and finally the bases). The effective charges of atoms were calculated via simple semiempirical quantum chemistry method (of Huckel and Del Re for π -electrons and σ -electrons, respectively) with the parameters adjusted to reproduce experimental values of dipole moments for related molecules. The primary scheme (Poltev and Sukhorukov 1970) contained polarization term as well, but it was shortly eliminated due to its small value for many cases and to avoid difficulties related to nonadditivity of atom-atom and molecule-molecule interactions. The parameter set was than amplified by consistent parameters for sugar-phosphate backbone (Zhurkin et al. 1980) and for water-DNA interactions (Poltev et al. 1984). This simple MM scheme specially adjusted to nucleic acid interactions enables us to rationalize extended set of experimental data and to forecast some nucleic acid properties before experimental evidence. Variability of DNA helix parameters (Khutorsky and Poltev 1976), dependence of mutual base-pair positions in energy minima on nucleotide sequence (Polozov et al. 1973), pathways for all the base-substitution errors (Poltev and Bruskov 1978), and DNA duplexes with mispairs (Chuprina and Poltev 1983) were predicted by such calculations before experimental data became available. The parameters of this simple scheme were refined later several times (like any other force field scheme discussed above and below) via adjustment to new experimental data and quantum mechanics considerations. We will mention here only one more series of early MM calculations related to nucleic acids performed by Indian scientists Renugopalakrishnan, Lakshminarayanan, and Sasisekharan (coauthor of Ramachandran et al. (1963) paper on Φ - Ψ plot for proteins). They suggested the first complete set of parameters for calculations of the conformations of nucleic acid fragments (Renugopalakrishnan et al. 1971, and references herein). The atom charges crucial for the base interactions have been calculated via the same procedure as in our earlier papers (e.g., Poltev and Sukhorukov 1970).

The Problems and Doubts of Further Development of the MM Approach

As follows from the previous section, the usefulness of MM approach was already demonstrated in the first decade of its extensive applications and modifications. At the same time, the problems of justification and of pathways of future development of the approach had arisen. From the very beginning, it was clear that the method cannot provide us with exact description of the structures and processes due to its semiempirical nature. The interesting problem of the method is the relative extent of empiricism and physical meaning of the scheme and its parameters.

Approaches to Improvement of MM Formulae and Parameters

Several ways of improvement of MM scheme were proposed during the 1960s and the 1970s. Two hypothetical approaches to refinement of MM representation and force fields can be considered. In the framework of the first approach, it is suggested to describe the physical nature of the system in the most exact way, e.g., to employ more exact equations for description of the interaction energy (e.g., not restricting expressions to first term in the expansion for bond stretching and angle bending, use of better grounded expressions for van der Waals interactions, etc.) and/or more detailed representation of the system considering not only point atoms but other centers of interactions, not restricting the scheme with scalar values but introducing vectors (such as dipole moments) or tensors (such as anisotropic polarizability). In the framework of the second approach, it would be possible to consider energy expressions as entirely empirical ones and to adjust the parameters to experimental data (or, later, to reliable quantum mechanics results) until the closest coincidence (e.g., via the least square method). Unsuccessful attempts of consistent and strict use of only one of the approaches had been undertaken during the first two decades of the MM computer simulations.

The second approach mentioned above is practically impossible to realize; usually, there is no sufficient quantitative experimental data not only to derive the form of dependences of the energy on inter-atomic distances but to obtain the coefficients of already accepted potential form (e.g., of Lennard-Jones). Even in a case we have sufficient number of experimental values, the equations for parameter calculations have no single definite solution. It was demonstrated in the paper of Momany et al. (1968). The authors of the abovementioned paper tried to adjust the coefficient of (6-12) potentials for C...C, C...H, and H...H interactions for benzene molecule to the energy and structure data of benzene crystal. Using three sets of experimental data for different temperatures, they obtained entirely repulsive contribution from C-C interactions. It means that qualitative estimations (relative values of attraction terms for various atoms, of equilibrium radii, of atom charges in the same or similar molecules, etc.) should be taken into account in adjusting the parameters of the force field. Most of the modern force fields originate

from previous sets of expressions and parameters derived from simple qualitative considerations (e.g., simplified formulae of dispersion term, van der Waals radii of atoms) and take into account these considerations automatically (e.g., using previous approximate parameters' values as starting points).

As for the first approach, the more complex expressions of the energy were suggested since the end of 1960s, and such expressions are used in some modern force fields, i.e., next terms in the energy expansions for stretching, bending, and van der Waals contributions. The inclusion of additional terms requires new parameters. Usually the number of reliable quantitative values is not sufficient, and such an approach becomes useful in case the area of applications of the force field is restricted to certain types of similar molecules (e.g., hydrocarbons). In any case, the expressions for each term remain the approximate ones, and more coefficients should be adjusted to target data. The more complex representation of the molecular system as compared to a set of point atoms was proposed by several researchers during the 1960s and the 1970s (including the author of this survey). Such a representation looks the most natural for atoms with lone pairs of electrons (inclusion of additional points for electrostatic interactions of pyridine nitrogen or keto oxygen located at the centers of lone-pair orbitals) or for atoms with π -orbitals (additional points for aromatic heterocycles located above and below the ring planes to account for quadrupole moments of the molecules). Additional lone pair centers for electrostatic interactions are included in some modern force fields for better reproduction of electric field around the molecules and the directionality of hydrogen bonds.

Although the introduction of such centers looks physically based, an inconsistency of such an approach can be detected rather easily. When assigning the negative charged interaction centers to some electron orbitals (and hence positively charged centers to nuclei locations), it looks natural to assign additional centers to chemical bonds (sites of the highest electron density between the nuclei). As a result, we have several times more centers (more computer resources are needed) and several times more adjustable parameters. Such an approach was consistently implemented into force field suggested by Scheraga and coauthors. The first version was titled "empirical potential using electrons and nuclei" (EPEN ; Shipman et al. 1975) and an improved version EPEN/2 was released in 3 years (Snir et al. 1978). In this model, the molecular interactions are modeled through distributed interaction sites, which account for the nuclei and electronic clouds. The positive charges are located at the atomic nuclei, and the negative charge centers are located off the nuclei. The bonding electrons are located along the bonds, while the lone-pair and π - electrons are located off the bonds. The energy of interaction is approximated by the sum of the coulomb interactions between all point charge centers, an exponential repulsion to represent electron–electron overlap repulsion, and an R^{-6} (R = distance) attraction to simulate attractive energies between the nuclei. The distances between the charge locations are the method parameters; they are fixed in the molecule fragments. The parametrization was optimized by least square fits to spectroscopic, crystallographic, and thermodynamic data. This approach (as well as other approaches considering many in addition to atom centers of interactions)

was not widely used in MM calculations. The situation can be accounted for by restrictions imposed by fixed geometry of the molecule fragments as well as by need for the parameter adjustment for molecules other than considered by the approach authors.

A separate problem is the choice of the force field parameters for most exact reproduction of experimental and/or quantum mechanics data. All the experimental values are determined with a definite accuracy; all the quantum mechanics data refer to gas phase and do not include implicitly third body interactions. The use of quantum mechanics data only (not depending on level of theory) results in errors in reproduction of condensed phase properties. The adjustment of parameters to characteristics of condensed phase (most experimental data refer to crystals or solutions) leads to wrong values of characteristics for separate molecules or their simple complexes in gas phase. Hence, various experimental and quantum mechanics data should be considered with different weights in the process of the adjustment of force fields, the weights being dependent on areas of intended applications of the force field.

Recently, a method and software package named ForceBalance for systematic force field optimization has been published (Wang et al. 2013a). The method enables researchers to parametrize a wide variety of functional forms using flexible combinations of target data. These data may come from experimental measurements or from quantum mechanics calculations. Various properties are included in a single objective function, which is then integrated over the entire configuration space. The method was used by the authors (Wang et al. 2013a) for developing a new polarizable water model with 27 parameters adjustable to quantum mechanics data for single water molecule and H-bonded water clusters. The water model contains five fluctuating charge sites including three virtual sites. The positions of virtual sites have been fully optimized; they do not coincide with lone pair centers. An interesting suggestion was made for description of van der Waals interactions. The authors propose specially modified (6-exp) potential. As it was mentioned in the first section, “classical” (6-exp) Buckingham function widely used on the first steps of MM-like calculations has unphysical dependence on interatomic distance at small distances. The authors of the model (Wang et al. 2013a) have chosen empirical van der Waals potential $E_{vdw}(r)$ with three parameters.

$$E_{vdw}(r) = 2\varepsilon \left(\rho^6 / (\rho^6 + r^6) \right) / (1 - 3 / (\gamma + 3)) [3 \exp(\gamma(1 - r/\rho)) / (\gamma + 3) - 1] \quad (7)$$

This function depends on equilibrium interatomic distance, ρ ; minimal energy values, ε ; and a dimensionless constant, γ , describing the steepness of the repulsion. Like Buckingham function, it tends to an attractive r^{-6} potential at large interatomic distances, tends to a repulsive exponential term at small distances, and has well-defined unique minimum. The authors note that their water model is quite accurate for some, but not all, properties of liquid water. We should note that this disadvantage is common for all the force fields derived from quantum mechanics results

only, without adjustment to experimental data. Improvements of water model using ForceBalance software and both quantum mechanics and experimental data will be considered below.

Various Schemes of Water Molecule in MM Calculations

In view of importance of water for life and for description of the biomolecular interactions as well as of “anomalous” physical properties of water in liquid and solid states, hundreds of models and their modifications for water molecule have been proposed. We will mention here only few of most frequently used and cited rigid models and some recent polarizable models. Simple atomic structure of the water molecule enables researchers to perform quantum mechanics calculations of rather high level unreachable for most organic molecules. The results of these computations for a single molecule and for H-bonded water clusters together with availability of quantitative experimental data for bulk water at various temperatures and pressures stimulate elaboration of new models and permanent improvement of existent ones. These models can be used for demonstration of possibilities and restrictions of the MM method in general, for comparison of various approaches to MM model construction.

Most water models describe the molecule by the number of interaction centers not coinciding exactly with atom centers. This diversion from simple MM scheme can be understood as a consequence of small size of the molecule and the inability of any simple charge distribution on atom centers to adequately describe the molecular dipole and quadrupole of the monomer at the same time. Inclusion of additional centers or/and displacement of interaction centers from atoms is necessary to reproduce charge distribution of this simple molecule. (The author of this survey noticed this fact earlier for heterocyclic compounds, but fortunately in this case the contributions of permanent quadrupole interactions can be implicitly accounted for by other terms of interaction energy.)

The first water molecule model (frequently referred to as BF model) has been proposed by Bernal and Fowler (1933). This model may be considered as the earliest molecular model suitable for MM calculations, and it was used for Monte Carlo calculations of liquid water performed in nearly a half of century for comparison with some later models (Jorgensen et al. 1983). The model contains four interaction sites: three charged sites, namely, two positive centers located at the hydrogen atoms and one negative center (so-called M-site) displaced by 0.15 Å from oxygen atom in the direction of H-O-H bisector, and one center for van der Waals interactions located on oxygen atom. It is interesting to note that Bernal and Fowler (1933) performed approximate evaluations of intermolecular interaction energy by the (1-6-12) potential functions. Jorgensen et al. (1983) used nearly the same position of centers and slightly modified charges in TIP4P four-site water model (one of their popular Transferable Intermolecular Potentials). Matsuoka et al. (1976) derived more complex four-site model from potential surface of water dimer constructed via ab initio quantum mechanics calculations with configuration interactions.

The analytical expression for interaction potential function between two water molecules consists of pair-wise Coulomb interactions of three charges located similar to BF or TIP4P models and exponential interactions of all the three atoms of one molecule with the atoms of the other one. This model (the so-called MCY model) was widely used during the first decade of liquid water simulations.

We will not consider many models including earliest ones which consist of three, five, or more centers but only briefly mention some of the rigid models cited till the present time and used in modern force fields. Stillinger and Rahman (1974) suggested the five-site model with two positive centers (hydrogen atoms), two negative centers (located at oxygen lone pairs), and one center (oxygen atom) for Lennard-Jones interactions. The model has been used successfully to study a wide variety of properties of liquid water. Mahoney and Jorgensen (2001), after extensive Monte Carlo simulations and parameters adjustment, suggested five-site model TIP5P which enables them to describe the density anomaly of liquid water better than previously existing models. Nada and Van der Eerden (2003) have designed six-site model of water molecule. Three of these sites are the three atoms of the molecule (they interact through a Lennard-Jones potential), and three other sites are point charges (O atom is electrically neutral; the two H atoms carry positive charges). The model can be considered as a combination of TIP4P and TIP5P models of Jorgensen. The Monte Carlo simulations of ice and water show that the six-site model reproduces well the real structural and thermodynamic properties of ice and water near the melting point.

Two three-site rigid water models, namely, TIP3P of Jorgensen et al. (1983) and SPC of Berendsen et al. (1981) should be specially mentioned, as these models (or their modifications) are used in modern force fields for biomolecular simulations. These models have (in accord with general MM principles for class I models) three interaction sites centered on the nuclei. Each site has a partial charge for computing the Coulomb energy and only one site (oxygen atom) for Lennard-Jones interactions. The TIP3P model demonstrates better reproduction of experimental thermodynamic and structural data for bulk water (Jorgensen et al. 1983).

Further progress in the study of water properties and its interactions with other molecules is related to new models introducing flexibility to the molecule (incorporating bond stretching and angle bending terms into interaction energy) and with the inclusion of electronic polarization. These effects are important for the quantitative description of water properties in liquid and solid states as well as of phase transitions. We mention here a few of recent water models beyond class I MM methods.

The model elaborated by Ren and Ponder (2003, 2004), AMOEBA (Atomic Multipole Optimized Energetics for Biomolecular Applications), includes full intramolecular flexibility, permanent atomic monopole, dipole, and quadrupole moments placed on each atomic center and buffered 7-14 potential for pairwise atom-atom van der Waals interactions. Polarization effects are explicitly treated in the AMOEBA force field via mutual induction of dipoles at atomic centers. The functional forms for bond stretching and angle bending were taken from the Allinger's MM3 force field and include anharmonicity through the use of higher-order deviations from ideal bond lengths and angles. An additional intramolecular

term, the Urey-Bradley term, consists of a simple harmonic function. The force field does not contain off-atom sites. It was parametrized by hand to fit results from *ab initio* calculations on gas phase clusters up to hexamers (Ren and Ponder 2003) and temperature and pressure dependent bulk phase properties (Ren and Ponder 2004). The model enables authors to reproduce well both the high-level *ab initio* results for various gas phase clusters and bulk water thermodynamics data, including the second virial coefficients over the whole temperature range. The authors mention that AMOEBA water model is approximately eight times slower than the TIP3P one (for MD simulations of a periodic system of 216 water molecules); nevertheless, they consider it as “the first step in the derivation of a next-generation polarizable force field for biomolecular simulation.” Later, AMOEBA force field was extended to organic molecules (Ren et al. 2011) and to proteins (Shi et al. 2013).

The iAMOEBA, i.e., “inexpensive AMOEBA” (Wang et al. 2013b) was developed using the ForceBalance automated procedure (Wang et al. 2013a). A direct approximation to describe electronic polarizability reduces the computational cost relative to a fully polarizable AMOEBA model, and the application of systematic optimization ForceBalance method results in raising the accuracy of iAMOEBA.

Recently (Laury et al. 2015), a set of improved parameters for the AMOEBA water model was developed using the automated procedure, ForceBalance (Wang et al. 2013a). An adjustment of 21 force field parameters has been performed to both high-level *ab initio* results for gas phase clusters, containing 2–20 water molecules, and six condensed phase properties at a range of temperatures (249–373 K) and pressures (1 atm to 8 kilobar). The enthalpy of vaporization and density dependence on temperature were given a greater weight (as compared to the other properties) in the optimization. The model represents a significant refinement of the original AMOEBA parametrization, namely, it provides a substantial improvement in the ability to predict experimental data, particularly for a number of liquid properties across a range of temperatures. The authors (creators of original AMOEBA models are among them) refer to new model as AMOEBA14 and to the original model (Ren and Ponder 2003, 2004) as AMOEBA03. The AMOEBA14 model has a similar accuracy level as the AMOEBA03 model for the interaction energy of the gas phase cluster ranging from dimers to 20-mers. They promise compatibility of AMOEBA14 water model with the previously determined AMOEBA force fields for organic molecules (Ren et al. 2011) and for proteins (Shi et al. 2013).

The authors of CHARMM force field and software package, widely used for biomolecular simulation (see description below), elaborate their own polarizable models of water based on classical Drude oscillator. Last model of their SWM (simple water model) series, six-site SWM6 one (Yu et al. 2013) was developed and optimized for liquid phase simulations under ambient conditions using CHARMM family of force fields. The atoms of the molecule kept its gas phase experimental geometry, and the positions of three other massless interaction sites correspond to the so-called M point located at a fixed distance from the oxygen atom along the bisector of the H–O–H angle, and two oxygen’s lone pairs (LP sites). The model is less computer time consuming as compared to more sophisticated AMOEBA; it has an improved balance between descriptions of microscopic and bulk phase

properties compared to most additive and polarizable water models developed previously. Besides, the local hydrogen bonding structures in the liquid phase are better reproduced in the model as indicated by the O-O distance distribution function. However, the model does not reproduce correctly the experimental data on liquid water density maximum. Authors note that the model is not developed for routine use but for studies when the local hydrogen bonding is important and high accuracy is needed.

We will not discuss many other recent sophisticated water models, including those developed using both experimental data and quantum mechanics computations (via both *ab initio* and DFT methods), such as Tröster's polarizable molecular mechanics (PMM) model (Tröster et al. 2014) and Pinilla's polarizable and dissociable force field (Pinilla et al. 2012). Selected old and recent MM water models, both simple and rather sophisticated, enable us to arrive at some conclusions on possibilities of molecular mechanics description of simple and complex molecular systems. Some of such conclusions are rather trivial, but additional evidence from the experience of hundreds of researchers on water molecule modeling can help to illustrate and reinforce them.

Till recent time, complete and reliable MM description of even this very simple biologically important molecule is a challenge for computationally oriented researchers. More complex expressions for separate energy terms grounded on physical theories, increase of the number of adjustable parameters, improved algorithms for parameter adjustment to target data, and the use of more reliable quantum mechanics results, all together help to better reproduce and rationalize experimental data, but some results are not accurately reproduced. Each model of the molecule, each force field, reproduces (and predicts) some characteristics better as compared to other force fields. The more sophisticated model is not necessarily the better one for specific MM applications and specific tasks of the study. This is true not only because of restrictions of computer resources but due to approximate nature of the MM description. This conclusion is a result of many trials and errors in water simulations. Class I molecular mechanics representations, i.e., simple three-site rigid water models (TIP3P and its modifications) are successfully used in many biomolecular computations in spite of the development of new force fields. This success can be accounted for not by the importance of additional terms but by their implicit compensation by parameter choice for simple model (Class I force fields). More sophisticated force fields (Class II and Class III), together with quantum mechanics, both *ab initio* and semiempirical, computations are useful for detailed description of mutual positions of molecules in water solutions of biomolecules.

Modern Molecular Mechanics Force Fields: Description, Recent Development, and Applications

The MM computations during the first two decades were mainly performed by the researchers using their own force fields and homemade computer programs. Most of the modern publications refer to standard, ready-to-use software with implemented

(or sometimes slightly modified) force field parameters. The number of program and parameter packages is rather great and new or newly modernized software and force fields appear every year. We will present below a short overview of the selected program sets and force fields most frequently used for study of biomolecular systems. Some of them have been already mentioned in previous sections. During last decade, some software packages such as NAMD (Phillips et al. 2005) and TINKER (Ponder 2015) have appeared which give an opportunity to perform computations using various molecular mechanics force fields. Some popular quantum mechanics software packages such as GAUSSIAN and SCHRODINGER supply users with the possibility to use MM force fields as well.

Allinger's Force Fields and Programs

We started description of the modern force field with short characterization of Allinger's parameters and programs as they were the first ones ready for use by any researcher. The first parameter set (MM1) was described in 1973 (Allinger and Sprague 1973), and the MM1 program was released through Quantum Chemistry Program Exchange in 1976. The force field and the program MM1 were followed by a series of improved and extended versions for various classes of organic molecules, MM2, MM3, MM4 (see Allinger et al. 1989, 1996; Lii et al. 2005 for references). These force fields have been parameterized based on experimental data, including the electron diffraction, vibrational spectra, heats of formation, and crystal structures. The calculation results were verified via comparison with high-level *ab initio* quantum chemistry computations, and the parameters were additionally adjusted. The last program versions include rather complex force field equations (including additional terms to harmonic potentials for stretching and bending and cross-terms; thus MM3 and MM4 force field are those of class II) and various calculation options (e.g., prediction of frequencies and intensities of vibrational spectra, calculating the entropy and heat of formation for a molecule at various temperatures). MM4's molecular dynamics option creates a description of the vibrational and conformational motion of molecules as a function of time. The program examines the atoms of a molecule and their environment and decides which atom type is appropriate. The program includes more energy terms and more complicated expressions for some terms than most other popular MM force fields. The force field contains greater number of the constants which are adjusted to extended set of experimental data. The stretching and bending energy terms include higher order contributions, several cross-terms are inserted; the electrostatic contribution includes interactions of bond dipoles.

The MM family of force fields designed by Allinger and coauthors is used till recent time for calculations on small and medium size organic molecules, e.g., steroidal-porphyrin aggregates (Lorecchio et al. 2014). New improvements to MM4 force field were suggested by Allinger (2011) recently. The classic of molecular mechanics, after some examples make the conclusion: "A good (well developed, Class 3) molecular mechanics force field will usually give molecular structures that

are approximately of chemical accuracy. When it fails to do so, there is a good chance that nature knows something that we don't" (Allinger 2011).

Merck Molecular Force Field (MMFF94)

This force field of class II was developed for a broad range of “medium size” molecules primary of importance for drug design. It differs from Allinger's and many other popular force fields in several aspects. The core portion of MMFF94 has primarily been derived from high-quality computational quantum chemistry data (up to MP4SDQ/TZP level of theory) for a wide variety of chemical systems of interest to organic and medical chemists (Halgren 1996, 1999b). Nearly all MMFF94 parameters have been determined in a mutually consistent fashion from the full set of available computational data. The force field reproduces well both computational and experimental data, including experimental bond lengths (0.014 Å rms), bond angles (1.2° rms), vibrational frequencies, conformational energies, and rotational barriers. The mathematical expressions of the force field differ from many other force fields. The expressions for stretching and bending energies (like Allinger's force fields) contain in addition to harmonic terms stretch-bend cross terms and out-of-plane terms. The van der Waals energy is expressed by buffered (7-14) potentials (Eq. 8, the designations are the same as in Eqs. 2, 3, 4, 5, 6, and 7)

$$E_{\text{vdw}} = \epsilon_{ij} \left(1.07 \rho_{ij} / (r_{ij} + 0.07 \rho_{ij})^7 \right) \left((1.12 \rho_{ij}^7 / (r_{ij}^7 + 0.12 \rho_{ij}^7)) - 2 \right) \quad (8)$$

The electrostatic term contains buffering constant as well. The specially formulated combination rules for ϵ_{ij} and ρ_{ij} are used. The MMFF94 version was developed for molecular dynamics simulations, and MMFF94s version (Halgren 1999a) was modified for energy minimization studies (*s* in the title means static). Both versions provide users with nearly the same results for majority of molecules and complexes. Additional parameters of force field and careful adjustment to high-level reference data result in good reproduction of extended set of experimental data on conformational energies of the molecules appeared after force field publication (Halgren 1999b). Nevertheless, Bordner et al. (2003) reveal that MMFF94 values of sublimation energy for a set of compounds are systematically 30–40 % lower than experimental data. It can be explained by “computational nature” of MMFF parameters and by the adjustment to quantum mechanics results without corrections for the experimental data, i.e., nonadditive contributions do not accounted for implicitly.

This force field is used in many recent studies of biologically important molecules, which employ combined experimental and computational approaches. Anti-inflammatory drugs (Pawar et al. 2014; Sawant et al. 2014) and anticholinergic and antiasthmatic drugs (Guo et al. 2014) are among the compounds considered recently with MMFF.

The Force Fields and Programs Designed by Scheraga and Coauthors

As we had already mentioned that the first MM parameter set for the simulation of proteins was described in 1975 by Scheraga and coauthors (Momany et al. 1975); their empirical conformational energy program for peptides (ECEPP) was released through *Quantum Chemistry Program Exchange* in the same year. This force field family was refined continuously till last years; we will briefly describe two versions of Scheraga's force field used for studies of protein three-dimensional structure and protein folding up to recent time, ECEPP/3 (Némethy et al. 1992) and ECEPP-05 (Arnautova et al. 2006). The ECEPP/3 force field in turn is the modified version of ECEPP/2; it contains updated parameters for proline and oxyproline residues. The ECEPP force fields utilize fixed bond lengths and bond angles obtained from a survey of the crystal structures for each of amino acid residue. The peptide energy is calculated and minimized as a function of torsion angles only, and it is a significant advantage for minimization approaches as it drastically reduces the variable space that must be considered. The energy function of the ECEPP/3 force field consists of torsion and nonbonded (Coulomb and van der Waals) terms (Eqs. 4 and 5). The partial charges of atoms are calculated by the molecular orbital CNDO/2 method, the parameters of (6-12) term are adjusted by comparison with crystal data. The (6-12) terms are substituted by (10-12) ones for the interactions of the hydrogen atoms capable to participate in H bonds with H-bond acceptor atoms. In spite of appearance of new improved and augmented versions of ECEPP force field, the ECEPP/3 is used until recently for protein simulations (e.g., McAllister and Floudas 2010).

The ECEPP-05 force field (Arnautova et al. 2006 and references herein) is adjusted to both new experimental data and quantum mechanics results. It has some distinctive features as compared to both ECEPP/3 version and many other popular force fields. The van der Waals term of the energy is modeled by using the "6-exp" potential function (potential of Buckingham)

$$E_{ij} = -A_{ij}r_{ij}^{-6} + B_{ij} \exp(-C_{ij}r_{ij}) \quad (9)$$

where r_{ij} is the distance between atoms i and j ; A_{ij} , B_{ij} , and C_{ij} are parameters of the potential. The combination rules are applied directly to these parameters.

$$A_{ij} = (A_{ii}A_{jj})^{1/2}; B_{ij} = (B_{ii}B_{jj})^{1/2}; C_{ij} = (C_{ii} + C_{jj})/2 \quad (10)$$

The parameters of (6-exp) potentials were derived by using so-called global-optimization-based method consisting of two steps. An initial set of parameters is derived from quantum mechanics interaction energies (at MP2/6-31G* level of ab initio theory) of dimers of selected molecules; at the second step, the initial set is refined to satisfy the following criteria: the parameters should reproduce the observed crystal structures and sublimation enthalpies of related compounds, and

the experimental crystal structure should correspond to the global minimum of the potential energy.

The atomic charges were fitted to reproduce the molecular ab initio electrostatic potential, calculated at HF/6-31G* level; the fitting was carried out using the restrained electrostatic potential (RESP) method taken from the AMBER program. The method was applied to obtain a single set of charges using several conformations of a given molecule (the multiple-conformation-derived charges). An additional point charge (with zero nonbonded parameters) is used to model the lone pair electrons of sp^2 nitrogen. The torsional parameters of the side chains of the 20 naturally occurring amino acids were computed by fitting to rotational energy profiles obtained from ab initio MP2/6-31G** calculations. The peptide backbone torsional parameters were obtained by fitting the energies to the Φ - Ψ energy maps of terminally blocked glycine and alanine amino acids constructed at MP2/6-31G**//HF/6-31G** level of theory. The performance of the force field was evaluated by simulating crystal structures of small peptides.

As the important problems of the protein structure and functions as well as of the natural science as a whole refer to prediction of three-dimensional structure and pathways of folding of proteins, Scheraga and coauthors have modified and augmented the force fields mentioned above by some theoretical approaches and concepts. We will notice a few of them related directly to MM calculations. The all-atom ECEPP05 force field was coupled with an implicit solvent-accessible surface area model (ECEPP05/SA, Arnautova and Scheraga 2008). Recognizing the impossibility of searching enormous conformational space of real protein with an all-atom potential functions, a hierarchical procedure was developed. Its main features are the initial use of a united residue (UNRES) potential functions and an efficient procedure, conformational space annealing (CSA) (Scheraga et al. 2002, and references herein). The protein is first optimized with the low-resolution “coarse-grained” UNRES model (Liwo et al. 1999). In UNRES force field, the backbone is represented as a virtual-bond chain of C_α atoms, and the side chains are depicted as ellipsoids. The interaction sites are the united-atom side chains and the centers of the peptide groups between C_α atoms. The lowest-energy UNRES conformation, as well as a set of distinct low-energy conformations, is then converted to all-atom models. Finally, the all-atom models are refined with the EDMC method, with inclusion of continuum hydration model.

The search for low-energy “native-like” structures includes several minimization and Monte Carlo procedures. The simplest of the MC methods is Monte Carlo with minimization, i.e., a Metropolis Monte Carlo (MCM) algorithm in which every trial state is first energy-minimized before the Boltzmann acceptance criterion is applied. The electrostatically driven Monte Carlo (EDMC) method employs a move set in which individual peptide groups are selected at random and rotated “in place” (i.e., the conformational change is localized to the peptide group as much as possible) so as to optimize the alignment of its dipole moment with the local electric field. The methodology assumes that a protein molecule is driven toward the native structure by the combined action of electrostatic interactions and stochastic conformational

changes associated with thermal movements (Ripoll and Scheraga 1988). The use of the force fields and methods enables Scheraga and coauthors not only to rationalize but to predict some interesting features of protein three-dimensional structure and pathways of folding. “With increasing refinement of the computational procedures, the computed results are coming closer to experimental observations, providing an understanding as to how physics directs the folding process” (Scheraga 2008).

Several recent successful applications of UNRES force to simulations of biological functions of proteins can be mentioned. The mechanism of growth of amyloid β -peptide fibrils (the main component of plaques formed in the human brain during Alzheimer disease) was suggested (Rojas et al. 2011) and supported by simulated 2D ultraviolet spectroscopy (Lam et al. 2013). The mechanism of HSP70 heat-shock protein action was proposed which was based on ATP-induced scissor-like motion of the two sub-domains of the nucleotide-binding domain (NBD) (Golas et al. 2012). The computationally obtained structure of this chaperon was confirmed then by experimental study. Some additional examples of UNRES applications are mentioned in very recently published review of Scheraga (2015). Similar approach was developed by Scheraga and coauthors for nucleic acids interactions. The first paper on coarse-grained models of nucleic acids represents NARES approach (Maciejczyk et al. 2010) to nucleic acid bases. Each base is simulated by a combination of three to five interaction centers of 6-12 van der Waals and permanent dipole interactions. Then, UNRES-2P model was developed (He et al. 2013) representing a polynucleotide chain by a sequence of virtual sugar atoms, located at the geometric center of the sugar ring, linked by virtual bonds with attached united base and united phosphate groups. This oversimplified model reproduces the double helix formation, some its thermodynamics properties (He et al. 2013), and was very recently applied to DNA-protein interactions (Yin et al. 2015).

Force Fields and Programs Developed by Kollman and Coauthors. AMBER

The computer software and force fields referred to as “AMBER” (Assisted Model Building with Energy Refinement) are the most popular of those designed for wide class of biomolecules including proteins and nucleic acids. The first description of the computer program AMBER appeared in 1981 (Weiner and Kollman 1981), and the first detailed specification of force field was published 3 years later (Weiner et al. 1984). The force field contained usual “minimalist” set of energy terms (Eqs. 1, 2, 3, 4, 5, and 6 of this survey), the parameters being adjusted to both experimental and quantum mechanics data. The parameters of their previous publications and those of other authors were used as starting points for the adjustment. Atomic charges are obtained by fitting a partial charge model to electrostatic potentials calculated by ab initio quantum mechanics calculations (with minimal STO 3G basis set). The (10-12) potential was included for description of H-bonding (this term was deleted in new versions of AMBER force fields and software). The force field accounted

for implicit solvent by using distance dependent dielectric constant ($\epsilon = R_{ij}$), united atom approach (i.e., several atoms, e.g., four atoms of a methyl group are considered as one particle) enabled one to perform calculations of sufficiently extended systems (such as fragments of DNA double helix of a few nucleotide pairs or peptides of dozens of amino acid residues). In spite of several deficiencies of the first AMBER force field (e.g., too short distances in stacking complexes due to short equilibrium radii for van der Waals interactions, defects in atomic charges due to very approximate quantum mechanics data), hundreds of papers were published with this force field and the program. In 2005, even after release of several new and improved AMBER force field versions, the paper (Weiner et al. 1984) was the 10th most-cited one in the history of the *Journal of the American Chemical Society* (Case et al. 2005).

Since those publications new versions of both force fields and program sets were released. Cornell et al. (1995) published “second generation” AMBER force field for simulating the structures, conformational energies, and interaction energies of proteins, nucleic acids, and many related organic molecules in condensed phases. The charges were determined using the calculations with 6-31G* basis set and restrained electrostatic potential (RESP) fitting and had been shown to reproduce interaction energies, free energies of solvation, and conformational energies of small molecules to a good degree of accuracy. The new van der Waals parameters were derived to account for liquid properties. Retaining most of torsion parameters of “the previous generation” of force field, the improvement of potentials for peptide backbone was performed for Φ and Ψ dihedrals as well as for the nucleoside χ dihedrals by adding extra Fourier terms. This “second generation” force field is usually referred to as *ff94* (parameter set *parm94*).

There are a number of AMBER parameter sets, with names beginning with “ff” and followed by a two-digit year number, such as *ff99*. We will briefly mention some new features of these force fields. Some versions differ from *ff94* by minor (but important for some problems) modifications. The *ff96* force field differs from *ff94* only in the peptide Φ - Ψ torsional potential, and *parm96* was developed because it was clear that *parm94* overstabilized α helices relative to β sheets. Thus, *parm94* seems adequate for comparing structures with similar secondary structures, but *parm96* seems to more accurately represent the relative stability of α and β secondary structures. The improved version *ff99* (Wang et al. 2000) was developed using the restrained electrostatic potential (RESP) approach to derive the partial charges. The adjustment of atom point charges and torsion constants for the set of 34 molecules to the highest level ab initio model (GVB/LMP2) and experimental data enables authors to reproduce data for 55-molecule set with the better accuracy than MM3, MMFF, and early versions of CHARMM force fields. It was demonstrated that “a well-parameterized harmonic force field with a reliable charge method can describe the structure and intramolecular energies for organic systems very well” (Wang et al. 2000). The authors tried to use the adjusted parameters (*parm99*) in nonadditive models (which include polarization), and obtained “reasonable results using the same parameters derived for the additive model, although additional torsional parameterization is required to achieve the same high level accuracy

as that found using the additive model” (Wang et al. 2000). This force field is widely used during more than 10 years. The other AMBER force field, “a third-generation point-charge all-atom force field for proteins” (referred to as *ff03*) was developed by Duan et al. (2003). The main difference from previous force fields is that all quantum mechanics calculations were done in the condensed phase with continuum solvent models and an effective dielectric constant of $\epsilon = 4$. Initial tests on peptides demonstrated a high degree of similarity between the calculated and the statistically measured Ramachandran maps for Glycine and Alanine peptide fragments. One more AMBER force field referred to as general Amber force field (GAFF) should be mentioned (Wang et al. 2004). GAFF have been designed as an extension of the AMBER force fields to be compatible with existing versions for proteins and nucleic acids and has parameters for most organic molecules of pharmaceutical importance that are composed of H, C, N, O, S, P, and halogens. The parameterization is based on more than 3000 MP2/6-31G* optimizations and 1260 MP4/6-311G(d,p) single-point calculations. Unlike most conventional force fields, parameters for all combinations of atom types are not contained in an exhaustive table but are determined algorithmically for each input molecule based on the bonding topology (which determines the atom types) and the geometry. A completely automated, table-driven procedure (called *antechamber*, a part of the late versions of AMBER program set) was developed to assign atom types, charges, and force field parameters to almost any organic molecule (Wang et al. 2006). New versions of AMBER software work with several force fields. The newest AMBER 11 version (Case et al. 2010) supports CHARMM fixed-charge force fields as well.

The initial AMBER force fields and program packages (due to the state of the theory and computer facilities) were generally aimed at the search for energy minima of separate molecular systems in vacuum. The current AMBER versions are strongly aimed at simulations (molecular dynamics, evaluations of free energy changes) of biomolecules in water solutions. Both explicit solvent models (using TIP3P, TIP4P, TIP5P, and SPC water models as well as models of some organic solvents) and implicit ones are supported. By default, explicit solvation model involves electrostatic interactions handled by a particle-mesh Ewald (PME) procedure, and long-range Lennard-Jones attractions are treated by a continuum model. The PME is a modified form of Ewald summation, a method to efficiently calculate the infinite range Coulomb interaction under periodic boundary conditions, and PME is a modification to accelerate the Ewald reciprocal sum to near linear scaling using the three-dimensional fast Fourier transform (3DFFT).

An accurate description of the aqueous environment is essential for atom-level biomolecular simulations but may become very expensive computationally. An implicit model replaces the discrete water molecules by an infinite continuum medium with some of the dielectric and “hydrophobic” properties of water. The continuum implicit solvent models have several advantages over the explicit water representation, especially in molecular dynamics simulations (e.g., they are often less expensive and generally scale better on parallel machines; they correspond to instantaneous solvent dielectric response; the continuum model corresponds to solvation in an infinite volume of solvent, there are no artifacts of periodic boundary conditions; estimating free energies of solvated structures is much more straight-

forward than with explicit water models). Despite the fact that the methodology represents an approximation at a fundamental level, it has in many cases been successful in calculating various macromolecular properties (Case et al. 2005).

The total energy of a solvated molecule can be written as a sum of molecule's energy in vacuum (gas phase) and the free energy of transferring the molecule from vacuum into solvent, that is, solvation free energy typically assumed as can be decomposed into the electrostatic and nonelectrostatic parts. The above decomposition is the basis of the widely used PB/SA (Poisson-Boltzman solvent accessible surface area) scheme. AMBER follows this way to compute the nonelectrostatic part of the energy. The most time-consuming part of solvation energy estimations is the computation of the electrostatic contribution. AMBER employs one of the most popular biomolecular applications the finite-difference method (FDPB) and analytic generalized Born (GB) method. In the GB model, a molecule in solution is represented as a set of spherical cavities of dielectric constant of 1 with charges at their centers embedded in a polarizable dielectric continuum solvent of a higher dielectric constant.

The AMBER software and force fields are widely used for the simulation of various systems of biological and material science importance. Some researchers develop proper additions and corrections to “standard” parameters for better description of specific systems. We refer to only few examples. Perez et al. (2007) reparameterized the *parm99* force field for nucleic acid simulations improving the representation of the α/γ conformational space. Zgarbova et al. (2011) refined description of glycosidic torsion angles of nucleic acids. Other work of Zgarbova et al. (2013) refers to ϵ and ζ DNA torsions. Very recently, Ogata and Nakamura (2015) suggested the improvement of parameters of the force field for phospholipids. Song et al. (2008) adjusted the AMBER force field to reproduce conformational properties of an oxidative DNA lesion, 2,6-diamino-4-hydroxy-5-formamidopyrimidine. New improved parameters for modified peptide chain were suggested by Grubišić et al. (2013) recently. Some of such improvements have been included into newer versions of AMBER package. AMBER force field can be used via other MM program packages, such as CHARMM, GROMACS, NAMD, and with widely used QM package GAUSSIAN.

The latest version of AMBER program package is AMBER14 distributed with AmberTools 15 (Case et al. 2015). The new versions of AMBER software support the option of allowing part of the system to be described quantum mechanically in an approach known as a hybrid (or coupled potential) QM/MM simulation. Both semiempirical and the density functional theory-based tight-binding (DFTB) Hamiltonian can be used. The system may contain both two nonbonded parts and covalently bonded QM and MM subsystems (Case et al. 2010).

Other Popular Force Fields and MM Software. CHARMM, OPLS, GROMOS

The force fields and program packages listed above are used for nearly the same type of simulations as those considered above. The main differences refer to the

organization of the programs and to relative role of experimental data, and quantum mechanics results in force field parameter adjustment. The first versions of force fields and programs as well as the whole research programs were initiated by such pioneers of MM applications as Karplus (CHARMM, Chemistry at HARvard Molecular Mechanics), Jorgensen (OPLS, Optimized Potentials for Liquid Simulations), Gunsteren and Berendsen (GROMOS, GRONingen MOlecular Simulation package), and GROMACS (GRONingen MACHine for Chemical Simulation). The progress and improvement of the force fields and programs are connected to comparison with the approaches and results of other programs. The parametrization of second generation AMBER force field (Cornell et al. 1995) had been influenced by Jorgensen OPLS potentials for proteins (Jorgensen and Tirado-Rives 1988), whereas these OPLS united atom potentials adopted bond stretch, angle bend, and torsional terms from the AMBER united-atom force field (Weiner et al. 1984). The OPLS parameters for the 20 neutral peptide residues were obtained primarily via Monte Carlo simulations for the 36 organic liquids, and the parametrization for the charged protein residues was performed via comparisons with ab initio results for ion-molecule complexes (6-31G(d) basis set) and on Monte Carlo simulations for hydrated ions (Jorgensen and Tirado-Rives 1988). The OPLS-AA (all atom) force field (Jorgensen et al. 1996) retain most of bond stretch and angle bending parameters from AMBER all-atom force fields, but torsion and nonbonding constants are reparametrized utilizing both experimental and ab initio (RHF/6-31G* level) data. This force field was improved for peptides by means of refitting the key Fourier torsional coefficients using accurate ab initio data (LMP2/cc-pVTZ (-f)/HF/6-31G** level) as the target (Kaminski et al. 2001).

Most of popular program sets utilize various force fields, not only those developed in the research groups of the authors of the program with the same title. The software suite GROMACS was developed by Berendsen group at the University of Groningen, The Netherlands, starting in early 1990s. This fast program for molecular dynamics simulation does not have a force field of its own but is compatible with GROMOS, OPLS, and AMBER force fields. The GROMACS (van der Spoel et al. 2005) was developed and optimized especially for use on PC-clusters. It originated from the Fortran package GROMOS developed by van Gunsteren et al. (1987). The GROMOS force fields are not pure all-atom force fields; aliphatic CH_n groups are treated as united atoms. The recent version, GROMOS05 (Christen et al. 2005), utilize new force field sets (53A5 and 53A6, the first number in the names of a parameter sets refer to the number of atom types) based on extensive reparameterization of the previous GROMOS force field (Oostenbrink et al. 2004). In contrast to the parameterization of most other biomolecular force fields, this parameterization is based primarily on reproducing the free enthalpies of hydration and apolar solvation for a range of organic compounds. Recently, 53A6 force field has been reparametrized by Pol-Fachin et al. (2014) by adjustment to QM data (HF/6-31G* level of theory) for applications to study Glycoproteins.

Very popular for the computations of wide range of macromolecular systems are CHARMM (Chemistry at HARvard Macromolecular Mechanics) program and force field sets. The computations include energy minimization, molecular

dynamics, and Monte Carlo simulations. CHARMM originated at Martin Karplus's group at Harvard University, the first publication on CHARMM program and force field (refer to Brooks et al. 1983). Several versions of both software and force field were released since the first ones. The improvement of the programs and force fields are in progress till now. The mathematical expressions for calculation of CHARMM energy are nearly the same as "minimalist" ones for other force fields (MacKerell 2004). The minor differences with e.g., AMBER or OPLS force fields refer to inclusion of harmonic improper and Urey-Bradley terms. The parameters of various versions of force field are consistently adjusted with emphasis to specific molecules to be applied. The first versions of CHARMM force fields were aimed primarily to protein molecular dynamics simulations. Then, the special adjustments were performed for the simulations of the nucleic acids (Foloppe and MacKerell 2000) and lipids (Klauda et al. 2008). The improvement of parameter for specific molecules continues till recent times, while other parameters can be used from the previous versions. Raman et al. (2010) recently extended the CHARMM additive carbohydrate all-atom force field to enable modeling glycosidic linkages in carbohydrates involving furanoses. Like in most popular modern force fields, both the ab initio quantum mechanics computations and experimental data for solid and liquid states are used in adjustment of the parameters of CHARMM force fields. The distinct feature of this adjustment refers to charge adsorption. Like OPLS force fields (Jorgensen et al. 1996), CHARMM utilize so-called supramolecular approach. The partial atomic charges are adjusted to reproduce ab initio (HF/6-31G* level) minimum interaction energies and geometries of model compounds with water or for model compound dimers (with energy and distance corrections for reproducing the correct experimental densities). On the other hand, the use of ab initio data on small clusters to optimize the van der Waals parameters leads to poor condensed phase properties. This requires that the optimization of these parameters be performed by empirical fitting to reproduce thermodynamics properties from condensed phase simulations, taking into account the relative values of the parameters obtained from high-level ab initio data on interactions of the model compounds with rare gases (Klauda et al. 2008).

Very recently, Vanommeslaeghe and MacKerell (2015) published detailed description of the development of CHARMM method and software. We will mention here only some most important for biological and medical applications recent advancements of both all-atom additive force field (on the way to CHARMM36 version, modern class I model) and polarizable force fields (class II models). Best et al. (2012) presented a combination of refinements important with respect to the equilibrium between helical and extended conformations in protein folding simulations. Peptide backbone (φ , ψ) potential has been refined against experimental solution NMR data. Side-chain χ_1 and χ_2 torsion parameters have been optimized by fitting to quantum-mechanical energy surfaces, followed by additional empirical optimization targeting NMR data. A comprehensive validation of the revised force field indicates that the revised CHARMM 36 parameters represent an improved model for modeling and simulation studies of proteins, including protein folding, assembly, and functionally relevant conformational

changes (Best et al. 2012). The refinement of the CHARMM27 all-atom additive force field for nucleic acids via adjustment of backbone parameters to QM data (MP2/6-31 + G(d) level of theory) followed by trial MD simulations of DNA duplexes enabled Hart et al. (2012) to improve treatment of the BI/BII equilibrium of DNA conformations. Many other specific refinements of the CHARMM additive force fields for these and other classes of biologically important molecules have been mentioned in the recent paper of Vanommeslaeghe and MacKerell (2015).

Along with comprehensive refinements and biomolecular applications of class I CHARMM force fields, polarizable CHARMM models are extensively developed during recent years for more accurate and physically based description of biologically important molecular systems. These force fields use the classical Drude oscillator (i.e., “charge-on-spring”) model. In the model, a virtual negatively charged particle (“Drude particle”) is connected to the core of each polarizable atom by means of a harmonic potential (“spring”). Description of this class II force field is out of scope of this survey, but we will mention some results of proteins and nucleic acid computations with such models. Very recently, Huang et al. (2014) summarized recent efforts to include the explicit treatment of induced electronic polarization in biomolecular force fields. They arrive with conclusion that the inclusion of explicit electronic polarizability leads to significant differences in the physical forces affecting the structure and dynamics of proteins (Huang et al. 2014). The polarizable force field more accurately models peptide-folding cooperativity (Huang and MacKerell 2014). Development of a CHARMM Drude polarizable model for nucleic acids (Baker et al. 2011) requires significant adjustments of the phosphodiester backbone and glycosidic bond dihedral parameters of base-sodium interactions and of selected electrostatic parameters in the model (Savelyev and MacKerell 2014a). The modern polarizable model satisfactorily treats the equilibrium between the A, BI, and BII conformations of DNA (Savelyev and MacKerell 2014b).

It is interesting to mention that multiple adjustments of different additive force fields mentioned above and other force fields result in an increase of similarity in both corresponding parameters values and the results of applications to complex molecular systems (such as protein and nucleic acid fragments), but many differences both in corresponding parameter values and computation results still remain.

Conclusions

The molecular mechanics computation approach to the study of the molecular systems arose a half of century ago and today has become a useful and powerful research tool for many branches of natural science. During this period the number of publications utilizing this approach increased by a few orders of magnitude. This increase continues up to present days, followed by new journals appearance and a flow of MM publications in the journals of rather wide area of coverage. The MM considers the molecular systems via classic Newtonian mechanics approach, i.e., using classical approximation to essentially quantum systems. The MM suggests

representation of the system energy as a sum of terms responsible for interactions of various physical natures.

The minimalist MM approach involves the simple expressions for chemical bond stretching, bond angle bending, torsions about the bonds, and nonbonded van der Waals and Coulomb contributions calculated via additive atom-atom scheme. The force fields (sets of mathematical formulae and numerical parameters) are derived from simple physical considerations followed by adjustment to the experimental data and precise quantum mechanics results. An additivity of the terms responsible for separate atom contributions and for interactions of different physical nature and transferability of the parameters between atoms and molecules of similar structure are the main assumptions of MM approach. Development of the approach results in elaboration of a variety of computer software and force fields for simulating different molecular systems of biological, medical, and industrial importance. Various force fields differ in the complexity of mathematical expressions and in the relative role of experimental and quantum mechanics results used for the parameter adjustment. The development of algorithms for the MM applications (including those for molecular dynamics and Monte Carlo techniques) and the increase of computer power enable researchers to approach such complex problems as predicting the pathways of the biopolymers three-dimensional structure, molecular recognition in various biological processes, assistance in creation of compounds with desirable properties (including drugs and industrial materials). Analysis of the current state of physicochemical study of biological processes suggests that MM simulations based on empirical force fields have an ever-increasing impact on understanding structure and functions of biomolecules. Rather close results obtained with different force fields can be accounted for by existing various solutions of the task of parameter adjustment even to the same target data (really, target data used when elaborating various force fields differ, slightly or considerably). Force fields are internally consistent. Their parameters are highly correlated within a force field. Several force fields have been elaborated recently going beyond the atom-atom approach and the additivity principle. Some force fields utilize a hierarchical procedure for consideration of complex systems.

Abstract

Arguments are advanced to support the view that at present it is not possible to derive molecular structure from the full quantum mechanical Coulomb Hamiltonian associated with a given molecular formula that is customarily regarded as representing the molecule in terms of its constituent electrons and nuclei. However molecular structure may be identified provided that some additional chemically motivated assumptions that lead to the clamped nuclei Hamiltonian are added to the quantum mechanical account.

Introduction

The traditional specification of a molecule in classical chemistry is in terms of atoms joined by bonds, and this accounts for the central fact of chemistry that the generic molecular formula is associated with the occurrence of isomers. Such an approach does not provide a useful basis for a physical theory since we do not know the general laws of interaction between atoms. Instead a more abstract description in terms of the particle constituents of a molecule, electrons and nuclei, is employed. We shall confine the discussion to the nonrelativistic level of theory; with this proviso the interactions between electrons and nuclei are assumed to be fully specified by Coulomb's law, and this makes possible the explicit formulation of a molecular Hamiltonian. This so-called Coulomb Hamiltonian will be given explicitly (Eq. 1) in the next section; it forms the starting point of the chapter.

We concentrate on two broad themes. It is obvious that the whole collection of isomers supported by a given molecular formula share the same Coulomb Hamiltonian. The first part of the chapter is concerned with how this fundamental fact has been treated in quantum chemistry through the introduction of the *clamped nuclei Hamiltonian*. This involves two crucial assumptions: (1) the nuclei can be treated as fixed ("clamped") classical particles that merely provide a classical external potential for the electrons and (2) formally identical nuclei can be treated as distinguishable. The second part of the chapter discusses in a general way the basic quantum mechanical theory of the clamped nuclei Hamiltonian, concentrating particularly on its symmetry properties.

The Clamped Nuclei Approximation

The conventional nonrelativistic Hamiltonian for a system of N electrons with position variables, \mathbf{x}_i^e , and a set of A nuclei with position variables \mathbf{x}_i^n may be written as

$$\begin{aligned}
 H(\mathbf{x}^n, \mathbf{x}^e) = & -\frac{\hbar^2}{2m} \sum_{i=1}^N \nabla^2(\mathbf{x}_i^e) + \frac{e^2}{8\pi\epsilon_0} \sum_{i,j=1}^{N'} \frac{1}{|\mathbf{x}_i^e - \mathbf{x}_j^e|} - \frac{e^2}{4\pi\epsilon_0} \sum_{i=1}^A \sum_{j=1}^N \frac{Z_i}{|\mathbf{x}_j^e - \mathbf{x}_i^n|} \\
 & - \frac{\hbar^2}{2} \sum_{k=1}^A \frac{\nabla^2(\mathbf{x}_k^n)}{m_k} + \frac{e^2}{8\pi\epsilon_0} \sum_{i,j=1}^{A'} \frac{Z_i Z_j}{|\mathbf{x}_i^n - \mathbf{x}_j^n|}.
 \end{aligned} \tag{1}$$

This is the *Coulomb Hamiltonian* for the electrons and nuclei specified by a given molecular formula. We use a Schrödinger representation in which the operators are simple time-independent multiplicative operators acting on functions of the coordinate variables ("wavefunctions"). Kato (1951) established that the Coulomb Hamiltonian, H , is essentially self-adjoint.¹ This property, which is stronger than Hermiticity, guarantees that the time evolution

¹The work was completed in 1944 and was actually received by the journal in October 1948.

$$\Psi(t) = \exp\left(\frac{-i\mathbf{H}t}{\hbar}\right)\Psi(0)$$

of a Schrödinger wavefunction is unitary, and so conserves probability. Furthermore the eigenvalues of \mathbf{H} are associated with a complete set of eigenfunctions. This is not necessarily true for operators that are Hermitian but not self-adjoint.² It was pretty obvious to applied mathematicians that the kinetic energy operator alone is indeed self-adjoint because of their classical mechanical experience. It was shown by Stone in the 1930s that multiplicative operators of the kind specified above are also self-adjoint but it was entirely unobvious that the sum of the operators would be self-adjoint because the sum of the operators is defined only on the intersection of their domains.

What Kato showed was that for a range of potentials including Coulomb ones, and for any function f in the domain \mathcal{D}_0 of the full kinetic energy operator \mathbf{T}_0 , the domain of the full problem \mathcal{D}_V contains \mathcal{D}_0 and there are two constants a and b such that

$$\|\mathbf{V}f\| \leq a\|\mathbf{T}_0f\| + b\|f\|,$$

where a can be taken as small as is liked. This result is often summarized by saying that the Coulomb potential is small compared to the kinetic energy. Given this result he then proved that the usual operator is indeed, for all practical purposes, self-adjoint and is bounded from below. Why worry about this? Well if the operator is not self-adjoint it could support solutions interpretable as a particle falling into a singularity or getting to infinity in a finite time and these are unacceptable as physical solutions. Such pathologies occur in, for example, the classical mechanics of three bodies in a Coulomb field. The practical significance of Kato's proof is the guarantee that such unphysical solutions will not arise from solving the quantum mechanical eigenvalue problem for the Coulomb Hamiltonian.

It is easily established that the Coulomb Hamiltonian is invariant under the coordinate transformations that correspond to uniform translations, rotation-reflections, and permutations of particles with identical masses and charges. Because of the symmetry of the Coulomb Hamiltonian its eigenfunctions will be basis functions for irreducible representations (irreps) of the translation group in three dimensions, the orthogonal group in three dimensions, and for the various symmetric groups corresponding to the sets of identical particles.

Quantum mechanical molecular structure calculations are most commonly attempted by first clamping the nuclei at fixed positions and then performing electronic structure calculations treating the clamped nuclei as providing a potential field for the electronic motion. With the nuclei clamped at a particular fixed

²An elementary example is afforded by the momentum operator $\widehat{p} = -i\hbar d/dq$, which is Hermitian on an appropriately defined class of L^2 functions $\phi(q)$; for these functions it is self-adjoint on $-\infty \leq q \leq +\infty$ but this property is lost if either of the ∞ limits is replaced by any finite value a – see, for example, Thirring (1981).

geometry specified by the constant vectors $\mathbf{x}_i^n = \mathbf{a}_i$, $i = 1, 2, \dots, A$, this modified Hamiltonian takes the form

$$\begin{aligned} H^{\text{cn}}(\mathbf{a}, \mathbf{x}^e) = & -\frac{\hbar^2}{2m} \sum_{i=1}^N \nabla^2(\mathbf{x}_i^e) - \frac{e^2}{4\pi\epsilon_0} \sum_{i=1}^A \sum_{j=1}^N \frac{Z_i}{|\mathbf{x}_j^e - \mathbf{a}_i|} + \frac{e^2}{8\pi\epsilon_0} \sum_{i,j=1}^{N'} \frac{1}{|\mathbf{x}_i^e - \mathbf{x}_j^e|} \\ & + \frac{e^2}{8\pi\epsilon_0} \sum_{i,j=1}^{A'} \frac{Z_i Z_j}{|\mathbf{a}_i - \mathbf{a}_j|}. \end{aligned} \quad (2)$$

It is customary to incorporate the nuclear repulsion energy into Eq. 2; the nuclear repulsion term is merely an additive constant and so does not affect the form of the electronic wavefunctions. Its inclusion modifies the spectrum of the clamped nuclei Hamiltonian only trivially by changing the origin of the energy. The eigenvalue equation for the clamped nuclei Hamiltonian is then

$$H^{\text{cn}}(\mathbf{a}, \mathbf{x}^e) \psi_p^{\text{cn}}(\mathbf{a}, \mathbf{x}^e) = E_p^{\text{cn}}(\mathbf{a}) \psi_p^{\text{cn}}(\mathbf{a}, \mathbf{x}^e), \quad (3)$$

in which the eigenvalues (“electronic energies”) have a parametric dependence on the constant nuclear position vectors $\{\mathbf{a}_i\}$.

It is sometimes asserted that the clamped nuclei Hamiltonian can be obtained from the Coulomb Hamiltonian by letting the nuclear masses increase without limit. The Hamiltonian that would result if this were done would be

$$\begin{aligned} H^{\text{nn}}(\mathbf{x}^n, \mathbf{x}^e) = & -\frac{\hbar^2}{2m} \sum_{i=1}^N \nabla^2(\mathbf{x}_i^e) - \frac{e^2}{4\pi\epsilon_0} \sum_{i=1}^A \sum_{j=1}^N \frac{Z_i}{|\mathbf{x}_j^e - \mathbf{x}_i^n|} + \frac{e^2}{8\pi\epsilon_0} \sum_{i,j=1}^{N'} \frac{1}{|\mathbf{x}_i^e - \mathbf{x}_j^e|} \\ & + \frac{e^2}{8\pi\epsilon_0} \sum_{i,j=1}^{A'} \frac{Z_i Z_j}{|\mathbf{x}_i^n - \mathbf{x}_j^n|}, \end{aligned} \quad (4)$$

with the formal Schrödinger equation, by analogy with Eq. 3,

$$H^{\text{nn}}(\mathbf{x}^n, \mathbf{x}^e) \psi_p^{\text{nn}}(\mathbf{x}^n, \mathbf{x}^e) = E_p^{\text{nn}}(\mathbf{x}^n) \psi_p^{\text{nn}}(\mathbf{x}^n, \mathbf{x}^e). \quad (5)$$

Given that the Coulomb Hamiltonian has eigenstates such that

$$H(\mathbf{x}^n, \mathbf{x}^e) \psi(\mathbf{x}^n, \mathbf{x}^e) = E \psi(\mathbf{x}^n, \mathbf{x}^e), \quad (6)$$

if the solutions of Eq. 5 were well defined, it would seem that the eigenstates in Eq. 6 could be expanded as a sum of products of the form

$$\psi(\mathbf{x}^n, \mathbf{x}^e) = \sum_p \Phi_p(\mathbf{x}^n) \psi_p^{\text{nn}}(\mathbf{x}^n, \mathbf{x}^e), \quad (7)$$

where the $\{\Phi\}$ play the role of “nuclear wavefunctions.”

In the Hamiltonian (Eq. 4), the nuclear variables are free and not constant and there are no nuclear kinetic energy operators to dominate the potential operators involving these free nuclear variables. The Hamiltonian thus specified cannot be self-adjoint in the Kato sense. The Hamiltonian can be made self-adjoint by clamping the nuclei because the electronic kinetic energy operators can dominate the potential operators which involve only electronic variables. The Hamiltonian (Eq. 2) is thus a proper one and the solutions Eq. 3 are a complete set. But since the Hamiltonian (Eq. 4) is not self-adjoint it is not at all clear that the hoped for eigensolutions of Eq. 5 form a complete set suitable for the expansion (Eq. 7). However that may be, it was observed more than 30 years ago (Woolley and Sutcliffe 1977) that the arguments for an expansion (Eq. 7) are quite formal because the Coulomb Hamiltonian has a completely continuous spectrum arising from the possibility of uniform translational motion and so its solutions cannot be properly approximated by a sum of this kind. This means too that the arguments of Born and Oppenheimer (1927), and of Born and Huang (1955) for their later approach to representations of this kind, are also quite formal.

As a basis for the Born–Oppenheimer and the Born approach, it is commonly assumed that it is possible to construct an analytic potential function $V(\mathbf{x}^n)$ such that

$$E_p^{\text{cn}}(\mathbf{a}) = V(\mathbf{a}), \text{ for some } p \text{ and for all } \mathbf{a} \quad (8)$$

and that this potential forms an adequate starting point for a discussion of the nuclear motion part of the full problem. Examination of the form of Eq. 2 makes it clear, however, that $E_p^{\text{cn}}(\mathbf{a})$ takes the same value for all choices of \mathbf{a} that differs from a given choice merely by a uniform translation. Similarly it remains unchanged if the \mathbf{a} differ only by a constant orthogonal transformation. Thus any potential formed according to Eq. 8 will have some variables under any change of which no change in the potential will be described. In the context of calculations of molecular spectra, these variables are often referred to as *redundant* ones. It is also the case that $E_p^{\text{cn}}(\mathbf{a})$ is invariant under the permutation of any nuclei with the same charge (nuclear mass does not enter into Eq. 3). This means that the potential in Eq. 8 will have the same value for all geometries that can be obtained from a given geometry by means of a permutation of nuclei with the same charge. Should the potential have any minima at all, it always has as many as there are permutations of the nuclei with the same charge. This would seem to make the assumption of a single isolated minimum in the potential, which is essential to the usual account of the Born–Oppenheimer approximation, a rather too restrictive one for comfort, except perhaps in the case of the diatomic system.

It is thus not at all clear to precisely which question the clamped nuclei Hamiltonian provides the answer and a further discussion of the properties of the Coulomb Hamiltonian is required before the clamped nuclei problem can be put into an appropriate form for yielding a potential. There are two main ways in which such a discussion can be attempted. If it is desired to stay with the Coulomb Hamiltonian in its laboratory-fixed form then the solutions must be expressed in coherent state

(wave-packet) form to allow for their continuum nature. If the solutions are required as L^2 -normalizable wavefunctions, then the translational motion must be separated from the Coulomb Hamiltonian and the solutions of the remaining translationally invariant part must be sought. It is in this second approach that it is easiest to make contact with the standard arguments and this will be considered in the following section.

The Separation of Translational Motion

All that is needed to remove the center-of-mass motion from the molecular Coulomb Hamiltonian is a linear point transformation symbolized by

$$(\mathbf{t}\xi) = \mathbf{x}\mathbf{V}. \quad (9)$$

In Eq. 9, \mathbf{t} is a $3 \times N_T - 1$ matrix ($N_T = N + A$) and ξ is a 3×1 matrix, so that the combined (bracketed) matrix on the left of Eq. 9 is $3 \times N_T$. \mathbf{V} is an $N_T \times N_T$ matrix which, from the structure of the left side of Eq. 9, has a special last column whose elements are

$$V_{iN_T} = M_T^{-1}m_i, \quad M_T = \sum_{i=1}^{N_T} m_i. \quad (10)$$

Hence ξ is the standard center-of-mass coordinate

$$\xi = M_T^{-1} \sum_{i=1}^{N_T} m_i \mathbf{x}_i. \quad (11)$$

As the coordinates \mathbf{t}_j , $j = 1, 2, \dots, N_T - 1$ are to be translationally invariant we require the condition,

$$\sum_{i=1}^{N_T} V_{ij} = 0, \quad j = 1, 2, \dots, N_T - 1 \quad (12)$$

on each remaining column of \mathbf{V} and it is easy to see that Eq. 12 forces $\mathbf{t}_j \rightarrow \mathbf{t}_j$ as $\mathbf{x}_i \rightarrow \mathbf{x}_i + \mathbf{a}$, all i .

The \mathbf{t}_i are independent if the inverse transformation

$$\mathbf{x} = (\mathbf{t}\xi) \mathbf{V}^{-1} \quad (13)$$

exists. The structure of the right side of Eq. 13 shows that the bottom row of \mathbf{V}^{-1} is special and, without loss of generality, its elements may be required to be

$$(\mathbf{V}^{-1})_{N_T i} = 1, \quad i = 1, 2, \dots, N_T. \quad (14)$$

The inverse requirement on the remainder of \mathbf{V}^{-1} implies that

$$\sum_{i=1}^{N_T} (\mathbf{V}^{-1})_{ji} m_i = 0, \quad j = 1, 2, \dots, N_T - 1. \quad (15)$$

The Coulomb Hamiltonian (Eq. 1) in the new coordinates becomes

$$\begin{aligned} \mathbf{H}(\mathbf{t}, \xi) &= -\frac{\hbar^2}{2} \sum_{i=1}^{N_T-1} \frac{1}{\mu_{ii}} \nabla^2(\mathbf{t}_i) - \frac{\hbar^2}{2} \sum_{i,j=1}^{N_T-1'} \frac{1}{\mu_{ij}} \vec{\nabla}(\mathbf{t}_i) \cdot \vec{\nabla}(\mathbf{t}_j) + \frac{e^2}{8\pi\epsilon_0} \sum_{i,j=1}^{N_T'} \frac{Z_i Z_j}{r_{ij}(\mathbf{t})} \\ &\quad - \frac{\hbar^2}{2M_T} \nabla^2(\xi) \\ &= \mathbf{H}'(\mathbf{t}) - \frac{\hbar^2}{2M_T} \nabla^2(\xi). \end{aligned} \quad (16)$$

Here the positive constants $1/\mu_{ij}$ are given by:

$$\frac{1}{\mu_{ij}} = \sum_{k=1}^{N_T} m_k^{-1} V_{ki} V_{kj}, \quad i, j = 1, 2, \dots, N_T - 1. \quad (17)$$

The operator r_{ij} is the interparticle distance operator expressed as a function of the \mathbf{t}_i . Thus

$$r_{ij}(t) = \left(\sum_{\alpha} \left(\sum_{k=1}^{N_T-1} \left((\mathbf{V}^{-1})_{kj} - (\mathbf{V}^{-1})_{ki} \right) t_{\alpha k} \right)^2 \right)^{1/2}. \quad (18)$$

In Eq. 16, the $\vec{\nabla}(\mathbf{t}_i)$ are gradient operators expressed in the Cartesian components of the \mathbf{t}_i and the last term represents the center-of-mass kinetic energy operator. Since the center-of-mass coordinate does not enter the potential energy term, the center-of-mass motion may be separated off completely so that the eigenfunctions of \mathbf{H} are of the form

$$T(\xi) \Psi(\mathbf{t}), \quad (19)$$

where $\Psi(\mathbf{t})$ is a wavefunction for the Hamiltonian $\mathbf{H}'(\mathbf{t})$, Eq. 16, which will be referred to as the *translationally invariant* Hamiltonian. The eigenfunctions of this Hamiltonian will be basis functions for irreps of the orthogonal group in three dimensions and for the various symmetric groups of the sets of identical particles.

It should be emphasized that different choices of \mathbf{V} are unitarily equivalent so that the spectrum of the translationally invariant Hamiltonian is independent of the

particular form chosen for \mathbf{V} , provided that it is consistent with Eqs. 10 and 12. In particular it is perfectly possible to put the kinetic energy operator into diagonal form by choosing an orthogonal matrix \mathbf{U} that diagonalizes the positive definite symmetric matrix of dimension $N_T - 1$ formed from the $1/\mu_{ij}$ and then replacing elements of the originally chosen \mathbf{V} according to

$$V_{ij} \rightarrow \sum_{k=1}^{N_T-1} V_{ik} U_{kj}, \quad j = 1, 2, \dots, N_T-1.$$

As can be seen from Eq. 18, the practical problem with any choice of \mathbf{V} is the complicated form given to the potential operator.

Choosing Electronic and Nuclear Variables in the Translationally Invariant Hamiltonian

In order to identify the electrons, let the translationally invariant electronic coordinates be chosen with respect to the center-of-nuclear mass

$$\mathbf{t}_i^e = \mathbf{x}_i^e - \mathbf{X}, \quad \mathbf{X} = M^{-1} \sum_{i=1}^A m_i \mathbf{x}_i^n, \quad M = \sum_{i=1}^A m_i.$$

In the case of the atom $A = 1$ and the origin is the nucleus. Other coordinate choices are possible, but this is the only choice that avoids a term in the kinetic energy operator coupling the electronic and nuclear variables and which allows the electronic part of the potential to be written in terms of the electronic variables and the clamped nuclei positions (see Mohallem and Tostes 2002; Sutcliffe 2000).

There is no need to specify the proposed $A - 1$ translationally invariant nuclear variables \mathbf{t}^n other than to say that they are expressed entirely in terms of the laboratory nuclear coordinates by means of a matrix \mathbf{V}^n exactly like \mathbf{V} in Eq. 9, but with side A and with M in place of M_T and \mathbf{X} in place of ξ . It is also sometimes useful to define a set of redundant Cartesian coordinates

$$\bar{\mathbf{x}}_i^n = \mathbf{x}_i^n - \mathbf{X}, \quad i = 1, 2, \dots, A, \quad \text{so that} \quad \sum_{i=1}^A m_i \bar{\mathbf{x}}_i^n = 0. \quad (20)$$

Of course the laboratory nuclear variable \mathbf{x}_i^n cannot be completely written in terms of the $A - 1$ translationally invariant coordinates arising from the nuclei, but in the electron-nucleus attraction and in the nuclear repulsion terms the center-of-nuclear mass \mathbf{X} cancels out. For ease of writing \mathbf{x}_i^n will continue to be used in those terms but it should be remembered that the nuclear potentials are functions of the translationally invariant coordinates defined by the nuclear coordinates.

On making this choice of electronic coordinates the electronic part of Eq. 16 is

$$\begin{aligned}
H'(\mathbf{x}^n, \mathbf{t}^e) = & -\frac{\hbar^2}{2m} \sum_{i=1}^N \nabla^2(\mathbf{t}_i^e) - \frac{\hbar^2}{2M} \sum_{i,j=1}^N \vec{\nabla}(\mathbf{t}_i^e) \cdot \vec{\nabla}(\mathbf{t}_j^e) - \frac{e^2}{4\pi\epsilon_0} \sum_{i=1}^A \sum_{j=1}^N \frac{Z_i}{|\mathbf{t}_j^e - \mathbf{x}_i^n|} \\
& + \frac{e^2}{8\pi\epsilon_0} \sum_{i,j=1}^{N'} \frac{1}{|\mathbf{t}_i^e - \mathbf{t}_j^e|} + \sum_{i,j=1}^{A'} \frac{Z_i Z_j}{|\mathbf{x}_i^n - \mathbf{x}_j^n|}.
\end{aligned} \tag{21}$$

This electronic Hamiltonian is translationally invariant and would yield the usual form were the nuclear masses to increase without limit. It has been noted (Kutzelnigg 2007) that to take (Eq. 21) as the electronic Hamiltonian is inconsistent with a consideration of the solution to the full problem being expressed in a series in terms of powers of the inverse total nuclear mass, since this Hamiltonian already contains a term involving the inverse of this mass to the first power. There is, however, no need to consider this term at the first stage of development of a solution to the full problem and it can be included at the point where terms of similar magnitude are considered. The remaining part of Eq. 21 is then exactly the same as the clamped nuclei form. The clamped nuclei form can be deployed consistently in an account of solutions to the full problem only if a uniform translational factor is included in the full solution. In the work of Nakai et al. (2005) (see also Sutcliffe 2005) the translational motion of the center-of-mass is subtracted to yield a Schrödinger eigenvalue problem from which the translational part of any continuous spectrum has been removed. Of course the spectrum of the resulting operator can have a continuous spectral range, as can the translationally invariant form itself, for reasons quite other than translational motion.

The nuclear part of Eq. 16 involves only kinetic energy operators and has the form:

$$K^n(\mathbf{t}^n) = -\frac{\hbar^2}{2} \sum_{i,j=1}^{A-1} \frac{1}{\mu_{ij}^n} \vec{\nabla}(\mathbf{t}_i^n) \cdot \vec{\nabla}(\mathbf{t}_j^n), \tag{22}$$

with the inverse mass matrix defined as a special case of Eq. 17 involving only the original nuclear variables.

Both (Eqs. 21 and 22) are invariant under any orthogonal transformation of both the electronic and nuclear variables. If the nuclei are clamped in Eq. 21 then invariance remains only under those orthogonal transformations of the electronic variables that can be reexpressed as changes in the positions of nuclei with identical charges while maintaining the same nuclear geometry. The form (Eq. 21) remains invariant under all permutations of the electronic variables and is invariant under permutations of the variables of those nuclei with the same charge. Thus if an electronic energy minimum is found at some clamped nuclei geometry there will be as many minima as there are permutations of identically charged nuclei. The kinetic energy operator (Eq. 22) is invariant under all orthogonal transformations of the nuclear variables and under all permutations of the variables of nuclei with the same mass.

The splitting of the translationally invariant Hamiltonian $H'(\mathbf{t})$ into two parts breaks its symmetry, since each part exhibits only a sub-symmetry of the full problem. If wavefunctions derived from approximate solutions to Eq. 21 are to be used to construct solutions to the full problem (Eq. 6) utilizing (Eq. 22) care will be needed to couple the sub-symmetries to yield solutions with full symmetry.

Atoms

For the atom there is no nuclear kinetic energy part and, denoting the nuclear mass by m_n , the full Hamiltonian is simply the electronic Hamiltonian

$$\begin{aligned} H'^e(\mathbf{t}^e) = & -\frac{\hbar^2}{2m} \sum_{i=1}^N \nabla^2(\mathbf{t}_i^e) - \frac{\hbar^2}{2m_n} \sum_{i,j=1}^N \vec{\nabla}(\mathbf{t}_i^e) \cdot \vec{\nabla}(\mathbf{t}_j^e) - \frac{e^2}{4\pi\epsilon_0} \sum_{j=1}^N \frac{Z_i}{|\mathbf{t}_j^e|} \\ & + \frac{e^2}{8\pi\epsilon_0} \sum_{i,j=1}^{N'} \frac{1}{|\mathbf{t}_i^e - \mathbf{t}_j^e|}. \end{aligned} \quad (23)$$

The electronic problem for the atom (Eq. 23) has exactly the same form and symmetry as the full problem and meets the requirements for Kato self-adjointness, for there is a kinetic energy operator in all of the variables that are used to specify the potential terms. This would continue to be the case were the nuclear mass to increase without limit.

The atom is sometimes used as an illustration when considering the original form of the Born–Oppenheimer approximation (as in Deshpande and Mahanty 1969), but the only aspect of the approximation that can be thus illustrated is the translational motion part and that is easily considered in first order by treating the second term in Eq. 23 as a perturbation to the solution obtained using an infinite nuclear mass. The inclusion of this term in this way is analogous to making the usual *diagonal Born–Oppenheimer* correction and it can be made exactly in the case of any one-electron atom (see Handy and Lee 1996). As noted in Hinze et al. (1998) it is usually made approximately simply by including the diagonal part of the mass polarization term (the second term in Eq. 23 above) to produce an electronic reduced mass

$$\frac{1}{\mu_e} = \frac{1}{m_n} + \frac{1}{m}$$

in place of $1/m$.

The Hamiltonian (Eq. 23) maintains full symmetry and is invariant under electronic permutations and under rotation-reflections of the electronic coordinates. Trial functions are usually constructed from atomic orbitals and from their spin-orbitals. Permutational antisymmetry is achieved by forming Slater determinants from the spin-orbitals. Rotational symmetry is usually realized by vector coupling

of orbitals that form bases for representations of the rotation group $SO(3)$. Spin-eigenfunctions too are achieved by vector coupling.³

Molecules

Even after separating the translational motion, for a molecule there is always at least one nuclear variable in the kinetic energy part of the operator, and self-adjointness cannot be achieved if such terms are neglected while the potential terms involving the nuclear variables are included except by clamping the nuclei. The treatment of molecules is, thus, technically much more difficult than is the treatment of atoms.

Although the discussion that follows is, for the most part, quite general, explicit consideration is confined to the diatomic case in order to avoid overburdening the exposition with details. However here too, there are certain technical features which simplify the diatomic case and which cannot be transferred to the polyatomic case so care will be taken in the following discussion not to make the diatomic the general case. For a system with two nuclei the natural nuclear coordinate is the internuclear vector which will be denoted here simply as \mathbf{t} . When needed to express the electron-nuclei attraction terms, \mathbf{x}_i^n is simply of the form $\alpha_i \mathbf{t}$ where α_i is a signed ratio of the nuclear mass to the total nuclear mass. In the case of a homonuclear system $\alpha_i = \pm \frac{1}{2}$. The di-nuclear electronic Hamiltonian is

$$\begin{aligned} H^{e}(\mathbf{t}^e) = & -\frac{\hbar^2}{2m} \sum_{i=1}^N \nabla^2(\mathbf{t}_i^e) - \frac{\hbar^2}{2(m_1+m_2)} \sum_{i,j=1}^N \vec{\nabla}(\mathbf{t}_i^e) \cdot \vec{\nabla}(\mathbf{t}_j^e) \\ & - \frac{e^2}{4\pi\epsilon_0} \sum_{j=1}^N \left(\frac{Z_1}{|\mathbf{t}_j^e + \alpha_1 \mathbf{t}|} + \frac{Z_2}{|\mathbf{t}_j^e + \alpha_2 \mathbf{t}|} \right) \\ & + \frac{e^2}{8\pi\epsilon_0} \sum_{i,j=1}^{N'} \frac{1}{|\mathbf{t}_i^e - \mathbf{t}_j^e|} + \frac{Z_1 Z_2}{R}, \quad R = |\mathbf{t}|, \end{aligned} \quad (24)$$

while the nuclear kinetic energy part is:

$$-\frac{\hbar^2}{2} \left(\frac{1}{m_1} + \frac{1}{m_2} \right) \nabla^2(\mathbf{t}) \equiv -\frac{\hbar^2}{2\mu} \nabla^2(\mathbf{t}). \quad (25)$$

The electronic part is not self-adjoint in the manner prescribed by Kato because it contains no kinetic energy terms involving the nuclear variable which would dominate the potential energy terms. The full Hamiltonian would not be Kato self-adjoint if both nuclear masses were to increase without limit either. It is seen from

³Some specifics of the implementation of permutational and rotational symmetry in quantum mechanics are discussed in section "The Symmetries of the Clamped Nuclei Electronic Hamiltonian."

Eq. 25, however, that if only one nuclear mass increases without limit then the kinetic energy term in the nuclear variable remains in the full problem and so the Hamiltonian remains self-adjoint in the Kato sense.

The di-nuclear case has been considered numerically by Frolov (1999) in a study of the hydrogen molecular ion. In extremely accurate calculations on the discrete states of this system, he investigated what happened when first one and then two nuclear masses are increased without limit. He showed that when one mass increased without limit, any discrete spectrum persisted but when two masses were allowed to increase without limit, the Hamiltonian ceased to be well-defined and this failure led to what he called *adiabatic divergence* in attempts to compute discrete eigenstates. This sort of behavior would certainly be anticipated from the present discussion.

Irrespective of any choices made for the nuclear masses, the electronic Hamiltonian (Eq. 24) becomes self-adjoint in the Kato sense if the nuclei are clamped for then the nuclear variables in the potential terms become constants and the only variables are the electronic ones. So the clamped nuclei potential is dominated by the electronic kinetic energy. Thus the usual practice of clamped nuclei electronic structure calculations is a consistent one.

Writing the variable \mathbf{t} in spherical polar coordinates, R , β , and α where $t_z = R \cos \beta$, were the clamped nuclei Hamiltonian to be used to define a potential it is easily seen that for $\mathbf{t} = \mathbf{a}$, $R = a$ then

$$E^{\text{cn}}(\mathbf{a}) = V(a), \quad (26)$$

so that the potential would have the form $V(R)$. But the potential is not just a curve, it is a series of spherical shells of rotation swept out by the curve by all choices of β and α . It is thus a genuine central-field potential. If the internuclear distance is fixed but \mathbf{a} allowed to rotate or invert, then $E^{\text{cn}}(\mathbf{a})$ is a sphere of constant energy as swept out by the variables β and α at radius a . If \mathbf{a} is oriented so as to define a z -axis then $E^{\text{cn}}(\mathbf{a})$ will take the same value at $+a_z$ and $-a_z$ so that if there is a minimum at $+a_z$ there will be another at $-a_z$. The electronic Hamiltonian is not invariant under inversion of the nuclear variables alone unless the two nuclei have identical charges in which case inversion and permutation will have identical effects. In differential geometry terms, the potential is homeomorphic to S^2 .

The Hamiltonian (Eq. 24) is invariant under all rotations of the electronic coordinates about the internuclear axis and all reflections in a plane containing the internuclear axis. The electronic states can be labeled by a quantum number m which takes the values $0, \pm 1, \pm 2, \dots$ corresponding to the eigenvalues of the z -component of the electronic angular momentum about the internuclear axis.

It is easily seen that the potential will tend to increase without limit as $R \rightarrow 0$ but the behavior as $R \rightarrow \infty$ presents a problem. To see this consider the asymptotic behavior of the electron-nucleus potential terms in the case of the one-electron homonuclear di-hydrogen molecule ion. The electronic coordinate is

$$\mathbf{t}^e = \mathbf{x} - \frac{1}{2}(\mathbf{x}_1^n + \mathbf{x}_2^n), \quad (27)$$

where \mathbf{x} is the laboratory coordinate of the electron. As the internuclear distance becomes very large, the nuclear repulsion term becomes very small and one would expect the trial wavefunction to approach the wavefunction for a one-electron ion corresponding to one of the atoms. Thus one might expect the lowest energy wavefunction to be of the form

$$Ne^{-cr}, \quad \mathbf{r} = \mathbf{x} - \mathbf{x}_1^n, \quad r = |\mathbf{r}|,$$

for instance. However working in the chosen coordinate set

$$\mathbf{r} = \mathbf{t}^e - \frac{1}{2}\mathbf{t},$$

so that the expected asymptotic electronic solution could be expressed only in terms of both the electronic and nuclear variables. This does not, of course, mean that the potential cannot approach the required value. It simply means that it cannot do so in any calculation in which the trial functions are confined to electronic functions whose variable origin is at the center-of-nuclear mass.

This sort of difficulty is a general one and obviously not confined simply to one-electron diatomic molecules. It would clearly be unwise to attempt to approximate solutions for molecules at energies close to their dissociation limits in terms of electronic coordinates with the origin at the center-of-nuclear mass. A trial function for the general case of the Born–Huang form

$$\psi(\mathbf{t}^n, \mathbf{t}^e) = \sum_p \Phi_p(\mathbf{t}^n) \psi_p^{\text{nn}}(\mathbf{t}^n, \mathbf{t}^e), \quad (28)$$

where the \mathbf{t}^e have an origin at the center-of-nuclear mass, could, therefore, approximate only a limited region of the spectrum of the full problem.

This difficulty cannot be got round by working in the laboratory frame. The solution to the full problem would be defined in terms of a three-dimensional subspace expressed in terms of a translation variable and a $3(N_T - 1)$ -dimensional subspace expressible in terms of translationally invariant variables. Translationally invariant variables must involve at least a pair of variables and so there must be at least one such variable which involves a laboratory frame electron and a laboratory frame nuclear variable. All this can be easily illustrated by considering the exact ground-state wavefunction of the hydrogen atom, as is seen in Kutzelnigg (2007).

This point is developed in more detail by Hunter (1981) in a paper considering to what extent a separation of electronic and nuclear motion would be possible if the exact solution to the Schrödinger equation for the Coulomb Hamiltonian was actually known. Were the exact solution known Hunter argues (1975) that it could be written in the form

$$\psi(\mathbf{t}^n, \mathbf{t}^e) = \chi(\mathbf{t}^n) \phi(\mathbf{t}^n, \mathbf{t}^e), \quad (29)$$

with a nuclear wavefunction defined by means of

$$|\chi(\mathbf{t}^n)|^2 = \int \psi(\mathbf{t}^n, \mathbf{t}^e)^* \psi(\mathbf{t}^n, \mathbf{t}^e) d\mathbf{t}^e.$$

Then, providing this function has no nodes,⁴ an “exact” electronic wavefunction could be constructed as

$$\phi(\mathbf{t}^n, \mathbf{t}^e) = \frac{\psi(\mathbf{t}^n, \mathbf{t}^e)}{\chi(\mathbf{t}^n)}, \quad (30)$$

if the normalization choice

$$\int \phi(\mathbf{t}^n, \mathbf{t}^e)^* \phi(\mathbf{t}^n, \mathbf{t}^e) d\mathbf{t}^e = 1$$

is made. In fact it is possible (Hunter 1981) to show that χ must be nodeless even though the usual approximate nuclear wavefunctions for vibrationally excited states do have nodes. The electronic wavefunction (Eq. 30) is, therefore, properly defined and a potential energy surface could be defined in terms of it as

$$U(\mathbf{t}^n) = \int \phi(\mathbf{t}^n, \mathbf{t}^e)^* H'(\mathbf{t}^n, \mathbf{t}^e) \phi(\mathbf{t}^n, \mathbf{t}^e) d\mathbf{t}^e. \quad (31)$$

Although no exact solutions to the full problem are known for a molecule, some extremely good approximate solutions for excited vibrational states of H_2 have been computed and Czub and Wolniewicz (1978) took such an accurate approximation for an excited vibrational state in the $J = 0$ rotational state of H_2 and computed $U(R)$. They found strong spikes in the potential at close to two positions at which the usual wavefunction would have nodes. To quote Czub and Wolniewicz (1978):

This destroys completely the concept of a single internuclear potential in diatomic molecules because it is not possible to introduce on the basis of non-adiabatic potentials a single, approximate, mean potential that would describe well more than one vibrational level.

It is obvious that in the case of rotations the situation is even more complex.

Bright Wilson suggested (1979) that using the clamped nuclei Hamiltonian instead of the full one in Eq. 31 to define the potential might avoid the spikes but Hunter (1981) showed why this was unlikely to be the case and Cassam-Chenai (2006) repeated the work of Czub and Wolniewicz using an electronic Hamiltonian and showed that exactly the same spiky behavior occurred. However Cassam-Chenai showed, as Hunter had anticipated, that if one simply ignored the spikes, the potential was almost exactly the same as would be obtained by deploying the electronic Hamiltonian in the usual way.

⁴A similar requirement must be placed on the denominator in Eq. 12 of Kutzelnigg (2007) for the equation to provide a secure definition.

Although the spiky nature of an “exact” potential has been demonstrated explicitly only for $J = 0$ states of a small diatomic molecule, there is no reason to suppose that its occurrence is not general. Matters would be further complicated by rotational motion. Thus the demonstrably smooth potentials generated by solving an electronic problem cannot be approximations to any exact form but are simply computationally useful intermediates in a solution to the full problem. It would therefore seem unwise to assign too much weight to them in explaining chemical structure.

In the standard approach to solving the nuclear motion part of the diatomic problem, the potential $V(R)$ is specified and the nuclear motion Hamiltonian becomes

$$-\frac{\hbar^2}{2\mu}\nabla^2(\mathbf{t}) + V(R). \quad (32)$$

Expressing this Hamiltonian in spherical polar coordinates one obtains the usual form

$$-\frac{\hbar^2}{2\mu}\left(\frac{1}{R^2}\frac{\partial}{\partial R}R^2\frac{\partial}{\partial R}\right) + \frac{1}{2\mu R^2}L^2 + V(R), \quad (33)$$

where L is the operator for the angular momentum of the nuclear motion. The angular part of the solution is known analytically and the solution of the nuclear motion problem can be reduced to one in the single variable R .

The eigensolutions to this problem are quite naturally eigenfunctions of the nuclear angular momentum and can easily be chosen with the required permutational symmetry. But things are not quite so clear for the electronic part of the problem because one does not in practice have a form which is explicit in the nuclear variables as it is computed only at fixed nuclear geometries. It is easy to achieve the correct permutational symmetry for the electronic part of the function at each and every nuclear geometry, but it would be not at all easy to make each function an eigenfunction of the electronic angular momentum.

To try to deal with the rotational motion it is possible to reformulate the diatomic problem to exhibit explicitly the angular symmetry of the Hamiltonian. As shown in Kołos and Wolniewicz (1963) and, in a somewhat more general way in Sutcliffe (2007), it is possible to define an internal coordinate system by a transformation that makes the internuclear vector \mathbf{t} the z -axis in a right-handed coordinate system and in this system the electronic Hamiltonian (Eq. 24) becomes

$$-\frac{\hbar^2}{2m}\sum_{i=1}^N\nabla^2(\mathbf{r}_i) - \frac{\hbar^2}{2(m_1 + m_2)}\sum_{i,j=1}^N\vec{\nabla}(\mathbf{r}_i)\cdot\vec{\nabla}(\mathbf{r}_j) + V(R, \mathbf{r}), \quad (34)$$

with

$$V(R, \mathbf{r}) = \frac{e^2}{8\pi\epsilon_0} \sum_{i,j=1}^{N'} \frac{1}{r_{ij}} + \frac{e^2}{4\pi\epsilon_0} \frac{Z_1 Z_2}{R} - \frac{e^2}{4\pi\epsilon_0} \sum_{j=1}^N \left(\frac{Z_1}{r_{j1}(R)} + \frac{Z_2}{r_{j2}(R)} \right), \quad (35)$$

where the \mathbf{r}_i are the electronic variables expressed in the transformed system. In this formulation the vector \mathbf{t} orients freely and ‘‘clamping the nuclei’’ comes down to simply choosing $R = a$. A clamped nuclei solution of Eq. 34 would lead to a clamped nuclei energy

$$E^{\text{cn}}(a) = V(a), \quad (36)$$

rather than the form given by Eq. 26. Thus any minima in $V(a)$ would not be duplicated by the requirement of rotational invariance. Inversion is achieved by means of

$$\beta \rightarrow \pi - \beta, \quad \alpha \rightarrow \pi + \alpha$$

and thus involves just the angular part of the formulation. An identical operation achieves the nuclear permutation. The electronic Hamiltonian is invariant under neither operation unless the nuclei have identical charge.

The nuclear kinetic energy operator (Eq. 25) becomes

$$-\frac{\hbar^2}{2\mu R^2} \frac{\partial}{\partial R} R^2 \frac{\partial}{\partial R} + \frac{1}{2\mu R^2} \mathbf{D}_1(\alpha, \beta, \mathbf{r}), \quad (37)$$

with

$$\mathbf{D}_1(\alpha, \beta, \mathbf{r}) = \left[(\mathbf{J}_x - \mathbf{l}_x)^2 + (\mathbf{J}_y - \mathbf{l}_y)^2 + \frac{\hbar}{i} \cot \beta (\mathbf{J}_y - \mathbf{l}_y) \right],$$

where the electronic angular momentum is

$$\mathbf{l} = \sum_{i=1}^N \mathbf{l}(i) = \frac{\hbar}{i} \sum_{i=1}^N \mathbf{r}_i \times \frac{\partial}{\partial \mathbf{r}_i}, \quad (38)$$

and the total angular momentum operator is denoted \mathbf{J} and involves both the electronic and nuclear variables in such a way that $\mathbf{J}_z = \mathbf{l}_z$. The Jacobian for this transformation is

$$R^2 \sin \beta.$$

It is seen that in this formulation any solution of the clamped nuclei form of the electronic Hamiltonian (Eq. 34) will give rise to a potential which is simply a curve and not a surface of rotation. However the angular part of the nuclear kinetic energy

operator now involves the electronic angular momentum so that the electronic motion and the overall rotational motion are coupled.

The electronic wavefunction in this case has the same axial symmetry as in the previous case and is characterized by the quantum number m . However the states can no longer be regarded as occurring in degenerate pairs for $m > 0$ since l_z is the z -component of the total angular momentum so m can take integer values lying between J and $-J$, where J is the total angular momentum. The coupling of the electronic and nuclear angular momenta lifts the m degeneracy as the Hamiltonian becomes a system of $2J + 1$ coupled partial differential equations.

In the first of the two possible ways of looking at the diatomic, one remains in the Cartesian product space $R^3 \times R^{3N}$ and it is thus necessary to give some explicit consideration to the angular properties of solutions to the electronic part of the problem. If the usual approach were taken to approximating solutions to the nuclear motion Hamiltonian using sums of products of electronic and nuclear parts, a typical term in the sum used as trial function for the form (Eq. 33) would be

$$\phi_{pm}(\mathbf{r}^e, R)^L \Phi_{pm}(R) \Theta_{Lm}(\beta, \alpha), \quad (39)$$

where p denotes an electronic state and L the nuclear angular momentum quantum number. There are no operators in the nuclear motion part of the problem which explicitly couple the electronic and nuclear motions. It is thus possible to represent for any electronic state, any number of rotational states specified by values of L , without considering any coupling. L in Eq. 24 is not the total angular momentum operator and so a description of rotational motion given in these terms yields only an approximate quantum number.

If one transforms to the manifold $R_+ \times S^2 \times R^{3N}$ then one can consider explicitly the rotational coupling of electronic and angular motions. The fact that the transformation is to a manifold rather than a vector space means that any operator built using coordinates defined on the manifold will be well defined only where the Jacobian for the transformation does not vanish. This does not cause great problems here because the only places where the Jacobian vanishes are when $R = 0$ and where $\beta = 0$ and $\beta = \pi$. The region around $R = 0$ is inaccessible because of the nuclear repulsion term and the exact angular wavefunctions take care of the problem with β .

It would not be consistent to use only a single term in a product approximation for a trial for the form (Eq. 37) with a potential $V(R)$ except in considering a $J = 0$ state. Here the minimum consistent product approximation is

$$\sum_{m=-J}^J \phi_{pm}(\mathbf{r}, R)^J \Phi_{pm}(R) \Theta_{Jm}(\beta, \alpha). \quad (40)$$

It is only for $J = 0$ states that the forms (Eqs. 39 and 40) are the same.

Of course the angular momentum coupling in Eq. 40 implies a coupling of different electronic states, between Σ and Π states or Σ and Δ states, for example. To allow explicitly for that possibility (Eq. 40) should really be extended to

$$\sum_{m=-J}^J \sum_{pm}^J \phi_{pm}(\mathbf{r}, R)^J \Phi_{pm}(R) \Theta_{Jm}(\beta, \alpha), \quad (41)$$

where the electronic state is denoted pm to indicate that the state must have quantum number m . Thus for $J = 2$ one would need at least five electronic states.

Which Is the “Correct” Clamped Nuclei Hamiltonian?

There is clearly a choice between the form (Eqs. 24 and 34) and although in the clamped nuclei approximation both would yield the same energies for any chosen internuclear separation a , the resulting energy would be a potential for two quite different situations.

To generalize from the diatomic case, if the usual approach were taken to approximating solutions to the nuclear motion Hamiltonian using sums of products of electronic and nuclear parts a typical term in the sum used as trial function for the form (Eq. 33) would be

$$\phi_p(\mathbf{t}^e, \mathbf{t}^n) \Phi_p(\mathbf{t}^n), \quad (42)$$

where p denotes an electronic state. The solutions are on the Cartesian product space $R^{3A-3} \times R^{3N}$. There is again no explicit coupling of the nuclear motion and electronic motions and it is thus possible to represent for any electronic state, any number of rotational states. It is only in the diatomic case that the nuclear angular momentum can be realized explicitly as part of the nuclear kinetic energy so it is not generally possible to choose Φ directly as an eigenfunction of the nuclear angular momentum, neither is it possible to choose ϕ directly as an eigenfunction of the electronic angular momentum. ϕ as usually computed belongs to the totally symmetric representation of the symmetric group of each set of nuclei with identical charges. Φ could then be a basis function for an irreducible representation of the symmetric group for each set of particles with identical masses if the permutational symmetry were properly considered in solving the nuclear motion problem.

Clamped nuclei calculations are usually undertaken so as to yield a potential that involves no redundant coordinates. Thus a translationally invariant electronic Hamiltonian like (Eq. 24) would actually generate a more general potential than this. A clamped nuclei potential is, therefore, more properly associated with the electronic Hamiltonian after the separation of rotational motion like (Eq. 34) than with the merely translationally invariant one. With this choice again, the minimum consistent product approximation is

$$\sum_{m=-J}^J \phi_{pm}(\mathbf{r}, \mathbf{R})^J \Phi_{pm}(\mathbf{R}) |JMm\rangle, \quad (43)$$

where \mathbf{R} represents the $3A - 6$ internal coordinates invariant under all orthogonal transformations of the \mathbf{t}^n and $|J M m\rangle$ is an angular momentum eigenfunction. The general solutions are on the manifold $R^{3A-6} \times S^3 \times R^{3N}$ though for triatomic molecules the internal coordinate part of the manifold is confined to $R_+ \times R^2$ because the three nuclear positions define a plane. It is only in the diatomic case that the electronic variables play a direct part in the specification of the angular momentum eigenfunctions and where there is therefore only one internal coordinate. However the Coriolis coupling terms in the angular part of the Hamiltonian contain terms in the electronic angular momentum so coupling of the electronic motion to the angular motion would still be anticipated, see sections V and VI of Sutcliffe (2000). Although the angular momentum coupling could imply a coupling of different electronic states, as it certainly does in a diatomic, it is not obviously implied in the general case. To achieve permutational symmetry in the nuclear motion part of the wavefunction would in the general case be very tricky. The nuclei are identified in the process of defining a body-fixed frame to describe the rotational motion, even if they are identical. If only a subset of a set of identical nuclei were used in such a definition, some permutation of the nuclear variables would induce a change in the definition of the body-fixed frame and thus spoil the rotational separation. Thus permutations of identical nuclei are considered usually only if such permutations correspond to point group operations which leave the body-fixing choices invariant.

If one considers the clamped nuclei Hamiltonian as providing input for the full Hamiltonian in which the rotational motion is made explicit, the basic nuclear motion problem should be treated as a $2J + 1$ dimensional problem. If this is done then the translational and rotational symmetries of the full problem are properly dealt with. However the solutions are not generally basis functions for irreps of the symmetric groups of sets of identical nuclei except for such subgroups as constitute the point groups used in frame fixing. This restriction of the permutations is usually assumed justified by appealing to the properties of the potential surface. The idea here was introduced by Longuet-Higgins (1963) and is widely used in interpreting molecular spectra.

As noted earlier, the original attempts to justify the Born–Oppenheimer and the Born approaches from the full Coulomb Hamiltonian lack rigorous mathematical foundations. So far there have been no attempts to make the foundations of the Born approach mathematically secure. However the coherent states approach has been used to give mathematically rigorous accounts of surface crossings and a review of this work can be found in Hagedorn and Joye (2007). It seems very unlikely that it would be possible to provide a secure foundation for the Born approach in anything like the manner in which it is usually presented.

The Born–Oppenheimer approximation, whose validity depends on there being a deep enough localized potential well in the electronic energy, has, however, been extensively treated. The mathematical approaches depend upon the theory of fiber bundles and the electronic Hamiltonian in these approaches is defined in terms of a fiber bundle. It is central to these approaches, however, that the fiber bundle should be trivial, that is that the base manifold and the basis for the fibers be

describable as a direct product of Cartesian spaces. This is obviously possible with the decomposition choice made for Eq. 42 but not obviously so in the choice made for Eq. 43.

The Born–Oppenheimer approach has been put on a rigorous foundation for diatomics with solutions of the form (Eq. 39) in work which is described in a helpful context in Combes and Seiler (1980). For solutions like (Eq. 40), it is possible that more than one vector (coordinate) space can be constructed on it because the transformation is to a manifold. In fact two coordinate spaces are possible on S^2 a trivial one and a twisted one, the latter associated with the possibility of an electronic wavefunction with a Berry phase and the “twisted” solutions are accounted for in Herrin and Howland (1997).

A mathematically satisfactory account of the Born–Oppenheimer approximation for polyatomics in an approach based on Eq. 43 has not yet been provided but it has proved possible to provide one based on Eq. 42 (see Klein et al. 1992). Because the nuclear kinetic energy operator in the space R^{3A-3} cannot be expressed in terms of the nuclear angular momentum, it is not possible in this formulation to separate the rotational motion from the other internal motions. This work also considers the possibility that there are two minima in the potential as indeed there would be because of inversion symmetry if the potential minimum were at other than a planar geometry. It does not, however, consider the possibility of such multiple minima as might be induced by permutational symmetry. It might be possible to extend the two minima arguments to the multiple minima case and perhaps provide a mathematically secure account of the Longuet-Higgins approach to ignoring some of the inconvenient permutations. This has not so far been attempted.

For a secure account to be given in terms of the separation (Eq. 43), which is what is really required if one is to use the clamped nuclei electronic Hamiltonian, it would be necessary to consider more than one coordinate space. On the manifold S^3 at least two coordinate spaces are required to span the whole manifold. The internal coordinates within any coordinate space are such that it is possible to construct two distinct molecular geometries at the same internal coordinate specification, so that a potential expressed in the internal coordinates cannot be analytic everywhere (Collins and Parsons 1993). It would therefore seem to be a very tricky job. But even if it were to be accomplished it seems very unlikely that a multiple minima argument could be constructed to account for point group symmetry in this context. It is possible to show (see section IV of Sutcliffe (2000)) that in the usual Eckart form of the Hamiltonian for nuclear motion, permutations can be such as to cause the body-fixed frame definition to fail completely.

If it is wished to perform a clamped nuclei calculation on a molecule containing three or more nuclei, avoiding translations and rigid rotations, it is necessary to fix the values of six of the $3A$ nuclear variables. In practice this is usually done by choosing one nucleus, x_1^n , at the origin, one nucleus, x_2^n , defining an axis and a third, x_3^n , defining a plane. Every possible geometry of the molecule, except where the three particles become collinear, can be specified with this choice but not every component of the $3A$ variables will appear in the clamped nuclei

electronic energy as six of them have been chosen to be zero. This means that even though the clamped nuclei electronic energy can be specified in terms of a molecular geometry in which the positions of A points can be given, the energy itself is a function of only the relative positions of a subset of the nuclei. Thus performing clamped nuclei calculations will not make possible the expression of the electronic energy in anything other than internal coordinates and the electronic energy when expressed in any set of internal coordinates cannot be analytic everywhere. Thus there cannot really be a “global” potential energy surface. In any case, as has been seen, the potential, even locally, cannot be regarded as an approximation to anything in particular and thus should be treated simply as a convenient peg on which to hang further calculations. From this perspective, the further calculations should properly be ones in which the electronic Hamiltonian results from the full Hamiltonian in which the rotational motion has been made explicit. Such Hamiltonians have only a local validity and can be defined only where the Jacobian for the transformation to the rotational variables does not vanish. However at present there is no satisfactory account of how nuclear permutational symmetry should be treated from this perspective, neither is there any secure mathematical justification of the Born–Oppenheimer approximation or of the Born approach.

Naturally any extension of the trial wavefunction for the full Coulomb Hamiltonian problem from a single term to a many term form must be welcomed as an advance; it is, however, simply a technical advance and it might prove premature to load that technical advance with too much physical import.

At present it is not possible to place properly the clamped nuclei electronic Hamiltonian in the context of the full problem, including nuclear motion. However if the nuclei were treated as distinguishable particles, even when formally identical, then some of difficulties that arise from the consideration of nuclear permutations would not occur. But it would still be necessary to be able to justify the choice of subsets of permutations among identical particles when such seem to be required to explain experimental results. A particular difficulty arises here for it is not possible to distinguish between isomers nor is it possible to specify a molecular geometry, unless it is possible to distinguish between formally identical particles.

But regarding the nuclei as distinguishable would not avoid the difficulty of constructing total angular momentum eigenfunctions from the nuclear and electronic parts. Such treatment of the nuclei would not make the traditional demonstrations of the Born–Oppenheimer or the Born approximations mathematically sound either. However it would ensure that the mathematically sound presentations of the Born–Oppenheimer approximation mentioned earlier need no further extension to include permutations of identical nuclei. There is, unfortunately, little good to be said, from a mathematical point of view, of the traditional Born argument. This is troubling because the Born approach is assumed to provide the basis for the consideration of chemical reactions on and between potential energy surfaces. However it is clear that the clamped nuclei electronic Hamiltonian can be usefully deployed in nuclear motion calculations if the nuclei are considered identifiable and in the next sections this Hamiltonian will be considered in detail.

The Symmetries of the Clamped Nuclei Electronic Hamiltonian

Before considering the symmetry under permutations of identical particles it is necessary first to say a little about the spin of particles. Each particle is specified not only by space variables but also by spin variables. These have not been considered so far because there are no spin operators in the Hamiltonians discussed in the previous sections. Nevertheless spin is, indirectly, very important in the construction of approximate wavefunctions.

Spin ideas are usually developed in terms of a vector operator S with three components S_α , $\alpha = x, y, z$ and functions $\Theta_{S, M_s, k}^N$ such that

$$S^2 \Theta_{S, M_s, k}^N = \hbar^2 S(S+1) \Theta_{S, M_s, k}^N, \quad S^2 = S_x^2 + S_y^2 + S_z^2,$$

and

$$S_z \Theta_{S, M_s, k}^N = \hbar^2 M \Theta_{S, M_s, k}^N,$$

with,

$$S = 0, 1, 2, \dots, \quad -S \leq M_s \leq S. \quad (44)$$

The $\Theta_{S, M_s, k}^N$ are called spin eigenfunctions and the k index denotes a particular member of a possible set. In the simple case of a single electron, $S = \frac{1}{2}$, $M_s = \pm \frac{1}{2}$, and $k = 1$ so usually $\Theta_{\frac{1}{2}, \frac{1}{2}, 1}^1$ is written as α and $\Theta_{\frac{1}{2}, -\frac{1}{2}, 1}^1$ as β .

It can be shown that under the operations of the full rotation-reflection group in three dimensions, O(3):

$$(S_x S_y S_z) \rightarrow (S_x S_y S_z) |\mathbf{R}| \mathbf{R}, \quad (45)$$

where \mathbf{R} is the matrix representation of the rotation inversion and is thus an orthogonal matrix with determinant $|\mathbf{R}|$ which is $+1$ for a rotation and -1 for a reflection. Clearly S^2 is an invariant operator. Thus, its eigenfunctions provide a basis for irreducible representations of O(3) and in general we label these representations by the S value to which they correspond, using k to distinguish between different basis functions for the same representation. Obviously the dimension of these is $2S + 1$ since the $2S + 1$ functions with $M_s = S, S - 1, \dots, -S$ are degenerate in the sense of having the same S eigenvalue.

It is useful to treat the spin functions as having variables s_i though these can take only discrete values and from now on to label the Cartesian space variables as \mathbf{r}_i so that \mathbf{x}_i can be used to denote the totality of variables. To construct a many-particle function to describe space and spin for a collection of N identical particles it is apparently simply necessary to form the products:

$$\Psi_n(\mathbf{x}_1, \mathbf{x}_2, \dots, \mathbf{x}_N) = \Psi_n(\mathbf{r}_1, \mathbf{r}_2, \dots, \mathbf{r}_N) \Theta_{S, M_s, k}^N(s_1, s_2, \dots, s_N) \quad (46)$$

at will, and the generalization to groups of sets of identical particles is obvious. However there is a snag. It turns out that there is an extra rule that must be obeyed. The Hamiltonian is invariant under the operators that permute the variable designations (space and spin) of sets of identical particles. For any one set, these operators form a group and the full invariance group of H is the direct product of the groups for all the sets of identical particles. This means that the eigenfunctions of H are a basis for the irreps of this group. The extra rule is related to what irreps can actually occur and it is usually called the *Pauli principle*. If the set of identical particles individually have spin $S = 0, 1, 2, 3$, etc., then the only irreps that can arise are the totally symmetric ones. Thus every wavefunction must be invariant under permutations that interchange the variable designations of particles with integer spins (*bosons*). If the particles individually have spin $S = \frac{1}{2}, \frac{3}{2}, \frac{5}{2}$ etc., then the only irreps are the antisymmetric ones. Thus every wavefunction must change sign if the permutation is odd or be invariant if the permutation is even for permutations that interchange the variable designations of particles with odd half-integer spin (*fermions*).

What this means is that not every function of the form (Eq. 46) actually corresponds to a physical state, but it can be shown that in any given problem there are enough eigenfunctions of S^2 with any given M_s value (i.e., k is sufficiently large) to form a basis for irreps of the permutation group of N particles. Similarly it can be shown that there are enough space functions to provide irreps of the same group. It is then possible to derive rules for combinations of the space and spin functions such that the resulting function obeys the Pauli principle.

Since in this and the following sections only the clamped nuclei Hamiltonian will be considered, it will be convenient to simplify the notation somewhat and to drop the superscripts on the electronic variables because, from now on, these will be the only variables to be considered. Thus Eq. 2 is rewritten as

$$\begin{aligned} H(\mathbf{a}, \mathbf{r}) = & -\frac{\hbar^2}{2m} \sum_{i=1}^N \nabla^2(\mathbf{r}_i) - \frac{e^2}{4\pi\epsilon_0} \sum_{j=1}^A \sum_{i=1}^N \frac{Z_j}{|\mathbf{r}_i - \mathbf{a}_j|} + \frac{e^2}{8\pi\epsilon_0} \sum_{i,j=1}^{N'} \frac{1}{|\mathbf{r}_i - \mathbf{r}_j|} \\ & + \frac{e^2}{8\pi\epsilon_0} \sum_{i,j=1}^{A'} \frac{Z_i Z_j}{|\mathbf{a}_i - \mathbf{a}_j|}, \end{aligned} \quad (47)$$

while Eq. 3 is rewritten as

$$H(\mathbf{a}, \mathbf{r}) \psi_p(\mathbf{a}, \mathbf{r}) = E_p(\mathbf{a}) \psi_p(\mathbf{a}, \mathbf{r}). \quad (48)$$

For later purposes it is useful to group the first two terms by writing

$$h(i) = -\frac{\hbar^2}{2m} \nabla^2(\mathbf{r}_i) - \frac{e^2}{4\pi\epsilon_0} \sum_{j=1}^A \frac{Z_j}{|\mathbf{r}_i - \mathbf{a}_j|} \equiv k(i) + V(i), \quad (49)$$

and to express the third term with

$$g(i, j) = \frac{e^2}{4\pi\epsilon_0} \frac{1}{|\mathbf{r}_i - \mathbf{r}_j|}. \quad (50)$$

The electronic part of the Hamiltonian for any given set of nuclear positions may then be written as

$$\mathbf{H} = \sum_{i=1}^N \mathbf{h}(i) + \frac{1}{2} \sum_{i,j=1}^{N'} g(i, j). \quad (51)$$

The operator \mathbf{h} is self-adjoint and a mathematically simple extension of the hydrogen atom operator. It therefore has some discrete one-particle eigenfunctions

$$\mathbf{h}(i)\phi(\mathbf{r}_i) = \epsilon\phi(\mathbf{r}_i). \quad (52)$$

Such one-particle functions are called *orbitals* and the associated energies ϵ are *orbital energies*. If there is only one nucleus, they are called *atomic orbitals* (AOs) and in the many nuclei case, *molecular orbitals* (MOs). The orbitals may be extended to become *spin-orbitals* by multiplying them with an α or β spin function and the resulting spin-orbitals are therefore denoted as $\phi(\mathbf{x}_i)$ to indicate the inclusion of spin. Clearly every orbital can generate two spin-orbitals.

It is usual in the case of electrons to work with functions that obey the Pauli principle from the start. This is possible when using an orbital basis through the use of Slater determinants of spin-orbitals which, by definition, change sign under odd permutations but are invariant under even permutations as is required for fermions. These will be explicitly considered later; first the permutational symmetry will be considered more generally.

Permutational Symmetry

The clamped nuclei Hamiltonian is invariant under the permutation of electrons so that its eigenfunctions must be basis functions for irreducible representations (irreps) of the symmetric group of degree N . However, because of the Pauli principle, not all irreducible representations of this group are allowed.

As noted above for electrons there are only two kinds of spin functions so that in any product of spin functions for N spin variables, only a limited set of permutations of the spin variables will lead to distinct product functions. Since there are no spin terms in the electronic Hamiltonian, the operators for total spin commute with the Hamiltonian and so its eigenfunctions must be spin eigenfunctions as well as basis functions for an irrep of the symmetric group. To see how these two requirements can be combined consider permutations rather generally.

The abstract permutation operator on N objects $1, 2, 3, \dots, N$ is always denoted by

$$P = \begin{pmatrix} 1 & 2 & 3 & \dots & N \\ i_1 & i_2 & i_3 & \dots & i_N \end{pmatrix}, \quad (53)$$

where the i_r are the set of objects $1, 2, 3, \dots, N$ at most in some new order. The effect of the operator on the original set of objects is

$$P(1, 2, 3, \dots, N) = (i_1 i_2 \dots i_N). \quad (54)$$

Clearly the product of any two permutations is a permutation, the products are associative, and there is an identity permutation, and every permutation possesses a unique inverse so the permutations form a group as required. The order of the group is obviously $N!$, because there are $N!$ distinct permutations of N objects. This is the symmetric group of degree N , usually denoted as S_N .

A permutation like

$$\begin{pmatrix} 1 & 2 & 3 \\ 2 & 3 & 1 \end{pmatrix} \quad \text{is often written as } (1\ 2\ 3), \quad (55)$$

on the interpretation that 2 replaces 1, 3 replaces 2, and 1 replaces 3. The right-hand expression in Eq. 55 is said to be in a *cycle* form and is a cycle of *length* 3. Any permutation can be decomposed uniquely into cycles of disjoint elements, thus for example:

$$\begin{pmatrix} 1 & 2 & 3 & 4 & 5 & 6 \\ 2 & 4 & 5 & 1 & 3 & 6 \end{pmatrix} = (1\ 2\ 4)(3\ 5)(6), \quad (56)$$

where the order in which the individual cycles are written down does not matter and where, of course, each cycle is invariant under cyclic permutations of its elements. A cycle of length two is called a *transposition* and is an involutory operation, that is:

$$(i_1 i_2) = (i_1 i_2)^{-1}. \quad (57)$$

A cycle can always be written as a product of transpositions, thus

$$(1\ 2\ 3) = (1\ 2)(2\ 3), \quad (58)$$

where the transposition on the right operates first, but the decomposition is obviously not unique nor are the transpositions always of disjoint elements. However the *number* of transpositions into which a cycle can be decomposed is obviously unique and this number is said to be the *parity* of the permutation, *even* if the number is even and *odd* if the number is odd. It follows, therefore, that we can classify the permutation operators themselves as either even or odd. Parity is usually indicated as $(-1)^p$ where p is the number of transpositions. The product of two

even permutations is an even permutation so that the even permutations constitute a subgroup (counting the identity permutation as even) of the symmetric group of order $N!$. This subgroup is called the *alternating* group. It is obvious then that the set of all distinct transpositions are the generators of the symmetric group.

It is reasonably easy to show that all permutations in the same class have the same cycle structure.⁵ Thus if the possible cycle structures are known, then the number of classes and hence the number of irreducible representations is known. But the number of cycle structures is obviously the number of possible ways that there is of dividing N objects in integer partitions. Thus for four objects the possible cycle structures are

$$\begin{aligned}
 & (i_1 i_2 i_3 i_4), \\
 & (i_1 i_2 i_3) (i_4), \\
 & (i_1 i_2) (i_3 i_4), \\
 & (i_1 i_2) (i_3) (i_4), \\
 & (i_1) (i_2) (i_3) (i_4).
 \end{aligned} \tag{59}$$

If there are m cycles in any partition, the cycle lengths are usually written symbolically as λ_i , where

$$\lambda_1 + \lambda_2 + \lambda_3 + \dots + \lambda_m = N, \tag{60}$$

and by convention

$$\lambda_1 \geq \lambda_2 \geq \lambda_3 \geq \dots \geq \lambda_m \geq 0. \tag{61}$$

Thus in Eq. 59 above in the first decomposition there is only one cycle and $\lambda_1 = 4$, in the second there are only two cycles $\lambda_1 = 3$ and $\lambda_2 = 1$. It is a custom to denote the totality of λ for any partition by the vector $[\lambda] \equiv 4[\lambda_1, \lambda_2 \dots \lambda_m]$ and to indicate r repeats of a cycle of given length λ by λ^r . Thus in Eq. 59 above the partitions should be denoted as $[4]$, $[3\ 1]$, $[2^2]$, $[2\ 1^2]$, and $[1^4]$.

The notation (Eq. 59) is not especially well adapted for present purposes and instead a notation invented by Young, the so-called Young diagram, is used. The Young diagrams equivalent to Eq. 59 are

⁵This means that the permutation and its inverse are always in the same class. A group with this property is said to be an *ambivalent* group.

$$\begin{array}{ccccc}
 \begin{array}{|c|c|c|c|} \hline \square & \square & \square & \square \\ \hline \end{array} &
 \begin{array}{|c|c|c|} \hline \square & \square & \square \\ \hline \square & & \\ \hline \end{array} &
 \begin{array}{|c|c|} \hline \square & \square \\ \hline \square & \square \\ \hline \end{array} &
 \begin{array}{|c|c|} \hline \square & \square \\ \hline \square & \\ \hline \square & \\ \hline \end{array} &
 \begin{array}{|c|} \hline \square \\ \hline \square \\ \hline \square \\ \hline \square \\ \hline \end{array} \\
 [4] & [3\ 1] & [2^2] & [2\ 1^2] & [1^4]
 \end{array} \tag{62}$$

where the boxes in each row stand for a cycle and different cycles form different rows in the diagram.

Since there are as many irreducible representations of a group as it has classes and there is one Young diagram for each class, Young diagrams can obviously be used to label each of the different irreducible representations. The dimensionality of the irreducible representation must pretty clearly be associated with the number of ways it is possible to put the objects 1, 2,... N into the boxes in the Young diagram, in a unique way. In fact it turns out that if the numbers 1, 2,... N are put into the boxes in a diagram so that when they are read across any row they are increasing and when they are read down any column they are also increasing, the totality of all such assignments is the dimension of the irreducible representation.

Thus the first diagram in Eq. 62 can only yield

$$\begin{array}{|c|c|c|c|} \hline 1 & 2 & 3 & 4 \\ \hline \end{array} \tag{63}$$

A Young diagram with numbers in it like (Eq. 63) is called a *Young tableau* and it is seen at once that there is only one tableau for the last Young diagram in Eq. 62, namely:

$$\begin{array}{|c|} \hline 1 \\ \hline 2 \\ \hline 3 \\ \hline 4 \\ \hline \end{array} \tag{64}$$

so that both [4] and [1⁴] correspond to one-dimensional irreducible representations.

The representation [3 1] yields

$$\begin{array}{|c|c|c|} \hline 1 & 3 & 4 \\ \hline 2 & & \\ \hline \end{array} \quad
 \begin{array}{|c|c|c|} \hline 1 & 2 & 4 \\ \hline 3 & & \\ \hline \end{array} \quad
 \begin{array}{|c|c|c|} \hline 1 & 2 & 3 \\ \hline 4 & & \\ \hline \end{array} \tag{65}$$

and in these circumstances it is clearly nice to have some sort of standard order; the one often adopted is to read the tableau across each row as if it were an ordinary number and then to arrange the tableaux in ascending order of these numbers, but other orders are used. Thus the numbers in Eq. 65 are

$$1342 \quad 1243 \quad 1234 \tag{66}$$

so that the standard order for the tableaux would be

$$\begin{array}{|c|c|c|} \hline 1 & 2 & 3 \\ \hline 4 & & \\ \hline \end{array}
 \quad
 \begin{array}{|c|c|c|} \hline 1 & 2 & 4 \\ \hline 3 & & \\ \hline \end{array}
 \quad
 \begin{array}{|c|c|c|} \hline 1 & 3 & 4 \\ \hline 2 & & \\ \hline \end{array}
 \tag{67}$$

This representation is therefore three-dimensional.

One can obviously get the tableaux for $[2 \ 1^2]$ simply by transposing the tableaux for $[3 \ 1]$ and a little reflection will show that this is generally the case, simply because of the structure of the Young diagrams. The representations $[2 \ 1^2]$ and $[3 \ 1]$ are said to be *conjugate* representations (or sometimes *adjoint*, or *dual* or *associated*). In the present case the representation $[2^2]$ is self-conjugate. Generally if the representation is denoted by $[\lambda]$ then the conjugate representation is denoted by $[\tilde{\lambda}]$, and of course both representations are of the same dimension.

Since there is obviously freedom in which is associated with which, the choice is made in the two one-dimensional cases that $[N]$ is associated with the symmetric representation and $[1^N]$ with the antisymmetric representation. Thus if one has a representation $[\lambda]$, then the conjugate representation $[\tilde{\lambda}]$ is just $[\lambda] \times [1^N]$.

The $[\lambda]$ symbols are also used to denote classes from time to time and in that context the correspondences established between Eqs. 62 and 59 are appropriate. Thus $[1^4]$ represents the last partition in Eq. 59 which is clearly the class that just contains the unit operator, $[2 \ 1^2]$ stands for the class containing all operators involving only one transposition and so on.

Now it can be shown that if one can find a basis for a representation $[\lambda]$ for the symmetric group and another basis which is a representation for $[\tilde{\lambda}]$ then the direct product of these two bases is a basis for the antisymmetric representation $[1^N]$. So to construct antisymmetric wavefunctions from space-spin products, as in constructing electronic wavefunctions, one can do so as

$$\Psi^{[1^N]} = \sum_i \Phi_i^{[\tilde{\lambda}]}(\mathbf{r}) \Theta_{S, M_S, i}^{[\lambda]}(s), \tag{68}$$

where the sum goes over all functions in the basis for the irrep and N identical particles are assumed involved. They can have any spins at all and although in the expression above they are assumed to be spin eigenfunctions this is obviously not necessary just as long as a suitable set of spin products is used. However if they are spin- $\frac{1}{2}$ particles then the only possible representations that can be constructed in the spin space are of the form $[\lambda_1, \lambda_2]$. No other irreps are possible. Furthermore in the case of N electrons properly coupled to a spin state S then

$$\lambda_1 + \lambda_2 = N, \quad \lambda_1 - \lambda_2 = 2S, \tag{69}$$

so that

$$\lambda_1 = \frac{N}{2} + \mathcal{S}, \quad \lambda_2 = \frac{N}{2} - \mathcal{S}, \quad (70)$$

where

Thus any allowed space wave functions, such as those formed from orbital products, must form a basis for $[\tilde{\lambda}]$.

This result arises basically because there are only *two* kinds of spin functions for spin- $\frac{1}{2}$ particles. Thus lots of permutations that *could* arise do not arise in practice because they are the same if they involve only, say, α spin particles. However it can also be shown that if the spin basis consists of spin eigenfunctions then the reps provided of \mathcal{S}_N are actually irreps and that they are the same irreps for any value of M_S . That is, there are *exactly* as many spin eigenfunctions with the same \mathcal{S} value as the dimension of the irrep $[\lambda_1, \lambda_2]$ of \mathcal{S}_N . This is an enormous blessing and makes life much easier in electronic structure calculations than it might otherwise be. For fermions of spin greater than $\frac{1}{2}$ it is not the case and it makes, for example, the problem of calculating statistical weights in molecular spectroscopy, or nuclear spin states in nuclear physics, much more complicated.

Point Groups and Transformations

In the Cartesian coordinate system, the Laplacian operator for the i th electron is written as

$$\nabla^2(i) = \frac{\partial^2}{\partial r_{xi}^2} + \frac{\partial^2}{\partial r_{yi}^2} + \frac{\partial^2}{\partial r_{zi}^2}, \quad (71)$$

and the inter-electron distance as

$$r_{ij} = \left(\sum_{\alpha} (r_{\alpha j} - r_{\alpha i})^2 \right)^{1/2}, \quad (72)$$

where here and hereafter sums over α run over x , y , and z . The electron-nucleus distance will be written as

$$r_{ai} = \left(\sum_{\alpha} (r_{ai} - a_{\alpha})^2 \right)^{1/2}, \quad (73)$$

where the α th coordinate of the nucleus a is written as a_{α} to emphasize that it is a pure number and not a variable, since the nuclear positions are assumed to be fixed.

It is easy to show that

$$r_{ij}^2 = (\mathbf{r}_j - \mathbf{r}_i)^T (\mathbf{r}_j - \mathbf{r}_i), \quad (74)$$

and

$$r_{ai}^2 = (\mathbf{r}_i - \mathbf{a})^T (\mathbf{r}_i - \mathbf{a}), \quad (75)$$

where the superscript T denotes the matrix transpose.

Now let it be supposed that \mathbf{r} is subject to positive rotation about the z -axis through an angle ϕ to yield the vector \mathbf{r}' . Positive rotations are in the direction of a right-handed screw-twist when the point of the screw is moving in the axis direction. It is then easy to show that the new and old vectors are related by an orthogonal matrix

$$\mathbf{r}' = \mathbf{R}(\phi) \mathbf{r}, \quad (76)$$

with

$$\mathbf{R}(\phi) = \begin{pmatrix} \cos \phi & -\sin \phi & 0 \\ \sin \phi & \cos \phi & 0 \\ 0 & 0 & 1 \end{pmatrix}. \quad (77)$$

In this section we shall be concerned only with transformations like (Eq. 77), that is, with *point transformations* and, in the case of the clamped nuclei Hamiltonian, consideration may be confined to *finite point groups*, specifically the crystallographic point groups. However from time to time it will be convenient to think a bit more generally and to recognize, for example, that the full rotation-reflection group in three dimensions is a point group, though an *infinite* one, and that some Hamiltonians are invariant under the operators of this group.

Now it should be understood quite clearly as to what happens in a transformation of variables in a fixed basis. It is supposed that *every* point in space goes over into its *image* according to the appropriate transformation rule

$$\mathbf{r}' = \mathbf{R}\mathbf{r}, \quad (78)$$

where \mathbf{R} is a constant orthogonal matrix.⁶

⁶By "constant" here is meant simply that the elements of the matrix are not themselves dependent on the variables.

Thus imagining the situation appropriate to the Schrödinger equation with Hamiltonian (Eq. 47), the assertion of a transformation of variables realized by \mathbf{R} would imply

$$\mathbf{r}'_i = \mathbf{R}\mathbf{r}_i, \quad i = 1, 2, \dots, N. \quad (79)$$

However, in the fixed nuclei approximation, it would *not* imply that

$$\mathbf{a}' = \mathbf{R}\mathbf{a}, \quad \mathbf{a} = \text{any nucleus.} \quad (80)$$

This is not for any sinister reason but simply because of the definition chosen of the clamped nuclei approximation. In this approximation the nuclear positions are triplets of numbers which take particular but fixed values once a particular basis is chosen.⁷

It is now very easy to show that the Laplacian and the inter-electronic distance are invariant under any constant orthogonal transformation of variables but that in general the electron-nucleus distances are not invariant. It is perhaps sensible to show how this comes about for it illustrates one or two points and makes the idea of *invariance* a bit clearer.

First the Laplacian. Using the chain rule for differentiation

$$\frac{\partial}{\partial r_{\alpha i}} = \sum_{\beta} \frac{\partial r'_{\beta i}}{\partial r_{\alpha i}} \frac{\partial}{\partial r'_{\beta i}}, \quad (81)$$

since the transformation does not “mix” \mathbf{r}_i and \mathbf{r}_j so that

$$\frac{\partial}{\partial r_{\alpha i}} = \sum_{\beta} R_{\beta\alpha} \frac{\partial}{\partial r'_{\beta i}}, \quad (82)$$

and hence

$$\frac{\partial}{\partial r_{\alpha i}^2} = \sum_{\gamma\beta} R_{\gamma\beta} R_{\beta\alpha} \frac{\partial^2}{\partial r'_{\gamma i} \partial r'_{\beta i}}, \quad (83)$$

but

$$\nabla^2(i) = \sum_{\alpha} \frac{\partial^2}{\partial r_{\alpha i}^2},$$

⁷It is sometimes convenient to think of the nuclear positions as *defining* a particular embedding for the basis vectors or coordinate frame.

and

$$\sum_{\alpha} R_{\gamma\alpha} R_{\beta\alpha} = \delta_{\gamma\beta} \quad (\mathbf{R}^T \mathbf{R} = E_3), \quad (84)$$

therefore

$$\nabla^2(i) = \sum_{\gamma\beta} \delta_{\gamma\beta} \frac{\partial^2}{\partial r'_{\gamma i} \partial r'_{\beta i}} = \sum_{\beta} \frac{\partial^2}{\partial r'_{\beta i}{}^2} = \nabla^2(i'). \quad (85)$$

But clearly if

$$\nabla^2(i) f(\mathbf{r}_i) = g(\mathbf{r}_i), \quad (86)$$

then

$$\nabla^2(i') f(\mathbf{r}'_i) = g(\mathbf{r}'_i), \quad (87)$$

so that $\nabla^2(i)$ is an invariant operator under the transformation since its effect on an arbitrary function is unchanged (except for the variable names which, in this context, are irrelevant). Notice that if ∇^2 had been set up in the primed system as $\nabla^2(i')$ the same argument would have shown that $\nabla^2(i') = \nabla^2(i)$, as required.

Next r_{ij} . From Eq. 78 it follows that

$$\mathbf{r}'_i = \mathbf{R} \mathbf{r}_i \quad \text{and} \quad \mathbf{r}_i = \mathbf{R}^T \mathbf{r}'_i. \quad (88)$$

Combining the form (Eqs. 74 with 88) we get

$$\begin{aligned} r_{ij}^2 &= \left(\mathbf{R}^T (\mathbf{r}'_j - \mathbf{r}'_i) \right)^T \left(\mathbf{R}^T (\mathbf{r}'_j - \mathbf{r}'_i) \right) \\ &= (\mathbf{r}'_j - \mathbf{r}'_i)^T \mathbf{R} \mathbf{R}^T (\mathbf{r}'_j - \mathbf{r}'_i) \\ &= (\mathbf{r}'_j - \mathbf{r}'_i)^T (\mathbf{r}'_j - \mathbf{r}'_i), \end{aligned}$$

so that

$$r_{ij}^2 = r'_{ij}{}^2, \quad (89)$$

showing that r_{ij}^2 and hence r_{ij} is invariant in the same sense as above.

For the electron-nucleus distance one gets

$$\begin{aligned} r_{ai}^2 &= (\mathbf{R}^T \mathbf{r}'_i - \mathbf{a})^T (\mathbf{R}^T \mathbf{r}'_i - \mathbf{a}) \\ &= (\mathbf{R}^T (\mathbf{r}'_i - \mathbf{R} \mathbf{a}))^T (\mathbf{R}^T (\mathbf{r}'_i - \mathbf{R} \mathbf{a})), \end{aligned}$$

so that

$$r_{ai}^2 = (\mathbf{r}'_i - \mathbf{R}\mathbf{a})^T (\mathbf{r}'_i - \mathbf{R}\mathbf{a}), \quad (90)$$

and this in general is obviously not $r_{ai}^{\prime 2}$. However, if the transformation \mathbf{R} is such that

$$\mathbf{b} = \mathbf{R}\mathbf{a} \quad \text{and} \quad \mathbf{a} = \mathbf{R}^T \mathbf{b}, \quad (91)$$

where \mathbf{b} is the position of another nucleus in the problem with the same charge as the nucleus whose position is \mathbf{a} , then it is clear that even though individual terms in the electron-nucleus attraction operator are *not* invariant, nevertheless the operator as a whole *is* invariant.

The generalization of this result is obvious. If the nuclear positions are divided into sets corresponding to nuclei of the same charge, the clamped nuclei Hamiltonian is invariant under all operators represented by orthogonal matrices \mathbf{R} such that if

$$\mathbf{b} = \mathbf{R}\mathbf{a}, \quad (92)$$

\mathbf{b} is to be found in the same set as \mathbf{a} was found.⁸

To look at it another way, were the coordinates of a set of equivalent nuclei to be written as a row matrix of the coordinates $\mathbf{a}_1 \mathbf{a}_2 \dots \mathbf{a}_p$ (so that the “row” is actually a $3 \times p$ matrix), the effect of an invariance preserving operator (a *symmetry* operator) could be symbolized in the partitioned matrix form

$$(\mathbf{b}_1 \mathbf{b}_2 \dots \mathbf{b}_p) = (\mathbf{a}_1 \mathbf{a}_2 \dots \mathbf{a}_p) \mathbf{P}, \quad (93)$$

where \mathbf{P} is a $p \times p$ permutation matrix, that is, one of the form

$$\mathbf{P} = \begin{pmatrix} 0 & 1 & 0 & 0 & \dots & 0 \\ 1 & 0 & 0 & 0 & \dots & 0 \\ \dots & \dots & \dots & \dots & \dots & \dots \\ \dots & \dots & \dots & \dots & \dots & \dots \\ 0 & 0 & 1 & 0 & \dots & 0 \end{pmatrix}, \quad (94)$$

where the permutation corresponds to the effective rearrangement of the nuclei in the electron-nucleus attraction operator. Permutation matrices have just one nonzero entry in any row or column and that entry is always 1 so that such matrices are always orthogonal matrices. Their determinant can, however, be ± 1 depending on the *parity* of the permutation.

⁸Notice that in this approximation the *mass* of the nucleus is of no consequence, only the charge matters.

Thus, to all intents and purposes, when considering the symmetry of a molecule to be represented by a clamped nuclei Hamiltonian, all we need to look at is those orthogonal operators that let equivalent nuclear positions carry a permutation representation of the operator in question. Any such operator is a symmetry operator of the problem. We thus never need to think about the electrons and it is usual in elementary books to start from the point reached here, as if the operations were carried out on the nuclear positions. From here one can go on to show, in the usual way, that the collection of symmetry operators form a group and that the group is a *point group* essentially corresponding to the geometrical figure formed by the equivalent nuclei in the nuclear framework.

Functions can always be visualized in terms of a fixed Cartesian basis and under the change (assumed orthogonal) $\mathbf{r}' = \mathbf{R}\mathbf{r}$ or $\mathbf{r} = \mathbf{R}^T\mathbf{r}'$ the change *induced* in a function $f(\mathbf{r})$ is

$$\mathbf{O}_R f(\mathbf{r}) = \overline{f}(\mathbf{r}) \equiv f(\mathbf{R}^T\mathbf{r}), \quad (95)$$

meaning that $\overline{f}(\mathbf{r})$ is constructed from $f(\mathbf{r})$ by substituting $(\mathbf{R}^T\mathbf{r})_\alpha$ wherever it occurs in the prescription for $f(\mathbf{r})$. \mathbf{O}_R symbolizes the operation in function space.

Considering the transformation of operators again, assuming that one specifies the operator form in a fixed basis, consider an operator \mathbf{A} (assumed linear and Hermitian) such that

$$\mathbf{A}f(\mathbf{r}) = g(\mathbf{r}), \quad (96)$$

and by formal operator algebra we can rewrite this to exhibit the effect of the operator \mathbf{O}_R as

$$\begin{aligned} \mathbf{O}_R \mathbf{A} f(\mathbf{r}) &= \mathbf{O}_R g(\mathbf{r}), \\ \mathbf{O}_R \mathbf{A} f(\mathbf{r}) &= \mathbf{O}_R \mathbf{A} \mathbf{O}_R^{-1} \mathbf{O}_R f(\mathbf{r}) = \mathbf{O}_R g(\mathbf{r}), \\ \mathbf{O}_R \mathbf{A} f(\mathbf{r}) &= \mathbf{O}_R \mathbf{A} \mathbf{O}_R^{-1} \overline{f}(\mathbf{r}) = \overline{g}(\mathbf{r}), \end{aligned} \quad (97)$$

so that we can say that if R induces \mathbf{O}_R then it induces a change in the operators acting on the original function space such that

$$\overline{\mathbf{A}} = \mathbf{O}_R \mathbf{A} \mathbf{O}_R^{-1}, \quad (98)$$

where the functions on which the operators act are implicit in the formalism.

Furthermore if the induced change is such that $\mathbf{A} = \overline{\mathbf{A}}$, that is, \mathbf{A} is an invariant operator, then

$$\mathbf{A} = \mathbf{O}_R \mathbf{A} \mathbf{O}_R^{-1}, \quad (99)$$

or

$$\mathbf{O}_R \mathbf{A} = \mathbf{A} \mathbf{O}_R,$$

or

$$\mathbf{O}_R \mathbf{A} - \mathbf{A} \mathbf{O}_R \equiv [\mathbf{O}_R \mathbf{A}] = 0,$$

and we say that the \mathbf{O}_R commute with \mathbf{A} . We can thus characterize the symmetry operators in the function space that constitutes the domain of \mathbf{A} as those operators which commute with \mathbf{A} . In particular we are interested in the case when \mathbf{A} is the Hamiltonian for the problem.

Now, in practice, (Eq. 98) is not of much use for actually checking on the transformation properties of operators since it does not actually provide a specific rule for the construction of $\bar{\mathbf{A}}$. However as seen before, the actual variable names in an operator relation do not matter, so that if we regard $\mathbf{R}^T \mathbf{r}$ as just a new variable name, say \mathbf{y} , then it follows immediately from Eqs. 96 and 97 that $\bar{\mathbf{A}}$ is just the operator \mathbf{A} made up in the same basis as \mathbf{A} but with $(\mathbf{R}^T \mathbf{r})_\alpha$ for every occurrence of r_α in the operator. This prescription is usable in an obvious way for multiplicative terms in the operator and, for derivative terms, a little thought shows that the replacement

$$\frac{\partial}{\partial r_\alpha} \rightarrow \sum_\gamma (\mathbf{R}^T)_{\alpha\gamma} \frac{\partial}{\partial r_\gamma} = \sum_\gamma R_{\gamma\alpha} \frac{\partial}{\partial r_\gamma} \quad (100)$$

is the appropriate one for the new operator set up on the original basis. (Compare with Eqs. 81 and 82.)

Thus we see that the momentum operator, for example, is not generally an invariant operator since from (Eq. 100)

$$\begin{aligned} \bar{p}_\alpha &= \frac{\hbar}{i} \sum_\gamma R_{\gamma\alpha} \frac{\partial}{\partial r_\gamma} = \sum_\gamma R_{\gamma\alpha} p_\gamma, \\ \bar{p}_\alpha &= (\mathbf{R}^T \mathbf{p})_\alpha, \end{aligned} \quad (101)$$

and (Eq. 101) is the equation that relates the elements of the transformed operator to those of the untransformed operator on a fixed basis. In fact it is easy to see from (Eq. 101) that in this case the operators actually provide a basis for the representation of R by \mathbf{R} as

$$\bar{\mathbf{p}} = \mathbf{p} \mathbf{R}, \quad (102)$$

where the operators are written as a row matrix. The transformation of operators is a matter to which we shall return later, but for the moment let it simply be noted that the arguments presented earlier in this section show that the clamped nuclei

Hamiltonian H is an invariant operator if R is a point group operation and we shall now look at the behavior of its eigenfunctions under O_R .

Any set of degenerate eigenfunctions of H carry a matrix representation of O_R . Thus if we denote the set of degenerate eigenfunctions as f_1, f_2, \dots, f_n and treat these as a row matrix f , then we can write

$$O_R f = f O_R, \quad (103)$$

and we say that O_R provides a matrix representation of O_R in the basis f_i so that a set of such functions in a function space play exactly the same role as do the unit vectors in a coordinate space and are, therefore, sometimes called *basis functions* of the representation.

The representations provided in the basis of degenerate eigenfunctions are usually irreducible and can be chosen to be unitary matrices (in fact usually orthogonal matrices if the functions are real functions). In practice, what one is usually faced with is a collection of functions which have arbitrary (but known) transformation properties and what one actually wants to do is to adapt these functions so that they actually transform like the true eigenfunctions of the problem. This can be done by means of the group theoretical projection operator.

If the unitary matrix irreducible representation of the point group is known and denoted by $\mathbf{D}^{(\mu)}(R)$, where μ labels the irreducible representation, then the projection operator is

$$P_{ij}^{(\mu)} = \frac{n_\mu}{g} \sum_R \left(\mathbf{D}^{(\mu)}(R) \right)_{ij}^* O_R, \quad (104)$$

where g is the order of the group and n_μ the dimension of $\mathbf{D}^{(\mu)}(R)$.⁹ This projection operator is such that

$$P_{ij}^{(\mu)} f = f_i^{(\mu)} \quad \text{or a null result,} \quad (105)$$

where f is an arbitrary function and $f_i^{(\mu)}$ is the i th function in the row matrix $f^{(\mu)}$ such that

$$O_R f^{(\mu)} = f^{(\mu)} \mathbf{D}^{(\mu)}(R). \quad (106)$$

The null result occurs in Eq. 105 if the arbitrary function has no component that lies in the subspace defined by the $f^{(\mu)}$.

In practice one often makes do with the character projection operator based on the characters $\chi^{(\mu)}$ of the irreducible representation,

⁹The operator in this form is clearly only possible for finite groups but similar operators are constructible for most infinite groups of interest.

$$\chi^{(\mu)}(R) = \sum_i \left(D^{(\mu)}(R) \right)_{ii}^*, \quad (107)$$

so that the character projection operator $\mathbf{P}^{(\mu)}$ is

$$\mathbf{P}^{(\mu)} = \frac{\eta^{(\mu)}}{g} \sum_R \left(\chi^{(\mu)}(R) \right)^* \mathbf{O}_R, \quad (108)$$

and produces from an arbitrary function (if not a null result) then a function which is said to *belong* to the μ th irreducible representation but which in general transforms like a linear combination of the basis functions for $\mathbf{D}^{(\mu)}$.

In practice, therefore, everything depends on knowing the representations of the group in question (and the irreducible representations are usually tabulated) and on knowing how the chosen functions actually transform under the operations of the group.

It is helpful at this stage to think of constructing MOs as a linear combination of atomic orbitals (LCAOs) and as a preliminary to this the idea of an MO and of an AO need to be developed a bit further.

It might be thought that orbitals could be best determined by solving the relevant one-electron problem specified by \mathbf{h} , (Eq. 49), for each molecule. This is not so easily done and if a wavefunction is constructed as a determinant of spin-orbitals so constructed it yields a very poor approximation to the electronic energy. This is because the electron interaction term is large and has not been considered in constructing the orbital. Thus to get useful orbitals the fact that the electrons interact strongly must somehow be incorporated into the single particle potential through some sort of effective field process. This was first attempted for atoms in the 1920s by W. Hartree and D. R. Hartree (1927; 1936) but without considering antisymmetry. Their method was developed by Fock (1930) and by Slater (1930) in a properly antisymmetric form. Molecules resisted this approach because it was extremely difficult to solve the one-electron problem with a potential that was not centrosymmetric. However since it was possible to get atomic orbitals, two approaches using them developed, one at the hands of Pauling (1939) using atomic orbitals directly and the other at the hands of Mulliken (1931) by writing molecular orbitals as a linear combination of atomic orbitals. The Pauling approach was called the Valence Bond (VB) method and the Mulliken one the Linear Combination of Atomic Orbitals Molecular Orbital (LCAO MO) method. Although it was the VB method that was used in the first successful molecular electronic structure calculation, on H_2 by Heitler and London (1927), it was the LCAO MO method that became standard in quantum chemical calculations following the work of Roothaan (1951) in the 1950s. Although these methods will be considered in great detail elsewhere in this volume, their basis can best be considered here.

The most familiar atomic orbitals are those for the hydrogen atom which are usually designated according to their angular parts as s for $l=0$, p for $l=1$, d for $l=2$, and so on where there are $2l+1$ orbitals of each type. For calculational

purposes Slater proposed that the radial part of the orbital, while still centered upon the nucleus, should be of the form

$$Nr^{n-1} \exp -\xi r, \quad n = 1, 2, \dots, \quad (109)$$

where N is a normalizing factor, and ξ may be chosen at will or used as a variational parameter.

It is customary to use a real form for the angular parts of the orbital so that, for example, the three p orbitals are specified as

$$x \exp -\xi r, \quad y \exp -\xi r, \quad z \exp -\xi r. \quad (110)$$

The most widespread atomic orbital form in use at present is the Gaussian which has the radial part

$$Nr^{n-1} \exp -\xi r^2, \quad n = 1, 2, \dots. \quad (111)$$

When it is not necessary to specify atomic orbitals in detail they will be denoted $\eta_i(\mathbf{r})$.

In elementary books it is often assumed that you can “eye-ball” the transformation properties from the “pictures” of the orbitals stuck on the nuclei. (Such pictures usually look a bit like twisted sausages and doughnuts.) Such an approach is a bit risky and knowing how to do this sort of thing algebraically avoids getting into the nasty mess that often happens if one relies on the pictures. Indeed, it is clear that it is quite impossible to draw a picture of an orbital. The sausages and doughnuts, therefore, must be at most projection representations in three (or two) dimensions and it is not clear that the transformation of the picture in three (or two) dimensions really corresponds correctly to the induced transformation of the orbital in the function space.

If the atomic orbital $\eta(\mathbf{r})$ is situated at the origin of coordinates and the origin is the invariant point of the point group operators, then any orbital constructed about this origin simply transforms under \mathbf{O}_R to a new functional form in the space

$$\mathbf{O}_R \eta(\mathbf{r}) = \bar{\eta}(\mathbf{r}) = \eta(\mathbf{R}^T \mathbf{r}). \quad (112)$$

If, however, the orbital is developed about another origin, say \mathbf{a} , so that the functional form is

$$\eta((\mathbf{r} - \mathbf{a})), \quad (113)$$

then the situation is a little more involved. The coordinate point \mathbf{a} is not a variable of the problem, but a parameter in the function construction. It does not change under the transformation so that

$$\begin{aligned} \mathbf{O}_R \eta((\mathbf{r} - \mathbf{a})) &= \eta((\mathbf{R}^T \mathbf{r} - \mathbf{a})) \\ &= \eta(\mathbf{R}^T (\mathbf{r} - \mathbf{Ra})), \end{aligned} \quad (114)$$

but clearly \mathbf{Ra} is some other fixed parameter point in the problem \mathbf{b} , say, so that

$$\begin{aligned} \eta(\mathbf{R}^T (\mathbf{r} - \mathbf{Ra})) &= \eta(\mathbf{R}^T (\mathbf{r} - \mathbf{b})) \\ &= \eta(\mathbf{R}^T \mathbf{r}_b). \end{aligned} \quad (115)$$

Effectively the origin of the function is changed, but about that new origin, the transformed function is constructed by the usual rules in terms of the variable $\mathbf{r}_b = (\mathbf{r} - \mathbf{b})$. Clearly if $\eta(\mathbf{R}^T \mathbf{r})$ is $\bar{\eta}(\mathbf{r})$ then $\eta(\mathbf{R}^T \mathbf{r}_b)$ will be $\bar{\eta}(\mathbf{r}_b)$ so that if one has worked out the transformation properties of an orbital at the origin ($a = 0$) then the functional form of the transformed orbital carries over immediately to an orbital at arbitrary point \mathbf{a} given that $\mathbf{b} = \mathbf{Ra}$ is known.

Thus if one chooses a set of AOs which are identical but on different centers then they carry a permutation representation of the operation, much like (Eq. 94) but with appropriate transformation matrices in place of the 0 s and 1 s there. So if, for example, one had a set of identical s-orbitals with one on each center, the transformation matrices under any point group operation would just be 1, so that the matrix would remain just as in Eq. 94. But if one had a set of three equivalent p-functions on each center the 0 s would become 3×3 null matrices and the 1 s would become those three-dimensional transformation matrices which represent the operation on a set of three equivalent p-functions at the origin and so on.

Once these transformation properties have been determined it is an easy matter to apply the projection operator either to construct functions that transform like irreducible representations or like a “special” representation.

Thus in practice we can always get one-particle symmetry functions relatively easily, but the symmetry problem is clearly more involved when it comes to considering many-particle functions.

The paradigm for an approximate many-particle function is a product of one-particle functions (*orbitals*)

$$\Phi(\mathbf{r}_1, \mathbf{r}_2, \mathbf{r}_3, \dots, \mathbf{r}_N) = \phi_1(\mathbf{r}_1) \phi_2(\mathbf{r}_2) \dots \phi_N(\mathbf{r}_N). \quad (116)$$

In thinking of approximate solutions to the clamped nuclei problem it is natural to think of the ϕ_r as molecular-orbitals and the \mathbf{r}_i as the electron variables, but the discussion that follows is quite general and it need not even be the case that the variables are those of identical particles. Now from what has been said before it can always be supposed that the orbitals are adapted to particular irreducible representations of the invariance group of the Hamiltonian and that one desires an approximate solution which is also adapted to a particular irreducible representation. The variable-space for the product function on the right-hand side of Eq. 116 is the *direct sum* of each of the variable-spaces for the particles, that is

$\mathbf{r}_1 \oplus \mathbf{r}_2 \oplus \mathbf{r}_3 \oplus \dots \oplus \mathbf{r}_N$. The functions ϕ_r built on each of these variable-spaces individually constitute a separate function space for each variable and the total function space is, therefore, the *direct product* of all these function spaces. If, for the moment, we restrict each of these function spaces to sufficient functions to carry irreducible representations of the invariance group, then the direct product function space is just

$$\phi^{(1)} \otimes \phi^{(2)} \otimes \dots \otimes \phi^{(N)}, \quad (117)$$

where the row matrix $\phi^{(1)}$ contains ϕ_1 and is a basis for the representation $\mathbf{D}^{(1)}$, of dimension n_1 , and so on, so that the total dimension of the space is $n_1 \times n_2 \times \dots \times n_N = P$.

The symmetry operation \mathbf{R} has an orthogonal representative \mathbf{R} in each of the variable-spaces and it has a representative in the total variable-space which is the direct sum of N repeats of \mathbf{R} .

Thus the effect of \mathbf{O}_R on the product function (Eq. 117) is to produce

$$\phi^{(1)}\mathbf{D}^{(1)}(R) \otimes \phi^{(2)}\mathbf{D}^{(2)}(R) \dots \phi^{(N)}\mathbf{D}^{(N)}(R), \quad (118)$$

which, by the ordinary rules of manipulation for direct products, is

$$\phi^{(1)} \otimes \phi^{(2)} \otimes \dots \otimes \phi^{(N)} \mathbf{D}^{(1)}(R) \otimes \mathbf{D}^{(2)}(R) \dots \otimes \mathbf{D}^{(N)}(R). \quad (119)$$

The elements of the row matrix arising from the direct product of the orbitals can obviously be written (with suitable reordering if necessary) as a row matrix of functions like (Eq. 116) but involving such other partner orbitals as are necessary.

Now if it happens that *all* the original orbitals belong to *one*-dimensional irreducible representations of the invariance group, then the matrix of direct products of representations in Eq. 119 is just a scalar, generally speaking ± 1 , so that, in this case, Φ obviously belongs to an irreducible representation of the invariance group of the problem. Otherwise the matrix of direct products of representations generally constitutes a *reducible* representation of the invariance group and in this case the product function (Eq. 116) and its partners do not, generally, carry an irreducible representation of the point group and must be suitably adapted to do so.

There are clearly two possible ways in which this might be done. One could start off from Φ and project out the required components, or one could recognize that there is a matrix relationship between the unadapted set and the adapted set and try to determine the matrix elements from group theoretical arguments. Both approaches have their uses but since the second approach has not yet been considered, it is appropriate to speak of it now.

If, for the moment, we consider the direct product of just two irreducible representations, then it follows at once, from the character orthogonality theorem, that we can write down the number of times that any irreducible representation occurs in the reduction of the direct product representation. If we are thinking of representations μ and ν in the direct product and σ as the resulting representation,

let us call this number $(\mu\nu\sigma)$. It is zero or an integer and of course it is known once the character table for all the irreducible representations of a group are known. This means that we can find a transformation \mathbf{U} such that

$$\mathbf{U}^\dagger \mathbf{D}^{(\mu)} \otimes \mathbf{D}^{(\nu)} \mathbf{U} = \sum_{\sigma} (\mu\nu\sigma) \mathbf{D}^{(\sigma)}, \quad (120)$$

where a direct sum is implied on the right-hand side, which runs over all the representations in the group. In Eq. 120 it is assumed that the representations $\mathbf{D}^{(\mu)}$, etc., are unitary so that from the definition of the direct product, $\mathbf{D}^{(\mu)} \otimes \mathbf{D}^{(\nu)}$ is unitary and can, therefore, be reduced to irreducible form by means of a unitary transformation.

Now if we denote by $\phi^{(\sigma)}$ the row of n_{μ} basis functions for $\mathbf{D}^{(\mu)}$, then the set of $n_{\sigma} = n_{\mu}n_{\nu}$ product functions $\phi^{(\mu)} \otimes \phi^{(\nu)}$ are a basis for the direct product representations and clearly the set of product functions $\phi_s^{(\sigma)}$, $s = 1, 2, \dots, n$ defined by

$$\phi^{(\sigma)} = \phi^{(\mu)} \otimes \phi^{(\nu)} \mathbf{U} \quad (121)$$

are a basis for the reduced representation on the right-hand side of Eq. 120. It is usual to rewrite (Eq. 121) in the form

$$\phi_s^{(\sigma)} = \sum_{i,j} \phi_i^{(\mu)} \phi_j^{(\nu)} (\mu i, \nu j | \sigma s), \quad (122)$$

and refer to the elements of the unitary matrix in Eq. 122 as *vector-coupling* or *Clebsch–Gordan* coefficients.

Care is needed here, because if $(\mu\nu\sigma)$ is zero then clearly (Eq. 122) makes no sense, but this can be taken care of at the formal level by defining the vector-coupling coefficient as zero if $(\mu\nu\sigma)$ is zero. There is also obviously some ambiguity if $(\mu\nu\sigma)$ is greater than one and it will then be necessary to define some standard ordering. But nevertheless, the ideas are clear enough. The point is that if the irreducible representations of the groups are known then it is always possible to discover the vector coupling coefficients and hence to synthesize product functions that carry irreducible representations. This process is often called vector-coupling and obviously having coupled a pair of functions one can then couple another one to that pair and so on. This technique finds its principal use in dealing with the construction of eigenfunctions of the rotation group, but it is a quite general procedure.

There are many different notations for the vector-coupling coefficients and great care must be exercised in determining just which convention a particular book is using, but it is perhaps appropriate to note that there is a common, pretty standard, notation in terms of the *Wigner 3-j* symbol defined, in our particular notation, so that (with the Wigner symbol as the object in brackets on the right-hand side)

$$(\mu i, \nu j | \sigma s)^* = [\sigma]^{1/2} \begin{pmatrix} \mu & \nu & \sigma \\ i & j & s \end{pmatrix}, \quad (123)$$

where $[\sigma]$ is the dimensionality of the σ th irreducible representation. There are, obviously, different sets of 3- j symbols for every group, but the ones most commonly tabulated are those for the three-dimensional rotation group; they are also available for the crystallographic point groups. Whether one chooses synthetic or projective methods to construct many-particle symmetry functions is a matter of choice in any given problem.

Having considered the transformation properties of functions, consider how these properties may be used in the construction of matrix elements of operators and, from this, consider again how operators themselves transform.

Consider the matrix elements of an arbitrary operator \mathbf{A} between two functions. We symbolize the matrix element A_{12} by

$$A_{12} = \int \phi_1^*(\mathbf{x}) \mathbf{A} \phi_2(\mathbf{x}) d\mathbf{x}, \quad (124)$$

where the integral is a definite one over all space and over all coordinates and where $d\mathbf{x}$ symbolizes the appropriate volume element. Since the variables of integration are dummy we may also write

$$A_{12} = \int \phi_1^*(\mathbf{y}) \mathbf{A}' \phi_2(\mathbf{y}) d\mathbf{y}, \quad (125)$$

where \mathbf{A}' symbolizes \mathbf{A} made up with \mathbf{y} just as \mathbf{A} was made up with \mathbf{x} . But now let it be supposed that \mathbf{y} corresponds to a variable change induced by a transformation so that $\mathbf{y} = \mathbf{R}^T \mathbf{x}$. Then

$$A_{12} = \int \bar{\phi}_1^*(\mathbf{x}) \bar{\mathbf{A}} \bar{\phi}_2(\mathbf{x}) |\mathbf{R}| d\mathbf{x}, \quad (126)$$

where $\bar{\mathbf{A}}$ is the transformed operator as in Eq. 98 and $\bar{\phi}_i$ the transformed function as in Eq. 95. $|\mathbf{R}|$ is the Jacobian of the transformation and since the matrix \mathbf{R} is orthogonal, $|\mathbf{R}|$ is ± 1 . If it is -1 then it can be shown that the signs of the limits change also so that the integral is unchanged and thus $|\mathbf{R}|$ can always be treated as $+1$. Thus (Eq. 126) may be rewritten as

$$A_{12} = \int \bar{\phi}_1^*(\mathbf{x}) \bar{\mathbf{A}} \bar{\phi}_2(\mathbf{x}) d\mathbf{x}. \quad (127)$$

Now assume for a moment that \mathbf{A} is \mathbf{H} then of course $\bar{\mathbf{A}}$ is also \mathbf{H} if \mathbf{R} is a symmetry operator of the problem; thus it is the case that

$$\int \phi_1^* \mathbf{H} \phi_2 d\mathbf{x} = \int \bar{\phi}_1^* \mathbf{H} \bar{\phi}_2 d\mathbf{x}. \quad (128)$$

But suppose it turned out that

$$\bar{\phi}_1 \equiv \mathbf{O}_R \phi_1 = -\phi_1, \quad (129)$$

and

$$\bar{\phi}_2 \equiv \mathbf{O}_R \phi_2 = \phi_2,$$

then one would have proved that

$$\int \phi_1^* \mathbf{H} \phi_2 \, d\mathbf{x} = - \int \phi_1^* \mathbf{H} \phi_2 \, d\mathbf{x}, \quad (130)$$

and clearly the only way for this to happen is for the integral to vanish. This is a familiar result as is its generalization, namely, that if ϕ_1 is a basis function for a particular irreducible representation and ϕ_2 is one for another irreducible representation, then the matrix element vanishes unless the direct product of these two representations is reducible to a direct sum of representations which includes the totally symmetric (unit) representation. It should be remembered that although the integral certainly vanishes if the totally symmetric representation is absent, even if this representation is present, the integral could also vanish, for reasons other than the symmetry considered. Thus in the context of the selection rules based on the matrix elements one can say that a particular transition is *forbidden* by symmetry, one cannot say that it is *allowed* by symmetry.

Spin and Point Group Symmetry

So far spin has not been considered explicitly. It is usual to ignore it in discussions of point group symmetry because the total spin operator is invariant under all point group transformations and the axis orientation is defined by the fixed frame choice so there is a fixed internal choice for the z -axis. Thus it is regarded as sufficient to require that the spatial part of any trial function has the correct point group symmetry and then to form properly antisymmetric functions from the spatial parts and the spin eigenfunctions in the manner outlined earlier. If orbitals are used to construct the spatial part, then it is usual simply to extend the symmetry orbitals to become symmetry spin-orbitals. Returning to the functional form used in Eq. 116 this would become

$$\Phi(\mathbf{x}_1, \mathbf{x}_2, \mathbf{x}_3, \dots, \mathbf{x}_N) = \mathbf{A} \phi_1(\mathbf{x}_1) \phi_2(\mathbf{x}_2) \dots \phi_N(\mathbf{x}_N), \quad (131)$$

where \mathbf{A} is the projection operator for the antisymmetric representation of the symmetric group of the electrons. It is usually just called the *antisymmetrizer*:

$$\mathbf{A} = \frac{1}{N!} \sum_p \in p \mathbf{O}_p,$$

where \mathbf{O}_p is the permutation operator and \mathbf{O}_p is the parity of the permutation. \mathbf{O}_p operates on the electronic variables and should thus be associated with

the inverse of a particular permutation. However since the symmetric group is ambivalent and the representation of interest is one-dimensional this is a distinction without a difference. In the case above where the initial function is an orbital product, the operator can equally well be treated as if it operated on the orbital index.

The space parts of the spin-orbitals ϕ_i and ϕ_j can be the same if the spin parts are different. If any two spin-orbitals are the same the projected function simply vanishes. This vanishing is the basis of what is usually called the ‘‘Pauli exclusion principle.’’ The function (Eq. 131) is clearly a determinant of spin-orbitals with the spin-orbital index designating a row (column) and the electron numbering designating a column (row). This was first recognized by Slater and so such determinants are called *Slater determinants* and often denoted by the shorthand

$$M |\phi_1(\mathbf{x}_1) \phi_2(\mathbf{x}_2) \dots \phi_N(\mathbf{x}_N)|,$$

where M is a normalizing factor.

Such Slater determinants are not themselves always spin eigenfunctions but they are eigenfunctions of S_z . They can be either coupled or projected to yield spin eigenfunctions for a particular M_s value and the resulting functions can then be further projected by the step-up operator

$$S_+ = S_x + iS_y$$

to produce functions with $M_s + 1$ or the step-down operator

$$S_- = S_x - iS_y$$

to produce functions with $M_s - 1$.

The presence of spin in the trial function does not modify the previous point group symmetry discussion. However the requirements of spin and permutational symmetry may mean that a trial function is constrained so that it might not be possible to have a trial function with a particular point group symmetry and a specified spin symmetry. As an example consider a determinant of doubly occupied orbitals for four electrons symbolized as

$$M |\phi_1(\mathbf{r}_1) \alpha(s_1) \phi_1(\mathbf{r}_2) \beta(s_2) \phi_2(\mathbf{r}_3) \alpha(s_3) \phi_2(\mathbf{r}_4) \beta(s_4)|.$$

This determinant is a spin eigenfunction with $S = 0$. If the orbitals are point group symmetry orbitals, the only possible symmetry of the many particle function is that generated by the direct product of each orbital symmetry with itself followed by the direct product of the resulting symmetries. If the orbitals belong to one-dimensional irreps then the many particle function must belong to the totally symmetric representation of the point group. It is not possible to represent other symmetries with a function of this form.

The Construction of Approximate Eigenfunctions of the Clamped Nuclei Hamiltonian

The basic mathematical tool used in the construction of approximate eigenfunctions is the variation theorem. This theorem asserts that for any square integrable function Φ which is of a definite and allowed symmetry for the Hamiltonian, the quotient

$$\frac{\int \Phi^* H \Phi d\mathbf{x}}{\int \Phi^* \Phi d\mathbf{x}} = E \geq E_f, \quad (132)$$

where E_f is the lowest energy of the particular symmetry. The function Φ is chosen to contain parameters which can be varied to minimize E to make it as close as possible to E_f . The function is usually scaled so that the denominator in the quotient is unity and the function with this scaling is said to be *normalized to unity* or just to be *normalized*. If Φ is chosen as a linear combination of functions with the coefficients as the parameters then minimizing E leads to a secular problem the roots of which are upper bounds not only to the lowest states of the particular symmetry, but to excited states of increasing energy. At this stage the secular problem can be approximated and approximations to the eigenfunctions can be developed by perturbation theory.

It is usual to construct approximate solutions to the electronic Schrödinger equation in terms of functions composed of spin-orbitals $\phi_r(\mathbf{x})$. In general it is supposed that we have available a set of m ($\geq N$) orbitals $\phi(\mathbf{r})$ and to each of these we attach an $\alpha(s)$ or $\beta(s)$ spin factor function to form the spin-orbitals. When we write \mathbf{x} as a variable designation we shall in future mean space *and* spin variables collectively. We can write formally

$$(\phi_1 \dots \phi_{2m}) = (\alpha\beta) \times (\phi_1 \dots \phi_m) \equiv \phi = \sigma \times \phi, \quad (133)$$

where \times denotes the standard direct (or Kronecker) product of matrices.

The N -electron functions Φ_k are composed of Slater determinants of N spin-orbitals or perhaps as a fixed linear combination of a number of such determinants. The matrix elements of H between such functions can be written in terms of one- and two-electron integrals over the spin-orbitals thus

$$H_{kl} \equiv \langle \Phi_k | H | \Phi_l \rangle = \sum_{rs} {}^{kl} Q_{rs}^1 \langle \phi_r | h | \phi_s \rangle + \frac{1}{2} \sum_{rstu} {}^{kl} Q_{rs,tu}^1 \langle \phi_r \phi_s | g | \phi_t \phi_u \rangle, \quad (134)$$

where the sums go over all spin-orbitals and where ${}^{kl} Q_{rs}^1$ and the ${}^{kl} Q_{rs,tu}^2$ are simple coefficients sometimes called *projective reduction coefficients* or *coupling coefficients* or alternatively one- and two-particle *density matrix elements*. These coefficients will of course be zero if any of the spin-orbitals shown in their indices do not occur in the pair of functions considered. The notation for the one and two-electron integrals is conventional,

$$\langle \phi_r | h | \phi_s \rangle = \int \phi_r^*(\mathbf{r}) h \phi_s(\mathbf{r}) d\mathbf{r}, \quad (135)$$

and

$$\langle \phi_r \phi_s | g | \phi_t \phi_u \rangle = \int \phi_r^*(\mathbf{r}_1) \phi_s^*(\mathbf{r}_2) g(\mathbf{r}_1, \mathbf{r}_2) \phi_t(\mathbf{r}_1) \phi_u(\mathbf{r}_2) d\mathbf{r}_1 d\mathbf{r}_2. \quad (136)$$

Similarly the overlap matrix elements can be written as

$$M_{kl} = \langle \Phi_k | \Phi_l \rangle = N^{-1} \sum_{rs}^{kl} Q_{rs}^1 \langle \phi_r | \phi_s \rangle. \quad (137)$$

Now let it be supposed that from a given set of spin-orbitals all possible functions Φ_k are constructed and that the resulting set has M members. The best wavefunctions that could be obtained from such a set would be a linear combination of these M terms with coefficients determined using the variation theorem. Use of the variation theorem on such a set leads to the familiar secular problem

$$H - EM | = 0 \quad (138)$$

whose solutions give M eigenvalues $E_1 \leq E_2 \leq E_3 \dots \leq E_M$ each of which is an upper bound to the first, second, third, and so on exact solution of the electronic Schrödinger problem.

In the special case where the spin-orbitals are orthonormal and the trial functions are Slater determinants the expressions for the projective reduction coefficients are both simple and limited, given by Slater's rules to be discussed in detail in later chapters in this work. With such a choice there are Hamiltonian matrix elements between functions that differ from each other only in two or fewer orbitals and $M_{kl} = \delta_{kl}$. The expressions for these coefficients when the orbitals are not orthogonal involve the overlap integrals S_{ij} between all the orbitals in the functions and there is no limitation on orbital differences between the functions and M_{kl} is not the unit matrix. Every electronic permutation must be considered in their evaluation. For non-orthogonal orbitals it is thus much more difficult to consider systems with more than a few electrons and, because atomic orbitals on different centers are not orthogonal, this difficulty has hindered the development of VB theory in a quantitative manner until very recently. An account of modern VB developments forms a later part of this handbook. Usually LCAO MOs are developed so as to be orthogonal so that given

$$\phi_i = \sum_{p=1}^m \eta_p C_{pi} \quad i = 1, 2, 3, \dots, m, \quad (139)$$

to evaluate the two-electron integral $\langle \phi_i \phi_j | g | \phi_k \phi_l \rangle$ involves evaluating all the two-electron integrals $\langle \eta_r \eta_s | g | \eta_t \eta_u \rangle$ and summing. To transform all the two-electron integrals would seem at first sight to involve m^8 multiplications and additions and thus put it beyond computational possibility for anything other than a small number of orbitals. However it actually needs operations only of the order of m^4 , which is bad enough, but can be dealt with.

Although it proved possible to develop the LCAO method with Slater orbitals for diatomic molecules, the evaluation of two-electron integrals when the atomic orbitals were centered on three or four distinct nuclei proved very difficult and is not, even now, commonly undertaken. However it proved possible by the use of Gaussian functions, as pioneered by McWeeny (1950) and developed by Boys (1950) in the 1950s to evaluate the two-electron integrals swiftly and to high precision. Tests on atoms and diatoms showed that although many more Gaussian functions were required to obtain results comparable with a given set of Slater orbitals, the computational time involved was not much longer. Results using Gaussian functions are now regarded as standard for polyatomic systems.

For ease of exposition we shall for the moment assume that the orbitals ϕ_r are orthonormal so that the spin-orbitals are also orthonormal. If the Φ_k are then chosen as normalized Slater determinants or proper linear combinations of them, they too may be chosen to be an orthonormal set so that $M_{kl} = \delta_{kl}$. The secular problem then simplifies to

$$|H - E 1_M| = 0, \quad (140)$$

and this is the form that is typically taken in a CI calculation with orthonormal Mos ϕ_r and orthonormal configuration functions Φ_k , while Eq. 138 is the form typically taken in a VB calculation where, in general, neither the orbitals nor the structure functions are orthonormal.

Let us consider what happens if we subject the spin functions to the transformations

$$\sigma \rightarrow \sigma \mathbf{U}(2), \quad (141)$$

and the orbitals to the transformations

$$\phi \rightarrow \phi \mathbf{U}(m), \quad (142)$$

where $\mathbf{U}(n)$ is an $n \times n$ unitary matrix. In this case the spin-orbitals change

$$\begin{aligned} \phi \rightarrow \phi' &= \sigma \mathbf{U}(2) \times \phi \mathbf{U}(m) \\ &= (\sigma \times \phi) (\mathbf{U}(2) \times \mathbf{U}(m)), \end{aligned} \quad (143)$$

and it is easy to show that the ϕ' form an orthonormal set still.

If we now make up the M functions Φ_k but using the spin-orbitals ϕ'_k rather than the ϕ_k , it is easy to show that the ϕ'_k continue to form an orthonormal set because the ϕ_r are orthonormal. Since the set Φ_k is complete, this means that the ϕ'_k are at most a unitary transformation of the ϕ_k , that is:

$$\Phi'_k = \sum_{n=1}^M \Phi_n U_{nk}(M), \quad (144)$$

where $\mathbf{U}(M)$ is an $M \times M$ unitary matrix. This in turn implies that the matrix \mathbf{H} is transformed as

$$\mathbf{H} \rightarrow \mathbf{H}' = \mathbf{U}^\dagger(M) \mathbf{H} \mathbf{U}(M). \quad (145)$$

The new secular problem is, therefore,

$$|\mathbf{H}' - E \mathbf{1}_M| = 0, \quad (146)$$

which can be rewritten as

$$|\mathbf{U}^\dagger(M) (H - E \mathbf{1}_M) \mathbf{U}(M)| = 0, \quad (147)$$

and using the property

$$|\mathbf{AB}| = |\mathbf{A}| |\mathbf{B}|$$

of determinants of square matrix products it follows at once that the secular problem (Eq. 147) is identical with the secular problem (Eq. 140). Thus the energies are completely unchanged by this unitary transformation.

All possible unitary matrices of a given dimension, say n , form a group under matrix multiplication, a group that is usually written as $U(n)$ and thus we can say that the secular problem is invariant under the operations that constitute the group $U(2) \times U(m)$.

It is wrong to think of this group as a transformation group in the same way as a point group. There is no coordinate transformation that corresponds to the unitary transformation on the orbital space. In this case the transformation on the function space is all that there is, the unitary matrices do not “correspond” to anything though of course, one can assert that each matrix formally represents a particular unitary operator if one wishes. If one does think in this way then we can regard the result that has just been shown as a very weak form of a fundamental result due to Wigner who showed that unitary invariance is a very deep invariance in any quantum mechanics based on square integrable eigenfunctions.

At one level the result just shown is quite useless because for m reasonably large M is astronomical. One can refine the result a little to make M less big, for one

can show that if one starts off with a set of determinants each containing $N_\alpha\alpha$ -spin-orbitals and $N_\beta\beta$ -spin-orbitals ($N_\alpha + N_\beta = N$) so that $M_s = (N_\alpha - N_\beta)/2$ for every determinant, then it is sufficient to include only transformed functions with the same M_s value. Further one can show that if one starts off with functions which are fixed linear combinations of determinants which are spin eigenfunctions (i.e., have a particular expectation value \mathbf{S} say, of \mathbf{S}^2), then again one only need consider the transformed functions that preserve \mathbf{S} . But to give some idea of how big the M can be, the following figures are relevant. For a system where the number of electrons, N , is equal to 10 (as in H_2O) and the number of orbitals, m , is equal to 30, the total number of determinants M is 7.54×10^{10} . If the process is restricted to those functions for which $M_s = 0$, M drops to 2.03×10^{10} and if the process is further restricted to those functions for which $S = 0$ then M becomes 4.04×10^9 .

Clearly it is not possible to compute all the matrix elements and then to solve the secular problem. However it is possible to utilize the group theoretical results in the design of computational methods that yield tractable problems. The key to the connection between matrix element evaluation and the unitary group $\mathbf{U}(m)$ is because the Hamiltonian can be expressed in terms of the generators of this group. The spatial parts of the trial functions can be chosen to provide a basis for irreducible representations of $U(m)$ corresponding to a particular choice of S and of M_s for spin symmetry by the use of *Weyl tableaux*. The required Young diagram for the particular choice of S and of M_s is constructed and then the conjugate diagram written down. Into this diagram the orbital indices are put in such a way that across any row the indices are nondecreasing and down any column they are strictly increasing. The resulting tableaux are the Weyl tableaux and each tableau labels a basis function for an irreducible representation of the group $U(m)$ of dimension equal to the total number of tableaux. Thus for a three electron problem using four orbitals, choosing the Young diagram [2 1] would yield 20 distinct Weyl tableaux. Rather convenient rules may then be specified for matrix elements between such functions. This approach will be considered more fully later in this work.

There is, however, one particularly simple and commonly useful case that is appropriate to consider here. That is the case where the trial wavefunction is simply a single Slater determinant of doubly occupied orbitals and it is a commonly useful form because many molecules have an even number of electrons and their electronic ground states are, in many cases, totally symmetric singlet states. The expected value of the Hamiltonian for such a trial function is

$$E = 2 \sum_r \langle \phi_r | \mathbf{h} | \phi_r \rangle + \sum_{rs} (2 \langle \phi_r \phi_s | \mathbf{g} | \phi_r \phi_s \rangle - \langle \phi_r \phi_s | \mathbf{g} | \phi_s \phi_r \rangle), \quad (148)$$

where the sum is over orbitals, the spin having been integrated out leaving only the spatial integrations to be performed. Using the form (Eq. 139) for the orbitals E may be written as

$$E = 2tr\mathbf{hR} + tr\mathbf{GR},$$

where

$$\begin{aligned}
 h_{ij} &= \langle \eta_i | \mathbf{h} | \eta_j \rangle, \\
 R_{ij} &= \sum_r C_{ir} C_{jr}, \\
 G_{ij} &= 2J_{ij} - K_{ij}, \quad J_{ij} = \sum_{kl} R_{kl} \langle \eta_i \eta_k | g | \eta_j \phi_l \rangle, \quad K_{ij} = \sum_{kl} R_{kl} \langle \eta_i \eta_k | g | \eta_l \phi_j \rangle.
 \end{aligned}$$

It can then be shown that the elements of \mathbf{C} that minimize the energy can be obtained by solving the generalized eigenvalue problem

$$\mathbf{h}^F \mathbf{C} = \mathbf{s} \mathbf{C} \epsilon,$$

where

$$\mathbf{h}^F = \mathbf{h} + \mathbf{G}, \quad S_{ij} = \langle \eta_i | \eta_j \rangle,$$

and ϵ is a diagonal matrix with the orbital energies ϵ_r along the diagonal.

Because the construction of \mathbf{h}^F involves a knowledge of \mathbf{C} the construction of eigenvalues must start with a first guess at \mathbf{C} too, obtain an improved guess, and be continued until no further improvement occurs. There are a number of ways in which this may be done but a popular way is simply to solve the generalized eigenvalue problem iteratively. This scheme has given the name self-consistent field (SCF) to the method generally. The contributions of Hartree and of Fock to its development are sometimes acknowledged by denoting it the HF SCF method.

The SCF method is, at present, the most widely used method in computational chemistry and forms a central feature of all the commonly available computer packages for computational chemistry. Provided that the basis of AOs is full enough, the resulting functions yield energies that are often sufficiently good to enable meaningful distinctions to be made between molecules with different nuclear geometries and so to aid the interpretation of spectroscopic results and reaction mechanisms. However the basis of AOs cannot be made too large because of the number of electron repulsion integrals that must be computed and the difficulties of storing and manipulating these.

It is seen, however, that the distinctive feature in the calculation of the electronic energy is the potential term $V(i)$, all the other terms being of precisely the same form whatever the geometry of a given molecule and between molecules. The potential depends only upon the coordinates of a single particle and thus can be realized in terms of one-particle integrals. This is usually expressed by saying that the potential depends only upon the one-particle density functional. It was shown by Hohenberg and Kohn (1964) that the electronic energy depended on the density functional in a unique way and that, if the density functional was known, then so was the energy. This result has led to the development of variants on the SCF method which involve approximations to the density functional form and require many fewer integral

evaluations than does the direct use of an LCAO MO SCF method. Thus much larger molecules can be tackled in this approach than would otherwise be possible.

Conclusions

It seems fair to say that if one treats the nuclei as distinguishable particles and takes the sum of the electronic energy obtained as an eigenvalue of the clamped nuclei Hamiltonian and the classical nuclear repulsion energy as a potential, the geometrical structure of the minimum in such a potential can be identified as the equilibrium molecular geometry. This can be done without appeal to the chemical bond, and without recognition of functional groups. Certain aspects of the transition state theory of chemical reactions can be rationalized in terms of structures anticipated using the potential at geometries away from the equilibrium one. If the occurrence of polar molecules is considered to be an aspect of molecular structure, polar molecules can be recognized from fixed nuclei electronic structure calculations by means of a dipole moment calculated as the sum of the electronic dipole and the classical nuclear dipole. And there are many other ways in which quantum mechanics formulated with the requirement that the nuclei may be treated as distinguishable clamped particles has been effectively used to illuminate chemical behavior.

However, even if this approach is regarded as giving a satisfactory account of chemical structure, it still remains to justify by full quantum mechanical means the treatment of the nuclei that it involves. But at present such a justification still eludes us. It may be in the future that the multiple well approach to nuclear permutational symmetry will be shown to be properly founded and thus the eigenvalues of the molecular Hamiltonian¹⁰ to be just those anticipated from the previous approach; even so one will still be left with eigenfunctions which exhibit full permutation and rotation-inversion symmetry and it seems impossible to anticipate anything at all like classical chemical structure from these using the standard quantum mechanical machinery.

An obvious objection to this discussion is that the full symmetries of the Coulomb Hamiltonian we have been discussing are manifested necessarily by its stationary states, whereas chemists are concerned with time-dependent states that may exhibit less symmetry. The time-dependent Schrödinger equation simply describes unitary time evolution of a prior state and will not change symmetries; any given initial state is the result of some previous time evolution so what is required is a quantum mechanical theory of initial states that are consistent with chemistry; about that nothing is known. The most that it seems possible to say is that chemical structure can be teased out in terms of a chosen ansatz (the imposition of fixed, distinguishable nuclei) if one has a good idea of what one is looking for. It seems

¹⁰The Coulomb Hamiltonian for the electrons and nuclei specified by the molecular formula.

unlikely that one would ever guess that it was there in the full Coulomb Hamiltonian for a molecular formula unless one had decided on its presence in advance.

Abstract

Methods of computational chemistry seem to often be simply a melange of undecipherable acronyms. Frequently, the ability to characterize methods with respect to their quality and applied approximations or to ascribe the proper methodology to the physicochemical property of interest is sufficient to perform research. However, it is worth knowing the fundamental ideas underlying the computational techniques so that one may exploit the approximations intention-

ally and efficiently. This chapter is an introduction to quantum chemistry methods based on the wave function search in one-electron approximation.

Introduction: What and Why?

Quantum chemistry is a branch of science originating from quantum mechanics that focuses on investigations of chemical systems. The mathematical roots of quantum chemistry allow it to be treated as a methodology for solving an eigenvalue equation for operators or – even simpler – finding solutions for some differential equations. We cannot totally escape this way of thinking, since this is how things really are. However, a chemist will comprehend quantum chemistry more as a helping tool in experimental work, supporting description of chemical reactions, a tool that plays a role similar to a spectrophotometer or a chromatographic column, a tool that can provide information about the system under consideration, and a powerful tool, the popularization of which was achieved thanks to the fast progress of computer power and the hard work of people who made the transformation from pure theory to computer programs possible. Their efforts were appreciated – in 1998, the Nobel Prize was awarded to Walter Kohn “for his development of the density functional theory” and John Pople “for his development of computational methods.”

From the point of view of the experimentalist, the apparatus of quantum chemistry can be perceived similarly as the NMR spectrometer. One knows that the quality of the obtained NMR spectrum depends not only on the magnetic field of the magnet but also on the signal-processing capabilities. To successfully use NMR spectroscopy in experimental work, detailed knowledge about the technology of production and preparation of the magnets and electronic equipment is not a requisite. It is enough to keep in mind that with the given frequency one gets corresponding accuracy and information. All the rest is simply skill in sample preparation and expertise in spectrum interpretation. For effective usage of computational techniques of quantum chemistry, one must be aware of applied approximation to tune the accuracy of calculations and possess knowledge of the physicochemical phenomenon one wants to describe.

The aim of the present chapter is to provide a gentle introduction to basic quantum chemistry methods – the methods of solving the electronic Schrödinger equation. The chapter is intended for people starting their adventure with computational chemistry and wanting it to become the tool, not the aim itself.

When discussing quantum chemistry, we cannot totally avoid quantum mechanics. However, let us use another comparison: Traveling abroad it is good to know some basic expressions in the local language of the country you go to. It makes life easier and gives pleasure in interpersonal contacts. Still, no one expects a tourist to speak a language as fluently as a native speaker. Therefore, to efficiently apply computational techniques in experimental research, one has to learn some basic quantum mechanical terms that will help during the journey through the remainder of this chapter.

Quantum Mechanics for Dummies

We will begin with the basic terms of quantum mechanics. In this section, they will be introduced in an intuitive manner, to enable understanding of the next sections' content, even by beginners.

We consider a system of N electrons in the field produced by the potentials arising from nuclei (the nuclei are not treated as particles consisting of nucleons but just as a point source of the electrostatic potential). We are interested only in one particular case:

- The probability of finding the electrons of the considered system on the infinite distance from the nuclei is equal to zero. In other words, we want our system to constitute the whole entirety, not breaking into separate and independent parts (this would be the case of the interaction of two electrons with no attraction – two negative charges would repel each other to infinity).
- The energies of this system constitute the discrete spectrum.
- We want to know only the lowest value of energy (the wider approach can be found in the next volume of the present book).

With such limitations, we do not need to consider all of the different general cases and can simply concentrate on the bound-state chemistry.

A central notion in quantum chemistry is a wave function. This is a function characterizing a state of the system. Therefore, it depends on the variables that are adequate for the given system. This means that the wave function has to depend, at least, on spatial coordinates describing motions of the particles in the investigated system. Moreover, the wave function depends on so-called spin variables (spin is an additional degree of freedom included a posteriori in nonrelativistic quantum mechanics). This spin dependency can be built into the wave function by introducing a spin function. For instance, for the electron with a label 1, its wave function depends on the spatial coordinates x_1, y_1 and z_1 and is multiplied by the spin function $\alpha(\sigma_1)$ or $\beta(\sigma_1)$, where σ_1 is a spin variable. The spin functions must fulfill the following requirements:

$$\int \alpha^*(\sigma_1) \alpha(\sigma_1) d\sigma_1 = \int \beta^*(\sigma_1) \beta(\sigma_1) d\sigma_1 = 1 \quad (1)$$

$$\int \alpha^*(\sigma_1) \beta(\sigma_1) d\sigma_1 = \int \beta^*(\sigma_1) \alpha(\sigma_1) d\sigma_1 = 0, \quad (2)$$

where the integration is carried out over the spin variable, which can be treated as the integration variable only. Such a construction may seem to be somehow unnatural; however, it is a convenient way of ascribing spins to the electrons without dealing with its origins.

In general, the wave function must depend on time to reproduce information about the time evolution of the system. However, since we are interested only in the ground state of the system, we can neglect the time dependency. Considering the bound state is equivalent to imposing the condition of the square integrability of the wave function. The integral over all variables in the full range must exist:

$$\iint \dots \int f^* f d\tau = q, \quad (3)$$

where q is a finite real number. An asterisk under the integral denotes the complex conjugate; it comes from the fact that the wave function can be complex in general. The square-integrability condition ensures that the wave function vanishes for the infinite values of all spatial variables and, therefore, that our molecule is kept together. In the above expression, the integration intervals and the integration variables are not stated explicitly. For the investigated N -electron system, the wave function depends on the $3N$ spatial variables (for each particle i , we have x_i , y_i , and z_i coordinates) and additionally N spin variables (σ_i for the particle i):

$$f = f(x_1, y_1, z_1, \sigma_1, x_2, y_2, z_2, \sigma_2, \dots, x_N, y_N, z_N, \sigma_N). \quad (4)$$

The volume element in this $4N$ -dimensional space is

$$d\tau = dV \cdot d\sigma, \quad (5)$$

where the spatial part can be written as

$$dV = dx_1 dy_1 dz_1 dx_2 dy_2 dz_2 \dots dx_N dy_N dz_N, \quad (6)$$

and the spin part is

$$d\sigma = d\sigma_1 d\sigma_2 \dots d\sigma_N. \quad (7)$$

The spatial variables change from $-\infty$ to ∞ and spin variables can take allowed values. One can see that writing all of the integrals, variables, and volume elements explicitly takes time and a lot of paper, even for relatively small systems. Therefore, one usually keeps them in mind, not writing them down.

The wave function contains all of the information about the state of the system. In order to extract it, operators are applied. An operator can be understood by an analogy to a function. The function ascribes a number to a number and the operator ascribes a function to another function. In other words, the operator is a recipe for how to obtain one function from another:

$$\widehat{A}f = g. \quad (8)$$

We will denote operators by hats above the symbol to distinguish them from functions and numbers. One of the particularly interesting cases is when the function g is proportional to the function f ,

$$g = af, \quad (9)$$

where a is a number. Then Eq. 8 takes the form

$$\widehat{A}f = af. \quad (10)$$

Equation 10 is called an eigenvalue equation of the operator \widehat{A} . The function f fulfilling this equation is called an eigenfunction and a is an eigenvalue of the operator \widehat{A} . The Schrödinger equation

$$\widehat{H}\Psi = E\Psi \quad (11)$$

is a typical eigenvalue equation in which the Hamilton operator \widehat{H} extracts the information about the energy E of the system from the wave function Ψ .

Like in the case of the wave function, we will not consider operators in general. Let us concentrate on the Hamilton operator and its properties to simplify our discussion. We need our operators ascribed to observables (Hamiltonian among others) to satisfy the following requirements:

- Linearity – the operators must fulfill the condition

$$\widehat{A}(\alpha f + \beta g) = \alpha\widehat{A}f + \beta\widehat{A}g, \quad (12)$$

where now α and β are numbers. This seems simple and obvious; however, it is not the property of all operators. For instance, the square root is not a linear operator, since the square root of the sum is not equal to the sum of the square roots.

- Real eigenvalues – only real values can be measured in a laboratory.

For these reasons, we will be interested in so-called Hermitian operators that can be defined by the relation

$$\iint \dots \int f_1^* (\widehat{A}f_2) d\tau = \iint \dots \int f_2 (\widehat{A}f_1)^* d\tau. \quad (13)$$

All the functions, variables, and integration intervals remain the same as in Eq. 3. Writing of all these things in the expressions was already troublesome enough, and things become even more complicated when operators appear. In order to make life easier, Dirac notation can be applied. In this notation Eq. 13 has the form

$$\langle f_1 | \widehat{A}f_2 \rangle = \langle \widehat{A}f_1 | f_2 \rangle, \quad (14)$$

where the left-hand side can be equivalently written as $\langle f_1 | \widehat{A} | f_2 \rangle$, and the integral of Eq. 3 becomes simply

$$\langle f | f \rangle = q. \quad (15)$$

In this very convenient notation, it is also assumed that the integration intervals and variables flow from the context.

Let us look at Hermitian operators more carefully, considering them in the example of Hamiltonian. It has already been mentioned that such operators have real eigenvalues. Furthermore, the eigenfunctions of the Hermitian operator that correspond to different eigenvalues are orthogonal. In other words, for

$$\widehat{H} f_1 = E_1 f_1 \quad \text{and} \quad \widehat{H} f_2 = E_2 f_2, \quad (16)$$

where $(E_1 \neq E_2)$, one has

$$\langle f_1 | f_2 \rangle = \langle f_2 | f_1 \rangle = 0. \quad (17)$$

This will be a very useful property, since it will cause various terms in complicated expressions to vanish. In the case of degeneration, or, in other words, when one of the eigenvalues corresponds to two or more eigenfunctions, the eigenfunctions f_1 and f_2 can be orthogonalized.

It is worth considering the integral

$$\langle f_1 | \widehat{H} | f_1 \rangle. \quad (18)$$

Since f_1 is the eigenfunction of \widehat{H} with the eigenvalue E_1 , it is obvious that

$$\langle f_1 | \widehat{H} | f_1 \rangle = \langle f_1 | E_1 f_1 \rangle = E_1 \langle f_1 | f_1 \rangle. \quad (19)$$

It would be certainly more convenient if the result was a single number – the eigenvalue E_1 . This would be the case if $\langle f_1 | f_1 \rangle = 1$ or if we say the function f_1 was normalized to unity. It would be consistent with the interpretation of the integral $\langle f_1 | f_1 \rangle$ as the probability of finding the system in the whole space – it should be surely equal 1. This is a very handy requirement. Any function that does not possess this property can be normalized by multiplying by the normalization factor $\mathcal{N} = 1/\sqrt{\langle f_1 | f_1 \rangle}$. Then, the new function \tilde{f}_1 will be given as

$$\tilde{f}_1 = \mathcal{N} f_1. \quad (20)$$

This new function \tilde{f}_1 is also an eigenfunction of the Hamiltonian, since f_1 was only divided by the number $\sqrt{\langle f_1 | f_1 \rangle}$ and Hamiltonian is linear:

$$\widehat{H} \tilde{f}_1 = \widehat{H} \mathcal{N} f_1 = \mathcal{N} \widehat{H} f_1 = \mathcal{N} E f_1 = E \mathcal{N} f_1 = E \tilde{f}_1. \quad (21)$$

In the case of unnormalized functions, the expression for the eigenvalue E_1 can be obtained from Eq. 19:

$$E_1 = \frac{\langle f_1 | \widehat{H} | f_1 \rangle}{\langle f_1 | f_1 \rangle}. \quad (22)$$

However, many of the applied functions are not the eigenfunctions of the Hamiltonian. Therefore, let us investigate another interesting integral,

$$\langle g | \widehat{H} | g \rangle, \quad (23)$$

where g is not an eigenfunction of \widehat{H} . In order to calculate this integral, an alternate important property of the Hermitian operators needs to be exploited: the fact that their eigenfunctions constitute a complete basis set. Each function depending on the same variables as the eigenfunctions can be expressed as the linear combination of the basis functions. Now, this concept seems to be hard-core mathematics; however, anybody using computational techniques knows well that the two things one must input to the ab initio program are the method and the basis set. Hence, let us make a break from the general considerations of operators and abstract space functions and concentrate for a while on the basis set concept in the example of simple trigonometric functions.

In a calculus course, one learns how to express a function using a set of other functions. For example, consider $\sin x$ function and expand it in the Taylor series around 0:

$$\sin x = \sum_{i=1}^{\infty} \frac{(-1)^{i-1}}{(2i-1)!} x^{2i-1} = x - \frac{x^3}{3!} + \frac{x^5}{5!} - \dots \quad (24)$$

In Eq. 24, $\sin x$ function is expressed in the basis set of monomials:

$$\sin x = \sum_{k=1}^{\infty} c_k x^k, \quad (25)$$

where c_k are the expansion coefficients that need to be determined. In our case it is simple, since c_k result directly from the Taylor expansion and are equal:

Table 1 Taylor expansion of x function and standard deviation for various expansion lengths

n	F_n	σ_n
1	x	3.93×10^{-1}
3	$x - \frac{1}{6}x^3$	4.05×10^{-2}
5	$x - \frac{1}{6}x^3 + \frac{1}{120}x^5$	2.08×10^{-3}
7	$x - \frac{1}{6}x^3 + \frac{1}{120}x^5 - \frac{1}{5,040}x^7$	6.39×10^{-5}

$$c_k = \begin{cases} \frac{(-1)^{(k-1)/2}}{k!} & \text{for odd } k, \\ 0 & \text{for even } k. \end{cases} \quad (26)$$

The summation in Eqs. 24 and 25 goes from 1 to ∞ . In practice, finite and possibly short expansions are applied:

$$F_n(x) = \sum_{i=1}^n c_i x^i. \quad (27)$$

This truncation of the series introduces an approximation to our function.

Let us analyze the x function in the range $x \in \langle -\frac{\pi}{2}; \frac{\pi}{2} \rangle$. The standard deviation works well as the accuracy measure:

$$\sigma_n \sqrt{\int_{-\frac{\pi}{2}}^{\frac{\pi}{2}} (\sin x - F_n(x))^2 dx}. \quad (28)$$

Table 1 summarizes data for small n values. Increasing the number of expansion terms causes a decrease of the standard deviation values and more accurate representation of the original x function. Given the required accuracy of the calculation, the necessary value length of the expansion, n , can be found.

The following question arises: Why use Taylor expansion instead of x function itself, if one needs to worry about the expansion accuracy? The answer is straightforward: simplifications and savings. It is much easier to operate on the polynomials than on the trigonometric functions (for instance, the integral $\int (x^i)^2 dx$ is much easier to handle than $\int \sin^2 x dx$). Moreover, the required accuracy can often be obtained with a relatively short expansion.

Let us now make the considerations more general. As was stated before, the set of eigenfunctions of the Hermitian operator \hat{H} is complete and orthonormal – functions are orthogonal and normalized:

$$\forall_{i,j} \left\langle f_i \left| f_j \right. \right\rangle = \delta_{ij}, \quad (29)$$

where δ_{ij} is a Kronecker symbol that takes value 1 for $i = j$ and 0 otherwise. The basis set completeness means that each function depending on the same set of variables can be expressed by the basis functions:

$$g = \sum_{i=1}^{\infty} c_i f_i, \quad (30)$$

where coefficients c_i need to be found. Knowing the normalized g function makes this task simple, because of the orthonormality of the $\{f_i\}$ set, the coefficients will be equal:

$$c_i = \langle f_i | g \rangle, \quad (31)$$

since

$$\langle f_i | g \rangle = \sum_{j=1}^{\infty} c_j \langle f_i | f_j \rangle = \sum_{j=1}^{\infty} c_j \delta_{ij} = c_i. \quad (32)$$

(Only one term for $i = j$, c_i , remains; all other vanish for the Kronecker delta equals zero if $i \neq j$.) Similarly,

$$\langle g | g \rangle = \sum_{j=1}^{\infty} c_j^* c_j. \quad (33)$$

However, things are not that easy, since we usually apply the expansion (Eq. 30) when we do not know the g function. Thus, the integrals (Eqs. 31 and 33) should be perceived rather as the interpretation of the c_i coefficients than the direct recipe for the calculations. From Eq. 30, the g function can be treated as the linear combination of the f_i functions. Moreover (see Eq. 33), the probability that a system described by the function g is in the state f_j is given by $c_j^* c_j$.

Now let us consider the expression

$$\langle g | \hat{H} | g \rangle \equiv \langle \hat{H} \rangle_g, \quad (34)$$

when g is not the Hamiltonian eigenfunction. Using the expansion Eq. 30 and the fact that f_i are the Hamiltonian eigenfunctions (Eq. 16), one obtains

$$\langle g | \hat{H} | g \rangle = \sum_{j=1}^{\infty} c_j^* c_j E_j. \quad (35)$$

The above integral is called an average (expectation) value, and Eq. 35 for Hamiltonian carries the information about the average energy of the system in the state described by the g function. Looking closer at Eq. 35 shows that this average energy is simply a weighted average of all possible E_j energies of the system. The weights are determined by the $c_j^* c_j$ products – the probability of finding the system in the f_j state. It should be noticed that we used the linearity of the Hamiltonian operator to achieve this result.

Conclusion? Very optimistic: We can say something about the sought energy value not knowing the eigenfunctions of the operator of interest, since for calculations of Eq. 35, we do not need f_j functions. Strange? Not at all, if we recall some linear algebra: Using three basis vectors, we can describe each and every point in the 3D space. Likewise, the wave function can be perceived as a vector, the Hermitian operator as the symmetric transformation matrix, an integral $\langle f | g \rangle$ as the dot product, orthogonality of functions as orthogonality of vectors, and normalization as dividing the vector components by its length.

Now, when the “linear algebra” term has already appeared, let us see how it is applied for solving the eigenequation. Almost all calculations are performed by applying the basis functions. This means that the unknown function Ψ describing the investigated system is expressed in the basis of known functions χ_i (see Eq. 30):

$$\Psi \approx \sum_{i=1}^n c_i \chi_i = \Phi, \quad (36)$$

where Ψ is the eigenfunction of the Hamiltonian corresponding to a given eigenvalue E (Eq. 11). The task is to find such c_i coefficients that the function Φ would be the best approximation to Ψ . Since Φ is an approximation to the wave function, the corresponding energy will also be only approximated. Let us call the approximation E_Φ . Basis functions χ_i are not the Hamiltonian eigenfunctions; therefore, to estimate the energy, an average value must be calculated. Therefore, substituting Eq. 36 for Eq. 11 and multiplying by $\Psi^* = \langle \sum_i c_i \chi_i |$ on both sides gives¹

$$\text{LHS} = \left\langle \sum_i c_i \chi_i \left| \hat{H} \left| \sum_j c_j \chi_j \right. \right. \right\rangle = \sum_i \sum_j c_i^* c_j \langle \chi_i | \hat{H} | \chi_j \rangle, \quad (37)$$

$$\text{RHS} = E_\Phi \sum_i \sum_j c_j^* c_j \langle \chi_i | \chi_j \rangle. \quad (38)$$

¹Here, different subscripts appear on the both sides of the integral. The sum does not depend on the name of the summation index; thus, any subscript can be applied. However, one should not apply the same index on both sides of the integral, since it can cause the erroneous omission of the off-diagonal terms. Compare the overlap integral

$$\begin{aligned} \langle \Psi | \Psi \rangle &= \left\langle \sum_i c_i \chi_i \left| \sum_j c_j \chi_j \right. \right\rangle = \langle c_1 \chi_1 + c_2 \chi_2 + c_3 \chi_3 + \dots | c_1 \chi_1 + c_2 \chi_2 + c_3 \chi_3 + \dots \rangle \\ &= c_1^* c_1 \langle \chi_1 | \chi_1 \rangle + c_1^* c_2 \langle \chi_1 | \chi_2 \rangle + c_1^* c_3 \langle \chi_1 | \chi_3 \rangle + \dots \end{aligned}$$

The explicit writing of all terms shows that not only the integrals $\langle \chi_i | \chi_i \rangle$ with the same function on both sides are present, but also the contributions $\langle \chi_i | \chi_j \rangle$ with $i \neq j$. Therefore, the diversification of the subscripts prevents mistakes.

In order to further simplify the notation, let us denote $\langle \chi_i | \widehat{H} | \chi_j \rangle$ by H_{ij} and $\langle \chi_i | \chi_j \rangle$ by S_{ij} . Then,

$$\sum_i \sum_j c_j^* c_j H_{ij} = E_\Phi \sum_i \sum_j c_i^* c_j S_{ij}. \quad (39)$$

Equivalently, in the matrix form

$$\mathbf{H}\mathbf{c} = \mathbf{S}\mathbf{c}E_\Phi, \quad (40)$$

where \mathbf{H} is the Hamiltonian matrix with the elements H_{ij} , \mathbf{S} is called the overlap matrix and is built of the overlap integrals S_{ij} , and \mathbf{c} denotes the vector of the c_i coefficients. The basis sets applied in practice are usually non-orthogonal, which causes the off-diagonal terms in the \mathbf{S} matrix to not vanish.

Such a method of finding approximate eigenvalues and eigenvectors of the Hamiltonian is known as the Ritz method and is frequently applied in quantum chemistry.

This simple introduction of basic terms of quantum mechanics is obviously far from complete. One can notice the lack of further discussion of the degeneration, the continuum spectrum, and many other topics. For these we encourage the reader to dive into the following excellent books on quantum mechanics and chemistry: Atkins and Friedman (2005), Griffiths (2004), Levine (2008), Lowe and Peterson (2005), McQuarrie and Simon (1997), Piela (2007), Ratner and Schatz (2000), and Szabo and Ostlund (1996).

On the Way to Quantum Chemistry

For the sake of simplification, we assume that the energy of the ground state of our system differs from other energy values. This allows one to avoid embroilment in technical details that are unnecessary at this point. Our system is described by the wave function Ψ fulfilling the Schrödinger Eq. 11. It is important to notice that this eigenvalue equation can be solved exactly only for hydrogen atoms. Any more complicated system requires approximate techniques. In order to explain this complication, let us look into the Hamilton operator. For the system of N electrons and M nuclei, the full Hamiltonian is a sum of the following terms:

- Kinetic energy of electrons, \widehat{T}_e
- Kinetic energy of nuclei, \widehat{T}_n
- Energy of interactions between electrons, \widehat{V}_{ee}
- Energy of interactions between nuclei, \widehat{V}_{nn}
- Energy of interactions between a nucleus and an electron, \widehat{V}_{ne}

In the atomic units, these terms have the following form:

$$\hat{T}_e = -\frac{1}{2} \sum_{i=1}^N \nabla_{\mathbf{r}_i}^2 \quad (41)$$

$$\hat{T}_n = -\sum_{i=1}^M \frac{1}{2m_i} \nabla_{\mathbf{R}_i}^2 \quad (42)$$

$$\hat{V}_{ee} = \sum_{i=1}^N \sum_{j>i}^N \frac{1}{r_{ij}} \quad (43)$$

$$\hat{V}_{nn} = \sum_{i=1}^M \sum_{j>i}^M \frac{Z_i Z_j}{R_{ij}} \quad (44)$$

$$\hat{V}_{ne} = -\sum_{i=1}^N \sum_{j=1}^M \frac{Z_j}{|\mathbf{r}_i - \mathbf{R}_j|} \quad (45)$$

where m_i is the mass of the nucleus i , Z_i stands for the nuclear charge, and r_{ij} denotes the distance between the electrons i and j , $r_{ij} = |\mathbf{r}_i - \mathbf{r}_j|$. Likewise, R_{ij} refers to the internuclear distance, $R_{ij} = |\mathbf{R}_i - \mathbf{R}_j|$. The presence of the mutual distances between the particles causes a serious problem when solving the Schrodinger equation; it does not allow one to decouple the equations.

Fortunately, from the chemist's point of view, such a Hamiltonian is not very useful. The chemist is not interested in each and every bit of information one can get about any N -electron M -nuclei system; however, she or he is focused on the given molecule, its conformations, interactions with the environment, and properties (spectroscopic, magnetic, electric, and so on). What makes quantum mechanics a valuable tool for chemists is the Born–Oppenheimer approximation, discussed in detail in the previous chapter of this volume. Let us briefly summarize it to maintain consistent notation throughout the chapter.

The chemist is concerned with the relative positions of the nuclei in the molecule and with the internal energy, but not with the motions of the molecule as a whole. This motion can be excluded from our consideration, for example, by elimination of the center-of-mass translation. Moreover, the intermolecular (electrostatic) forces acting on electrons and nuclei would be similar. This would cause much slower internal motion of the heavy nuclei in comparison to light electrons. For this reason, the approximate description of electron motion with parametric dependence on the static positions of nuclei is justified. Such reasoning leads to adiabatic approximation and finally to Born–Oppenheimer approximation.

According to this approximation, the Hamiltonian can be written as

$$\hat{H} = \hat{T}_n + \hat{H}_e + \hat{V}_{nn}, \quad (46)$$

where \widehat{T}_n now has a meaning of nuclear kinetic energy of the molecule for which the center of mass is stopped (however, there are still oscillations and rotations), and

$$\widehat{H}_e = \widehat{T}_e + \widehat{V}_{ee} + \widehat{V}_{en} \quad (47)$$

is called an electronic Hamiltonian, and it represents the energy of the system after omitting the nuclear kinetic energy term and nuclear repulsion. One can now focus on the solution of the equation of the form

$$\left[\widehat{T}_n(\mathbf{R}) + \widehat{H}_e(\mathbf{r}; \mathbf{R}) + \widehat{V}_{nn}(\mathbf{R}) \right] \Psi(\mathbf{r}, \mathbf{R}) = E \Psi(\mathbf{r}, \mathbf{R}). \quad (48)$$

Here, the dependence on the electronic spatial variables $\mathbf{r} = (x_1, y_1, z_1, \dots, x_N, y_N, z_N)$ and the nuclear spatial variables $\mathbf{R} = (X_1, Y_1, Z_1, \dots, X_M, Y_M, Z_M)$ is written explicitly. The semicolon sign in the \widehat{H}_e term denotes the parametric dependence – for various \mathbf{R} the various electronic equations are obtained.

With such a Hamiltonian, it seems reliable to distinguish also the nuclear $f(\mathbf{R})$ and electronic $\Psi_e(\mathbf{r}; \mathbf{R})$ part in the wave function

$$\Psi(\mathbf{r}, \mathbf{R}) \approx \Psi_e(\mathbf{r}; \mathbf{R}) f(\mathbf{R}), \quad (49)$$

which leads to a significant reduction of the problem.

Now Eq. 48 can be separated into three equations:

$$\widehat{H}_e(\mathbf{r}; \mathbf{R}) \Psi_e(\mathbf{r}; \mathbf{R}) = E_e(\mathbf{R}) \Psi_e(\mathbf{r}; \mathbf{R}) \quad (50)$$

$$\left(\widehat{H}_e(\mathbf{r}; \mathbf{R}) + \widehat{V}_{nn}(\mathbf{R}) \right) \Psi_e(\mathbf{r}; \mathbf{R}) = U(\mathbf{R}) \Psi_e(\mathbf{r}; \mathbf{R}) \quad (51)$$

$$\left(\widehat{T}_n(\mathbf{R}) + \widehat{U}(\mathbf{R}) \right) f(\mathbf{R}) = E f(\mathbf{R}) \quad (52)$$

The first two describe electronic motion for a given position of nuclei. The difference between $E_e(\mathbf{R})$ and $U(\mathbf{R})$ is that in $U(\mathbf{R})$ nuclear repulsion energy is taken into account. These equations are milestones in our considerations for two reasons. First, since we are now talking about “fixed positions of the nuclei,” finally we have got molecules instead of an unspecified system containing some electrons and some nuclei. The second is hidden in Eq. 52: Electronic energy and nuclear repulsion energy constitute the potential, in which nuclei are moving. That is why the proper description of electronic movement in a molecule is so important: The electrons glue the whole molecule together.

Our attention in the rest of the chapter will be focused only on Eq. 50; hence, to simplify notation, all the subscripts denoting the electronic case will be omitted:

$$\widehat{H}_e \rightarrow \widehat{H} \quad (53)$$

$$\Psi_e \rightarrow \Psi \quad (54)$$

$$\widehat{H}_e \Psi_e (r; R) = E_e \Psi_e (r; R) \rightarrow \widehat{H} \Psi = E \Psi \quad (55)$$

The electronic wave function Ψ satisfies all the requirements discussed in the previous sections, depends on the coordinates of N electrons, and additionally must be antisymmetric with respect to the exchange of coordinates of two electrons.²

It should be noted that the analytic solution of Eq. 50 is not known even for the smallest molecule, i.e., H_2 . Therefore, the approximate techniques must be applied to extract the necessary information about molecules of interest. Quantum mechanics provides two tools:

- Variational principle
- Perturbation theory

Variational Principle: An Indicator

The variational principle allows one to judge the quality of the obtained solutions. It can be formulated as follows: For the arbitrary trial function χ that is square-integrable, differentiable, and antisymmetric and depends on the same set of variables as a sought ground-state Ψ_0 function, we have

$$E_0 \leq \frac{\langle \chi | \widehat{H} | \chi \rangle}{\langle \chi | \chi \rangle}, \quad (56)$$

where E_0 is the ground-state energy corresponding to Ψ_0 (Eq. 50). The important consequence of the variational principle is that to estimate the energy of the system, one does not need to solve the eigenequation (this we already know; see Eq. 35), and moreover – what is crucial – the estimated energy value will always not be lower than the exact eigenvalue E_0 .

The proof of the inequality (Eq. 56) is straightforward and can be derived from Eqs. 30 and 35. The function χ that satisfies the above requirements can be expanded on the basis of the Hamiltonian eigenfunctions:

$$\chi = \sum_{i=0}^{\infty} c_i f_i, \quad (57)$$

²In order to explain the antisymmetry requirement, we have to refer again to theory that is beyond the scope of the present chapter. Let us simply state here that wave functions must be antisymmetric without belaboring the point. This will mean that the exchange of the coordinates of the two electrons causes the wave function to change the sign: $\Psi(\tau_1, \tau_2) = -\Psi(\tau_2, \tau_1)$.

where f_i fulfill the eigenproblem $\widehat{H} f_i = E_i f_i$. Thus,

$$\frac{\langle \chi | \widehat{H} | \chi \rangle}{\langle \chi | \chi \rangle} = \frac{\sum_{i=0}^{\infty} c_i^* c_i E_i}{\sum_{i=0}^{\infty} c_i^* c_i} \geq \frac{\sum_{i=0}^{\infty} c_i^* c_i E_0}{\sum_{i=0}^{\infty} c_i^* c_i} = E_0, \quad (58)$$

with the assumption that E_0 is the lowest of all Hamiltonian eigenvalues (Atkins and Friedman 2005; Levine 2008; Lowe and Peterson 2005; McQuarrie and Simon 1997; Piela 2007; Szabo and Ostlund 1996).

Perturbation Calculus: The Art of Estimation

Due to the variational principle that is satisfied for the electronic Hamiltonian, the group of methods of searching for parameters optimizing the energy value can be constructed. The way of verification of the given wave function is the corresponding energy value: The lower, the better. Besides this “quality control,” the variational principle does not give the prescription for the choice of the trial wave functions. Here comes the perturbation calculus – the method frequently applied in physics for the estimation of the functions or values on the basis of partial knowledge about the solutions of the investigated problem. We will consider here the Rayleigh–Schrödinger variant of the perturbation calculus (Atkins and Friedman 2005; Levine 2008; Lowe and Peterson 2005; McQuarrie and Simon 1997; Piela 2007; Ratner and Schatz 2000).

Let us assume that the total electronic Hamiltonian of the investigated system can be divided into

$$\widehat{H} = \widehat{H}^0 + \widehat{H}^1, \quad (59)$$

in such a fashion that we know the exact solutions of

$$\widehat{H}^0 \Psi_k^{(0)} = E_k^{(0)} \Psi_k^{(0)}, \quad (60)$$

where the subscript k enumerates the eigenvalues of the \widehat{H}^0 operator in such a way that $E_0^{(0)}$ is the lowest energy. Now, one can say that the operator \widehat{H} describes the system for which \widehat{H}^0 is an unperturbed operator and \widehat{H}^1 denotes a perturbation. We can assume that if the change in the system represented by \widehat{H}^1 is minor, then the functions $\Psi_k^{(0)}$ would be a good approximation to Ψ_k . Considering \widehat{H}^0 , one postulates its Hermiticity and that its eigenvalues are not degenerate (in our case, for the ground state at least $E_0^{(0)}$ must not be equal to any other eigenvalue). This condition will become clear in a moment.

Knowing only the unperturbed solutions (Eq. 60), we would like to say something more about the ground-state energy of the investigated system. Nothing is easier – we can calculate the average value of the full electronic Hamiltonian with

the $\Psi_0^{(0)}$ function. The variational principle states that the resulting energy will be not lower than the exact energy:

$$E_0 \leq \left\langle \Psi_0^{(0)} \left| \widehat{H}^0 + \widehat{H}^1 \right| \Psi_0^{(0)} \right\rangle = E_0^{(0)} + E_0^{(1)}. \quad (61)$$

The term modifying $E_0^{(0)}$ is simply

$$E_0^{(1)} = \left\langle \Psi_0^{(0)} \left| \widehat{H}^1 \right| \Psi_0^{(0)} \right\rangle. \quad (62)$$

So far, the only new thing is the manner of partitioning the total energy into the energy of the unperturbed system and the corrections (where $E_0^{(1)}$ is not the only term):

$$E_0 = E_0^{(0)} + E_0^{(1)} + E_0^{(2)} + \dots \quad (63)$$

Likewise, the wave function can be written as

$$\Psi_0 = \Psi_0^{(0)} + \Psi_0^{(1)} + \Psi_0^{(2)} + \dots, \quad (64)$$

where $\Psi_0^{(1)}, \Psi_0^{(2)}$ and so forth are the corrections to the wave function of the unperturbed system $\Psi_0^{(0)}$. Now, the electronic Schrödinger Eq. 50 becomes

$$\begin{aligned} & \left(\widehat{H}^0 + \widehat{H}^1 \right) \left(\Psi_0^{(0)} + \Psi_0^{(1)} + \Psi_0^{(2)} + \dots \right) \\ & = \left(E_0^{(0)} + E_0^{(1)} + E_0^{(2)} + \dots \right) \left(\Psi_0^{(0)} + \Psi_0^{(1)} + \Psi_0^{(2)} + \dots \right). \end{aligned} \quad (65)$$

Introducing the expansions (Eqs. 63 and 64) does not increase our knowledge about the energy or the wave function; it is only a different way of expressing the unknowns by other unknowns. However, now we have a starting point for further investigations.

The comparison of the terms on the left- and right-hand side of the above expression is instructive. Let us regard as similar the terms with the same sum of the superscripts (so-called perturbation order, by analogy to the multiplication and ordering of polynomials). Simple multiplication in Eq. 65 and directing the terms of the same order to separate equations gives

$$\widehat{H}^0 \Psi_0^{(0)} = E_0^{(0)} \Psi_0^{(0)}, \quad (66)$$

$$\widehat{H}^0 \Psi_0^{(1)} + \widehat{H}^1 \Psi_0^{(0)} = E_0^{(0)} \Psi_0^{(1)} + E_0^{(1)} \Psi_0^{(0)}, \quad (67)$$

$$\begin{aligned} \widehat{H}^0 \Psi_0^{(2)} + \widehat{H}^1 \Psi_0^{(1)} &= E_0^{(0)} \Psi_0^{(2)} + E_0^{(1)} \Psi_0^{(1)} + E_0^{(2)} \Psi_0^{(0)}. \\ &\vdots \end{aligned} \quad (68)$$

These equations link the corrections to the wave function and to the energy. Before detailed investigation of the subsequent corrections, one more thing should be underlined. Up to now, the function Ψ_0 is not normalized; only $\Psi_k^{(0)}$ are normalized. Until the corrections to Ψ_0 were found, we would not be able to normalize it. We can only write the normalization constant as $\mathcal{N} = \frac{1}{\sqrt{\langle \Psi_0 | \Psi_0 \rangle}}$. However, it is not necessary at this moment. Now the intermediate normalization condition is more useful:

$$\langle \Psi_0^{(0)} | \Psi_0 \rangle = 1. \quad (69)$$

Such a concept is based on the information that the eigenfunctions of \widehat{H}^0 form an orthonormal complete set of functions (that is one of the reasons why the Hermiticity of \widehat{H}^0 was required) and they can be applied to express any other function, for instance, Ψ_0 as

$$\Psi_0 = \sum_{k=0}^{\infty} c_k \Psi_k^{(0)} + \sum_{k \neq 0}^{\infty} c_k \Psi_k^{(0)}. \quad (70)$$

In this linear combination, the function $\Psi_0^{(0)}$ has a distinguished meaning ($c_0 = 1$); this is the approximation of the wave function of the considered system. Therefore, one can require that $\Psi_0^{(0)}$ does not have a contribution to the higher corrections: $\Psi_0^{(1)}$, $\Psi_0^{(2)}$, and so on:

$$\sum_{k \neq 0}^{\infty} c_k \Psi_k^{(0)} = \Psi_0^{(1)} + \Psi_0^{(2)} + \dots \quad (71)$$

Here, the benefits from the intermediate normalization are obvious: The function $\Psi_0^{(0)}$ is orthogonal to each of the corrections (or, in other words, the corrections are defined in such a way that they are orthogonal to $\Psi_0^{(0)}$).

Therefore, there is an additional set of equations to be satisfied:

$$\langle \Psi_0^{(0)} | \Psi_0^{(n)} \rangle = \delta_{0n}, \quad (72)$$

where the superscript n denotes the n th-order correction to the ground-state wave function Ψ_0 . Now we can go back to Eqs. 66, 67, and 68 and extract the corrections to energy. For this purpose, each of the equations must be multiplied from the left-hand side by $\Psi_0^{(0)}$ and integrated:

$$E_0^{(0)} = \langle \Psi_0^{(0)} | \widehat{H}^0 | \Psi_0^{(0)} \rangle, \quad (73)$$

$$E_0^{(1)} = \langle \Psi_0^{(0)} | \widehat{H}^1 | \Psi_0^{(0)} \rangle, \quad (74)$$

$$E_0^{(2)} = \langle \Psi_0^{(0)} | \widehat{H} | \Psi_0^{(1)} \rangle, \quad \vdots \quad (75)$$

The integrals $\langle \Psi_0^{(0)} | \widehat{H}^0 | \Psi_0^{(n)} \rangle$ vanish, since

$$\langle \Psi_0^{(0)} | \widehat{H}^0 | \Psi_0^{(n)} \rangle = \langle \widehat{H}^0 \Psi_0^{(0)} | \Psi_0^{(n)} \rangle = E_0^{(0)} \langle \Psi_0^{(0)} | \Psi_0^{(n)} \rangle = 0. \quad (76)$$

Thus, obtaining the energy corrections of any order is straightforward. The general expression for the n th-order correction can be written as

$$E_0^{(n)} = \langle \Psi_0^{(0)} | \widehat{H}^1 | \Psi_0^{(n-1)} \rangle \quad \text{for } n > 1. \quad (77)$$

The problem is that to obtain the corrections to the energy in the second or higher orders, the corrections to the wave function are necessary. Then, let us try to find $\Psi_0^{(1)}$. This function can be expressed as the linear combination of the functions from the orthonormal set $\{\Psi_k^{(0)}\}$ for $k \neq 0$:

$$\Psi_0^{(1)} = \sum_{k \neq 0}^{\infty} c_k^{(1)} \Psi_k^{(0)}, \quad (78)$$

where $c_k^{(1)}$ are the expansion coefficients in the first-order correction. Again, the whole thing reduces to finding the coefficients c_k . Substituting Eq. 78 to Eq. 67 gives

$$\left(\widehat{H}^0 - E_0^{(0)} \right) \sum_{k \neq 0}^{\infty} c_k^{(1)} \Psi_k^{(0)} = \left(E_0^{(1)} - \widehat{H}^1 \right) \Psi_0^{(0)}. \quad (79)$$

Integrating this equation with the $\Psi_l^{(0)}$ function leads to

$$\begin{aligned} \text{LHS} &= \left\langle \Psi_l^{(0)} \left| \widehat{H}^0 - E_0^{(0)} \right| \sum_{k \neq 0}^{\infty} c_k \Psi_k^{(0)} \right\rangle = \sum_{k \neq 0}^{\infty} c_k \left\langle \Psi_l^{(0)} \left| \widehat{H}^0 - E_0^{(0)} \right| \Psi_k^{(0)} \right\rangle \\ &= \sum_{k \neq 0}^{\infty} c_k \left(E_l^{(0)} - E_0^{(0)} \right) \left\langle \Psi_l^{(0)} \left| \Psi_k^{(0)} \right\rangle = \sum_{k \neq 0}^{\infty} c_k \left(E_l^{(0)} - E_0^{(0)} \right) \delta_{lk} \\ &= c_l \left(E_l^{(0)} - E_0^{(0)} \right) \end{aligned} \quad (80)$$

and

$$\begin{aligned} \text{RHS} &= \left\langle \Psi_l^{(0)} \left| E_0^{(1)} - \widehat{H}^1 \right| \Psi_0^{(0)} \right\rangle = E_0^{(1)} \left\langle \Psi_l^{(0)} \left| \Psi_0^{(0)} \right\rangle - \left\langle \Psi_l^{(0)} \left| \widehat{H}^1 \right| \Psi_0^{(0)} \right\rangle \\ &= - \left\langle \Psi_l^{(0)} \left| \widehat{H}^1 \right| \Psi_0^{(0)} \right\rangle. \end{aligned} \quad (81)$$

Altogether, these allow one to write the coefficients of the expansion (Eq. 78) as

$$c_l = \frac{\langle \Psi_l^{(0)} | \widehat{H}^1 | \Psi_0^{(0)} \rangle}{E_0^{(0)} - E_l^{(0)}}. \quad (82)$$

Hence, the first correction to the wave function is already known:

$$\Psi_0^{(1)} = \sum_{k \neq 0}^{\infty} \frac{\langle \Psi_k^{(0)} | \widehat{H}^1 | \Psi_0^{(0)} \rangle}{E_0^{(0)} - E_k^{(0)}} \Psi_k^{(0)}, \quad (83)$$

and, thereby, the second-order correction to the energy can be calculated as

$$E_0^{(2)} = \sum_{k \neq 0}^{\infty} \frac{\langle \Psi_k^{(0)} | \widehat{H}^1 | \Psi_0^{(0)} \rangle}{E_0^{(0)} - E_k^{(0)}} \langle \Psi_0^{(0)} | \widehat{H}^1 | \Psi_k^{(0)} \rangle. \quad (84)$$

This is also equivalently written as

$$E_0^{(2)} = \sum_{k \neq 0}^{\infty} \frac{\left| \langle \Psi_k^{(0)} | \widehat{H}^1 | \Psi_0^{(0)} \rangle \right|^2}{E_0^{(0)} - E_k^{(0)}}. \quad (85)$$

The energy difference in the denominator of the above expression cannot be equal to zero, and for this reason the non-degenerated ground state was assumed. The higher-order corrections are sought in a similar manner, which just requires more operations.

One of the interesting issues is the problem of variationality of the perturbation calculus built upon the variational Hamiltonian. This is, however, a sophisticated problem for advanced readers and will not be discussed here. It should be added, in summary, that the manner of partitioning of the Hamilton operator was arbitrary. The only prerequisites were the Hermitian character of the operators (for the eigenfunctions to form the orthonormal set) and the non-degenerated ground-state eigenenergy and nothing more. One should also remember that, in practice, even solving the unperturbed problem cannot be performed exactly and the approximations must be applied. The consequence could be the loss of accuracy for higher-order corrections. Moreover, good convergence of the perturbation expansion can be expected when the consecutive corrections are small in comparison to the total estimated value. However, in such a case, the low orders of the series would reproduce the sought value with relatively good accuracy. Thus, application of the low orders of perturbation calculus is highly recommended.

One-Electron Approximation: Describe One and Say Something About All

Equipped with general knowledge about the tools for the Schrödinger equation solution, one can move to many-electron systems.

The electronic Hamiltonian for any many-electron system in atomic units has the following form (compare Eqs. 41, 42, 43, 44, and 45):

$$\hat{H} = -\frac{1}{2} \sum_{i=1}^N \Delta_{r_i} + \sum_{i=1}^N \sum_{j=1}^M \frac{Z_j}{|\mathbf{r}_i - \mathbf{R}_j|} + \sum_{i=1}^N \sum_{j=i+1}^N \frac{1}{|\mathbf{r}_i - \mathbf{r}_j|}. \quad (86)$$

Let us look more closely. In the first term, we sum up over the number of electrons N ; in the second term, the summations run over the number of electrons N and number of nuclei M ; and the third term contains the double sum over the number of electrons N . Thus, one can simplify the notation of the first two terms:

$$-\frac{1}{2} \sum_{i=1}^N \Delta_{r_i} + \sum_{i=1}^N \sum_{j=1}^M \frac{Z_j}{|\mathbf{r}_i - \mathbf{R}_j|} = \sum_{i=1}^N \left(-\frac{1}{2} \Delta_{r_i} + \sum_{j=1}^M \frac{Z_j}{|\mathbf{r}_i - \mathbf{R}_j|} \right). \quad (87)$$

Now, denoting the term in parenthesis by $\hat{h}(i)$,

$$\hat{h}(i) = -\frac{1}{2} \Delta_{r_i} + \sum_{j=1}^M \frac{Z_j}{|\mathbf{r}_i - \mathbf{R}_j|}, \quad (88)$$

we get the part of the Hamiltonian depending only on the coordinates of one electron i (and nuclear coordinates, but it does not bother us). Hence, the total electronic Hamiltonian (Eq. 86) can be rewritten as the sum of one-electron and two-electron contributions:

$$\hat{H} = \sum_{i=1}^N \hat{h}(i) + \sum_{i=1}^N \sum_{j=i+1}^N \hat{g}(i, j), \quad (89)$$

where we introduced a symbol:

$$\hat{g}(i, j) = \frac{1}{|\mathbf{r}_i - \mathbf{r}_j|}. \quad (90)$$

It should be noticed that each of the one-electron Hamiltonians $\hat{h}(i)$ describes a single electron in the field of some potentials. Therefore, the exact solutions of the eigenvalue problem for these one-electron operators are available. The problem lies

in the $\hat{g}(i, j)$ operator that couples two electrons together: It is not possible to separate their coordinates exactly.

All electronic Hamiltonians have the same general form; they differ only in the number of electrons N and the nuclear potential hidden in $\hat{h}(i)$. One can choose any possible chemical compounds and try to write the corresponding equations; however, one would soon note the similarity of all of them. Therefore, we will not invest time in describing the procedure for a polypeptide or a nanotube, but for simplicity we will start from the two-electron helium atom (the simplest many-electron system) and later try to generalize the considerations. For the helium atom:

- $N = 2$ – two electrons
- $M = 1$ – one nucleus

The generalization of the helium discussion into the larger (N -electron) systems should be straightforward:

$$\hat{h}(1) + \hat{h}(2) = \sum_{i=1}^2 \hat{h}(i) \rightarrow \sum_{i=1}^N \hat{h}(i), \quad (91)$$

$$\hat{g}(1, 2) = \sum_{i=1}^2 \sum_{j=i+1}^2 \hat{g}(i, j) \rightarrow \sum_{i=1}^N \sum_{j=i+1}^N \hat{g}(i, j), \quad (92)$$

and finally

$$\hat{h}(i) = -\frac{1}{2}\Delta_{r_i} + \frac{Z_1}{|\mathbf{r}_i - \mathbf{R}_1|} \rightarrow -\frac{1}{2}\Delta_{r_i} + \sum_{j=1}^M \frac{Z_j}{|\mathbf{r}_i - \mathbf{R}_j|}. \quad (93)$$

Recall that the exact solutions of the one-electron problem are known, and the task is to solve the full problem. The ideas of the perturbation theory were explained in the previous section. Now it is the time to apply the knowledge. The one-electron part can be treated as the unperturbed Hamiltonian and the rest as the perturbation:

$$\hat{H}^0 = \hat{h}(1) + \hat{h}(2), \quad \hat{H}^1 = \hat{g}(1, 2), \quad (94)$$

where the normalized solutions for the one-electron part are known:

$$\hat{h}(1)\phi_i(1) = \epsilon_i\phi_i(1), \quad (95)$$

$$\hat{h}(2)\phi_j(2) = \epsilon_j\phi_j(2). \quad (96)$$

These functions require more attention. Although the electronic Hamiltonian – and thereby the one-electron operators – do not act on the spin variables, the wave

functions ϕ_k must carry on the spin dependence. Therefore, the function $\phi_k(l)$ is a product of the spatial part depending on the three spatial coordinates of the electron l and on the spin part and is called a spin-orbital. For simplicity, the set of coordinates τ_l is written as a label of the electron, i.e., l . Such convention will be applied from now on, with an exception where the τ_l labeling is really needed.

If an operator can be written as a sum of contributions acting on different variables, its eigenfunction takes a form of the product of the eigenfunctions of the subsequent operators in the summation. In the case of the helium atom, where \widehat{H}^0 is a sum of $\widehat{h}(1)$ and $\widehat{h}(2)$, the wave function $\Psi(1, 2)$ can be denoted as the product of one-electron functions:

$$\Psi(1, 2) = \phi_i(1)\phi_j(2). \quad (97)$$

The eigenproblem for such a function gives the eigenvalue that is simply the sum of the one-electron eigenvalues:

$$\begin{aligned} [\widehat{h}(1) + \widehat{h}(2)] \phi_i(1)\phi_j(2) &= \widehat{h}(1)\phi_i(1)\phi_j(2) + \widehat{h}(2)\phi_i(1)\phi_j(2) \\ &= [\widehat{h}(1)\phi_i(1)] \phi_j(2) + [\widehat{h}(2)\phi_j(2)] \phi_i(1) \\ &= [\epsilon_i \phi_i(1)] \phi_j(2) + [\epsilon_j \phi_j(2)] \phi_i(1) \\ &= [\epsilon_i + \epsilon_j] \phi_i(1)\phi_j(2). \end{aligned} \quad (98)$$

However, here the antisymmetry requirement should also be taken into account. The many-electron function must change the sign with respect to the exchange of labels of any two electrons:

$$\Psi(1, 2) = -\Psi(2, 1). \quad (99)$$

The product (Eq. 97) is not antisymmetric; the interchange of the electron labels leads to

$$\Psi(2, 1) = \phi_i(2)\phi_j(1) \neq -\Psi(1, 2), \quad (100)$$

and the result is a function different from the original $\Psi(1, 2)$. But another function,

$$\Psi(1, 2) \sim [\phi_i(1)\phi_j(2) - \phi_i(2)\phi_j(1)], \quad (101)$$

satisfies the antisymmetry condition.

Moreover, the wave function $\Psi(1, 2)$ has to be normalized. This can be achieved by calculating the following (overlap) integral:

$$\begin{aligned}
\langle \Psi(1, 2) | \Psi(1, 2) \rangle &= \langle \mathcal{N}(\phi_i(1)\phi_j(2) - \phi_j(1)\phi_i(2)) | \mathcal{N}(\phi_i(1)\phi_j(2) - \phi_j(1)\phi_i(2)) \rangle \\
&= \mathcal{N}^2 \left(\langle \phi_i(1)\phi_j(2) | \phi_i(1)\phi_j(2) \rangle - \langle \phi_i(1)\phi_j(2) | \phi_j(1)\phi_i(2) \rangle \right. \\
&\quad \left. - \langle \phi_j(1)\phi_i(2) | \phi_i(1)\phi_j(2) \rangle + \langle \phi_j(1)\phi_i(2) | \phi_j(1)\phi_i(2) \rangle \right). \tag{102}
\end{aligned}$$

The spin-orbitals of electrons 1 and 2 are mutually independent; thus,

$$\langle \phi_i(1)\phi_j(2) | \phi_k(1)\phi_l(2) \rangle = \langle \phi_i(1) | \phi_k(1) \rangle \langle \phi_j(2) | \phi_l(2) \rangle = \delta_{ik}\delta_{jl}, \tag{103}$$

where $\langle \phi_i(1) | \phi_k(1) \rangle = \delta_{ik}$ arises from the fact that the eigenfunctions of the Hermitian operator $\widehat{h}(1)$ form the orthonormal set. Hence, in Eq. 102 only the first and last integral will be nonvanishing, and, finally,

$$\langle \Psi(1, 2) | \Psi(1, 2) \rangle = 2\mathcal{N}^2 = 1, \tag{104}$$

and, therefore, the normalization constant \mathcal{N} must equal $1/\sqrt{2}$. In order to fulfill the normalization and the antisymmetry request, the trial wave function can be written as

$$\Psi(1, 2) = \frac{1}{\sqrt{2}} (\phi_i(1)\phi_j(2) - \phi_j(1)\phi_i(2)) = \frac{1}{\sqrt{2}} \begin{vmatrix} \phi_i(1) & \phi_i(2) \\ \phi_j(1) & \phi_j(2) \end{vmatrix}. \tag{105}$$

Thereafter, the expectation value of the Hamiltonian can be calculated using the same tricks as in Eq. 102³:

$$\begin{aligned}
\langle \widehat{H}(1, 2) \rangle_{\Psi(1,2)} &= \langle \Psi(1, 2) | \widehat{H}(1, 2) | \Psi(1, 2) \rangle \\
&= \langle \phi_i(1) | \widehat{h}(1) | \phi_i(1) \rangle + \langle \phi_j(2) | \widehat{h}(2) | \phi_j(2) \rangle \\
&\quad + \langle \phi_i(1)\phi_j(2) | \frac{1}{r_{12}} | \phi_i(1)\phi_j(2) \rangle \\
&\quad - \langle \phi_i(1)\phi_j(2) | \frac{1}{r_{12}} | \phi_j(1)\phi_i(2) \rangle. \tag{106}
\end{aligned}$$

³Since the value of the integral does not depend on the name of the variable, the obvious equality $\int_a^b f(x)dx = \int_a^b f(y)dy$ in the above case takes the form

$$\langle \phi_i(1)\phi_j(2) | \frac{1}{r_{12}} | \phi_j(1)\phi_i(2) \rangle = \langle \phi_i(2)\phi_j(1) | \frac{1}{r_{12}} | \phi_j(2)\phi_i(1) \rangle.$$

The only difference with respect to the overlap integral is that the integrals containing $1/r_{12}$ cannot be separated.

In the spirit of perturbation calculus, the expectation value (Eq. 106) can be treated as the energy corrected up to the first order of perturbation expansion. According to the variational principle, this integral is an upper bound of the exact energy of the two-electron system under consideration. The recipe for correcting the trial function is given by the perturbation theory: Apply functions corresponding to the remaining states of the unperturbed system in the expansion. In other words, in order to improve the wave function, the expansion built from products of the remaining states of the systems should be used.

Let us summarize. The many-electron function of the system can be approximately written as the antisymmetrized product of the one-electron functions being the solutions for the one-electron eigenvalue problem. This is the idea of the popular one-electron approximation (Atkins and Friedman 2005; Lowe and Peterson 2005; McQuarrie and Simon 1997; Ratner and Schatz 2000). In the N -electron case, one obtains the trial function as the antisymmetrized product of N one-electron functions that can be written in the form of the Slater determinant:

$$\Psi(1, 2, \dots, N) = \frac{1}{\sqrt{N!}} \begin{vmatrix} \phi_1(1) & \phi_1(2) & \dots & \phi_1(N) \\ \phi_2(1) & \phi_2(2) & \dots & \phi_2(N) \\ \vdots & \vdots & \ddots & \vdots \\ \phi_N(1) & \phi_N(2) & \dots & \phi_N(N) \end{vmatrix}. \quad (107)$$

$1/\sqrt{N!}$ factor ensures the normalization of the wave function. Often, instead of writing the whole determinant, only the diagonal is written down:

$$\begin{vmatrix} \phi_1(1) & \phi_1(2) & \dots & \phi_1(N) \\ \phi_1(2) & \phi_2(2) & \dots & \phi_2(N) \\ \vdots & \vdots & \ddots & \vdots \\ \phi_N(1) & \phi_N(2) & \dots & \phi_N(N) \end{vmatrix} = |\phi_1(1)\phi_2(2) \dots \phi_N(N)|. \quad (108)$$

It is important to realize that the many-electron function in the form of the Slater determinant is only an approximation. Intuition tells us that describing the many-electron system using only one-electron functions cannot be exact. One needs to be aware of the fact that such an approach causes the loss of some information included in the sought wave function. In particular, the one-electron function cannot “see” another electron; therefore, the terms coupling the mutual electron positions are missing in the one-electron approximation.

For example, consider the two-electron function (Piela 2007)

$$F(1, 2) \sim (e^{-ar_1-br_2-cr_{12}} - e^{-ar_2-br_1-cr_{12}}), \quad (109)$$

where r_1, r_2 are the electron–nucleus distances, r_{12} denotes the distance between two electrons, and a, b , and c stand for the coefficients. $F(1, 2)$ contains the factor c correlating the electron motions. In the one-electron approach, such a function would be approximated by the antisymmetrized function

$$f(1, 2) \sim (e^{-ar_1-br_2} - e^{-ar_2-br_1}), \quad (110)$$

with total neglect of this correlation. From the practical point of view, this means that the trial function written as the single determinant does not allow reproduction of the exact electronic energy, even when using the best possible one-electron functions for its construction.

The question arises: Why use such an approach, knowing from the very beginning that it is bad? The answer is simple. First, including the electron correlation in the wave function is very expensive. For two electrons, one additional term appears; for three, three terms; for four, six. In general, for N electrons there are $N(N - 1)/2$ terms (the triangle of the $N \times N$ matrix without the diagonal elements). Therefore, the number of coefficients describing the electron correlation is much bigger than the number of one-electron terms. Calculating even the one-electron coefficients is very time-consuming, and moreover, calculating the overlap integrals and Hamiltonian matrix elements becomes prohibitively complicated with the correlated functions. Second, perturbation theory provides ways of improving the results. Expansion built on a higher number of determinants will lead to better energy. Third, a chemist does not usually need exact data but only an appropriate accuracy (furnishing a house does not require caliper measurements, just a quick glance to estimate the size of the door and the furniture).

Therefore, let us stick to the one-electron approximation. The next section will explain how to find the best possible spin-orbitals.

Hartree–Fock Method: It Is Not That Sophisticated

Now we are prepared to concentrate on the methods for solving the electron equation. As you will see, they are only an extension of the already-discussed techniques. We start with the fundamental Hartree–Fock method.

The main goal of this approximation is to find the spin-orbitals applied for construction of the Slater determinant that will best reproduce the exact wave function. We again begin our considerations with the two-electron system. The problem is that the operator $\hat{h}(i)$ does not contain the part arising from the potential of the second electron, and an operator responsible for this missing part must be found. What we do know is that such an interaction is included in the two-electron part of Eq. 106:

$$\left\langle \frac{1}{r_{12}} \right\rangle_{\Psi(1,2)} = \left\langle \phi_1(1)\phi_j(2) \left| \frac{1}{r_{12}} \right| \phi_i(1)\phi_j(2) \right\rangle - \left\langle \phi_i(1)\phi_j(2) \left| \frac{1}{r_{12}} \right| \phi_j(1)\phi_i(2) \right\rangle. \quad (111)$$

Unfortunately, Eq. 111 contains the integrals that cannot be exactly separated into a product of the simpler integrals depending only on the coordinates of one electron. What we can propose is rewriting this equation in the following form:

$$\left\langle \frac{1}{r_{12}} \right\rangle_{\Psi(1,2)} = \langle \phi_i(1) | \widehat{v}(1) | \phi_i(1) \rangle + \langle \phi_j(2) | \widehat{v}(2) | \phi_j(2) \rangle + \text{the rest}, \quad (112)$$

where $\widehat{v}(1)$ and $\widehat{v}(2)$ are introduced to extract only the terms depending on the coordinates of a single electron from Eq. 111 and “the rest” is what remains from $\left\langle \frac{1}{r_{12}} \right\rangle_{\Psi(1,2)}$ after this extraction.

If such extraction were possible, the operators $\widehat{v}(1)$ and $\widehat{v}(2)$ could be applied to improve our one-electron operators, which leads to the following equations:

$$\left[\widehat{h}(1) + \widehat{v}(1) \right] \phi_i(1) = \epsilon_i \phi_i(1), \quad (113)$$

$$\left[\widehat{h}(2) + \widehat{v}(2) \right] \phi_j(2) = \epsilon_j \phi_j(2). \quad (114)$$

The solutions of such equations (spin-orbitals ϕ_i, ϕ_j) can be used to build up the Slater determinant. They ensure better approximation than Eqs. 95 and 96, since they somehow provide for the influence of the second electron.

Therefore, our goal now is to utilize Eq. 106 (treating ϕ_i and ϕ_j) as known functions) to find the best form of the operators $\widehat{v}(1)$ and $\widehat{v}(2)$. Adding zero, written as

$$0 = \left\langle \frac{1}{r_{12}} \right\rangle_{\Psi(1,2)} - \left\langle \frac{1}{r_{12}} \right\rangle_{\Psi(1,2)}, \quad (115)$$

to Eq. 111 allows one to ascribe, for instance,

$$\begin{aligned} \langle \phi_i(1) | \widehat{v}(1) | \phi_i(1) \rangle &= \left\langle \phi_i(1) \phi_j(2) \left| \frac{1}{r_{12}} \right| \phi_i(1) \phi_j(2) - \phi_j(1) \phi_i(2) \right\rangle, \\ \langle \phi_j(2) | \widehat{v}(2) | \phi_j(2) \rangle &= \left\langle \phi_i(1) \phi_j(2) \left| \frac{1}{r_{12}} \right| \phi_i(1) \phi_j(2) - \phi_j(1) \phi_i(2) \right\rangle, \\ \text{the rest} &= - \left\langle \phi_i(1) \phi_j(2) \left| \frac{1}{r_{12}} \right| \phi_i(1) \phi_j(2) - \phi_j(1) \phi_i(2) \right\rangle. \end{aligned}$$

Consider in more detail the integral containing $\widehat{v}(1)$. We want it to be expressed in such a way that only the coordinates of the electron labeled by 1 are explicitly written under the integral:

$$\begin{aligned} \langle \phi_i(1) | \widehat{v}(1) | \phi_i(1) \rangle &= \left\langle \phi_i(1) \phi_j(2) \left| \frac{1}{r_{12}} \right| \phi_i(1) \phi_j(2) - \phi_j(1) \phi_i(2) \right\rangle \\ &= \int \int \phi_i^*(\tau_1) \phi_j^*(\tau_2) \frac{1}{r_{12}} \phi_i(\tau_1) \phi_j(\tau_2) d\tau_1 d\tau_2 \\ &\quad - \int \int \phi_i^*(\tau_1) \phi_j^*(\tau_2) \frac{1}{r_{12}} \phi_j(\tau_1) \phi_i(\tau_2) d\tau_1 d\tau_2 \\ &= \int \phi_i^*(\tau_1) \left(\int \phi_j^*(\tau_2) \frac{1}{r_{12}} \phi_j(\tau_2) d\tau_2 \right) \phi_i(\tau_1) d\tau_1 \end{aligned}$$

$$\begin{aligned}
& - \int \phi_i^* (\tau_1) \left(\int \phi_j^* (\tau_2) \frac{1}{r_{12}} \phi_i (\tau_2) d\tau_2 \right) \phi_j (\tau_1) d\tau_1 \\
& = \int \phi_i^* (\tau_1) \left(\widehat{J}_j(1) \phi_i (\tau_1) \right) d\tau_1 \\
& \quad - \int \phi_j^* (\tau_1) \left(\widehat{K}_j(1) \phi_i (\tau_1) \right) d\tau_1 \tag{116} \\
& = \left\langle \phi_i(1) \left| \widehat{J}_j(1) \right| \phi_i(1) \right\rangle - \left\langle \phi_i(1) \left| \widehat{K}_j(1) \right| \phi_i(1) \right\rangle \\
& = \left\langle \phi_i(1) \left| \widehat{J}_j(1) - \widehat{K}_j(1) \right| \phi_i(1) \right\rangle,
\end{aligned}$$

where two operators were defined:

$$\widehat{J}_j(1) \phi_i(1) = \left(\int \phi_j^* (\tau_2) \frac{1}{r_{12}} \phi_j (\tau_2) d\tau_2 \right) \phi_i(1), \tag{117}$$

$$\widehat{K}_j(1) \phi_i(1) = \left(\int \phi_j^* (\tau_2) \frac{1}{r_{12}} \phi_i (\tau_2) d\tau_2 \right) \phi_j(1). \tag{118}$$

Despite a slightly different way of defining, they are still ordinary operators. An operator is a function of a function. The operators $\widehat{J}_j(1)$ and $\widehat{K}_j(1)$ act on the function $\phi_i(1)$, producing another function, as was written in Eq. 8. The operator $\widehat{J}_j(1)$ acting on $\phi_i(1)$ transforms it into the same function:

$$\phi_i(1) \xrightarrow{\widehat{J}_j(1)} \left(\int \phi_j^* (\tau_2) \frac{1}{r_{12}} \phi_j (\tau_2) d\tau_2 \right) \phi_i(1), \tag{119}$$

and the operator $\widehat{K}_j(1)$ produces $\phi_j(1)$:

$$\phi_i(1) \xrightarrow{\widehat{K}_j(1)} \left(\int \phi_j^* (\tau_2) \frac{1}{r_{12}} \phi_i (\tau_2) d\tau_2 \right) \phi_j(1). \tag{120}$$

The expressions on the right-hand side of the arrows are some functions of a dependent variable τ_1 (the integration eliminates the dependence on τ_2 ; however, its result is not a number but a function depending on τ_1). The interpretation of the $\widehat{J}_j(1)$ and $\widehat{K}_j(1)$ operators by ascribing them to observables is not straightforward. These operators appear in the equations when we try to write the interaction between two electrons as the average value of the one-electron operator calculated with the one-electron function. However, in fact, they do appear as the difference:

$$\widehat{v}_i^{\text{HF}}(1) = \widehat{J}_j(1) - \widehat{K}_j(1). \tag{121}$$

And the physical sense should be sought in this difference. Here, $\widehat{v}_i^{\text{HF}}(1)$ is an operator of the average interaction of the electron labeled as 1, described by a spin-orbital ϕ_i with the second electron characterized by $\phi_j(2)$. It should be noticed that the potential $\widehat{v}_i^{\text{HF}}(1)$ depends on $\phi_j(2)$, since this spin-orbital is necessary to define $\widehat{J}_j(1)$ and $\widehat{K}_j(1)$ operators.

Similarly,

$$\widehat{v}_j^{\text{HF}}(2) = \widehat{J}_i(2) - \widehat{K}_i(2), \quad (122)$$

where the action of operators $\widehat{J}_j(1)$ and $\widehat{K}_j(1)$ on the function $\phi_j(2)$ is defined by

$$\widehat{J}_i(2)\phi_j(2) = \left(\int \phi_i^*(\tau_1) \frac{1}{r_{12}} \phi_i(\tau_1) d\tau_1 \right) \phi_j(2) \quad (123)$$

$$\widehat{K}_i(2)\phi_j(2) = \left(\int \phi_i^*(\tau_1) \frac{1}{r_{12}} \phi_j(\tau_1) d\tau_1 \right) \phi_i(2). \quad (124)$$

Here, one more important circumstance should be mentioned. The electronic Hamiltonian does not depend on spin. However, the electronic wave function is spin dependent. During the construction of the HF equations, this dependence is introduced to the operators \widehat{K} since they depend on two different spin-orbitals.

Let us briefly review. We want to have a one-electron operator that includes the interaction between the electrons in some averaged way. Such an operator must depend on the function describing the motion of the second, adjacent electron. Therefore, for the two-electron case, two coupled equations must be solved (Eqs. 113 and 114). The word “coupled” that distinguishes this set of equations from Eqs. 95 and 96 is crucial. Denoting

$$\widehat{f}_i(1) = \widehat{h}(1) + \widehat{v}_i^{\text{HF}}(1), \quad (125)$$

one can rewrite the above equations as

$$\widehat{f}_k(1)\phi_k(1) = \epsilon_k\phi_k(1), \quad \text{for } k = i, j. \quad (126)$$

$\widehat{f}_i(1)$ is called the Fock operator and Eq. 114 gives the Hartree–Fock equations.

It should be noted that the label of electrons determines only the name of the integration variables, and the result of the integration does not depend on the name of the variable. Therefore, what is really important is the label of the spin-orbital. It will be even more pronounced in the N -electron case, when the electron labels are applied only to show that the operator acts on one or two electron coordinates. The form of the N -electron wave function depends only on the spin-orbitals and not on the electron labels; they are just the integration variables.

The most popular way of solving Eq. 126 is the iterative procedure. It starts from the guessed or chosen spin-orbitals $\phi_i(1)$ and $\phi_j(2)$ applied to construct the potentials $\widehat{v}_i^{\text{HF}}(1)$ and $\widehat{v}_j^{\text{HF}}(2)$. Next, the obtained potentials are substituted to Eq. 125 and solutions of Eq. 126 give the improved form of the $\phi_i(1)$ and $\phi_j(2)$ spin-orbitals. These, on the other hand, are treated as the starting point again, and the whole procedure is repeated until the starting and final orbitals of the given iteration

do not differ much. This technique is called self-consistent field (SCF). Often the abbreviations HF for Hartree–Fock method and SCF are used interchangeably. They can also be joined together as SCF–HF, denoting the self-consistent way of solving Hartree–Fock equations.

Let us assume that the spin-orbitals are already known. Concentrate on the calculations of the average value of the Hamiltonian with the determinant build of these spin-orbitals using the operators defined previously. Writing down the two-electron part:

$$\begin{aligned} \left\langle \frac{1}{r_{12}} \right\rangle_{\Psi(1,2)} &= \left\langle \phi_i(1) \left| \widehat{J}_j(1) - \widehat{K}_j(1) \right| \phi_i(1) \right\rangle \\ &= \left\langle \phi_j(2) \left| \widehat{J}_i(2) - \widehat{K}_i(2) \right| \phi_j(2) \right\rangle, \end{aligned}$$

one obtains the integrals that can be denoted by

$$\begin{aligned} J_{ij} &= \left\langle \phi_i(1) \left| \widehat{J}_j(1) \right| \phi_i(1) \right\rangle, \\ K_{ij} &= \left\langle \phi_i(1) \left| \widehat{K}_j(1) \right| \phi_i(1) \right\rangle. \end{aligned}$$

With this notation, the expression (Eq. 106) takes the following form:

$$\left\langle \widehat{H}(1, 2) \right\rangle_{\Psi(1,2)} = \left\langle \phi_i(1) \left| \widehat{f}(1) \right| \phi_i(1) \right\rangle + \left\langle \phi_j(2) \left| \widehat{f}(2) \right| \phi_j(2) \right\rangle - (J_{ij} - K_{ij}), \quad (127)$$

or if one wants to apply the spin-orbital energies ϵ calculated earlier:

$$\left\langle \widehat{H}(1, 2) \right\rangle_{\Psi(1,2)} = \epsilon_i + \epsilon_j - (J_{ij} - K_{ij}). \quad (128)$$

Now it is time to generalize these considerations into the N -electron case. The recipe for this transformation was given previously (Eqs. 91, 92, and 93). For the system of N electrons, the set of N -coupled equations of the form

$$\widehat{f}_i(1)\phi_i(1) = \epsilon_i\phi_i(1), \quad \text{for } i = 1, \dots, N \quad (129)$$

must be solved. Here,

$$f_i(1) = h(1) + \sum_{j \neq i}^N \left(\widehat{J}_j(1) - \widehat{K}_j(1) \right). \quad (130)$$

The summation in the expression for the one-electron Fock operator arises from the fact that now the given electron described by the spin-orbital i interacts with $(N - 1)$ electrons in the states determined by the remaining spin-orbitals.

In searching for the ground state energy, one is interested in the lowest possible energy. Therefore, the functions of choice are the spin-orbitals corresponding to the lowest values of ϵ . Such a set of spin-orbitals, called occupied, is opposite to any other solutions of the Fock equations corresponding to higher energies. These are known as virtual (unoccupied) orbitals.

Finally, the average value of the Hamiltonian can be written as

$$\left\langle \widehat{H}(1, 2, \dots, N) \right\rangle_{\Psi^{(0)}(N)} = \sum_{i=1}^N \epsilon_i - \sum_{i=1}^N \sum_{j>i}^N (J_{ij} - K_{ij}) = E_0^{\text{HF}}$$

It should be emphasized that the energy estimated in this manner is not the simple sum of the orbital energies. If the terms $\sum_{i=1}^N \sum_{j>i}^N (J_{ij} - K_{ij})$ are neglected, the double summation of the electron–electron interaction would take place (Atkins and Friedman 2005; Cramer 2004; Jensen 2006; Levine 2008; Lowe and Peterson 2005; McQuarrie and Simon 1997; Piela 2007; Ratner and Schatz 2000; Roos and Widmark 2002; Szabo and Ostlund 1996).

Møller–Plesset Perturbation Theory: HF Is Just the Beginning

From here forward, we will treat the Hartree–Fock function as the basis for the further investigations and denote it as $\Psi_0^{(0)}$, where the subscript 0 indicates the ground state and the superscript (0) is the reference function. We will also omit the explicit writing of the dependence of the Hamiltonian and the wave function on the coordinates of N electrons. As a consequence,

$$\left\langle \Psi_0^{(0)} \left| \widehat{H} \right| \Psi_0^{(0)} \right\rangle = E_0^{\text{HF}}. \quad (131)$$

One of the possible ways of improving the HF results is the application of the perturbation theory (Atkins and Friedman 2005; Cramer 2004; Jensen 2006; Levine 2008; McQuarrie and Simon 1997; Piela 2007; Ratner and Schatz 2000; Szabo and Ostlund 1996). The Hamiltonian (Eq. 89) can be partitioned into the unperturbed part and the perturbation in the following manner:

$$\widehat{H}^0 = \sum_{i=1}^N \widehat{f}(i), \quad \widehat{H}^1 = \sum_{i=1}^N \left(\sum_{j>i}^N \frac{1}{r_{ij}} - \widehat{v}^{\text{HF}}(i) \right) \quad (132)$$

(compare Eq. 125). Up to the first order in the perturbation theory, the energy is

$$E_0^{\text{HF}} = E_0^{(0)} + E_0^{(1)} = \left\langle \Psi_0^{(0)} \left| \widehat{H}^0 + \widehat{H}^1 \right| \Psi_0^{(0)} \right\rangle = \left\langle \widehat{H} \right\rangle_{\Psi_0^{(0)}}. \quad (133)$$

The correction to the HF energy appears in the second order:

$$E_0^{(2)} = \sum_{k \neq 0}^{\infty} \frac{\left| \langle \Psi_0^{(0)} | \widehat{H}^1 | \Psi_k^{(0)} \rangle \right|^2}{E_0^{(0)} - E_k^{(0)}}. \quad (134)$$

During calculations, the expansion of the spin-orbitals in the finite basis set is applied. This allows identification of only the finite number of spin-orbitals. But the number of all possible $\Psi_k^{(0)}$ functions can still be horrifyingly large. In practice, this is equivalent to the finite but long expansion in the above summation. In quantum chemistry we are interested in the best quality results with moderate expenses and are continuously searching for more economical methods.

Careful examination of the second-order energy correction $E_0^{(2)}$ shows that a significant number of its terms do not contribute to the final result. Some work invested in the manipulation of expressions allows one not only to learn the basic computational apparatus but also to save a lot of effort.

In order to proceed comfortably, the notation should again be simplified. Let us drop the superscript (0) denoting the zeroth-order functions (other functions will not appear in our considerations). Additionally, we omit the subscript k from the determinants containing the virtual spin-orbitals. In return, we explicitly specify the pattern of spin-orbital exchange. Using Eq. 108, the Slater determinant can be written as

$$\left| \Psi_0 \right\rangle = |\phi_1(1)\phi_2(2)\phi_3(3)\phi_4(4) \dots \phi_N(N)\rangle. \quad (135)$$

The numbers of the occupied spin-orbitals vary from 1 to N . Thus, the virtual spin-orbitals will be labeled starting from $N + 1$ onward. Now consider the example of the determinant in which the occupied spin-orbital ϕ_3 is exchanged for the virtual one, ϕ_{N+8} . The new determinant can be written as

$$\left| \Psi_3^{N+8} \right\rangle = |\phi_1(1)\phi_2(2)\phi_{N+8}(3)\phi_4(4) \dots \phi_N(N)\rangle, \quad (136)$$

where the subscript in Ψ_3^{N+8} denotes the occupied orbital that is exchanged and the superscript denotes the virtual one that takes its place. To generalize, one could denote the occupied orbitals building the Ψ_0 function by first alphabet letters a, b, c, d, \dots and the virtuals by p, q, r, s, \dots . Therefore, Ψ_3^{N+8} can be written as Ψ_a^p , where $a = 3$ and $p = N + 8$. Likewise, any determinant can be represented.

Thereafter, the influence of the function choice on the values of the integrals appearing in the electronic energy calculations can be investigated. Similarly, as in the case of Hamiltonian, the integrals can also be divided into two groups with one-electron operator

$$\widehat{o}_1 = \sum_{i=1}^N \widehat{o}(i), \quad (137)$$

where in place of $\hat{o}(i)$ operators $\hat{h}, (i)$ or $\hat{f}(i)$ will be used, and with two-electron operator,

$$\hat{O}_2 = \sum_i \sum_{j>i} \left(\frac{1}{r_{ij}} \right). \quad (138)$$

To get a full picture, we should analyze the following types of integrals:

$$\langle \Psi_0 | \hat{o}_1 | \Psi_a^p \rangle \quad \text{and} \quad \langle \Psi_0 | \hat{O}_2 | \Psi_a^p \rangle, \quad (139)$$

$$\langle \Psi_0 | \hat{o}_1 | \Psi_{ab}^{pq} \rangle \quad \text{and} \quad \langle \Psi_0 | \hat{O}_2 | \Psi_{ab}^{pq} \rangle, \quad (140)$$

$$\langle \Psi_0 | \hat{o}_1 | \Psi_{abc}^{pqr} \rangle \quad \text{and} \quad \langle \Psi_0 | \hat{O}_2 | \Psi_{abc}^{pqr} \rangle. \quad (141)$$

Any other will be equal to zero (Levine 2008; Szabo and Ostlund 1996).

Recall that the determinant of the $N \times N$ matrix can be represented as the sum of the $N!$ products of the matrix elements. According to Laplace's formula, a determinant can be expanded along a row or a column. Thus, calculation of the $\langle \Psi_0 | \hat{o}_1 | \Psi_a^p \rangle$ integrals, when the occupied orbital a in Ψ_0 has been exchanged with the virtual orbital p in Ψ_a^p , can be performed by expanding the determinant Ψ_0 along the a -th row and the determinant Ψ_a^p along the p -th row:

$$\Psi_0 = \frac{1}{\sqrt{N!}} \sum_{i=1}^N \phi_a(i) C_{ai}, \quad (142)$$

$$\Psi_a^p = \frac{1}{\sqrt{N!}} \sum_{i=1}^N \phi_p(i) C_{pi}. \quad (143)$$

The cofactors C can be perceived as the $(N - 1)$ -electron determinants that have been obtained from Ψ_0 and Ψ_a^p via the elimination of the a -th and p -th spin-orbitals, respectively. Thus, after elimination of what is different in the two determinants, we get both cofactors equal to each other. Hence,

$$\begin{aligned} \langle \Psi_0 | \hat{o}_1 | \Psi_a^p \rangle &= \frac{1}{N!} \left\langle \sum_{i=1}^N \phi_a(i) C_{ai} \left| \sum_{j=1}^N \hat{o}(j) \right| \sum_{k=1}^N \phi_p(k) C_{pi} \right\rangle \\ &= \frac{1}{N!} \sum_{i=1}^N \langle \phi_a(i) | \hat{o}(i) | \phi_p(i) \rangle \langle C_{ai} | C_{pi} \rangle \\ &= \frac{1}{N} \sum_{i=1}^N \langle \phi_p(i) | \hat{o}(i) | \phi_p(i) \rangle \\ &= \langle \phi_a(1) | \hat{o}(1) | \phi_p(1) \rangle, \end{aligned} \quad (144)$$

where

$$\langle C_{ai} | C_{pi} \rangle = (N - 1)!, \quad (145)$$

$$\sum_{i=1}^N \langle \phi_a(i) | \widehat{\partial}(i) | \phi_a(i) \rangle = N \langle \phi_a(1) | \widehat{\partial}(1) | \phi_a(1) \rangle \quad (146)$$

was applied. If the cofactors are not the same – this would be the case when the determinants differ from two or more spin-orbitals – the corresponding overlap matrix is equal to zero according to the orthogonality condition. Thus,

$$\begin{aligned} \langle \Psi_0 | \widehat{\partial}_1 | \Psi_a^p \rangle &= \langle \phi_a(1) | \widehat{\partial}(1) | \phi_p(1) \rangle, \\ \langle \Psi_0 | \widehat{\partial}_1 | \Psi_{ab}^{pq} \rangle &= 0, \\ \langle \Psi_0 | \widehat{\partial}_1 | \Psi_{abc}^{pqr} \rangle &= 0. \end{aligned} \quad (147)$$

Similar (but a little more time-consuming) considerations for the two-electron operators lead to the following expressions:

$$\begin{aligned} \langle \Psi_0 | \widehat{\mathcal{O}}_2 | \Psi_a^p \rangle &= \sum_{i=1}^N \left(\left\langle \phi_a(1) \phi_i(2) \left| \frac{1}{r_{12}} \right| \phi_p(1) \phi_i(2) \right\rangle \right. \\ &\quad \left. - \left\langle \phi_a(1) \phi_i(2) \left| \frac{1}{r_{12}} \right| \phi_i(1) \phi_p(2) \right\rangle \right) \\ \langle \Psi_0 | \widehat{\mathcal{O}}_2 | \Psi_{ab}^{pq} \rangle &= \left\langle \phi_a(1) \phi_b(2) \left| \frac{1}{r_{12}} \right| \phi_p(1) \phi_q(2) \right\rangle \\ &\quad - \left\langle \phi_a(1) \phi_b(2) \left| \frac{1}{r_{12}} \right| \phi_q(1) \phi_p(2) \right\rangle \\ \langle \Psi_0 | \widehat{\mathcal{O}}_2 | \Psi_{abc}^{pqr} \rangle &= 0. \end{aligned} \quad (148)$$

In the first contact with these equations, one can have the feeling that something is lost here. We start from the integrals with the N -electron functions and we finish with the integral of only the electrons labeled by 1 and 2. What happened to the rest? Again, it should be emphasized here that the electron labels symbolize only the integration variables. What matters is the functions of these variables, namely, spin-orbitals. Thus, in the integral with the one-electron operator, the electron label 1 means that the integration is performed only over the variables of one electron. Likewise, the two-electron operator integral depends on the variables of two electrons, which is symbolized by two labels: 1 and 2.

In the integration of one-electron expressions, the electron label can be omitted without any harm: $\langle \phi_a(1) | \widehat{\partial}_1(1) | \phi_a(1) \rangle$. Likewise, in the two-electron case, we can declare that the spin-orbitals are written in the given order. So,

$$\left\langle \phi_x(1) \phi_y(2) \left| \frac{1}{r_{12}} \right| \phi_v(1) \phi_z(2) \right\rangle = \left\langle \phi_x \phi_y \left| \frac{1}{r_{12}} \right| \phi_v \phi_z \right\rangle. \quad (149)$$

Moreover, now there is no reason to explicitly write the ϕ symbol. Thereby, the next simplification of the notation is obvious:

$$\begin{aligned}\langle \phi_a | \widehat{o}_1 | \phi_a \rangle &= \langle a | \widehat{o}_1 | a \rangle, \\ \langle \phi_x \phi_y | \frac{1}{r_{12}} | \phi_v \phi_z \rangle &= \langle xy | \frac{1}{r_{12}} | vz \rangle,\end{aligned}\tag{150}$$

and finally, since the combination of the integrals $\langle xy | 1/r_{12} | vz \rangle - \langle xy | 1/r_{12} | zv \rangle$ appears frequently, the following symbol is introduced:

$$\langle xy || zv \rangle = \langle xy | \frac{1}{r_{12}} | vz \rangle - \langle xy | \frac{1}{r_{12}} | zv \rangle.\tag{151}$$

Now Eqs. 147 and 148 can be rewritten as

$$\begin{aligned}\langle \Psi_0 | \widehat{o}_1 | \Psi_a^p \rangle &= \langle a | \widehat{o}_1 | p \rangle, \\ \langle \Psi_0 | \widehat{o}_1 | \Psi_{ab}^{pq} \rangle &= 0, \\ \langle \Psi_0 | \widehat{o}_1 | \Psi_{abc}^{pqr} \rangle &= 0, \\ \langle \Psi_0 | \widehat{O}_2 | \Psi_a^p \rangle &= \sum_{i=1}^N \langle ai || pi \rangle, \\ \langle \Psi_0 | \widehat{O}_2 | \Psi_{ab}^{pq} \rangle &= \langle ab || pq \rangle, \\ \langle \Psi_0 | \widehat{O}_2 | \Psi_{abc}^{pqr} \rangle &= 0.\end{aligned}\tag{152}$$

These simple equations, known as the Slater rules, allow for the following general remark: If the one-electron operator is integrated with functions that differ by more than one spin-orbital, the corresponding integral vanishes. Similarly, the result is zero for the integration of two-electron operators with functions differing by more than two spin-orbitals. Hitherto, only the integrals with Ψ_0 were considered. However, it is easy to notice that functions Ψ_{ab}^{pq} and Ψ_{abc}^{pqr} differ by only one exchange (spin-orbital $\phi_c \rightarrow \phi_r$), etc. Therefore, the above considerations can be also applied in any other cases.

In this abundance of equations, our main goal cannot be lost: All these derivations were necessary to limit the types of the Ψ_k functions present in the MP2 energy expression. Now, with a recognition of the above Slater rules, one can safely neglect the integrals with the pairs of the Ψ_k functions differing with more than two spin-orbital exchanges. But this is not everything.

Let us consider the integral

$$\langle \Psi_0 | \widehat{H} | \Psi_a^p \rangle = \langle a | \widehat{h} | p \rangle + \sum_j \left(\langle aj | \frac{1}{r_{ij}} | pj \rangle - \langle aj | \frac{1}{r_{ij}} | jp \rangle \right).\tag{153}$$

Since

$$\left\langle aj \left| \frac{1}{r_{ij}} \right| pj \right\rangle = \left\langle a \left| \widehat{J}_j \right| p \right\rangle, \quad (154)$$

and

$$\left\langle aj \left| \frac{1}{r_{ij}} \right| jp \right\rangle = \left\langle a \left| \widehat{K}_j \right| p \right\rangle, \quad (155)$$

one gets

$$\left\langle \Psi_0 \left| \widehat{H} \right| \Psi_a^p \right\rangle = \left\langle a \left| \widehat{H}^0 \right| p \right\rangle, \quad (156)$$

which has to vanish, because

$$\left\langle a \left| \widehat{H}^0 \right| p \right\rangle = \left\langle a \left| \sum_{i=1}^N f(i) \right| p \right\rangle = \langle a | f | p \rangle = \epsilon_p \delta_{ap} = 0, \quad (157)$$

for it was assumed that $a \neq p$.

The obtained result,

$$\left\langle \Psi_0 \left| \widehat{H} \right| \Psi_a^p \right\rangle = 0, \quad (158)$$

is known as the Brillouin theorem. Applying it allows one also to show that

$$\left\langle \Psi_0 \left| \widehat{H}^1 \right| \Psi_a^p \right\rangle = 0. \quad (159)$$

Indeed, using

$$\widehat{H}^1 = \widehat{H} - \widehat{H}^0, \quad (160)$$

one obtains

$$\begin{aligned} \left\langle \Psi_0 \left| \widehat{H}^1 \right| \Psi_a^p \right\rangle &= \left\langle \Psi_0 \left| \widehat{H} \right| \Psi_a^p \right\rangle - \left\langle \Psi_0 \left| \widehat{H}^0 \right| \Psi_a^p \right\rangle \\ &= 0 - \left(\sum_{i=1}^N \epsilon_i \right) \left\langle \Psi_0 \left| \Psi_a^p \right\rangle \right. \\ &= 0. \end{aligned} \quad (161)$$

Now is the time for an important conclusion: In order to calculate the correction to the energy in MP2, the functions arising from Ψ_0 only by the exchange of precisely two spin-orbitals need to be applied, not more, not less. Life becomes easier when not calculating zero contributions in a complicated way.

Let us exploit the above knowledge to transform Eq. 134. The integral on the right-hand side will be calculated with the functions Ψ_{ab}^{pq} . Assuming $b > a$ and $q > p$ allows avoidance of the integration with the same functions. The upper limit for

the summations over a and b will be equal to N . For the remaining spin-orbitals, it should be ∞ ; however, in practice, the finite basis is applied and the upper limit will be determined by the basis set size. Let us look into the numerator of Eq. 134 carefully. Denoting the total Fock operator as $\widehat{F} = \sum_i \widehat{f}(i)$, one gets

$$\begin{aligned} \langle \Psi_0 | \widehat{H}^1 | \Psi_{ab}^{pq} \rangle &= \langle \Psi_0 | \widehat{H} | \Psi_{ab}^{pq} \rangle - \langle \Psi_0 | \widehat{F} | \Psi_{ab}^{pq} \rangle \\ &= \langle ab | \frac{1}{r_{ij}} | pq \rangle - \langle ab | \frac{1}{r_{ij}} | pq \rangle, \end{aligned} \quad (162)$$

since

$$\langle \Psi_0 | \widehat{F} | \Psi_{ab}^{pq} \rangle = 0 \quad (163)$$

(integration of the one-electron operator with the functions differing by two spin-orbitals; see Eq. 152).

Now consider the denominator of Eq. 134. The energy of the ground state is simply a sum of N lowest spin-orbital energies:

$$E_0^{(0)} = \sum_{i=1}^N \epsilon_i. \quad (164)$$

The energy of the zeroth order for the function Ψ_{ab}^{pq} is a similar sum with ϵ_a and ϵ_b replaced by ϵ_p and ϵ_q :

$$E_{(pq)}^{(0)} = E_0^{(0)} - \epsilon_a - \epsilon_b + \epsilon_p + \epsilon_q. \quad (165)$$

Thus, the final form of Eq. 134 is

$$E_0^{(2)} = \sum_{b>a} \sum_{q>p} \frac{|\langle ab || pq \rangle|^2}{\epsilon_p + \epsilon_q - \epsilon_a - \epsilon_b}. \quad (166)$$

Why was it worth our hard work? Not only for satisfaction. These derivations are necessary to understand the mechanisms employed in computational methods of quantum chemistry. With the Slater rules, it is straightforward to recognize the vanishing integrals. The double exchanges appear to be most important, since these are the only exchanges that give rise to the energy corrections in the MP2 method.

According to the perturbation calculus, the wave function corrected in the first order can be written as

$$\Psi \approx \Psi_0 + \sum_{k \neq 0} c_k \Psi_k, \quad (167)$$

where c_k is given by

$$c_k = \frac{\langle \Psi_0 | \widehat{H}^1 | \Psi_k \rangle}{E_0 - E_k}. \quad (168)$$

From the Slater rules, it is easy to estimate that the only nonvanishing terms will arise from the double spin-orbital exchange in the wave function. The intuitive statement is that the low-order corrections should have the larger impact and the above considerations lead to the most important accomplishment of this section: The largest contribution to the corrections of the Hartree–Fock function arises from the functions with the doubly exchanged spin-orbitals.

Beyond the HF Wave Function

Having done all this hard work, one can now sit comfortably in an armchair and think. The main goal of the quantum chemistry is to find the best possible description of the state of the system (the best possible wave function). The exact solutions of the Hamiltonian eigenproblem are unavailable and all we have are approximations. We have become used to approximations in everyday life. The important thing is to realize that the Hartree–Fock solutions can be improved. At the beginning of this chapter, various properties of operators were discussed. Among others, it was stated that the eigenfunctions of the Hermitian operators constitute the complete sets and any other function of the same variables can be represented by applying them. The one-electron spin-orbitals that are the eigenfunctions of the Fock operator are accessible. They form the complete set, but only for the one-electron functions. However, they can be applied to build up the N -electron determinants. The set of all possible determinants is also complete and, therefore, can be applied to express any N -electron function (Cramer 2004; Jensen 2006; Levine 2008; Lowe and Peterson 2005; Piela 2007; Ratner and Schatz 2000; Roos and Widmark 2002; Szabo and Ostlund 1996):

$$\Psi = c_0 \Psi_0 + \sum_{a,p} c_a^p \Psi_a^p + \sum_{a,b,p,q} c_{ab}^{pq} \Psi_{ab}^{pq} + \sum_{a,b,c,p,q,r} c_{abc}^{pqr} \Psi_{abc}^{pqr} + \dots \quad (169)$$

For this purpose, only the coefficients $c_0, c_a^p, c_{ab}^{pq}, c_{abc}^{pqr}, \dots$ need to be found. In the ideal case, all the summations would be infinite and the problem must be reduced. Still, instead of using the infinite expansions, the finite and relatively small number of terms can be sufficient. Moreover, solving the Hartree–Fock equations in the finite basis, one possesses only the finite number of orbitals that can be exchanged.

Anyway, it is instructive to see how large the number of terms in Eq. 169 can be. Consider the methane molecule CH_4 . Calculations with the minimal basis set (each orbital described by a single one-electron function; for carbon single functions for each of the orbitals, 1 s , 2 s , $2p_x$, $2p_y$, $2p_z$, and for hydrogen a single function for 1 s orbital) require 9 orbitals/18 spin-orbitals for the 10-electron system. From the probability theory, the number of combinations (K) of k elements from the n -element set can be calculated as

$$K = \binom{n}{k} = \frac{n!}{(n-k)!k!}. \quad (170)$$

In the case of methane, 10 electrons can be placed in 18 spin-orbitals on $\binom{18}{10} = 43,758$ ways. This is equivalent to the 43,758 terms in the expansion (Eq. 169). Impressive. And one needs to remember that the minimal basis set gives relatively bad Hartree–Fock solutions and is not recommended in *ab initio* calculations. However, increasing the basis set size causes the number of expansion terms to grow dramatically. For instance, in the case of the so-called double- ζ basis set (two functions per each orbital) for methane, one has 36 spin-orbitals, which makes 254,186,856 combinations! And double- ζ is still not much . . .

Therefore, it is necessary to find some way to reduce the size of the problem. The symmetry of the molecules can be applied here, and the fact that the chosen determinants (or their linear combinations) must be the given functions of the spin operators can be beneficial. Moreover, one would like to eliminate from the expansion the determinants that are not crucial for the quality of the wave function, and their neglect does not cause the deterioration of the description of the system (or causes only slight deterioration). In other words, only the determinants that have the significant contribution to the total energy must be chosen for the wave function construction. Let us begin with the classification of the determinants, taking into account the number of the spin-orbitals exchanged with respect to Ψ_0 . For this purpose, the averaged value of Hamiltonian calculated with Ψ will be useful. We can write the wave function expansion as

$$\Psi = c_0\Psi_0 + \mathbf{S}\mathbf{c}_S + \mathbf{D}\mathbf{c}_D + \mathbf{T}\mathbf{c}_T + \mathbf{Q}\mathbf{c}_Q + \dots \quad (171)$$

The symbols' meaning can be clearly deciphered by comparison with Eq. 169. \mathbf{S} denotes a vector build of the determinants constructed from Ψ_0 by single exchanges, and \mathbf{c}_S is a vector of coefficients corresponding to the functions in \mathbf{S} :

$$\mathbf{S}\mathbf{c}_S = \sum_a \sum_q c_a^q \Psi_a^q. \quad (172)$$

In other words, \mathbf{S} contains all the functions with the single exchanged spin-orbital. Similarly, \mathbf{D} would be the combination of the functions with double exchanges, \mathbf{T} with triple exchanges, and so forth. With such a notation, the function Ψ can be treated as the scalar product of the basis vectors $\Psi_0, \mathbf{S}, \mathbf{D}, \dots$, and the coefficient vector

$$|\Psi\rangle = [|\Psi_0\rangle, |\mathbf{S}\rangle, |\mathbf{D}\rangle, |\mathbf{T}\rangle, |\mathbf{Q}\rangle, \dots] \cdot \begin{bmatrix} c_0 \\ \mathbf{c}_S \\ \mathbf{c}_D \\ \mathbf{c}_T \\ \mathbf{c}_Q \\ \vdots \end{bmatrix}. \quad (173)$$

Using this notation, the Hamiltonian \widehat{H} of the system can be linked in an elegant way to a matrix \mathbf{H} . Let us apply this form of the wave function for the calculation of the Hamiltonian average value. To simplify the expressions, let us limit ourselves to the truncated expansion:

$$\Psi_{\text{SD}} = [\Psi_0 \mathbf{S} \mathbf{D}] \begin{bmatrix} c_0 \\ \mathbf{c}_S \\ \mathbf{c}_D \end{bmatrix} = c_0 \Psi_0 + \mathbf{S} \mathbf{c}_S + \mathbf{D} \mathbf{c}_D. \quad (174)$$

The average value of the Hamiltonian can now be written as

$$\langle H \rangle_{\Psi_{\text{SD}}} = \langle \Psi_{\text{SD}} | \widehat{H} | \Psi_{\text{SD}} \rangle = [c_0 \mathbf{c}_S \mathbf{c}_D]^\dagger \begin{bmatrix} \langle \Psi_0 | \\ \langle \mathbf{S} | \\ \langle \mathbf{D} | \end{bmatrix} \widehat{H} \begin{bmatrix} | \Psi_0 \rangle, | \mathbf{S} \rangle, | \mathbf{D} \rangle \end{bmatrix} \begin{bmatrix} c_0 \\ \mathbf{c}_S \\ \mathbf{c}_D \end{bmatrix}. \quad (175)$$

The vector multiplication leads to the following expression:

$$\begin{aligned} \langle H \rangle_{\Psi_{\text{SD}}} &= c_0^* \langle \Psi_0 | \widehat{H} | \Psi_0 \rangle c_0 + c_0^* \langle \Psi_0 | \widehat{H} | \mathbf{S} \rangle \mathbf{c}_S + c_0^* \langle \Psi_0 | \widehat{H} | \mathbf{D} \rangle \mathbf{c}_D \\ &\quad + \mathbf{c}_S^\dagger \langle \mathbf{S} | \widehat{H} | \Psi_0 \rangle c_0 + \mathbf{c}_S^\dagger \langle \mathbf{S} | \widehat{H} | \mathbf{S} \rangle \mathbf{c}_S + \mathbf{c}_S^\dagger \langle \mathbf{S} | \widehat{H} | \mathbf{D} \rangle \mathbf{c}_D \\ &\quad + \mathbf{c}_D^\dagger \langle \mathbf{D} | \widehat{H} | \Psi_0 \rangle c_0 + \mathbf{c}_D^\dagger \langle \mathbf{D} | \widehat{H} | \mathbf{S} \rangle \mathbf{c}_S + \mathbf{c}_D^\dagger \langle \mathbf{D} | \widehat{H} | \mathbf{D} \rangle \mathbf{c}_D. \end{aligned} \quad (176)$$

Such an equation is not very useful, since we still do not know the c_0 , \mathbf{c}_S and \mathbf{c}_D coefficients determining the Ψ_{SD} function. The only thing that can be said about them so far comes from the normalization requirement for Ψ_{SD} :

$$1 = c_0^* c_0 + \mathbf{c}_S^\dagger \mathbf{c}_S + \mathbf{c}_D^\dagger \mathbf{c}_D. \quad (177)$$

This is not enough to uniquely determine the wave function. However, going back to Eq. 175 and multiplying only the inside vectors, one obtains

$$\mathbf{H}_{\text{SD}} = \begin{bmatrix} \langle \Psi_0 | \\ \langle \mathbf{S} | \\ \langle \mathbf{D} | \end{bmatrix} \widehat{H} \begin{bmatrix} | \Psi_0 \rangle, | \mathbf{S} \rangle, | \mathbf{D} \rangle \end{bmatrix} = \begin{bmatrix} \langle \Psi_0 | \widehat{H} | \Psi_0 \rangle & \langle \Psi_0 | \widehat{H} | \mathbf{S} \rangle & \langle \Psi_0 | \widehat{H} | \mathbf{D} \rangle \\ \langle \mathbf{S} | \widehat{H} | \Psi_0 \rangle & \langle \mathbf{S} | \widehat{H} | \mathbf{S} \rangle & \langle \mathbf{S} | \widehat{H} | \mathbf{D} \rangle \\ \langle \mathbf{D} | \widehat{H} | \Psi_0 \rangle & \langle \mathbf{D} | \widehat{H} | \mathbf{S} \rangle & \langle \mathbf{D} | \widehat{H} | \mathbf{D} \rangle \end{bmatrix}. \quad (178)$$

We can then associate finding the approximate Hamiltonian eigenvalues with its matrix in the Ψ_{SD} basis:

$$\langle \mathbf{H} \rangle_{\Psi_{\text{SD}}} = [c_0^* \mathbf{c}_S^\dagger \mathbf{c}_D^\dagger] = \begin{bmatrix} \langle \Psi_0 | \widehat{H} | \Psi_0 \rangle & \langle \Psi_0 | \widehat{H} | \mathbf{S} \rangle & \langle \Psi_0 | \widehat{H} | \mathbf{D} \rangle \\ \langle \mathbf{S} | \widehat{H} | \Psi_0 \rangle & \langle \mathbf{S} | \widehat{H} | \mathbf{S} \rangle & \langle \mathbf{S} | \widehat{H} | \mathbf{D} \rangle \\ \langle \mathbf{D} | \widehat{H} | \Psi_0 \rangle & \langle \mathbf{D} | \widehat{H} | \mathbf{S} \rangle & \langle \mathbf{D} | \widehat{H} | \mathbf{D} \rangle \end{bmatrix} \begin{bmatrix} c_0 \\ \mathbf{c}_S \\ \mathbf{c}_D \end{bmatrix}. \quad (179)$$

Because of the Hermitian character of the Hamilton operator, the \mathbf{H}_{SD} matrix is symmetric and real. Its diagonalization provides the set of the eigenvalues corresponding to its eigenvectors. We are interested in the ground-state energy and thus, we need only the lowest eigenvalue of the \mathbf{H}_{SD} matrix and the respective normalized eigenvector Ψ_{SD} .

Knowing the procedure for the finite basis (only single- and double-orbital exchanges), we can see how it looks for the full (Eq. 171) expansion. The matrix notation leads to the average value of the Hamiltonian, written as

$$\langle H \rangle_\Psi = [c_0, \mathbf{c}_S, \mathbf{c}_D, \mathbf{c}_T, \mathbf{c}_Q] \begin{bmatrix} \langle \Psi_0 | \\ \langle \mathbf{S} | \\ \langle \mathbf{D} | \\ \langle \mathbf{T} | \\ \langle \mathbf{Q} | \\ \vdots \end{bmatrix} \widehat{H} [\Psi_0 | \mathbf{S} \rangle, | \mathbf{D} \rangle, | \mathbf{T} \rangle, | \mathbf{Q} \rangle, \dots] \begin{bmatrix} c_0 \\ \mathbf{c}_S \\ \mathbf{c}_D \\ \mathbf{c}_T \\ \mathbf{c}_Q \\ \vdots \end{bmatrix}. \quad (180)$$

The vector multiplication permits one to perceive the average value as the eigenproblem of the Hamiltonian matrix:

$$\mathbf{H} = \begin{bmatrix} \langle \Psi_0 | \widehat{H} | \Psi_0 \rangle & 0 & \langle \Psi_0 | \widehat{H} | \mathbf{D} \rangle & 0 & 0 & \dots \\ 0 & \langle \mathbf{S} | \widehat{H} | \mathbf{S} \rangle & \langle \mathbf{S} | \widehat{H} | \mathbf{D} \rangle & \langle \mathbf{S} | \widehat{H} | \mathbf{T} \rangle & 0 & \dots \\ \langle \mathbf{D} | \widehat{H} | \Psi_0 \rangle & \langle \mathbf{D} | \widehat{H} | \mathbf{S} \rangle & \langle \mathbf{D} | \widehat{H} | \mathbf{D} \rangle & \langle \mathbf{D} | \widehat{H} | \mathbf{T} \rangle & \langle \mathbf{D} | \widehat{H} | \mathbf{Q} \rangle & \dots \\ 0 & \langle \mathbf{T} | \widehat{H} | \mathbf{S} \rangle & \langle \mathbf{T} | \widehat{H} | \mathbf{D} \rangle & \langle \mathbf{T} | \widehat{H} | \mathbf{T} \rangle & \langle \mathbf{T} | \widehat{H} | \mathbf{Q} \rangle & \dots \\ 0 & 0 & \langle \mathbf{Q} | \widehat{H} | \mathbf{D} \rangle & \langle \mathbf{Q} | \widehat{H} | \mathbf{T} \rangle & \langle \mathbf{Q} | \widehat{H} | \mathbf{Q} \rangle & \dots \\ \vdots & \vdots & \vdots & \vdots & \vdots & \ddots \end{bmatrix}. \quad (181)$$

It can be clearly seen that some blocks in this matrix are equal to zero. This happens in two cases:

- The integrals between Ψ_0 and functions of the \mathbf{S} type (single exchange of spin-orbitals) vanish due to the Brillouin theorem, as was shown in the previous section.

- The integrals between the functions that differ by more than two exchanges, for instance, **S** and **Q** type, vanish due to the Slater rules.

Even not knowing combinatorics, one can expect that the number of functions in a block will grow drastically with and increase in the number of exchanges (block **S** will contain less functions than **D** etc.). A bit of thinking in the beginning would help to save a lot of time by not calculating zero integrals. Let's see: Only in the case of $\langle \Psi_0 | \widehat{H} | \mathbf{D} \rangle$ and $\langle \mathbf{S} | \widehat{H} | \mathbf{S} \rangle$ blocks should all the elements be calculated. The remaining matrices are sparse. For example, the $\langle \mathbf{D} | \widehat{H} | \mathbf{D} \rangle$ block contains the integrals of the following types: $\langle \Psi_{ab}^{pq} | \widehat{H} | \Psi_{ab}^{pq} \rangle$ (the same function on both sides), $\langle \Psi_{ab}^{pq} | \widehat{H} | \Psi_{ab}^{pr} \rangle$ (differing by one exchange), $\langle \Psi_{ab}^{pq} | \widehat{H} | \Psi_{ab}^{rs} \rangle$ (differing by two exchanges), $\langle \Psi_{ab}^{pq} | \widehat{H} | \Psi_{ac}^{pq} \rangle$ (differing by three exchanges), and $\langle \Psi_{ab}^{pq} | \widehat{H} | \Psi_{dc}^{pq} \rangle$ (differing by four exchanges). Obviously, the two latter cases produce zeros.

With the large number of exchanges, the size of the blocks grows abruptly, but most of the elements would be equal to zero. The simplification in this case would be the limitation of the **H** matrix size by the elimination of the functions including more than a given number of exchanges from the expansion. Let us leave only the single exchange block. Thus, the Hamiltonian matrix has the form

$$\mathbf{H}_s = \begin{bmatrix} \langle \Psi_0 | \widehat{H} | \Psi_0 \rangle & 0 \\ 0 & \langle \mathbf{S} | \widehat{H} | \mathbf{S} \rangle \end{bmatrix}. \quad (182)$$

This is the block diagonal matrix. One of the properties of such matrices is that their eigenvalue set is a sum of the eigenvalues of the diagonal blocks. This means that the lowest possible eigenvalue is $E_0 = \langle \Psi_0 | \widehat{H} | \Psi_0 \rangle$, and in consequence, there is no improvement in the ground-state energy with respect to the Hartree–Fock theory when taking only the single orbital exchanges.

Hence, let us also include the functions of the **D** type. Now the Hamilton matrix can be written as

$$\mathbf{H}_{SD} = \begin{bmatrix} \langle \Psi_0 | \widehat{H} | \Psi_0 \rangle & 0 & \langle \Psi_0 | \widehat{H} | \mathbf{D} \rangle \\ 0 & \langle \mathbf{S} | \widehat{H} | \mathbf{S} \rangle & \langle \mathbf{S} | \widehat{H} | \mathbf{D} \rangle \\ \langle \mathbf{D} | \widehat{H} | \Psi_0 \rangle & \langle \mathbf{D} | \widehat{H} | \mathbf{S} \rangle & \langle \mathbf{D} | \widehat{H} | \mathbf{D} \rangle \end{bmatrix}. \quad (183)$$

It is no longer a block diagonal matrix – all blocks contribute to its eigenvalues and one can count on some improvement. An interesting observation, however, is that here the functions with the single spin-orbital exchange also have influence on the energy via the $\langle \mathbf{S} | \widehat{H} | \mathbf{D} \rangle$ and $\langle \mathbf{D} | \widehat{H} | \mathbf{S} \rangle$ blocks.

Next, subsequent groups of functions can be applied containing more than two spin-orbital exchanges. However, the calculations become prohibitively expensive, even for moderate size of the systems, and the consecutive corrections are smaller and smaller. The distinguished character of the double spin-orbital exchange was already discussed within the MP2 method. Now one can also expect that including double exchanges produces reasonable results with the moderate computational cost. Then, why not save more and diagonalize only

$$\mathbf{H}_D = \begin{bmatrix} \langle \Psi_0 | \hat{H} | \Psi_0 \rangle & \langle \Psi_0 | \hat{H} | \mathbf{D} \rangle \\ \langle \mathbf{D} | \hat{H} | \Psi_0 \rangle & \langle \mathbf{D} | \hat{H} | \mathbf{D} \rangle \end{bmatrix} \quad (184)$$

instead of \mathbf{H}_{SD} ? This can be done; however, savings are not that great, since the number of \mathbf{S} functions is significantly smaller than the number of \mathbf{D} functions. Thus, if one can afford \mathbf{H}_D diagonalization, \mathbf{H}_{SD} diagonalization is probably also within easy reach.

The above reasoning has led to the sequence of quantum chemistry methods. The best results can be obtained within full CI (FCI) by applying the full expansion (Eq. 171) within the given basis set. This is certainly the most expensive variant. Cheaper – but also worse – are, respectively, CISD based on the \mathbf{H}_{SD} matrix and CID neglecting single exchanges (Cramer 2004; Jensen 2006; Levine 2008; Lowe and Peterson 2005; Piela 2007; Ratner and Schatz 2000; Szabo and Ostlund 1996).

So far, the reference function has been a single determinant. Such an approach is very limited. For instance, it does not allow one to describe a dissociation process. Correct description of dissociation requires at least one determinant for each subsystem. And, even in the cases when multi-determinant reference state description is not obligatory, such an elastic wave function will provide an improved description of the system of interest (Cramer 2004; Jensen 2006; Levine 2008; Piela 2007; Roos and Widmark 2002).

The multi-determinant wave function Ψ depends both on the expansion coefficients and on the spin-orbitals building up the determinants. Both these sets of variables can be optimized simultaneously. The particular case of this procedure, when taking only the first expansion term, is the Hartree–Fock approximation (SCF–HF). Therefore, the optimization of the multi-determinant wave function is called the multiconfiguration (MC) SCF method. Even without a detailed study of the MC–SCF equations, an improvement in the results with respect to the HF energy can be expected. However, this approach is much more expensive, since the spin-orbitals are optimized several times. Again, a time saving is desired. Therefore, let us search for the spin-orbitals with the highest influence on the total energy value. It has been observed that not all doubly exchanged functions provide the same contribution to the energy. Some improve the result more and others less. This is due to the spin-orbital energy differences. The exchange of the spin-orbitals of significantly different energies does not contribute much to the total energy improvement. Therefore, it can be requested that the exchange is included in calculations only if the energy difference between the involved spin-orbitals is

smaller than some given value. Hence, only some groups of spin-orbitals can be exchanged.

Up to now, the spin-orbital notion was used. However, let us switch to the orbital language that is frequently used for MC–SCF considerations.

For the N -electron system, the orbitals can be divided into three groups:

- Core orbitals, which are not varied, since they have too low orbital energies, but are applied in the wave function expansion (doubly occupied orbitals)
- Active orbitals, which are exchanged in the expansion (partially occupied orbitals)
- Virtual orbitals, which are not varied and not applied in the expansion (unoccupied orbitals)

Instead of optimization of all the orbitals, only the active orbitals will be varied within the complete active space self-consistent field (CASSCF) approximation. In the acronym of this method, the number of active orbitals and active electrons is also provided for the given system. For instance, CASSCF (6,4) denotes the calculations with the expansion including all the possible exchanges of the four electrons within the six active orbitals. The CASSCF approach leads to all possible exchanges in the given active space, and for a moderately sized system, the size of the active spaces can quickly exceed the computational resources. In such a case, the solution can be the restricted active space self-consistent field (RASSCF) method, which supplies a way of limiting the size of the active space.

Additionally, one needs to remember that for a powerful tool such as perturbation theory, there is no obstacle to applying the multi-determinant reference function as the unperturbed function in perturbation calculus. Thus, similar to the SCF–HF and MP2 approaches, CASPT2 would be the second-order perturbation theory complete active space method – the perturbationally corrected CASSCF.

Coupled Cluster Approximation: The Operator Strikes Back

It would seem that all the straightforward ways to improve wave function in the one-electron approximation have been exploited. However, we now next discuss one of the most accurate (and simultaneously most expensive) methods applied in quantum chemistry.

The idea is simple. Consider again the expansion (Eq. 171). Introducing an operator

$$\widehat{C} = \widehat{C}_0 + \widehat{C}_1 + \widehat{C}_2 + \widehat{C}_3 + \widehat{C}_4 + \dots, \quad (185)$$

defined as

$$\widehat{C}_0 |\Psi_0\rangle = c_0 |\Psi_0\rangle, \quad (186)$$

$$\widehat{C}_1 |\Psi_0\rangle = \mathbf{S}c_s, \quad (187)$$

$$\widehat{C}_2 |\Psi_0\rangle = \mathbf{Dc}_D, \quad (188)$$

$$\widehat{C}_3 |\Psi_0\rangle = \mathbf{Tc}_T, \quad (189)$$

$$\widehat{C}_4 |\Psi_0\rangle = \mathbf{Qc}_Q, \quad (190)$$

⋮

allows one to write Eq. 171 in a very compact form:

$$\Psi = \widehat{C} \Psi_0. \quad (191)$$

Now the problem of finding the appropriate expansion can be replaced by the problem of finding the adequate operator. This is the essence of the coupled cluster (CC) method. Here the assumption is made that the wave function can be expressed by

$$\Psi = e^{\widehat{T}} \Psi_0, \quad (192)$$

where Ψ_0 is a reference function (depending on the approach, this can be the one-determinant HF function or the multi-determinant function arising from MC-SCF) and \widehat{T} is a sought operator. Applying the expansion of the exponential function, it can be written that

$$e^{\widehat{T}} = \widehat{1} + \widehat{T} + \frac{1}{2!} \widehat{T}^2 + \frac{1}{3!} \widehat{T}^3 + \dots \quad (193)$$

Such an expanded form makes the interpretation of the \widehat{T} operators easier. Putting

$$\widehat{T} = \widehat{T}_1 + \widehat{T}_2 + \widehat{T}_3 + \widehat{T}_4 + \dots, \quad (194)$$

one can identify the subsequent \widehat{T}_i operators as corresponding to i -tuple exchanges of the spin-orbitals in the reference function:

$$\widehat{T}_1 \Psi_0 = \sum_{a,p} t_a^p \Psi_a^p, \quad (195)$$

$$\widehat{T}_2 \Psi_0 = \sum_{a,b,p,q} t_{ab}^{pq} \Psi_{ab}^{pq}, \quad (196)$$

and so forth. The coefficients t (called “amplitudes”) are in general not equivalent to the c coefficients in the CI expansion (see Eq. 171). In order to find their mutual relation, let us consider the approximate operator:

$$\widehat{T} \approx \widehat{T}_1 + \widehat{T}_2 + \widehat{T}_3 + \widehat{T}_4. \quad (197)$$

The operator (Eq. 193) takes the form

$$\begin{aligned}
& e^{\widehat{T}_1 + \widehat{T}_2 + \widehat{T}_3 + \widehat{T}_4} = \widehat{1} \\
& + \widehat{T}_1 + \widehat{T}_2 + \widehat{T}_3 + \widehat{T}_4 \\
& + \frac{1}{2!} \left(\widehat{T}_1 + \widehat{T}_2 + \widehat{T}_3 + \widehat{T}_4 \right)^2 \\
& + \frac{1}{3!} \left(\widehat{T}_1 + \widehat{T}_2 + \widehat{T}_3 + \widehat{T}_4 \right)^3 \\
& + \frac{1}{4!} \left(\widehat{T}_1 + \widehat{T}_2 + \widehat{T}_3 + \widehat{T}_4 \right)^4.
\end{aligned} \tag{198}$$

Limiting ourselves to the terms corresponding to not more than four spin-orbital exchanges and writing it in the ordered way according to the number of exchanges, one gets

$$\begin{aligned}
& e^{\widehat{T}_1 + \widehat{T}_2 + \widehat{T}_3 + \widehat{T}_4} = \widehat{1} \\
& + \widehat{T}_1 \\
& + \widehat{T}_2 + \frac{1}{2} \widehat{T}_1^2 \\
& + \widehat{T}_3 + \widehat{T}_1 \widehat{T}_2 + \frac{1}{3} \widehat{T}_1^3 \\
& + \widehat{T}_4 + \widehat{T}_1 \widehat{T}_3 + \frac{1}{2} \widehat{T}_2^2 + \frac{1}{2} \widehat{T}_1^2 \widehat{T}_2 + \widehat{T}_1^4.
\end{aligned} \tag{199}$$

Now the direct comparison can be made:

$$\widehat{C}_1 = \widehat{T}_1, \tag{200}$$

$$\widehat{C}_2 = \widehat{T}_2 + \frac{1}{2} \widehat{T}_1^2, \tag{201}$$

$$\widehat{C}_3 = \widehat{T}_3 + \widehat{T}_1 \widehat{T}_2 + \frac{1}{3} \widehat{T}_1^3, \tag{202}$$

$$\widehat{C}_4 = \widehat{T}_4 + \widehat{T}_1 \widehat{T}_3 + \frac{1}{2} \widehat{T}_2^2 + \frac{1}{2} \widehat{T}_1^2 \widehat{T}_2 + \widehat{T}_1^4. \tag{203}$$

We have the relation between the \widehat{C}_i and \widehat{T}_i operators, but still neither \widehat{C}_i nor \widehat{T}_i are known. Recall from the earlier sections that the double exchanges have a significant influence on the energy improvement with respect to the Hartree–Fock results. Taking double exchanges into account within the coupled cluster formalism means that the operators \widehat{T}_1 and \widehat{T}_2 need to be determined. However, as a side effect, they also allow inclusion of some not negligible contributions arising from the triple and higher exchanges. In the above comparison, the \widehat{T}_1 and \widehat{T}_2 operators recover two out of three terms in \widehat{C}_3 and three out of five terms in \widehat{C}_4 . This is the power of the CC method.

Unfortunately, the strength of this method does not go together with ease of calculations. Obtaining the expressions for the operators \widehat{T} is ransomed with

compromises. Not only is the operator expansion (Eq. 194) truncated, but the basis set is finite. Moreover, the variational character of the method is sacrificed.

In order to realize the complications, let us consider step-by-step the energy calculation within the CC formalism. We begin, as usual, with the electron Schrödinger Eq. 50. Substituting Eq. 192 gives

$$\widehat{H}e^{\widehat{T}}\Psi_0 = Ee^{\widehat{T}}\Psi_0. \quad (204)$$

Taking into account that, due to (Eq. 193),

$$\langle \Psi_0 | \Psi \rangle = \langle \Psi_0 | e^{\widehat{T}} | \Psi_0 \rangle = \langle \Psi_0 | \Psi_0 \rangle = 1, \quad (205)$$

the energy can be calculated as

$$E = \langle \Psi_0 | \widehat{H}e^{\widehat{T}} | \Psi_0 \rangle = \langle \Psi_0 | \widehat{H} | \Psi \rangle. \quad (206)$$

This is not the Hamiltonian average value expression. Additionally, the operator inside the bracket is not Hermitian. But, until we assume that (Eq. 192) is true, such an approach works. We can also construct an integral:

$$\langle \Psi_{ab}^{pq} | \widehat{H}e^{\widehat{T}} | \Psi_0 \rangle = E \langle \Psi_{ab}^{pq} | e^{\widehat{T}} | \Psi_0 \rangle, \quad (207)$$

which is the consequence of Eq. 204 and will be applied in the near future.

We should now concentrate on the way of determining the form of amplitudes. To simplify the considerations, we can assume

$$\widehat{T} \approx \widehat{T}_2, \quad (208)$$

which is equivalent to the CCD variant. We are interested in finding the amplitudes t_{ab}^{pq} . The final result of the calculations will be the approximate energy:

$$E_{\text{CCD}} = \langle \Psi_0 | \widehat{H}e^{\widehat{T}_2} | \Psi_0 \rangle. \quad (209)$$

The information about the amplitude t_{ab}^{pq} can be extracted from the integral

$$t_{ab}^{pq} = \langle \Psi_{ab}^{pq} | \widehat{T}_2 | \Psi_0 \rangle \quad (210)$$

(see Eq. 196). However, the amplitudes are still not known, since we do not know the \widehat{T}_2 operator. Therefore, one more equation is necessary to elicit the sought information. Let us begin with the approximated expression (Eq. 207):

$$\begin{aligned} \langle \Psi_{ab}^{pq} | \widehat{H} e^{\widehat{T}_2} | \Psi_0 \rangle &= E_{\text{CCD}} \langle \Psi_{ab}^{pq} | e^{\widehat{T}_2} | \Psi_0 \rangle \\ &= \langle \Psi_0 | \widehat{H} e^{\widehat{T}_2} | \Psi_0 \rangle \langle \Psi_{ab}^{pq} | e^{\widehat{T}_2} | \Psi_0 \rangle. \end{aligned} \quad (211)$$

The expansion (Eq. 193) tailored to the present case,

$$e^{\widehat{T}_2} = \widehat{1} + \widehat{T}_2 + \frac{1}{2} \widehat{T}_2^2 + \dots, \quad (212)$$

and substituted to the left-hand side of Eq. 211 gives

$$\langle \Psi_{ab}^{pq} | \widehat{H} e^{\widehat{T}} | \Psi_0 \rangle = \langle \Psi_{ab}^{pq} | \widehat{H} \left(\widehat{1} + \widehat{T}_2 + \frac{1}{2} \widehat{T}_2^2 \right) | \Psi_0 \rangle. \quad (213)$$

Further terms are not necessary; in such a case, the functions on both sides of the integral would differ with four and more spin-orbital exchanges (and Hamiltonian is still a sum of one- and two-electron operators). Similarly, the expansion in the integral $\langle \Psi_0 | \widehat{H} e^{\widehat{T}_2} | \Psi_0 \rangle$ will also be truncated on the second term:

$$\langle \Psi_0 | \widehat{H} e^{\widehat{T}_2} | \Psi_0 \rangle = \langle \Psi_0 | \widehat{H} \left(\widehat{1} + \widehat{T}_2 \right) | \Psi_0 \rangle. \quad (214)$$

Remembering that

$$E_0^{(0)} = \langle \Psi_0 | \widehat{H} | \Psi_0 \rangle, \quad (215)$$

one gets

$$\langle \Psi_0 | \widehat{H} e^{\widehat{T}_2} | \Psi_0 \rangle = E_0^{(0)} + \langle \Psi_0 | \widehat{H} \widehat{T}_2 | \Psi_0 \rangle. \quad (216)$$

The last integral on the right-hand side of Eq. 211, $\langle \Psi_{ab}^{pq} | e^{\widehat{T}} | \Psi_0 \rangle$, can be nonvanishing only if the functions on the right and left side are the same. This is possible for

$$\langle \Psi_{ab}^{pq} | e^{\widehat{T}_2} | \Psi_0 \rangle = \langle \Psi_{ab}^{pq} | \widehat{T}_2 | \Psi_0 \rangle. \quad (217)$$

This is the integral that can provide information about the desired amplitudes of Eq. 210. Putting all these together, one gets

$$\langle \Psi_{ab}^{pq} | \widehat{H} \left(\widehat{1} + \widehat{T}_2 + \frac{1}{2} \widehat{T}_2^2 \right) | \Psi_0 \rangle = \left(E_0 + \langle \Psi_0 | \widehat{H} \widehat{T}_2 | \Psi_0 \rangle \right) \langle \Psi_{ab}^{pq} | \widehat{T}_2 | \Psi_0 \rangle. \quad (218)$$

Therefore, the amplitude $t_{ab}^{pq} = \langle \Psi_{ab}^{pq} | \hat{T}_2 | \Psi_0 \rangle$ can be expressed as

$$t_{ab}^{pq} = \frac{\langle \Psi_{ab}^{pq} | \hat{H} (\hat{1} + \hat{T}_2 + \frac{1}{2} \hat{T}_2^2) | \Psi_0 \rangle}{E_0 + \langle \Psi_0 | \hat{H} \hat{T}_2 | \Psi_0 \rangle}. \quad (219)$$

Unluckily, this does not mean that the amplitudes are known. Still, the above expression also contains the t_{ab}^{pq} amplitudes on the right-hand side in the \hat{T}_2 operators. Moreover, all other amplitudes are also present on the right-hand side. The consequence of this aggravation is that the CC equations cannot be solved separately, one by one. All together, the complicated set of nonlinear equations must be handled. The number of equations is equal to the number of sought amplitudes. This is the main reason for the huge computational cost of the CC calculations, even though the variationality of the method was abandoned (Atkins and Friedman 2005; Cramer 2004; Jensen 2006; Levine 2008; Piela 2007; Roos and Widmark 2002).

It can be seen that solving the CC equations is quite complicated, even in the simplified case of the CCD approach. If one wanted to use the variational Hamiltonian and apply its average value, the following integrals would appear:

$$\langle \Psi | \hat{H} | \Psi \rangle = \langle \Psi_0 | e^{\hat{T}} \hat{H} e^{\hat{T}} | \Psi_0 \rangle = \langle e^{\hat{T}} \Psi_0 | \hat{H} | e^{\hat{T}} \Psi_0 \rangle. \quad (220)$$

In order to calculate them, one needs to know the form of all the \hat{T}_i operators, since not only the function on the right-hand side of the above integral will contain the exchanged spin-orbitals but also the function on the left-hand side. Therefore, one needs to calculate terms like $\langle \hat{T}_3 \Psi_0 | \hat{H} | \hat{T}_2 \Psi_0 \rangle$ and many others. This causes the significant increase of the computational costs of the CC method.

Like in the MP n case, the CC method is worth using for the short expansion of the \hat{T} operator. Thus, relatively good accuracy is obtained with a moderate price.

Conclusions

We have finally reached the end of the zeroth iteration in the process of learning quantum chemistry methods. The beginner may feel saturated or even overwhelmed; however, we hope that this chapter arouses interest. Our aim was to show that simple ideas underlie quantum chemistry methods. The purpose is to put complicated things in a simpler and more convenient form. One of the most popular rules in computational chemistry is as follows: “If you cannot calculate something, divide it into parts in such a way that you can calculate some contribution while the other is too difficult.” For instance, nonrelativistic energy can be divided into HF energy and correlation energy. Correlation energy accounts for the contribution that we cannot calculate in practice, but methods such as MP n , CC, and CI allow one to find some

part of it. It may happen (and it often does!) that what we can calculate will be enough.

This chapter should be treated as the introduction to more advanced handbooks or as a guide through the symbols and concepts applied in the later parts of this book. Thus, some of the concepts are just touched upon, and many are omitted. If the reader noticed this and wants to know more, it means that this chapter has met its goal.

Acknowledgments Authors are grateful to Dr Krzysztof Strasburger, Dr Andrej Antušek, Agnieszka Zawada, and Łukasz Mentel for helpful comments.

Abstract

A detailed derivation of the adiabatic approximation and the Born-Oppenheimer approximation is presented, the difference between these two approximations is discussed and the circumstances under which the adiabatic approximation

M. Stanke (✉)

Institute of Physics, Faculty of Physics, Astronomy and Informatics, Nicholas Copernicus
University, Toruń, Poland

e-mail: monika@fizyka.umk.pl

collapses are discussed. It is shown that the solution of the Schrödinger equation in the adiabatic approximation can be divided into one representing the motion of electrons in the field of fixed nuclei and another one representing the motion of nuclei in the potential generated by the presence of the electrons. The shapes of the potential energy curves generated by the electrons and the motion of the nuclei in these potentials are also analyzed. Finally, the state-of-the-art highly accurate calculations for diatomic molecules performed without the use of the Born-Oppenheimer approximation is presented.

Solving the Schrödinger equation is very complex, even in the case of atoms. For molecules the complexity of the calculations becomes so great that often we are unable to perform them at all. Then we have to resort to the Born-Oppenheimer (BO) approximation (Born and Oppenheimer 1927) which is one of the most fundamental approximations in quantum chemistry. The BO approximation allows to separate the electronic and the nuclear motion in the molecule. The high accuracy of this approximation¹ is a consequence of a very small ratio of the mass of electron and the masses of the nuclei. Due to this difference, the nuclei are sluggish in their motions relative to the fast-moving electrons. For clarity and simplicity, the discussion is restricted to the case of diatomic molecules.

In this chapter, the reader will find a detailed derivation of the adiabatic approximation and the BO approximation. The significant difference between the two approximations will be shown. It will be also shown that the solution of the Schrödinger equation in the adiabatic approximation can be divided into the solution representing the motion of electrons in the field of fixed nuclei and the solution representing the motion of nuclei in the potential generated by the presence of the electrons in areas around the nuclei and between the nuclei in the molecule. In the next part, we will discuss the possible shapes of the potential energy curve generated by the electrons and how the motion of nuclei in this potential can be described. The circumstances in which the adiabatic approximation collapses will also be discussed. At the end the section, the reader will be introduced to the area of state-of-the-art highly accurate calculations for diatomic molecules performed without the use of the BO approximation.

The atomic units are used in this work; however, the electron mass is always explicitly shown in the formulas.

¹Precisely, the BO and adiabatic approximations are based on the difference of the time scales of movements of the nuclei and the electrons. For example, in some weakly bound molecular anions, the excess electron is very weakly bound (e.g., in the water anion). Such an electron moves at a speed comparable to the oscillating motion of atomic nuclei. A complete description of the dynamics of such an anion in the framework of the adiabatic approximation is doomed to failure. The failure can be attributed to the fact that the electron may be unbound for some large areas of the configuration space of the nuclei. In these areas the electronic wave function is not square integrable and the adiabatic corrections are divergent.

Multi-electron Molecule

Let us consider a molecule composed of N_n nuclei with masses M_a (for $a = 1, \dots, N_n$) and N_e electrons of masses m in a Cartesian reference frame referred to as the laboratory reference frame. For simplicity let us take a three-electron diatomic molecule with the nuclear masses M_1, M_2 located, respectively, at $\mathbf{R}'_1 = [X'_1, Y'_1, Z'_1]$, $\mathbf{R}'_2 = [X'_2, Y'_2, Z'_2]$. The electron coordinates are denoted as $\mathbf{r}'_i = [x'_i, y'_i, z'_i]$, $i = 1, 2, 3$ Fig. 1.

The Hamiltonian for this molecule is a sum of the kinetic energy operator $\hat{T}(\mathbf{r}') + \hat{T}(\mathbf{R}')$, and the Coulomb potential energy operator $\hat{V}(|\mathbf{R}'|, |\mathbf{r}'|)$, which depends on the inter-particle distances only:

$$\hat{H} = \hat{T}(\mathbf{R}') + \hat{T}(\mathbf{r}') + \hat{V}(|\mathbf{R}'|, |\mathbf{r}'|), \quad (1)$$

where

$$\hat{T}(\mathbf{R}') = -\frac{1}{2} \left(\frac{1}{M_1} \Delta_{\mathbf{R}'_1} + \frac{1}{M_2} \Delta_{\mathbf{R}'_2} \right) \quad (2)$$

$$\hat{T}(\mathbf{r}') = -\frac{1}{2m} \sum_{i=1}^3 \Delta_{\mathbf{r}'_i} \quad (3)$$

$$\hat{V}(|\mathbf{R}'|, |\mathbf{r}'|) = \sum_{a < b}^2 \frac{Z_a Z_b}{|\mathbf{R}'_{ab}|} - Z_a \sum_{i=1}^3 \frac{1}{|\mathbf{r}'_{ia}|} - Z_b \sum_{i=1}^3 \frac{1}{|\mathbf{r}'_{ib}|} + \sum_{i < j}^3 \frac{1}{|\mathbf{r}'_{ij}|}. \quad (4)$$

The first term describes the Coulomb repulsion between nuclei, the second and third the attraction between electrons and nuclei, and the fourth the mutual repulsion between the electrons. In formulas we have used the abbreviations

Fig. 1 Diatomic molecule in a Cartesian coordinate system. By $\mathbf{R}'_a = [X'_a, Y'_a, Z'_a]$ and $\mathbf{r}'_i = [x'_i, y'_i, z'_i]$, where $a = 1, 2$ and $i = 1, 2, 3$, are denoted as the position vectors of nuclei and electrons, respectively

$$|\mathbf{R}'_{ab}| = |\mathbf{R}'_a - \mathbf{R}'_b|, \quad |\mathbf{r}'_{ia}| = |\mathbf{r}'_i - \mathbf{R}'_a|, \quad |\mathbf{r}'_{ib}| = |\mathbf{r}'_i - \mathbf{R}'_b|, \quad |\mathbf{r}'_{ij}| = |\mathbf{r}'_i - \mathbf{r}'_j|.$$

In a general case, the Hamiltonian reads

$$\hat{T}(\mathbf{R}') + \hat{T}(\mathbf{r}') = -\frac{1}{2m} \sum_{i=1}^{N_e} \Delta_{\mathbf{r}'_i} - \frac{1}{2} \sum_{a=1}^{N_n} \frac{1}{M_a} \Delta_{\mathbf{R}'_a} \quad (5)$$

$$\hat{V}(|\mathbf{R}'|, |\mathbf{r}'|) = \underbrace{\sum_{a < b}^{N_n} \frac{Z_a Z_b}{|\mathbf{R}'_{ab}|}}_{\text{nuclears repulsion}} - \underbrace{\sum_{a=1}^{N_n} Z_a \sum_{i=1}^{N_e} \frac{1}{|\mathbf{r}'_{ia}|}}_{\text{electron-nucleus-attraction}} + \underbrace{\sum_{i < j}^{N_e} \frac{1}{|\mathbf{r}'_{ij}|}}_{\text{electrons repulsion}}. \quad (6)$$

Since we are not interested in molecular collisions, we assume that the center of mass of the molecule does not move relative to the laboratory reference frame. Therefore, it is convenient to introduce *internal coordinates*. The new coordinates, in the case of the diatomic molecule, are defined as follows²

$$\mathbf{R} = [R_x, R_y, R_z] = \mathbf{R}'_1 - \mathbf{R}'_2 \quad (7)$$

\mathbf{R} vector of the relative position of the nuclei

$$\mathbf{R}_{\text{CM}} = [X_{\text{CM}}, Y_{\text{CM}}, Z_{\text{CM}}] = \frac{1}{M} \left(\sum_{a=1}^2 M_a \mathbf{R}'_a + \sum_{i=1}^3 m \mathbf{r}'_i \right) \quad (8)$$

\mathbf{R}_{CM} coordinates of the center of mass (CM) of the molecule, where

$$M = \sum_{a=1}^2 M_a + \sum_{i=1}^3 m_i \quad (9)$$

M the total mass of the molecule

$$X_{\text{CM}} = \frac{1}{M} \left(\sum_{a=1}^2 M_a X'_a + \sum_{i=1}^{N_e} m x'_i \right), \quad Y_{\text{CM}} = \frac{1}{M} \left(\sum_{a=1}^2 M_a Y'_a + \sum_{i=1}^{N_e} m y'_i \right),$$

$$Z_{\text{CM}} = \frac{1}{M} \left(\sum_{a=1}^2 M_a Z'_a + \sum_{i=1}^{N_e} m z'_i \right)$$

$$\mathbf{r}_i = [x_i, y_i, z_i] = \mathbf{r}'_i - \frac{1}{2}(\mathbf{R}'_1 + \mathbf{R}'_2) \quad (10)$$

\mathbf{r}_i is the vector of the electron position anchored at the geometric center of the molecule, and

²We use the most common definition of the new coordinates. Internal coordinates may be defined in many different ways, see, e.g., Piela (2007).

$$x_i = x'_i - \frac{1}{2} (X'_1 + X'_2), \quad y_i = y'_i - \frac{1}{2} (Y'_1 + Y'_2), \quad z_i = z'_i - \frac{1}{2} (Z'_1 + Z'_2). \quad (11)$$

Similarly, in the extended formalism, for any molecule with N_n nuclei of mass M_a and n_n electrons, we have

$$M = \sum_{a=1}^{N_n} M_a + N_e \cdot m, \quad (12)$$

$$\mathbf{R}_{ab} = \mathbf{R}'_a - \mathbf{R}'_b \quad (a \neq b) \quad a, b = 1, \dots, N_n, \quad (13)$$

$$\mathbf{R}_{\text{CM}} = [X_{\text{CM}}, Y_{\text{CM}}, Z_{\text{CM}}] = \frac{1}{M} \left(\sum_{a=1}^{N_n} M_a \mathbf{R}'_a + \sum_{i=1}^{N_e} m \mathbf{r}'_i \right), \quad (14)$$

$$\mathbf{r}_i = \mathbf{r}_i - \frac{1}{2} (\mathbf{R}^{(n)} + \mathbf{R}'_{N_n}) \quad \text{where} \quad \mathbf{R}^{(n)} = \frac{1}{2} (\mathbf{R}^{(n-1)} + \mathbf{R}'_{N_{n-1}}) \quad \text{for} \quad n = N_n - 1. \quad (15)$$

In order to transform the molecular Hamiltonian to the new reference system, one has to perform some rather tedious algebra (for details, see Appendix A). The molecular Hamiltonian in the new reference frame may be written as

$$\hat{H} = \hat{H}_{\text{CM}} + \hat{H}_0 + \hat{H}', \quad (16)$$

$$\hat{H}_{\text{CM}} = -\frac{1}{2M} \Delta_{\mathbf{R}_{\text{CM}}}, \quad (17)$$

$$\hat{H}_0 = -\frac{1}{2m} \sum_{i=1}^{N_e} \Delta_{\mathbf{r}_i} + \hat{V}(|\mathbf{R}|, |\mathbf{r}|), \quad (18)$$

$$\hat{H}' = \underbrace{-\frac{1}{2} \left(\frac{1}{M_1} + \frac{1}{M_2} \right) \Delta_{\mathbf{R}}}_{-\frac{1}{2\mu} \Delta_{\mathbf{R}}} - \underbrace{\frac{1}{8} \left(\frac{1}{M_1} + \frac{1}{M_2} \right) \left(\sum_{i=1}^{N_e} \nabla_{\mathbf{r}_i} \right)^2 - \frac{1}{2} \left(\frac{1}{M_1} - \frac{1}{M_2} \right) \nabla_{\mathbf{R}} \sum_{i=1}^{N_e} \nabla_{\mathbf{r}_i}}_{\hat{H}''} \quad (19)$$

where

$$\hat{V}(|\mathbf{R}|, |\mathbf{r}|) = \frac{Z_1 Z_2}{|\mathbf{R}|} - \sum_{i=1}^{N_e} \frac{Z_1}{|\mathbf{r}_i - \frac{1}{2}\mathbf{R}|} - \sum_{i=1}^{N_e} \frac{Z_2}{|\mathbf{r}_i + \frac{1}{2}\mathbf{R}|} + \sum_{i>j=1}^{N_e} \frac{1}{|\mathbf{r}_i - \mathbf{r}_j|}. \quad (20)$$

The kinetic energy of CM is described by \hat{H}_{CM} and is responsible for the translational motion of the entire molecule. Therefore, it does not carry any information essential for us. Hereafter, we will consider the molecular Hamiltonian of the following form

$$\hat{H} = \hat{H}_0 + \hat{H}'. \quad (21)$$

The motion of electrons in the Coulomb field generated by fixed nuclei is described by \hat{H}_0 with \hat{V} describing Coulomb interactions between all particles. The nuclear motion and the coupling between the nuclei and electrons is described by \hat{H}' . Here the nuclear part $-1/2\mu \Delta_{\mathbf{R}}$ (in (19)) is equal to the kinetic energy of a "pseudonucleus" with mass $\mu = M_1 M_2 / (M_1 + M_2)$. The second term, \hat{H}'' , describes the coupling of the nuclear and the electronic motion. The last term in \hat{H}'' , known as the mass-polarization term, vanishes in the case of homonuclear diatomic molecules.³

The coordinate transformation (7), (8), (9), and (10) is not unique. It is possible, for example, to use another transformation, proposed by Author in Dalgarno and McCarroll (1956), where instead of the geometric center of the molecule, one takes the center of the nuclear masses:

$$\mathbf{R} = \mathbf{R}'_a - \mathbf{R}'_b \quad \mathbf{r}_i = \mathbf{r}'_i - \frac{1}{M_a + M_b} (M_a \mathbf{R}'_a + M_b \mathbf{R}'_b).$$

In this case,

$$\hat{H}_0 = -\frac{1}{2m} \sum_{i=1}^{N_e} \Delta_{\mathbf{r}_i} + \hat{V}(|\mathbf{R}|, |\mathbf{r}|) \quad (22)$$

$$\hat{H}' = -\frac{1}{2} \left(\frac{1}{M_1} + \frac{1}{M_2} \right) \Delta_{\mathbf{R}} - \frac{1}{2} \left(\frac{1}{M_1} + \frac{1}{M_2} \right) \left(\sum_{i=1}^{N_e} \nabla_{\mathbf{r}_i} \right)^2. \quad (23)$$

There is no mass-polarization term, but the coordinates \mathbf{r}_i and, consequently, also $\hat{V}(|\mathbf{R}|, |\mathbf{r}|)$ depend on the nuclear masses. Hereafter transformation (16), (17), (18), and (19) is used.

The Equation for the Motion of Nuclei

Our aim is to solve the stationary Schrödinger equation with Hamiltonian (21),

$$(\hat{H}_0 + \hat{H}')\Psi(\mathbf{r}, \mathbf{R}) = E\Psi(\mathbf{r}, \mathbf{R}).$$

Let us allow our imagination to help – this will facilitate the understanding our further considerations. The nuclei, due to their heaviness, move very slowly.

³“Frolov’s calculations showed that when one mass increased without limit (the atomic case), any discrete spectrum persisted, but when two masses were allowed to increase without limit (the molecular cause), the Hamiltonian ceased to be well defined, and this failure led to what he called adiabatic divergence in attempts to compute discrete eigenstates of (21). This divergence is discussed in some mathematical detail in the Appendix to Frolov (1999). It does not arise from the choice of a translationally invariant form for the electronic Hamiltonian; rather it is due to the lack of any kinetic energy term to dominate the Coulomb potential. Thus it really is essential to characterize the spectrum of H_{elec} to see whether the traditional approach can be validated.” (Sutcliffe 2003)

Electrons, on the contrary, quickly react to changes in the positions of the nuclei. This means that the electronic charge distribution depends on the instant positions of the nuclei rather than on their motion. As a consequence, the motions of the nuclei and electrons in a molecule can be separated to a very good *approximation*. In terms of formalism, this implies that the wave function $\Psi(\mathbf{r}, \mathbf{R})$ can be expressed as a product of its electronic and nuclear parts. In fact, exactly, the wave function can be expressed as an infinite expansion

$$\Psi(\mathbf{r}, \mathbf{R}) = \sum_k \psi_k^{\text{el}}(\mathbf{r}; R) \chi_k(\mathbf{R}), \quad (24)$$

where

- $\psi_k^{\text{el}}(\mathbf{r}; R)$ is the wave function that describes k -th state of electrons in the molecule at a given position of the nuclei ($|\mathbf{R}| = R$). This function is a solution of the electronic Schrödinger equation:

$$\hat{H}_0 \psi_k^{\text{el}}(\mathbf{r}; R) = E_k^0(R) \psi_k^{\text{el}}(\mathbf{r}; R). \quad (25)$$

- $\chi_k(\mathbf{R})$ is an expansion coefficient which depends on \mathbf{R} ; it is also the wave function describing the nuclear motion.

Let us return to the eigenvalue problem of Hamiltonian (21) and the wave function (24). It is convenient to rewrite the molecular Hamiltonian (21) in a slightly modified form by splitting (19) to the pseudonuclei kinetic energy operator $-1/2\mu\Delta_{\mathbf{R}}$ and the operators which couple electron-nuclear variables (\hat{H}''):

$$\left(-\frac{1}{2m} \sum_{i=1}^3 \Delta_{\mathbf{r}_i} + \hat{V}(|\mathbf{R}|, |\mathbf{r}|) + \hat{H}' \right) \Psi(\mathbf{r}; R) = E \Psi(\mathbf{r}; R), \quad (26)$$

where

$$\Psi(\mathbf{r}, \mathbf{R}) = \sum_k \psi_k^{\text{el}}(\mathbf{r}; R) \chi_k(\mathbf{R}),$$

$$\hat{H}' = -\frac{1}{2\mu} \Delta_{\mathbf{R}} + \hat{H}'', \quad (27)$$

$$\hat{H}'' = -\frac{1}{8\mu} \left(\sum_{i=1}^3 \nabla_{\mathbf{r}_i} \right)^2 - \frac{1}{2} \left(\frac{1}{M_a} - \frac{1}{M_b} \right) \nabla_{\mathbf{R}} \sum_{i=1}^3 \nabla_{\mathbf{r}_i}. \quad (28)$$

Multiplying Eq. (26) on the lhs by $\psi_l^{\text{el}}(\mathbf{r}; R)$ and integrating over the electron coordinates, we get⁴:

⁴For the sake of simplicity, we denote $\psi_k^{\text{el}}(\mathbf{r}; R) \equiv \psi_k^{\text{el}}$ and $\chi_k(\mathbf{R}) \equiv \chi_k$.

$$\begin{aligned}
& \sum_k \langle \psi_l^{\text{el}} | \hat{H}_0 + \hat{H}' | \psi_k^{\text{el}} \chi_k \rangle_{\text{el}} = E \sum_k \langle \psi_l^{\text{el}} | \psi_k^{\text{el}} \chi_k \rangle_{\text{el}} \\
& \sum_k \left(\int \mathbf{dr} \psi_l^{\text{el}} \hat{H}_0 \psi_k^{\text{el}} \right) \chi_k + \sum_k \int \mathbf{dr} \psi_l^{\text{el}} \hat{H}' \psi_k^{\text{el}} \chi_k = E \sum_k \int \mathbf{dr} \psi_l^{\text{el}} \psi_k^{\text{el}} \chi_k \\
& \sum_k E_k^0(R) \delta_{kl} \chi_k + \sum_k \int \mathbf{dr} \psi_l^{\text{el}} \hat{H}' \psi_k^{\text{el}} \chi_k = E \sum_k \delta_{kl} \chi_k \\
& (E_l^0(R) - E) \chi_l(\mathbf{R}) + \sum_k \int \mathbf{dr} \psi_l^{\text{el}}(\mathbf{r}; R) \hat{H}' \psi_k^{\text{el}}(\mathbf{r}; R) \chi_k(\mathbf{R}) = 0.
\end{aligned}$$

$\langle \rangle_{\text{el}}$ denotes integration over electronic coordinates. The last equation, in the Dirac notation, takes a simple form:

$$(E_l^0(R) - E) \chi_l(\mathbf{R}) + \sum_k \langle \psi_l^{\text{el}}(\mathbf{r}; R) | \hat{H}' | \psi_k^{\text{el}}(\mathbf{r}; R) \chi_k(\mathbf{R}) \rangle = 0. \quad (29)$$

Using the explicit form of \hat{H}' , one can easily transform the matrix element of \hat{H}' in Eq. (29) in the following way:

$$\langle \psi_l^{\text{el}} | \hat{H}' | \psi_k^{\text{el}} \chi_k \rangle = \langle \psi_l^{\text{el}} | -\frac{1}{2\mu} \Delta_{\mathbf{R}} + \hat{H}'' | \psi_k^{\text{el}} \chi_k \rangle, \quad (30)$$

where

$$\begin{aligned}
\Delta_{\mathbf{R}} (\psi_k^{\text{el}} \chi_k) &= \nabla_{\mathbf{R}}^T \cdot \nabla_{\mathbf{R}} (\psi_k^{\text{el}} \chi_k) = \nabla_{\mathbf{R}}^T \cdot [(\nabla_{\mathbf{R}} \psi_k^{\text{el}}) \chi_k + \psi_k^{\text{el}} (\nabla_{\mathbf{R}} \chi_k)] \\
&= [(\Delta_{\mathbf{R}} \psi_k^{\text{el}}) \chi_k + (\nabla_{\mathbf{R}}^T \psi_k^{\text{el}}) (\nabla_{\mathbf{R}} \chi_k) + (\nabla_{\mathbf{R}}^T \chi_k) (\nabla_{\mathbf{R}} \psi_k^{\text{el}}) + \psi_k^{\text{el}} (\Delta_{\mathbf{R}} \chi_k)] \\
&= [(\Delta_{\mathbf{R}} \psi_k^{\text{el}}) \chi_k + 2 (\nabla_{\mathbf{R}}^T \psi_k^{\text{el}}) (\nabla_{\mathbf{R}} \chi_k) + \psi_k^{\text{el}} (\Delta_{\mathbf{R}} \chi_k)]. \quad (31)
\end{aligned}$$

The first term in the last equation corresponds to the kinetic energy of the pseudonuclei. The remaining two terms are the so-called non-adiabatic contributions (to be discussed hereafter). Substituting (31) to (30), we get

$$\begin{aligned}
\langle \psi_l^{\text{el}} | \hat{H}' | \psi_k^{\text{el}} \chi_k \rangle &= -\frac{1}{2\mu} \langle \psi_l^{\text{el}} | \Delta_{\mathbf{R}} | \psi_k^{\text{el}} \rangle \chi_k - \frac{1}{\mu} \langle \psi_l^{\text{el}} | \nabla_{\mathbf{R}}^T | \psi_k^{\text{el}} \rangle \nabla_{\mathbf{R}} \chi_k \\
&\quad - \frac{1}{2\mu} \langle \psi_l^{\text{el}} | \psi_k^{\text{el}} \rangle \Delta_{\mathbf{R}} \chi_k + \langle \psi_l^{\text{el}} | \hat{H}'' | \psi_k^{\text{el}} \rangle \chi_k. \quad (32)
\end{aligned}$$

Now Eq. (29) may be rewritten as

$$\begin{aligned}
(E_l^0(R) - E) \chi_l &- \frac{1}{2\mu} \sum_k \langle \psi_l^{\text{el}} | \Delta_{\mathbf{R}} | \psi_k^{\text{el}} \rangle \chi_k - \frac{1}{\mu} \sum_k \langle \psi_l^{\text{el}} | \nabla_{\mathbf{R}}^T | \psi_k^{\text{el}} \rangle \nabla_{\mathbf{R}} \chi_k \\
&- \frac{1}{2\mu} \sum_k \langle \psi_l^{\text{el}} | \psi_k^{\text{el}} \rangle \Delta_{\mathbf{R}} \chi_k + \sum_k \langle \psi_l^{\text{el}} | \hat{H}'' | \psi_k^{\text{el}} \rangle \chi_k = 0
\end{aligned} \quad (33)$$

or, in a modified form, as

$$\begin{aligned}
 (E_l^0(\mathbf{R}) - E) \chi_l + \sum_k \langle \psi_l^{\text{el}} | \underbrace{-\frac{1}{2\mu} \Delta_{\mathbf{R}} + \hat{H}''}_{\hat{H}'(R)} | \psi_k^{\text{el}} \rangle \chi_k \\
 - \frac{1}{\mu} \sum_k \langle \psi_l^{\text{el}} | \nabla_{\mathbf{R}}^T | \psi_k^{\text{el}} \rangle \nabla_{\mathbf{R}} \chi_k - \frac{1}{2\mu} \sum_k \delta_{kl} \Delta_{\mathbf{R}} \chi_k = 0 \\
 (E_l^0(\mathbf{R}) - E) \chi_l + \sum_k c_{kl}(\mathbf{R}) \chi_k - \frac{1}{2\mu} \Delta_{\mathbf{R}} \chi_l = 0, \quad (34)
 \end{aligned}$$

where

$$c_{kl}(\mathbf{R}) = \langle \psi_l^{\text{el}} | \hat{H}' | \psi_k^{\text{el}} \rangle - \frac{1}{\mu} \langle \psi_l^{\text{el}} | \nabla_{\mathbf{R}}^T | \psi_k^{\text{el}} \rangle \nabla_{\mathbf{R}}. \quad (35)$$

Note that \hat{H}' depends on the length of \mathbf{R} but not on its direction. Equation (34) may be expressed in a more convenient form as

$$\left(-\frac{1}{2\mu} \Delta_{\mathbf{R}} + E_l^0(\mathbf{R}) \right) \chi_l(\mathbf{R}) + \sum_k c_{kl}(\mathbf{R}) \chi_k(\mathbf{R}) = E \chi_l(\mathbf{R}), \quad (36)$$

where

$$c_{kl}(\mathbf{R}) = \langle \psi_l^{\text{el}} | \hat{H}' | \psi_k^{\text{el}} \rangle - \frac{1}{\mu} \langle \psi_l^{\text{el}} | \nabla_{\mathbf{R}}^T | \psi_k^{\text{el}} \rangle \nabla_{\mathbf{R}}.$$

The above equation is an equation for the nuclear wave function $\chi_l(\mathbf{R})$. This equation together with the Schrödinger equation for the electronic energy and the wave function (Eq. 25) forms a system of coupled equations. The coupling between the electron and nuclear function is in the $c_{kl}(\mathbf{R})$ term. This is a *non-adiabatic coupling operator*. The coupling coefficients $c_{kl}(\mathbf{R})$ are matrix elements of differential operators. Thus, at this point, the concept of the potential energy surface (PES) has no physical meaning. (It should be emphasized at this point that c_{kl} cannot be regarded as part of the potential energy operator.) A physically justified concept of PES appears only when we separate the electronic and the nuclear motions. This happens when we apply the adiabatic or BO approximation (see section “Born-Oppenheimer Approximation”). Then the PSE $E_l^0(\mathbf{R})$ is defined by a presumed configuration of the nuclei in a given electronic state.

Adiabatic Approximation

Equations (36) may be decoupled if we neglect all $c_{kl}(R)$ except the diagonal ones, i.e., if we set $c_{kl} = c_{ll} \delta_{kl}$. The decoupled equations read

$$\left(-\frac{1}{2\mu} \Delta_{\mathbf{R}} + E_l^0(R) + c_{ll}(R) \right) \chi_l(\mathbf{R}) = E \chi_l(\mathbf{R}) - \sum_{k \neq l} c_{kl}(R) \chi_k(\mathbf{R}). \quad (37)$$

Diagonal terms $c_{ll}(R)$ can be simplified using the normalization condition for ψ_l^{el} :

$$\langle \psi_l^{\text{el}} | \psi_l^{\text{el}} \rangle = 1 \quad \Rightarrow \quad \nabla_{\mathbf{R}}^T \langle \psi_l^{\text{el}} | \psi_l^{\text{el}} \rangle = 2 \langle \psi_l^{\text{el}} | \nabla_{\mathbf{R}}^T | \psi_l^{\text{el}} \rangle = 0.$$

Then, from Eq. (35) results that

$$c_{ll}(R) = \langle \psi_l^{\text{el}} | \hat{H}' | \psi_l^{\text{el}} \rangle. \quad (38)$$

Thus, the diagonal elements in the expression (35) take the form⁵

$$c_{ll}(R) = \langle \psi_l^{\text{el}} | \hat{H}' | \psi_l^{\text{el}} \rangle = -\frac{1}{2\mu} \langle \psi_l^{\text{el}} | \Delta_{\mathbf{R}} | \psi_l^{\text{el}} \rangle = +\frac{1}{2\mu} \int d\mathbf{r} |\nabla_{\mathbf{R}} \psi_l^{\text{el}}|^2. \quad (39)$$

This diagonal term is usually very small compared to $E_l^0(R)$. Using the definition (39), Eq. (36) fulfilled by $\chi_l(\mathbf{R})$ can now be written as

$$\left(-\frac{1}{2\mu} \Delta_{\mathbf{R}} + E_l^0(R) + \frac{1}{2\mu} \int d\mathbf{r} |\nabla_{\mathbf{R}} \psi_l^{\text{el}}|^2 \right) \chi_l(\mathbf{R}) = E \chi_l(\mathbf{R}) - \sum_{k \neq l} c_{kl}(R) \chi_k(\mathbf{R}). \quad (40)$$

The off-diagonal terms $c_{kl}(R)$, $k \neq l$, in Eq. (40) usually cause difficulties in solving the relevant Schrödinger equation. For this reason and due to the fact that this term is very small, they are usually neglected in calculation. Such an approximation is called *the adiabatic approximation*. Thus, in the zero-order approximation, the functions $\chi_l(\mathbf{R})$ are solutions of the following equation:

$$\left(-\frac{1}{2\mu} \Delta_{\mathbf{R}} + U_l(R) \right) \chi_l(\mathbf{R}) = E \chi_l(\mathbf{R}) \quad (41)$$

$$\text{for } U_l(R) = E_l^0(R) + \frac{1}{2\mu} \int d\mathbf{r} |\nabla_{\mathbf{R}} \psi_l^{\text{el}}(\mathbf{r}; \mathbf{R})|^2,$$

⁵As a result of simple transformations:

$$\Delta \langle \psi | \psi \rangle = 0$$

but

$$\begin{aligned} \nabla^T (\nabla \langle \psi | \psi \rangle) &= 2 \nabla^T \langle \psi | \nabla | \psi \rangle = 2 \langle \nabla \psi | \nabla | \psi \rangle + 2 \langle \psi | \Delta | \psi \rangle \\ &\Rightarrow \langle \nabla \psi | \nabla | \psi \rangle = - \langle \psi | \Delta | \psi \rangle = - |\nabla \psi|^2 \end{aligned}$$

where $U_i(R)$ is called *effective potential*, where the diagonal correction $c_{ii}(R)$ (39) is usually very small compared to $E_i^0(R)$. The effective potential $U_i(R)$ depends on the nuclear masses ($1/\mu = 1/M_a + 1/M_b$). Therefore, it is different for different isotopes. The term $c_{ii}(R)$ does not appear when in the description of the molecules we use the BO approximation (section “Born-Oppenheimer Approximation”). Therefore, in the BO approximation, the effective potential is the same for all isotopes, e.g., for H₂, HD, D₂.

In the adiabatic approximation, one assumes that the expansion of the wave function (24) may be reduced to a single term (Kołos and Wolniewicz 1963; Kołos 1970; Davydov 1965), i.e.,

$$\Psi_k(\mathbf{r}, \mathbf{R}) \approx \psi_k^{\text{el}}(\mathbf{r}; R) \chi_k(\mathbf{R}). \quad (42)$$

This is the essence of the adiabatic approximation.

Adiabatic approximation: to solve the eigenvalue problem of operator (21), we use function (42). Because we cannot provide the eigenfunctions (21) as a combination of products of functions solely dependent on the nuclear coordinates ($\{\phi_a(\mathbf{R})\}$) and functions solely dependent on the electrons coordinates ($\{\phi_i(\mathbf{r})\}$)

$$\Psi(\mathbf{r}, \mathbf{R}) = \sum_{i,a} A_{i,a} \phi_i(\mathbf{r}) \phi_a(\mathbf{R}),$$

we use the adiabatic approximation. First, we solve the electronic Schrödinger equation:

$$\hat{H}_0(R) \psi_k^{\text{el}}(\mathbf{r}; R) = E_k^0(R) \psi_k^{\text{el}}(\mathbf{r}; R),$$

where H_0 does not depend on the motion of the nuclei, although $\hat{V}(|\mathbf{R}|, |\mathbf{r}|)$ depends on the positions of the nuclei. Solutions $E_k^0(R)$ and $\psi_k^{\text{el}}(\mathbf{r}; R)$ depend on \mathbf{R} parametrically. The parametric dependence is indicated by the semicolon. By solving equation (25) for fixed internuclear distances \mathbf{R} , we get the energy $E_k^0(R)$ for a rigid molecule. Hence, $|\psi_k^{\text{el}}(\mathbf{r}; R)|^2$ determines the charge distribution in the k -th electronic state (for more details, the reader is referred to Piela 2007). In the next step, for the new positions of the nuclei, we again solve the problem (25), to get a new value $E_k^0(R)$. Eigenfunctions of the molecular Hamiltonian (21) may then be expanded in terms of the eigenfunctions of the electronic Hamiltonian \hat{H}_0 :

$$\Psi(\mathbf{r}, \mathbf{R}) \approx \psi_k^{\text{el}}(\mathbf{r}; R) \chi_k(\mathbf{R}),$$

where the coefficients $\chi_k(\mathbf{R})$ are functions of \mathbf{R} . The following orthonormal conditions are fulfilled:

$$\langle \psi_k^{\text{el}}(\mathbf{r}; R) | \psi_l^{\text{el}}(\mathbf{r}; R) \rangle_{\text{el}} = \delta_{kl} \quad \text{integration over electronic coordinates} \quad (43)$$

$$\langle \chi_k(\mathbf{R}) | \chi_l(\mathbf{R}) \rangle_n = \delta_{kl} \quad \text{integration over nuclear coordinates} \quad (44)$$

Qualitative Analysis of the Adiabatic Approximations

In this section a sketch of a rather simple exercise (Kręglewski 1979) that allows us to understand the criteria for determining the range of applicability of the adiabatic approximation is presented. The task is to solve the Schrödinger equation

$$\left(-\frac{1}{2\mu_1} \frac{\partial^2}{\partial x_1^2} + \frac{1}{2} k_1 x_1^2 - \frac{1}{2\mu_2} \frac{\partial^2}{\partial x_2^2} + \frac{1}{2} k_2 x_2^2 + k_{12} x_1 x_2 \right) \Psi(x_1, x_2) = E(1, 2) \Psi(x_1, x_2), \quad (45)$$

exactly using the adiabatic approximation. The equation we have to solve describes two coupled harmonic oscillators. The choice of the harmonic oscillator model is not accidental. First, each of the readers, after a basic course of quantum mechanics, can solve the corresponding eigenvalue problem. Second, harmonic oscillator model always describes bound states. Hence, the proposed exercise avoids difficulties and traps that may arise if continuous spectrum is present, though many aspects related to processes where the continuous spectrum is involved (e.g., dissociation) are completely missing. Another advantage of this problem is its exact solubility. By comparing the exact solutions with the approximate ones, we can see the limits of the applicability of the adiabatic approximation.

Step 1: Adiabatic approximation. Let us introduce new variables:

$$\sqrt{\mu_i} x_i = y_i \quad \text{for } i = 1, 2 \quad (46)$$

and new designations:

$$\lambda_i \equiv \frac{k_i}{\mu_i}, \quad \kappa \equiv \frac{k_{12}}{\sqrt{\mu_1 \mu_2}} \quad \text{for } i = 1, 2. \quad (47)$$

Now Eq. (45) reads

$$\left(\hat{H}(y_1) + \hat{H}(y_2) + \kappa y_1 y_2 \right) \Psi(y_1, y_2) = E(1, 2) \Psi(y_1, y_2), \quad (48)$$

where, in order to simplify the equations, we have introduced the following markings on one particle Hamiltonians

$$\hat{H}(y_1) \equiv -\frac{1}{2} \frac{\partial^2}{\partial y_1^2} + \frac{1}{2} \lambda_1 y_1^2 \quad \text{and} \quad \hat{H}(y_2) \equiv -\frac{1}{2} \frac{\partial^2}{\partial y_2^2} + \frac{1}{2} \lambda_2 y_2^2. \quad (49)$$

According to the adiabatic approximation, we assume that the eigenfunctions in Eq. (48) can be approximated as

$$\Psi(y_1, y_2) = \phi_1(y_1, y_2) \phi_2(y_2). \quad (50)$$

Substituting functions (50) to Eq. (48), we obtain

$$\begin{aligned} & \left(\hat{H}(y_1) + \hat{H}(y_2) + \kappa y_1 y_2 \right) \phi_1(y_1, y_2) \phi_2(y_2) = \varepsilon \phi_1(y_1, y_2) \phi_2(y_2) \\ & \left[\left(\hat{H}(y_1) + \kappa y_1 y_2 \right) \phi_1(y_1, y_2) \right] \phi_2(y_2) + \\ & \left[\hat{H}(y_2) \phi_1(y_1, y_2) \right] \phi_2(y_2) + \left[\hat{H}(y_2) \phi_2(y_2) \right] \phi_1(y_1, y_2) = \varepsilon \phi_1(y_1, y_2) \phi_2(y_2). \end{aligned}$$

Assuming that

$$\left(-\frac{1}{2} \frac{\partial^2}{\partial y_1^2} + \frac{1}{2} \lambda_1 y_1^2 + \kappa y_1 y_2 \right) \phi_1(y_1, y_2) = E_1(y_2) \phi_1(y_1, y_2), \quad (51)$$

we get

$$E_1(y_2) \phi_1(y_1, y_2) \phi_2(y_2) + \left[\hat{H}(y_2) \phi_2(y_2) \right] \phi_1(y_1, y_2) = \varepsilon \phi_1(y_1, y_2) \phi_2(y_2).$$

Multiplying the last equation on the lhs by $\phi_1(y_1, y_2)$ and integrating with respect to y_1 , we obtain

$$\left(\hat{H}(y_2) + E_1(y_2) \right) \phi_2(y_2) + \langle \phi_1(y_1, y_2) | -\frac{1}{2} \frac{\partial^2}{\partial y_1^2} \phi_1(y_1, y_2) \rangle \phi_2(y_2) = \varepsilon \phi_2(y_2). \quad (52)$$

Equation (51) can be rewritten as

$$\left(-\frac{1}{2} \frac{\partial^2}{\partial y_1^2} + \frac{1}{2} \lambda_1 \left(y_1 + \frac{\kappa}{\lambda_1} y_2 \right)^2 \right) \phi_1(y_1, y_2) = \left(E_1(y_2) + \frac{1}{2} \frac{\kappa^2}{\lambda_1} y_2^2 \right) \phi_1(y_1, y_2). \quad (53)$$

It can be recognized as the harmonic oscillator Schrödinger equation. The eigenfunctions are the well-known Hermite polynomials and energy is equal to

$$\phi_1(\tilde{y}) = \phi_{n_1}(\tilde{y}) = N_{n_1} H_{n_1} \left(\sqrt[4]{\lambda_1} \tilde{y} \right) \exp \left[-\frac{1}{2} \sqrt{\lambda_1} \tilde{y}^2 \right] \quad \text{where} \quad \tilde{y} \equiv y_1 + \frac{\kappa}{\lambda_1} y_2$$

$$E_1 = E_{n_1} = \sqrt{\lambda_1} \left(n_1 + \frac{1}{2} \right) - \frac{1}{2} \frac{\kappa^2}{\lambda_1} y_2^2 \quad \text{where} \quad n_1 = 0, 1, 2, \dots$$

In order to solve Eq. (52), let us first calculate the value of

$$\langle \phi_1(y_1, y_2) | -\frac{1}{2} \frac{\partial^2}{\partial y_2^2} \phi_1(y_1, y_2) \rangle = -\frac{1}{2} \int_0^\infty dy_1 \phi_1(y_1, y_2) \frac{\partial^2}{\partial y_2^2} \phi_1(y_1, y_2).$$

By introducing a new variable $y_1 + \frac{\kappa}{\lambda_1} y_2 \equiv \tilde{y}$, we get

$$-\frac{1}{2} \left(\frac{\kappa^2}{\lambda_1} \right)^2 \int_0^\infty d\tilde{y}_1 \phi_1(y_1, y_2) \frac{\partial^2}{\partial \tilde{y}^2} \phi_1(y_1, y_2) = \frac{1}{2} \sqrt{\lambda_1} \left(n_1 + \frac{1}{2} \right) \frac{\kappa^2}{\lambda_1}.$$

In this way Eq. (52) may be rewritten as

$$\left(\hat{H}(y_2) + \sqrt{\lambda_1} \left(n_1 + \frac{1}{2} \right) - \frac{1}{2} \frac{\kappa^2}{\lambda_1} y_2^2 \right) \phi_2(y_2) + \frac{1}{2} \sqrt{\lambda_1} \left(n_1 + \frac{1}{2} \right) \frac{\kappa^2}{\lambda_1} \phi_2(y_2) = \varepsilon \phi_2(y_2)$$

$$\left(-\frac{1}{2} \frac{\partial^2}{\partial y_2^2} + \frac{1}{2} \left(\lambda_2 - \frac{\kappa^2}{\lambda_1} \right) y_2^2 \right) \phi_2(y_2) = \left(\varepsilon - \frac{1}{2} \sqrt{\lambda_1} \left(n_1 + \frac{1}{2} \right) \left(\frac{\kappa^2}{\lambda_1} + 2 \right) \right) \phi_2(y_2). \quad (54)$$

As we see, Eq. (54), similarly to Eq. (53), is of the form of one-dimensional harmonic oscillator, and its solutions are expressed in terms of one-dimensional harmonic oscillator wave functions and energies:

$$\phi_2(y_2) = \phi_{n_2}(y_2) = N_{n_2} H_{n_2} \left(\sqrt[4]{\lambda_2 - \frac{\kappa^2}{\lambda_1}} y_2 \right) \exp \left[-\frac{1}{2} \sqrt{\lambda_2 - \frac{\kappa^2}{\lambda_1}} y_2^2 \right]$$

$$\varepsilon_{n_1, n_2} = \sqrt{\lambda_1} \left(1 + \frac{1}{2} \frac{\kappa^2}{\lambda_1^2} \right) \left(n_1 + \frac{1}{2} \right) + \sqrt{\lambda_2 - \frac{\kappa^2}{\lambda_1}} \left(n_2 + \frac{1}{2} \right) \quad \text{where} \quad n_1, n_2 = 0, 1, 2, \dots \quad (55)$$

In this way we get the solution of the Schrödinger equation (48) in the adiabatic approximation.

Step 2: Exact solution. The second step of the task is the exact solution of the eigenvalue problem of (48). By introducing new coordinates, which diagonalize the quadratic form $\lambda_1 y_1^2 + \lambda_2 y_2^2 + 2\kappa y_1 y_2$, we find

$$\text{exact} E_{n_1, n_2} = \sqrt{\text{exact} \lambda_1} \left(n_1 + \frac{1}{2} \right) + \sqrt{\text{exact} \lambda_2} \left(n_2 + \frac{1}{2} \right) \quad (56)$$

$$\text{exact} \Psi_{n_1, n_2}(y_1, y_2) = \Psi_{n_1}(q_1) \Psi_{n_2}(q_2) \quad (57)$$

where

$$\text{exact } \lambda_{1,2} = \frac{1}{2} \left[(\lambda_1 + \lambda_2) \pm \sqrt{(\lambda_1 - \lambda_2)^2 + 4\kappa^2} \right].$$

A comparison of the results

1. Let $(\lambda_1 - \lambda_2)^2 \gg 4\kappa^2$ and $\lambda_1 \gg \lambda_2$

The Condition $(\lambda_1 - \lambda_2)^2 \gg 4\kappa^2$ allows us to expand $\text{exact } \lambda_{1,2}$ in the exact energy expression (56) to a power series:

$$\begin{aligned} \text{exact } \lambda_{1,2} &= \frac{1}{2} \left[(\lambda_1 + \lambda_2) \pm \sqrt{(\lambda_1 - \lambda_2)^2 + 4\kappa^2} \right] \\ &= \frac{1}{2} \left[(\lambda_1 + \lambda_2) \pm (\lambda_1 - \lambda_2) \sqrt{1 + \left(\frac{2\kappa}{(\lambda_1 - \lambda_2)} \right)^2} \right] \\ &\cong \frac{1}{2} \left[\lambda_1 + \lambda_2 \pm (\lambda_1 - \lambda_2) \left(1 + \frac{2\kappa^2}{(\lambda_1 - \lambda_2)^2} + \dots \right) \right] \\ &\cong \frac{1}{2} \left[\lambda_1 + \lambda_2 \pm (\lambda_1 - \lambda_2) \left(1 + \frac{1}{2} \left(\frac{2\kappa}{(\lambda_1 - \lambda_2)} \right)^2 + \dots \right) \right] \\ \text{exact } \lambda_1 &\cong \lambda_1 + \frac{\kappa^2}{\lambda_1 - \lambda_2} \quad \text{and} \quad \text{exact } \lambda_2 \cong \lambda_2 - \frac{\kappa^2}{\lambda_1 - \lambda_2}. \end{aligned}$$

Assuming now that $\lambda_1 \gg \lambda_2$, we obtain

$$\text{exact } \lambda_1 \cong \lambda_1 + \frac{\kappa^2}{\lambda_1} \quad \text{and} \quad \text{exact } \lambda_2 \cong \lambda_2 - \frac{\kappa^2}{\lambda_1}. \quad (58)$$

Corollary:

When the frequencies of both oscillators are very different from each other and the first frequency is much larger than the second one (cf. the relative mobility of electrons and nuclei), then the energies obtained by the approximate and by the exact procedures remain in an excellent agreement (cf. (55) and (56)):

$$\begin{aligned} \varepsilon_{n_1, n_2} &= \sqrt{\lambda_1 \left(1 + \frac{1}{2} \frac{\kappa^2}{\lambda_1^2} \right)^2} \left(n_1 + \frac{1}{2} \right) + \sqrt{\lambda_2 - \frac{\kappa^2}{\lambda_1}} \left(n_2 + \frac{1}{2} \right) \\ &\cong \sqrt{\lambda_1 + \frac{\kappa^2}{\lambda_1}} \left(n_1 + \frac{1}{2} \right) + \sqrt{\lambda_2 - \frac{\kappa^2}{\lambda_1}} \left(n_2 + \frac{1}{2} \right) \\ \text{exact } E_{n_1, n_2} &= \sqrt{\text{exact } \lambda_1} \left(n_1 + \frac{1}{2} \right) + \sqrt{\text{exact } \lambda_2} \left(n_2 + \frac{1}{2} \right) \\ &\cong \sqrt{\lambda_1 + \frac{\kappa^2}{\lambda_1}} \left(n_1 + \frac{1}{2} \right) + \sqrt{\lambda_2 - \frac{\kappa^2}{\lambda_1}} \left(n_2 + \frac{1}{2} \right) \end{aligned}$$

In this case the adiabatic approximation works very well!

2. Let $k_1 = k_2 = k_{12}$

The conditions $(\lambda_1 - \lambda_2)^2 \gg 4\kappa^2$ and $\lambda_1 \gg \lambda_2$ where $k_1 = k_2 = k_{12}$ leads to

$$1 \ll \frac{\mu_2}{\mu_1}$$

Corollary:

The accuracy of the adiabatic approximation depends on the ratio of masses of the two oscillators. This means that in the case of molecules, in which the interaction between all particles have the same character, the accuracy of the adiabatic approximation depends on the ratio of masses of the particles. And because the mass ratio of the nucleus and the electron is of the order 10^3 – 10^5 , the condition under discussion is met.

3. Let $\mu_1 = \mu_2$

The condition $(\lambda_1 - \lambda_2)^2 \gg 4\kappa^2$ and $\lambda_1 \gg \lambda_2$ where $\mu_1 = \mu_2$ leads to

$$\frac{(k_1 - k_2)^2}{\mu^2} \gg \frac{k_{12}}{\mu^2} \quad \Rightarrow \quad k_1 \gg k_2$$

Corollary:

The accuracy of the adiabatic approximation depends on the values of the coupling constant k_{12} . The approximation is valid if the coupling constant is much smaller than the difference between k_1 and k_2 . This means that in a system where masses of the compound particles are the same, the accuracy of the adiabatic approximation depends mainly on the binding energy. For example, in the case of an atom with an infinite-mass nucleus, the accuracy of the adiabatic method is determined by the electron density distribution in the state under consideration.

Born-Oppenheimer Approximation

The equation of motion of nuclei (36) assuming

$$\sum_k c_{lk}(R) \chi_k(\mathbf{R}) \cong 0, \quad (59)$$

can be written as

$$\left(-\frac{1}{2\mu} \Delta_{\mathbf{R}} + E_l^0(R) \right) \chi_l(\mathbf{R}) = E \chi_l(\mathbf{R}). \quad (60)$$

It allows for a substantial simplification of the equations of motion of a molecular system and is the essence of BO approximation, named for its original creators, Max Born and Robert Oppenheimer (Born and Oppenheimer 1927).⁶

The omission of terms $\sum_k c_{lk}(R) \chi_k(\mathbf{R})$ in Eq. (36), except for the diagonal term $c_{ll}(R) \chi_l(\mathbf{R})$, corresponds to the adiabatic approximation. If also this term is neglected, we get the BO approximation. A description of molecules using the BO approximation ignores any kind of coupling between the movement of electrons and of the nuclei ($c_{ll}(R) = 0$). The physical idea is that light and fast-moving electrons adapt to the nuclear displacements instantaneously. If we solve the electronic Schrödinger equation for each possible arrangement of the nuclei, then we obtain the electronic effective potential $U_l(R) = E_l^0(R)$.

Equation (60) offers a possibility of examining the movement of electrons under the assumption that the nuclei in the molecule are immobile (i.e., their masses are infinite) and are located at a fixed distance $|\mathbf{R}_i|$ from each other. The function $E_l^0(R)$ determines the potential energy surface (PES). The nuclear wave function $\chi_l(\mathbf{R})$ determines the probability amplitude of the nuclear positions in the l -th quantum state. PES $E_l^0(R)$ is usually given numerically as a set of numbers evaluated for various nuclear positions. The shape of $E_l^0(R)$ for a diatomic molecule is shown in Fig. 2.

Electronic Terms of Diatomic Molecules: Symmetry

In atomic spectroscopy, the atomic electronic states are labeled by spectral term $^{2S+1}L_J$ indices. Usually the classification of atomic terms is performed according to the values of the total orbital angular momentum L and total spin angular momentum S , because the electronic Hamiltonian commutes with L^2 and S^2 (and also with L_z and S_z). In molecules the operator representing the square of the electronic angular momentum does not commute with the Hamiltonian because the electric field of several nuclei is not centrally symmetric. However, for diatomic molecules (or linear molecules in general), the field has axial symmetry about the axis passing through the two nuclei. Hence, the operator representing the angular momentum component along this axis commutes with the Hamiltonian. Therefore, the electronic terms of diatomic molecules are classified according to the projection of the electronic orbital angular momentum on the molecule axis. The absolute value of the projection of the orbital angular momentum on the axis of the molecule is usually denoted as Λ , where $\Lambda = 0, 1, 2, \dots$. The electronic

⁶More inventive faculty trying to explain to students the BO approximation takes an example of a cow (symbolizes the nucleus) and flies flying around it (electrons). Flies almost immediately adapt to the current position of the cow, just because they are lighter and move faster. Therefore, the cow only sees a cloud of flies, while the flies only see a static cow.

Fig. 2 Potential energy curve for a bound electronic state of a diatomic molecule. The graph shows the energy as a function of the interatomic distance. The case when R tends to infinity $E_l^{(0)}(R) = E_1 + E_2$ is equal to the energy of the isolated atoms 1 and 2. The value of R for which the potential reaches its minimum is called the equilibrium position and is denoted R_e . The binding energy of the molecule, $E_l^0(R = \infty) - E_l^0(R_e)$, is denoted as ϵ_e . For $R < R_e$, the nuclear repulsion energy dominates and $E_l^0(R)$ grows up to infinity while $R \rightarrow 0$

states with $\Lambda = 0$ are called Σ -states, those with $\Lambda = 1$ are Π -states, those with $\Lambda = 2$ are Δ -states, etc. The total spin S is denoted as an upper-left index: $^{2S+1}\Lambda$, where $2S + 1$ is equal to the spin degeneracy of the term. There is also a reflection symmetry about an arbitrary plane passing through the axis of symmetry of the molecule. In this case, the reflected and the original state of the molecule differ by sign of the angular momentum projection. This means that the electron terms with $\Lambda \neq 0$ (Π, Δ, Φ, \dots states) are double-degenerate. If $\Lambda = 0$ then the state of the molecule does not change under a reflection. Therefore, Σ terms are not degenerate. But because a double reflection in the same plane results in the identity transformation, among Σ terms we distinguish the ones for which the wave function does not change, Σ^+ , and the ones for which it changes the sign, Σ^- . Homonuclear diatomic molecules have another symmetry called *parity*. The molecule has the symmetry center at the point bisecting the line joining the two nuclei. In such a case the Hamiltonian is invariant with respect to the change of sign of all electron coordinates. The wave functions which do not change under this transformation are called *even* and labeled by an index g . The wave function changing their sign is called *odd* and labeled by u . The electronic terms for homonuclear diatomic molecules are denoted as $^{2S+1}\Lambda_u$ or $^{2S+1}\Lambda_g$.

Rotations and Vibrations of Diatomic Molecules

In the previous section, we discussed only the electronic states of the molecule. The share of the kinetic energy of the nuclei in the total energy of the molecule is usually by two orders of magnitude smaller than that of the electronic energy. Nevertheless, the effects of the nuclear motion significantly influences the molecular structure and spectra. In this section we show that the shape of the potential energy curve determines rotation and vibration of the nuclei. For the sake of simplicity of the description, we usually consider rotation and vibration of a molecule as independent of each other. In reality these motions are coupled.

Separation of Rotation and Vibration

We are going to solve the equation describing the nuclear motion (41) within adiabatic approximation (because we do not neglect the c_{ll}) term:

$$\left(-\frac{1}{2\mu} \Delta_{\mathbf{R}} + U_l(R) \right) \chi_l(\mathbf{R}) = E \chi_l(\mathbf{R}) \quad \text{where} \quad U_l(R) = E_l^0(R) + c_{ll}(R).$$

The motion of the nuclei is described by the changes of the length and the direction of $\mathbf{R} = \mathbf{R}_1 - \mathbf{R}_2$. The change of the length of \mathbf{R} corresponds to the *vibrations* of the molecule and the change of its direction – to the *rotation* of the molecule. Since the potential in Eq. (36) depends only on $R = |\mathbf{R}|$, the problem described by this equation is spherically symmetric as, e.g., in the case of the hydrogen atom. Therefore, it may be conveniently solved by introducing spherical coordinates. Using the well-known expression for the Laplace operator in the spherical coordinates (r, θ, φ)

$$\Delta_{\mathbf{R}} = \frac{1}{R^2} \frac{\partial}{\partial R} \left(R^2 \frac{\partial}{\partial R} \right) - \frac{\hat{\mathbf{J}}^2}{R^2},$$

where

$$\hat{\mathbf{J}}^2 = -\frac{1}{\sin \theta} \frac{\partial}{\partial \theta} \sin \theta \frac{\partial}{\partial \theta} + \frac{1}{\sin^2 \theta} \frac{\partial^2}{\partial \varphi^2}$$

is the square of the angular momentum operator, we can rewrite Eq. (36) in the form

$$\frac{1}{2\mu} \left[-\frac{1}{R^2} \frac{\partial}{\partial R} \left(R^2 \frac{\partial}{\partial R} \right) + \frac{\hat{\mathbf{J}}^2}{R^2} \right] \chi_l(\mathbf{R}) + U_l(R) \chi_l(\mathbf{R}) = E \chi_l(\mathbf{R}). \quad (61)$$

The first term in the square bracket corresponds to the kinetic energy of vibrations and the second term to the rotational energy. Since the Hamiltonian operator in (61)

Fig. 3 Diatomic molecule as a rigid rotor. The rotation axis shown in the figure is perpendicular to the center of mass (CM) of the molecule

is a sum of operators which depend on different variables, the function $\chi_l(\mathbf{R})$ can be expressed as a product of two functions: the radial function $R^{-1}\chi_l^{\text{vib}}(R)$ and the angular function $Y_{JM}(\theta, \varphi)$

$$\chi_l(\mathbf{R}) = R^{-1}\chi_l^{\text{vib}}(R)Y_{JM}(\theta, \varphi). \quad (62)$$

The angular function is an eigenfunction of the square of the angular momentum operator

$$\hat{\mathbf{J}}^2 Y_{JM}(\theta, \varphi) = J(J + 1) Y_{JM}(\theta, \varphi),$$

where $J = 0, 1, \dots$ is the rotation quantum number.

A diatomic molecule with nuclear masses M_1 and M_2 can rotate around any axis passing through the center of the mass. The rotation energy of such a molecule is

$$E^{\text{rot}} = \frac{1}{2}I\omega^2, \quad (63)$$

where ω is the angular velocity and I (see Fig. 3) is the moment of inertia of the molecule. If the rotation axis is perpendicular to the axis of the molecule, then $I = M_1M_2/(M_1 + M_2)R^2$. Combining Eqs. (62) and (61) and using the eigenvalue equation for the rigid rotor (Appendix B), we get

$$\left[-\frac{1}{2\mu} \frac{\partial^2}{\partial R^2} + (U_l(R) - E) \right] \chi_l^{\text{vib}}(R) = -\frac{1}{2I} J(J + 1) \chi_l^{\text{vib}}(R). \quad (64)$$

The last equation may be rewritten in a more compact form as

$$\left[-\frac{1}{2\mu} \frac{\partial^2}{\partial R^2} + V_{lJ}(R) \right] \chi_{lvJ}^{\text{vib}}(R) = E_{lvJ} \chi_{lvJ}^{\text{vib}}(R), \quad (65)$$

where

$$V_{lJ}(R) = E_l^0(R) + c_{ll}(R) + \frac{1}{2I} J(J+1) \quad (66)$$

is the effective potential for the nuclear motion. As one can see, it is a sum of the adiabatic potential $U_l(R)$ and the centrifugal potential associated with the rotation of the molecule. In the BO approximation, $U_l(R)$ is replaced by $E^0(R)$:

$$V_{lJ}(R) = E_l^0(R) + \frac{1}{2I} J(J+1), \quad (67)$$

the potential generated by the cloud of electrons. The consecutive eigenfunctions $\chi_{lvJ}^{\text{vib}}(R)$ and eigenvalues E_{lvJ} are labeled by the vibrational quantum number $v = 0, 1, 2, \dots$.

$$\left[-\frac{1}{2\mu} \frac{\partial^2}{\partial R^2} + V_{lJ}(R) \right] \chi_{lvJ}^{\text{vib}}(R) = E_{lvJ} \chi_{lvJ}^{\text{vib}}(R)$$

where

$$V_{lJ}(R) = E_l^0(R) + c_{ll}(R) + J(J+1) \frac{1}{2I}, \quad (68)$$

in the adiabatic approximation, and

$$V_{lJ}(R) = E_l^0(R) + J(J+1) \frac{1}{2I}, \quad (69)$$

in the BO approximation.

- J – rotational quantum number.
- $v = 0, 1, 2, 3, \dots$ – vibrational quantum number.
- $V_{lJ}(R)$ represents the potential energy of the motion of the nuclei; depends only on the nuclear distance R , i.e., it is independent of the orientation of the molecule in space. It is spherically symmetric.
- The centrifugal term in Eq. (66) describes the dependence of the molecular rotation. The rotation energy is equal to $J(J+1)$. It describes the weakening of bond energy due to the centrifugal force.

Nuclear Vibrations: Harmonic Approximation

In the case of the low-energy states, more precisely the states with low energies, bound in sufficiently deep minima of the potential energy curves, the motion of the nuclei is limited to a small range of R , close to the equilibrium distance R_e .⁷ At $R = R_e$ the potential $V_{l(J=0)}(R) \equiv U_l(R)$ has minimum, so $R = R_e$ is the value for which the interaction energy of the atoms in the rotor has a minimum. Expanding $U_l(R)$ into a power series around $R = R_e$, we get

$$U_l(R) = U_l(R)|_{R=R_e} + \left. \frac{dU_l(R)}{dR} \right|_{R=R_e} (R-R_e) + \frac{1}{2!} \left. \frac{d^2U_l(R)}{dR^2} \right|_{R=R_e} (R-R_e)^2 + \dots \quad (70)$$

Since at $R = R_e$ the potential $U_l(R)$ reaches a minimum, and limiting the expansion (70) up to quadratic terms, we have

$$\left. \frac{dU_l(R)}{dR} \right|_{R=R_e} = 0 \quad \Rightarrow \quad U_l(R) \approx U_l(R_e) + \frac{1}{2!} \kappa (R - R_e)^2, \quad (71)$$

where

$$\kappa = \left. \frac{d^2U_l(R)}{dR^2} \right|_{R=R_e} \quad (72)$$

is called force constant. For $R = R_e$ and $J \neq 0$, we can assume that

$$J(J+1) \frac{1}{2\mu R^2} \approx J(J+1) \frac{1}{2\mu R_e^2} \equiv J(J+1) B_e, \quad (73)$$

where B_e is the *rotational constant* determined by the reduced mass μ and the equilibrium nuclear distance R_e . Thus, the potential in Eq. (68) can be written as

$$V_{lJ}(R) = U_l(R_e) + \frac{1}{2} \kappa (R - R_e)^2 + J(J+1) B_e. \quad (74)$$

The first and last terms in this equation are constant. We denote them as

$$E' \equiv U_l(R_e) + J(J+1) B_e. \quad (75)$$

With the above approximations, Eq. (65) becomes

⁷In fact, there exist rovibrational states, e.g., in the helium dimer, which cannot be properly described by the model of a harmonic oscillator.

$$\left[-\frac{1}{2\mu} \frac{\partial^2}{\partial R^2} + \frac{1}{2} \kappa (R - R_e)^2 \right] \chi_{l\nu J}^{\text{vib}}(R) = (E_{l\nu J} - E') \chi_{l\nu J}^{\text{vib}}(R). \quad (76)$$

It is easy to recognize this equation as the Schrödinger equation for the harmonic oscillator, where $R - R_e$ is the deviation from the equilibrium position. Hence, the energies (the eigenvalues of (76)) may be readily written as

$$E_{l\nu J} = E' + E_{\nu}^{\text{vib}}, \quad \text{where} \quad E_{\nu}^{\text{vib}} = \omega \left(\nu + \frac{1}{2} \right), \quad \nu = 0, 1, 2, \dots, \quad (77)$$

where $\nu = 0, 1, 2, \dots$ is vibrational quantum number and ω is the classical frequency of the oscillator. In the molecular spectroscopy, the term values rather than energies are frequently used:

$$G_{\nu} = \frac{E_{\nu}^{\text{vib}}}{hc} = \bar{\nu}_{\text{vib}} \left(\nu + \frac{1}{2} \right), \quad \text{where} \quad \bar{\nu}_{\text{vib}} = \frac{1}{2\pi c} \sqrt{\frac{\kappa}{\mu}} \quad (78)$$

and $G_0 = 1/2\bar{\nu}_{\text{vib}}$ is called *zero-energy vibration*.

Equations (75) and (77) yield the following symbolic expression for the energy levels in a molecule:

$$E_{l\nu J} = E_l^{\text{el}} + E_{\nu}^{\text{vib}} + E_J^{\text{rot}}. \quad (79)$$

The first term, E_l^{el} (see (41)) is the electronic energy, the second term is the energy of vibrations of the nuclei (77), and the third one is the rotational energy (75).

The molecular energy within adiabatic approximation and harmonic decoupling of vibronic and rotation motions model, may be expressed as a sum of the electronic, vibrational, and rotational components:

$$\begin{aligned} E_{l\nu J}(R) &= \underbrace{U_l(R_e)}_{E_l^{\text{el}}} + \underbrace{\bar{\nu}_{\text{vib}} \left(\nu + \frac{1}{2} \right)}_{E_{\nu}^{\text{vib}}} + \underbrace{J(J+1)B}_{E_J^{\text{rot}}} = \\ &= E_l^0(R) + c_{ll}(R) + \bar{\nu}_{\text{vib}} \left(\nu + \frac{1}{2} \right) + J(J+1)B. \end{aligned} \quad (80)$$

This expression for the molecular energy levels is correct only for the low excited states which lie sufficiently close to the of ground level where the assumption on the harmonic character of the nuclear vibrations and the assumption about the separability of the vibrational and rotational motions are valid. We should also remember that in Eq. (80), the kinetic energy of the molecular center of mass is omitted.

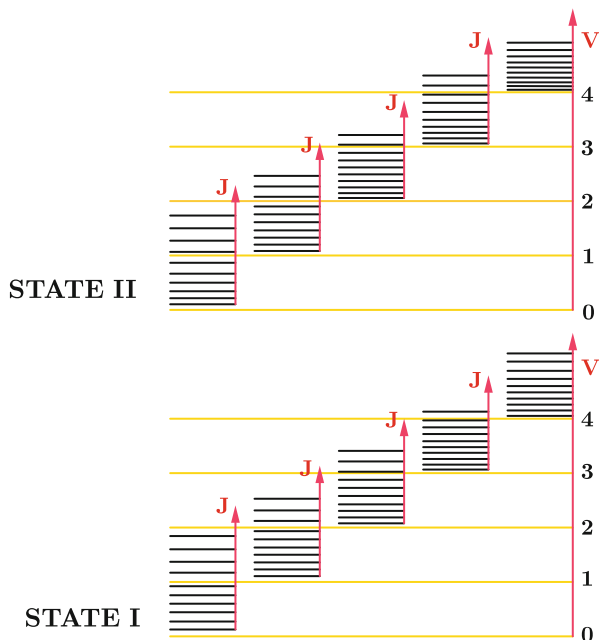

Fig. 4 Vibrational levels (labeled by the vibrational quantum numbers $\nu = 0, 1, 2, 3, \dots$) and rotational levels (quantum numbers J) of two electronic states of a molecule, denoted as “State I” and “State II.” More details on the structure of molecular spectra may be found, e.g., in Landau and Lifschitz (1981) and Haken and Wolf (2004)

According to Eq. (80), the nuclear motion causes a splitting of each electronic term to a series of energy levels characterized by quantum numbers ν and J . For each value of J , we have infinite number of levels with different values of ν , cf. Fig. 4. One can show Landau and Lifschitz (1981), Haken and Wolf (2004), and Herzberg (1951) that

$$\{E_l^{\text{el}} : E_\nu^{\text{vib}} : E_J^{\text{rot}}\} = \left\{ 1 : \sqrt{\frac{m}{M}} : \frac{m}{M} \right\},$$

where m and M are, respectively, the masses of electron and of the nucleus. Assuming that $m/M \sim 10^{-4} - 10^{-5}$, we obtain the distribution of the molecular energy levels given by the following inequality

$$\Delta E^{\text{el}} \gg \Delta E^{\text{vib}} \gg \Delta E^{\text{rot}}. \quad (81)$$

A separation of rotation and vibration in higher-order approximations is no longer possible. In higher orders of the perturbation theory, the molecular energy may be expressed as an expansion in powers of the quantum numbers ν and J (Demtröder 2010).

A More Detailed Look at the Molecule

In the following paragraphs, we present a more detailed picture of a molecule going beyond the rigid molecule approximation and beyond the harmonic description of the molecular vibrations.

Nuclear Vibrations: Anharmonic Approximation

The harmonic potential represented by a symmetric parabola, cannot correctly represent the real potential $E_i^{el}(R)$ across the variability of R . In this model the potential and the repulsion force increase indefinitely with the increasing distance from the equilibrium position. This cannot be correct for a real molecule because when $R \rightarrow \infty$, i.e., if the distance between the atoms is very large, the attractive force between them must be zero, and the potential has to be constant. This asymptotic constant value is equal to the total energy of the separated atoms. For $R < R_e$, the potential energy must be steeper than in the case of the harmonic oscillator, because reduction of the distance between atoms leads to a short-distance repulsive force, which exceeds the Coulomb interaction. These characteristics of the potential of the molecule is partly fulfilled by the Morse potential Fig. 5, which has the following functional form:

$$E(R) = D_e \{ 1 - \exp[-a(R - R_e)] \}^2, \quad (82)$$

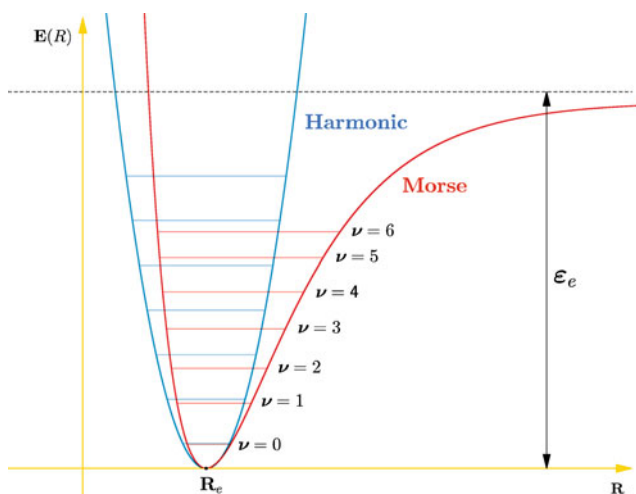

Fig. 5 The potential curve is approximately harmonic (a parabola) near the bottom. A better, and still analytic but anharmonic, potential is the Morse potential. The vibrational energy levels ν for both potentials and the dissociation energy ϵ_e for the Morse potential are also shown

where D_e is the dissociation energy and a determines the width of the potential well and is characteristic for the pair of atoms forming the molecule. One of advantages of the Morse potential is that for this potential, the Schrödinger equation is analytically solvable. As one can see, near the minimum of the potential energy curve the harmonic oscillator gives a good approximation, while at large distances from the equilibrium, $R > R_e$, one has to use an anharmonic potential. In particular, it may be relatively well described by the Morse potential. In the general case, the anharmonicity modifies the vibrational energy levels (77) to form (Herzberg 1951):

$$E_v^{\text{vib}} = \bar{\nu}_{\text{vib}} \left(\nu + \frac{1}{2} \right) - x_e \bar{\nu}_{\text{vib}} \left(\nu + \frac{1}{2} \right)^2 + y_e \bar{\nu}_{\text{vib}} \left(\nu + \frac{1}{2} \right)^3 + \dots, \quad (83)$$

where x_e , y_e are anharmonic constants, usually much smaller than the harmonic one, $\bar{\nu}_{\text{vib}}$. The anharmonic constants are always positive (Haken and Wolf 2004; Kolos and Sadlej 1998). In this way we retained the Morse potential qualitative description of the vibration spectrum. It should be remembered that in the case of high-precision calculations, one has to use more accurate potential functions. For example, good results may be obtained with a five-parameter Hulburt-Hirschfelder function (Hulburt and Hirschfelder 1941) or with the Taylor series expansion of the exact potential to high powers of $R - R_e$:

$$E(R) = D_e \{ [1 - \exp[-x]]^2 + c[x]^3 \exp[-2x] (1 + bx) \}, \quad \text{for } x = a(R - R_e), \quad (84)$$

where b, c are additional parameters that allow us to adjust the curve to the experimental data.

Rotations: Non-rigid Rotor

As we have shown (80), the energy of a molecule treated as a rigid rotor may be expressed as a sum of the electronic energy at the equilibrium positions of the nuclei, the energy of vibration, and the energy of rotation. In the rigid rotor approximation, the rotational energy of a molecule may be expressed as $E_J^{\text{rot}} = J(J + 1)B_e$. Let us note that a molecule can vibrate without rotation (the states with $J = 0$). However, it cannot rotate without vibrations, because even in the lowest energy vibrational state, it executes the $\nu = 0$ vibrations. The real molecule rotates and vibrates at the same time. Since the vibrational frequency $\bar{\nu}_{\text{vib}}$ is larger than the rotational constant B_e , the nuclear distance changes periodically during one full rotation. It follows that in describing molecular rotations, we should consider them as an average over a vibrational period. Therefore, instead of $1/R_e^2$ in Eq. (73), we should take the average value $1/R^2$, calculated for a given vibrational state:

$$B_e \rightarrow B_v = \frac{1}{2\mu R^2} \langle \chi_v^{\text{vib}}(R) \left| \frac{1}{R^2} \right| \chi_v^{\text{vib}}(R) \rangle, \quad (85)$$

where the integral is calculated with respect to the nuclear variables. Thus, the rotational constant B from Eq.(73)) is now defined as the average over the vibrational motion. In this way the rotational energy may be expressed as the average over the vibrational period

$$E_J^{\text{rot}} = \frac{1}{2\mu} J(J+1) \langle \chi_v^{\text{vib}}(R) \left| \frac{1}{R^2} \right| \chi_v^{\text{vib}}(R) \rangle. \quad (86)$$

As one can see from Eq. (85), the rotational constant depends on v . As a result, now the potential is not symmetric around the point $R = R_e$. For a general anharmonic potential, the rotational constant may be expressed as a v -dependent power series (Herzberg 1951):

$$B_v = B_e - \alpha_e \left(v + \frac{1}{2} \right) + \beta_e \left(v + \frac{1}{2} \right)^2 + \gamma_e \left(v + \frac{1}{2} \right)^3 + \dots, \quad (87)$$

where $B_e \gg \alpha_e \gg |\beta_e| \gg |\gamma_e|$ are empirically determined constants. Constants B_e and α_e are positive, but the subsequent terms can be positive or negative.

The introduction of different rotational constants for each vibrational state resulted in important amendments. However, we still remain in the rigid rotor model. The next step to correct the description of the molecular rotation is the assumption that the bond length is flexible. The degree of the flexibility is described by the force constant κ . This means that the degree to which bond length increases due to the centrifugal force is controlled by κ . The centrifugal force increases with increasing J and therefore also the bond length is larger for larger J . In the simplest model of the harmonic vibrations, the dependence of R_{min} on J is given by;

$$\frac{d}{dr} \left[\frac{1}{2} \kappa (R - R_e)^2 + \frac{J(J+1)}{2\mu R_e^2} \right]_{R=R_{\text{min}}} = \kappa (R_{\text{min}} - R_e) - \frac{J(J+1)}{\mu R_{\text{min}}^3} = 0 \quad (88)$$

$$\Rightarrow R_{\text{min}} = R_e \left(1 + \frac{J(J+1)}{\kappa \mu R_e^4} \right) \equiv R_e (1 + x), \quad \text{with} \quad x \ll 1, \quad (89)$$

where R_{min} corresponds to the minimum of potential (88) (the harmonic potential supplemented by a term describing the centrifugal force. As a result, the rotational energy of the non-rigid rotor is then

$$E_J^{\text{rot}} = \frac{1}{2} \kappa (R_{\text{min}} - R_e)^2 + \frac{J(J+1)}{2\mu R_{\text{min}}^2} = \frac{1}{2} \kappa R_e^2 x^2 + \frac{J(J+1)}{2\mu R_e^2} (1+x)^{-2}. \quad (90)$$

Inserting the power series expansion $(1 + x)^{-2} \approx 1 - 2x + 3x^2 + \dots$ to the last equation, we get

$$\begin{aligned} E_J^{\text{rot}} &\approx \frac{1}{2} \kappa R_e^2 x^2 + \frac{J(J+1)}{2\mu R_e^2} - 2 \frac{J(J+1)}{2\mu R_e^2} x + 3 \frac{J(J+1)}{2\mu R_e^2} x^2 \pm \dots \\ &= \frac{J(J+1)}{2\mu R_e^2} - \frac{J^2(J+1)^2}{2\mu^2 \kappa R_e^6} + \frac{3J^3(J+1)^3}{2\mu^3 \kappa^2 R_e^{10}} \pm \dots \end{aligned} \quad (91)$$

The resulting expression for the modified rotational energy of the molecule may be rewritten in a compact way as

$$E_J^{\text{rot}}(R) = J(J+1)B_v - J^2(J+1)^2 D_v + J^3(J+1)^3 H_v + \dots, \quad (92)$$

with the rotational constants

$$D_v = \frac{1}{2\mu^2 \kappa} \langle \chi_v^{\text{vib}}(R) | \frac{1}{R^6} | \chi_v^{\text{vib}}(R) \rangle, \quad H_v = \frac{1}{2\mu^3 \kappa^2} \langle \chi_v^{\text{vib}}(R) | \frac{1}{R^{10}} | \chi_v^{\text{vib}}(R) \rangle, \quad (93)$$

where we have introduced an average centrifugal constant D_v . For the general potential, the average centrifugal constant may be defined as

$$D_v = D_e + \tilde{\alpha}_e \left(\nu + \frac{1}{2} \right) + \tilde{\beta}_e \left(\nu + \frac{1}{2} \right)^2 + \tilde{\gamma}_e \left(\nu + \frac{1}{2} \right)^3 + \dots \quad (94)$$

The resulting expression (93) leads to the improved rotational energy (actually rotational-vibrational energy, because constants B_μ and D_μ depend on ν). We derived corrections to the energy, associated with stretching the bond in the molecule. These corrections may be neglected for small values of J . In turn, they become important for large J .

Collecting the results of this and of the previous sections, that is taking into account Eqs. (83) and (93), the energy of a rotational-vibrational level, for an anharmonic potential, can then be expressed as the power series of $(\nu + 1/2)$ and $J(J+1)$ as follows

$$E_{\nu J}^{\text{rot-vib}} = \bar{\nu}_{\text{vib}} \left(\nu + \frac{1}{2} \right) - x_e \bar{\nu}_{\text{vib}} \left(\nu + \frac{1}{2} \right)^2 + J(J+1)B_v - J^2(J+1)^2 D_v, \quad (95)$$

where the higher-order terms are neglected.

The Influence of the Electronic Motion

In order to refine the description of the rotational movement of molecules, we have to consider the contribution of the electronic motion to the energy of rotation of molecules. The reasoning presented here applies when the magnitudes of the angular

momenta of electrons and of the nuclei are comparable. Electrons process in the cylindrically symmetric potential of the nuclei. In this discussion the influence of the electronic spin is omitted. In this case, the quantity conserved is the projection of the electronic orbital angular momentum on the molecular axis. Then, the molecule can be seen as a symmetric top.⁸ In this model, two main components of the moment of inertia tensor are equal to each other (they are denoted as $I_B = I_C$), while the third one, describing the moment of inertia of electrons relative to the axis A of the molecule (I_A) is determined by the distribution of the electronic charge. Because the light electrons move much faster than heavy nuclei, the angular momentum of electrons is comparable to the angular momentum of the nuclei. Thus, the part of the Hamiltonian describing rotation may be written as

$$\hat{H}^{\text{rot}} = \frac{\hat{J}_A^2}{2I_A} + \frac{\hat{J}_B^2}{2I_B} + \frac{\hat{J}_C^2}{2I_C}. \quad (96)$$

The eigenvalues of the Hamiltonian (96) are equal to the total rotational energy of the molecule. In order to find these eigenvalues, we introduce the total angular momentum

$$\hat{J}^2 = \hat{J}_A^2 + \hat{J}_B^2 + \hat{J}_C^2, \quad \text{where} \quad |\mathbf{J}| = \sqrt{J(J+1)} \quad (97)$$

and its projection on the molecular axis A

$$\hat{J}_A^2, \quad \text{where} \quad |\mathbf{J}|_A = \Lambda \quad (98)$$

describes the contribution from the electronic motion. The quantum number Λ refers to the projection of the electronic angular momentum on the molecular axis A . Hence, Eq. (96) can be written as

$$\hat{H}^{\text{rot}} = \frac{\hat{J}^2}{2I_B} + \hat{J}_A^2 \left(\frac{1}{2I_A} - \frac{1}{2I_B} \right), \quad (99)$$

and the molecular rotational energy is given by

$$\begin{aligned} E^{\text{rot}} &= J(J+1) \frac{1}{2I_B} + \Lambda^2 \left(\frac{1}{2I_A} - \frac{1}{2I_B} \right) = J(J+1)B_e + \Lambda^2(\tilde{A} - B_e) \\ &= B_e [J(J+1) - \Lambda^2] + \Lambda^2 \tilde{A}, \end{aligned} \quad (100)$$

where B_e it the rotational constants introduced earlier in (73) and

$$\tilde{A} = \frac{1}{2I_A}. \quad (101)$$

⁸This model works well for molecules like NH_3 , CH_3Cl , C_6H_6 . In a general case the asymmetric top model should be used (see Haken and Wolf 2004 for details).

Because the term $\Lambda^2 \tilde{A}$ is constant for a given electronic state, it does not depend on J . Therefore, it may be added to the electronic energy. As a result, the rotational energy may be expressed as

$$E^{\text{rot}} = B_e [J(J + 1) - \Lambda^2], \quad (102)$$

where

$$J = \Lambda, \Lambda + 1, \Lambda + 2, \dots \quad (103)$$

The energy of a diatomic molecule obtained within the adiabatic approximation i.e., neglecting terms coupling the nuclear and the electronic motion ($c_{kl}(R) = 0$ for $k \neq l$), on different levels of approximation reads:

- Molecule as a rigid rotor, assuming harmonic vibrations of the nuclei

$$E_{l\nu J}(R) = E_l^0(R) + c_{ll}(R) + \bar{\nu}_{\text{vib}} \left(\nu + \frac{1}{2} \right) + J(J + 1)B_e \quad (104)$$

- Molecule as a non-rigid rotor, assuming anharmonic vibrations of the nuclei

$$E_{l\nu J}(R) = E_l^0(R) + c_{ll}(R) + \bar{\nu}_{\text{vib}} \left(\nu + \frac{1}{2} \right) - x_e \bar{\nu}_{\text{vib}} \left(\nu + \frac{1}{2} \right)^2 + J(J + 1)B_v - J^2(J + 1)^2 D_v \quad (105)$$

- Taking into account the rotational motion of electrons in the potential of the nuclei in the harmonic approximation

$$E_{l\nu J}(R) = E_l^0(R) + c_{ll}(R) + \bar{\nu}_{\text{vib}} \left(\nu + \frac{1}{2} \right) + [J(J + 1) - \Lambda^2] B_e \quad (106)$$

- Taking into account the rotational motion of electrons in the potential of the nuclei, for the anharmonic potential

$$E_{l\nu J}(R) = E_l^0(R) + c_{ll}(R) + \bar{\nu}_{\text{vib}} \left(\nu + \frac{1}{2} \right) - x_e \bar{\nu}_{\text{vib}} \left(\nu + \frac{1}{2} \right)^2 + [J(J + 1) - \Lambda^2] B_e \quad (107)$$

The Collapse of the Adiabatic Approximation

When does the Born-Oppenheimer approximation break down? The intuitive and general answer must be: adiabatic and BO approximation collapses whenever the electrons cannot follow the nuclear motion instantaneously, when the nuclei are

moving too fast, or the electrons cannot move fast enough. The consequence of such behavior is mixing of electronic and nuclear states of the molecule. Wave functions mix when there is a small or negligible energy difference between the mixing states. A typical situation, when the adiabatic and BO approximation is collapsing, is shown in Fig. 6a.

The starting point for our discussion is the complete Hamiltonian

$$\hat{H} = \hat{H}_0 + \hat{H}' = \hat{H}_0 + \lambda \hat{W},$$

where $\lambda \hat{W}$, defined in Eq. (19), is a small perturbation. Parameter $\lambda < 1$ determines the magnitude of the perturbation. It depends on the ratio m/M of the electron, m , and the nuclear, M , masses. The adiabatic wave function defined in Eq. (42)

$$\Psi_{lvJ}^{\text{ad}}(\mathbf{r}, \mathbf{R}) = \psi_l^{\text{el}}(\mathbf{r}; R) \chi_{lvJ}(\mathbf{R}) \equiv \Psi^{\text{ad}}. \quad (108)$$

is an eigenfunction of the unperturbed Hamiltonian \hat{H}_0 which is a sum of two Hamiltonians. One of them acts in the electronic coordinate space where the nuclear coordinates are parameters. The eigenfunctions of this Hamiltonian are $\psi_l^{\text{el}}(\mathbf{r}; R)$. The second one acts in the nuclear coordinate space. Its eigenfunctions are $\chi_{lvJ}(\mathbf{R})$. The product functions (108) are the total unperturbed wave functions.

$$\Psi^{(0)} \equiv \Psi^{\text{ad}}. \quad (109)$$

The first-order energy is equal to the expectation value of the complete Hamiltonian \hat{H} . The first-order correction to the wave function, according to the perturbation theory, can be determined as

$$\Psi_l^{(1)} = \sum_{l \neq k} d_{lk} \Psi_k^{(0)}, \quad \text{where} \quad d_{lk} = \frac{\langle \psi_k^{\text{el}} \chi_{kvJ} | \hat{H}' | \psi_l^{\text{el}} \chi_{lv\tilde{J}} \rangle}{E_{kvJ}^{(0)} - E_{lv\tilde{J}}^{(0)}}. \quad (110)$$

The integration in Eq. (110) has to be performed over both nuclear and electronic coordinates. This expression is the basis for the formulation of the criterion for the adiabatic and for the BO approximation to be valid. It follows from Eq. (110) that, when $|d_{kl}| \ll 1$ then the non-adiabatic correction (correction to the BO energy) is only a small contribution to the adiabatic solution. However, the adiabatic approximation becomes invalid when the denominator $E_{kvJ}^{(0)} - E_{lv\tilde{J}}^{(0)}$ in d_{kl} is much smaller than the matrix element in the numerator, $\langle \psi_k^{\text{el}} \chi_{kvJ} | \hat{W} | \psi_l^{\text{el}} \chi_{lv\tilde{J}} \rangle$. From a physical standpoint, the adiabatic approximation collapses, when the electronic energies $E_{kvJ}^{(0)}$ and $E_{lv\tilde{J}}^{(0)}$ are not separated. This happens when the electronic quantum states l and k become degenerate or nearly degenerate. However, it may happen that also term (110) is zero. This situation occurs, for example, when the vibrational functions are in different regions of R and the overlap between χ_{lvJ} and $\chi_{k\tilde{v}\tilde{J}}$ is zero.

To analyze such a case, let us consider a diatomic molecule (40). Non-adiabatic coupling, which breaks the BO approximation, is in $c_{kl}(R)$. The non-adiabatic coupling arises because the electronic wave functions and the electronic Hamiltonian change with R . We can get rid of the R dependence by choosing a fixed set of basis functions for electrons. We assume that the basis is complete. Any complete fixed basis set of electronic states which describes the non-degenerate eigenstates of Hamiltonian $\hat{H}_0(R)$ (unperturbed operator) is called a diabatic basis (*dia*) (Piela 2007). The choice of such a basis set reduces (40), because, if the diabatic electronic states do not depend on R , the nuclear operators disappear. The electronic Hamiltonian is more complicated. To illustrate this problem, it is useful to work an example.

Consider a fixed point R_0 . For R_0 the electronic Hamiltonian, which depends on R , is $\hat{H}_0(R_0)$. Let Hamiltonian $\hat{H}_0(R_0)$ have two near-degenerate, but different eigenvalues $E_1(R_0)$ and $E_2(R_0)$:

$$\hat{H}_0(R_0) \psi_1^{\text{dia}}(\mathbf{r}; R_0) = E_1(R_0) \psi_1^{\text{dia}}(\mathbf{r}; R_0) \quad (111)$$

$$\hat{H}_0(R_0) \psi_2^{\text{dia}}(\mathbf{r}; R_0) = E_2(R_0) \psi_2^{\text{dia}}(\mathbf{r}; R_0). \quad (112)$$

Energies $E_1(R_0)$ and $E_2(R_0)$ are called the diabatic energies. Since $\hat{H}_0(R_0)$ is Hermitian and $E_1(R_0) \neq E_2(R_0)$, the diabatic functions $\psi_i^{\text{dia}}(\mathbf{r}; R_0)$ for $i = 1, 2$ satisfy the orthogonality condition $\langle \psi_i^{\text{dia}} | \psi_j^{\text{dia}} \rangle = \delta_{ij}$. Let us now examine whether changing the distance $|\mathbf{R}_0|$ by δR will bring a situation in which the electronic energies, E_1 and E_2 , have the same values. If we change the distance R_0 by δR , the Hamiltonian \hat{H}_0 becomes

$$\hat{H}_0(R_0 + \delta R) = \hat{H}_0(R_0) + \delta R \frac{\partial \hat{H}_0}{\partial R} \equiv \hat{H}_0(R_0) + \hat{V}(R_0 + \delta R). \quad (113)$$

$\hat{V}(R_0 + \delta R)$ is a small correction to the unperturbed Hamiltonian $\hat{H}_0(R_0)$. The eigenvalues of the new Hamiltonian $\hat{H}_0(R_0 + \delta R)$ can be calculated using the perturbation theory, where \hat{V} is regarded as a perturbation to \hat{H}_0 . To solve the eigenvalue problem with Hamiltonian (113), we cannot use the ordinary perturbation theory, because the eigenvalues E_1 and E_2 of the unperturbed problem are very close to each other. The difference $E_1 - E_2$ compared with the magnitude of the perturbation is very small and tends to zero. Hence, we need to employ the perturbation theory suitable for degenerate states (Landau and Lifschitz 1981). As the initial zero-order approximation for the eigenfunctions of (113), we take linear combinations of the diabatic states:

$$\psi^{\text{el}}(\mathbf{r}; R) = d_1(R) \psi_1^{\text{dia}}(\mathbf{r}; R_0) + d_2(R) \psi_2^{\text{dia}}(\mathbf{r}; R_0). \quad (114)$$

(Diabatic states ψ_1^{dia} and ψ_2^{dia} satisfy Eqs. (112) and (111).) Substituting expression (114) in the perturbed Schrödinger equation can be symbolically written as

$$(\hat{H}_0 + \hat{V}) \psi^{\text{el}}(\mathbf{r}; R) = E \psi^{\text{el}}(\mathbf{r}; R). \quad (115)$$

Multiplying this equation on the left by $\psi_1^{\text{dia}*}$ and $\psi_2^{\text{dia}*}$ and integrating, we obtain the following algebraic equations:

$$\begin{aligned} d_1(E_1 + V_{11} - E) + d_2 V_{12} &= 0 \\ d_1 V_{21} + d_2(E_2 + V_{22} - E) &= 0, \end{aligned} \quad (116)$$

where we used

$$\langle \psi_i^{\text{dia}} | \hat{H}_0 + \hat{V} | \psi_i^{\text{dia}} \rangle = E_i + V_{ii}, \quad \text{where} \quad V_{ij} \equiv \langle \psi_i^{\text{dia}} | \hat{V} | \psi_j^{\text{dia}} \rangle. \quad (117)$$

Since \hat{H}_0 and \hat{V} are Hermitian, $V_{12} = V_{21}^*$ and V_{11} and V_{22} are real. The condition for the nontrivial solution of Eqs. (116) is

$$\det \begin{bmatrix} E_1 + V_{11} - E & V_{12} \\ V_{21} & E_2 + V_{22} - E \end{bmatrix} = 0. \quad (118)$$

Hence we get that

$$E_{\pm}(R) = \frac{1}{2}(E_1 + E_2 + V_{11} + V_{22}) \pm \sqrt{\left(\frac{E_1 - E_2 + V_{11} - V_{22}}{2}\right)^2 + |V_{12}|^2}. \quad (119)$$

This is a quadratic equation with respect to E which has two real roots, E_+ and E_- . In general $E_1 + V_{11} \neq E_2 + V_{22}$ and $V_{12} \neq 0$. Hence the eigenvalues E_- and E_+ are different. When the curves intersect at some R , it means that $E_- = E_+$ and the term under the square root would need to be zero. Since the expression under the square root is a sum of two squares, the following two equations need to be satisfied:

$$E_1 - E_2 + V_{11} - V_{22} = 0 \quad \text{and} \quad V_{12} = 0. \quad (120)$$

There are two conditions, but there is only one degree of freedom – one arbitrary parameter – giving the perturbation \hat{V} having the magnitude proportional to δR . In general, it is not possible to satisfy two independent equations having only one parameter. The $E_- = E_+$ degeneracy may occur only if more than one parameter can be varied. One thus needs at least two degrees of freedom to get an intersection. It may happen that V_{12} vanishes identically. Then only one equation remains (120), which can be satisfied for appropriately selected δR . From a physical point of view, that is the case when the two terms have different symmetries. (By symmetry we mean all possible forms of the molecular symmetry including the symmetry of the rotational state, the electronic state, etc.) For a diatomic molecule, this means that the intersecting states correspond to different Λ 's, different parities, or multiplicity.

Referring to the groups theory, for this to happen ψ_1^{dia} and ψ_2^{dia} must belong to two different irreducible representations of Hamiltonian symmetry groups. In such a situation, we are talking about vibronic coupling, i.e., the coupled between the motions of the nuclei and the electrons. Thus, in a diatomic molecule, only terms of different symmetry can intersect⁹ and it is impossible to have an intersection of states with the same symmetry. If, as a result of some calculation, we obtain wave functions and energies of two intersecting states of the same symmetry, then the mixing of the two states, which produces two new states, can be described using the perturbation theory. The energy difference between the two new states is that the greater, the smaller is the $|E_1 - E_2|$ energy difference.

This situation is described in graphs (6). Figure 6a represents a situation when two electronic states intersect and mix. In accordance with the discussion conducted above, we know that this situation can happen only when the two states have different symmetry. In the figure it is assumed that the electronic states have energies E_{000} and E_{100} . This means that the matrix element V_{12} vanishes identically and eigenvalues of Hamiltonian $\hat{H}_0(R_0 + \delta R)$ are degenerate. In this case for $R_0 + \delta R$, “the nuclear motion” occurs on the one potential energy surface (in Fig. 6b on the dotted lines, which symbolize the vibrational levels). The total wave function of the Hamiltonian \hat{H}_0 is therefore a superposition of two BO states, the first state ($l = 0$) with an excited nuclear vibrational wave function ($\nu = 1, J = 0$ marked in Fig. 6b with the blue color) and the second state ($l = 1$) with the ground-state vibrational wave function ($\nu = 0, J = 0$) marked in Fig. 6b with the red color). At internuclear

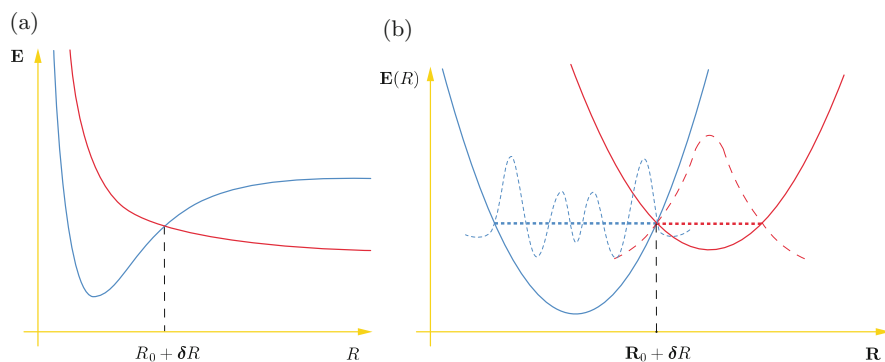

Fig. 6 Two diabatic states – a schematic view. The distance R , for which there is an intersection of the energy levels molecule, is designated as $R_0 + \delta R$. **(a)** Intersection of the electronic energy curves for states with different symmetries. **(b)** Two electronic states, in the harmonic approximation, and the wave functions corresponding to the crossing point energy, E_{000} and E_{100} . See text for details

⁹Crossing the states of the same symmetry is possible if you work within the adiabatic approximation.

distances R , the primary curves (corresponding to the ionic ground state and the covalent excited state) correspond to different diabatic functions, ψ_1^{dia} and ψ_2^{dia} .

What happens if the electronic states have the same symmetry? Then the adiabatic curves come close to each other, then nearly intersect (in Fig. 7a this happens at distance $R_0 + \delta R$) and then begin to separate (“avoided crossing”) to avoid an intersection. In the case when two states almost cross, we have near degeneracy. Classic examples of the curve non-crossing rule are the ground and first excited state potential curves for NaCl (Fig. 7). The original curves, ionic and covalent, correspond to diabatic states (see Fig. 7b). In accordance with Eq. (114), these states are represented by ψ_1^{dia} and ψ_2^{dia} , respectively. At small internuclear distances, wave function ψ_1^{dia} dominates in the total wave function (large $d_1(R)$). However, as it is apparent from Fig. 7b at larger internuclear distances ψ_2^{dia} becomes dominant (large $d_2(R)$). This means that as the atoms approach each other, a qualitative change of the interatomic interaction takes place. Thus, the adiabatic state changes its character. The predominantly ionic curve transforms to the predominantly covalent curve. This switching involves an electron jumping from Na to Cl. This is the so-called harpooning effect. The jumping of the electron takes place near 10 \AA . The time associated with the adjustment of the wave function to the non-BO perturbation is of the order of $h/2V_{12}$ which is the splitting of the adiabatic surfaces. Thus, the non-BO coupling is large in the vicinity of an avoided crossing.

This result not only applies to a diatomic molecule, but it is a general theorem of quantum mechanics. The result is true, when the Hamiltonian contains a parameter and its eigenvalues are functions of that parameter.

The number of degrees of freedom, which are the parameters that change (e.g., internuclear distances), is larger when dealing with a multi-atomic molecule. It can be shown that even for molecules with three centers, a degeneracy between states can occur (120). Even then the intersection only occurs at a point. This point is called a “conical intersection” because it has a characteristic shape of two surfaces that touch at a point. The special case of a conical intersection is also sometimes called a Jahn-Teller distortion (Jahn and Teller 1937). Jahn and Teller proved that for

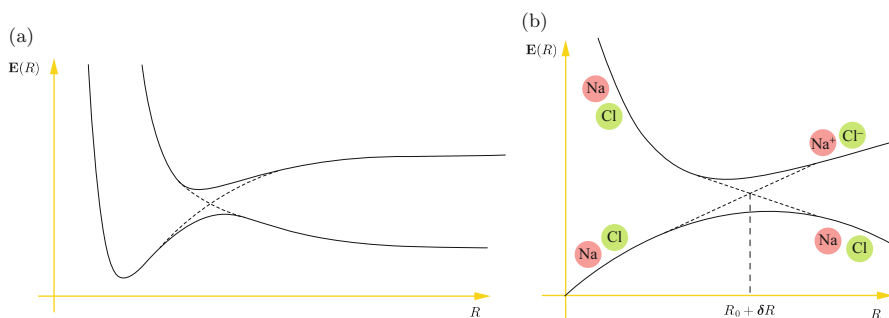

Fig. 7 Adiabatic states in the vicinity of an avoided crossing. (a) Avoided crossing. (b) The ground and the first excited state of NaCl molecule

degenerate electronic states, any symmetrical position of the nuclei, except collinear, is unstable. As a result of this instability, the nuclei move in such a way that the degeneracy of the electronic state is removed. In this way the ground state of a symmetrical, nonlinear molecule can become non-degenerate. An exception is linear molecules. For them, the linear position of the nuclei is stable even if the electronic state is degenerate. This was shown by Ruch and Schönhofer (1965). The reader can find extensive analysis of this phenomenon in Landau and Lifschitz (1981), Haken and Wolf (2004), and Piela (2007).

Non-adiabatic effects can be important in spectroscopy and photochemistry (see, e.g., Landau and Lifschitz 1981; Haken and Wolf 2004).

Examples of molecules for which the BO approximation fails are muonic molecules. In the muonic molecules, one or more electrons are replaced by muons. Muons are unstable subatomic particles. They are similar to electrons (muon has the charge of an electron), but they are about 207 times more massive. In determining bound states of the muonic molecules, it is erroneous to assume that the muon, like the electron, is much lighter than the nuclei and the nuclei can be treated as infinitely heavy. As a consequence, the BO approximation ceases to function.

Apart from the BO Approximation

In most cases, in particular in multi-atomic molecules, the BO approximation is the basic tool of quantum chemistry. However, in the case of small two- and three-center molecules containing several electrons, nonrelativistic (Kingham and Adamowicz 1997; Cafiero and Adamowicz 2002; Pavanello et al. 2012) and relativistic (Stanke et al. 2007a, 2006, 2009a, 2008) calculations, which do not use the BO approximation, have been executed. In this section I discuss this possibility and show that taking into account the coupling between electronic and nuclear motions exactly leads to very interesting conclusions.

Not assuming the Born-Oppenheimer approximation means that the theoretical model does not neglect the motion of the heavy particles – the nuclei – and thus all particles (nuclei and electrons) are treated on equal footing. Due to this equal treatment, also the description of the relativistic effects is uniformly accurate for all particles forming the system at the nonrelativistic level of quantum mechanics. Therefore, in this section, the notation is slightly different than in the previous part of the chapter. In particular, the numbering of the particles is different and their masses and charges of *all* particles are denoted by M_i and Q_i . The nonrelativistic (nr) description without the BO approximation starts with the following N -particle laboratory-frame molecular or atomic Hamiltonian:

$$H^{\text{nr}}(\mathbf{P}, \mathbf{R}) = \sum_{i=1}^N \frac{\mathbf{P}_i^2}{2M_i} + \sum_{i=1}^N \sum_{j>i}^N \frac{Q_i Q_j}{\|\mathbf{R}_i - \mathbf{R}_j\|}. \quad (121)$$

In the next step the center-of-mass motion (H_{cm}^{nr}) is separated out from the all-particle Hamiltonian (121), and internal Hamiltonian H_{int}^{nr} is obtained. This separation is possible due to a certain choice of the new coordinate system. The new coordinates are Cartesian, again a special choice, with the first three describing the position of the center of mass and the remaining $3N - 3 \equiv 3n$ being the internal coordinates. The transformation from the laboratory coordinates, \mathbf{R}_i , to the new coordinates is applied to the position vectors and the momentum vectors, \mathbf{P}_i , of all particles. Let us also denote the masses of the particles as M_i and the charges as Q_i . Let us denote the center-of-mass coordinates as \mathbf{r}_{cm} and the internal coordinates as \mathbf{r}_i , where $i = 1, \dots, n$, with $n = N - 1$. The \mathbf{r}_i vectors describe the positions of the particles $2, \dots, N$ with respect to particle 1, which is chosen to be the so-called reference particle. Let us denote the momenta corresponding to the \mathbf{r}_i coordinated as \mathbf{p}_i . Also, let us denote the reduce masses as μ_i . The coordinate transformation and the transformation of the momenta can be symbolically written as

$$\begin{aligned} O : \mathbf{R} &\longrightarrow \mathbf{r} & \mathbf{r} &= O\mathbf{R}, \\ O : \mathbf{P} &\longrightarrow \mathbf{p} & \mathbf{p} &= (O)^{-1}\mathbf{P}, \end{aligned}$$

where O denotes the following coordinate transformation:

$$O = \begin{bmatrix} \frac{M_1}{M_T} & \frac{M_2}{M_T} & \frac{M_3}{M_T} & \dots & \frac{M_N}{M_T} \\ -1 & 1 & 0 & \dots & 0 \\ -1 & 0 & 1 & \dots & 0 \\ \vdots & \vdots & \vdots & \ddots & \vdots \\ -1 & 0 & 0 & \dots & 1 \end{bmatrix} \otimes I_3, \quad (122)$$

$$\mathbf{R} \longrightarrow [\mathbf{r}_{cm}^T, \mathbf{r}^T]^T,$$

where

$$M_T = \sum_{i=1}^N M_i.$$

The type of variables used to describe the internal state of the system and the position of the attachment of the system in space is arbitrary. The reference particle in our approach is usually the heaviest particle. The transformation of the coordinate system results in the total Hamiltonian, H_{tot}^{nr} , separating to a sum of two parts, the Hamiltonian describing the kinetic energy of the center-of-mass motion and the internal Hamiltonian:

$$H_{\text{tot}}^{\text{nr}}(\mathbf{r}_{cm}, \mathbf{p}_{cm}, \mathbf{r}, \mathbf{p}) = \left(-\frac{1}{2} \frac{1}{M_T} \nabla_{\mathbf{r}_{cm}}^T \cdot \nabla_{\mathbf{r}_{cm}} \right) + \left(-\frac{1}{2} \sum_i^n \frac{1}{\mu_i} \nabla_{\mathbf{r}_i}^T \cdot \nabla_{\mathbf{r}_i} - \frac{1}{2} \sum_{i \neq j}^n \frac{1}{M_1} \nabla_{\mathbf{r}_i}^T \cdot \nabla_{\mathbf{r}_i} + \sum_{i < j}^n \frac{q_i q_j}{r_{ij}} + \sum_{i=1}^n \frac{q_0 q_i}{r_i} \right), \quad (123)$$

where M_1 is the mass of the reference particle, and M_T is total mass of the system. $\nabla_{\mathbf{r}_i}$ denotes the gradient vector expressed in terms of the \mathbf{r}_i coordinates, and r_{ij} is the distance between the i -th and j -th particles, defined as $r_{ij} = \|\mathbf{r}_i - \mathbf{r}_j\| = \|\mathbf{R}_{i+1} - \mathbf{R}_{j+1}\|$. The relative distances with respect to the reference particle are $r_j = \|\mathbf{r}_j\| = \|\mathbf{R}_{j+1} - \mathbf{R}_1\|$. In Eq.(123) one can see the separation of the nonrelativistic Hamiltonian, $H_{\text{tot}}^{\text{nr}}$, into the kinetic energy operator of the motion of the center of mass, $H_{\text{cm}}^{\text{nr}}(\mathbf{r}_{cm}, \mathbf{p}_{cm})$, and the internal Hamiltonian, $H_{\text{int}}^{\text{nr}}(\mathbf{r}, \mathbf{p})$:

$$H_{\text{tot}}^{\text{nr}}(\mathbf{r}_{cm}, \mathbf{p}_{cm}, \mathbf{r}, \mathbf{p}) = H_{\text{cm}}^{\text{nr}}(\mathbf{r}_{cm}, \mathbf{p}_{cm}) + H_{\text{int}}^{\text{nr}}(\mathbf{r}, \mathbf{p}). \quad (124)$$

Both old and new coordinate systems provide a complete description of the positions of all particles in space. In the non-BO calculations, the internal Hamiltonian, $H_{\text{int}}^{\text{nr}}(\mathbf{r}, \mathbf{p})$, is used.

The internal Hamiltonian can be viewed as describing a system of $n - 1$ pseudoparticles with the masses equal to the reduced masses, μ_i , and the charges $q_{i-1} = Q_i$ ($i = 1, \dots, n + 1$). q_0 is the charge of the reference particle. The pseudoparticles interact with each other by the Coulomb potential and their motions are coupled through the mass-polarization terms. The internal Hamiltonian in the nonrelativistic approximation includes the operators representing the kinetic energy of the pseudoparticles:

$$-\frac{1}{2} \sum_i^n \frac{1}{\mu_i} \nabla_{\mathbf{r}_i}^T \cdot \nabla_{\mathbf{r}_i},$$

the mass-polarization term:

$$-\frac{1}{2} \sum_{i \neq j}^n \frac{1}{M_1} \nabla_{\mathbf{r}_i}^T \cdot \nabla_{\mathbf{r}_i}$$

and the Coulomb potential:

$$\sum_{i < j}^n \frac{q_i q_j}{r_{ij}} + \sum_{i=1}^{n-1} \frac{q_0 q_i}{r_i}.$$

What is accomplished by the above-described coordinate transformation for an isolated system in vacuum is also separation of the energy into a non-quantized

translational energy of the center-of-mass motion and the internal energy of the system, which for the bound states is quantized. In the new coordinates, the total wave function of the system can be written as a simple product of a wave function for the center of mass and the wave function representing an internal state of the system:

$$\Phi(\mathbf{r}_{cm}, \mathbf{r}_1, \dots, \mathbf{r}_n) = \Psi(\mathbf{r}_{cm}) \Psi(\mathbf{r}_1, \mathbf{r}_2, \dots, \mathbf{r}_n).$$

Recent progress in the development of high-precision laser-based spectroscopy techniques to study atomic and molecular spectra has been offering new capabilities to measure energy levels of small atoms and molecules in the gas phase with unprecedented accuracy. Due to these developments, the energy levels of atomic and molecular bound states and the corresponding transition energies are known with sub 0.001 cm^{-1} accuracy.

The experimental results can be directly compared with the theoretical calculations. This comparison not only tests the correctness of the quantum mechanical model used in the calculations, but also it sheds light on the nature of the chemical bonding, contributes to the measurements of the fundamental constants, and provides information on the chemical composition of distant interstellar objects. Very accurate experimental measurements challenge the theoreticians to improve the quantum mechanical models used in the calculations and to carry out the development of new algorithms for more accurate determination of bound states of atomic and molecular systems. The measurements also provide data for testing more approximate quantum mechanical methods developed for calculations of larger atoms and molecules.

For a full description of atoms and molecules without the BO approximation, an approach that allows to go beyond the Schrödinger description and to calculate relativistic and quantum electrodynamics corrections is needed. For systems comprising light nuclei and electrons, satisfactory accuracy can be achieved by representing the system energy in terms of powers of the fine-structure parameter $\alpha = 1/c$. In this way different effects are systematically accounted for. The terms proportional to α^2 are the leading relativistic effects (Bethe and Salpeter 1957) ($\alpha^2 \Delta E^{\text{rel}}$), and the terms proportional to α^3 ($\alpha^3 \Delta E_{\text{QED}}$) and α^4 ($\alpha^4 \Delta E_{\text{QED}}$) are the leading quantum electrodynamics (QED) effects. The basis for the calculation of relativistic effects is therefore the nonrelativistic Schrödinger Hamiltonian written without the BO approximation, which is treated as the nonperturbative operator.

The relativistic and QED effects can be determined as corrections with the use of the Rayleigh-Schrödinger perturbation theory¹⁰:

$$E_{\text{tot}} = E^{\text{nr}} + \alpha^2 \Delta E^{\text{rel}} \quad (125)$$

¹⁰From now on the symbol “tot” will be used to denote the sum of the total nonrelativistic energy and the corrections up to the certain order in terms of the hyperfine constant α .

If the relativistic calculations shall be calculated for states of the S symmetry for atoms and Σ symmetry for the diatomic molecules, the set of relativistic corrections must be included: the mass-velocity correction (mv), one- and two-particle Darwin corrections (d1,d2), and the Fermi spin-spin (ss) and orbit-orbit (oo) corrections.

The contribution of the spin-orbit correction and a part of the spin-spin correction to the energy for S states are equal to zero. The relativistic operators, before their use to calculate the relativistic energy corrections as expectation values of these operators, were transformed to the internal coordinate frame. I calculated these expectation values using the nonrelativistic wave functions obtained without assuming the Born-Oppenheimer (BO) approximation. To fulfill the symmetry requirements of the problem for the wave function and to effectively describe the correlation effects in our calculations, we have used the following explicitly correlated all-particle Gaussian (ECG) functions in calculations of atoms with s electrons

$$\psi_k(\mathbf{r}) = \exp[-\mathbf{r}^T \bar{\mathbf{A}}_k \mathbf{r}] \quad (126)$$

and the following Gaussians in calculations of diatomic molecules with σ electrons

$$\phi_k = r_1^{m_k} \exp[-\mathbf{r}^T (\mathbf{A}_k \otimes \mathbf{I}_3) \mathbf{r}] = r_1^{m_k} \exp[-\mathbf{r}^T \bar{\mathbf{A}}_k \mathbf{r}], \quad (127)$$

where

$$r_1 = |\mathbf{R}_1 - \mathbf{R}_2|.$$

is the distance between the two nuclei. Matrix $\bar{\mathbf{A}}$ occurring in the formulas (126) and (127) is a symmetric matrix of the nonlinear variational parameters.¹¹ $\bar{\mathbf{A}}$ is a positive-definite $3n \times 3n$ matrix obtained as the following product of the $n \times n$ matrix \mathbf{A} and a 3×3 unit matrix \mathbf{I}_3 :

$$\bar{\mathbf{A}} = \mathbf{A} \otimes \mathbf{I}_3.$$

As one can see, both functions (126) and (127) via their explicit dependence on the distances between the pseudoparticles can effectively describe the correlation effects associated with their coupled motion. In the case of the (126) basis set, only the correlated motion of pseudoelectrons with respect the center of the coordinate system, where the charge of the nucleus is located, needs to be described. The atomic basis functions (126) are spherically symmetric around the center of the positive charge of the nucleus as required by the symmetry of the problem. As the internal Hamiltonian for a molecular system is, alike in the atomic case, also isotropic with respect to

¹¹Optimal values of these parameters in the basis functions (126) and (127) are determined using the gradient method.

rotations about the center of the coordinate system, where the charge of the reference particle is located, the diatomic basis functions (127) are also spherically symmetric with respect to this center. However, due to the need to describe the nucleus-nucleus correlation effects in the calculation for a diatomic system the atomic ECG basis functions (126) have to be modified. As the correlation effect increases with the increase of the masses of the interacting particles, the simple ECGs, which only depend on the nucleus-nucleus distance in the exponent, are not sufficient for the molecular case. For diatomics, an additional preexponential factor needs to be included in the Gaussians in the form of a nonnegative power of the internuclear distance, $r_1^{m_k}$ (127). This factor shifts the maximum of the Gaussian away from the reference particle. The higher the power, the larger the shift. m_k has a value in the 0–250 range in our calculations. The presence of $r_1^{m_k}$ in the Gaussians also helps describe radial nodes in wave functions of higher vibrational states. Gaussian basis functions are not as efficient as the Hylleraas- or Slater-type basis functions in describing bound states of multiparticle systems interacting with Coulomb forces. The Gaussians do not have the correct behavior at very short and at very long inter-particle distances. However, in calculations of both atomic and molecular with more than three electrons, the Gaussians are the only functions which can be used, because the use of other types of basis functions leads to Hamiltonian integrals too difficult to calculate. Also, as our atomic and molecular calculations have demonstrated, properly optimized Gaussian basis sets allow to achieve in the calculations an accuracy level similar to the accuracy of the most exact experiments performed for small atomic and diatomic systems (Stanke et al. 2007a, b, 2009b).

Charge Asymmetry in Pure Vibrational States of the HD Molecule

The consequences of taking into account the coupling between electronic and nuclear motion is illustrated by the example of the molecule HD (Bubin et al. 2009). In the approach without the Born-Oppenheimer approximation, all particles are treated on equal footing. The coupled electron-nucleus motion is a part of the description of the system. The calculation of the expectation values of the relative inter-particle distance was performed in the basis set of explicitly correlated Gaussians. These functions explicitly depend on the inter-particle distance which for HD are the electron-electron, deuteron-proton, deuteron-electron, and proton-electron distances. Such dependency allows for describing very accurately the correlation effects related to the coupled motion of the nuclei and the electrons.

In consequence, the increase of the vibrational excitation (particularly for large v) results in mixing into the total wave function of some small contributions of electronically excited states. In high vibrationally excited states, the corresponding wave functions become to some (small) degree superpositions of the product of the electronic ground-state Σ_g wave function times the corresponding vibrational wave function and a higher electronic state (states) times vibrational wave functions with

Fig. 8 The differences between the average inter-particle electron-proton and electron-deuteron distances ($\langle r_{12} \rangle - \langle r_2 \rangle$) as a function of the number of the vibrational state of the HD molecule. The calculations were done with 6,000 ECGs per state

smaller v 's. Because of this state mixing, it is difficult to ambiguously assign a single vibrational quantum number to the state the molecule is in. In consequence, the vibrational quantum number, which usually corresponds to the number of nodes in the wave function describing the nuclear motion, in the description of the molecule provided by the non-BO approach is not, strictly speaking, a good quantum number. In general, it is not possible to strictly separate the vibrational and electronic contributions to the total wave function. Thus assigning vibrational quantum numbers to consecutive states is only approximate, and it is merely a way of numbering the states in the rising-energy order. It would be more correct to use a different description of the states we calculate. Perhaps the term *rotationless* reflecting the zero value of the angular momentum for those states would be a more correct designation.

The superposition of different electronic states in high excited vibrational states introduces an interesting effect of electronic asymmetry. Using the expectation values of the deuteron-electron and proton-electron inter-particle distances, we determined these values as a function of the vibrational-state number. The results provided an evidence of the asymmetry, which is the highest for the $v = 8$ and the lowest for the $v = 17$ state. The electronic asymmetry causes that the dipole moment of the HD molecules changes by 50% in the transition from the $v = 17$ state to the $v = 8$ state. This behavior is depicted in Fig. 8.

Molecular Relativistic Corrections Determined in the Framework Where the Born-Oppenheimer Approximation Is Not Assumed

Equally interesting is the dependence of the relativistic corrections on the vibrational quantum number. Such a study has been performed for the heteronuclear isotopologues of the hydrogen molecular ion, the HD^+ ion (Stanke and Adamowicz 2013). There are two dissociation channels for HD^+ : deuter + proton ($\text{D} + \text{H}^+$) and deuteron and hydrogen ($\text{D}^+ + \text{H}$). The former is energetically lower than the latter. The point which has been examined is the convergence pattern of the relativistic corrections with the increasing vibrational quantum number. It has been demonstrated that the values of the mass-velocity (mv), Darwin (d1 + d2), and orbit-orbit (oo) corrections in the highest vibrational states approach the corresponding values for deuteron and not hydrogen. Though such a behavior of the relativistic corrections is expected, it can only be described if the corrections are calculated in the framework where the BO approximation is not assumed. In this framework the relativistic corrections are calculated for all particles comprising the system (i.e., deuteron, proton, and electron). This is different from the BO approach, where the only moving particle for which the relativistic corrections are calculated is the electron. The non-BO calculation of the relativistic corrections is performed using ECG basis functions which explicitly depend on all inter-particle distances, i.e., the deuteron-proton, deuteron-electron, and proton-electron.

In Table 1 results of Stanke et al. (Stanke and Adamowicz 2013) obtained without assuming the BO approximation as well as of Wolniewicz (1995), Wolniewicz and Orlikowski (1991), and of Howells and Kennedy (1990) obtained in the BO framework have been collected.¹² Despite the absence of the results for the $v = 22$ state, an analysis of the results reveals a definite trend, namely, the results of Wolniewicz, contrary to our non-BO results, converge to the theoretical value calculated for the system comprising of a hydrogen atom with an infinitely heavy nucleus and a proton (${}^\infty\text{H} + \text{H}^+$), i.e., to the asymptotic value one obtains in the BO approximation for the dissociation channel, $\text{D} + \text{H}^+$. In the same time, the values obtained without assuming the BO approximation converge to correct limit corresponding to the deuter+proton dissociation channel. It is worth stressing that the values of the total relativistic correction calculated by us and those calculated with assuming the BO approximation are close for all pure vibrational states of HD^+ .

It is also interesting that the values of the total relativistic correction for the different dissociation channels of HD^+ are the same. The equality of the α^2 corrections for channels $\text{H} + \text{D}^+$ and $\text{D} + \text{H}^+$ arises from the fact that, as proven by Pachucki (Pachucki and Grotch 1995), the component of the recoil correction proportional to $1/M$ for a one-electron atom disappears (although its components do not disappear).

¹²Unfortunately in the results of Wolniewicz, the values for the $v = 22$ are missing.

Table 1 A comparison of our non-BO results for the individual contributions to the relativistic correction, i.e., mass-velocity (mv), one- and two-body Darwin corrections (d1 + d2), and orbit-orbit (oo) correction, and the total relativistic correction (rel cor) for the pure vibrational states of the HD⁺ ion with the results of Wolniewicz and Orlikowski 1991 and of Howells and Kennedy (1990) obtained in the BO framework. The non-BO calculations for the $v = 0$ and $v = 1$ states were performed with 1,000 ECGs, for the $v = 2, \dots, 21$ states with 2,000 ECGs, and for the $v = 22$ state with 4,000 ECGs. All quantities in the table are in cm^{-1}

I am grateful to Professor Krzysztof Strasburger, the reviewer, for his valuable comments and to Professors Jacek Karwowski and Ludwik Adamowicz for useful discussions. Thanks are extended to Ms. Ewa Palikot, MSc. for drawing the figures.

Appendix A

Detailed derivation of the Laplace operator in the new coordinate (7), (8), (9), and (10)

- First derivatives of the nuclear coordinates:
 - nucleus a

$$\begin{aligned} \frac{\partial}{\partial X'_a} &= \frac{\partial X_{CM}}{\partial X'_a} \frac{\partial}{\partial X_{CM}} + \frac{\partial Y_{CM}}{\partial X'_a} \frac{\partial}{\partial Y_{CM}} + \frac{\partial Z_{CM}}{\partial X'_a} \frac{\partial}{\partial Z_{CM}} + \frac{\partial R_x}{\partial X'_a} \frac{\partial}{\partial R_x} + \frac{\partial R_y}{\partial X'_a} \frac{\partial}{\partial R_y} + \frac{\partial R_z}{\partial X'_a} \frac{\partial}{\partial R_z} + \\ &+ \sum_{i=1}^{N_e} \left(\frac{\partial x_i}{\partial X'_a} \frac{\partial}{\partial x_i} + \frac{\partial y_i}{\partial X'_a} \frac{\partial}{\partial y_i} + \frac{\partial z_i}{\partial X'_a} \frac{\partial}{\partial z_i} \right) = \frac{M_a}{M} \frac{\partial}{\partial X_{CM}} + \frac{\partial}{\partial R_x} - \frac{1}{2} \sum_{i=1}^{N_e} \frac{\partial}{\partial x_i} \end{aligned} \quad (128)$$

analogously:

$$\begin{aligned} \frac{\partial}{\partial Y'_a} &= \frac{M_a}{M} \frac{\partial}{\partial Y_{CM}} + \frac{\partial}{\partial R_y} - \frac{1}{2} \sum_{i=1}^{N_e} \frac{\partial}{\partial y_i}, \\ \frac{\partial}{\partial Z'_a} &= \frac{M_a}{M} \frac{\partial}{\partial Z_{CM}} + \frac{\partial}{\partial R_z} - \frac{1}{2} \sum_{i=1}^{N_e} \frac{\partial}{\partial z_i} \end{aligned} \quad (129)$$

- nucleus b - analogous:

$$\frac{\partial}{\partial X'_b} = \frac{M_a}{M} \frac{\partial}{\partial X_{CM}} - \frac{\partial}{\partial R_x} - \frac{1}{2} \sum_{i=1}^{N_e} \frac{\partial}{\partial x_i} \quad (130)$$

and similarly for the nuclear coordinates \tilde{y}_b and \tilde{z}_b

- First derivatives of the electron coordinates:

$$\begin{aligned} \frac{\partial}{\partial x'_i} &= \frac{X_{CM}}{\partial x'_i} \frac{\partial}{\partial X_{CM}} + \frac{Y_{CM}}{\partial x'_i} \frac{\partial}{\partial Y_{CM}} + \frac{Z_{CM}}{\partial x'_i} \frac{\partial}{\partial Z_{CM}} + \frac{R_x}{\partial x'_i} \frac{\partial}{\partial R_x} + \frac{R_y}{\partial x'_i} \frac{\partial}{\partial R_y} + \frac{R_z}{\partial x'_i} \frac{\partial}{\partial R_z} + \\ &+ \sum_{j=1}^{N_e} \left(\frac{\partial x_j}{\partial x'_i} \frac{\partial}{\partial x_j} + \frac{\partial y_j}{\partial x'_i} \frac{\partial}{\partial y_j} + \frac{\partial z_j}{\partial x'_i} \frac{\partial}{\partial z_j} \right) = \frac{m}{M} \frac{\partial}{\partial X_{CM}} + \sum_{j=1}^{N_e} \left(\delta_{ij} \frac{\partial}{\partial x_j} \right) = \\ &= \frac{m}{M} \frac{\partial}{\partial X_{CM}} + \frac{\partial}{\partial x_i} \end{aligned} \quad (131)$$

and similarly for the electron coordinates y'_i and z'_i

- Second derivatives of the nuclear coordinates (we use the formula $[a+(b+c)]^2 = a^2 + b^2 + c^2 + 2ab + 2bc + 2ac$):
 - nucleus a

$$\begin{aligned}
 \frac{\partial^2}{\partial X'_a{}^2} &= \left(\frac{M_a}{M} \frac{\partial}{\partial X_{\text{CM}}} + \frac{\partial}{\partial R_x} - \frac{1}{2} \sum_{i=1}^{N_e} \frac{\partial}{\partial x_i} \right) \left(\frac{M_a}{M} \frac{\partial}{\partial X_{\text{CM}}} + \frac{\partial}{\partial R_x} - \frac{1}{2} \sum_{i=1}^{N_e} \frac{\partial}{\partial x_i} \right) = \\
 &= \left(\frac{M_a}{M} \right)^2 \frac{\partial^2}{\partial X_{\text{CM}}^2} + \frac{\partial^2}{\partial R_x^2} + \frac{1}{4} \sum_{i=1}^{N_e} \left(\frac{\partial}{\partial x_i} \right) + \\
 &\quad + 2 \frac{M_a}{M} \frac{\partial^2}{\partial X_{\text{CM}} \partial R_x} - \frac{\partial}{\partial X_{\text{CM}}} \sum_{i=1}^{N_e} \frac{\partial}{\partial x_i} - \frac{M_a}{M} \frac{\partial}{\partial R_x} \sum_{i=1}^{N_e} \frac{\partial}{\partial x_i} \quad (132)
 \end{aligned}$$

- nucleus b

$$\begin{aligned}
 \frac{\partial^2}{\partial X'_b{}^2} &= \left(\frac{M_b}{M} \frac{\partial}{\partial X_{\text{CM}}} - \frac{\partial}{\partial R_x} - \frac{1}{2} \sum_{i=1}^{N_e} \frac{\partial}{\partial x_i} \right) \left(\frac{M_b}{M} \frac{\partial}{\partial X_{\text{CM}}} - \frac{\partial}{\partial R_x} - \frac{1}{2} \sum_{i=1}^{N_e} \frac{\partial}{\partial x_i} \right) = \\
 &= \left(\frac{M_b}{M} \right)^2 \frac{\partial^2}{\partial X_{\text{CM}}^2} + \frac{\partial^2}{\partial R_x^2} + \frac{1}{4} \sum_{i=1}^{N_e} \left(\frac{\partial}{\partial x_i} \right) + \\
 &\quad - 2 \frac{M_b}{M} \frac{\partial^2}{\partial X_{\text{CM}} \partial R_x} + \frac{\partial}{\partial X_{\text{CM}}} \sum_{i=1}^{N_e} \frac{\partial}{\partial x_i} - \frac{M_b}{M} \frac{\partial}{\partial R_x} \sum_{i=1}^{N_e} \frac{\partial}{\partial x_i} \quad (133)
 \end{aligned}$$

- Second derivatives of the electron coordinates:

$$\begin{aligned}
 \frac{\partial^2}{\partial x_i'^2} &= \left(\frac{m}{M} \frac{\partial}{\partial X_{\text{CM}}} + \frac{\partial}{\partial x_i} \right) \left(\frac{m}{M} \frac{\partial}{\partial X_{\text{CM}}} + \frac{\partial}{\partial x_i} \right) \\
 &= \left(\frac{m}{M} \right)^2 \frac{\partial^2}{\partial X_{\text{CM}}^2} + \frac{\partial^2}{\partial x_i^2} + 2 \frac{m}{M} \frac{\partial^2}{\partial X_{\text{CM}} \partial x_i} \quad (134)
 \end{aligned}$$

Similarly, the remaining coordinates.

Appendix B

Flat rotor – a system of two particles with masses m_1 and m_2 at a constant distance R from each other. In this system there are no external forces, but it can rotate around its center of mass. Hamiltonian for this system has a form:

$$\hat{H} = -\frac{1}{2m_1} \nabla_{\mathbf{r}_1}^2 - \frac{1}{2m_2} \nabla_{\mathbf{r}_2}^2, \quad (135)$$

where \mathbf{r}_1 and \mathbf{r}_2 are vectors that describe the positions of the two bodies in the laboratory reference frame. Alternatively one can describe the same system, in the center-of-mass reference frame. The coordinates of the center of mass in the laboratory frame are given by

$$\mathbf{R} = \frac{m_1 \mathbf{r}_1 + m_2 \mathbf{r}_2}{m_1 + m_2} = [X, Y, Z] \quad (136)$$

If one wants to express the Hamiltonian in the center-of-mass coordinates, one has to express the second derivatives in the new variables. Proceeding as in Appendix A one gets

$$\begin{aligned} \frac{\partial}{\partial x_1} &= \frac{\partial X}{\partial x_1} \frac{\partial}{\partial X} + \frac{\partial Y}{\partial x_1} \frac{\partial}{\partial Y} + \frac{\partial Z}{\partial x_1} \frac{\partial}{\partial Z} + \frac{\partial x}{\partial x_1} \frac{\partial}{\partial x} + \frac{\partial y}{\partial x_1} \frac{\partial}{\partial y} + \frac{\partial z}{\partial x_1} \frac{\partial}{\partial z} \\ &= \frac{\partial X}{\partial x_1} \frac{\partial}{\partial X} + \frac{\partial x}{\partial x_1} \frac{\partial}{\partial x} \\ &= \frac{m_1}{m_1 + m_2} \frac{\partial}{\partial X} + \frac{\partial}{\partial x}, \end{aligned} \quad (137)$$

$$\begin{aligned} \frac{\partial}{\partial x_2} &= \frac{\partial X}{\partial x_2} \frac{\partial}{\partial X} + \frac{\partial Y}{\partial x_2} \frac{\partial}{\partial Y} + \frac{\partial Z}{\partial x_2} \frac{\partial}{\partial Z} + \frac{\partial x}{\partial x_2} \frac{\partial}{\partial x} + \frac{\partial y}{\partial x_2} \frac{\partial}{\partial y} + \frac{\partial z}{\partial x_2} \frac{\partial}{\partial z} \\ &= \frac{\partial X}{\partial x_2} \frac{\partial}{\partial X} + \frac{\partial x}{\partial x_2} \frac{\partial}{\partial x} \\ &= \frac{m_2}{m_1 + m_2} \frac{\partial}{\partial X} - \frac{\partial}{\partial x}. \end{aligned} \quad (138)$$

Similarly, for the remaining coordinates. The second derivatives are given by

$$\begin{aligned} \frac{\partial^2}{\partial x_1^2} &= \left(\frac{m_1}{m_1 + m_2} \frac{\partial}{\partial X} + \frac{\partial}{\partial x} \right) \cdot \left(\frac{m_1}{m_1 + m_2} \frac{\partial}{\partial X} + \frac{\partial}{\partial x} \right) \\ &= \left(\frac{m_1}{m_1 + m_2} \right)^2 \frac{\partial^2}{\partial X^2} + \frac{2m_1}{m_1 + m_2} \frac{\partial^2}{\partial X \partial x} + \frac{\partial^2}{\partial x^2} \end{aligned} \quad (139)$$

$$\begin{aligned} \frac{\partial^2}{\partial x_2^2} &= \left(\frac{m_2}{m_1 + m_2} \frac{\partial}{\partial X} - \frac{\partial}{\partial x} \right) \cdot \left(\frac{m_2}{m_1 + m_2} \frac{\partial}{\partial X} - \frac{\partial}{\partial x} \right) \\ &= \left(\frac{m_2}{m_1 + m_2} \right)^2 \frac{\partial^2}{\partial X^2} - \frac{2m_2}{m_1 + m_2} \frac{\partial^2}{\partial X \partial x} + \frac{\partial^2}{\partial x^2} \end{aligned} \quad (140)$$

Thus, after substituting the second derivatives, one obtains the Hamiltonian operator (135) in the new variables

$$\begin{aligned}
\hat{H} &= -\frac{1}{2} \left[\frac{m_1}{(m_1 + m_2)^2} + \frac{m_2}{(m_1 + m_2)^2} \right] \left(\frac{\partial^2}{\partial X^2} + \frac{\partial^2}{\partial Y^2} + \frac{\partial^2}{\partial Z^2} \right) \\
&\quad - \frac{1}{2} \left[\frac{1}{m_1} + \frac{1}{m_2} \right] \left(\frac{\partial^2}{\partial x^2} + \frac{\partial^2}{\partial y^2} + \frac{\partial^2}{\partial z^2} \right) \\
&= -\frac{1}{2M} \Delta_{\mathbf{R}} - \frac{1}{2\mu} \Delta_{\mathbf{r}} \equiv \hat{H}_{\mathbf{R}} + \hat{H}_{\mathbf{r}},
\end{aligned} \tag{141}$$

where

$$\begin{aligned}
M &= m_1 + m_2, & \frac{1}{\mu} &= \frac{1}{m_1} + \frac{1}{m_2}, & \Delta_{\mathbf{R}} &= \frac{\partial^2}{\partial X^2} + \frac{\partial^2}{\partial Y^2} + \frac{\partial^2}{\partial Z^2}, \\
\Delta_{\mathbf{r}} &= \frac{\partial^2}{\partial x^2} + \frac{\partial^2}{\partial y^2} + \frac{\partial^2}{\partial z^2},
\end{aligned} \tag{142}$$

and μ is the reduced mass. For the two particles moving freely in the space, that is assuming that $V = 0$, the eigenvalue equation of (141) can be written as $\hat{H}_{\mathbf{R}}$ and $\hat{H}_{\mathbf{r}}$:

$$(\hat{H}_{\mathbf{R}} + \hat{H}_{\mathbf{r}})\psi(\mathbf{R}, \mathbf{r}) = E\psi(\mathbf{R}, \mathbf{r}) \tag{143}$$

for

$$\psi(\mathbf{R}, \mathbf{r}) = \psi_{\mathbf{R}}(\mathbf{R}) \psi_{\mathbf{r}}(\mathbf{r}),$$

where

$$\hat{H}_{\mathbf{R}} \psi_{\mathbf{R}}(\mathbf{R}) = E_{\mathbf{R}} \psi_{\mathbf{R}}(\mathbf{R}) \quad \text{and} \quad \hat{H}_{\mathbf{r}} \psi_{\mathbf{r}}(\mathbf{r}) = E_{\mathbf{r}} \psi_{\mathbf{r}}(\mathbf{r}).$$

We focus only on the relative motion Hamiltonian $\hat{H}_{\mathbf{r}}$. The eigenfunction $\psi_{\mathbf{r}}(\mathbf{r})$ of this Hamiltonian depends on three variables. However, due to the fact that r is constant ($r^2 = x^2 + y^2 + z^2 = \text{const}$), only two angular variables are independent. In the spherical coordinates, with variables r, θ, ϕ , where $r = \text{const}$:

$$\begin{aligned}
x &= x(r, \theta, \phi) = r \sin \theta \cos \phi \\
y &= y(r, \theta, \phi) = r \sin \theta \sin \phi \\
z &= z(r, \theta, \phi) = r \cos \theta.
\end{aligned}$$

the Laplacian can be written as

$$\Delta_{\mathbf{r}} = \frac{1}{r^2} \left[\frac{\partial}{\partial r} \left(r^2 \frac{\partial}{\partial r} \right) + \frac{1}{\sin \theta} \frac{\partial}{\partial \theta} \left(\sin \theta \frac{\partial}{\partial \theta} \right) + \frac{1}{\sin^2 \theta} \frac{\partial^2}{\partial \phi^2} \right].$$

Consequently, the rigid rotor Hamiltonian becomes

$$\hat{H} = -\frac{1}{2I} \left[\frac{1}{\sin \theta} \frac{\partial}{\partial \theta} \left(\sin \theta \frac{\partial}{\partial \theta} \right) + \frac{1}{\sin^2 \theta} \frac{\partial^2}{\partial \phi^2} \right],$$

where

$$I = \mu R^2$$

is the moment of inertia. The eigenvalue problem of the rigid rotor is, thus, reduced to the equation

$$-\frac{1}{2I} \left[\frac{1}{\sin \theta} \frac{\partial}{\partial \theta} \left(\sin \theta \frac{\partial}{\partial \theta} \right) + \frac{1}{\sin^2 \theta} \frac{\partial^2}{\partial \phi^2} \right] Y(\theta, \phi) = E Y(\theta, \phi),$$

analogous to the problem of the angular momentum

$$-1 \left[\frac{1}{\sin \theta} \frac{\partial}{\partial \theta} \left(\sin \theta \frac{\partial}{\partial \theta} \right) + \frac{1}{\sin^2 \theta} \frac{\partial^2}{\partial \phi^2} \right] Y(\theta, \phi) = l(l+1)Y(\theta, \phi).$$

Thus, we can immediately conclude that the rigid rotor eigenfunctions are equal to the spherical harmonics

$$Y_J^M(\theta, \phi) = \frac{1}{\sqrt{2\pi}} N_{J,|M|} P_J^{|M|}(\cos \theta) e^{iM\phi},$$

where

$$P_l^m(x) = (1-x^2)^{m/2} \frac{d^m}{dx^m} P_l(x)$$

is the associate Legendre polynomial. The eigenvalues are given by

$$E_J = \frac{1}{2I} J(J+1),$$

where $1/2I$ is the rotational constant.

Abstract

Two aspects are quintessential if one seeks to successfully perform DFT calculations: a basic understanding of how the concepts and models underlying the various manifestations of DFT are built and an essential knowledge of what can be expected from DFT calculations and how to achieve the most appropriate results. This chapter expands on the development and philosophy of DFT and aims to illustrate the essentials of DFT in a manner that is intuitively accessible. An analysis of the performance and applicability of DFT focuses on a representative selection of chemical properties, including bond lengths, bond angles, vibrational frequencies, electron affinities and ionization potentials, atomization energies, heats of formation, energy barriers, bond energies, hydrogen bonding, weak interactions, spin states, and excited states.

Introduction

Density functional theory (DFT) is an enticing subject. It appeals to chemists and physicists alike, and it is entrancing for those who like to work on mathematical physical aspects of problems, for those who relish computing observable properties from theory, and for those who most enjoy developing correct qualitative descriptions of phenomena. It is this combination of a qualitative model that at the same time furnishes quantitative reliable estimates that makes DFT particularly attractive for chemists.

DFT is an alternative, and complementary, to wave function theory (WFT). Both approaches are variations of the basic theme of electronic structure theory, and both methods originated during the late years of the 1920s. Whereas WFT evolved rapidly and gained general popularity, DFT found itself in a state of shadowy existence. It was the appearance of the key papers by Hohenberg and Kohn (1964) and by Kohn and Sham (1965), generally perceived as the beginning of modern DFT, which changed the perception and level of acceptance of DFT. With the evolution of reliable computational technologies for DFT chemistry, and with the advent of the generalized gradient approximation (GGA) during the 1980s, DFT emerged as powerful tool in computational chemistry, and without exaggeration the 1990s can be called the decade of DFT in electronic structure theory. During this time period, despite the lack of a complete development, DFT was already competitive with the best WFT methods. Furthermore, the advancement of computational hardware as well as software has progressed to a state where DFT calculations of “real molecules” can be performed with high efficiency and without major technical hurdles.

But at the end of the first decade of the new millennium, it appeared that DFT might have become a victim of its own success. DFT has transformed into an off-the-shelf technology and ready-to-crunch component and often was and still is used as such. Still and all, it became clear that the happy days of black-box DFT were over and that not all the promises of DFT came to fruition. DFT has its

own limitations and shortcomings, and the numbers obtained from DFT calculations began to lose some of their awe-inspiring admiration they enjoyed at the end of the first millennium. At the same time, DFT has matured into a standard research tool, used routinely by many experimental chemists to support their work.

Despite the fact that DFT has evolved into a first-choice approach for a stunning potpourri of applications throughout chemistry and materials science, it is all too well known that DFT in its current form still has serious limitations; Cohen et al. (2012) identify and analyze current challenges to DFT. Moreover, it appears that the philosophical, theoretical, and computational framework of DFT might lose its prominent position in electronic structure theory. Fifty years after its formal inception, Becke (2014) reviewed the development and current status of Kohn–Sham density functional theory and raises the concern that increasing pressure to deliver higher and higher accuracy and to adapt to ever more challenging problems “may submerge the theory in the wave-function sea” (Becke 2014). But in whatever direction the path of extended development will guide users and developers of DFT, it seems evident that DFT will continue its role as research tool not only for computational but also for theoretical inclined chemists.

We have composed our short instruction manual for chemists in view of the ontogeny of DFT. A chemist using DFT calculations should be aware of the fact that all approximations and simplifications of any general theory may lead to failures in computed data. Every principally correct theory, if not executed with specific care, may produce essentially wrong results and therefore erroneous predictions. Two aspects are quintessential if one seeks to successfully perform DFT calculations: a basic understanding of how the concepts and models underlying the various manifestations of DFT are built and an essential knowledge of what can be expected from DFT calculations and how to achieve the most appropriate results. Thus, we have divided the main body of our directions into two parts.

In section “[DFT: A Paradigm Shift in Theoretical Chemistry](#),” we expand on the development and philosophy of DFT. We do not present a course or textbook work on DFT; the interested reader will find a selection of references to the literature for more elaborate and detailed descriptions. Rather, we aim to illustrate the essentials of DFT in a manner that is intuitively accessible. For this reason, we will avoid mathematical equations as much as possible, incorporate formulas into the flow of the text, and only on occasion add the odd-numbered equation to the elaboration. As a consequence, we have to abandon the rigor that unambiguous and well-defined derivations require and introduce a certain degree of sloppiness. We hope that such a treatment will facilitate the flow of our arguments and emphasize that what we think are indispensable aspects of DFT.

In section “[DFT: Computational Chemistry in Action](#),” we present an analysis of the performance and applicability of DFT. We focus on a representative selection of chemical properties and system types and base our review on a selection of representing benchmarking studies, which encompass several well-established density functionals together with the most recent efforts in the field. Due to the multitude of papers that report DFT applications, our analysis is far from complete,

but we aim to present a representative snapshot of the current situation of DFT at the beginning of the second decade of the new millennium.

We will close our work with two additional short sections “DFTips” and “A Concise Guide to the Literature,” where we present the reader with a few tips how to use DFT, and with a collection of selected references as a concise guide to the by now vast literature of DFT.

DFT: A Paradigm Shift in Theoretical Chemistry

Density functional theory is primarily a theory of electronic ground-state structure, which is based on the electron density distribution $\rho(r)$. In contrast to DFT, wave function theory is an approach to electronic structure, which is based on the many-electron wave function $\Psi(\mathbf{r}_n)$. In order to put the innovation of DFT into proper perspective, we begin with a brief overview of WFT, before we illustrate the essentials and growth of DFT.

The objective of WFT is the exact solution of the time-independent Schrödinger equation (TISE), $H\Psi = E\Psi$, for a system of interest. [We recall that in quantum mechanics, associated with each measurable parameter in a physical system is an operator, and the operator associated with the energy of a system is called the Hamiltonian H . The Hamiltonian contains the operations associated with the kinetic and potential energies of all particles that comprise a system. We further note that the terms function, operator, and functional are to be understood such that a function is a prescription which maps one or more numbers to another number, an operator is a prescription which maps one function to another function, and a functional takes a function and provides a number.] The solution to the TISE yields the wave function Ψ as well as the energy E for the system of interest. In a systematic, variational search, one looks for the wave function that produces the lowest energy and arrives at a description for the system in its ground state.

If we consider a system of nuclei and N electrons, solving the TISE – within the Born–Oppenheimer separation between the apathetic ambulation of nuclei and the rapid ramble of electrons – yields the electronic molecular wave function $\Psi_{\text{el}}(\mathbf{r})$. This wave function depends explicitly on the $3N$ coordinates of all N electrons, all of which might undergo positional permutation due to repulsive Coulomb interaction. A first approximation to the challenging task of solving the TISE slackens the interaction between electrons by any exchange and thus reduces the function $\Psi_{\text{el}}(\mathbf{r})$ of $3N$ variables to a product of N functions ϕ each depending only on three variables, $\Psi_{\text{el}}(\mathbf{r}) = \prod_{i=1,N} \phi_i(\mathbf{r}_i)$. Atomic orbitals are conveniently chosen to represent the functions ϕ . However, such a *Hartree* product of atomic orbitals violates the Pauli exclusion principle due to the fermion nature of electrons, and hence the appropriate form for a system of noninteracting electrons is a single determinant $|\phi_1(\mathbf{r}_1), \dots, \phi_n(\mathbf{r}_n)|$, known as *Slater* determinant. Such a wave function, from the mathematical properties of determinants, is antisymmetric with respect to exchange of two sets of electronic variables as it should be.

One row of a *Slater* determinant carries contributions from all atomic orbitals ϕ and is commonly referred to as molecular orbital (MO) $\psi\psi^{\text{MO}}$. This approximate method for the determination of the ground-state wave function and ground-state energy is the well-known Hartree–Fock (HF) method.

Although in the HF method the electrons obey exchange as required by the Pauli exclusion principle, the electrons are noninteracting, and the movement of one electron within the system is independent from the movement of all other electrons. However, as the presence of Coulomb repulsion between electrons would suggest, the electrons move in a correlated fashion. In order to allow for electron correlation, configuration interaction (CI) is introduced in that the wave function is constructed as a linear combination of several *Slater* determinants, obtained from a permutation of electron occupancies among all MOs available. Increasing the number of *Slater* determinants increases the accuracy of the calculations, although the added accuracy comes with the price of added computational cost that often becomes the limiting factor for WFT calculations.

This brief exposition brings about two main differences between DFT and WFT. A WFT calculation in general, and increasing the accuracy of WFT calculations in particular, is computationally demanding. DFT seems to be more cost-efficient; after all, the simplest HF wave function $\Psi_{\text{el}}(\mathbf{r})$ depends on $3N$ spatial coordinates, whereas the probability distribution of electrons in space $\rho(\mathbf{r})$ depends only on three coordinates. But there exist strategies how the result of WFT can be systematically improved, whereas there is no methodical, standardized scheme to improve DFT calculations. In the following, we will explore reasons for the WFT–DFT differences.

In WFT, atoms and molecules constitute the basic systems of interest. Since the distribution and redistribution of electrons within atoms and molecules are central to chemical properties and reactivity, we now limit ourselves to systems comprised of N electrons in motion, with some two-particle interaction. The Hamiltonian of such a system reads $H = T + U + V$, where T and U denote the operators for kinetic energy and for electron–electron interaction energy, respectively. Whereas U results in the *internal* potential energy of our system, the moving electrons might in addition interact with an *external* potential, and the operation V recovers the potential energy due to this extra interaction. For systems of electrons that move in a field of fixed nuclei, the external potential V is always just the nuclear field. Systems of electrons in combination with fields of fixed nuclei represent the essential building blocks of matter such as molecules or solids. For a chemist, it might appear counterintuitive that nuclei, being an essential part of a molecule, represent an *external* potential, but the nuclear potential – although internal to a molecule – is external to the density of the moving electrons.

If we consider the external potential to be a uniformly distributed background positive charge, we arrive at the uniform or homogeneous electron gas (UEG or HEG), also known as jellium. At zero temperature, the properties of jellium depend solely upon the constant electron density distribution $\rho(\mathbf{r}) \{= \text{const.}\}$. Such a treatment of electronic density, the Thomas–Fermi (TF) model, constitutes the origins of

DFT (Parr and Yang 1989). The TF model is able to describe the kinetic energy of the UEG as functional of the electronic density, and later on Dirac added a density functional for the exchange energy as a conclusion of the Pauli principle. The UEG formalism itself provides the basis for the local density approximation (LDA).

Before we proceed, we take a small step back to WFT. At the beginning of the 1950s, Slater (1951) described the then current situation in WFT as follows: “The Hartree-Fock equations furnish the best set of one-electron wave functions for use in a self-consistent approximation to the problem of the motion of electrons in the field of atomic nuclei. However, they are so complicated to use that they have not been employed except in relatively simple cases.” Facing the decision “Do you want to calculate it, or do you want it to be accurate?,” Slater decided to replace the peculiar exchange term in the HF equations by something equivalent, yet easier to calculate. Slater used the free-electron approximation for the exchange potential, which, as Dirac has shown, could be expressed as a density functional. His new method, termed HFS, “was easy enough to apply so that we can look forward to using it even for heavy atoms” (Slater 1951), and in order to check its applicability, he performed calculations for the transition metal ion Cu^+ . The exchange potential functional derived from the exchange energy functional contains one additional, scalable parameter α , which led to the development of the $X\alpha$ – method. This model enjoyed a significant amount of popularity among physicists and is still a topic of ongoing research activities (Zope and Dunlap 2006). The HFS – or the $X\alpha$ – method – became the first practically used DFT method in chemistry.

Two points that were fundamental for the progress of DFT were already anticipated within the advancements of the HFS – or $X\alpha$ – method: (1) Every density functional method to some degree contains one or more empirical parameters. Therefore, DFT has often been regarded as “Yet another Semi-Empirical Method” (YaSEM). The Hartree–Fock–Slater model, which can be regarded as ancestor of modern DFT, is such an example. But whereas the HFS method is *intrinsically* approximate, modern DFT is in principle exact (Kohn et al. 1996). (2) Transition metal chemistry has played and continues to play a major role in the progression of DFT. The work of Baerends and Ros (1978) is representative of the transition-metal–HFS era, and Ziegler’s contributions, summarized in his early review article (Ziegler 1991), have provided the impetus that changed the perception of calculations based on densities from YaSEM to DFT, “Das Future Tool.” A review article by Cramer and Truhlar (2009) is dedicated solely to developments and progress of DFT for transition metal chemistry and summarizes the state of affairs at the end of the first decade of the new millennium.

At the heart of modern DFT is the rigorous, simple lemma of Hohenberg and Kohn (1964), which states that the specification of the ground-state density, $\rho(\mathbf{r})$, determines the external potential $V(\mathbf{r})$ uniquely (Eq. 1):

$$\rho(\mathbf{r}) \rightarrow V(\mathbf{r}) \text{ (unique)} \quad (1)$$

This first theorem by Hohenberg and Kohn (HK-I) is not difficult to prove (Parr and Yang 1989), but for a chemist, the essentials of HK-I that given a

Fig. 1 Visualization of the first Hohenberg–Kohn theorem (density map drawn for a contour envelope of 0.01 a.u.)

density, only one external potential corresponds to that density, are intuitively clear. A pictorial representation of HK-I is shown in Fig. 1; we consider the density created by 32 electrons that move around the external potential created by one oxygen, three carbon, and six hydrogen nuclei. By inspection of a density map of a certain density value, it becomes obvious that of all the atomic constellations considered, only one seems to be consistent with the shape of the density map. Such a consideration reflects ideas developed in the context of “conceptual DFT” (Geerlings et al. 2003).

HK-I also expresses the fact that there is a one-to-one mapping between the potential $V(r)$, the particle density $\rho(r)$, and the ground-state wave function Ψ_0 (Eq. 2):

$$\rho(r) \longleftrightarrow V(r) \longleftrightarrow \Psi_0 \quad (2)$$

This implies that all properties of a system are functionals of the ground-state density, since any property may be determined as the expectation value of the corresponding operator. With the help of this lemma, a minimal principle for the energy as functional of $\rho(r)$ can be derived. The second Hohenberg–Kohn theorem (HK-II) provides the necessary guidelines to obtain the ground-state energy. Following HK-II, a variational principle is established, according to which the ground-state density of a system of interest can be determined.

In order to put the promise of the HK theorems that all properties of a system can be obtained from its ground-state density, into reality, one would need a construction that is computationally accessible while maintaining the formal exactness of HK-I and HK-II. To this end, Kohn and Sham (1965) introduced a fictitious system of N noninteracting electrons that have for their overall ground-state density the same density as some real system of interest where the electrons do interact. Using some aspects of HF theory, the ground-state wave function Ψ_0 of such a noninteracting system is described by a single *Slater* determinant. The orbitals, which form this

Slater determinant, known as Kohn–Sham (KS) orbitals φ^{KS} , are solutions of N single-particle equations. Following the variational principle, the ground-state energy and the ground-state density are determined from variations in φ^{KS} .

The essential contribution to the KS energy comes from the so-called exchange–correlation energy E_{XC} . It incorporates corrections to the kinetic energy due to the interacting nature of the electrons of the real system, *all* nonclassical corrections to the electron–electron repulsion, as well as electron self-interaction corrections. If E_{XC} is ignored, the physical content of the theory becomes identical to that of the *Hartree* approximation. Thus, within the KS formalism, the electronic energy of the ground state of a system of N electrons moving within an external potential of nuclei is expressed – without approximations – as a functional of the ground-state density (Eq. 3):

$$E[\rho] = T_s[\rho] + U[[\rho(1), \rho(2)]] + V_{\text{ne}}[\rho] + E_{\text{XC}}[\rho] \quad (3)$$

In Eq. 3, the first term represents the kinetic energy of the system of N noninteracting electrons, the second term corresponds to the Coulombic repulsions between the total charge distributions at two different positions within the system, and the third term accounts for nuclear–electron interactions, due to the presence of an external potential. It is the fourth term, the functional for the exchange–correlation energy E_{XC} , which is responsible for the power and magic of DFT. What makes current DFT applications approximate is the unknown analytic expression of E_{XC} , for which an approximation is needed.

The KS formalism is closely related to the HF formalism. What differentiates the KS operator from the HF operator is the exchange–correlation potential V_{XC} . V_{XC} in turn is a functional derivative of the exchange–correlation energy E_{XC} . Furthermore, the Hamiltonian H operating on the wave function that is associated with the density of a fictitious system of N noninteracting electrons can be expressed as sum of one-electron operators.

Whereas increasing the accuracy of HF calculations is accompanied with a steep increase in computational cost, increasing the accuracy of DFT calculations apparently requires modifications in V_{XC} , which – if at all – only lead to a moderate increase in computational cost. However, whereas it is well known how to systematically improve the accuracy and quality of HF calculations, no comparable strategy exists for DFT calculations within the confines of a KS approach. It appears that a detailed knowledge of the exchange–correlation energy E_{XC} is essential for designing more accurate density functionals.

Holes and Electron Pairs

The exchange–correlation energy E_{XC} is a relatively small part of the total energy of a typical system, although it is by far the largest part of “nature’s glue” that binds atoms together (Kurth and Perdew 2000). It arises because the electrons do not

Fig. 2 Electrons in distress: While trying to maximize the attraction from the nuclei, an electron experiences enhanced repulsion from the other electron as it moves around in the molecular framework (*top*). To minimize the repulsion, each electron creates an exclusion area around itself, into which no other electron can penetrate (*bottom*) (Cartoon by Lauren Bertolino)

move randomly through the density but avoid one another. Ziegler (1995) illustrates the situation as follows: An electron will try to maximize the attraction from the nuclei and minimize the repulsion from the other electrons, as it moves around in the molecular framework. To do so, it creates an exclusion area or “no-fly zone” around itself into which no other electron can penetrate, as pictorial exemplified in Fig. 2. The exclusion zone is referred to as the exchange and correlation (XC) hole, and it is the way in which the XC hole is modeled that distinguishes one electronic theory from another. Each density functional has its own characteristic XC fingerprint.

The XC hole also determines to a large part E_{XC} , which however contains *three* different contributions. The first is the potential energy of exchange, which also should include corrections for self-exchange or self-interaction. The second is the potential energy of correlation due to the effect of Coulomb repulsion. Both potential energies are negative and determined by the nature of the XC hole. The third contribution to E_{XC} is a smaller positive kinetic energy of correlation due to the extra swerving motion of the electrons as they avoid one another (Perdew et al. 2009).

The XC hole arises from an extension of the concept of the unconditional one-electron probability density $\rho(1)$ by considering pairs of electrons and a resulting conditional probability. When a reference electron is known to be at position 1, the conditional probability $\rho^{\text{cond}}(2, 1)$ of the other electron to be at position 2 can be written as the sum of the unconditional probability $\rho(2)$ of the other electron and the XC-hole density $\rho^{\text{XC-hole}}(2, 1)$. Thus, the hole $\rho^{\text{XC-hole}}(2, 1)$ describes how the conditional density of the other electron deviates from its unconditional density $\rho(2)$.

It is instructive to have a closer look at hole profiles, and as simple example, we will consider the hydrogen molecule H_2 with only two electrons or one electron pair. In Fig. 3, hole densities for H_2 are shown; the two nuclei H_A and H_B are separated by 72 pm, and the reference electron is placed 15 pm to the left of nucleus H_B .

Fig. 3 Hole densities in the hydrogen molecule: Only the full XC-hole $\rho^{\text{XC-hole}}(2, 1)$ has physical meaning (Adapted from Baerends and Gritsenko (1997), with permission by the American Chemical Society)

The XC hole can be split into contributions from the exchange or X hole, which arises from the fermion nature of an electron obeying the Pauli principle and the correlation or C hole due to Coulomb repulsion within the pair of electrons. [The X hole and C hole are often referred to as Fermi hole and Coulomb hole, respectively.]

The X hole puts an emphasis on the reference electron. It creates a taboo zone for the other electron with a negative $\rho^{\text{X-hole}}(2, 1)$ probability density not only around the region in space where the reference electron currently *is* but also where it *might be*. Regions in the vicinity of both nuclei H_A and H_B are declared as “no-fly zone.” The C hole on the other hand puts an emphasis on the other electron. It excludes regions where the other electron might experience Coulomb repulsion with the reference electron, but it also maps out regions where the other electron can benefit from attractive Coulomb interactions with nuclei. We see a negative $\rho^{\text{C-hole}}(2, 1)$ probability density around H_B but a positive $\rho^{\text{C-hole}}(2, 1)$ probability, a buildup of density, around H_A far away from the reference electron. Whereas the X hole and C hole illustrate exchange and correlation, only the combined XC hole has physical meaning.

Before we continue, a short remark on the use of some language is in order. Since the terms *local* and *nonlocal* are often recurred to in the context of DFT, and often with different meanings, we briefly define how the terms *local* and *nonlocal* are used in this work. An approximation is said to be *local* if its energy density and related properties at any position of interest depend only on the electron density neighborhood of the given position. Otherwise, an approximation is said to be fully *nonlocal*. [We note that some physicists separate local approximations into “strictly local” and “semilocal.”]

From an inspection of Fig. 3, it appears that both the C hole and the X hole are inherently nonlocal (the same as the HF exchange energy). The XC hole, too, must therefore be nonlocal, but its dominant contributions arise from the region around its reference electron – the XC hole appears to be more local and less nonlocal than the X or C hole. This observation already anticipates that local density functionals might be able to produce approximate models for the nonlocal XC hole.

Fig. 4 The Jacob's ladder of density functional approximations to the exchange-correlation energy (Reprinted from Perdew *et al.* (2009), with permission by the American Chemical Society)

Although it seems that there exists no systematic approach like in WFT to improve the accuracy of DFT, the advancement of density functionals depends on more precise descriptions not only of the XC hole but also of the exchange-correlation energy E_{XC} . This task can be approached in a methodical manner.

Climbing Jacob's Ladder

Perdew and Schmidt (2001) compare the development of enhanced density functionals to a climb of Jacob's ladder, leading the way from the *Hartree* world to the heaven of chemical accuracy, illustrated in Fig. 4. Each rung of the ladder adds a refinement to the approximation of the exchange-correlation energy.

First Rung: The Local Density Approximation

The first rung employs only the local densities in the description of the exchange-correlation energy. This method is known as the local density approximation (LDA). [Although vital to the fermion nature of electrons, so far we have treated spin rather nonvercal. But the issue of spin can be treated as well in density functional theory, and the local spin density approximation (LSD or LSDA) replaces the spin-averaged energy density with the energy density for a polarized homogeneous electron gas. LDA and LSDA are now often used synonymously.]

LDA takes its densities from the uniform electron gas (UEG), and an analytical form of a density functional for the exchange energy of the UEG can be derived (the same exchange energy as used in the HFS method). No such expression exists for the correlation energy, but the UEG correlation energy can be calculated numerically

and fit in various ways. One successful and popular parameterization comes from the work of Vosko, Wilk, and Nussair, referred to as VWN (Vosko et al. 1980).

LDA performs surprisingly well in predicting molecular properties that are based on relative energy differences within a given density. Molecular geometries for representative main group compounds could be reproduced in close agreement to the experiment (Versluis and Ziegler 1988). For transition metal complexes, metal–ligand separations are slightly underestimated, but still within acceptable conformity with X-ray data (Ziegler 1995). However, properties that are based on absolute energy differences between densities, such as bond energies, are not well described by LDA, where a clear overbinding tendency emerged. LDA is therefore a remarkably useful structural, though not thermochemical, tool. The disappointing performance of LDA in estimating thermochemical properties spawned the development of gradient-based methods, the second rung on Jacob’s ladder.

Second Rung: The Generalized Gradient Approximation

The second rung or generalized gradient approximation (GGA) adds the gradients of the local densities to the exchange–correlation picture. It became clear that the homogeneous electron gas is only of limited use as a model of the inhomogeneous electron density within molecules, and approximations for exchange and correlation energy were augmented by density gradients. [In the older literature, GGAs are sometimes called nonlocal (LDA/NL), since the gradient implies a directional change within the density.] Two early models for correlation (Perdew 1986) and exchange (Becke 1988a) in combination resulted in the BP86 functional, the GGA that was most influential in the early developments of transition metal DFT (Ziegler 1991). Gradient corrections are essential for a quantitative estimate of bond energies as well as metal–ligand bond distances (Ziegler 1995).

Third Rung: Meta-Functionals

The third rung adds the kinetic energy density to the description of density functionals (Tao et al. 2003) and addresses the smaller third contribution to E_{XC} . Such functionals are referred to as meta-functionals and, when built on second rung functionals, as meta-GGA (MGGA).

The first three rungs of Jacob’s ladder all represent local functionals. They often work because of proper accuracy for a slowly varying density or because of error cancellation between exchange and correlation. Error cancellation can occur because the exact XC hole is usually more localized around its reference electron than the exact X hole (compare Fig. 3). Regions in which no error cancellation is expected are regions where exchange dominates correlation (Perdew et al. 2009).

Climbing up the ladder, the approximations become more complicated, more sophisticated, and typically more accurate. Computation times increase modestly from the first to the third rungs and much more steeply after that. The added ingredients on each higher rung of the ladder can be used to satisfy more exact constraints or to achieve better agreement with experimental data (or both). These two strategies define the nonempirical and semiempirical approaches commonly

used to improve density functionals. Beginning with the fourth rung, the nature of the density functionals changes from local to nonlocal.

Fourth Rung: Hyper-Functionals

The fourth rung, which also represents the first fully nonlocal rung, adds the exact exchange energy density. Such a functional is termed hyper-GGA (HGGA). After reaching the second rung, DFT progressed rapidly and took one giant step from the second to the fourth rung, omitting meta-GGAs. Following the idea of adiabatic connection, Becke derived a functional for exchange, which contained contributions from the exact HF exchange (1993a). He then designed an advanced functional for the exchange-correlation contribution containing three parameters for its various parts, including gradient corrections for correlation, gradient corrects for exchange, as well as an exact exchange contribution (1993b). These semiempirical coefficients have been determined by a linear least-square fit to 56 atomization energies, 42 ionization potentials, eight proton affinities, and ten first-row total atomic energies. Becke's functional, combining HF theory and DFT with the use of three empirical coefficients, was the first example and initiated the evolution of so-called hybrid functionals. The hybrid functional B3LYP, based on Becke's parameterization, was to a large part responsible for the meteoric ascent of DFT during the 1990s.

While the first three rungs of Jacob's ladder require no fitting of experimental data, empiricism seems unavoidable on the fourth rung. This has caused some skepticism, and it appeared that the success of "empirical DFT" would eventually be responsible for the death of "true DFT." Gill humorously described the situation at the beginning of the new millennium in his obituary to DFT (Gill 2001). The Jacob's letter metaphor puts the addition of exact exchange to density functionals into proper perspective.

The step from the third rung to the fourth rung results in a new class of functionals, so-called HMGGAs. HMGGA functionals are currently a field of active development and appear to produce promising results. M06, for example, is a HMGGA with good accuracy for a variety of different chemical applications ranging from transition metals over main-group thermochemistry to barrier heights of chemical reactions. Thus, HMGGAs might be considered as a class of density functionals with broad applicability in chemistry (Zhao and Truhlar 2008a). Whether HMGGA is read as hybrid meta-GGA or hyper meta-GGA is a matter of taste; fortunately, both specifications result in the same acronym.

Fifth Rung

The fifth rung of Jacob's ladder adds exact correlation as new ingredient. One might think of this as an expansion of the density space of a system by adding virtual densities into the picture. One approach to this problem is the use of the random-phase approximation (RPA). RPA in DFT in turn is closely related to time-dependent DFT (TD-DFT). The essence of RPA might be described as constructing the excited states of a system as a superposition of particle-hole excitations.

When building a fifth-rung density functional for the exchange-correlation energy, the RPA utilizes full exact exchange and constructs the correlation with the

help of the unoccupied Kohn–Sham orbitals. Like the first three rungs of Jacob’s ladder, the fifth rung requires no fitting. Although the essentials of RPA originated in the 1950s, fifth-rung methodologies were considered too computationally expensive for widespread use and application. Yet improvements in hardware and algorithms also entered the development of RPA technology, and it seems that “RPA has the potential to become a building block of future generations of electronic structure methods” (Furche 2008).

In the early days of modern density functional theory, hazy clouds of ambiguity that enfolded the XC hole obscured the view of Jacob’s ladder. The existence of the third rung of Jacob’s ladder was recognized before the fourth rung entered the Jacob’s ladder picture (Becke and Roussel 1989), but at first it did not appear as a safe and secure stage for the ascent toward the heaven of chemical accuracy. Thus, although MGGAs predate HGGAs, the computational development of HGGAs predates that of MGGAs. Only after the clouds of ambiguity lifted, MGGAs became a recognized DFT approach in computational chemistry, and HMGGAs began to appear.

The Jacob’s ladder scheme is not the only way to arrive at exact functionals. When leaving the confines of ordinary KS-DFT methods, and using ideas from WFT, one arrives at *ab initio* density functional theory, the seamless connection of DFT and WFT (Bartlett et al. 2005). While these methods have not yet positively established themselves as standard approaches in computational chemistry, the fundamental conception that guided the way to the fourth rung – capturing the best of both worlds – marks the beginning of *ab initio* DFT and led to the notion of double-hybrid theory (Grimme 2006a), in which DFT calculations are supported not only by exact exchange but also by HF correlation. Along the same lines, range-separated functionals (Leininger et al. 1997) base their decision on how to deal with electron–electron correlation – the DFT or WFT way – on the central variable that describes a pair of electrons. The idea also found its entry into the realm of exchange (Tsuneda and Hirao 2014), and at the time of writing, it appears that the offspring of parent functionals is ever more growing in number.

Practical DFT and the Density Functional Zoo

A practical DFT-based calculation is in many ways similar to a traditional HF treatment in that the final outcome is a set of orbitals, the Kohn–Sham orbitals φ^{KS} . The KS orbitals are often expanded in terms of a basis set as in the traditional linear combination of atomic orbital (LCAO) approach of traditional HF methods. Most often, Gaussian-type basis functions are used to construct atomic orbitals (GTO). A major exception is the Amsterdam Density Functional (ADF) suite of programs, where Slater-type basis functions (STO) are used. ADF constitutes one of the first programs developed essentially for applications of DFT.

The evaluation of matrix elements of the Kohn–Sham exchange–correlation potential always requires at some step a 3-day numerical integration. Solutions to the problem of carrying out 3D numerical integration for polyatomic systems to

arbitrary precision (Becke 1988b) provided a major thrust for computational DFT, and proficient improvements were made in connection with developments of the ADF computer code (Boerrigter et al. 1988). The availability of economical numerical integration schemes made the choice of STOs over GTOs computationally compatible.

The local nature of the effective potential in the one-electron Kohn–Sham equations affords efficient computational schemes. During the development of ADF, the remaining Coulomb problem, the two-electron-integral “bottleneck,” has been addressed by the introduction of auxiliary basis sets, the so-called density fitting (Baerends et al. 1973).

Many of the pioneering improvements made during the development of the ADF suite of programs have become standard tools in density functional calculations, and as a result, DFT calculations perform compatible to, if not better than HF methods. We note that a density fit is not possible, when the chosen functional utilizes exact exchange.

By now, a plethora of density functionals is available for electronic structure calculations. Toward the end of the first decade of the new millennium, Sousa and coworkers have presented an authoritative review, in which they evaluate the performance of over 50 different density functionals (Sousa et al. 2007). The authors also report the percentage of occurrences of the names of different functionals in journal titles and abstracts; we interpret these numbers as measure for usage and popularity of the corresponding functional. Although new functionals appear every year, the popularity ranking seems to possess some stability within a time interval of several years. Thus, in Fig. 5, we have compiled data for the seven most popular functionals, taken from the work of Sousa and coworkers, and include a popularity pie chart as well.

FUNCTIONAL (YEAR)	TYPE	USAGE
B3LYP (1994)	HGGA	80 %
BLYP (1988)	GGA	5 %
B3PW91 (1993)	HGGA	4 %
BP86 (1988)	GGA	3 %
PBE (1996)	GGA	2 %
BPW91 (1991)	GGA	1 %
TPSS (2003)	MGGA	1 %

Fig. 5 Most popular density functionals at the end of the first decade of the new millennium (Data based on results of extensive literature searches (Sousa et al. 2007))

The key information conveyed in Fig. 5 is the fact that B3LYP is by far the most popular density functional in chemistry, representing 80 % of the total of occurrences of density functionals in the literature, in the period 1990–2006 (Sousa et al. 2007). Other popular density functionals such as BLYP, B3PW91, and BP86 acquire usage shares of 5 % and less and can only be considered as also-rans in the functional race.

It seems advisable to briefly talk about how to decipher the density functional code. With the advent of GGAs at the end of the 1980s, the abbreviation for each GGA functional usually consisted of two parts: the first for exchange and the second for correlation. As an example, BP86 takes its exchange contribution from the work of Becke (1988a) and correlation from the work of Perdew (1986). Similarly, BLYP breaks down into B exchange and LYP correlation. Later, when gradient corrections for exchange and correlation were often taken from the same work, the functional is usually referred to by one combined code only. The GGA functional PBE takes its gradients for exchange as well as for correlation from the work of Perdew, Burke, and Ernzerhof. The same holds true for the MGGA TPSS. Strictly spoken, the PBE functional should be referred to as PBEPBE. It is also possible that the individual parts are combined with other functionals, for example, PBELYP or BPBE. HGGAs usually contain one number that indicates the degree of parameterization when building the hybrid: B3LYP refers to a three-parameter mixing of B exchange, LYP correlation, and exact exchange, whereas B1LYP refers to a one-parameter hybrid density functional. As density functionals get more elaborate and more complex, the XC coding is not always strictly followed. The HMGGA M06 and its variations (M06-L, M06-2X, M06-HF), for example, refer to a set of functionals developed at the University of Minnesota in 2006.

The pie chart presented in Fig. 5 bears a striking resemblance to *Pac-Man*. Like the arcade game *Pac-Man*, often credited with being a landmark in video game history and virtually synonymous with video games, B3LYP has to be considered a landmark in electronic structure theory and is often used as a synonym for DFT. However, the same as there is more to video games than just *Pac-Man*, there is more to density functional theory than just B3LYP. In section “[DFT: Computational Chemistry in Action](#),” we will explore the characteristics and capabilities of density functional in more detail.

The reader, who would like to know more about the details and derivations of DFT, will find valuable information about the basics in the *A Chemist's Guide to Density Functional Theory* (Koch & Holthausen 2002) and will learn more about advanced aspects in the *A Primer in Density Functional Theory* (Fiolhais et al. 2003).

DFT: Computational Chemistry in Action

The breakthrough of DFT coincided with a rise of computational power at the end of the last millennium. CPU architectures advanced from CISC to RISC designs, supercomputers transformed from single vector processors to computing clusters.

However, as the computational power increased, the problems too became more and more demanding, and the molecules that found their way into input files for density functional programs grew bigger and bigger. Computing time remains to be a crucial factor when assessing the performance of computational methods, and linear-scaling approaches are one of the great strengths of DFT (Yang 1991). However, these techniques fall out of the scope of our review and assessment, and we begin with a comparison of computational demands of representative density functionals, following standard approaches.

Computational Performance

We start this section remarking that there is not something like “the best functional and basis set for all properties.” Rather, the specific methodological approach to be used depends from the specific problem at hand. Nevertheless, many functionals are robust enough to give rather reasonable results in a large series of chemical properties, and the scope of this section is to provide an overview of the performances of typical functionals and basis sets, trying to highlight which ones perform remarkably better or remarkably worse than the average, if this is known. Further, as a practical *vademecum*, the scope of this section is to give an overview of performances under “standard working conditions.” Thus, the focus will be on performances that can be expected when working with real-size systems (50–100 atoms including a transition metal), which requires a compromise between the computer resources available and the combination of functional and basis set used, rather than peak performances that can be reached with a sophisticated last-generation functional in combination with a very extended basis. On the other hand, there are several excellent reviews that provide an accurate and critical assessment of the various methods, with a particular focus on the best performances that can be achieved, independently from the computational cost (Sousa et al. 2007; Cramer and Truhlar 2009). Methods that currently are computationally too expensive might become the standard computational tools in the future.

Finally, the number of possible functionals is very large, so that it is more confusing than enlightening to review all of them. In addition, it might well be that the best functional for a specific problem has not been tested in the several benchmarking studies published in the literature. As a general rule, before wasting huge amounts of computer power with the wrong functional and/or basis set, it is wiser to invest some time to read the literature to find which computational method works better (or acceptably well) for a given problem and possibly have a feeling of the accuracy through test calculations on small selected systems.

To give an idea of the relative cost of the various functionals, the relative computational time required by some functionals in two standard applications such as the calculations of the energy and of the first derivatives of the energy with respect to the atomic coordinates (which must be calculated at each geometry optimization step) and the calculation of the second derivatives of the energy with respect to the atomic coordinates (which must be calculated for vibrational analysis) is reported

Table 1 Relative performance of various functionals, as implemented in the Gaussian 09 package, in the calculation of energy and gradients, or second derivatives, for an organometallic complex of formula $\text{RuC}_{31}\text{H}_{33}\text{Cl}_2\text{N}_3$

Method		E + gradients	2nd derivatives	E + gradients
		SVP		TZVP
BP86 (density fit)	GGA	1.0	1.0	1.6
BP86	GGA	1.5	1.9	4.1
PBE	GGA	1.5	1.8	4.2
B3LYP	HGGA	2.6	2.9	8.9
PBE1PBE	HGGA	3.0	3.2	9.2
TPSS (density fit)	MGGA	1.6	1.9	2.6
TPSS	MGGA	2.1	2.3	5.1
TPSSh	HMGGA	3.5	3.5	9.4
M06	HMGGA	3.6	4.0	10.6

in Table 1. The system considered in these calculations is a 70 atom Ru complex whose brute formula is $\text{RuC}_{31}\text{H}_{33}\text{Cl}_2\text{N}_3$.

The data reported in Table 1 clearly indicate that GGA calculations are computationally very effective. In addition, for DFT methods that do not rely on exact exchange, the performance can be further improved by using an auxiliary basis set to fit the electron density (usually called density fit or resolution of identity). Indeed, without this technical setup, the same GGA or MGGA functional – compare the BP86 (density fit) and the simple BP86 values in Table 1 – is roughly 50 % slower. The same consideration applies when MGGA functionals are considered; compare the TPSS (density fit) and the simple TPSS values in Table 1. We note that this technical acceleration is not possible when the Hartree–Fock exchange must be evaluated, and thus HGGA and HMGGA calculations cannot benefit from it. Generally speaking, there are marginal differences within a family of functionals, and HGGA functionals are roughly 2–3 times slower than GGA functionals. MGGA functionals, particularly when the resolution of identity technique is invoked, are roughly 50 % slower than GGA functionals and thus are quite faster than HGGA functionals. HMGGA functionals are roughly 3–4 times slower than GGA functionals. This relative speed between the different families of functionals is maintained when second derivatives are evaluated. Moving to the effect of the size of the basis set, calculations performed with a triple- ζ plus one polarization function of main group atoms results in an increase of the required computational time by a factor of 2–3 roughly. Thus, on going from an accelerated GGA functional in combination with a split valence plus one polarization function basis set, to a HMGGA functional in combination with a triple- ζ plus one polarization function, basis set result in an increase of the computational time by a factor of 10 roughly. In other words, a GGA/SVP calculation that would take one day would require more than one week, roughly, if performed at the HMGGA/TZVP level. This indicates that the selection of the most appropriate computational method (both functional and

basis set) must be a trade between the accuracy needed and the computational time (or power) available. Of course, degradation of accuracy below the level required by the specific problem at hand is not possible.

Properties of Molecular and Electronic Structure

To explore the capabilities of various density functionals, we have selected twelve representative properties of atoms and molecules. We begin with molecular structure (bond lengths, bond angles, vibrational frequencies) and basics of electronic structure (electron affinities and ionization potentials). We then proceed to the energetics of transformations of molecules (atomization energies, heats of formation, energy barriers), which will carry us to chemical bonding. The nature of the chemical bond remains a central theme in theoretical chemistry, and we discuss regular bonds as well as weak bonds, all being at the focus of ongoing research activities (bond energies, hydrogen bonding, weak interactions). The issue of spin in DFT deserves particular attention (spin states). Although DFT essentially is a ground-state theory, excited states too can be treated with density functional theory, and with our last property we briefly touch this topic (excited states). Time-dependent density functional theory (TD-DFT) is a topic in its own right, and an appropriate coverage of TD-DFT falls out of the scope of the present work. The reader will find an entry into this excited field when studying the articles compiled by Marques and coworkers (2006).

The twelve topics we selected in no way exhaust the capabilities of DFT, and any property that can be treated with WFT is in principle accessible with DFT as well. As an example, we refer the reader to a most instructive review by Neese (2009) that illustrates the capabilities of DFT in the field of molecular spectroscopy.

When evaluating the performance of computational methods, benchmarking is an essential procedure in which calculated properties are evaluated against accurate experimental data. By now, a large number of problem-specific databases have been established, which cover a wide variety of different physicochemical properties, such as proton affinities, atomization energies, barrier heights, reaction energies, and spectroscopic properties. However, these databases are not free from chemical biases and often narrowed by the structural space of chemical intuition. There is always the risk that when following established procedures, benchmark studies might lose some of their general appeal. As to avoid the dangers of casual benchmarking, Korth and Grimme have developed a “mindless” DFT benchmarking protocol. Here, the databases consist of randomly generated molecules that rely on systematic constraints (Korth and Grimme 2009) rather than on what is supposed to be chemical insight.

In the following, we will make extensive reference to published benchmark studies. However, it might well be that a particular molecule of interest to the reader is not covered within one of the existing benchmark databases, and benchmark studies in general provide good starting points for calculations, but no guarantee for correctness.

One: Bond Lengths

It is well established that almost any DFT approach, beyond LDA, is able to reproduce correctly the geometry of molecular systems composed of main group atoms. With the increase of computer resources, it is becoming customary to test the performances of various methods through calculations on a rather large set of molecules and to report statistical values. In one of such comparative studies, 17 closed-shell molecules composed by first-row atoms, for which accurate experimental geometries determined in the gas phase were available, confirmed that the performance of commonly used GGA (BLYP, BPW91, and BP86) and HGGA (B3LYP, B3PW91, and B3P86) is quite accurate, although the mean unsigned error (MUE) on the bond length obtained with the GGA functionals, between 0.015 and 0.020 Å roughly, is slightly larger than that calculated with the HGGA functionals, usually below 0.010 Å (Wang and Wilson 2004). The convergence of the geometry was tested with respect to increasing basis set size from cc-pVDZ to aug-cc-pV5Z and was shown to occur quickly. Convergence is typically reached at the triple- ζ level, and beyond this level minor fluctuations, in the order of 0.002 Å, were observed. Thus, excellent performances require that at least a triple- ζ basis set is used. Similar conclusions were reached in a different benchmark study on a dataset of 44 small molecules (Riley et al. 2007). Again, GGA functionals in combination with Pople basis sets of the 6-31G family result in MUE between 0.015 and 0.020 Å, while HGGA functional results in MUE below 0.010 Å. The MGGA functionals tested resulted in a minor improvement relative to GGA functionals, while the tested HMGGA functionals substantially reproduce the performance of HGGA functionals. This indicates that the advantage of meta-functionals certainly is not in bond distances.

To give an idea of the performance of some popular functionals, and also to show the effect of the basis set, the dependence of the O–H bond length in water is reported in Table 2 as an exemplary case. The data indicate that reasonably accurate bond lengths (within 0.02 Å from the experimental value) can be achieved with computationally cheap GGA functionals and that HGGA performs slightly better with modest basis sets. As a general trend, the HGGA bond lengths are slightly shorter than the corresponding GGA value and independent of the computational approach; slightly shorter bond lengths are predicted with basis sets of increasing quality. It is noteworthy that with the extended aug-cc-pV5Z basis set, the GGA values slightly overestimate the experimental value, whereas the HGGA values slightly underestimate it. Importantly, rather good results can be achieved also with relatively small basis sets, which allow calculating geometries for fairly large systems with a reasonable accuracy.

The very good performance of almost any functional to calculate accurately bond lengths of molecular systems composed by main group atoms is not replicated when bonds to transition metals are considered. Focusing on an extensive benchmark of 42 functionals on a database of 13 metal–ligand bond lengths, the MLBL13/05 database, all functionals provide rather good results, with MUE normally between 0.01 and 0.02 Å when a basis set of triple- ζ quality is used (Schultz et al. 2005a).

Table 2 Performance of selected functionals and basis sets in predicting the experimental value of the O–H bond length of water, 0.956 Å

	BP86	revPBE	B3LYP	TPSS	TPSSh	M06

aug-cc-pVQZ	0.970	0.968	0.961	0.967	0.963	0.956
aug-cc-pV5Z	0.970	0.968	0.960	0.967	0.963	0.956

Extending the benchmark to a database containing the bond length of eight metal–metal dimers, the TMBL8/05 databases, the situation deteriorates. GGA functionals, including the popular BP86, BLYP, and PBE functionals, still provide rather good results, with MUE between 0.02 and 0.03 Å when a basis set of triple- ζ quality is used, while reducing the quality of the basis set to double- ζ deteriorates performances remarkably, with MUE between 0.06 and 0.09 Å (Schultz et al. 2005b). In the GGA family, the HTCH and OLYP functionals, with MUE greater than 0.03 Å, should be avoided. The rather good performance of GGA functionals is not replicated by HGGA functionals, including the popular B3LYP and PBE1PBE functionals, with MUE between 0.08 and 0.09 Å. In the HGGA family, the BH&HLYP and MPW1K functionals, with MUE greater than 0.12 Å, should be avoided. Interestingly, MGGA functionals do not perform as or better than GGA functionals in predicting bond lengths, but rather worse. Indeed, including also the popular BB95 and TPSS functionals, they result in MUE greater than 0.06 Å. Introduction of HF exchange partially improves the performance of MGGA functionals, and the tested HMGGA functionals, including the B1B95 and the TPSSh functionals, result in MUE between 0.03 and 0.07 Å (Schultz et al. 2005a). Finally, the M06 functional performs particularly poor, with a MUE of 0.131 Å (Zhao and Truhlar 2008b).

To give an idea of the performance of some popular functionals in the calculation of the M–ligand distances and of the effect of the metal on the bond distance of the ubiquitous CO ligand, analysis of these distances in three typical binary carbonyl complexes involving first-row transition metals is reported in Table 3.

Basically, all the functionals reproduce the experimental M–CO distances well within 0.02 Å, but many of the functionals tested underestimate the difference in the axial and equatorial Fe–CO distances. In this respect, HGGA and HMGGA functionals seem to perform slightly better, although there is quite a debate on the exact

Table 3 Performance of selected functionals, in combination with the TZVP basis set on all the atoms, in predicting the experimental value of the M–C and C–O bond length (in Å) in three first-row M(CO)_n complexes

assignment of the Fe–CO distances in Fe(CO)₅. Similar good behavior is shown by all the functionals in the prediction of the CO distance when bonded to a transition metal, although the GGA and MGGA functionals tested yield systematically longer CO distances. In this respect, HGGA and HMGGA functionals do perform slightly better.

Two: Bond Angles

The good performance of almost every functional to predict correctly bond lengths of molecular systems composed by main group atoms is confirmed in the case of bond angles. Again, a benchmark study on 17 closed-shell molecules composed by first-row atoms, for which accurate experimental geometries determined in the gas phase was available, confirmed that the performance of commonly used GGA (BLYP, BPW91, and BP86) and HGGA (B3LYP, B3PW91, and B3P86) functionals is quite accurate, with a MUE between 1.0° and 1.5° (Wang and Wilson 2004). Differently from bond lengths, GGA and HGGA methods perform rather similarly on bond angles. Also for bond angles, the convergence was tested with respect to increasing basis set size from cc-pVDZ to aug-cc-pV5Z and was shown to occur quickly, and again convergence is typically reached at the triple- ζ level. Similar conclusions were reached in a different benchmark study on a dataset of 44 small molecules (Riley et al. 2007). All the functionals considered resulted in MUE between 1.0° and 1.5°, independent of the functional used.

To give an idea of the performance of some popular GGA and HGGA functionals, and also to show the effect of the basis set, the dependence of the H–O–H angle in water is reported in Table 4 as an exemplary case. Accurate bond angles (within 1.0° from the experimental value) can be achieved with all functionals and moderate basis sets.

Table 4 Performance of selected functionals and basis sets in predicting the experimental value of the H–O–H angle of water, 105.2°

aug-cc-pV5Z	104.2	104.3	105.1	104.3	104.6	105.1

Three: Vibrational Frequencies

Benchmarking various DFT methods to reproduce accurately vibrational frequencies of 35 molecular systems composed by main group atoms revealed that GGA methods, with a MUE of roughly 40 cm^{-1} , are among the most accurate functionals (Riley et al. 2007). Indeed, the performance of several HGGA methods was at least 20 cm^{-1} worse, with MUE between 60 and 80 cm^{-1} , and meta-functionals are not an improvement. As for other geometrical properties, accurate performance requires that a triple- ζ basis set be used. The GGA functionals also performed better than HGGA functionals in the prediction of the vibrational frequency in nine homonuclear 3d metal dimers, with a MUE around 100 cm^{-1} for BLYP and BP86 and around 120 cm^{-1} for B3LYP and B3P86. Nevertheless, both families of functionals resulted in a rather large deviation from accurate data (Barden et al. 2000).

The performance of various functionals in the prediction of the CO stretching frequency in typical binary carbonyl complexes with first-row transition metals is exemplified in Table 5. Simple GGA and also MGGA functionals perform better and are able to capture the experimental value with an accuracy of roughly $50\text{--}100\text{ cm}^{-1}$, while Hartree–Fock exchange seems to deteriorate results, since the HGGA and HMGGA functionals reproduce the experimental value with an accuracy of roughly $150\text{--}200\text{ cm}^{-1}$. In terms of percent, the GGA and MGGA functionals overestimate the experimental values by 3–4 %, while the HGGA and HMGGA functional by 6–10 %. While these results may seem quite accurate, almost all the functionals considered are unable differentiate too little between metals. In fact, the experimental value decreases by 58.1 cm^{-1} on going from $\text{Ni}(\text{CO})_4$ to $\text{Cr}(\text{CO})_6$, but the functionals examined are unable to capture this difference. The best performing are the B98 functional, with a difference of merely 15.0 cm^{-1} , and the HGGA and HMGGA with differences slightly smaller than 10 cm^{-1} .

On the other hand, the simple BP86 GGA functional has been also tested in the prediction of the CO stretching frequency in rather large organometallic complexes.

Table 5 Performance of selected functionals, in combination with the TZVP basis set on all the atoms, in predicting the symmetric frequency of the CO stretching mode in selected first-row transition metal binary carbonyl complexes. Next to each calculated frequency is reported the %error calculated as $\%err = 100 * (v_{Exp.} / v_{DFT})$. The final column reports the difference between the $Ni(CO)_4$ and the $Cr(CO)_6$ frequencies

Fig. 6 Iridium complexes that bear N-heterocyclic carbene ligands

For these large and computationally demanding systems, which are displayed in Fig. 6, computationally effective methods are needed.

The data reported in Table 6 clearly show the very good performance of the BP86 functional, which is able to reproduce the higher frequency symmetric CO stretching with an error of roughly 20 cm^{-1} only and the lower frequency asymmetric CO stretching with an error of roughly 30 cm^{-1} . Further, despite the poor performances discussed above in the ability of GGA functionals to differentiate between different binary $M(CO)_n$ complexes, comparison of the saturated N-heterocyclic carbene complexes (SIPr and SIMes) with their unsaturated counterparts (IPr and IMes) indicates that the DFT values reproduce the experimental finding that both CO stretches are about 1 or 2 cm^{-1} smaller in the complexes with the unsaturated N-heterocyclic carbene ligand (Kelly et al. 2008).

Table 6 Experimental and DFT calculated CO stretching frequencies, in cm^{-1} , in several N-heterocyclic carbene complexes

Method	Experimental		BP86	
	(IAd)Ir(CO) ₂ Cl	2063.4	1979.8	2082

Ni(CO) ₃	24.8	35.3	27.9

Four: Electron Affinities and Ionization Potentials

A benchmark study of 24 molecules from the G2/97 dataset, with the addition of PO₂, indicated that, with some exceptions, DFT methods reproduce the electron affinity of molecular systems composed by main group atoms with a MUE close to 4 kcal/mol. Some hybrid functionals, such as the B98 functional, performs slightly better (MUE = 3.15 kcal/mol), while GGA functionals with the P86 correlation term usually perform rather poorly, with MUE around 6 kcal/mol (Riley et al. 2007). Finally, meta-functionals are not an improvement. As for any molecular system with a negative charge, the calculation of electron affinity requires that basis set containing diffuse functions are used. Moving to ionization potentials, the performance of the various methods on 36 molecules from the G2/97 dataset, with the addition of PO₂, substantially replicates that found for electron affinities, although the MUE, between 5 and 6 kcal/mol, is slightly larger (Wang and Wilson 2004). The B1B95 MHGGA functional provided the best performance, with a MUE of 4.25 kcal/mol.

Moving to selected cases (see Table 7), the BP86 GGA functional seems quite more accurate than the HGGA B3LYP functional in predicting the electron affinity of highly unsaturated late transition metal M(CO)_n complexes, but the HGGA functional seems to be more accurate when the unsaturation at the metal is reduced (Zhou et al. 2001). These results exemplify the difficulty to extract trends from benchmarks, if the specific case at hand has not been included in the testing dataset.

Five: Atomization Energies

A benchmark study on 17 first-row closed-shell molecules indicated that in the calculation of the atomization energy with the Dunning correlation-consistent basis sets, the HGGA functionals, with a MUE of roughly 2.2 kcal/mol, outperform GGA functionals, such as BLYP (MUE = 7.2 kcal/mol), with BP86 performing particularly bad (MUE = 16.2 kcal/mol) (Wang and Wilson 2004). In another benchmark study on the atomization energy of a dataset composed by 109 main groups of organic and inorganic molecules, calculated with the MG3S basis set, HGGA functionals were again confirmed to perform well, with MUE smaller than 1.0 kcal/mol, while GGA functionals, such as the PBE, with a MUE of 3.0 kcal/mol, again performed poorly. The peak performance of 0.40 kcal/mol was produced with the B1B95 functional, while the classic B3LYP resulted in a MUE of 0.91 kcal/mol. Finally, HMGGA functionals were shown to perform similarly to HGGA functionals (Zhao and Truhlar 2005a). A set of range-corrected functionals, including the CAM-B3LYP, the LC- ω PBE, and the ω B97 family, also performed particularly well, with MUE between 0.51 and 0.89 kcal/mol (Peverati and Truhlar 2014). On the other hand, GGA functionals perform well when the atomization energy of 9 metal dimers in the TMAE9/05 database is calculated, with MUE in the range of 5–8 kcal/mol. HGGA functionals, instead, resulted in MUE around 15–30 kcal/mol, with only the B97-1, B97-2, and B98 functionals with MUE below 10 kcal/mol. MGGA and HMGGA functionals substantially replicate the results obtained with non-meta-functionals, although the M05 and M06 functionals result in the very low MUE of 6.9 and 4.7 kcal/mol, respectively (Zhao and Truhlar 2008b). These results are another indication that hybrid functionals usually perform better for molecules composed by main group atoms, whereas GGA and MGGA functionals perform better for transition metal chemistry.

Six: Heats of Formation

The accurate calculation of this property, even for rather simple molecular systems composed by main group atoms, still represents a challenge for several functionals. Indeed, the MUE on the heat of formation in a benchmark study on 24 molecules from the G2/97 dataset, with the addition of PO₂, spans the rather broad range of 10–30 kcal/mol, even if basis set of rather good quality, such as the 6-31++G* basis set, are used. Functionals to be avoided are those containing the P98 correlation term among the GGA, the B1LYP and the B98 among the MGGA, the PBEKICIS among the MGGA, and the BBIK among the HMGGA. On the other side, good performances were obtained with the PBELYP, PW91LYP, MPWPW91, and MPWPBE GGA functionals, the PBE1PBE and B3PW91 HGGA functionals, and finally the TPSS and the TPSSKICIS MGGA functionals. With these functionals, the MUE on the heats of formation usually is below 10 kcal/mol (Riley et al. 2007). Augmented correlation-consistent Dunning-type basis sets usually lead to slightly better performances. Nevertheless, some computational results have cast a shadow on the common procedure to test heats of formation on small molecules. Indeed, it has been shown that almost all the functionals, including the popular

B3LYP functional, are unable to predict correctly the heats of formation of *n*-alkanes (Curtiss et al. 1997, 2000). Due to the inability to describe properly long-range attractive dispersion interaction, practically all functionals introduce a systematic error in the calculation of the isodesmic stabilization energy (Eq. 4). This systematic error ranges between 0.90 kcal/mol for the HMGGGA MPWB1K functional and 1.82 kcal/mol for the OLYP functional. The BP86 and PBE GGA functionals result in an error of 1.25 and 1.08 kcal/mol, respectively, while the HGGA functional B3LYP results in an error of 1.33 kcal/mol. While these errors may seem to be not dramatic, they are per CH₂ unit, so that the errors are between 10 and 20 kcal/mol for a simple molecule such as *n*-decane (Wodrich et al. 2006).

Seven: Energy Barriers

The performance of a series of functionals was tested to reproduce the barrier height for a series of reactions. Starting from hydrogen transfer reactions, the forward and backward barrier for the following 3 reactions OH • + CH₄ → CH₃• + H₂O, OH • + H • → O (³P) + H₂, and H • + H₂S → HS • + H₂, which constitute the BH6 database (Lynch and Truhlar 2003), GGA functionals systematically underestimate the barriers, with a MUE between 7.8 and 9.4 kcal/mol. Better results were obtained with HGGA functionals, with MUE around 4.5–5.0 kcal/mol. The mPWPW91 MGGA functional is not a clear improvement, with a MUE of 8.5 kcal/mol, while HMGGGA functionals such as the mPW1PW91 and the MPW1K perform better, with MUE of 3.9 and 1.4 kcal/mol, respectively (Zhao et al. 2004). Testing the functional on the larger BH42/04 database, consisting of 42 transition-state barrier heights of hydrogen transfer reactions in mostly open-shell systems, gave substantially similar results (Zhao & Truhlar 2004). The HGGA functionals underestimate barriers by a MUE of roughly 4 kcal/mol, while HMGGGA functionals give better results, with peak performances from the BB1K, XB1K, and MPWB1K resulting in MUE around 1.2–1.3 kcal/mol. Similar conclusions are achieved when the HTBH38 database, which contains 38 transition-state barrier heights for 19 hydrogen transfer reactions, 18 of which involve radicals as reactant and product, is considered. In this case, 10 examined HGGA functionals result in an average MUE of 3.7 kcal/mol, while 7 range-corrected functionals slightly decrease this value to 2.7 kcal/mol (Peverati and Truhlar 2014). Moving to 38 transition-state barrier heights for non-hydrogen transfer reactions constituting the NHTBH38/04 database, and comprising 12 barrier heights for heavy-atom transfer reactions, 16 barrier heights for nucleophilic substitution reactions, and 10 barrier heights for non nucleophilic substitution unimolecular and association reactions, GGA functionals, such as the PBE, still approximate barriers severely, with a MUE of 8.64 kcal/mol. HGGA functionals, such as the B3LYP and the PBE1PBE functionals, perform better, although the MUE, around 4 kcal/mol, still is quite large (Zhao et al. 2005). MGGA functionals perform similarly to the GGA functionals, while the performance of HMGGGA is rather scattered. For example, the TPSSh and the MPW1KCIS functionals do not perform impressively, with MUE of 6.6 and

Table 8 Selected mean errors for HTBH38 and NHTBH38 database

Method		Hydrogen transfer	Heavy atom transfer	Nucleophilic substitution	Unimolecular and association
PBE	GGA	9.32	14.93	6.97	3.35
BLYP	GGA	7.52	14.66	8.40	3.51
B3LYP	HGGA	4.23	8.49	3.25	2.02
PBE1PBE	HGGA	4.22	6.62	2.05	2.16
TPSS	MGGA	7.71	14.65	7.75	4.04
TPSSK CIS	MGGA	4.69	9.26	4.88	2.12
TPSSh	HMGGA	5.97	11.51	5.78	3.23
BB1K	HMGGA	1.16	1.58	1.30	1.44

4.6 kcal/mol, respectively, while the MPW1K and the BB1K are very accurate, with MUE of 1.3 and 1.2 kcal/mol, respectively (Zhao and Truhlar 2005a). As for hydrogen transfer reactions, comparison between 7 range-separated functionals and 10 HGGA functionals indicated that the range-separated functionals, with an average MUE of 2.9 kcal/mol, perform slightly better than the HGGA functional, with an average MUE of 3.7 kcal/mol. However, the peak performance of the MPW1K and B97-3 HGGA functionals, with MUE around 1.5 kcal/mol, is not reached by any of the range-separated functionals, with a minimum MUE of 2.41 kcal/mol achieved by the ω B97 functional (Peverati and Truhlar 2014).

The breakdown of these cumulative MUEs for selected functionals is reported in Table 8. Clearly, the most problematic cases are the transfer reaction of both hydrogen and heavy atoms. With the exception of the BB1K, all the other functionals fail to a large and embarrassing extent. For the HTBH38 dataset, the M06 and M06-2X HMGGA functionals, with MUE of 2.00 and 1.13 kcal/mol, also perform well (Zhao and Truhlar 2005a). Barrier heights of nucleophilic substitutions are predicted better, although GGA functionals still result in a too large MUE. Finally, the barrier heights of unimolecular and association reactions are predicted with reasonable accuracy by all functionals. Again, the performance of the BB1K functional is extremely good for the four classes of reactions considered. Similarly good and well-balanced performances are also obtained with other HMGGA functionals such as the PW6BK and the MPWB1K functionals.

Similar extensive tests on another dataset, comprising the barrier height for 23 reactions of small systems with a radical transition state, also highlighted the good performances of the HMGGA BB1K functional, with a MUE of 1.05 kcal/mol, in predicting energy barriers. However, when the same functionals were tested on a dataset of 6 barrier heights of larger systems with a singlet transition state, the best performance was obtained with the simple HGGA B1LYP functional, with a MUE of 2.58 kcal/mol, and the performance of the B3LYP functional, with a MUE of 3.10 kcal/mol, was slightly worse, while all the HMGGA functionals tested, including the BB1K functional, resulted in MUE greater than 4 kcal/mol (Riley et al. 2007).

Eight: Bond Energies

The performance of several functionals to predict bond energies on a database of 21 metal–ligand bond energies, the MBL21/05 database (Schultz et al. 2005a), indicated that GGA functionals predict metal–ligand bond energies with a MUE between 6 and 12 kcal/mol, with the BLYP, PBE, and BP86 among the worst, and that performances can be quite better at the HGGA level, with MUE normally in the 5–7 kcal/mol range. MGGA and HMGGA functionals do not offer an improvement, as exemplified by the MUE of the TPSS and TPSSh functionals, 7.9 and 5.5 kcal/mol, respectively, and by the M06 functional, with a MUE of 5.4 kcal/mol (Zhao and Truhlar 2008b).

Taking again some selected binary carbonyl complexes of first-row transition metals as examples, the performance of various functionals in the prediction of the first bond dissociation energy is reported in Table 9. The first clean result is that the binding energy is strongly affected by the basis set quality, and a triple- ζ basis set yields binding energies that are roughly 3–4 kcal/mol lower. Focusing on the TZVP results, the GGA functionals examined consistently overestimate the CO binding energy in the three complexes by roughly 3–6 kcal/mol. The PBE1PBE HGGA functional performs like the GGA functionals examined, whereas the B3LYP, and particularly the B98 functional, is among the best performing functionals. Meta-functionals only offer a marginal improvement.

Nine: Hydrogen Bonding

Benchmarking various DFT methods to reproduce the H–bond interaction energy of ten systems composed by main group atoms revealed that HGGA functionals generally perform better than GGA functionals, with MUE around 0.5 kcal/mol, and the B3LYP functional among the best. GGA functionals, instead, result in

Table 10 H-bond interaction energy, in kcal/mol, of selected nucleic acid base pairs

Base pair	MP2/aug-cc-pVQZ	B3LYP/6-31G(d,p)	PW91/6-31G(d,p)
G:C Watson–Crick	−27.7	−25.5	−27.7
A:T Watson–Crick	−15.1	−12.3	−14.5
G:U Wobble	−15.7	−13.4	−14.8
U:U Calcutta	−9.6	−7.5	−8.7

MUE between 0.5 and 2.0 kcal/mol, with the BLYP, MPWPW91, and MPWPBE among the best performing (Riley et al. 2007). MGGA and HMGGA functionals perform close to the B3LYP functional. In all cases, the quality of the basis sets had a strong impact on the quality of the results, and at least a 6-31G(d,p) basis set should be used. Further tests were performed on a database consisting of the binding energies of 6 hydrogen bonding dimers, the HB6/04 database (Zhao and Truhlar 2005b). Also these tests indicated that the performance of GGA functionals is generally not very impressive, with MUE normally between 0.5 and 4 kcal/mol, with the exception of the very well-performing PBE functional, with a MUE of 0.25 kcal/mol only. On the average HGGGA performs better, with MUE between 0.3 and 1.0 kcal/mol, with the PBE1PBE functional, with a MUE of 0.27 kcal/mol, among the best, while the B3LYP functional, with a MUE of 0.87 kcal/mol, does not perform impressively. Meta-GGA and meta-HGGGA functionals are not a great improvement. These results have been achieved with the rather large aug-cc-pVTZ basis set, using the 6-31+G(d,p) basis set leading to slightly lower performances.

Extensive tests of the performance of the B3LYP and PW91 functionals in the case of H-bonded nucleic acid–base pairs indicated that the PW91 GGA functional replicates with better accuracy the MP2/aug-cc-pVQZ values than the B3LYP HGGGA functional (Sponer et al. 2004). The B3LYP calculations underestimate the interaction energies by few kcal/mol with relative error of 2.2 kcal/mol. Representative values for Watson–Crick (G–C, A–T) purine–pyrimidine (G–U) and pyrimidine–pyrimidine (U–U) pairs are presented in Table 10.

Ten: Weak Interactions

For a long time, one of the well-known failures of DFT was in the description of long-range dispersion forces, which are the glue that keeps together Van der Waals complexes and are at the basis of the well-known $\pi - \pi$ stacking interactions. Members of the former family are the rare-gas dimers that almost invariably are predicted to be unbound (or bound by effect of the basis set superposition error) by many GGA and HGGGA functionals. Indeed, an extensive benchmark on the WI4/04 datasets, composed by four rare-gas dimers (HeNe, NeNe, HeAr, and NeAr) indicated that the B3LYP functional simply does not predict a energy well for three out of the four dimers if the basis set superposition error is corrected by the counterpoise procedure and that even including the basis set superposition error the interaction energy is underestimated by 0.23 kcal/mol, and equilibrium distances are overestimated by more than 1 Å. On the other hand, HMGGA functionals were shown to reproduce with good accuracy both the interaction energy and the

equilibrium distance of these dimers, with MUE on the counterpoise-corrected binding energies below 0.05 kcal/mol by several functionals, such as the X1B95 and the MPWB1K, and with MUE on the equilibrium distances as low as 0.10 Å, which is a remarkable result for weakly interacting systems (Zhao and Truhlar 2004).

Enlarging the dataset to include also organic molecules, such as the C₆H₆-Ne, and the (C₂H₄)₂ and (CH₄)₂ dimers, indicated that standard GGA functionals systematically underestimate the interaction energy by a MUE of roughly 0.4–1.0 kcal/mol, with the exception of the PBE functional, with a MUE of 0.30 kcal/mol. MGGA functionals do not perform much better, while a small improvement is shown by HGGA functionals, with the best results from B97-1 with a MUE of 0.20 kcal/mol. HMGGA functionals do not offer better performances, although the largest MUE is reduced to 0.64 kcal/mol (Zhao and Truhlar 2005b). Finally, better performances were shown by the M05-2X and M06-2X functionals, with a MUE of only 0.03 and 0.09 kcal/mol, respectively, when applied to a dataset formed by the four rare-gas dimers above, C₆H₆ – Ne, CH₄ – Ne, and the (CH₄)₂ dimer. Surprisingly, on this reduced dataset, the well-performing B97-1 functional was not tested (Zhao and Truhlar 2005b).

Moving to π – π stacking interactions, the performance of a series of functionals was tested on the PPS5/05 database, which consists of binding energies of five π – π stacking complexes, namely, (C₂H₂)₂, (C₂H₄)₂, and sandwich, T-shaped, and parallel-displaced (C₆H₆)₂ (Zhao and Truhlar 2005a). Basically, all the functionals tested underestimated the binding energies in the PPS5/05 database, with MUE in the range of 1.0–3.8 kcal/mol. This is not a minor failure, since the average binding energy in the PPS5/05 dataset amounts to 2.02 kcal/mol only. The PBE GGA functional, with a MUE of 2.1 kcal/mol, performs better than the B3LYP HGGA functional, which results in a MUE of 3.2 kcal/mol. The best performances, slightly above 1 kcal/mol, are obtained with the PWB6K, PW6B95, and MPWB1K. A clear improvement is obtained with the M06-2X functional, with a MUE of 0.30 kcal/mol only. Reducing the amount of Hartree–Fock exchange deteriorates somewhat performances, as evidenced by the MUE of 0.60 kcal/mol yielded by the M06 functional (Zhao and Truhlar 2008b).

Focusing on π – π stacking interactions between nucleic acid bases, which are fundamental to describe properly the base–base stacking in nucleic acids, the popular B3LYP is simply unable to find a minimum corresponding to the A...T as well as the G...C base pairs in a stacked geometry. Of the six functionals tested, only the MPWB1K and the PWB6K functionals resulted in stable stacked base pairs, with an underestimation of the stacking energy of roughly 2–3 kcal/mol (Zhao & Truhlar 2005c).

Range-separated functionals, which were developed with the particular intent of describing properly the exchange term at long distances, offer a clear improvement over the performance of classic HGGA functionals on weak interacting systems. For example, when the performance of different families of functionals is compared through the NCCE31/05 database, which comprises the various databases described above, seven range-separated functionals, including the CAM-B3LYP, the LC- ω PBE, and the ω B97 functionals, with an average MUE of

0.61 kcal/mol, perform clearly better than 10 HGGA functionals, with a MUE of 0.92 kcal/mol. However, it is important to remark that on the same NCCE31/05 database, functionals fitted to reproduce non-covalent interactions, as the M06 functional, with a MUE of 0.41 kcal/mol, also perform remarkably well (Peeverati and Truhlar 2014).

As a final remark, we note that, based on an idea earlier proposed for Hartree–Fock calculations (Hepburn et al. 1975; Ahlrichs et al. 1977), the addition of an empirical $C_6 \cdot R^{-6}$ dispersion term represents a very simple cure to the failure of standard density functionals to predict dispersion interactions (Grimme 2006b). This approach is treated extensively in Chapter 12, so we do not discuss it here in details. We only remark the very good performance of a range-separated functional that also include an empirical dispersion term, such as the wB97X-D functional, on the NCCE31/05 database, with a MUE of only 0.32 kcal/mol.

Eleven: Spin States

The problem of a reliable prediction of the relative ordering of different spin states in transition metal complexes remains a tough challenge for DFT – not only for a quantitative judgment (energy separation between the different spin states) but even for a qualitatively assessment (correct prediction of the spin ground state). There is general consensus that GGA functionals overestimate the stability of low-spin states, whereas the inclusion of Hartree–Fock exchange in the HGGA functionals results in an overestimation of the stability of high spin states (Ghosh 2006; Swart 2008). This led to the development of the B3LYP* functional, in which the amount of the Hartree–Fock exchange is reduced from 20 % of the original B3LYP functional to 15 % (Reiher et al. 2001). Furthermore, it has been suggested that results obtained with Slater-type basis sets converge rapidly with the basis set size, while this convergence in case of Gaussian-type basis sets is much slower, and demanding basis sets like Dunning’s correlation-consistent basis are needed to achieve good results (Güell et al. 2008).

Besides the above general comment, benchmark tests of the different functionals in this case are often hampered by the problem of accurate reference data and by the problem that functionals that seem to behave properly for a metal or system simply fail if the system changes (Ghosh 2006). Focusing on Fe complexes, a benchmark study versus CASPT2 values (see Table 11) indicated that the OPBE functional performs definitely better than commonly used GGA and HGGA functionals. In a similar study, the performance of some DFT functionals to describe CASPT2 results for a series of five Fe complexes indicated that the OLYP functional performed remarkably well in these cases, whereas the success of the HGGA PBE1PBE, B3LYP, and B3LYP* functionals varied from case to case (Pierloot and Vancoillie 2008). Finally, another benchmark study, in which various properties of Fe_2 , Fe_2^- , and FeO^+ , as obtained from a series of GGA, HGGA, MGGA, and HMGGA functionals, were calculated, indicated that no single functional was found to yield a satisfactory description of all characteristics for all states of these species (Sorkin et al. 2008). These results clearly indicate that the spin-state problem still is an open challenge for DFT.

Table 11 Singlet–quintet splitting, $E_{\text{singlet}}-E_{\text{quintet}}$ in kcal/mol, for selected Fe complexes (Swart 2008)

	$\text{Fe}(\text{H}_2\text{O})_6^{2+}$	$\text{Fe}(\text{NH}_3)_6^{2+}$	$\text{Fe}(\text{bpy})_3^{2+}$	MAD

PBE1PBE	46.0	24.7	9.0	9.1
OPBE	49.3	19.0	-14.9	1.9

MAD mean absolute deviation

Twelve: Excited States

Testing the performance of several functionals in the TD-DFT prediction of 21 valence and 20 Rydberg excitation energies in N_2 , O_2 , HCOOH , and tetracene indicated that valence excitations are easier to predict than Rydberg excitation. Indeed, valence excitations were predicted by 15 functionals with a MUE of 0.36 eV, while Rydberg excitations were predicted with a MUE of 1.13 eV. Focusing on valence excitations, HMGGGA functionals such as TPSSh, B98, and B97-3 are the best performers, with MUE as small as 0.25 eV. Nevertheless, GGA and HGGA functionals, with a MUE of 0.32 and 0.28 eV for the PBE and B3LYP functionals, respectively, also perform reasonably well. Differently, for the accurate prediction of Rydberg excitations, a high amount of Hartree–Fock exchange, as in the M06-2X and M06-HF functionals, with MUE lower than 0.4 eV, is beneficial. With the exception of the also well-performing BMK functional, almost all the other functionals tested results in MUE greater than 0.78 eV, with the PBE and B3LYP functionals resulting in a MUE of 1.95 and 1.07 eV, respectively. When Rydberg and valence excitations are combined into a single database, the best average performance is of the M06-2X and BMK functionals, with a MUE around 0.35 eV (Zhao and Truhlar 2008b).

With regards to charge-transfer excitations, the performance of 16 functionals was tested in the prediction of three charge-transfer excitation energies in tetracene and in the $\text{NH}_3 \cdots \text{F}_2$ and $\text{C}_2\text{H}_4 \cdots \text{C}_2\text{F}_4$ complexes. The average MUE over the 16 functionals examined, 3.86 eV, is depressive. The only working functional is M06-HF, with a MUE of 0.09 eV. However, the inclusion of Hartree–Fock exchange is not the only reason for this surprisingly good performance, since simple HF and the HFLYP functional results in MUE around 1 eV. With the exception of the M05-2X and M06-2X, with a MUE around 2.5 eV, all the other functionals tested resulted in a MUE greater than 3 eV (Zhao and Truhlar 2008b). As a final note, it would be interesting to test the performance of the M06-HF on a larger database.

Moving to more complex organic molecules, the $\pi \rightarrow \pi^*$ transitions of more than 100 dyes from the major classes of chromophores have been investigated using a TD-DFT with the PBE, PBE1PBE, and long-range corrected hybrid functionals. The PBE1PBE and CAMB3LYP were shown to outperform all other approaches, with the latter functional especially adequate to treat molecules with delocalized

excited states. The PBE1PBE functional resulted in a MUE of 22 nm (0.14 eV) with no deviation exceeding 100 nm (0.50 eV), thus delivering reasonable estimates of the color of most organic dyes of practical or industrial interest. Long-range functionals allowed a better description of the low-lying excited-state energies than HGGA functionals, and linearly corrected long-range approaches yield an average error of 10 nm (Jacquemin et al. 2008).

An extended test of the performance of 41 functionals in the calculation of the electronic absorption spectra of Cu and Zn complexes by TD-DFT methods indicated that HGGA functionals outperform GGA functionals. In the case of the spin-unrestricted calculations on the Cu^{II}(thiosemicarbazonato) complex, the functional best performing in the reproduction of the experimental spectra and geometry was the B1LYP, while the B3LYP functional was ranked 8. This order was not replicated in case of the spin-restricted Zn^{II}(thiosemicarbazonato) complex, where the best functional was PBE1PBE, with the B3LYP ranked 10. In both cases, HGGA functionals did not offer an improvement. In almost all the cases, the calculations underestimated the experimental excitation energies (Holland and Green 2010). Nevertheless, it may be worth noting that the OPBE and the OBLYP functionals, which were shown to perform well in other cases, were not considered.

Orbitals in DFT

Since chemists long have used and continue to use orbitals as natural language to explain and rationalize the complex reality of molecules that define the realms of inorganic and organic chemistry, we conclude with a few remarks on orbitals obtained from density functional calculations.

Originally, chemists have built their understanding of orbitals on constructs that resulted from WFT analyses, and such an orbital is usually referred to as molecular orbital (MO). One important aspect of an MO analysis is the investigation of orbital overlap. A simplified wave function theory that emphasizes this particular feature of orbital interaction, the extended Hückel theory (EHT), has revolutionized the general perception of molecular structure and reaction mechanisms.

Since the Kohn–Sham orbitals, introduced and used in DFT, serve a different purpose than creating a reasonable single determinantal wave function Ψ , chemists were seeking answers to the question “what do the Kohn–Sham orbitals and eigenvalues mean?” as DFT moved into the spotlight of electronic structure theory. A simple answer was based on a comparison of orbitals of small molecules (H₂O, N₂, PdCl₄²⁻) obtained from WFT (Hartree–Fock, EHT) and DFT calculations: The shape and symmetry properties of the KS orbitals are very similar to those calculated by HF and EHT methods. The energy order of the occupied orbitals is in most cases in agreement between WFT and DFT methods. Overall, the KS orbitals are a good basis for qualitative interpretation of molecular orbitals (Stowasser and Hoffmann 1999). This simple conception of the meaning and the use of KS orbitals by now has gained general acceptance, and chemists often use KS orbitals in ways that are familiar to them from MO analysis.

Baerends and Gritsenko (1997) have provided an answer to the same question based on fundamental concepts of density functional theory. Among other aspects, the authors identify the following two important characteristics of KS orbitals:

1. The highest occupied Kohn–Sham orbital energy is equal to the exact first ionization energy. This is a property that is very desirable in qualitative MO theory in general and is often simply assumed in such theories.
2. The lowest unoccupied Kohn–Sham orbital energy and all other virtual orbital energies are solutions in exactly the same potential as the occupied orbitals. They are therefore not shifted toward higher energies in the same way as Hartree–Fock virtual orbitals are – HF orbital energy differences are not estimates of excitation energies. Further, it has been observed empirically for a long time that KS orbital energy differences are good approximations to excitation energies, and the KS orbital energy differences play a role as a first approximation to the excitation energy in the treatment of excitation energies using time-dependent DFT.

The authors therefore recommend KS orbitals and one-electron energies as tools in the traditional qualitative MO considerations on which much of the rationalizations of contemporary chemistry are based. The Kohn–Sham one-electron model and KS orbitals provide an ideal MO theoretical context to apply concepts such as “charge control” and “orbital control.” KS orbitals usually follow the expected behavior, in terms of bonding and antibonding character in terms of geometrical distortions and in terms of interaction with other atoms or molecules.

About 10 years later, Cramer and Truhlar (2009) presented a more conservative view of the use of KS orbitals. One should be careful not to stretch the interpretation of KS orbitals beyond its limits, since KS orbitals correspond to a fictitious noninteracting system with the same electron density as the correct many-body function. Since the density computed from KS orbitals is an approximation to the exact density, properties that depend on individual orbitals, with the exception of the energy of the highest occupied orbitals, should be interpreted with care. Nonetheless, many studies published in the literature do employ DFT molecular orbitals to interpret the electronic origins of chemical bonding and reactivity.

The quality of the KS orbitals depends to a large part on the ability of a chosen density functional to correctly represent the ground-state density of a given molecule. In most cases, different density functionals produce qualitatively identical orbitals, which also agree with WFT orbitals. For molecules that might possess a spin-polarized ground-state density, different methods of electronic structure calculation not only produce *quantitatively* different results but also lead to *qualitatively* contrastive conclusions. One such case is illustrated in Fig. 7.

Figure 7 Energies and shapes of the two highest occupied (red-blue) and the two lowest unoccupied (yellow-green) KS orbitals (contour envelope 0.05 a.u.) of $\text{Fe}(\text{S}_2\text{C}_2\text{H}_2)_2$ extracted from an unpolarized ground-state density according to GGA and HGGA DFT calculations. The molecule was constructed according to D_{2h} symmetry with a Fe–S bond length of 220 pm. Also shown for the sake of comparison are orbitals obtained from an extended Hückel calculation.

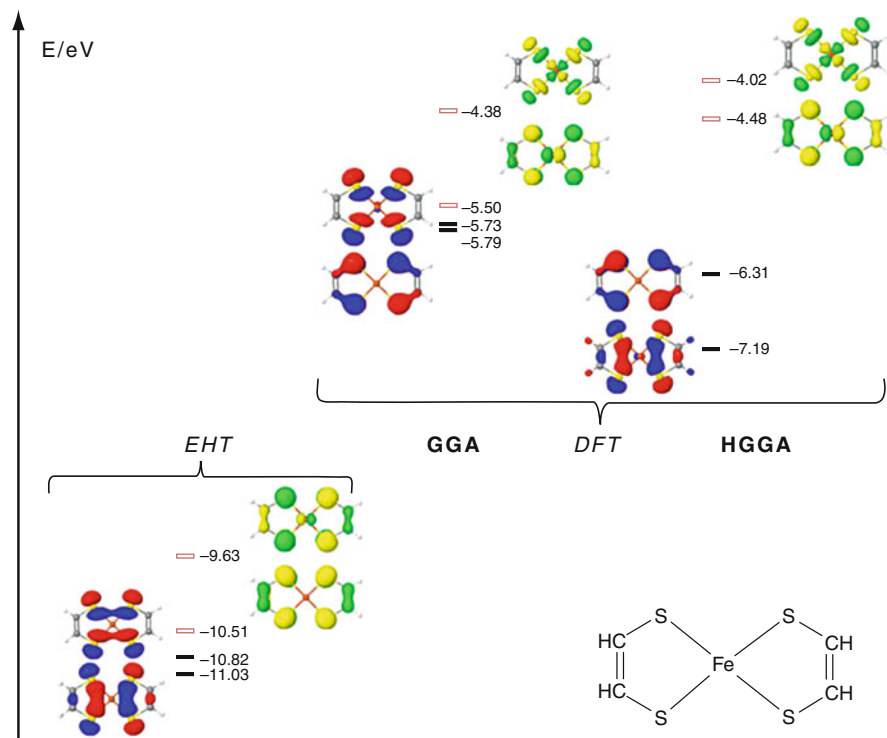

Fig. 7 Energies and shapes of the two highest occupied (*red-blue*) and the two lowest unoccupied (*yellow-green*) KS-orbitals (contour envelope: 0.05 a.u.) of $\text{Fe}(\text{S}_2\text{C}_2\text{H}_2)_2$ extracted from an unpolarized ground state density according to GGA and HGGA DFT calculations. The molecule was constructed according to D_{2h} symmetry with a Fe-S bond length of 220 pm. Also shown for the sake of comparison are orbitals obtained from an extended Hückel calculation

But the essential understanding of chemical orbitals itself is open to interpretation; Autschbach (2012) elaborates on the use and misuse of orbitals in quantum theory and chemistry. Naturally, KS orbitals play an essential role in this challenging controversy. We leave it to the reader to decide whether or not chemically meaningful information can be extracted from the orbital picture as displayed in Fig. 7.

DFTips

The advertent reader has noticed the many technical recommendations that we have given within the discussion of the twelve selected scenarios for properties of atoms and molecules. Here, we will close our instruction manual with a few pieces of general advice.

B3LYP Is No Synonym for DFT

Some researchers hold the opinion that given the fact that the B3LYP functional has been identified as the most successful DFT method in an overwhelming number of systematic investigations in very many areas of chemical research, there is no persuasive motivation to recommend its replacement by one of the other functionals. We do not agree with such a judgment. Although the B3LYP functional is largely responsible for DFT becoming one of the most popular tools in computational chemistry, it does have unsatisfactory performance issues, notably the unreliable results obtained for transition metal chemistry (Zhao and Truhlar 2008a). One should become aware of the capabilities and shortcomings of particular density functionals. It might well be that B3LYP is the proper approach to many chemical problems, but choosing a functional for its previous success while ignoring its potential failures cannot be the right strategy to approach DFT calculations.

Choose Your DFT Method Carefully

We agree with Burke's interpretation of "The good, the bad and the ugly": It is *good* to choose one functional of each kind and stick with it. It is *bad* to run several functionals and pick the "best" answer. And it is *ugly* to design your own functional with 2300 parameters.

In view of the many functionals available, it is likely that one will find a functional that fits one's own particular problems. In view of possibilities offered by computational programs that make it fairly easy to create new sets of parameterized hybrid functionals, it is almost certain that for each chemical problem, the right functional can be designed.

Following such an approach, density functional calculations lose their generality and meaning. One should aim for consistency within one's calculations, rather than for the best agreement with experiment. If one choose a particular functional for its characteristics and capabilities, the results of DFT calculations gain a predictive quality.

Read the Fine Print

During the early days of HGGA development, it became clear that B3LYP is not B3LYP (Hertwig and Koch 1997). Different programs based their implementation of the B3LYP functional on different models of the underlying LDA and produced slightly different results for the same chemical problem. The same considerations apply to the gradient corrections for correlation; P86 requires a different choice of LDA than LYP. Some computer programs automatically make the right choice, while other programs rely on correct input instructions given by the user.

Familiarize yourself with the default values and basic implementations of your favorite DFT code. Default values are chosen with much consideration and, most of the time, are just adequate. However, for subtle problems, you might find it necessary, for example, to change the accuracy of the numerical integration routines.

DFT Does Not Hold the Universal Answer to All Chemical Problems

You can expect that not all of your DFT calculations will produce satisfying results. An increasing number of problem molecules are currently identified for which standard density functionals fail to produce satisfactory results. Seemingly simple stereoelectronic effects in alkane isomers provided a serious challenge for many standard functionals, such as B3LYP, BLYP, or PBE (Grimme 2006c). However, such failures are not bad news for DFT but rather good news. The origin of the dissatisfying DFT performance has been carefully analyzed and led to the design of improved functionals (Zhao et al. 2006). Be honest with your DFT results and accept apparent failures – it might be just another small step climbing Jacob's ladder.

Make DFT an Integral Part of Your Work

Although in some areas of chemical research DFT is at the verge of becoming a standard research tool, necessary for the complete characterization of new molecules, not every chemical problem warrants a full-fledged DFT investigation. However, if you structure your computational approach beginning with an elaboration of qualitative aspects before addressing a problem in a quantitative way, a few quick DFT calculations might provide you with valuable insights how to further pursue your line of work.

Follow Your Interests

As final advice we will leave you with the words of Nobel Prize laureate Harold Kroto: Do something which interests you or which you enjoy, and do it to the absolute best of your ability. If it interests you, however mundane it might seem on the surface, still explore it because something unexpected often turns up just when you least expect it.

We hope that our work could satisfy some old interests as well as perk some new interests. We wish that our short instruction manual serves as a valuable guide for the perplexed and provides some food for thought for the enlightened, be it in agreement or in disagreement. If you follow your interests, keep an open mind, and maintain a broad perspective, good things will happen.

Bibliography

The literature on DFT is large and rich in excellent reviews and overviews. At the same time, while thousands of papers on DFT have been published, most of them will become out of date in the future, as the picture and perception of DFT, chemistry, and science in general is in a state of constant flux. It was necessary to make a conscious selection that of course is not unbiased – some references represent the most recent developments in DFT, while others have been part of our DFT folder for a long time. The reader will find references to books, review articles, and articles that illustrate developments and applications of DFT.

Abstract

This chapter provides a concise introduction to quantum chemical response theory as implemented in a number of widely used electronic structure software packages. While avoiding technical derivations of response functions, the fundamental idea of response theory, namely, the calculation of field-induced molecular properties through changes in expectation values, is explained in a manner equally valid for approximate wave function and density functional theories. Contrasting response theory to textbook treatments of perturbation theory, key computational concepts such as iterative solution of response equations and the identification and calculation of electronic excitation energies are elucidated. The wealth of information that can be extracted from approximate linear, quadratic, and higher-order response functions is discussed on the basis of the corresponding exact response functions. Static response functions and

e-mail: thomas.b.pedersen@gmail.com

their identification and numerical calculation as energy derivatives are discussed separately. Practical issues related to the lack of gauge and origin invariance in approximate calculations are discussed without going into too much theoretical detail regarding the sources of these problems. Finally, the effects of nuclear motion (molecular vibrations, in particular) and how to include them in computational studies are treated in some detail.

Introduction

The ultimate vision of computational chemistry is to provide a virtual laboratory for chemical explorations. The goal is not to replace but rather complement the real lab. In the virtual lab, it is easy to change “experimental” conditions and to experiment with hypothetical what-if scenarios. Virtual synthesis of chemical compounds can be done with a few mouse clicks, whereas the virtual measurement of physical and chemical properties is the often burdensome task of a computational engine based on the laws of classical and/or quantum physics. Most research efforts, therefore, are aimed at improving the algorithms and approximations implemented in the computational engines. The main role of quantum chemical response theory, which is the subject of this chapter, is the virtual measurement of optical properties of molecules.

The scope of this chapter is to provide a rudimentary understanding of response theory as implemented in a number of molecular electronic structure packages based on wave function models or density functional theory. Only the general structure of response theory and its computer implementation are discussed, leaving out the often complicated details of advanced wave function and density functional models. For these details the reader is referred to the literature mentioned in the last section and references therein. Although the discussion of this chapter is restricted to nonrelativistic theory, it is the same line of reasoning that is applied in relativistic response theory. In conjunction with the chapter on applications of response theory, the reader should become sufficiently familiar with the concepts and practices of response theory to allow educated use of quantum chemistry software packages.

As the name indicates, response theory describes the response of a molecular system to external potentials such as electromagnetic fields. The meaning of *external* depends on the definition of the molecular system. For example, the magnetic field due to nuclear spins would typically be considered an external potential. The fundamental assumption is that the external potentials are weak compared to the internal potentials of the molecule. That is, the external potentials can be regarded as perturbations of the isolated molecule. This assumption can be justified by noting that the electric field strength in the hydrogen atom is on the order of 10^{11} Vm^{-1} , which is well above the external field strengths applied in almost all experimental setups. Experimental observations are then rationalized by means of response functions, which may be expressed entirely in terms of states and energies of the unperturbed (isolated) molecule. Response functions are thus characteristic properties of a molecule. The objective of quantum chemical response theory is the computation of response functions from first principles.

Response functions quantify the field-induced change in a given observable such as the electric dipole moment. It is therefore necessary to know the state of the molecule before the field is applied. This unperturbed state is normally taken to be the molecular ground state, which is usually assumed to be nondegenerate. Calculation of the molecular ground state is, however, a daunting task and approximations are invoked in practice. We will use the clamped-nucleus Born–Oppenheimer approximation to separate the electronic degrees of freedom from the nuclear ones. Focusing on the response of the electronic ground state, the coupling between the nuclei and the external field is neglected. This is justified for field frequencies much larger than vibrational and rotational frequencies.

The electronic ground state $|0\rangle$ is computed as an approximate solution to the time-independent Schrödinger equation, that is,

$$H_0 |0\rangle \approx E_0 |0\rangle \quad (1)$$

where H_0 is the electronic Hamiltonian (see below) and E_0 is the ground state energy in the absence of external fields. The approximate solution (energy and wave function or density) can be obtained using standard methods such as density functional theory (DFT), Hartree–Fock (HF) theory, multiconfigurational self-consistent field (MCSCF) theory, configuration interaction (CI), or coupled cluster (CC) theory. For fixed nuclear positions (clamped-nucleus approximation), the electronic Hamiltonian is given by

$$H_0 = \frac{1}{2m_e} \sum_{s=1}^{N_e} (\mathbf{p}^s)^2 - \sum_{s=1}^{N_e} \sum_{K=1}^{N_n} \frac{e^2 Z_K}{4\pi\epsilon_0 |\mathbf{r}^s - \mathbf{R}^K|} + \sum_{K=2}^{N_n} \sum_{L=1}^{K-1} \frac{e^2 Z_K Z_L}{4\pi\epsilon_0 |\mathbf{R}^K - \mathbf{R}^L|} + \sum_{s=2}^{N_e} \sum_{t=1}^{s-1} \frac{e^2}{4\pi\epsilon_0 |\mathbf{r}^s - \mathbf{r}^t|} \quad (2)$$

Here, N_e is the number of electrons, N_n is the number of nuclei, m_e is the mass of the electron, e is the elementary charge, ϵ_0 is the vacuum permittivity, \mathbf{r}^s and \mathbf{p}^s are the position and momentum operators of electron s , and \mathbf{R}^K and Z_K are the position and atomic number of nucleus K . Starting from the Schrödinger equation (Eq. 1), relativistic effects as described by the Breit–Pauli Hamiltonian can be treated as perturbations on an equal footing with external fields. Effects of nuclear motion (vibrations and rotations) can be estimated once the electronic response functions have been calculated.

Response functions are functions of the frequencies of the external fields, and although response theory is based on time-dependent perturbation theory, it is more appropriate to describe response theory as frequency dependent rather than time dependent. Nevertheless, response theory for approximate quantum chemical models is sometimes referred to as time dependent, for example, time-dependent DFT (TDDFT) and time-dependent HF (TDHF) theory. Related by Fourier transformation, the time and frequency domains are two sides of the same coin. In practice, however, response functions are computed for a limited number of perturbation frequencies without any explicit reference to the time evolution of the quantum state.

Response Theory

Approximate wave function and density functional theories provide information about the electronic structure of molecules in their electronic ground state. The information includes the electronic charge density, total energy, electric multipole moments (dipole, quadrupole, octupole, etc.), forces on the nuclei, and vibrational frequencies, which is sufficient to model a wide range of chemical phenomena. For example, equilibrium structures and transition states can be calculated from the forces, and vibrational frequencies are not only useful for the interpretation of vibrational spectra but also enable the calculation of thermochemical data from first principles. These theories are sufficient to model experimental conditions where only the electronic ground state is significantly populated.

When a molecule is subjected to external fields, however, quantum mechanics tells us that the electronic ground state responds by becoming a superposition of many electronic states. Response theory takes this wave function change into account and thus facilitates calculations of molecular properties beyond the reach of the ground state theory. Computation of the ground state response allows extraction of information about transitions from the ground state to excited states induced by one or more photons and even allows us to calculate properties of the excited states without explicitly computing the excited state wave functions.

Response theory describes the change in observable quantities such as electric and magnetic multipole moments due to external fields. The starting point of response theory therefore is the time evolution of the expectation value $\langle A \rangle$ of a Hermitian operator A representing the observable quantity (e.g., the electric or magnetic dipole moment). In order to monitor the change in an observable quantity, we need to know the state of the molecule before the external field is switched on. As mentioned above, the electronic ground state $|0\rangle$ is the proper choice under most experimental conditions. With this initial condition, the time evolution can be written as the perturbation expansion

$$\begin{aligned}
 \langle A \rangle &= \langle 0 | A | 0 \rangle \\
 &+ \int_{-\infty}^{\infty} \langle \langle A; V(\omega) \rangle \rangle_{\omega} \exp(-i\omega t) d\omega \\
 &+ \frac{1}{2} \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} \langle \langle A; V(\omega), V(\omega') \rangle \rangle_{\omega, \omega'} \exp(-i(\omega + \omega')t) d\omega d\omega' \\
 &+ \dots
 \end{aligned} \tag{3}$$

where the operator $V(\omega)$ describes the interaction between the electrons and the external field of frequency ω . It should be noted that the perturbation expansion cannot generally be guaranteed to converge. Moreover, the perturbation expansion does not make sense when the external potential is comparable to or larger than the internal potential of the molecule. In most cases of practical interest, including the interaction of molecular electrons with laser fields, the perturbation expansion may be used.

Frequency-dependent response functions can only be computed within approximate electronic structure models that allow definition of the time-dependent expectation value. Hence, frequency-dependent response functions are not defined for approximate methods that provide an energy but no wave function. Such methods include Møller–Plesset (MP) perturbation theory, multiconfigurational second-order perturbation theory (CASPT2), and coupled cluster singles and doubles with noniterative perturbative triples [CCSD(T)]. As we shall see later, it is possible to derive static response functions for such methods.

Common methods that do allow calculation of frequency-dependent response functions include DFT, HF, MCSCF, and members of the CC hierarchy of wave functions (CCSD(T) is not a member of this hierarchy, as it does not provide a wave function). In these models, the wave function (or density in the case of DFT) is written in terms of time-dependent parameters which are determined from the time-dependent Schrödinger equation with the initial condition that the approximate ground state wave function (or density) is recovered in the limit ($t \rightarrow -\infty$), that is, before the external fields are switched on. The zeroth-order parameters are thus determined in the same way as in the ground state model, and response theory calculations are naturally performed on top of a standard ground state calculation. First-, second-, and higher-order parameters are determined from response equations that take into account the coupling with the external field in a manner consistent with the time-dependent Schrödinger equation. The response equations have the general matrix form (the detailed form of these matrices and vectors depends on the approximate theory used)

$$[\mathcal{H} - \omega\mathcal{S}] \lambda^{(n)}(\omega) = -\mathcal{V}^{(n)}(\omega) \quad (4)$$

where $\lambda^{(n)}(\omega)$, the unknown quantity in this equation, is a vector containing the n th-order ($n > 0$) wave function parameters in a suitable order. While the matrices \mathcal{H} and \mathcal{S} only depend on the unperturbed ground state wave function, the vector on the right-hand side additionally depends on the lower-order wave function parameters ($\lambda^{(1)}, \lambda^{(2)}, \lambda^{(3)}, \dots, \lambda^{(n-1)}$) as well as on one or more perturbation operators $V(\omega)$. This implies that the solution of the first-order equations must be known before the second-order equations can be solved, and so on. The frequency ω represents the sum of the frequencies corresponding to the perturbations included in the vector on the right-hand side of Eq. 4.

Solving the response equations (Eq. 4) is formally simple, namely,

$$\lambda^{(n)}(\omega) = -[\mathcal{H} - \omega\mathcal{S}]^{-1} \mathcal{V}^{(n)}(\omega) \quad (5)$$

where we assume that the matrix $[\mathcal{H} - \omega\mathcal{S}]$ is nonsingular. Those frequencies ω for which the matrix is singular have a special significance, as will be discussed below. Since the matrices \mathcal{H} and \mathcal{S} only depend on the ground state wave function or density, they may in principle be computed once and for all. For each frequency and right-hand side vector we may then calculate the inverse $[\mathcal{H} - \omega\mathcal{S}]^{-1}$ followed by a simple matrix–vector multiplication to obtain the response parameters according to

Eq. 5. Unfortunately, this simple solution strategy is too computationally demanding to be useful in practice. The large number of matrix elements in \mathcal{H} and \mathcal{S} makes it expensive to compute the matrices and to compute the inverse which, in addition, needs to be done for each frequency ω . The number of matrix elements is given by the square of the number of ground state wave function parameters. For DFT or HF, for example, the number of ground state parameters is given by OV where O and V are the number of occupied and virtual (Kohn–Sham or HF) orbitals, respectively. For the more complicated coupled cluster singles and doubles (CCSD) wave function, the number of ground state wave function parameters is roughly $O^2V^2/2$. To get an impression of the orders of magnitude, consider a simple benzene molecule with the aug-cc-pVDZ basis set. In this case, there are approximately 3,600 DFT or HF ground state parameters and over six million CCSD parameters. The number of elements in the \mathcal{H} and \mathcal{S} matrices would therefore be approximately 13 million for DFT and HF and 36×10^{12} for CCSD. For two benzene molecules, these numbers would increase to approximately 207 million matrix elements for DFT and HF and 10^{16} for CCSD. Just storing the matrices in computer memory would quickly pose an insurmountable problem, and a different solution strategy is needed.

Rather than straightforward application of Eq. 5, the response equations (Eq. 4) are solved in an iterative procedure in which the matrices and vectors are projected onto a small subspace. In this procedure, an initial guess (a trial vector) is generated according to Eq. 5 by neglecting all off-diagonal elements of \mathcal{H} and \mathcal{S} such that the inverse matrix $[\mathcal{H} - \omega\mathcal{S}]^{-1}$ is readily computed. The iterations proceed by refining the trial vector until the norm of the residual vector

$$\mathbf{R} = (\mathcal{H} - \omega\mathcal{S})\lambda^{(n)} + \mathcal{V}^{(n)} \quad (6)$$

falls below a specified tolerance. Although quantum chemistry software packages provide reasonable default values for the tolerance, it may occasionally be necessary to lower the value to obtain sufficient accuracy in the computed response functions.

From the perturbative corrections to the wave function parameters we obtain perturbative corrections to the expectation value of the operator A , that is,

$$\langle A \rangle = \langle A \rangle^{(0)} + \langle A \rangle^{(1)} + \langle A \rangle^{(2)} + \dots \quad (7)$$

We may then identify response functions for each of the approximate electronic structure models by comparing with Eq. 3:

$$\langle A \rangle^{(0)} = \langle 0 | A | 0 \rangle \quad (8)$$

$$\langle A \rangle^{(1)} = \int_{-\infty}^{\infty} \langle \langle A; V(\omega) \rangle \rangle_{\omega} \exp(-i\omega t) d\omega \quad (9)$$

$$\begin{aligned} \langle A \rangle^{(2)} &= \frac{1}{2} \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} \langle\langle A; V(\omega), V(\omega') \rangle\rangle_{\omega, \omega'} \exp(-i(\omega + \omega')t) d\omega d\omega' \\ &\vdots \end{aligned} \quad (10)$$

Response theory deviates in one crucial aspect from the formulation of time-dependent perturbation theory in most textbooks on quantum mechanics: the response parameters $\lambda^{(n)}$ are not explicitly expressed in terms of the excited states. As a consequence, knowledge of the excited state wave functions is not needed in response theory. Instead, we must solve the response equations (Eq. 4) for each set of perturbation operators $V(\omega)$. This is a tremendous computational advantage as there are significantly fewer perturbation operators, and hence response equations to solve, than excited states in virtually all cases of practical interest.

In order to illuminate the wealth of information that can be extracted from response functions for approximate wave functions, it is instructive to study the details of the exact response functions expressed in terms of electronic excited states.

The Linear Response Function

The linear response function describing the first-order induced electric dipole moment due to an oscillating and spatially uniform electric field is related to the frequency-dependent electric dipole polarizability as

$$\alpha_{ij}(-\omega; \omega) = -\langle\langle \mu_i; \mu_j \rangle\rangle_{\omega} \quad (11)$$

The i th Cartesian component of the electronic electric dipole operator is given by

$$\mu_i = -e \sum_s r_i^s \quad (12)$$

where the sum is over all electrons in the molecule. This identification is obtained by substituting $A \rightarrow \mu_i$ and $V(\omega) \rightarrow -\mu \cdot \mathbf{F}(\omega)$ in Eq. 3. The uniform electric field amplitude vector at frequency ω is here represented by $\mathbf{F}(\omega)$. In an approximate calculation, the electric dipole polarizability is thus obtained by computing (minus) the linear response function from first-order wave function parameters determined by Eq. 4 with the three Cartesian components of the electric dipole operator as perturbation operators. Note that the response equations must be solved for each frequency.

More information can be extracted from the linear response function, however. This is most easily seen by studying the exact linear response function. Unlike the approximate theories, the exact linear response function is expressed in terms of the ground and excited states satisfying the time-independent Schrödinger equation

$$H_0 |k\rangle = E_k |k\rangle \quad (13)$$

where $k \geq 0$ and H_0 is the molecular electronic Hamiltonian in the clamped-nucleus Born–Oppenheimer approximation, Eq. 2. The exact linear response function is given by

$$\langle\langle A; B \rangle\rangle_\omega = \frac{1}{\hbar} \sum_{k \neq 0} \left(\frac{\langle 0 | A | k \rangle \langle k | B | 0 \rangle}{\omega - \omega_{k0}} - \frac{\langle 0 | B | k \rangle \langle k | A | 0 \rangle}{\omega + \omega_{k0}} \right) \quad (14)$$

where $\hbar\omega_{k0} = E_k - E_0$ is the excitation energy for the transition from the ground state to the k th excited state. This formulation of the linear response function is often referred to as the sum-over-states expression or spectral resolution.

The exact linear response function is singular at the molecular excitation energies, that is, it has poles at $\omega = \pm\omega_{k0}$. This is exploited in approximate theories to identify excitation energies as those frequencies for which the approximate linear response function is singular. In principle, the search for excitation energies could be done by scanning over frequencies in a manner analogous to measurements of absorption spectra. In practice, however, it is straightforward to identify the poles of the approximate linear response function as the frequencies for which the response equations (Eq. 4) are singular. As discussed above, this occurs at frequencies where the matrix $\mathcal{H} - \omega\mathcal{S}$ cannot be inverted. This, in turn, occurs when ω equals one of the eigenvalues w_n of the generalized eigenvalue problem

$$(\mathcal{H} - w_n\mathcal{S}) \mathbf{V}_n = 0 \quad (15)$$

where \mathbf{V}_n is the eigenvector corresponding to the eigenvalue w_n . The generalized eigenvalue problem does not depend on the perturbation, and it can therefore be solved to directly obtain the excitation energies, identifying $\omega_{k0} = w_k, k = 1, 2, 3, \dots$, without explicit calculation of neither the excited state wave functions nor their energies. The eigenvectors \mathbf{V}_n are the closest we get to an explicit wave function representation of the excited states in response theory. In practice, therefore, analysis of these eigenvectors is used to extract the (approximate) orbital nature of an excitation, for example, as a $\pi - \pi^*$ orbital transition. Since we know the ground state energy E_0 from the prerequisite unperturbed calculation, the excited state energy may be deduced from the excitation energy as

$$E_k = E_0 + \hbar\omega_{k0} \quad (16)$$

Solving the eigenvalue problem, Eq. 15, does not necessarily yield all excited states. With a spin-adapted wave function, only excited states with the proper spin symmetry would be produced. For example, only spin-singlet excited states can be found with a spin-singlet wave function parameterization. Triplet states require a suitable spin-triplet adaptation of the wave function response. In unrestricted

theories, the ground and excited states need not be spin eigenfunctions and the labeling of states as spin-singlet, spin-triplet, etc., is not well defined.

It is important to realize, however, that the number of eigenvalues w_n equals the number of excited states within a given approximate theory. Calculation of all eigenvalues is very computationally demanding. The number of excited states in an approximate theory equals the number of ground state wave function parameters, which grows quickly with the size of the molecule, as discussed above. One would most often be interested in just a few, typically on the order of 10, of the lowest excitation energies. Iterative techniques have been devised that allow the solution of Eq. 15 for a given number of eigenvalues and eigenvectors in ascending order. In order to calculate the excitation energy ω_{k0} , it is therefore necessary to compute all excitation energies below this one as well, that is, $\omega_{10}, \omega_{20}, \omega_{30}, \dots, \omega_{k-1,0}$.¹ The iterative solution of the generalized eigenvalue problem Eq. 15 is carried out by refining trial vectors and eigenvalues until the norm of the residuals

$$\mathbf{R}_n = (\mathcal{H} - w_n \mathcal{S}) \mathbf{V}_n \quad (17)$$

falls below a given tolerance.

Another important piece of information can be extracted from the pole structure of the linear response function. The residue of the linear response function at an excitation energy provides the one-photon transition strength:

$$\langle 0 | A | k \rangle \langle k | B | 0 \rangle = \lim_{\omega \rightarrow \omega_{k0}} \hbar (\omega - \omega_{k0}) \langle \langle A; B \rangle \rangle_{\omega} \quad (18)$$

This observation allows us to identify transition moments between the ground state and the k th excited state, $\langle 0 | A | k \rangle$, in approximate theories by computing the residue of the linear response function at the k th excitation energy. Again, this is achieved without explicitly computing the excited state wave function. In practice, the transition moment is expressed in terms of the k th eigenvector of Eq. 15 and the matrix representation of the operator A in the molecular orbital (or spin orbital) basis. It is therefore possible, in principle, to compute the linear response function for an approximate wave function using the sum-over-states expression with excitation energies calculated according to Eq. 15 and transition moments from Eq. 18. If all excitation energies and residues are included, the result is identical to the response function computed from the response equations (Eq. 4). From a computational point of view, of course, this approach is not advisable unless the combined number of perturbation operators and frequencies is larger than the number of excited states. This is practically never the case.

¹Although techniques exist which solve an eigenvalue equation around a specific energy, these techniques are not used for quantum chemical calculations of excitation energies, as the energy range is rarely known in advance.

Within approximate wave function or density functional theories, it thus becomes possible to calculate one-photon absorption intensities such as the electric dipole oscillator strength of a transition from the ground state to the k th excited state from the following residue of the frequency-dependent electric dipole polarizability:

$$\begin{aligned} f_{k0} &= \frac{2m_e}{3e^2\hbar} \omega_{k0} \langle 0 | \mu | k \rangle \cdot \langle k | \mu | 0 \rangle \\ &= \frac{2m_e}{3e^2\hbar} \omega_{k0} \sum_i \lim_{\omega \rightarrow \omega_{k0}} \hbar (\omega - \omega_{k0}) \alpha_{ii}(-\omega; \omega) \end{aligned} \quad (19)$$

where m_e is the mass of the electron.

In approximate theories, the iterative solution of the response equations (Eq. 4) becomes difficult and may even fail to converge when the frequency is too close to one of the excitation energies. As a consequence, linear response functions should only be calculated in transparent spectral regions. In absorptive spectral regions (“close” to an excitation energy), so-called anomalous dispersion is observed experimentally. Anomalous dispersion can be understood theoretically by taking into account the finite lifetime of the excited electronic states, leading to damped response theory. The exact damped linear response function is given by

$$\langle\langle A; B \rangle\rangle_\omega = \frac{1}{\hbar} \sum_{k \neq 0} \left(\frac{\langle 0 | A | k \rangle \langle k | B | 0 \rangle}{\omega - \omega_{k0} + i\Gamma_k/2} - \frac{\langle 0 | B | k \rangle \langle k | A | 0 \rangle}{\omega + \omega_{k0} - i\Gamma_k/2} \right) \quad (20)$$

The broadening Γ_k is proportional to the probability of the excited state $|k\rangle$ decaying into any of the other states, and it is related to the lifetime of the excited state as $\tau_k = 1/\Gamma_k$. For $\Gamma_k = 0$, the lifetime is infinite and Eq. 14 is recovered from Eq. 20. Unfortunately, it is not possible to account for the finite lifetime of each individual excited state in approximate theories based on the response equations (Eq. 4). We would be forced to use a sum-over-states expression, which is computationally intractable. Moreover, the lifetimes cannot be adequately determined within a semiclassical radiation theory as employed here and a fully quantized description of the electromagnetic field is required. In addition, all decay mechanisms would have to be taken into account, for example, radiative decay, thermal excitations, and collision-induced transitions. Damped response theory for approximate electronic wave functions is therefore based on two simplifying assumptions: (1) all broadening parameters are assumed to be identical, $\Gamma_1 = \Gamma_2 = \dots = \Gamma$, and (2) the value of Γ is treated as an empirical parameter. With a single empirical broadening parameter, the response equations take the same form as in Eq. 4 with the substitution $\omega \rightarrow \omega + i\Gamma/2$, and the damped linear response function can be calculated from first-order wave function parameters, which are now inherently complex. For absorption spectra, this leads to a Lorentzian line-shape function which is identical for all transitions.

Figure 1 shows the damped linear response function calculated from the real part of Eq. 20 with different values of the broadening. Only a section of the frequency

Fig. 1 The damped linear response function computed from the real part of Eq. 20 with the indicated values of the broadening Γ (corresponding to 0, 250, 500, 1,000, and 2,000 cm^{-1}). Electric dipole transition moments and excitation energies were obtained using CCSD for the hydrogen molecule with the aug-cc-pVDZ basis set

spectrum around the lowest excitation energy is shown. With infinite lifetime ($\Gamma = 0$), the linear response function goes to $\pm\infty$ as the frequency approaches the excitation. This is avoided when the finite lifetime ($\Gamma > 0$) is taken into account. In the absorptive region, the behavior of the damped linear response function depends strongly on the value of the broadening. Since the broadening parameter can be chosen freely, the results obtained in this region must be treated with great care: changing the value of the broadening could give a very different result. Sufficiently far from the excitation energy, on the other hand, the effect of the broadening is small and can be neglected. In the transparent region, we may therefore safely use the undamped linear response function.

A long list of molecular electromagnetic properties can be obtained by inserting suitable operators in the linear response function. The electric dipole polarizability is an important example. To further illustrate the procedure of obtaining molecular properties from linear response functions, we now consider the induced electric dipole moment due to higher-order multipole components of the electromagnetic field. The induced electric dipole moment due to a time-dependent uniform magnetic field is, to first order in the field, given by the electric dipole – magnetic dipole polarizability

$$G'_{ij}(-\omega; \omega) = -\text{Im}\langle\langle \mu_i; m_j \rangle\rangle_{\omega} \quad (21)$$

where the j th Cartesian component of the magnetic dipole operator is defined as

$$m_j = -\frac{e}{2m_e} \sum_s L_j^s \quad (22)$$

with the angular momentum operator of electron s given by $\mathbf{L}^s = \mathbf{r}^s \times \mathbf{p}^s$. This identification is obtained from Eq. 3 by substituting $A \rightarrow \mu_i$ and $V(\omega) \rightarrow -\mathbf{m} \cdot \mathbf{B}(\omega)$, where $\mathbf{B}(\omega)$ is the magnetic field amplitude at frequency ω . Using multipole expansions of the electric and magnetic fields, the Maxwell equations show that a time-dependent uniform magnetic field is always accompanied by a quadrupolar electric field, and the contribution to the induced dipole moment from the electric dipole – electric quadrupole polarizability

$$a_{i,jk}(-\omega; \omega) = -\langle\langle \mu_i; q_{jk} \rangle\rangle_{\omega} \quad (23)$$

is of the same order of magnitude as \mathbf{G}' . Here, $q_{jk} = -e \sum_s r_j^s r_k^s$ is the j, k component of the Cartesian electric quadrupole moment operator. The electric dipole – magnetic dipole and electric dipole – electric quadrupole polarizabilities govern the optical rotation of chiral molecules. For samples of randomly oriented molecules, the contribution from the electric dipole – electric quadrupole polarizability averages to zero, and only the trace (the sum of the diagonal elements) of the electric dipole – magnetic dipole polarizability contributes to the optical rotation. The frequency-dependence of the linear response functions gives rise to optical rotation dispersion. The residues of the electric dipole – magnetic dipole polarizability are related to the rotatory strength

$$R_{k0} = \text{Im}[\langle 0 | \mu | k \rangle \cdot \langle k | \mathbf{m} | 0 \rangle] = -\sum_i \lim_{\omega \rightarrow \omega_{k0}} \hbar(\omega - \omega_{k0}) G'_{ii}(-\omega; \omega) \quad (24)$$

which determines the differential intensity of electronic circular dichroism spectra. If the molecules are oriented, the rotatory strength is a tensor (since the intensity will depend on the orientation of the molecule relative to the propagation direction of the photon) that also includes contributions from the residues of the electric dipole – electric quadrupole polarizability.

Finally, we note that the linear response function satisfies the permutation and conjugation relations

$$\langle\langle A; B \rangle\rangle_{\omega} = \langle\langle B; A \rangle\rangle_{-\omega} \quad (25)$$

$$\langle\langle A; B \rangle\rangle_{\omega}^* = \langle\langle A^{\dagger}; B^{\dagger} \rangle\rangle_{-\omega} \quad (26)$$

where the asterisk denotes complex conjugation and A^{\dagger} is the adjoint of the operator A ($A^{\dagger} = A$ for Hermitian operators, by definition). It follows from these relations that the electric dipole polarizability is an even function of frequency,

$\alpha_{ij}(-\omega; \omega) = \alpha_{ij}(\omega; -\omega)$, and a symmetric tensor, $\alpha_{ij}(-\omega; \omega) = \alpha_{ji}(-\omega; \omega)$, which implies that only six of the nine Cartesian components of the polarizability need to be computed. The permutation and conjugation relations are satisfied by approximate linear response functions as well.

Quadratic and Higher-Order Response Functions

The quadratic response function describing the second-order induced electric dipole moment due to a uniform time-dependent electric field is related to the frequency-dependent electric dipole hyperpolarizability as

$$\beta_{ijk}(-\bar{\omega}; \omega, \omega') = -\langle\langle \mu_i; \mu_j, \mu_k \rangle\rangle_{\omega, \omega'} \quad (27)$$

where $\bar{\omega} = \omega + \omega'$. With a procedure completely analogous to that of the linear response functions, this identification is obtained by substituting $A \rightarrow \mu_i$ and $V(\omega) \rightarrow -\mu \cdot \mathbf{F}(\omega)$ in Eq. 3. A variety of optical processes are governed by the electric hyperpolarizability depending on the values of the frequencies, including Second Harmonic Generation through $\beta_{ijk}(-2\omega; \omega, \omega)$ and Optical Rectification through $\beta_{ijk}(0; \omega, -\omega)$. In an approximate calculation, the electric dipole hyperpolarizability can be obtained by computing (minus) the quadratic response function from first-order wave function parameters determined by Eq. 4 with the three Cartesian components of the electric dipole operator as perturbation operators at each set of frequencies ω , ω' , and $\bar{\omega}$. In accordance with Wigner's $2n+1$ rule, which states that the n th-order wave function parameters determine the response functions up to order $2n+1$, second-order wave function parameters are not needed. In this context, the order of the response function corresponds to the number of operators it contains such that the ground state expectation value is of order 1, the linear response function is of order 2, the quadratic response function is of order 3, and so on. The $2n+1$ rule is essential for efficient computer implementations of response theory.

To learn more about the information that can be extracted from the quadratic response function in approximate calculations, we now study the exact one. Like the exact linear response function, the exact quadratic response function can be calculated from excitation energies and transition matrix elements of the unperturbed molecule:

$$\langle\langle A; B, C \rangle\rangle_{\omega, \omega'} = \frac{1}{\hbar^2} P_{BC} \sum_{k, l \neq 0} \left\{ \begin{aligned} & \frac{\langle 0 | A | k \rangle \langle k | \bar{B} | l \rangle \langle l | C | 0 \rangle}{(\omega + \omega' - \omega_{k0}) (\omega' - \omega_{l0})} \\ & + \frac{\langle 0 | C | k \rangle \langle k | \bar{B} | l \rangle \langle l | A | 0 \rangle}{(\omega + \omega' + \omega_{l0}) (\omega' - \omega_{k0})} \\ & - \frac{\langle 0 | B | k \rangle \langle k | \bar{A} | l \rangle \langle l | C | 0 \rangle}{(\omega + \omega_{k0}) (\omega' - \omega_{l0})} \end{aligned} \right\} \quad (28)$$

The bar signals that the operator has been shifted to a zero-point defined by its ground state expectation value. For example,

$$\bar{B} = B - \langle 0 | B | 0 \rangle I \quad (29)$$

where I is the identity operator. The operator P_{BC} permutes the pairs (B, ω) and (C, ω') :

$$P_{BC} f(B, \omega, C, \omega') = f(B, \omega, C, \omega') + f(C, \omega', B, \omega) \quad (30)$$

giving a total of six distinct terms in the quadratic response function. The quadratic response function is singular at the molecular excitation energies, that is, when $\omega + \omega' = \pm \omega_{k0}$ or when $\omega = \pm \omega_{k0}$ or when $\omega' = \pm \omega_{k0}$ for some $k > 0$. These singularities can be avoided by taking into account the finite lifetime of the excited molecular states, as discussed for the linear response function in the previous section.

The quadratic response function, for exact as well as approximate states, satisfies the permutation and conjugation relations

$$\begin{aligned} \langle\langle A; B, C \rangle\rangle_{\omega, \omega'} &= \langle\langle A; C, B \rangle\rangle_{\omega', \omega} \\ &= \langle\langle B; A, C \rangle\rangle_{-\omega-\omega', \omega'} = \langle\langle B; C, A \rangle\rangle_{\omega', -\omega-\omega'} \\ &= \langle\langle C; A, B \rangle\rangle_{-\omega-\omega', \omega} = \langle\langle C; B, A \rangle\rangle_{\omega, -\omega-\omega'} \end{aligned} \quad (31)$$

$$\langle\langle A; B, C \rangle\rangle_{\omega}^* = \langle\langle A^\dagger; B^\dagger, C^\dagger \rangle\rangle_{-\omega, -\omega'} \quad (32)$$

The assumption, known as Kleinman symmetry, that the quadratic (and higher-order) response function is symmetric under interchange of any pair of operators is only true at zero frequency, as is easily verified from Eq. 31. Note that the quadratic response function is symmetric when permuting the operators B and C at $\omega = \omega'$, which is the case for, for example, Second Harmonic Generation: $\beta_{ijk}(-2\omega; \omega, \omega) = \beta_{ikj}(-2\omega; \omega, \omega)$. Kleinman symmetry is often assumed in calculations of the electric dipole hyperpolarizability at low frequencies where it is approximately valid. This reduces the number of independent tensor elements and thus the computational effort.

Owing to the more complicated dependence on field frequencies, the residues of the quadratic response function provide more information than those of the linear response function. One of the most important residues of the quadratic response function is

$$\begin{aligned} &\lim_{\omega' \rightarrow \omega_{m0}} \hbar (\omega' - \omega_{m0}) \langle\langle A; B, C \rangle\rangle_{-\omega, \omega'} \\ &= - \left[\frac{1}{\hbar} \sum_k \left(\frac{\langle 0 | A | k \rangle \langle k | B | m \rangle}{\omega_{k0} - (\omega_{m0} - \omega)} + \frac{\langle 0 | B | k \rangle \langle k | A | m \rangle}{\omega_{k0} - \omega} \right) \right] \langle m | C | 0 \rangle \end{aligned} \quad (33)$$

where the summation over k includes the ground state $|0\rangle$. The quantity in square brackets is an element of the transition matrix for two-photon excitation from the ground state to the excited state m . Another useful (double) residue is

$$\begin{aligned} & \lim_{\omega \rightarrow -\omega_{n0}} \hbar (\omega' + \omega_{m0}) \left[\lim_{\omega' \rightarrow \omega_{m0}} \hbar (\omega' - \omega_{m0}) \langle\langle A; B, C \rangle\rangle_{-\omega, \omega'} \right] \\ & = \delta_{mn} \langle 0 | A | 0 \rangle \langle 0 | B | n \rangle \langle n | C | 0 \rangle - \langle 0 | B | n \rangle \langle n | A | m \rangle \langle m | C | 0 \rangle \end{aligned} \quad (34)$$

From this expression it is possible to extract transition moments between excited states [$\langle n | A | m \rangle$]. With the specific choice $n = m$ it thus becomes possible to compute excited state properties such as dipole moments from the quadratic response of the ground state.

Higher-order response functions (cubic, quartic, quintic, etc.) can also be written in terms of molecular excitation energies and eigenstates. These functions possess singularities at the excitation energies, and the associated residues (single, double, etc. residues) can be used to identify a wide range of molecular properties. For example, residues of the cubic response function provide two-photon transition strengths (the product of two-photon transition matrix elements) and three-photon transition matrix elements, while the three-photon transition strength is obtained from the quintic response function. Linear response functions for the excited states can be extracted from the cubic response function. By calculating ground state response functions we may thus extract all molecular properties.

Static Response Functions

The interaction between a molecule and time-independent external fields is described by frequency-independent perturbation operators. Time-independent fields are nonoscillating, and interactions with molecular electrons are therefore characterized by perturbation operators at zero frequency. The limit $\omega \rightarrow 0$ is often referred to as the static limit and response functions at zero frequency are called static response functions. Although static response functions can be calculated in the same way as dynamic (frequency-dependent) ones, they are special in the sense that they are related to changes in ground state energy. For example, the electronic ground state energy of a molecule in the presence of a static uniform electric field, \mathbf{F} , can be expanded as

$$E = E_0 - \langle 0 | \mu | 0 \rangle \cdot \mathbf{F} - \mathbf{F} \cdot \alpha(0; 0) \cdot \mathbf{F} + \dots \quad (35)$$

where E_0 is the energy in the absence of the field. The expectation value of the dipole moment operator thus determines the first-order energy due to the field, whereas the static polarizability determines the second-order energy. Higher-order energy corrections are determined by the static hyperpolarizability, second

hyperpolarizability, etc. This explains why ground state expectation values are often classified as first-order properties, linear response functions as second-order properties, and so on.

The relation between static response functions and energy corrections implies that molecular properties can be identified as derivatives of the total energy at zero field strength. For example,

$$\langle 0 | \mu_i | 0 \rangle = -\frac{\partial E}{\partial F_i} \quad (36)$$

$$\alpha_{ij}(0; 0) = -\frac{\partial^2 E}{\partial F_i \partial F_j} \quad (37)$$

where it is implicitly understood that the derivatives must be evaluated at zero field strength ($\mathbf{F} = \mathbf{0}$). Hence, the calculation of static response functions does not require a wave function and may therefore be computed with electronic structure theories that only provide the energy (e.g., MP2, CASPT2, and CCSD(T)).

Even if a quantum chemical software package does not feature an implementation of a given static response property, it is often possible to evaluate the property as an energy derivative by finite difference. Most packages allow the addition of external static fields to the Hamiltonian, making it possible to compute the energy at a specified field strength, $E(\mathbf{F})$. From the definition of the partial derivative, we may thus compute the dipole moment and polarizability from finite difference formulas such as

$$\frac{\partial E}{\partial F_i} \approx \frac{E(\delta_i) - E(-\delta_i)}{2\delta_i} \quad (38)$$

$$\frac{\partial^2 E}{\partial F_i^2} \approx \frac{E(\delta_i) - 2E(0) + E(-\delta_i)}{\delta_i^2} \quad (39)$$

$$\frac{\partial^2 E}{\partial F_i \partial F_j} \approx \frac{E(\delta_i, \delta_j) + E(-\delta_i, -\delta_j) - E(-\delta_i, \delta_j) - E(\delta_i, -\delta_j)}{4\delta_i \delta_j} \quad (40)$$

where $\delta_i(\delta_j)$ is a small field strength along the i th (j th) Cartesian direction. The error in these numerical derivative formulas is quadratic in the field strength which should therefore be chosen as small as possible. Choosing too small field strengths, however, may lead to numerical instabilities when computing the difference between two large and almost identical numbers. It is therefore advisable to conduct a convergence study with respect to the field strength when computing numerical derivatives.

A number of static perturbations arise from internal interactions or fields, which are neglected in the nonrelativistic Born–Oppenheimer electronic Hamiltonian. The relativistic correction terms of the Breit–Pauli Hamiltonian are considered as perturbations in nonrelativistic quantum chemistry, including Darwin corrections, the mass-velocity correction, and spin–orbit and spin–spin interactions. Some properties, such as nuclear magnetic resonance shielding tensors and shielding

polarizabilities, are computed from perturbation operators that involve both internal and external fields.

Gauge and Origin Invariance

As described above, molecular properties are identified as response functions by selecting the observable quantity whose change is to be monitored and the external field(s) inducing the change. The operator describing the coupling between the external field and the electrons is not unique, however. The electric field $\mathbf{F}(\mathbf{r}, t)$ can be written in terms of the vector potential $\mathbf{A}(\mathbf{r}, t)$ and the scalar potential $\phi(\mathbf{r}, t)$ as

$$\mathbf{F}(\mathbf{r}, t) = -\frac{\partial \mathbf{A}(\mathbf{r}, t)}{\partial t} - \nabla \phi(\mathbf{r}, t) \quad (41)$$

while the magnetic field $\mathbf{B}(\mathbf{r}, t)$ is given by

$$\mathbf{B}(\mathbf{r}, t) = \nabla \times \mathbf{A}(\mathbf{r}, t) \quad (42)$$

Since the electric and magnetic fields are obtained by differentiation, adding a constant to the vector and scalar potentials does not alter the physical electric and magnetic fields. More generally, adding the gradient of a continuous function $\xi(\mathbf{r}, t)$ to the vector potential, that is, $\mathbf{A} \rightarrow \mathbf{A} + \nabla \xi$, while subtracting the time derivative of the same function from the scalar potential, that is, $\phi(\mathbf{r}, t) \rightarrow \phi(\mathbf{r}, t) - \partial \xi / \partial t$ will not change the electric and magnetic fields. This feature is known as gauge invariance and implies that there is a manifold of scalar and vector potentials related by gauge transformations that describe the same physical field. This leads to a manifold of different quantum mechanical operators describing the interaction between the electrons and the field. The time-dependent Schrödinger equation is invariant under such gauge transformations and the computed properties therefore also should be invariant. This is indeed the case for exact response functions.

As an example, consider again the interaction between electrons and a uniform electric field. In section “The Linear Response Function,” the electric dipole polarizability was identified using the length gauge perturbation operator

$$V(\omega) = -\boldsymbol{\mu} \cdot \mathbf{F}(\omega) \quad (43)$$

An equally valid choice would have been the velocity gauge perturbation operator

$$V(\omega) = -\frac{ie}{\omega m_e} \mathbf{p} \cdot \mathbf{A}(\omega) \quad (44)$$

where $\mathbf{A}(\omega)$ is the amplitude vector of the electromagnetic vector potential in the electric dipole approximation and $\mathbf{p} = \sum_s \mathbf{p}^s$ is the total electronic momentum

operator. This operator leads to the following expression for the electric dipole polarizability:

$$\alpha_{ij}(-\omega; \omega) = -\frac{ie}{\omega m_e} \langle\langle \mu_i; p_j \rangle\rangle_{\omega} \quad (45)$$

While Eq. 11 is called the length gauge or dipole-length gauge expression, Eq. 45 is often called the mixed gauge form since it involves both the electric dipole operator and the momentum operator. The length and mixed gauge polarizabilities are equivalent due to the equation of motion

$$\hbar\omega \langle\langle A; B \rangle\rangle_{\omega} = \langle\langle [A, H_0]; B \rangle\rangle_{\omega} + \langle 0 | [A, B] | 0 \rangle \quad (46)$$

which is satisfied by the exact linear response function, and due to the commutator relations

$$[\mu_j, H_0] = -\frac{ie\hbar}{m_e} p_j \quad (47)$$

$$[\mu_i, \mu_j] = 0 \quad (48)$$

Such relations (equation of motion and commutators) guarantee that exact linear response functions are gauge invariant. In addition, transition moments deduced from residues of the exact linear response function are also gauge invariant.

For approximate theories, however, different results are always obtained with different perturbation operators related by gauge transformations. The use of a finite basis set implies that operators are represented as finite matrices and, consequently, the commutator relations no longer hold. As the basis set quality is increased, the commutators converge to the exact values. Gauge invariance thus is recovered in the limit of a complete basis set, provided that the equation of motion Eq. 46, is fulfilled. While this is the case in theories with fully variational orbitals such as DFT, HF, and MCSCF, it is not the case in approximate theories with fixed (nonvariational) orbitals such as CI and CC.

The exact quadratic and higher-order response functions satisfy similar equations of motion, for example,

$$\hbar(\omega + \omega') \langle\langle A; B, C \rangle\rangle_{\omega, \omega'} = \langle\langle [A, H_0]; B, C \rangle\rangle_{\omega, \omega'} + \langle\langle [A, B]; C \rangle\rangle_{\omega'} + \langle\langle [A, C]; B \rangle\rangle_{\omega} \quad (49)$$

ensuring gauge invariance of higher-order molecular properties. In analogy to the case of the linear response function, the higher-order equations of motion are satisfied in approximate theories with variational determination of the orbitals such as DFT, HF, MCSCF, but not in theories such as CI and CC.

It is therefore necessary to specify which gauge (typically, length or velocity) is used when reporting computed response properties such as electric dipole (hyper-)polarizabilities and transition moments. With reasonably flexible basis sets,

each of the DFT, HF, and MCSCF methods typically provides length and velocity gauge results that are quite close to each other, whereas CC results occasionally show significant differences between length and velocity gauge. For example, the specific optical rotation of (1*S*,4*S*)-norbornenone calculated at the CC singles and doubles (CCSD) level is $-558 \text{ deg dm}^{-1} (\text{g/ml})^{-1}$ with the length gauge and $-740 \text{ deg dm}^{-1} (\text{g/ml})^{-1}$ with the velocity gauge (corrected for an unphysical static limit, see below). The fundamental problem is that there is no general physical reason to trust one gauge formulation more than another.

In some cases, however, there may be good reasons for favoring one gauge formulation over others in approximate calculations. One such example is optical rotation which is governed by the trace of the electric dipole – magnetic dipole polarizability, whose length gauge formulation is given by Eq. 21. Within the clamped-nucleus Born–Oppenheimer approximation, every electronic structure calculation is performed with fixed nuclear positions. The coordinate system used to specify the nuclear positions can be chosen arbitrarily. In particular, the results of the calculation should be independent of the choice of origin of the coordinate system.

Suppose that we translate the origin of the coordinate system along a vector \mathbf{O} . As a consequence, the positions of nuclei and electrons are shifted by the same vector, for example, $\mathbf{r}^s \rightarrow \mathbf{r}^s - \mathbf{O}$, and the electric dipole – magnetic dipole polarizability changes according to

$$\mathbf{G}'(-\omega; \omega) \rightarrow \mathbf{G}'(-\omega; \omega) + \frac{e}{2m_e} \text{Im} [\langle \langle \boldsymbol{\mu}; \mathbf{p} \rangle \rangle_{\omega} \times \mathbf{O}] \quad (50)$$

which shows that the tensor is origin dependent. The culprit is the origin-dependence of the magnetic dipole operator:

$$\mathbf{m} \rightarrow \mathbf{m} - \frac{e}{2m_e} \mathbf{p} \times \mathbf{O} \quad (51)$$

This translation of the operator can also be achieved by a particular type of gauge transformation of the magnetic vector potential, explaining why the term *gauge-origin* is often used for \mathbf{O} in the context of magnetic properties.

It can be shown that the trace of the tensor \mathbf{G}' , and hence the computed optical rotation of a sample of randomly oriented chiral molecules, is independent of the origin provided that the linear response function satisfies Eq. 46 and that the commutator of Eq. 47 is fulfilled. Consequently, approximate linear response calculations of the length gauge optical rotation depend on the chosen coordinate origin. On the other hand, the trace of the velocity gauge formulation of the electric dipole – magnetic dipole polarizability

$$\mathbf{G}'(-\omega; \omega) = \frac{e}{\omega m_e} \langle \langle \mathbf{p}; \mathbf{m} \rangle \rangle_{\omega} \quad (52)$$

is unconditionally independent of the chosen origin, also in approximate theories. (Note that Eq. 52 is only valid for real wave functions.) It may thus be argued that

the velocity gauge formulation of optical rotation should be preferred over the length gauge expression. It must be added, however, that the velocity gauge optical rotation calculated with an approximate theory suffers from a serious artifact: it predicts a nonvanishing optical rotation at zero frequency (at zero frequency, there is no light and the optical rotation must be zero). This can be traced back to the lack of gauge invariance and is rectified by the modified velocity gauge where the static limit simply is subtracted from the linear response function, that is, $\langle\langle p_i; m_i \rangle\rangle_\omega$ is replaced by $\langle\langle p_i; m_i \rangle\rangle_\omega - \langle\langle p_i; m_i \rangle\rangle_0$.

The most widely used technique for ensuring origin invariance of magnetic properties, however, is based on so-called Gauge Including Atomic Orbitals (GIAOs, also known as London Atomic Orbitals [LAOs]). Belonging to the class of perturbation-dependent basis sets, GIAOs are obtained from any conventional atomic orbital basis set by multiplying each basis function with a complex phase factor that depends explicitly on an external uniform static magnetic field. In a finite GIAO basis set, the magnetic dipole moment operator depends on the chosen coordinate origin according to

$$\mathbf{m} \rightarrow \mathbf{m} - \frac{i}{2\hbar} [\boldsymbol{\mu}, H_0] \times \mathbf{O} \quad (53)$$

which is identical to Eq. 51 in the limit of a complete basis set where the commutator of Eq. 47 is fulfilled. For fully variational approximate theories (DFT, HF, MCSCF), GIAOs thus remove the condition that the commutator must be fulfilled and the length gauge optical rotation becomes manifestly independent of origin. For approximate theories lacking variational orbital optimization (CI, CC), GIAOs are unable to remove the origin dependence of the length gauge optical rotation, since the equation of motion, Eq. 46, is not satisfied. The velocity gauge formulation with GIAOs is origin dependent in all approximate theories and, therefore, is never used.

The greatest strength of GIAOs lies in origin invariant calculation of molecular properties involving static uniform magnetic fields, including static magnetic properties such as magnetizabilities and rotational g tensors, and nuclear magnetic shieldings as well as optical properties aided by a static magnetic field such as magneto-optical activity. The use of GIAOs makes it possible to calculate the total energy in the presence of a static uniform magnetic field in an origin-independent manner for variational as well as nonvariational approximate theories, implying that the molecular properties identified as energy derivatives are independent of origin as well. In addition, owing to their being atomic eigenfunctions of the angular momentum operator correct to first order in the applied magnetic field, GIAOs provide vastly improved basis set convergence of static magnetic properties.

Effects of Nuclear Motion

Within the clamped-nucleus Born–Oppenheimer approximation, electronic response functions are computed for fixed nuclear geometries. Just like the electronic ground state energy, the excitation energies and response functions

thus become parametric functions of nuclear positions. For example, by solving the eigenvalue problem, Eq. 15, at a range of geometries, it becomes possible to compute excited state potential energy surfaces using Eq. 16 at each point. This, in turn, allows us to optimize excited state geometries using either a simple scan of the excited state potential energy surface or analytic gradients derived from Eq. 16. Since the ground state energy is required to compute the excited state energy in the response approach, calculations of excited state potential energy surfaces should only be carried out for geometries where the approximate wave function is valid. For single-reference methods such as HF and CC, one should only compute excitation energies (and thus excited state energies) for geometries not too far from the ground state equilibrium structure. As a consequence, these single-reference methods cannot be used to compute dissociative excited state surfaces, except at points close to the ground state equilibrium geometry. Multiconfigurational methods are required to describe such unbound excited states. For bound excited states, Eq. 16 also provides a viable path to excited state vibrational frequencies and wave functions. Along with those of the ground state, it then becomes possible to calculate 0–0 transition energies rather than the vertical excitation energies provided by the poles of the response functions. In addition, the vibrational structure of electronic bands becomes amenable to theoretical computations.

Electronic ground state response functions are most often calculated at the (ground state) equilibrium geometry. The geometry optimization and response function evaluation may be performed at different levels of theory and using different basis sets. For example, it may be sufficient to optimize the geometry of a covalently bonded molecule at the DFT level of theory with a relatively small polarized basis set, while the response functions are evaluated at the CC level of theory (at the DFT equilibrium geometry) with a large polarized basis set augmented with diffuse functions to ensure the correct pole structure of the response functions. In other cases, it may be advantageous to use different DFT functionals and basis sets for the geometry optimization and property calculation.

If high accuracy is required, vibrational effects must be taken into account. In a proper adiabatic Born–Oppenheimer treatment, the ground state wave function would be written as a product of an electronic and a vibrational wave function. The response of this wave function should then be computed and subsequently used to construct vibronic response functions. The sum-over-states expressions would include contributions from vibrational states in the electronic ground and excited states. Since each set of vibrational wave functions is tied to a specific electronic state within the adiabatic Born–Oppenheimer approximation, this approach is not feasible in practice. Hence, the electronic properties are considered as electronic ground state properties and therefore averaged in a vibrational state of the electronic ground state.

Computing the expectation value of the electronic property $P(\mathbf{q})$, which may be a response function or a sum of response functions depending parametrically on the dimensionless normal coordinates \mathbf{q} , in the vibrational state $|v_0\rangle$ of the electronic ground state, the vibrational correction becomes

$$\Delta P = \langle v_0 | P(\mathbf{q}) | v_0 \rangle - P_0 \quad (54)$$

where P_0 is the value of the electronic property at the equilibrium geometry. The analytic form of the dependence of P on normal coordinates normally is not known. Even if it were known, it would be too computationally demanding to evaluate the property on a grid of normal coordinates to fit the values to the analytic form. Instead, the property is expanded in a Taylor series. This implies that derivatives of the property with respect to the normal coordinates must be evaluated at the expansion point of the Taylor series. The property derivatives can themselves be expressed in terms of response functions (by considering the nuclear displacement terms of the Hamiltonian as perturbations), or they may be computed by numerical techniques analogous to the static properties of section “Static Response Functions.” The vibrational wave functions may be computed in the same manner as in the ground state theory. That is, they are computed on the basis of the harmonic approximation and often include anharmonic effects to first order in perturbation theory. In another approach, the vibrational problem is viewed as so-called mode dynamics and solved in a manner resembling electronic structure theory. This approach also makes it possible to compute the vibrational expectation value directly and only requires that an electronic structure program is available for computing energies and properties at specified nuclear geometries.

The relatively small difference between vibrational energy levels implies that a range of vibrational states are occupied at finite temperature. Including anharmonic effects to first order, the temperature-dependent vibrational correction can be expressed as

$$\begin{aligned} \Delta P = & -\frac{1}{4\hbar} \sum_n \frac{1}{\omega_n} \frac{\partial P}{\partial q_n} \sum_m k_{nmm} \coth\left(\frac{\hbar\omega_m}{2k_B T}\right) \\ & + \frac{1}{4} \sum_n \frac{\partial^2 P}{\partial q_n^2} \coth\left(\frac{\hbar\omega_n}{2k_B T}\right) \end{aligned} \quad (55)$$

where the property derivatives are to be evaluated at the equilibrium geometry, ω_n is the harmonic vibrational frequency of normal mode n , k_B is the Boltzmann constant, T is the temperature, and the cubic (anharmonic) force constants are given by

$$k_{nmm} = \frac{\partial^3 E_0}{\partial q_n \partial q_m^2} \quad (56)$$

which is also evaluated at the equilibrium geometry (E_0 is the electronic ground state energy surface, $E_0 = E_0(\mathbf{q})$). The first term in Eq. 55 accounts for the anharmonicity of the potential energy surface, whereas the second term is purely harmonic and arises from the curvature of the property surface. If anharmonic effects are neglected, only the second term is included. Anharmonic effects can be as large as the harmonic contribution and should generally be included, in particular when the molecule contains low-frequency vibrational modes (such as torsional

motions). Most quantum chemistry programs are able to compute the harmonic vibrational frequencies and normal coordinates, and some also provide cubic force constants (if not, these can be computed numerically). The property derivatives are most often computed by numerical differentiation. At zero temperature, only the vibrational ground state is populated and the zero-point vibrational correction (ZPVC) is obtained from Eq. 55 by taking the limit $T \rightarrow 0$ where the hyperbolic cotangent factors approach 1. Once the property and energy derivatives have been calculated, the temperature dependence of the vibrationally averaged property can be easily computed, including the ZPVC.

Conformationally flexible molecules are characterized by multiple low-lying minima on the potential energy surface, each minimum defining a conformer of the molecule. All conformers contribute to the experimentally observed property and must be taken into account in theoretical calculations. In the simplest approach, provided that the barriers separating the minima are sufficiently large, the vibrationally corrected property can be computed along the lines discussed above for each conformer (letting the conformer structure play the role of equilibrium geometry in each case). The total (observed) property is then obtained as a Boltzmann average of the results for each conformer:

$$\bar{P} = \sum_i^{\text{conformers}} \langle P \rangle_i X_i \quad (57)$$

Here, $\langle P \rangle_i$ and X_i are the vibrationally corrected property and mole fraction of conformer i , respectively. Note that the same formula can be applied to compute the average of the purely electronic contribution to the property (i.e., not vibrationally corrected). The mole fraction is computed according to

$$X_i = \frac{\exp(-G_i/k_B T)}{\sum_j^{\text{conformers}} \exp(-G_j/k_B T)} \quad (58)$$

where G_i is Gibbs free energy of conformer i , which, assuming the ideal gas approximation, is given by

$$G_i = E_{0,i} + \epsilon_{0,i} + RT - TS_i \quad (59)$$

where R is the universal gas constant. The electronic ground state energy of conformer i is denoted $E_{0,i}$ and $\epsilon_{0,i}$ is the zero-point vibrational energy of conformer i in the harmonic oscillator approximation. The entropy is computed from the electronic, vibrational, and rotational partition functions,

$$S_i = -k_B T \ln(Z_{\text{el},i} Z_{\text{vib},i} Z_{\text{rot},i}) \quad (60)$$

$$Z_{\text{el},i} = 1 \quad (61)$$

$$Z_{\text{vib},i} = \sum_n g_{n,i}^{\text{vib}} \exp(-\epsilon_{n,i}/k_B T) \quad (62)$$

$$Z_{\text{rot},i} = \sum_m g_{m,i}^{\text{rot}} \exp(-\epsilon_{m,i}/k_B T) \quad (63)$$

The electronic partition function is unity, as only the electronic ground state is assumed populated. The vibrational energies of conformer i , $\epsilon_{n,i}$, are computed in the harmonic oscillator approximation, which facilitates analytic summation over all vibrational levels. The rotational energy of conformer i , $\epsilon_{m,i}$, is calculated within the rigid rotor approximation. The factors $g_{n,i}^{\text{vib}}$ and $g_{m,i}^{\text{rot}}$ are the degeneracies of the vibrational and rotational energy levels, respectively. Hence, the data needed to evaluate the Boltzmann average can be obtained from ground state calculations (electronic ground state energy at the equilibrium structure, harmonic vibrational energies, and rotational constants).

The simple Boltzmann averaging relies on a range of approximations that tend to benefit from fortuitous cancellation of errors. In particular, the assumption that the conformers can be treated as independent with no couplings between their vibrational states is fragile, as barriers are often insufficient to warrant the assumption. A more correct description would be obtained by solving the vibrational problem for the entire ground state potential energy surface instead of using a first-order anharmonic approximation in the vicinity of the minima. Calculation of the entire potential energy surface is, however, out of the question for all but the smallest systems. One way out might be to compute the nuclear motion using molecular dynamics and parametrized force fields, sampling the electronic property along the trajectory. Also this approach, however, may easily turn out to be too demanding in terms of the number of electronic structure calculations required.

Further Reading

This section contains a short description of suggested references for further study of the concepts and techniques described above. The list of references is highly incomplete and should be considered as a mere starting point.

The time-independent perturbation operators describing internal molecular interactions are taken from the Breit–Pauli Hamiltonian, which includes relativistic corrections to the molecular electronic Hamiltonian of Eq. 2. The Breit–Pauli Hamiltonian is discussed in more detail in the textbooks by Bethe and Salpeter (1957) and by Moss (1973). Appropriate operators for the interaction between charged particles and external electromagnetic fields are discussed in the paper by Fiutak (1963). The textbook by Craig and Thirunamachandran (1984) contains derivations of a long range of optical properties in terms of exact molecular states, while Barron’s book (1982) is highly recommended for its thorough discussion of optical activity phenomena. The expressions derived in these books may be

translated into response functions amenable to calculation by means of approximate wave functions.

Olsen and Jørgensen (1985, 1995) have derived and discussed response functions for exact, HF, and MCSCF wave functions in great detail, while Koch and Jørgensen (1990) presented a derivation for CC wave functions. The latter was modified by Pedersen and Koch (1997) to ensure proper symmetry of the response functions. Christiansen et al. (1998) have presented a derivation of dynamic response functions for variational as well as nonvariational wave functions that resembles the way in which static response functions are deduced from energy derivatives. Linear and higher-order response functions based on DFT have been presented by Sałek et al. (2002). Damped response theory has been discussed by Norman et al. (2001) in the context of HF and MCSCF response theory. Nonperturbative calculations of static magnetic properties at the HF level have been presented by Tellgren et al. (2008, 2009).

Gauge invariance of HF and MCSCF response theory has been shown in terms of the equations of motion for the response functions by Olsen and Jørgensen (1985, 1995), whereas the lack of gauge invariance in CC response theory was demonstrated by Pedersen et al. (Pedersen and Koch 1997; Pedersen et al. 2001). The use of GIAOs to ensure origin invariance of static magnetic properties has been discussed by Helgaker et al. (Helgaker and Jørgensen 1991; Olsen et al. 1995) and for optical rotations by Bak et al. (1995).

Different approaches to the calculation of vibrational corrections to response properties can be found in the work of Sauer and Pack (2000), Ruud et al. (2000), and Kongsted and Christiansen (2006). The Boltzmann averaging procedure for conformationally flexible molecules has been critically reviewed by Crawford and Allen (2009). Mort and Autschbach (2008) have proposed an approach based on a decoupling of hindered rotations from the remaining (high-frequency) vibrational modes, which allows for a separate calculation of the hindered rotations without invoking the harmonic approximation.

Acknowledgments The author wishes to thank Profs. Michał Jaszuński, Antonio Rizzo, T. Daniel Crawford, and Trygve Helgaker for commenting on the manuscript.

physical systems and develop detailed and more predictive theoretical models, it becomes even more important to provide an accurate description of the underlying molecular interactions. The goal of this chapter is to describe recent developments in the theory of intermolecular interactions that have revolutionised the field due to their comparatively low computational costs and high accuracies. These are the symmetry-adapted perturbation theory based on density functional theory (SAPT(DFT)) for interaction energies and the Williams–Stone–Misquitta (WSM) method for molecular properties in distributed form. These theories are applicable to systems of small organic molecules containing as many as 30 atoms each and have demonstrated accuracies comparable to the best electronic structure methods. We also discuss the numerical aspects of these theories and recent applications which demonstrate the range of problems that can now be approached with these accurate *ab initio* methods.

Introduction

Intermolecular, or van der Waals, interactions are responsible for a wide variety of phenomena in the fields of physics, chemistry, and biology. The thermodynamic properties of gases, liquids, and solids depend on these interactions. In fact, many liquids and many solids would not exist without van der Waals forces. Amongst other properties that depend strongly on the van der Waals interactions are microwave and infrared spectra of molecular complexes and bulk phases. Due to their long-range nature, van der Waals forces determine the entrance channels for chemical reactions. Some of the more exotic systems in which van der Waals interactions play an important role are Bose–Einstein condensates (BECs) and helium nanodroplets (Chang et al. 2003; Xu et al. 2003). In biological systems, van der Waals interactions are particularly important, subtle, and often hard to model. The stability of DNA and RNA arise, in part, from the stacking energy (Hobza and Sponer 2002), which is determined by this interaction. One of the important problems in which van der Waals interactions play an important role is the problem of protein folding (Lehninger 1970).

This chapter is an introduction to the field of intermolecular interaction and to the modern *ab initio* electronic structure methods – primarily those based on perturbation theory – that have been developed to study them. We will be mainly concerned with applications to small organic molecules for which accuracies of the order of a kJ mol^{-1} or less are sufficient. High-accuracy calculations on small dimers can be orders of magnitude more accurate, but these are the subject of a specialist review (see Szalewicz et al. 2005 for a review and references). Nor are we concerned with empirical methods. Our focus will be on first principles methods for the interactions of closed-shell systems in the non-relativistic limit. In the last decade, *ab initio* methods have been used to successfully model the structure of liquid water (Bukowski et al. 2007) studied the interactions between DNA base tetramers (Fiethen et al. 2008) and predicted the crystal structure of an organic

molecule (Misquitta et al. 2008b). The goal of this chapter is to describe the main theoretical developments that have been responsible for these applications.

Definition of the Interaction Energy

The interaction energy of a cluster of N interacting *rigid* molecules is defined to be

$$E_{\text{int}} = E_{ABC\dots} - E_A - E_B - E_C - \dots \quad (1)$$

Here $E_{ABC\dots}$ is the energy of the cluster and E_X , $X = A, B, C$, etc., is the energy of molecule X . Non-rigid molecules undergo a deformation in the cluster, with an associated *deformation energy cost*: $\delta E_X = E_X(x_X^*) - E_X(x_X^0)$, where x_X^0 is the geometry of monomer X in isolation and x_X^* is the geometry in the cluster. This deformation energy cost should be included as part of the interaction energy defined above, but since this chapter is mainly concerned with the interactions of rigid molecules, we will assume that the deformation energies δE_X are obtained in a suitable manner, and concern ourselves only with the interaction energy defined by Eq. 1.

E_{int} can be evaluated directly, but for computational efficiency as well as physical interpretation it is worthwhile to partition the N -body interaction energy into contributions from dimers, trimers, and so on. This leads to an exact reformulation of E_{int} that is known as the many-body expansion:

$$E_{\text{int}}(ABC\dots) = \sum_{X<Y} E_{\text{int}}(XY) + \sum_{X<Y<Z} \Delta E_{\text{int}}(XYZ) + \dots, \quad (2)$$

where $\Delta E_{\text{int}}(XYZ)$ is the three-body correction, defined as

$$\Delta E_{\text{int}}(XYZ) = E_{\text{int}}(XYZ) - E_{\text{int}}(XY) - E_{\text{int}}(XZ) - E_{\text{int}}(YZ). \quad (3)$$

In the same way, we can define four-body corrections, five-body corrections, and so on. For a cluster of N molecules, this expansion terminates at the N -body correction.

The many-body expansion would not be of much use if we had to evaluate all terms in Eq. 2. But experience has shown that the expansion converges quickly and terms beyond those involving three bodies are not so important. This is fortunate as the two-body interactions are well understood and can be evaluated for moderate-sized molecules using a variety of methods, while good approximations are available for the terms involving three and more bodies, which usually arise from the effects of polarization in the cluster.

The Two-Body Interaction Energy

The interaction energy of a pair of interacting molecules is defined as

$$E_{\text{int}} = E_{AB} - E_A - E_B. \quad (4)$$

If we calculate all three energies using a suitable electronic structure method – some of which will be described later – this definition provides a simple method for calculating the interaction energy of a pair of interacting molecules. This approach, known as the *supermolecular* method, provides us with a single number: the interaction energy E_{int} . We gain considerable physical insight into E_{int} by evaluating it not as the difference in energies suggested by the above definition, but through *perturbation theory*, which enables us to partition E_{int} into physical components: the electrostatic, induction (or polarization), dispersion, and exchange-repulsion energies. This breakup proves invaluable not only as an aid to interpretation, but also forms the basis for all analytic atom–atom potentials (Stone and Misquitta 2007).

Consider the dimer Hamiltonian partitioned as

$$H(\lambda) = H_0 + \lambda V, \quad (5)$$

where $H_0 = H_A + H_B$ is the sum of the Hamiltonians of the unperturbed monomers A and B , and V is the intermonomer interaction operator that consists of electron–electron, electron–nuclear, and nuclear–nuclear interactions between the monomers. We may now carry out a Rayleigh–Schrödinger perturbation theory – also known as the *polarization expansion* (Jeziorski et al. 1994) – using as our zeroth-order wave function the unsymmetrized product $\Phi_0 = \Phi_0^A \Phi_0^B$. The zeroth-order energy is then $E_0 = E_0^A + E_0^B$. The interaction energy appears at first and higher orders in perturbation theory (setting $\lambda = 1$):

$$E_{\text{int}} = E_{\text{pol}}^{(1)} + E_{\text{pol}}^{(2)} + \dots, \quad (6)$$

where we have used the subscript “pol” to indicate these are energies from the polarization expansion and do not include any of the effects of electron exchange between monomer. The individual terms in this series can be evaluated using the usual methods of perturbation theory (Stone 1996). At first order we have

$$E_{\text{pol}}^{(1)} = \left\langle \Phi_0^A \Phi_0^B \left| V \Phi_0^A \Phi_0^B \right. \right\rangle, \quad (7)$$

which is identified as the electrostatic energy of the interacting dimer and can be written in terms of the unperturbed total charge densities of the monomers:

$$E_{\text{pol}}^{(1)} = E_{\text{elst}}^{(1)} = \iint \rho_A^{\text{tot}}(\mathbf{r}_1) \frac{1}{|\mathbf{r}_1 - \mathbf{r}_2|} \rho_B^{\text{tot}}(\mathbf{r}_2) d\mathbf{r}_1 d\mathbf{r}_2. \quad (8)$$

Here, the total charge density of monomer X is defined as

$$\rho_X^{\text{tot}} = \sum_{\alpha \in X} Z_\alpha \delta(\mathbf{r} - \mathbf{R}_\alpha) - \rho_X \quad (9)$$

where ρ_X is the unperturbed electronic charge density of the monomer and the term containing the Dirac delta functions represents the nuclear charge density.

At second order we get

$$E_{\text{pol}}^{(2)} = \sum'_{rs} \frac{\left| \left\langle \Phi_0^A \Phi_0^B \middle| V \Phi_r^A \Phi_s^B \right\rangle \right|^2}{E_0^A + E_0^B - E_r^A - E_s^B}, \quad (10)$$

where r and s label the excited states of monomers A and B respectively. The prime indicates that at least one of r or s refer to an excited state. The above expression can be split into two physically motivated terms: the second-order induction and second-order dispersion energies. The second-order induction energy is obtained when the summation in Eq. 10 is restricted to those dimer states including only one excited monomer. This has two natural contributions: the ground state of monomer A interacting with excitations on monomer B, and vice versa. Thus,

$$E_{\text{ind,pol}}^{(2)} = E_{\text{ind,pol}}^{(2)}(A) + E_{\text{ind,pol}}^{(2)}(B), \quad (11)$$

where,

$$E_{\text{ind,pol}}^{(2)}(A) = \sum'_r \frac{\left| \left\langle \Phi_0^A \Phi_0^B \middle| V \Phi_r^A \Phi_0^B \right\rangle \right|^2}{E_0^A - E_r^A}. \quad (12)$$

Similarly, we can define $E_{\text{ind,pol}}^{(2)}(B)$.

From Eq. 12, we see that $E_{\text{ind,pol}}^{(2)}(A)$ may be interpreted as the second-order energy correction arising when the monomer A is perturbed by the external field Ω_B of monomer B. Thus the second-order induction energy can be interpreted as a *response* to a static field, and is therefore also called the polarization energy.

The remaining part of the second-order term $E_{\text{pol}}^{(2)}$ is the dispersion energy which is defined as

$$E_{\text{disp,pol}}^{(2)} = \sum_{r \neq 0} \sum_{s \neq 0} \frac{\left| \left\langle \Phi_0^A \Phi_0^B \middle| V \Phi_r^A \Phi_s^B \right\rangle \right|^2}{E_0^A + E_0^B - E_r^A - E_s^B}. \quad (13)$$

The dispersion is purely quantum mechanical in origin and is the only term at second order in λ that describes intermonomer electron correlation. The second-order dispersion energy is long ranged, always negative, and exists between all types of molecules.

The starting wave function $\Phi_0 = \Phi_0^A \Phi_0^B$ used in the polarization expansion is not antisymmetric with respect to electron interchanges between the monomers and thus cannot be expected to be reliable when overlap effects between the monomers become important. In this region, only a fully antisymmetric theory is valid. Various procedures exist to achieve the complete antisymmetrization and these are discussed by Jeziorski and Szalewicz (2002) and Szalewicz et al. (2005). The result is that corresponding to each of the three interaction energy components discussed above we get an exchange counterpart. At first order we get the

first-order exchange-repulsion energy $E_{\text{exch}}^{(1)}$, and at second order we get the second-order exchange-induction and exchange-dispersion energies, $E_{\text{ind,exch}}^{(2)}$ and $E_{\text{disp,exch}}^{(2)}$.

We now define the *total* induction and *total* dispersion energies as the sum of their polarization and exchange terms:

$$E_{\text{ind,tot}}^{(2)} = E_{\text{ind,pol}}^{(2)} + E_{\text{ind,exch}}^{(2)} \quad (14)$$

$$E_{\text{disp,tot}}^{(2)} = E_{\text{disp,pol}}^{(2)} + E_{\text{disp,exch}}^{(2)}. \quad (15)$$

These sums are the physically relevant energies; the individual components are useful from the theoretical standpoint, but are somewhat arbitrary and depend on the particular perturbation theory used.

Therefore, the total interaction energy can be defined as

$$E_{\text{int}} = E_{\text{elst}}^{(1)} + E_{\text{exch}}^{(1)} + E_{\text{ind,tot}}^{(2)} + E_{\text{disp,tot}}^{(2)} + \Delta E_{\text{int}}^{(3-\infty)}, \quad (16)$$

where the last term collects all contributions of third order and higher in the interaction operator V . We will describe the theoretical methods for calculating the interaction energy components in section “[Perturbation Theory](#).” Now let us see the kind of interpretational power perturbation theory gives us by taking a look at a few examples.

Examples

Based on the relative contributions of the interaction energy components, we can classify intermolecular bonds. For example, hydrogen-bonded complexes tend to be bound primarily by the electrostatic and induction (polarization) components of the interaction energy, while van der Waals complexes are bound primarily by the dispersion energy. Of course, most complexes will fall in between, so it is probably better not to regard such classifications as being rigorous, but they are useful as they provide us with a physical picture of the mechanisms of the intermolecular bond.

Interaction energies and components for three representative complexes are presented in Table 1. We have used both approaches: perturbation theory and the supermolecular method.

- *Hydrogen bonding*: At its minimum energy geometry, the water dimer shows a bonding pattern that is typical of hydrogen-bonded complexes (Buckingham et al. 2008). Binding is primarily due to the electrostatic and induction energies. In fact, this is the only one of the three complexes which is bound at first order, that is, the sum of the first-order energies is negative. Even so, the dispersion energy is certainly non-negligible and contributes almost 40 % of the binding of this complex. The terms of third and higher orders contribute significantly to the binding of these complexes.
- *van der Waals bonding*: The benzene dimer in the sandwich geometry is a typical example of a van der Waals bound complex. The dimer is unbound at first order and the electrostatic and induction energies make minor contributions to the interaction energy. Almost all the binding arises at second order from the

Table 1 Interaction energy components for the water dimer, benzene dimer, and the $\text{Cl}_2 \cdots \text{OH}_2$ complex. The water dimer is in its equilibrium geometry, the benzene dimer is in the parallel stacked geometry with center-of-mass separation 3.7 Å, and the $\text{Cl}_2 \cdots \text{OH}_2$ complex is in a symmetrical complex with all atoms in a plane and collinear with $r(\text{Cl} \cdots \text{O}) = 2.755$ Å. All energies are reported in kJ mol^{-1}

Energy	$(\text{H}_2\text{O})_2$	$\text{Cl}_2 \cdots \text{OH}_2$	$(\text{C}_6\text{H}_6)_2$
Perturbation theory [SAPT(DFT)]:			
$E_{\text{elst}}^{(1)}$	-28.90	-19.24	-1.63
$E_{\text{exch}}^{(1)}$	23.97	24.96	20.99
$E_{\text{ind,pol}}^{(2)}$	-10.96	-16.09	-7.65
$E_{\text{ind,exch}}^{(2)}$	5.79	12.21	6.70
$E_{\text{ind,tot}}^{(2)}$	-5.16	-3.88	-0.95
$E_{\text{disp,pol}}^{(2)}$	-10.02	-12.49	-29.03
$E_{\text{disp,exch}}^{(2)}$	1.68	1.76	2.89
$E_{\text{disp,tot}}^{(2)}$	-8.34	-10.73	-26.14
$\Delta E_{\text{int}}^{(3-\infty)}$	-2.82	-3.24	+0.34
E_{int}	-21.26	-12.13	-7.39
Supermolecular:			
$E_{\text{int}}[\text{MP}(2)]$	-20.34	-12.43	-15.23 ^a
$E_{\text{int}}[\text{CCSD}(T)]$	-20.45	-11.21	-7.57 ^a

^aFrom Sinnokrot et al. (2002). These energies are close to the basis set limit

dispersion energy. Third- and higher-order terms are generally small for van der Waals complexes, and in this particular case, they are positive.

- *Intermediate case:* As an example of an intermediate case consider the so-called halogen-bonded complex $\text{Cl}_2 \cdots \text{OH}_2$. The exchange-repulsion energy of this complex is similar to that of the water dimer, but the electrostatic and induction energies are not as strong. The dispersion contributes a substantial fraction of the interaction energy, but less than for the benzene dimer. Third- and higher-order terms are quite large for this particular system.

By comparison, the supermolecular methods provide just the interaction energy: a single number. But perturbation theory does not provide only physical interpretation; the breakup of the interaction energy proves invaluable when constructing model interaction potentials (Stone and Misquitta 2007) and semi-empirical methods, some of which we shall see later.

Practical Methods for the Two-Body Interaction Energy

Supermolecular Methods

The two-body interaction energy can be calculated directly through Eq. 4 as the difference in energies of the dimer and the monomers. This approach, known as the *supermolecular method*, has the advantage of allowing E_{int} to be calculated

using a variety of electronic structure methods. We will only briefly describe some aspects of this method below; for a more complete description see Chalasinski and Szczesniak (2000).

Two of the most commonly used electronic structure methods to evaluate E_{int} are MP2 (second-order Moller–Plesset perturbation theory) and CCSD(T) (coupled-cluster with singles and doubles and non-iterated triples). Interaction energies calculated using these methods are shown in Table 1. Interaction energies calculated using MP2 are usually close to those calculated using the more sophisticated and computationally expensive CCSD(T), but the exception is the benzene dimer system for which MP2 overestimates the binding by almost a factor of 2. This deserves some explanation.

Moller–Plesset perturbation theory starts from a Hartree–Fock description of the system and builds in electron correlation perturbatively. In MP2, electron correlation is described using second-order perturbation theory. For a pair of interacting molecules the two orders of perturbation theory are used to describe the dispersion interaction, and therefore cannot be used to simultaneously describe electron correlation *within* each of the interacting molecules. This seems to cause severe problems for systems with π -bonding for which MP2 is completely inappropriate. Recently, this problem has been corrected using a hybrid scheme in which the dispersion component of the MP2 interaction energy is replaced with the dispersion energy calculated using SAPT(DFT) (see below) (Pitonak and Hesselmann 2010).

The CCSD(T) method takes a very different approach to electron correlation and is today regarded as the reference method for many kinds of problems. However, the computational cost of CCSD(T) scales as the seventh power of the system size, and therefore this method cannot be applied to large systems.

One of the sources of error in a supermolecular calculation of the interaction energy is the basis set superposition error (BSSE). This is the artificially enhanced binding that occurs because of the use of finite basis sets. This problem has been discussed at length in the literature, so we will not get into details here. A simple way of correcting for this error was suggested by Boys and Bernardi (1970) who suggested that the BSSE could be reduced by using the dimer basis to calculate the monomer energies. This leads to the *counterpoise* (CP) corrected interaction energy defined as

$$E_{\text{int}}^{\text{CP}} = E_{AB}(AB) - E_A(AB) - E_B(AB). \quad (17)$$

Here $E_A(AB)$ is the energy of A calculated in the dimer basis AB, and likewise for $E_B(AB)$. The CP form of the interaction energy should always be used, except possibly when the basis set is too poor. However, in this case, neither the CP corrected nor the uncorrected energies may be meaningful.

There is another aspect of the BSSE worth keeping in mind: An energy minimum on the CP corrected surface will generally occur at a different geometry from the corresponding minimum on the uncorrected surface. Since geometry optimizations are typically performed on the latter surface, the resulting structure will need to

be re-optimized on a CP corrected surface, but this is often rather difficult and computationally expensive.

Density Functional Theory

Density functional theory (DFT) is not presently suitable for intermolecular interactions (Tsuzuki and Lüthi 2001; van Mourik and Gdanitz 2002). The main reason for this failure of DFT is the highly non-local nature of the dispersion interaction which is present even when charge densities do not overlap. Since most density functionals are local or semi-local in the density, that is, they depend on the electron density and gradients of the density, they are unable to account for non-local correlations, and therefore cannot describe the dispersion energy.

Recently, there have been many attempts made to include the dispersion in DFT, either *explicitly* through a dispersion correction (Grimme 2004; Neumann and Perrin 2005) or *implicitly* through a non-local functional (Dion et al. 2004). The former method is necessarily empirical and makes a priori assumptions about the nature of the dispersion interaction. Though the latter methods are promising, it is still unclear if they are accurate enough in practice. Also recently, Becke and Johnson (2005) have proposed that the dispersion energy could be included in DFT through correlations in the exchange-hole dipole moments evaluated using the occupied orbitals. This method is promising and has been given a theoretical justification by Angyan (2007) and Hesselmann (2009).

In a recent development, Pernal et al. (2009) have used SAPT(DFT) (see below) interaction energies for a number of dimers to develop an exchange-correlation functional that does not include the dispersion energy. They have subsequently added the dispersion energy calculated from SAPT(DFT). This is a significant development as it is far better founded on theoretical grounds than other dispersion-corrected DFT methods. In practice a more efficient, but less accurate method could be to use dispersion models such as the WSM models described below.

Perturbation Theory

Symmetry-Adapted Perturbation Theory

Until recently, and possibly still so for certain applications, one of the most successful perturbation theories for intermolecular interactions was the symmetry-adapted perturbation theory (SAPT) (Jeziorski and Szalewicz 2002; Jeziorski et al. 1994). SAPT is a triple perturbation theory based on a Hartree–Fock description of the interacting monomers. Intramolecular correlation is built up using two of the perturbations, and intermolecular correlation by the third. SAPT has been applied to a large number of systems with very good success. See for example, applications to the water dimer (Mas et al. 1997), the carbon dioxide dimer (Bukowski et al. 1999), the He–HCCCN dimer (Akin-Ojo et al. 2003), Ar–CO₂ dimer (Misquitta et al. 2000), and the Ne–HCN dimer (Murdachaew et al. 2001). However, SAPT, like the CCSD(T) method, is computationally expensive with scaling of $\mathcal{O}N^7$, where N is the size of the system (which can be taken to be the number of electrons), and

quickly become impossible to apply as this size increases, and cannot be applied to systems of more than about ten atoms without a significant reduction to the level of correlation.

Symmetry-Adapted Perturbation Theory Based on DFT

Fairly recently, Szalewicz, Misquitta, and Jeziorski (Misquitta and Szalewicz 2002, 2005; Misquitta et al. 2003, 2005b), and independently, Jansen and Hesselmann (Hesselmann and Jansen 2002a, b, 2003a, b) developed a variant of SAPT based on DFT that has largely superseded SAPT both in terms of accuracy as well as computational efficiency. In this method, termed SAPT(DFT) or DFT-SAPT, the interaction energy components are formulated to make their dependence on molecular properties like the charge density and density response functions explicit. These molecular properties are then calculated using DFT and linear-response time-dependent DFT. In some sense, DFT is used to describe intramolecular correlation effects, thereby significantly simplifying the perturbation theory as the intramolecular perturbation operators are no longer required.

The first-order electrostatic energy $E_{\text{elst}}^{(1)}$ has already been shown to arise from the Coulomb interaction of the unperturbed total charge densities of the interacting monomers (Eq. 8). In SAPT(DFT), these densities are obtained from DFT. To see how the second-order induction and dispersion energies can be expressed in terms of molecular properties we need to define the frequency-dependent density susceptibility (FDDS):

$$\alpha_X(\mathbf{r}, \mathbf{r}' | \omega) = 2 \sum_{r \neq 0} \frac{E_r^X - E_0^X}{(E_r^X - E_0^X)^2 - \omega^2} \langle \Phi_0^X | \hat{\rho}_X(\mathbf{r}) | \Phi_r^X \rangle \langle \Phi_r^X | \hat{\rho}_X(\mathbf{r}') | \Phi_0^X \rangle, \quad (18)$$

where ω is a frequency and $\hat{\rho}_X(\mathbf{r}) = -\sum_{i \in X} \delta(\mathbf{r} - \mathbf{r}_i)$ is the electron density operator. The FDDS describes the linear response of the electron density to a frequency-dependent perturbation.

$E_{\text{ind,pol}}^{(2)}(A)$ can be written in terms of the FDDS evaluated at zero frequency (Magnasco and McWeeny 1991):

$$E_{\text{ind,pol}}^{(2)}(A) = -\frac{1}{2} \iint V_B(\mathbf{r}) \alpha_A(\mathbf{r}, \mathbf{r}' | 0) V_B(\mathbf{r}') d\mathbf{r} d\mathbf{r}' \quad (19)$$

where $V_B(\mathbf{r}) = \int \rho_B^{\text{tot}}(\mathbf{r}') / |\mathbf{r} - \mathbf{r}'| d\mathbf{r}'$ is the electrostatic potential of monomer B, and similarly for $E_{\text{ind,pol}}^{(2)}(B)$. We therefore see that the induction energy is a *response* energy of the molecule to the potential arising from the interacting partner.

The dispersion energy involves the FDDSs of the two molecules evaluated at imaginary frequency (Longuet-Higgins 1965; Zaremba and Kohn 1976):

$$E_{\text{disp,tot}}^{(2)} = -\frac{1}{2\pi} \int_0^\infty d\omega \int d\mathbf{r}_1 d\mathbf{r}'_1 d\mathbf{r}_2 d\mathbf{r}'_2 \frac{\alpha_A(\mathbf{r}_1, \mathbf{r}'_1; i\omega) \alpha_B(\mathbf{r}_2, \mathbf{r}'_2; i\omega)}{|\mathbf{r}_1 - \mathbf{r}_2| |\mathbf{r}'_1 - \mathbf{r}'_2|}. \quad (20)$$

There is no easy way to interpret this expression which is a coupling of the response functions of the two molecules, but at imaginary frequency. However, see the discussion in Angyan (2007) and Hesselmann (2009) where an approximate form of this expression is related to correlations in fluctuating exchange-holes of the monomers.

Linear-response time-dependent DFT, also known as coupled Kohn–Sham (CKS), provides us with a convenient framework for evaluating the FDDS. CKS theory has been used for some time now to obtain excitation energies of small systems (Grabo et al. 2000; Onida et al. 2002) and molecular properties like polarizabilities and hyperpolarizabilities (Adamo et al. 1999; Tozer and Handy 1998) (see Koch 2000 for a comprehensive summary), so it is not surprising that it can also be used to evaluate the second-order dispersion and induction energies through the FDDS (Hesselmann and Jansen 2003b; Misquitta et al. 2003). Within CKS theory (and also coupled Hartree–Fock (CHF) theory), the FDDS takes the form (Casida 1995; Colwell et al. 1995; Petersilka et al. 1996):

$$\alpha(r, r' | \omega) = \sum_{i v, i' v'} C_{i v, i' v'}(\omega) \phi_i(\mathbf{r}) \phi_v(\mathbf{r}) \phi_{i'}(\mathbf{r}') \phi_{v'}(\mathbf{r}'), \quad (21)$$

where the subscripts i and i' (v and v') denote occupied (virtual) molecular orbitals and ϕ_i is a molecular orbital obtained from Kohn–Sham DFT. The coupling between the molecular orbitals is contained in the coefficients $C_{i v, i' v'}(\omega)$ which are defined in Colwell et al. (1995), Ioannou et al. (1997), Misquitta et al. (2005b), and Podeszwa et al. (2006b). These coefficients involve Coulomb integrals of the molecular orbitals as well as integrals containing the functional derivative of the exchange–correlation potential. The method used to evaluate the coefficients $C_{i v, i' v'}(\omega)$ is quite important as the dispersion energy calculated through Eq. 20 varies appreciably depending on the type of FDDS (Misquitta et al. 2005b).

The exchange energies depend explicitly on molecular wavefunctions through the interaction density matrix (Jeziorski et al. 1994; Moszyński et al. 1994). In SAPT(DFT), these energies are evaluated using Kohn–Sham molecular orbitals and, for the second-order exchange energies, the effect of orbital relaxation is estimated by scaling:

$$E_{\text{ind,exch}}^{(2)} = E_{\text{ind,exch}}^{(2)}(\text{KS}) \times \frac{E_{\text{ind,pol}}^{(2)}}{E_{\text{ind,pol}}^{(2)}(\text{KS})} \quad (22)$$

$$E_{\text{disp,exch}}^{(2)} = E_{\text{disp,exch}}^{(2)}(\text{KS}) \times \frac{E_{\text{disp,pol}}^{(2)}}{E_{\text{disp,pol}}^{(2)}(\text{KS})} \quad (23)$$

where the energies calculated without orbital relaxation are indicated by “KS,” that is, they use un-relaxed Kohn–Sham orbitals. The validity of using Kohn–Sham orbitals for the first-order exchange-repulsion energy has been justified by an asymptotic analysis of the exact and Kohn–Sham interaction density matrices (Misquitta and Szalewicz 2002) as well as extensive numerical tests (Misquitta and Szalewicz 2005). In the DFT-SAPT formulation, the second-order exchange energies are defined via coupled-response theory (Hesselmann et al. 2005).

Exchange-correlation functional: Which exchange-correlation functional should be used in SAPT(DFT) calculations? The short answer is that while SAPT(DFT) interaction energies are not very sensitive to the exchange-correlation functional used, it has been concluded from extensive numerical experiments that the asymptotically corrected (Tozer 2000; Tozer and Handy 1998) PBE0 (Adamo and Barone 1999) exchange-correlation functional results in the most accurate interaction energies for a variety of systems. For details see Hesselmann and Jansen (2002a), Misquitta and Szalewicz (2005), and Misquitta et al. (2005b). The PBE0 functional (also called PBE1PBE) is a hybrid functional with 75 % of its exchange energy determined from PBE and 25 % from the so-called exact, or Hartree–Fock exchange. This means that the FDDS must also be constructed as the hybrid of the FDDSs from CKS and CHF theories. This is quite important as significant errors in the dispersion energy are introduced if the FDDS is constructed using CKS theory alone (Misquitta et al. 2005b). For large molecules, however, the terms in the coefficients $C_{i_v, i'v'}(\omega)$ that depend on the functional derivative of the exchange-correlation potential are computationally demanding to evaluate using the PBE functional. Instead, a more practical approach is to calculate these coefficients using the exchange-only LDA functional. Therefore, while the Kohn–Sham molecular orbitals and eigenvalues are obtained using the PBE0 functional, the FDDS is best constructed using the less accurate LDA + CHF kernel. This approximation results in a small (less than 1 %) loss in accuracy which is more than compensated by an order of magnitude reduction in computational expense (Misquitta et al. 2005b).

Asymptotic correction: The asymptotic correction is needed to correct the tails of the exchange-correlation potential, and consequently, the density tails that are crucial for intermolecular interactions. In order to implement the asymptotic correction, accurate vertical ionization potentials (IPs) are needed for the monomers. When they are not available experimentally, good estimates may be obtained from the difference between the energies of the N and $N - 1$ electron systems. The PBE0 functional is best suited for this calculation too as tests on atoms, diatoms, and small organic molecules have shown that it gives IPs with mean errors centered about 0.0 a.u. with a standard deviation of only 0.007 a.u. (Ernzerhof and Scuseria 1999). This correction is definitely needed if the individual interaction energy components are required to be accurate. However, it is cumbersome to apply for large systems, when a single IP may be questionable and local IPs are hard to define. In such cases, the asymptotic correction is best neglected, particularly if total interactions are all that is desired.

Density-Fitting

The SAPT(DFT) interaction energy components are not evaluated directly through the expressions provided in the previous section, but are formulated to make use of a procedure known as density-fitting (DF) or the resolution of the identity (RI) (Dunlap 2000; Dunlap et al. 1979). The idea here is to expand pairs of molecular orbitals that appear in the energy expressions in an auxiliary basis. For example, we may perform the DF expansion of one such pair that appears in the FDDS defined through Eq. 21 as follows:

$$\rho_{iv}(\mathbf{r}) = \phi_i(\mathbf{r})\phi_v(\mathbf{r}) \approx \tilde{\rho}_{iv}(\mathbf{r}) = \sum_k D_{iv,k} \chi_k(\mathbf{r}), \quad (24)$$

where χ_k are the auxiliary basis functions and $D_{iv,k}$ are the expansion coefficients. In the standard density-fitting procedure (Dunlap et al. 1979), the fitted density $\tilde{\rho}$ is found by minimizing the integrals

$$\Delta_{iv} = \int \int (\tilde{\rho}_{iv}(\mathbf{r}) - \rho_{iv}(\mathbf{r})) \frac{1}{|\mathbf{r} - \mathbf{r}'|} (\tilde{\rho}_{iv}(\mathbf{r}') - \rho_{iv}(\mathbf{r}')) d\mathbf{r} d\mathbf{r}'. \quad (25)$$

With these expansions, the FDDS can be rewritten as (Misquitta et al. 2003)

$$\alpha(\mathbf{r}, \mathbf{r}' | \omega) = \sum_{k,l} \tilde{C}_{kl}(\omega) \chi_p(\mathbf{r}) \chi_q(\mathbf{r}'), \quad (26)$$

where $\tilde{C}_{kl}(\omega)$ are the transformed coefficients given by $\tilde{C}_{kl}(\omega) = \sum_{i_v, i'v'} D_{iv,k} C_{i_v, i'v'}(\omega) D_{i'v', l}$. Now the FDDS defined through Eq. 21 involves a quadruple sum over molecular orbitals, but in Eq. 26 the sum is over only two indices. This represents a huge reduction in computational expense provided that the size of the density-fitting basis – commonly called the *auxiliary basis* – is of the same order as the size of the main basis (the basis used to obtain the molecular orbitals), which is indeed the case with optimized auxiliary basis sets.

With the density-fitted formulation of SAPT(DFT), commonly called DF-SAPT(DFT) or DF-DFT-SAPT, the computational cost of the second-order interaction energy scales as only $\mathcal{O}(N^5)$ if hybrid functionals are used (Bukowski et al. 2005; Podeszwa et al. 2006b). In the DFT-SAPT implementation the FDDS is calculated without a contribution from CHF theory. This reduces the computational scaling for evaluating the FDDS to $\mathcal{O}(N^4)$, but the overall scaling is still $\mathcal{O}(N^5)$ because of the 4-index two-electron integrals (Hesselmann et al. 2005). This is the same computational scaling as MP2, though DF-SAPT(DFT) calculations take a few times longer due to the additional complexity of the method. Compare this to the $\mathcal{O}(N^7)$ scaling of SAPT and CCSD(T).

Higher-Order Contributions

Contributions of third and higher order to the two-body interaction energy are often large and cannot be neglected. In particular, for systems of polarizable molecules with large permanent multipole moments terms of third and higher order can contribute as much as 30 % of the binding energy at equilibrium geometries. Such systems tend to have a large $E_{\text{ind,pol}}^{(2)}$. Examples are the water dimer and the $\text{Cl}_2 \cdots \text{OH}_2$ systems in Table 1. For dispersion-bound systems the higher-order contributions are smaller and constitute only as much as 5 % of the total interaction energy (see the benzene dimer in Table 1) and can therefore be neglected if high accuracies are not required.

The most common method for approximating the terms of third and higher-order, $E_{\text{int}}^{(3-\infty)}$, is the $\delta_{\text{int,resp}}^{\text{HF}}$ correction (Jeziorska et al. 1987; Moszynski et al. 1996):

$$E_{\text{int}}^{(3-\infty)} \approx \delta_{\text{int,resp}}^{\text{HF}} = E_{\text{int}}^{\text{HF}} - \left(E_{\text{elst}}^{(1)}(\text{HF}) + E_{\text{exch}}^{(1)}(\text{HF}) + E_{\text{ind,tot}}^{(2)}(\text{CHF}) \right), \quad (27)$$

where the $E_{\text{int}}^{\text{HF}}$ is the counterpoise-corrected supermolecular interaction energy calculated using Hartree–Fock theory, and the interaction energies are calculated using Hartree–Fock orbitals (denoted by “HF”) or, for the second-order induction energy, using CHF theory. This approximation was used to evaluate $E_{\text{int}}^{(3-\infty)}$ for the water dimer and $\text{Cl}_2 \cdots \text{OH}_2$ systems (Table 1) for which this term contributes 13 % and 27 % of the total interaction energy.

There is evidence (Patkowski et al. 2006) that the $\delta_{\text{int,resp}}^{\text{HF}}$ estimate is not appropriate for dispersion-bound systems, for which a better estimate of $E_{\text{int}}^{(3-\infty)}$ is (Misquitta and Stone 2008a)

$$E_{\text{int}}^{(3-\infty)} \approx E_{\text{ind,tot}}^{(3)}(\text{KS}) \quad (28)$$

where $E_{\text{ind,tot}}^{(3)}(\text{KS})$ is the total third-order induction energy evaluated without relaxation, that is, using uncoupled Kohn–Sham theory. This estimate has been used for the benzene dimer in Table 1.

For large systems it is quite conceivable that no clear distinction may be possible that would justify the use of either one of these approximations. In such cases, it would probably be better to use the $\delta_{\text{int,resp}}^{\text{HF}}$ approximation rather than ignore the higher-order energies altogether.

Basis Sets: Charge-Transfer

In general, the basis sets used to calculate intermolecular interaction energies need to be large and augmented with diffuse functions. In part, this is because of the second-order energies which are response energies. Consequently, the basis set has to be good enough to describe not only the charge density accurately (particularly in the region of the density tail), but also the *response* of the density to perturbations. These requirements are adequately met only by basis sets of the augmented triple- ζ

kind (and larger), such as aug-cc-pVTZ (Kendall et al. 1992; Woon and Dunning 1994) and Sadlej-pVTZ (Sadlej 1992; Sadlej and Urban 1991).

However, when the overlap of the charge densities of the interacting monomers becomes significant (typically at around the equilibrium separation) the basis set must be flexible enough to describe the intermolecular electron–electron cusp as well as the intermolecular charge-transfer (CT). The former effect is manifested as part of $E_{\text{disp,tot}}^{(2)}$ and the latter as part of $E_{\text{ind,tot}}^{(2)}$.

It is often quite difficult to converge $E_{\text{disp,tot}}^{(2)}$ with basis set. This is because it is hard to describe the intermolecular electron–electron cusp in the bonding region using basis functions located on atomic sites only (Burcl et al. 1995). In this case, fairly high-angular-momenta functions are needed in order to do so. However, this leads to very large basis sets and a consequent increase in computational requirements. An alternative is to use basis sets augmented with the so-called *mid-bond* functions: a small set of basis functions located in the bonding region (see Burcl et al. 1995; Williams et al. 1995 and references therein). The dispersion energy is not so sensitive to the exact composition of the mid-bond basis, which is usually chosen to consist of a set of 3 *s*, 2 *p*, and 1 *d* diffuse functions (Mas et al. 1997). A convenient choice for the location of the mid-bond set has been given in Akin-Ojo et al. (2003).

An alternative to mid-bond functions is to use the basis set extrapolation scheme of Helgaker et al. (1997). For intermolecular interactions, this involves calculating $E_{\text{disp,tot}}^{(2)}$ using two correlation-consistent basis sets, say the aug-cc-pV *n*Z and the aug-cc-pV(*n* + 1)Z Dunning bases. This energy can be fitted to the form $a + b/X^3$ where $X = n$ and $n + 1$ and the constants determined. The complete basis set (CBS) estimate of $E_{\text{disp,tot}}^{(2)}$ is obtained by extrapolating $X \rightarrow \infty$, that is, it is the constant *a*. This scheme has the advantage that it applies equally well to small as well as large molecules, for which the mid-bond scheme is potentially ambiguous. However, two electronic structure calculations need to be performed, so there is an increase in computational cost.

Charge transfer poses a very different problem. This subject is discussed more completely in Stone and Misquitta (2009) and Stone (1996). The CT energy is the part of the short-range induction energy that involves excitations from the occupied orbitals on one molecule into the virtual orbitals of another. Consequently, in Stone (1993) it was suggested that the CT energy could be calculated as the difference of $E_{\text{ind,tot}}^{(2)}$ calculated in the dimer and monomer basis. The understanding here is that the monomer basis is localized, so excitations into the virtual space of the interacting partner should be suppressed. In any case, if CT excitations are to be correctly included, the induction energy should be calculated using the dimer basis. In practice, this is rather excessive, and it has been shown (Williams et al. 1995) that only a subset of the basis of the interacting partner need be included. This is typically taken to be just the functions of *s* and *p* symmetry. Thus, when calculating the induction energy of A in the presence of B, that is, $E_{\text{ind,tot}}^{(2)}(A)$, we use in addition to the basis set of A, the *s* and *p* symmetry functions of B located where the atomic sites of B would be. These ghost functions are known as the *far-bond* functions.

The combined basis consisting of functions on the molecule and the mid-bond and far-bond functions is referred to as the *monomer-centered plus* or “MC+” basis type. The “+” indicating the presence of the additional basis functions. A typical SAPT(DFT) calculation of the interaction energy would involve two such bases; one for each of the two interacting molecules.

The additional functions are required for the second-order energies. If all that is needed are the first-order energies, the MC basis can be used, that is, basis functions need be included only on the monomer. First-order electrostatic and exchange-repulsion energies calculated in such a basis are generally very close to those calculated in the larger MC+ type of basis if a triple- ζ -quality basis is used.

Finally, if each molecule is described using the dimer basis we obtain the DC or DC+ basis types; the latter additionally including the mid-bond set. These basis types must be used for supermolecular calculations of the interaction energy.

Auxiliary Basis Sets

One downside of density-fitting is that the auxiliary basis used needs to be paired with the main basis. Nevertheless, optimized auxiliary basis sets are available (Weigend et al. 1998, 2002) for most of the commonly used main basis sets. These tend to be between two and three times larger than the main basis.

A few points should be noted when using density-fitting for intermolecular forces:

- The auxiliary basis used needs to be of the DC or DC+ type even if the main basis is of the MC or MC+ type. It is not clear why this is the case, but a failure to do so sometimes results in unacceptable errors in $E_{\text{elst}}^{(1)}$ and $E_{\text{ind,tot}}^{(2)}$.
- The Sadlej-pVTZ basis does not have an optimized auxiliary basis associated with it, but experience suggests that the aug-cc-pVTZ auxiliary basis may be used.
- When using the Dunning aug-cc-pV nZ basis sets, higher accuracies may be obtained by using auxiliary basis sets optimized for the aug-cc-pV($n+1$)Z bases.

Multipole Expansion for the Interaction Energy

One of the major strengths of perturbation theory is that each of the interaction energy components possesses a multipole expansion that allows us to evaluate the interaction energy analytically in terms of molecular properties alone, at least when the molecular charge densities do not overlap appreciably.

The intermolecular interaction operator V defined through Eq. 5 can be written as

$$V = \sum_{\alpha \in A} \sum_{\beta \in B} \frac{q_{\alpha} q_{\beta}}{r_{\alpha\beta}}, \quad (29)$$

where $\alpha(\beta)$ label all the particles (electrons and nuclei) of monomers A (B), q_{α} is the charge (in atomic units) of particle α , and $r_{\alpha\beta}$ is the inter-particle distance. If

A and B are well separated so that their charges are distinct and do not overlap (strictly this is never exactly possible), we can expand the interaction operator in the multipole expansion to give (in the compact notation of Stone 1996):

$$V = \sum_{t,u} \widehat{Q}_t^A T_{tu}^{AB} \widehat{Q}_u^B. \quad (30)$$

There is a lot compressed in this expression so it is well that we spend some time unravelling it. First of all, the subscripts t and u label the angular momenta of the real spherical harmonics and take the lm values 00, 10, 11 *c*, 11 *s*, 20, 21 *c*, 21 *s*, 22 *c*, 22 *s*, ... (the labels “*c*” and “*s*” stand for cosine and sine respectively). \widehat{Q}_t^A is the real form of the multipole moment operator of rank t centered on A and expressed in the local-axis system of A, while T_{tu}^{AB} is the so-called T -tensor that carries the distance and angular dependence. The T -function of ranks l_1 and l_2 has a distance dependence $R^{-l_1-l_2-1}$ where R is the separation between the centers of A and B.

Using this form of the interaction energy operator, the first-order electrostatic energy can be written as

$$E_{\text{elst}}^{(1)}(\text{MP}) = \sum_{t,u} Q_t^A T_{tu}^{AB} Q_u^B, \quad (31)$$

where Q_t^A is now the rank t multipole moment of the total charge density of A. This expression, which follows directly from Eqs. 8 and 30, is convenient as multipole moments are relatively easy to calculate. Therefore, Eq. 31 provides us an easy method for calculating the first-order electrostatic energy. But consider the following points:

- Contributions to the electrostatic energy that decay exponentially with separation R do not contribute to the multipole expansion. Such terms arise when the charge densities overlap and are therefore referred to as the *penetration* contributions to the interaction energy.
- The non-expanded electrostatic energy (Eq. 8) exhibits a R^{-1} divergence when the nuclei of the interacting molecules approach each other, but the multipole expansion introduces a higher-order divergence because it includes terms of the form R^{-n} with $n > 1$. These terms need to be *damped* out at short range. This is usually done using a *damping function* $f_n(R)$ that has the property that $f_n(R) \rightarrow R^n$ for small R and $f_n(R) \rightarrow 1$ at large R . We will discuss specific forms of these functions later.

Therefore, we can write the electrostatic energy as

$$E_{\text{elst}}^{(1)} = Ae^{-\alpha R} + \sum_{t,u} Q_t^A f_{(tu)}(R) T_{tu}^{AB} Q_u^B, \quad (32)$$

where the first term is the exponential penetration contribution (that is usually negative) and the second is the damped multipole expansion of the electrostatic energy. In general, the coefficients A and α in the penetration term will depend on orientation and possibly on distance. The exact form is not critical, what is important is that this term exists at short separations and that it can be large in magnitude.

This analysis also applies to the multipole expansions for the second-order induction and dispersion energies. But before getting to these, let us ask an important question: When is the single-center multipole expansion valid? To answer this question fully would take us beyond the scope of this chapter. Instead we will introduce the main ideas here without proof, and refer the reader to the detailed discussion in Chap. 7 of Stone (1996).

A key concept is the idea of the sphere of divergence. This is defined as the sphere centered on the expansion center (typically the center-of-mass) and just enclosing all charges. For a molecule this poses a problem as the electronic density formally extends to infinity. But it has been shown (Stone and Alderton 1985) that for charge densities expressed as the sum of Gaussian functions, it is sufficient that the sphere enclose all nuclear sites. The multipole expansion is valid only if the spheres of divergence of all interacting molecules *do not overlap*.

This poses a problem for all but the smallest of molecules. For example, consider the benzene dimer in the sandwich configuration used in Table 1. The equilibrium separation is about 3.7 Å, but the radius of a benzene molecule is about 2.4 Å, so the molecules would have to be at least 4.8 Å apart before the single-center multipole expansion could be used. And even then, the expansion would be only slowly convergent.

A solution to this problem is to use a multi-centered multipole expansion, more commonly called a *distributed multipole expansion*. In principle the centers could be arbitrarily chosen, but it is convenient to use the atomic nuclei as centers. The distributed multipole expansion of the intermolecular interaction operator V is

$$V = \sum_{a \in A} \sum_{b \in B} \sum_{tu} \widehat{Q}_t^a T_{tu}^{ab} \widehat{Q}_u^b, \quad (33)$$

which is similar to Eq. 30 except that now \widehat{Q}_t^a is the rank t multipole moment operator for site a . We will define the precise form of these multipole moment operators later.

We are now in a position to define the distributed multipole expansions for $E_{\text{elst}}^{(1)}$, $E_{\text{ind,tot}}^{(2)}$, and $E_{\text{disp,tot}}^{(2)}$. Recall that the exchange energies decay exponentially with molecular separation and have no expansion in $1/R$. Consequently, the multipole expansion for $E_{\text{ind,tot}}^{(2)}$ is the same as that for $E_{\text{ind,pol}}^{(2)}$ and will be denoted simply by $E_{\text{ind}}^{(2)}(\text{MP})$. Likewise for $E_{\text{disp}}^{(2)}(\text{MP})$. The damping functions have been omitted from the expansions given below. To insert them is straightforward: for every T_{tu}^{ab} include a damping function of the form $f_{(tu)}(r_{ab})$.

- Electrostatic energy: The generalization of the single-center expansion is straightforward and we get

$$E_{\text{elst}}^{(1)}(\text{MP}) = \sum_{a \in A} \sum_{b \in B} \sum_{tu} Q_t^a T_{tu}^{ab} Q_u^b. \quad (34)$$

- Second-order induction: The second-order induction energy for molecule A is given by

$$E_{\text{ind}}^{(2)}(\text{MP}) = (A) = -\frac{1}{2} \sum_{a, a' \in A} \sum_{b, b' \in B} \sum_{tu t' u'} Q_u^b T_{tu}^{ab} \alpha_{tt'}^{aa'} T_{t'u'}^{a'b'} Q_{u'}^{b'}, \quad (35)$$

where $\alpha_{tt'}^{aa'}$ is the static polarizability of rank t by t' for sites a and a' and is defined by

$$\alpha_{tt'}^{aa'} = \iint \widehat{Q}_t^a(\mathbf{r}) \alpha(\mathbf{r}, \mathbf{r}' | 0) \widehat{Q}_{t'}^{a'}(\mathbf{r}') d\mathbf{r} d\mathbf{r}'. \quad (36)$$

Likewise, we define $E_{\text{ind}}^{(2)}(\text{MP}) (B)$.

From Eq. 35 we see that the second-order induction energy of A is a *linear response* to permanent multipoles of B.

- Second-order dispersion: The second-order dispersion energy has the distributed multipole expansion

$$E_{\text{disp}}^{(2)}(\text{MP}) = -\frac{1}{2\pi} \sum_{a, a' \in A} \sum_{b, b' \in B} \sum_{tu t' u'} T_{tu}^{ab} T_{t'u'}^{a'b'} \int_0^\infty \alpha_{tt'}^{aa'}(i\omega) \alpha_{uu'}^{bb'}(i\omega) d\omega, \quad (37)$$

where $\alpha_{tt'}^{aa'}(i\omega)$ is the frequency-dependent distributed polarizability defined analogously to Eq. 36 and evaluated at imaginary frequency. This form of the asymptotic dispersion energy involves a quadrupole sum over sites and is too cumbersome for most applications. Instead, very often a simplification is made by *localizing* the distributed polarizabilities to obtain a polarizability description that contains terms that contain one site index only. With this simplification, the dispersion expansion involves a double sum over sites and can be cast into the more familiar site–site form (Stone and Tough 1984):

$$\begin{aligned} E_{\text{disp}}^{(2)}(\text{MP}) &= -\frac{1}{2\pi} \sum_{a \in A} \sum_{b \in B} \sum_{tu t' u'} T_{tu}^{ab} T_{t'u'}^{ab} \int_0^\infty \alpha_{tt'}^a(i\omega) \alpha_{uu'}^b(i\omega) d\omega \\ &= -\sum_{a \in A} \sum_{b \in B} \left(\frac{C_6^{ab}}{R_{ab}^6} + \frac{C_7^{ab}}{R_{ab}^7} + \frac{C_8^{ab}}{R_{ab}^8} + \dots \right). \end{aligned} \quad (38)$$

In general, the dispersion coefficients are angle dependent (Stone and Tough 1984), but for the special case of spherical sites (an idealization), they are independent of angle and only terms of even order survive.

Damping Functions

As explained above, the divergence of the multipole expansions of the interaction energies must be damped out using *damping functions*. The exact form of the damping functions are not known, particularly for the induction energy, but experience from high-accuracy calculations on small dimers suggests that the damping functions from Tang and Toennies (1992), which are incomplete gamma functions, are probably the most suitable. The order- n Tang–Toennies damping function takes the form

$$f_n(\beta R_{ab}) = 1 - \exp(-\beta R_{ab}) \sum_{k=0}^n \frac{(\beta R_{ab})^k}{k!} \quad (39)$$

where β is the damping constant which may be angle dependent, but is often assumed to be a simple constant dependent on the pair of sites (a , b). Often, even the site dependence is dropped and β is assumed to depend on the molecular types alone.

In general, the damping constant β will need to be determined by comparison with the non-expanded energies [from SAPT(DFT)]. For the induction energy, since the multipole expansion does not include the charge transfer energies, the comparison should be made with $E_{\text{ind,tot}}^{(2)}$ calculated in the MC basis. This differs from the recommendation in Misquitta and Stone (2008a) where it was suggested that the damping constant be derived from the ionization energies of the interacting molecules as

$$\beta = \sqrt{2I_A} + \sqrt{2I_B}, \quad (40)$$

where I_A and I_B are the molecular vertical ionization energies in atomic units. There is now evidence (Sebetci and Beran 2010) to suggest that this results in too small a damping when used to evaluate the many-body induction energy through the polarization expansion, potentially resulting in a divergence of the expansion. However, there is extensive evidence that this value of the damping constant is appropriate for the dispersion energy (Misquitta and Stone 2008b) and results in accurate dispersion energies even at molecular charge-density overlap.

Many-Body Contributions to the Interaction Energy

In the condensed phase and in clusters, the two-body energy is often a poor approximation to the total interaction energy which can contain a substantial contribution from the many-body energies (Eqs. 2 and 3). These terms contribute most strongly in systems of polarizable molecules with strong permanent multipole moments such

as those that exhibit strong hydrogen-bonding. For example, Milet et al. (1999) have shown that in clusters of water molecules, the three-body contribution to the interaction energy can be as much as 28 % at the equilibrium geometries and even more – as much as 50 % – at the barriers. Likewise, the many-body non-additive energies have been shown to be responsible for the structural properties of liquid water (Bukowski et al. 2006). Many-body effects are also present in dispersion-bound systems like the argon liquid (Bukowski and Szalewicz 2001) small trimers containing inert gases (Ernesti and Hutson 1997) and the benzene crystal (Podeszwa et al. 2008). In all cases the non-additive dispersion makes a small but non-negligible contribution to the total interaction energy.

The three-body correction (Eq. 3) is the dominant source of non-additivity (Bukowski et al. 2006; Mas et al. 2003a, b). This correction may be calculated using the supermolecular approach, but the calculation is tedious and the BSSE needs to be corrected for. Nevertheless, this approach is possible for small clusters (Hodges et al. 1997). The most appropriate method for calculating the three-body correction is through a three-body version of SAPT(DFT) (Podeszwa and Szalewicz 2007). Using representative trimers of benzene, Podeszwa et al. (2008) have estimated the three-body SAPT(DFT) contribution to the lattice energy of the benzene crystal and have found the result to be in good agreement with experiment. However this cannot be done in general as the number of trimers in the condensed phase scales as the cube of the number of molecules. One solution is to construct an analytic representation of the three-body correction. Though this has been successfully done for water (Mas et al. 2003a, b), it is a formidable task, and is likely unreasonable to perform for most systems.

There are, however, alternative, computationally feasible procedures that are based on the (distributed) multipole forms of the induction and dispersion that are the dominant source of non-additivity in clusters (Bukowski and Szalewicz 2001; Mas et al. 2003b). The exchange non-additivity is significant in small clusters (Hodges et al. 1997; Milet et al. 1999), but it is relatively less important in large clusters and the condensed phase (Mas et al. 2003b).

From a detailed examination of the three-body SAPT energies for the argon liquid, Bukowski et al. (Bukowski and Szalewicz 2001) have concluded that the bulk of the three-body dispersion energy can be estimated using the Axilrod–Teller–Muto triple dipole term. For isotropic local distributed polarizabilities this takes the form (Stone 1996)

$$\Delta E_{\text{disp}}^{3\mu}(ABC) = \sum_{a \in A} \sum_{b \in B} \sum_{c \in C} C_9 \frac{(1 + 3 \cos \hat{a} \cos \hat{b} \cos \hat{c})}{R_{ab}^3 R_{bc}^3 R_{ac}^3}, \quad (41)$$

where R_{ab} , etc., are the lengths of the sides and \hat{a} , \hat{b} , and \hat{c} are the angles of the triangle formed by the three atoms, and

$$C_9 = \frac{3}{\pi} \int_0^{\infty} \alpha^a(i\omega) \alpha^b(i\omega) \alpha^c(i\omega) d\omega. \quad (42)$$

One of the most efficient and convenient ways of approximating the many-body induction energy is through a *polarizability model* based on distributed polarizabilities. The many-body induction energy of a cluster of molecules can be calculated using a generalization of Eq. 35 (Stone 1996):

$$E_{\text{ind}} (\text{Many} - \text{body}) = \frac{1}{2} \sum_A \sum_{a \in A} \sum_{B \neq A} \sum_{b \in B} \sum_{tu} \Delta Q_t^a T_{tu}^{ab} Q_u^b. \quad (43)$$

Here ΔQ_t^a is the *change* in multipole moment t at a due to the self-consistent polarization of site a in the field of all sites on other molecules and is given by

$$\Delta Q_t^a = - \sum_{a' \in A} \sum_{B \neq A} \sum_{b \in B} \sum_{t'v} \alpha_{tt'}^{aa'} T_{t'v}^{a'b} (Q_v^b + \Delta Q_v^b), \quad (44)$$

Notice that Eq. 44 must be solved iteratively for all molecules in the system, as the ΔQ occur on both sides of the equation. The cumulative effect of the iterations is small for a dimer, but can be substantial for a cluster. As before, each of the T -functions should be associated with a suitable damping function. Mas et al. (2003b) have validated this model for the many-body energies in liquid water.

Molecular Properties

In order to evaluate the distributed multipole forms of the interaction energy components we need to calculate distributed multipoles and distributed frequency-dependent polarizabilities of the interacting molecules.

There is no unique method for distributed molecular properties. Rather than get into a philosophical discussion of the concept of an *atom-in-a-molecule* (Matta and Bader 2006; Parr et al. 2005) (see also the discussion in Lillestolen and Wheatley 2008) we will adopt the more pragmatic approach and require that whatever the method used, the distributed properties be the most accurate possible within the constraints imposed by the model. Additionally, we also need the methods used to be numerically robust, applicable to small organic molecules, relatively easy to use, and theoretically consistent with the electronic structure method used to calculate the non-expanded energies, which, in our case, will be SAPT(DFT).

Distributed Multipoles

The distribution of the multipole moments has been the subject of many decades of research (see Stone 1996 and Stone and Misquitta 2007 for reviews). The Distributed Multipole Analysis (DMA) of Stone and Alderton (1985) is widely

used, and a recent modification (Stone 2005) overcomes a shortcoming of the earlier method that arose when diffuse functions were present in the basis.

A special case of distributed multipoles are the point charge models. Such models may be obtained in a variety of ways. In one of the most commonly used methods the charge model is required to reproduce (in a least-squares sense) the molecular electrostatic potential at a set of points around the molecule (Singh and Kollman 1984). These points are generally chosen to lie sufficiently far as to exclude or minimize the effects of penetration. Another possibility is to require that the charges best reproduce some of the molecular multipole moments.

The simplicity of the point charge models comes at a price. While such models may be adequate for systems with an insignificant contribution from the electrostatic energy, they are clearly inadequate for others, in particular, when hydrogen bonding is present. This is because hydrogen bonds are strongly directional (Buckingham and Fowler 1983; Buckingham et al. 2008), whereas the electrostatic interaction between two point charges is completely isotropic. Besides the energetic importance of the hydrogen bond, the strong directionality significantly reduces the available configuration space. This can have important consequences in simulations and crystal energy landscape searches (Day et al. 2005).

Basis set: The higher-ranking multipoles require large and more diffuse basis sets to be well described. Experience has shown that an augmented triple- ζ basis is often adequate.

Distributed Polarizabilities

The distributed polarizability is defined through Eq. 36. This definition suggests at least two methods for performing the distribution: one possibility is to require that the site multipole moment operator \widehat{Q}_t^a is non-zero only around site a , and likewise for $\widehat{Q}_{t'}^{a'}$. This *real-space* partitioning scheme has been implemented using integration grids (Le Sueur and Stone 1994) and Bader's theory of atoms in a molecule (Angyan et al. 1994). However, the shapes of the atomic domains in these schemes tend to be irregular, which could lead to artifacts in the higher-rank polarizabilities. Additionally, these methods tend to result in unphysically large charge-flow terms that are hard to localize. These terms are rank zero contributions to the polarizability (where one or both of the subscripts t and t' are 00 in Eq. 36) that describe the flow of charge along the molecule (Stone 1996). The effects of the charge-flow terms can often be described using higher-ranking polarizabilities, but in order to do so, the charge-flow terms must be small.

Yet another possibility is to partition the FDDS that appears in Eq. 36 into contributions from pairs of atoms. These are known as the *basis-space* partitioning methods. Early attempts to do so failed as the resulting polarizabilities were completely unphysical for large basis sets (Le Sueur and Stone 1993).

More recent methods (Gagliardi et al. 2004; Lillestolen and Wheatley 2007; Wheatley and Lillestolen 2008) have been more successful, but are either applicable

only to the static polarizability or are too cumbersome to use routinely. Also very recently, distribution schemes were proposed by Williams and Stone (2003) and Misquitta and Stone (2006). These two methods have been combined into the Williams–Stone–Misquitta (WSM) method which has proved to be one of the most successful methods for obtaining distributed polarizabilities. This is what we will describe next.

Williams–Stone–Misquitta (WSM) Distribution

The WSM method involves three stages. In the first, the constrained density-fitting scheme (Misquitta and Stone 2006) is used to calculate distributed, non-local polarizabilities. These are then *localized* in stage two. And subsequently, in the final stage, *refined* using a method based on Ref. Williams and Stone (2003).

Stage 1: From Eq. 26 we see that the density-fitted FDDS can be partitioned into atom–atom contributions by partitioning the auxiliary basis set into contributions from individual sites, that is, $\{\chi\} = \{\chi^{(1)}, \chi^{(2)}, \dots\}$, and then the FDDS can be written as

$$\alpha(\mathbf{r}, \mathbf{r}' | \omega) \approx \sum_{aa'} \alpha^{a,a'}(\mathbf{r}, \mathbf{r}' | \omega), \quad (45)$$

where the contribution from sites a and a' is given by

$$\alpha^{a,a'}(\mathbf{r}, \mathbf{r}' | \omega) = \sum_{p \in a, p' \in a'} \tilde{C}_{pp'}(\omega) \chi_p(\mathbf{r}) \chi_{p'}(\mathbf{r}'). \quad (46)$$

We can now insert $\alpha^{a,a'}(\mathbf{r}, \mathbf{r}' | \omega)$ in Eq. 36 to define the distributed polarizability for sites (a, a') :

$$\alpha_{tt'}^{aa'}(\omega) = \sum_{p \in a, p' \in a'} \tilde{C}_{pp'}(\omega) \mathcal{N}_t^p \mathcal{N}_{t'}^{p'}, \quad (47)$$

where $\mathcal{N}_t^p = \int \hat{Q}_t(\mathbf{r} - \mathbf{a}) \chi_p(\mathbf{r}) d^3\mathbf{r}$, where \mathbf{a} is a suitable reference origin for site a that will typically be taken to be the nucleus. Here $\hat{Q}_t(\mathbf{r} - \mathbf{a}) \equiv \hat{Q}_t^a$ is the multipole moment operator of rank t , centered on site a .

This simple idea fails when the standard density-fitting procedure is used. The resulting distributed polarizabilities are very sensitive to the auxiliary basis used (Misquitta and Stone 2006) and become unphysical as the basis grows larger and more complete. This is because in a large diffuse basis, diffuse functions on a site can be used to describe properties on another, adjacent site. This means that the basis functions located on a site are not representative of the site properties.

This problem can be overcome by modifying the density-fitting algorithm (section “Density-Fitting”) to include two additional constraints: one to impose orthogonality and the other to remove the non-physical terms (Misquitta and Stone

2006). With this modification, the density-fitted form of the FDDS leads to much more sensible values (Misquitta and Stone 2006) and are only weakly dependent on the basis set used.

Step 2: The distributed polarizabilities obtained using this constrained density-fitting procedure contain non-local terms, that is, terms involving pairs of distinct sites. In contrast to other distribution methods, the non-local terms describing flow of charge from site to site are very small (around 10^{-2} and 10^{-3} a.u. in magnitude) for all systems, irrespective of the type of bonding involved. Nevertheless, non-local terms are best avoided as they complicate the description unnecessarily. The localization methods of Le Sueur and Stone (1994) and Lillestolen and Wheatley (2007) can be used to transform the non-local terms into local polarizabilities and remove the charge-flow terms altogether. The localization by this procedure causes a deterioration of the convergence properties of the model, because multipole expansions are used to move the polarizabilities around. In principle, the Le Sueur and Stone procedure can increase the radius of divergence of the description to be equal to the size of the molecule, thereby causing significant losses in accuracy for large molecules for which the Lillestolen and Wheatley localization method may be more appropriate. Thus, while good results have been obtained for molecules like formamide and urea, there is already an appreciable loss in accuracy for *N*-methyl propanamide (Misquitta and Stone 2006).

Step 3: The quality of the local polarizability model from the previous step can be dramatically improved using the method of Williams and Stone (2003). In this step, the local polarizabilities are *refined* by requiring them to reproduce a set of point-to-point polarizabilities which describe the response of the electrostatic potential at a point to the frequency-dependent potential produced by a unit oscillating point charge at another. Details of the refinement process are given in Misquitta and Stone (2008a) and Misquitta et al. (2008a).

Analyzing the Models

The WSM method can be used to construct a variety of polarization models. These can include terms to rank 3 and can even be made isotropic. The refinement step ensures that whatever the choice of model, it will be the most accurate possible. A convenient way of assessing the accuracy of the models is by mapping induction energies onto a suitable surface around the molecule in question (Misquitta et al. 2008a). Such a mapping can be performed using a spherical energy probe which, for the induction energy, is best taken to be a point charge with charge qe . The induction energy of a molecule in the field of a point charge depends quadratically on the magnitude of the charge, and an appropriate value of q needs to be used in interpreting the energy scales in these maps. Setting $q = 1$ gives the response to a unit charge, but this is larger than typical local charges in a molecule, which are not expected to exceed $0.5 e$. The surface around the molecule is constructed using the algorithm described in Misquitta et al. (2008a).

In Fig. 1 we show difference maps of the induction energy of the formamide molecule in the field of a unit point charge, computed using the non-local models, local models, and WSM local models, respectively. The large errors in the

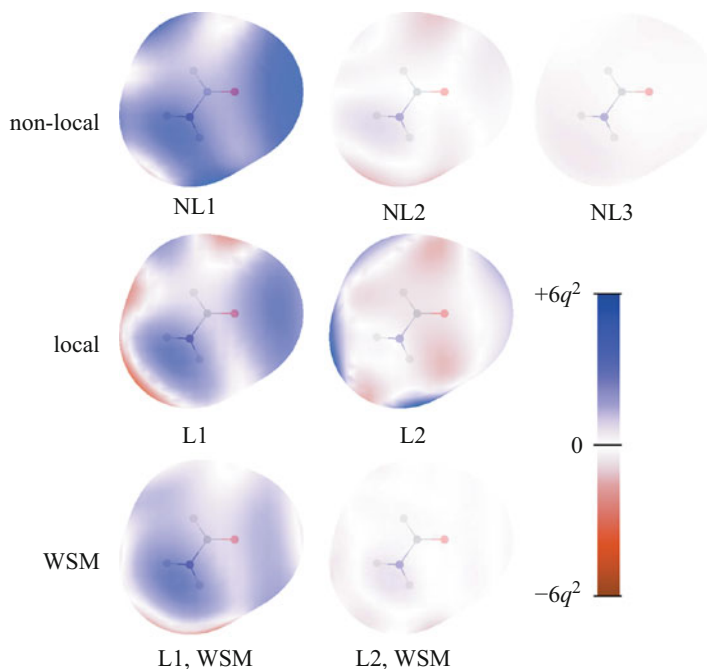

Fig. 1 Difference maps of the induction energy (kJ mol^{-1}) arising from a charge q atomic units on the $\text{vdW} \times 2$ surface of formamide using distributed non-local description of ranks 1, 2, and 3, distributed local description of ranks 1 and 2 obtained from the non-local models using the Le Sueur and Stone localization technique (Le Sueur and Stone 1994), and WSM distributed local descriptions of ranks 1 and 2. The differences are taken against SAPT(DFT) second-order induction energies obtained using a molecular description with the Sadlej/MC basis set

non-local rank 1 model, particularly near the oxygen and the polar hydrogen atoms, are quite clearly displayed. These errors are reduced in the rank 1 local model and are still smaller in the WSM rank 1 local model. The largest residual errors always seem to occur in the same regions, perhaps indicating the need for higher-ranking polarizabilities on some sites than on others. At rank 2, the non-local model is in almost perfect agreement with SAPT(DFT), but the local model obtained using the Le Sueur and Stone localization method exhibits rather large deficiencies near the polar hydrogens. These are removed in the WSM rank 2 local model which is comparable in accuracy to the rank 2 non-local model.

Distributed Dispersion Coefficients

Having obtained the localized frequency-dependent polarizabilities, we can now evaluate the dispersion coefficients that appear in Eq. 38. The dispersion coefficients depend on integrals of the form

$$\int_0^{\infty} \alpha_{ll'}^a(\nu) \alpha_{ll'}^b(\nu) d\nu, \quad (48)$$

where rank- l_1 – rank- l'_1 and rank- l_2 – rank- l'_2 polarizability tensors contribute to a C_n coefficient with $n = l_1 + l'_1 + l_2 + l'_2 + 2$. At present, the WSM polarizabilities can be calculated to rank 3, so while we can calculate C_{10} and C_{12} terms, they will lack the contributions from the hexadecapole and higher-rank polarizabilities. However, this has been shown not to be a serious limitation (Misquitta and Stone 2008b).

Basis sets: For a good dispersion model the basis set needs to be large and diffuse. To be consistent with SAPT(DFT) interaction energies calculated using the MC+ (or DC+) basis types, the dispersion coefficients should be calculated using a more diffuse basis than was used for the monomer part of the SAPT(DFT) basis. This is to compensate for the effects of the mid-bond functions that cannot be used when calculating dispersion coefficients. For example, if an aug-cc-pVTZ MC+ basis is used to calculate SAPT(DFT) interaction energies, the dispersion model should be constructed from WSM polarizabilities calculated using a d-aug-cc-pVTZ basis (Misquitta and Stone 2008b).

Models: Dispersion models need to be rather elaborate before they are accurate enough to describe the dispersion energy at small separations. Figure 2 shows dispersion energy maps for benzene and N-methyl propanamide using neon as a probe atom as described in Misquitta and Stone (2008b). From the error maps we see

Fig. 2 Dispersion energy maps of benzene and N-methyl propanamide with neon as a probe. The SAPT(DFT) dispersion energy $E_{\text{disp,pol}}^{(2)}$ is displayed using an absolute scale in kJ mol^{-1} . The model dispersion energies are displayed as *differences* taken against $E_{\text{disp,tot}}^{(2)}$ from SAPT(DFT). The models are not damped. The d-aug-cc-pVTZ basis has been used for N-methyl propanamide and the aug-cc-pVTZ basis for benzene

Fig. 3 Dispersion energies for the benzene dimer. Scatter plot of dispersion energies calculated using the damped anisotropic C_{10} and C_{12} models and the isotropic scaled C_6 model plotted against $E_{\text{disp,tot}}^{(2)}$ calculated using SAPT(DFT). Also shown are undamped dispersion energies calculated using the C_6 parameters from the Williams' 01 potential (Williams 2001a, b)

that the C_6 dispersion models significantly underestimate the dispersion interaction, and it is only with the C_{10} model that we get a good representation of the dispersion. More examples are provided in Misquitta and Stone (2008b).

However, the C_{10} model is rather elaborate and unwieldy. For many applications simpler models may suffice. Fortunately, the WSM method allows the construction of far simpler *isotropic* dispersion models. Even more simplifications can be made by scaling the isotropic C_6 WSM model to best reproduce the SAPT(DFT) dispersion energies (Misquitta and Stone 2008b), and the results are quite acceptable. From Fig. 3 we see that the scaled isotropic C_6 dispersion model (damped) is quite acceptable for the benzene dimer and is a significant improvement over the empirical dispersion model from a popular and well parameterized empirical potential. The significant failure occurs at the stacked configurations where anisotropy is essential to describe the dispersion interaction correctly.

Case Studies

Applications

Over the last few years, SAPT(DFT) has been used to study the interactions between a number of small and medium-sized molecules. Initial applications tended to

Fig. 4 Interaction energy scan for the He \cdots CO system. Comparison of SAPT, SAPT(DFT), and CCSDT (From Peterson and McBane 2005)

focus on small systems such as dimers of rare gas atoms (Misquitta et al. 2005a; Podeszwa and Szalewicz 2005) where detailed comparisons were possible with the more established CCSD(T) method, from which the accuracy of SAPT(DFT) was validated. The agreement was generally excellent. Consider for example the He \cdots CO complex (Fig. 4). The agreement of SAPT(DFT) energies with the CCSDT energies extrapolated to the complete basis set limit (Peterson and McBane 2005) is remarkable. By contrast, SAPT yields a potential energy curve that is somewhat too negative.

Subsequently, applications were made to larger systems such as the ethyne and benzene dimers (Hesselmann et al. 2005; Podeszwa and Szalewicz 2005) where, once again, the accuracy of the method was demonstrated. More recently, the DFT-SAPT implementation has been used to study the interaction of water on graphene (Jenness and Jordan 2009), DNA base pairs (Hesselmann et al. 2006), and DNA base pair tetramers (Fiethen et al. 2008). Calculations of such accuracy are simply not possible using conventional electronic structure methods in the supermolecular approach, particularly as the only correlated ab initio method with a reasonable computational scaling is MP2, and MP2 is not suitable for the interactions of systems with π -bonding (Sinnokrot et al. 2002).

In a truly remarkable application on water, Bukowski et al. (2006) derived a SAPT(DFT) two-body potential, together with a three-body potential from SAPT (Mas et al. 2003a, b) and a polarization model for the many-body effects, and were able to describe not only the vibrational-rotational tunneling spectrum of the water dimer and trimer, but also the structure of liquid water.

Complete potential energy surfaces of a few complexes have been calculated using SAPT(DFT). These include the CO dimer, for which ro-vibrational transitions were calculated and found to be in good agreement with experiment (Vissers et al. 2005), and the benzene dimer (Podeszwa et al. 2006a). Recently, an anisotropic, transferable atom–atom potential for polyaromatic hydrocarbons has been parametrized from SAPT(DFT) calculations on the benzene, naphthalene, anthracene, and pyrene dimers (Podeszwa and Szalewicz 2008; Totton et al. 2010). Such potentials could bring a new level of accuracy to the simulations of condensed matter.

Polarization in Organic Crystals

One of the successes of the WSM polarizability models has been in describing the role of polarization in organic crystals (Welch et al. 2008). Amongst the many crystals of organic molecules studied by Welch et al. let us consider one here: oxalyl dihydrazide (Fig. 5). This molecule has been found to crystallize in five polymorphic forms. In the α form, the molecular conformation is quite different from the other four, with two fewer internal hydrogen bonds. While the experimental lattice energies of these five forms are not known, it is generally expected that they should lie close together in energy. However, lattice energies calculated using methods that only modeled the exchange-repulsion, dispersion, electrostatic, and conformational energies predict the lattice energy of the α form to be between 20 and 28 kJ mol⁻¹ higher than the others. Such a high energy is generally considered to be out of the range of possible polymorphism.

Using a WSM polarizability model, Welch et al. showed that this difference could be explained as arising from polarization (induction) effects that were missing in the empirical force fields (see Fig. 5). When polarization is taken into account explicitly and added to the lattice energy (without subsequent lattice relaxation) all five polymorphs of oxalyl dihydrazide are seen to have a similar lattice energy. It is not hard to see why an explicit model was found to be important here. Empirical force fields (Williams 2001a, b) will always contain some of the effects of polarization in an average manner. This is why they work in many cases. But when there is a difference in the hydrogen-bonding network, such as happens in polymorphs of oxalyl dihydrazide where we see a difference in the number of intra and intermolecular hydrogen bonds, these potentials are no longer able to describe the relative energies of the systems, and we need an explicit treatment of the polarization. See Karamertzanis et al. (2008) for a detailed investigation of this instance of conformational polymorphism.

These effects will undoubtedly be important in other systems which involve different hydrogen-bonding environments such as biological molecules. It is very likely that even a simple treatment of polarization may significantly improve the predictions of the properties of such systems.

Fig. 5 Lattice energy of the five polymorphs of oxalyl dihydrazide calculated with and without an explicit polarization contribution. Without polarization, the α form is too high in energy compared with the others, but on calculating the polarization contribution to the lattice energy self-consistently, the five forms are seen to be similar in energy, which is what would be expected for polymorphs (Welch et al. 2008)

Crystal Structure Prediction

One of the significant successes of the electronic structure methods described in this chapter is the high level of predictive power they have brought to the field of organic crystals. Consider that just about 20 years ago the inability of computational scientists to predict crystal structures of organic molecules was considered a “scandal” (Maddox 1988). While we still cannot claim to have solved the problem, we do now have a number of noteworthy successes in this field.

One of the target molecules in the 2007 blind test of organic crystal structure prediction organized by the Cambridge Crystallographic Data Center (CCDC) was 1,3-dibromo-2-chloro-5-fluorobenzene ($C_6Br_2ClFH_2$). This molecule contains halogen atoms which are not well represented by most empirical potentials, primarily because they are strongly anisotropic (Day and Price 2003; Stone 1996) and empirical atom–atom potentials assume spherical atomic shapes. Using an anisotropic atom–atom potential calculated using first-order SAPT(DFT) energies and a dispersion model from WSM polarizabilities, Misquitta et al. (2008b) were able to predict a crystal structure for this system that was later found to correspond exactly with the experimental one (Fig. 6) (Day et al. 2009). This was the first completely ab initio prediction of a crystal structure of an organic molecule.

Fig. 6 Two views of the overlay of the experimental (*black*) and predicted (*gray*) crystal structures of $C_6Br_2ClFH_2$. The two structures are hard to separate as the overlay is nearly perfect

Also recently, Podeszwa et al. (2008) have used potentials derived from SAPT(DFT) to model the crystal structures of cyclotrimethylene trinitramine (RDX) and benzene, the latter being arguably the more difficult of the two systems. This once again demonstrates the accuracy of force fields derived from SAPT(DFT) energies.

Outlook

Applications such as these would have been almost unthinkable as little as a decade ago. It is developments in the theory of intermolecular forces together with improvements in our computational resources that have made these calculations possible. We can only speculate where future developments will take us in the next few years. For many applications computational requirement will limit us to use atom–atom intermolecular potentials. We have already seen examples of the success of such potentials when derived using accurate *ab initio* methods, but this is only the beginning of what is possible. Accurate *ab initio* methods like SAPT(DFT) and the WSM method can be the basis of a new generation of atom–atom potentials that will surpass any empirical potential in accuracy.

While we have good reason for optimism, it is worthwhile bearing in mind that at least some of the successes described here are fortuitous. The crystal structure predictions listed above were successful because the observed crystal form corresponded to the global minimum in the free energy. However, this is not always true, particularly for industrially important polymorphic molecules for which kinetic effects can be important. If we are to fully understand the interplay between kinetic and thermodynamic effects, we first need to remove any uncertainty in our ability to model molecular interactions – probably of both the intra and intermolecular types.

This raises the question of intramolecular flexibility which has not yet been adequately addressed. The potential energy surface involving intermolecular and intramolecular degrees of freedom is a formidable object and so far has been constructed for only a small number of small dimers. Methods for the inclusion of internal degrees of freedom have been suggested (Jankowski 2004, 2008; Jankowski and Ziolkowski 2006; Murdachaew et al. 2002), but so far have been applied to dimers of small systems only. This remains one of the outstanding problems with this approach.

Yet another outstanding problem is the correct treatment of the interactions of small gap materials such as fullerenes. It is quite likely that second-order perturbation will not be adequate for such systems. Furthermore, the strong electron delocalization in these semi-conductor-like materials means that the standard atom–atom models of interaction fail due to their inherent assumption of locality (Misquitta et al. 2010). This is possibly the next hurdle to be faced by the theory of intermolecular interactions.

Programs

There are a large number of programs that can be used to study intermolecular interactions. If the supermolecular method is used, practically any electronic structure program capable of using correlated methods like MP2 and CCSD(T) can be used. However, the following programs are likely more suited than most for this field.

- **SAPT2008:** (free, source available, parallel) The SAPT2008 program (Bukowski et al. 2002) contains implementations of both SAPT and DF-SAPT(DFT) and allows the calculation of three-body energies through the three-body SAPT and SAPT(DFT) theories. Besides the usual interaction energy corrections, this program also contains a variety of state-of-the-art energy components. The SAPT2008 program uses molecular orbitals and eigenvalues from a variety of SCF programs, but the DF-SAPT(DFT) module works only with the DALTON 2.0 program.
- **CAMCASP:** (free, source available, serial) The CAMCASP (Misquitta and Stone 2007) contains implementations of DF-SAPT(DFT), the WSM method for molecular properties, and a variety of modules and programs to analyze and interpret mechanisms of intermolecular interactions in small organic molecules (through interfaces with the ORIENT program) and construct analytic, polarizable atom–atom potentials for small organic molecules. Additionally, distributed multipoles can be calculated using CAMCASP through the included GDMA 2.2 module. This program has been used for almost all the results presented in this chapter. CAMCASP uses molecular orbitals and eigenvalues calculated using the DALTON 2.0 program (Helgaker et al. 2005).
- **ORIENT:** (free, source available, serial) ORIENT (Stone et al. 2006) is not an electronic structure program, but is a very versatile platform for calculating

interaction energies of clusters, performing geometry optimizations, simulations and displaying energies using the Open-GL module. This program is used quite closely by CAMCASP through a variety of interfaces.

- MOLPRO 2008: (commercial, source available, parallel) The MOLPRO 2008 program (Werner et al. 2008) contains a number of state-of-the-art electronic structure methods including DF-DFT-SAPT. This program is probably the most computationally efficient implementation of SAPT(DFT), though the FDDS cannot include any fraction of CHF (see section “Symmetry-Adapted Perturbation Theory Based on DFT”).
- DALTON 2.0: (free, source available, parallel) The DALTON 2.0 program (Helgaker et al. 2005) is used by both SAPT2008 and CAMCASP as the front-end to calculate the Kohn–Sham molecular orbitals and eigenvalues and some of the integrals needed to evaluate the FDDS.

Annotated Bibliography

The papers highlighted in this section are meant to be the most recent or comprehensive in the subject. This list is by no means complete. They should be a good starting point for researchers entering the field.

- Intermolecular forces: The book by Stone (1996) is probably the most comprehensive introduction to the theory from the atomistic point of view. Israelachvili (2007) takes a very different approach and is more concerned with the manifestations of these forces on surfaces, bulk media, and complex systems. Yet another approach is taken by Parsegian (2005) who tackles the Casimir forces between extended media in various geometries. The two volumes – (Wales 2005a, b) – offer articles on the current status of the field.
- Types of intermolecular bonds: An excellent overview of hydrogen bonds can be found in the article by Buckingham, Del Bene, and McDowell (Buckingham et al. 2008). In the last few years interest has developed in halogen bonded systems. See Bernal-Uruchurtu et al. (2009) for an introduction and an analysis based on a SAPT decomposition of the interaction energy.
- SAPT: The review articles by Jeziorski, Szalewicz, and others (Jeziorski and Szalewicz 1998, 2002; Jeziorski et al. 1994; Szalewicz 2002; Szalewicz et al. 2005) are probably the most comprehensive articles on symmetry-adapted perturbation theory. See also the discussion of these theories in Stone (1996). For a detailed examination of symmetry-forcing techniques and the convergence of intermolecular perturbation theories see Szalewicz et al. (2005).
- SAPT(DFT): The theory of the SAPT(DFT) method is described in Misquitta et al. (2005b) and DF-SAPT(DFT) in Podeszwa et al. (2006b). The DF-DFT-SAPT method is described in Hesselmann et al. (2005).
- Potentials: Obtaining an analytic expression for the intermolecular interaction energy in atom–atom form is often difficult. See Misquitta et al. (2008b) and Stone and Misquitta (2007) for a discussion of how this could be done.

- Crystal structure prediction: The field of organic crystal structure prediction remains one of the best testing grounds for intermolecular potentials. Accuracies need not be as high as that needed for spectroscopic calculations, but the effects of molecular flexibility and many-body non-additivity need to be accounted for. See Price (2008, 2009) for recent reviews of this subject. For a description of dispersion-corrected DFT methods specially parametrized for organic crystals see Neumann and Perrin (2005). For a comprehensive examination of the role of detailed distributed multipole models in this field see Day et al. (2005).

Acknowledgments The theoretical methods described in this chapter have been strongly influenced by Anthony Stone and Krzysztof Szalewicz. I owe particular thanks to Anthony who has had a strong influence on this chapter through the many discussions we have had and papers we have written together.

Abstract

This chapter provides an overview of different hierarchical levels of molecular dynamics (MD) spanning a wide range of time and length scales – from first-principles approaches via classical atomistic methods to coarse-graining techniques. The theoretical background of the most widely used methods and algorithms is briefly reviewed, and practical instructions are given on the choice of input parameters for an actual computer simulation. In addition, important postprocessing procedures such as data analysis and visualization are discussed.

Introduction

Molecular dynamics (MD) simulations in their different flavors are widely used in a large variety of research areas of computational physics and chemistry. They represent a powerful tool to study the motion of atoms in molecules, liquids, and solids. The term MD typically refers to the propagation of point particles – atomic nuclei or effective particles combining several nuclei – according to the laws of classical mechanics. In particular, the forces acting on the particles are calculated “on the fly” only at discrete points along the trajectory. Following this definition, we discuss in this chapter *ab initio* MD (AIMD), i.e., the atomic forces are calculated from first principles, classical atomistic MD using analytical empirical interaction potentials (force fields), which sometimes is referred to as force-field molecular dynamics; and coarse-grained MD using analytical empirical potentials between effective particles representing groups of atoms. We exclude methods which go beyond classical nuclei, such as path integral MD (Tuckerman et al. 1993; Tuckerman and Hughes 1998; Tuckerman 2002) and wave packet dynamics (Balint-Kurti 2008; Worth et al. 2008), or beyond the Born–Oppenheimer approximation (Doltsinis and Marx 2002a, b). This overview, furthermore, leaves out the vast area of semi-empirical methods (see, e.g., Bredow and Jug (2005) for a recent review) including self-consistent charge density functional tight-binding (SCC-DFTB) (Elstner et al. 1998) and empirical valence-bond (EVB) theory (Warshel 1991; Aqvist and Warshel 1993; Shurki and Warshel 2003; Warshel 2003).

The aim of this chapter is to offer practical guidance on how to choose the appropriate technique for a particular physical problem, how to set up a simulation, and how to analyze and visualize the output. In addition it should provide the theoretical background required to become a competent user of the available simulation software packages.

Choosing the Right Method

When choosing which type of molecular dynamics simulations to perform, it is important to understand the capabilities of each technique. The differences in the various methods are basically dependent on the detail with which each one models a physical system.

The most detailed molecular dynamics simulation technique is the ab initio (quantum) molecular dynamics simulation approach that explicitly models the electrons within the system by solving the time-independent Schrödinger equation in some approximate fashion whereas force-field atomistic molecular dynamics simulations model the interactions between the atoms within the system by analytical functions that include the effects of the electrons only implicitly. Then the method that incorporates the least amount of detail is that of coarse-grained molecular dynamics models where multiple atoms are grouped together before being represented by a single interaction "bead."

Therefore, ab initio molecular dynamics simulations will generate the most accurate and versatile modeling of interatomic interactions as electrons are the basis of all such interactions. Quantum simulations allow for certain phenomena like electronic excitation or charge transport within a system to be modeled, which cannot be modeled in force-field or coarse-grained molecular dynamics simulations because they do not treat electrons explicitly. Also, in order to model chemical reactions, quantum simulations are the most accurate approach (note: there have been force-field and coarse-grained molecular dynamics simulations that have modeled the formation and breaking of bonds, but some a priori knowledge must then be included in the model to allow for the reaction to take place). The major limitation of quantum simulations is that they are very computationally intensive, which results in the capability to model only small system sizes (typically 10^2 – 10^3 atoms) and short times (10^{-12} – 10^{-10} s). Thus, the systems that can be modeled are limited to relatively small- to medium-sized molecules or portions of larger molecules (i.e., specific amino acids within a protein).

Atomistic force-field molecular dynamics simulations offer the ability to model molecules at the particle level. Often, information from quantum simulations is used to develop the empirical interaction potentials (force field) that are used to describe the interactions between particles. Because force-field molecular dynamics simulations use less detail than the quantum simulations, they are able to model systems that are significantly larger in size ($\sim 10^6$ particles) for a longer period of time ($\sim 10^{-6}$ s). Therefore, measuring the structural, mechanical, and/or transport properties of medium- to large-sized systems (i.e., proteins, functionalized nanoparticles, . . .) is possible.

Finally, coarse-grained molecular dynamics simulations reduce the number of degrees of freedom within the simulated system even further by grouping several atoms into one interaction bead. Therefore, even larger system sizes ($\sim \mu\text{m}$) and times (on the order of seconds) are accessible via these simulations. Several of the same properties measured via atomistic force-field molecular dynamics simulations can be measured with coarse-grained molecular dynamics simulations (i.e., structural, mechanical, and transport properties). However, due to the reduced detail in the models of the molecules, it is not possible to investigate specific chemical interactions within a system, such as hydrogen bonding.

Once you have chosen the appropriate method for the particular system and property to be investigated, the next choice is what simulation package to use. For classical MD simulations, there are several free molecular dynamics packages

that can be found on the Web including DL_POLY (Smith et al. 2002; http://www.cse.scitech.ac.uk/ccg/software/DL_POLY/), GROMACS (Spoel et al. 2005; <http://www.gromacs.org/>), HOOMD (Anderson et al. 2008; <http://codeblue.umich.edu/hoomd-blue/about.html/>), LAMMPS (Plimpton 1995; <http://lammps.sandia.gov/>), MOLLY (Refson 2000; <http://www.ccp5.ac.uk/moldy/moldy.html/>), TINKER (<http://dasher.wustl.edu/tinker/>), and NAMD (Phillips et al. 2005; <http://www.ks.uiuc.edu/Research/namd/>), and there are also commercial packages including AMBER (Case et al. 2005; <http://ambermd.org/>), CHARMM (Brooks et al. 2009; <http://www.charmm.org/>), and GROMOS (Scott et al. 1999; <http://www.igc.ethz.ch/GROMOS/index/>). Generally, these codes can be divided into those that are mostly used for simulations of biological systems (AMBER, CHARMM, GROMACS, GROMOS, NAMD) and those that are more general simulation packages (HOOMD, LAMMPS, MOLLY). When choosing between these options, an important criterion is to choose a code that you feel comfortable using. Outside of comfort, another aspect to take into consideration is that packages will differ in the features they offer and the additional tools to perform analysis (usually lists of analysis tools can be found in the packages' documentation).

For AIMD simulations the user may choose from a large number of codes, for instance, ABINIT (www.abinit.org; Aulbur et al. 2000), CASTEP (www.tcm.phy.cam.ac.uk/castep/; Segall et al. 2002; Clark et al. 2005), CONQUEST (www.conquest.ucl.ac.uk/; Bowler et al. 2006), CP2K (Hutter et al.; VandeVondele et al. 2005, 2006), CPMD (Hutter et al.; Marx and Hutter 2000, 2009), CP-PAW (<https://orion.pt.tu-clausthal.de/paw/>; Blochl 1994; Blochl et al. 2003), DACAPO (<http://dcwww.camp.dtu.dk/campos/Dacapo/>), FHI98md (www.fhi-berlin.mpg.de/th/fhimd/; Bockstedte et al. 1997), NWChem (www.emsl.pnl.gov/docs/nwchem; Kendall et al. 2000), ONETEP (www.tcm.phy.cam.ac.uk/onetep/; Skylaris et al. 2005), PINY (<http://homepages.nyu.edu/~mt33/PINY.MD/PINY.html>), PWscf (www.pwscf.org/; Giannozzi et al. 2009), QuantumEspresso (www.quantum-espresso.org; Giannozzi et al. 2009), SIESTA (www.uam.es/siesta/; Soler et al. 2002; Artacho et al. 2008), S/PHI/nX (www.sphinxlib.de; Boeck 2009), or VASP (<http://cms.mpi.univie.ac.at/vasp/>; Kresse and Furthmüller 1996).

To perform hybrid quantum/classical (QM/MM) simulations, one needs to interface a force-field MD program with an ab initio electronic structure code. This can be done, for example, with the following codes: ChemShell (www.chemshell.org/), CPMD (Hutter et al.), CP2K (Hutter et al.), LAMMPS (<http://lammps.sandia.gov/>), AMBER (<http://ambermd.org/>), and GROMACS (<http://www.gromacs.org/>).

Theoretical Background

Born–Oppenheimer Approximation

Let us begin by introducing our nomenclature and by reviewing some well-known basic relations within the Schrödinger formulation of quantum mechanics. A complete, nonrelativistic description of a dynamic system of N atoms hav-

ing the positions $\mathbf{R} = \{\mathbf{R}_1, \mathbf{R}_2, \dots, \mathbf{R}_I, \dots, \mathbf{R}_N\}$ with n electrons located at $\mathbf{r} = \{\mathbf{r}_1, \mathbf{r}_2, \dots, \mathbf{r}_i, \dots, \mathbf{r}_n\}$ would involve solving the time-dependent Schrödinger equation

$$\mathcal{H}\Phi(\mathbf{r}, \mathbf{R}; t) = i\hbar \frac{\partial}{\partial t} \Phi(\mathbf{r}, \mathbf{R}; t), \quad (1)$$

with the total Hamiltonian

$$\mathcal{H}(\mathbf{r}, \mathbf{R}) = \mathcal{T}(\mathbf{R}) + \mathcal{T}(\mathbf{r}) + \mathcal{V}_{\text{nn}}(\mathbf{R}) + \mathcal{V}_{\text{ne}}(\mathbf{r}, \mathbf{R}) + \mathcal{V}_{\text{ee}}(\mathbf{r}), \quad (2)$$

being the sum of kinetic energy of the atomic nuclei,

$$\mathcal{T}(\mathbf{R}) = -\frac{\hbar^2}{2} \sum_{I=1}^N \frac{\nabla_I^2}{M_I}, \quad (3)$$

kinetic energy of the electrons,

$$\mathcal{T}(\mathbf{r}) = -\frac{\hbar^2}{2m_e} \sum_{i=1}^n \nabla_i^2, \quad (4)$$

internuclear repulsion,

$$\mathcal{V}_{\text{nn}}(\mathbf{R}) = \frac{e^2}{4\pi\epsilon_0} \sum_{I=1}^{N-1} \sum_{J>I}^N \frac{Z_I Z_J}{|\mathbf{R}_I - \mathbf{R}_J|}, \quad (5)$$

electronic–nuclear attraction,

$$\mathcal{V}_{\text{ne}}(\mathbf{r}, \mathbf{R}) = -\frac{e^2}{4\pi\epsilon_0} \sum_{I=1}^N \sum_{i=1}^n \frac{Z_I}{|\mathbf{r}_i - \mathbf{R}_I|}, \quad (6)$$

and interelectronic repulsion,

$$\mathcal{V}_{\text{ee}}(\mathbf{r}) = \frac{e^2}{4\pi\epsilon_0} \sum_{i=1}^{n-1} \sum_{j>i}^n \frac{1}{|\mathbf{r}_i - \mathbf{r}_j|}. \quad (7)$$

Here, M_I and Z_I denote the mass and atomic number of nucleus I ; m_e and e are the electronic mass and elementary charge, and ϵ_0 is the permittivity of vacuum. The nabla operators ∇_I and ∇_i act on the coordinates of nucleus I and electron i , respectively. The total wave function $\Phi(\mathbf{r}, \mathbf{R}; t)$ simultaneously describes the motion of both electrons and nuclei.

The Born–Oppenheimer approximation (Kołos 1970; Kutzelnigg 1997; Doltsinis and Marx 2002b) separates nuclear and electronic motion based on the assumption that the much faster electrons adjust their positions instantaneously to the comparatively slow changes in nuclear positions. The electronic problem is then reduced to the time-independent (electronic) Schrödinger equation for clamped nuclei,

$$\mathcal{H}_{\text{el}}(\mathbf{r}; \mathbf{R})\Psi_k(\mathbf{r}; \mathbf{R}) = E_k(\mathbf{R})\Psi_k(\mathbf{r}; \mathbf{R}), \quad (8)$$

where $\mathcal{H}_{\text{el}}(\mathbf{r}; \mathbf{R})$ is the electronic Hamiltonian,

$$\mathcal{H}_{\text{el}}(\mathbf{r}, \mathbf{R}) = \mathcal{T}(\mathbf{r}) + \mathcal{V}_{\text{nn}}(\mathbf{R}) + \mathcal{V}_{\text{ne}}(\mathbf{r}, \mathbf{R}) + \mathcal{V}_{\text{ee}}(\mathbf{r}), \quad (9)$$

and $\Psi_k(\mathbf{r}; \mathbf{R})$ is the electronic wave function of state k . Meanwhile, nuclear motion is described by

$$[\mathcal{T}(\mathbf{R}) + E_k(\mathbf{R})]\chi_k = i\hbar \frac{\partial}{\partial t} \chi_k \quad (10)$$

with the nuclear wave function $\chi_k(\mathbf{R}, t)$ evolving on the potential energy surface $E_k(\mathbf{R})$ of the electronic state k . The total wave function is then the direct product of the electronic and the nuclear wave function,

$$\Phi(\mathbf{r}, \mathbf{R}; t) = \Psi_k(\mathbf{r}, \mathbf{R})\chi_k(\mathbf{R}, t) \quad (11)$$

In the classical limit (Doltsinis and Marx 2002b), the nuclear wave equation (10) is replaced by Newton’s equation of motion

$$M_I \ddot{\mathbf{R}}_I = -\nabla_I E_k \quad (12)$$

For a great number of physical situations the Born–Oppenheimer approximation can be safely applied. On the other hand, there are many important chemical phenomena such as charge transfer and photoisomerization reactions, whose very existence is due to the inseparability of electronic and nuclear motion. Inclusion of nonadiabatic effects is beyond the scope of this chapter and the reader is referred to the literature (e.g., Refs. Doltsinis and Marx 2002b; Doltsinis 2006) for more details.

The above approximations form the basis of conventional molecular dynamics, Eqs.(22) together with (8) being the working equations. Thus, in principle, a classical trajectory calculation merely amounts to integrating Newton’s equations of motion (22). In practice, however, this deceptively simple task is complicated by the fact that the stationary Schrödinger equation (8) cannot be solved exactly for any many-electron system. The potential energy surface therefore has to be approximated using ab initio electronic structure methods or empirical interaction potentials (the so-called force-field molecular dynamics (Sutmann 2002; Allen and Tildesley 1987)). The former approach, usually referred to as ab initio molecular dynamics

(AIMD), will be the subject of section “Ab Initio Molecular Dynamics,” while the latter – force-field molecular dynamics – will be discussed in section “Classical Molecular Dynamics.”

Ab Initio Molecular Dynamics

In the following, we shall focus on first-principles molecular dynamics methods. Due to the high computational cost associated with ab initio electronic structure calculations of large molecules, computation of the entire potential energy surface prior to the molecular dynamics simulation is best avoided. A more efficient alternative is the evaluation of electronic energy and nuclear forces “on the fly” at each step along the trajectory.

Born–Oppenheimer Molecular Dynamics

In the so-called Born–Oppenheimer implementation of such a scheme (Marx and Hutter 2000), the nuclei are propagated by integration of Eq. (22), where the exact energy E_k is replaced with the eigenvalue, \tilde{E}_k , of some approximate electronic Hamiltonian, $\tilde{\mathcal{H}}_{\text{el}}$, which is calculated at each time step. For the electronic ground state, i.e., $k = 0$, the use of Kohn–Sham (KS) density functional theory (Parr and Yang 1989; Dreizler and Gross 1990) has become the method of choice.

Car–Parrinello Molecular Dynamics

In order to further increase computational efficiency, Car and Parrinello have introduced a technique to bypass the need for wave function optimization at each molecular dynamics step (Car and Parrinello 1985; Marx and Hutter 2000). Instead, the molecular wave function is dynamically propagated along with the atomic nuclei according to the equations of motion

$$M_I \ddot{\mathbf{R}}_I = -\nabla_I \langle \Psi_k | \tilde{\mathcal{H}}_{\text{el}} | \Psi_k \rangle \quad (13)$$

$$\mu_i \ddot{\psi}_i = -\frac{\delta}{\delta \psi_i^*} \langle \Psi_k | \tilde{\mathcal{H}}_{\text{el}} | \Psi_k \rangle + \sum_j \lambda_{ij} \psi_j, \quad (14)$$

where the KS one-electron orbitals ψ_i are kept orthonormal by the Lagrange multipliers λ_{ij} . These are the Euler–Lagrange equations

$$\frac{d}{dt} \frac{\partial \mathcal{L}}{\partial \dot{q}} = \frac{\partial \mathcal{L}}{\partial q}, \quad (q = \mathbf{R}_I, \psi_i^*) \quad (15)$$

for the Car–Parrinello Lagrangian (Car and Parrinello 1985)

$$\mathcal{L} = \sum_I \frac{1}{2} M_I \dot{\mathbf{R}}_I^2 + \sum_i \frac{1}{2} \mu_i \langle \dot{\psi}_i | \dot{\psi}_i \rangle - \langle \Psi_k | \tilde{\mathcal{H}}_{\text{el}} | \Psi_k \rangle + \sum_{ij} \lambda_{ij} (\langle \psi_i | \psi_j \rangle - \delta_{ij}) \quad (16)$$

that is formulated here for an arbitrary electronic state Ψ_k , an arbitrary electronic Hamiltonian $\hat{\mathcal{H}}_{\text{el}}$, and an arbitrary basis (i.e., without invoking the Hellmann–Feynman theorem).

Classical Molecular Dynamics

While first-principles molecular dynamics simulations deal with the electrons in a system, this results in a large number of particles and inevitably requires the use of quantum mechanics. Therefore, the calculations become significantly time-consuming. Classical molecular dynamics ignore electronic motions and calculate the energy of a system as a function of the nuclear positions only and therefore are used to simulate larger, less detailed systems for larger time scales. The successive configurations of the system are generated by solving the differential equations that constitute Newton's second law (Eq. 22):

$$\frac{d^2 X_I}{dt^2} = \frac{F_{X_I}}{M_I} \quad (17)$$

This equation describes the motion of particle I of mass M_I along one dimension (X_I), where F_{X_I} is the force on the particle in that dimension. The solution of these differential equations results in a trajectory that specifies how the positions and velocities of the particles in the system vary with time.

In realistic models of intermolecular interactions, the force on particle I changes whenever particle I changes its position or whenever another atom with which particle I interacts changes its position. Therefore, the motions of all the particles are coupled together, which results in a many-body problem that cannot be solved analytically. Therefore, finite difference methods are used to integrate the equations of motion.

Generally, the integration of Eq. (17) is broken into consecutive steps that are conducted at different times t that are separated by increments of δt , which is generally referred to as the time step. First, the total force on each particle in the system at time t is calculated as the vector sum of its interactions with other particles.

Then, assuming the force is constant over the course of the time step, the accelerations of the particles are calculated, which are then combined with positions and velocities of the particles at time t to determine the positions and velocities at time $t + \delta t$. Finally, the forces on the particles in their new positions are determined, and then new accelerations, positions, and velocities are determined at $t + 2\delta t$ and so on.

A common approach in the various finite difference methods used to integrate the equations of motions for classical molecular dynamics simulations is that it is assumed that the positions, velocities, and accelerations (as well as all other dynamic properties) can be approximated using Taylor series expansions:

$$\mathbf{R}(t + \delta t) = \mathbf{R}(t) + \delta t \mathbf{V}(t) + \frac{1}{2} \delta t^2 \mathbf{A}(t) + \frac{1}{6} \delta t^3 \mathbf{B}(t) + \frac{1}{24} \delta t^4 \mathbf{C}(t) + \dots \quad (18)$$

$$\mathbf{V}(t + \delta t) = \mathbf{V}(t) + \delta t \mathbf{A}(t) + \frac{1}{2} \delta t^2 \mathbf{B}(t) + \frac{1}{6} \delta t^3 \mathbf{C}(t) + \dots \quad (19)$$

$$\mathbf{A}(t + \delta t) = \mathbf{A}(t) + \delta t \mathbf{B}(t) + \frac{1}{2} \delta t^2 \mathbf{C}(t) + \dots \quad (20)$$

where \mathbf{R} is the position, \mathbf{V} ($= \dot{\mathbf{R}}$) is the velocity, \mathbf{A} ($= \ddot{\mathbf{R}}$) is the acceleration, and \mathbf{B} and \mathbf{C} are the third and fourth derivatives of the positions with respect to time, respectively.

Verlet Algorithm

One of the most widely used finite difference methods in classical molecular dynamics simulations is the Verlet algorithm (Verlet 1967). In the Verlet algorithm, the positions and accelerations at time t and the positions from the previous time step $\mathbf{R}(t - \delta t)$ are used to calculate the updated positions $\mathbf{R}(t + \delta t)$ using the equation:

$$\mathbf{R}(t + \delta t) = 2\mathbf{R}(t) - \mathbf{R}(t - \delta t) + \delta t^2 \mathbf{A}(t). \quad (21)$$

The accelerations can be conveniently calculated using Newton's equation (17), where the forces are obtained by differentiating the energy with respect to the nuclear positions,

$$\mathbf{A} = \frac{\mathbf{F}}{M} = -\frac{\nabla E}{M} \quad (22)$$

While the velocities do not explicitly appear in Eq. (21), they can be calculated from the difference in position over the entire time step:

$$\mathbf{V}(t) = |\mathbf{R}(t + \delta t) - \mathbf{R}(t - \delta t)| / 2\delta t \quad (23)$$

or the difference in position over a half time step ($t + \frac{1}{2}\delta t$):

$$\mathbf{V}(t + \frac{1}{2}\delta t) = |\mathbf{R}(t + \delta t) - \mathbf{R}(t)| / \delta t \quad (24)$$

The fact that the velocities are not explicitly represented in the Verlet algorithm is one of the drawbacks to this method in that no velocities are available until the positions have been determined at the next time step. Also, in order to calculate the position of particles at $t = \delta t$, it is necessary to determine the positions at $t = -\delta t$ since the algorithm requires the position at time $t - \delta t$ to calculate the position at time $t + \delta t$. Often, this drawback is overcome by using the Taylor series to calculate $\mathbf{R}(-\delta t) = \mathbf{R}(0) - \delta t \mathbf{V}(0) + \frac{1}{2} \delta t^2 \mathbf{A}(0) + \dots$. A final drawback of the Verlet algorithm is that there may be a loss of precision in the resulting trajectories that result from the fact that the positions are calculated by adding a small term ($\delta t^2 \mathbf{A}(t)$) to the difference of two larger terms ($2\mathbf{R}(t)$ and $\mathbf{R}(t - \delta t)$) in equation (21).

“Leap-Frog” Algorithm

In an attempt to improve upon the original Verlet algorithm, several variations have been developed. The leap-frog algorithm (Hockney 1970) is one of the variations that use the following equations to update the positions:

$$\mathbf{R}(t + \delta t) = \mathbf{R}(t) + \delta t \mathbf{V}(t + \frac{1}{2} \delta t), \quad (25)$$

and the velocities:

$$\mathbf{V}(t + \frac{1}{2} \delta t) = \mathbf{V}(t - \frac{1}{2} \delta t) + \delta t \mathbf{A}(t). \quad (26)$$

In the leap-frog algorithm, the velocities $\mathbf{V}(t + \frac{1}{2} \delta t)$ are first calculated from the velocities at time $t - \frac{1}{2} \delta t$ and the accelerations at time t using Eq. (25). Then the positions $\mathbf{R}(t + \delta t)$ are calculated from the velocities $\mathbf{V}(t + \frac{1}{2} \delta t)$ and the positions $\mathbf{R}(t)$ using Eq. (26). The algorithm gets its name from the fact that the velocities are calculated in a manner such that they “leap-frog” over the positions to give their values $t - \frac{1}{2} \delta t$. Then the positions are calculated such that they “leap-frog” over the velocities, and then the algorithm continues.

The “leap-frog” algorithm improves upon the standard Verlet algorithm in that the velocity is explicitly included in the calculations and also the “leap-frog” algorithm does not require the calculation of the differences of large numbers so the precision of the calculation should be improved. However, the fact that the calculated velocities and positions are not synchronized in time results in the fact that the kinetic energy contribution to the total energy cannot be calculated for the time at which the positions are defined. In response to this shortcoming in the “leap-frog” algorithm, a formalism to calculate the velocities at time t has been developed that follows

$$\mathbf{V}(t) = [\mathbf{V}(t + \frac{\delta t}{2}) + \mathbf{V}(t - \frac{\delta t}{2})]/2 \quad (27)$$

Velocity Verlet Algorithm

The velocity Verlet method (Swope et al. 1982), which is a variation of the standard Verlet method, calculates the positions, velocities, and accelerations at the same time by using the following equations:

$$\mathbf{R}(t + \delta t) = \mathbf{R}(t) + \delta t \mathbf{V}(t) + \frac{1}{2} \delta t^2 \mathbf{A}(t) \quad (28)$$

$$\mathbf{V}(t + \delta t) = \mathbf{V}(t) + \frac{1}{2} \delta t [\mathbf{A}(t) + \mathbf{A}(t + \delta t)]. \quad (29)$$

The velocity Verlet method is a three-stage algorithm because the calculation of the new velocities (Eq. 29) requires both the acceleration at time t and at time $t + \delta t$.

Therefore, first, the positions at $t + \delta t$ are calculated using Eq. (28) and the velocities and accelerations at time t . The velocities at time $t + \frac{1}{2}\delta t$ are then calculated using

$$\mathbf{V}(t + \frac{1}{2}\delta t) = \mathbf{V}(t) + \frac{1}{2}\delta t \mathbf{A}(t). \quad (30)$$

Then the forces are computed from the current positions, which results in being able to calculate $\mathbf{A}(t + \delta t)$. Then the final step consists of calculating the velocities at time $t + \delta t$ using:

$$\mathbf{V}(t + \delta t) = \mathbf{V}(t + \frac{1}{2}\delta t) + \frac{1}{2}\delta t \mathbf{A}(t + \delta t). \quad (31)$$

Therefore, the velocity Verlet allows for the velocities and positions to be calculated in a time-synchronized manner and thus allows for the kinetic energy contribution of the total energy. Also, the precision of the results will be improved upon those from the standard Verlet algorithm as there are no differences of large numbers within the formalism of the method.

The selection of the best time integration method for a given problem and the size of the time step to use will be discussed in section “Setting the Timestep.”

Hybrid Quantum/Classical (QM/MM) Molecular Dynamics

The *ab initio* and classical simulation techniques discussed in the previous sections can be viewed as complementary. While AIMD is capable of dealing with electronic processes such as chemical reactions, charge transfer, and electronic excitations, its applicability is limited to systems of modest size, precluding its use in complex, large-scale biochemical simulations. Classical MD, on the other hand, can describe much larger systems on longer time scales but misses any of the abovementioned electronic effects, e.g., bond breaking and formation. The basic idea of the QM/MM approach is to combine the strengths of the two methods treating a chemically active region at the quantum level and the environment using molecular mechanics (i.e., a force field). There are several excellent review articles on the QM/MM method in the literature (Senn and Thiel 2009; Thiel 2009; Groenhof 2013).

Partitioning Schemes

The entire system, **S**, is partitioned into a chemically active inner region, **I**, and a chemically inert outer region, **O**. If the border between these regions cuts through chemical bonds, so-called link atoms, **L**, are usually introduced to cap the inner region (see section “Bonds Across the QM/MM Boundary”).

Subtractive Scheme

In a subtractive scheme, the total energy, $E_{\text{QM/MM}}^{\text{S}}$, of the entire system,

$$E_{\text{QM/MM}}^{\text{S}} = E_{\text{MM}}^{\text{S}} + E_{\text{QM}}^{\text{I,L}} - E_{\text{MM}}^{\text{I,L}} \quad (32)$$

is calculated from three separate energy contributions: (i) the MM energy of the entire system, E_{MM}^{S} , (ii) the QM energy of the active region (including any link atoms), $E_{\text{QM}}^{\text{IL}}$, and (iii) the MM energy of the active region $E_{\text{MM}}^{\text{IL}}$.

The role of the third term in Eq. (32) is to avoid double counting and to correct for any artifacts caused by the link atoms. For the latter to be effective, the force field has to reproduce the quantum-mechanical forces reasonably well in the link region.

Additive Scheme

In an additive scheme, the total energy of the system is given by

$$E_{\text{QM/MM}}^{\text{S}} = E_{\text{MM}}^{\text{O}} + E_{\text{QM}}^{\text{IL}} + E_{\text{QM-MM}}^{\text{IO}} \quad (33)$$

The difference to the subtractive scheme is that here a pure MM calculation is performed for only the outer region and the interaction between QM and MM regions is achieved by an explicit coupling term,

$$E_{\text{QM-MM}}^{\text{IO}} = E_{\text{QM-MM}}^{\text{bond}} + E_{\text{QM-MM}}^{\text{vdW}} + E_{\text{QM-MM}}^{\text{el}} \quad (34)$$

where $E_{\text{QM-MM}}^{\text{bond}}$, $E_{\text{QM-MM}}^{\text{vdW}}$, and $E_{\text{QM-MM}}^{\text{el}}$ are bonded, van der Waals, and electrostatic interaction energies, respectively.

The simplest way to treat electrostatic interactions between the **I** and **O** subsystems is to assign fixed electric charges to all **I** atoms (*mechanical embedding*). In this case the QM problem is solved for the isolated subsystem **I** without taking into account the effects of the surrounding atomic charges in **O**. The majority of implementations use an *electrostatic embedding* scheme in which the MM point charges of region **O** are incorporated in the QM Hamiltonian through a QM-MM coupling term,

$$\hat{H}_{\text{QM-MM}}^{\text{el}} = - \sum_i \sum_{\alpha \in \text{O}} \frac{q_\alpha}{|\mathbf{r}_i - \mathbf{R}_\alpha|} + \sum_{I \in \text{I+L}} \sum_{\alpha \in \text{O}} \frac{q_\alpha Z_I}{|\mathbf{R}_I - \mathbf{R}_\alpha|} \quad (35)$$

where q_α are the MM point charges at positions \mathbf{R}_α (all other symbols as defined in section “Born–Oppenheimer Approximation”). In this way, the electronic structure of the QM region adjusts to the moving MM charge distribution. A problem that arises when an MM point charge is in close proximity to the QM electron cloud is overpolarization of the latter, sometimes referred to as a “spill-out” effect. This can be avoided by modifying the Coulomb potential in the first term of Eq. (35) at short range (see, e.g., Laio et al. 2002).

At present, in all commonly used partitioning schemes, the partitions remain *fixed* over time, i.e., an MM atom cannot turn into a QM atom and vice versa. This can present a serious limitation, for instance, in the case of solvent diffusion through the chemically active region. A number of *adaptive* partitioning methods have been proposed to remedy this problem (Kerdcharoen et al. 1996; Hofer et al. 2005; Kerdcharoen and Morokuma 2002; Heyden et al. 2007; Buló et al. 2009; Nielsen et al. 2010; Pezeshki and Lin 2011; Pezeshki et al. 2014; Waller et al. 2014);

however, the computational overhead is significant and physical conservation laws are not strictly satisfied.

Bonds Across the QM/MM Boundary

Partitioning the total system into QM and MM regions in such a way that cuts chemical bonds is best avoided. However, in many cases this is inevitable. Then one has to make sure that any atoms participating in chemical reactions are at least three bonds away from boundary. Furthermore, it is preferable to cut a bond that is unpolar and not part of a conjugated chain.

Link Atoms

Cutting a single covalent bond will create a dangling bond which must be capped by a so-called link atom, and in most applications a hydrogen atom is chosen. In the QM calculation, the atoms of region **I** together with the link atoms **L** are treated as an isolated molecule in the presence of the point charges of the environment **O**. The original QM–MM bond, cut by the partitioning, is only treated at the MM level.

Boundary Atoms

Boundary atom schemes have been developed to avoid the artifacts introduced by a link atom. The boundary atom appears as a normal MM atom in the MM calculation while carrying QM features to saturate the QM–MM bond and to mimic the electronic properties of the MM side. The QM interactions are achieved by placing a pseudopotential at the position of the boundary atom, parametrized to reproduce electronic properties of a certain chemical end group, e.g., a methyl group in the case of a cut C–C bond. Among the various flavors that have been proposed, the pseudobond method for first principles QM calculations (Zhang et al. 1999; Zhang 2005, 2006) and the pseudopotential approach for plane-wave DFT (Laio et al. 2002) are the most relevant in the present context.

Frozen Localized Orbitals

The basic idea behind the various frozen orbital methods (Warshel and Levitt 1976; Théry et al. 1994; Monard et al. 1996; Assfeld and Rivail 1996; Assfeld et al. 1998; Ferré et al. 2002; Fornili et al. 2003, 2006a, b; Sironi et al. 2007; Loos and Assfeld 2007; Philipp and Friesner 1999; Murphy et al. 2000; Gao et al. 1998; Amara et al. 2000; Garcia-Viloca and Gao 2004; Pu et al. 2004a, b, 2005; Jung et al. 2007; Jensen et al. 1994; Day et al. 1996; Kairys and Jensen 2000; Gordon et al. 2001; Nemukhin et al. 2002, 2003; Grigorenko et al. 2002) is to saturate the cut QM–MM bond by placing on either the MM or the QM atom at the boundary localized orbitals that have been determined in a prior quantum-mechanical SCF calculation on a model molecule containing the bond under consideration. To preserve the properties of the bond, the localized orbitals are then kept fixed in the subsequent QM/MM calculation. Different flavors are the local SCF (LSCF) method (Théry et al. 1994; Monard et al. 1996; Assfeld and Rivail 1996; Assfeld et al. 1998; Ferré et al. 2002), extremely localized molecular orbitals (ELMOs) (Fornili et al. 2003, 2006a; Sironi et al. 2007), frozen core orbitals (Fornili et al. 2006b), optimized

LSCF (Loos and Assfeld 2007), frozen orbitals (Philipp and Friesner 1999; Murphy et al. 2000), generalized hybrid orbitals (Gao et al. 1998; Amara et al. 2000; Garcia-Viloca and Gao 2004; Pu et al. 2004a, b, 2005; Jung et al. 2007), and effective fragment potentials (EFP) (Jensen et al. 1994; Day et al. 1996; Kairys and Jensen 2000; Gordon et al. 2001; Nemukhin et al. 2002, 2003; Grigorenko et al. 2002).

Of the three types of boundary treatment, the link atom method is the simplest both conceptually and in practice and is hence the most widely used. The boundary atom and in particular the frozen orbital methods can potentially achieve higher accuracy but require careful a priori parametrization and bear limitations on transferability (Senn and Thiel 2009).

Coarse-Grained Molecular Dynamics

A large number of important problems in fields that are often studied using molecular dynamics simulations (i.e., soft condensed matter physics, structural biology, chemistry, and materials science) take place over a time span of microseconds to seconds and distances of few hundred nanometers to a few microns. However, these time and length scales are still unattainable via quantum or atomistic force-field molecular dynamics methods despite significant computational hardware advances (Shirts and Pande 2000; Mervis 2001; Reed 2003) and the development of increasingly powerful software (MacKerell et al. 1998; Lindahl and van der Spoel 2001; Wang et al. 2004a; Phillips et al. 2005). Therefore, one approach that has been utilized in order to be able to study these complex problems is to reduce the computational demand of the simulation by reducing the number of atoms represented and therefore the degrees of freedom of the simulated system. This procedure of reducing the number of atoms represented in a system is done by grouping atoms together and representing them as a single interaction site and is generally referred to as “coarse graining” of the system. Figure 1 shows a comparison of the atomistic, united-atom, and coarse-grained representation.

The “bead-spring” coarse-grained model of polymer chains that was created by Kremer and Grest in 1990 has served as the foundation for many of the coarse-grained models that have been developed for a wide range of phenomena (at the current date this paper has been cited over 1440 times) including various studies of polymers and biomolecules including DNA solutions. Many of the more recent coarse-grained models have been developed for biological macromolecules since there are many examples of interesting biophysical phenomena that occur at large length and time scales. The most widely used coarse-grained models for biological systems include the generic model of Lipowsky et al. (Goetz et al. 1999; Shillcock and Lipowsky 2002), the solvent-free model of Deserno et al. (Cooke et al. 2005), and the specific models of the Klein group (Shelley et al. 2001), the Voth group (which is called the multi-scale coarse-grained model) (Izvekov and Voth 2005, 2006), the Essex group (called the ELBA force-field) (Orsi et al. 2011), and the Marrink group (called the MARTINI force-field) (Marrink et al. 2007). The above coarse-grained models have generally been developed for lipid

Fig. 1 Atomistic, united-atom, and coarse-grained representations of organic molecules

membranes; however, there are also coarse-grained force fields for proteins (as reviewed in Tozzini (2005) and some more recent examples Betancourt and Omovie (2009), Bereau and Deserno (2009), de Jong et al. (2013), and Kar et al. (2013)), carbohydrates (Lopez et al. 2009), and DNA (Tepper and Voth 2005; Khalid et al. 2008).

When developing a coarse-grained model for a system, there are two important decisions to be made: (1) how many atoms to combine (coarse grain) into a single interaction site and (2) how to parameterize the coarse-grained force field. In deciding the number of atoms to combine into a single interaction site, one must consider the obvious trade-off of how much detail are you able to sacrifice in order to simulate larger length and/or time scale phenomena and still be able to actually accurately model the phenomena of interest. The least amount of coarse graining that has been used is represented by what is called a “united-atom” representation of a molecule where all “heavy” atoms (generally all non-hydrogen elements in a molecule) are represented and the “light” (i.e., hydrogen) atoms are grouped with the heavy atom to which they are bonded into one interaction site. United-atom versions of many of the popular all-atom force fields listed are in section “Classical Force Fields” exist and have been successfully used in several studies. In addition to united-atom models, there are several existing coarse-graining methods that will combine a different number of atoms together into one interaction site.

A mapping function C is required to develop a description of the desired system in terms of the coarse-grained interaction sites. This mapping function uses a set of n atomic coordinates in the atomistic system ($\mathbf{r}^n = \mathbf{r}_1, \dots, \mathbf{r}_n$) and maps them to a unique configuration of coordinates for N interaction sites ($\mathbf{R}^N = \mathbf{R}_1, \dots, \mathbf{R}_N$) in the coarse-grained system. Then the mapping function generally has the form:

$$\mathbf{R} = \mathbf{C}\mathbf{r} \quad (36)$$

where \mathbf{R} and \mathbf{r} are vectors of length $3N$ and $3n$, respectively, and \mathbf{C} is a matrix with dimensions $3N \times 3n$ and contains the elements c_{Ii} that are used to link the descriptions of each coarse-grained interaction site, I , to the atoms in the all-atom configuration it represents:

$$\mathbf{R}_I = \sum_{i=1}^n c_{Ii} \mathbf{r}_i. \quad (37)$$

The most common form of mapping is where the coarse-grained interaction sites are mapped to the center of mass of the atoms within the all-atom configuration, and therefore $c_{Ii} = m_i / \sum_{i=1}^n m_i$.

In general, coarse-grained systems are governed by similar potential terms as are found in atomistic models such as nonbonded terms (both pairwise interactions and electrostatic interactions) and bond-stretching terms, and then in more sophisticated models even angle and dihedral terms will be included as well. Generally, all specific models are parameterized based on comparison to atomistic simulations and/or detailed experimental data. The “top-down” approach generally parameterizes the interactions without explicit consideration of a more detailed model. The interactions are often determined using physicochemical intuition or generic physical principles or certain emergent structural or thermodynamic properties that are observed on even larger scales. The most popular example of a “top-down” coarse-grained model is the Martini model (Marrink et al. 2004; de Jong et al. 2013; Lopez et al. 2009). The Martini model provides transferable potentials that describe effects of hydrophobic, van der Waals, and electrostatic interactions between sites, which are characterized based on their polarity and charge. The Martini potentials have been optimized to reproduce the partitioning of model compounds between aqueous and hydrophobic environments (Marrink et al. 2004, 2007). For more information about developing Martini force fields for molecules which have as of yet to be modeled, please refer to this website (Martini <http://md.chem.rug.nl/cgmartini/index.php/parametrizing-new-molecule>).

Effective coarse-grained potentials have also been extracted from atomistic simulations (often referred to as “bottom-up” approaches) using a variety of different methods including, but not limited to, those that we briefly introduce in this chapter as they are currently among the most popular methods: inverse Iterative Boltzmann Inversion approaches (Muller-Plathe 2002; Reith et al. 2003), Monte Carlo schemes (Lyubartsev 2005; Elezgaray and Laguerre 2006) and force matching (Ercolessi and Adams 1994; Izvekov and Voth 2005, 2006; Lu et al. 2013).

Iterative Boltzmann Inversion (IBI) is one of the most commonly used bottom-up approaches to parameterizing coarse-grained potentials because it utilizes a straightforward and generally robust algorithm. In general, this method is used to construct nonbonded pairwise additive potential functions between every type of interaction site in a given system. The potential functions are iteratively refined in order to match target radial distribution functions (see section “Spatial Distribution Functions”) that are determined from atomistic simulations, whose trajectories have been mapped into the coarse-grained representation of the systems. The general

philosophy behind the IBI method is similar to the philosophy behind deriving atomistic pair potentials which have been used to reproduce structure factors determined from neutron scattering experiments (Schommers 1973; Soper 1996). In the iterative process of refining the pair potentials, the initial guesses for each of these interactions are calculated from the potential of mean force, U_{PMF} , from the target radial distribution functions, $g(r)$:

$$U_{\text{PMF}}(r) = -k_B T \ln[g(r)] \quad (38)$$

where k_B and T are the Boltzmann constant and temperature, respectively. The intramolecular potential energies are calculated using the observed distributions P_q of each type of interaction (i.e., bond lengths, bond angles, and dihedral angles) from the reference atomistic simulations using an analogous approach as used for the pair potentials in Eq. (38):

$$U(q) = -k_B T \ln[P_q(q)] \quad (39)$$

where q is the bond length, bond angle, or dihedral angle, for the various terms of the intramolecular potential energy. Then using the initial guess for the nonbonded pair potentials (Eq. (38)) and these intramolecular potential energies, a coarse-grained simulation is performed and radial distribution functions $g_{\text{CG}}^n(r)$ are calculated and compared to the target radial distribution functions $g_t(r)$ to update the pair potential energy functions for the next iteration of the algorithm:

$$U^{(n+1)}(r) = U^n(r) + \lambda \Delta U^n(r) = U^n(r) + \lambda k_B T \ln \frac{g_{\text{CG}}^n(r)}{g_t(r)} \quad (40)$$

where λ scales the potential update, and should be chosen in order to ensure stability of the algorithm. This iterative process is repeated until the measured radial distribution functions in the CG simulations are within a user-defined tolerance of the target radial distribution functions. This method has been automated in a software package called VOTCA (<http://www.votca.org/home>) that can be used in combination with the popular molecular dynamics simulation packages GROMACS (Spoel et al. 2005; <http://www.gromacs.org/>), LAMMPS (<http://lammps.sandia.gov/>; Plimpton 1995), and DL-POLY (Smith et al. 2002; http://www.cse.scitech.ac.uk/ccg/software/DL_POLY/).

The Inverse Monte Carlo (IMC) algorithm is another iterative method that corrects a guessed interaction potential to reproduce a target radial distribution function. However, the IMC method applies a correction to the potential which is determined from statistical mechanical arguments that account for the fact that small changes in the potential energies at a given distance r can lead to variation in the radial distribution functions at all distances. Generally speaking, one can summarize this approach by stating that the Hamiltonian (potential energy) H of the system depends on a series of parameters $\lambda_1, \lambda_2, \dots, \lambda_M$, and the desire is to reproduce canonical averages of a given measurable $\langle S_1 \rangle, \langle S_2 \rangle, \dots, \langle S_M \rangle$

(e.g., radial distribution functions). In Inverse Monte Carlo, the desire is to calculate the values of the parameters used to calculate the potential energy λ_M from the canonical averages $\langle S_M \rangle$. In order to do so, in the vicinity of an arbitrary point in the space of the Hamiltonians, it can be shown that:

$$\Delta \langle S_\alpha \rangle = \sum_\gamma \frac{\delta \langle S_\alpha \rangle}{\delta \lambda_\gamma} \Delta \lambda_\gamma \quad (41)$$

where

$$\frac{\delta \langle S_\alpha \rangle}{\delta \lambda_\gamma} \Delta \lambda_\gamma = \left\langle \frac{\delta S_\alpha}{\delta \lambda_\gamma} \right\rangle - \beta \left[\left\langle \frac{\delta H}{\delta \lambda_\alpha} S_\gamma \right\rangle - \left\langle \frac{\delta H}{\delta \lambda_\alpha} \right\rangle \langle S_\gamma \rangle \right]. \quad (42)$$

Using Eqs. (41) and (42), then this problem can be solved iteratively.

The IBI and IMC methods are both designed to reproduce a target radial distribution function and therefore are commonly called structure-based coarse-graining methods. Another class of bottom-up coarse graining approaches are those that are designed to match the force distributions on the coarse-grained interaction sites to the force distributions measured within the atomistic trajectory on the atoms that are mapped into the various interaction sites. This force-matching approach was first used for obtaining atomistic potential energies by fitting forces and trajectories from ab initio calculations (Ercolessi and Adams 1994). It has since been extended to fitting coarse-grained potentials by Izvekov and Voth (Izvekov and Voth 2005, 2006; Lu et al. 2013), who call their method multi-scale coarse graining (MSCG). In this force-matching scheme, $\mathbf{f} = \mathbf{F}\boldsymbol{\phi}$, where \mathbf{f} is a vector composed of the atomistic force data. $\boldsymbol{\phi}$ is a vector containing all of the coarse-grained force-field parameters, and \mathbf{F} is a matrix that is related to the input atomistic configurations. Since this equation is a standard least squares matrix equation, it can be converted to

$$\mathbf{G}\boldsymbol{\phi} = \mathbf{b}, \quad (43)$$

where \mathbf{G} is the square matrix $\mathbf{F}^T\mathbf{F}$ and \mathbf{b} is the vector $\mathbf{F}^T\mathbf{f}$. Therefore, $\mathbf{G}\Delta\boldsymbol{\phi} = \delta\mathbf{b}$, which can be used to iterate the values of $\boldsymbol{\phi}$ in order to converge on the appropriate forces within the coarse-grained simulations.

We have attempted to introduce some of the more popular approaches that are utilized to develop coarse-grained potentials for use in simulating biological, polymeric, and colloidal systems in this section. However, by no means is this a complete summary of all of the approaches that have been used, so for more lengthy discussions of the various approaches, we would recommend some recent review articles including (Noid 2013; Saunders and Voth 2013; Brini et al. 2013; Riniker et al. 2012; de Pablo 2011). In general, the advantage of using a bottom-up approach is that the resulting force field will produce a higher level of accuracy and closer resemblance to atomistic simulations. However, these schemes produce force fields that are useful for a given state point and therefore are not transferable, whereas the advantages of the thermodynamic approach include that it produces a potential that has a broader range of applicability and also the thermodynamic approach does not require atomistic simulations to be done in the first place.

Interaction Potentials/Force Fields

Classical Force Fields

Classical, or empirical, force fields are generally used to calculate the energy of a system as a function of the nuclear positions of the particles within the system while ignoring the behavior of the individual electrons. As stated in section "Born–Oppenheimer Approximation," the Born–Oppenheimer approximation makes it possible to write the energy as a function of the nuclear coordinates. Another approximation that is key to the implementation of classical Force fields is that it is possible to model the relatively complex motion of particles within the system with fairly simple analytical models of inter- and intramolecular interactions. Generally, an empirical force field consists of terms that model the nonbonded interactions ($E_{\text{nonbonded}}$), which include both the van der Waals and Coulombic interactions, the bonded interactions (E_{bond}), the angle bending interactions (E_{angle}), and the dihedral (bond rotations) interactions (E_{dihedral}):

$$E(\mathbf{R}) = E_{\text{nonbonded}} + E_{\text{bond}} + E_{\text{angle}} + E_{\text{dihedral}}. \quad (44)$$

Figure 2 presents representative cartoons of the bond, angle, and dihedral interactions from a molecular perspective. The form that each of these individual terms takes is dependent on the Force field that you are using. There are several different force-field options available for various systems. The best way to find the most suitable force field for your specific problem is to conduct a literature and/or Internet search in order to find which force field has the capability to model the molecules you are interested in studying. However, if you are interested in modeling organic/biological molecules, there are several large force fields that may be a good place to start, including CHARMM (MacKerell et al. 1998), OPLS (Jorgensen and Swenson 1984), Amber (Cornell et al. 1995), and COMPASS (Sun et al. 1998). The CHARMM and AMBER force fields each have recently developed generalized versions of their force fields and tools to help researchers develop force-field parameters for small molecules that they may be interested in modeling for which parameters do not currently exist. In the AMBER force field, this general force field is called GAFF (generalized AMBER force field) (Wang et al. 2004b; <http://ambermd.org/antechamber/gaff.html>). While in the CHARMM force field, CGENFF is the generalized force field (Vanommeslaeghe et al. 2010; Yu et al. 2012; CGENFF <http://mackerell.umaryland.edu/~kenno/cgenff>; ParamChem <http://cgenff.paramchem.org>).

Likewise, there are several well-known large force fields that can be used for solids, like the BKS potential (van Beest et al. 1990) for oxides and the embedded-atom method (EAM) (Daw and Baskes 1983, 1984; Finnis and Sinclair 1984) and modified embedded-atom method (MEAM) (Baskes 1992) force fields. In addition to defining the functional forms used for the various terms in the general potential formulation, a force field will also define the variables used in the potential which

Fig. 2 Intramolecular terms of classical force fields: bond, angle, and dihedral interactions

are derived from a combination of quantum simulation results and experimental observations.

In the following sections, each of the terms in Eq. (44) will be discussed further and typical functional forms that are used in the previously mentioned force fields and others to represent each term will be shown. To this end, we limit the discussion to simple nonpolarizable force fields in which the individual atoms carry fixed charges. They capture many-body effects such as electronic polarization only in an effective way. More sophisticated, polarizable force fields have been developed over the past two decades (see, e.g., Ponder et al. 2010 and references therein); however, they are computationally substantially more demanding. Some of the most common polarizable force field methods will later be introduced at the end of section “Classical Polarizable Electrostatical Models”.

Nonbonded Interactions

There are two general forms of nonbonded interactions that need to be accounted for by a classical force field: (1) the van der Waals (vdw) interactions and (2) the electrostatic interactions.

van der Waals Interactions

In order to model the van der Waals interactions, we need a simple empirical expression that is not computationally intensive and that models both the dispersion and repulsive interactions that are known to act upon atoms and molecules. The most commonly used functional form of van der Waals energy (E_{vdw}) in classical force fields is the Lennard–Jones 12-6 function that has the form:

$$E_{\text{vdw}}(\mathbf{R}) = \sum_{I>J} 4\epsilon_{IJ} \left[\left(\frac{\sigma_{IJ}}{R_{IJ}} \right)^{12} - \left(\frac{\sigma_{IJ}}{R_{IJ}} \right)^6 \right], \quad (45)$$

where σ_{IJ} is the collision diameter and ϵ_{IJ} is the well depth of the interaction between atoms I and J . Both σ_{IJ} and ϵ_{IJ} are adjustable parameters that will have different values to describe the interactions between different pairs of particles (i.e., the values of σ and ϵ used to describe the interaction between two carbon atoms are different than the values of σ and ϵ used to describe the interaction between a carbon and an oxygen).

Equation (45) models both the attractive part (the R^{-6} term) and the repulsive part (the R^{-12} term) of the nonbonded interaction. Other formulations of the Lennard–Jones nonbonded potential commonly have the same power law description of the attractive part of the potential but will have different power law dependence for the repulsive part of the interaction, such as the Lennard–Jones 9-6 function:

$$E_{\text{vdW}}(\mathbf{R}) = \sum_{I>J} 4\epsilon_{IJ} \left[\left(\frac{\sigma_{IJ}}{R_{IJ}} \right)^9 - \left(\frac{\sigma_{IJ}}{R_{IJ}} \right)^6 \right]. \quad (46)$$

When the nonbonded interactions of a system that contains multiple particle types and multiple molecules are modeled using a Lennard–Jones-type nonbonded potential, it is necessary to be able to define the values of σ and ϵ that apply to the interaction between particles of type I and J . The parameters for these cross interactions are generally found using one of the two following mixing rules. One common mixing rule is the Lorentz–Berthelot rule where the value of σ_{IJ} is found from the arithmetic mean of the two pure values and the value of ϵ_{IJ} is the geometric mean of the two pure values:

$$\sigma_{IJ} = (\sigma_I + \sigma_J)/2 \quad (47)$$

$$\epsilon_{IJ} = \sqrt{\epsilon_I \epsilon_J} \quad (48)$$

The other commonly used mixing rule is the one that defines both σ_{IJ} and ϵ_{IJ} as the geometric mean of the values for the pure species:

$$\sigma_{IJ} = \sqrt{\sigma_I \sigma_J} \quad (49)$$

$$\epsilon_{IJ} = \sqrt{\epsilon_I \epsilon_J} \quad (50)$$

Most force fields use the Lorentz–Berthelot mixing rule; however, the OPLS force field is one force field that utilizes the geometric mixing rule.

In other nonbonded pairwise potentials, the repulsive portion of the interaction is modeled with an exponential term, which is in better agreement with the functional form of the repulsive term determined from quantum mechanics. One example of such a potential is the Buckingham potential (Buckingham 1938):

$$E_{\text{vdW}}(\mathbf{R}) = \sum_{I<J} A_{IJ} \exp(-B_{IJ} R_{IJ}) - \frac{C_{IJ}}{R_{IJ}^6}, \quad (51)$$

where A_{IJ} , B_{IJ} , and C_{IJ} are adjustable parameters that will have unique values for different types of particles. Another form of the nonbonded interaction is the Born–Mayer–Huggins potential (Fumi and Tosi 1964; Tosi and Fumi 1964):

$$E_{\text{vdw}}(\mathbf{R}) = \sum_{I < J} A_{IJ} \exp(B_{IJ}(\sigma_{IJ} - R_{IJ})) - \frac{C_{IJ}}{R_{IJ}^6} + \frac{D_{IJ}}{R_{IJ}^8}, \quad (52)$$

where A_{IJ} , B_{IJ} , C_{IJ} , D_{IJ} and σ_{IJ} are adjustable parameters that will have unique values for different types of particles. The Born–Mayer–Huggins potential (Eq. 52) is identical to the Buckingham potential (Eq. 51) when $\sigma = D = 0$.

All of the nonbonded potential functional forms that have been presented to this point are pairwise additive, i.e., they take into account the effect that one particle has on another particle based solely on the distance between the two particles. However, in some systems like metals and alloys as well as some covalently bonded materials like silicon and carbon, the nonbonded potential is a function of more than just the distance between two particles, i.e., many-body effects play an important role. In order to model these systems, the embedded-atom method (EAM) (Daw and Baskes 1983, 1984; Finnis and Sinclair 1984) and modified embedded-atom method (MEAM) (Baskes 1992) utilize an embedding energy, F_I , which is a function of the atomic electronic density ρ_I of the embedded atom I and a pair potential interaction ϕ_{IJ} such that:

$$E_I(\mathbf{R}) = F_I \left(\sum_{J \neq I} \rho_I(R_{IJ}) \right) + \frac{1}{2} \sum_{J \neq I} \phi_{IJ}(R_{IJ}). \quad (53)$$

The multi-body nature of the EAM potential is a result of the embedding energy term.

So while the EAM and MEAM potentials have a term to account for multi-body interactions, they are still only a pairwise potential, as are all the other nonbonded potentials presented to this point. However, there are multi-body potentials that will explicitly account for how the presence of a third, fourth, ... atom affects the nonbonded energy felt by any given atom. One example of a 3-body potential is the Stillinger–Weber potential (Stillinger and Weber 1985):

$$E(\mathbf{R}) = \sum_I \sum_{J > I} \phi_2(R_{IJ}) + \sum_I \sum_{J \neq I} \sum_{K > J} \phi_3(R_{IJ}, R_{IK}, \theta_{IJK}), \quad (54)$$

where there is a two-body term ϕ_2 :

$$\phi_2(R_{IJ}) = A_{IJ} \epsilon_{IJ} \left[B_{IJ} \left(\frac{\sigma_{IJ}}{R_{IJ}} \right)^{p_{IJ}} - \left(\frac{\sigma_{IJ}}{R_{IJ}} \right)^{q_{IJ}} \right] \exp \left(\frac{\sigma_{IJ}}{R_{IJ} - a_{IJ} \sigma_{IJ}} \right) \quad (55)$$

and a three-body term ϕ_3 :

$$\begin{aligned} \phi_3(R_{IJ}, R_{IK}, \theta_{IJK}) &= \lambda_{IJK} \epsilon_{IJK} \left[\cos \theta_{IJK} - \cos \theta_{0,IJK} \right]^2 \\ &\times \exp \left(\frac{\gamma_{IJ} \sigma_{IJ}}{R_{IJ} - a_{IJ} \sigma_{IJ}} \right) \\ &\times \exp \left(\frac{\gamma_{IK} \sigma_{IK}}{R_{IK} - a_{IK} \sigma_{IK}} \right). \end{aligned} \quad (56)$$

The Stillinger–Weber potential has generally been used for modeling crystalline silicon; however, more recently it has also been used for organic molecules as well. Another example of a three-body interatomic potential is the Tersoff potential (Tersoff 1988, 1989), which also was created initially in an attempt to accurately model silicon solids.

Electrostatic Interactions

Due to the fact that not all particles in a molecule have the same electronegativity, different particles will have stronger attractions to electrons than others. However, since classical force fields do not model the flow of electrons, the different particles within a molecule are assigned a partial charge that remains constant during the course of a simulation. Generally these partial charges q_I are assigned to the nuclear centres of the particles. The electrostatic interaction between particles in different molecules or particles that are separated by at least two other atoms in a given molecule is calculated as the sum of the contributions between pairs of these partial charges using Coulomb's law:

$$E_{\text{coul}} = \sum_I \sum_J \frac{q_I q_J}{4\pi \epsilon_0 R_{IJ}} \quad (57)$$

where the charges of each particle are q_I and q_J and ϵ_0 is the dielectric constant.

In practice, an Ewald sum (Ewald 1921) is generally used to evaluate the electrostatic interactions within a classical MD simulation. However, this is a very computationally expensive algorithm to implement and it results in a computational cost of $N^{3/2}$, where N is the number of particles in the system. In order to obtain better computational scaling, fast Fourier transforms (FFTs) have been used to calculate the reciprocal space summation required within the Ewald sum. By using the FFT algorithm, one can reduce the cost of the electrostatic algorithm to $N \log N$. The most popular FFT algorithm that has been adopted for use in classical MD simulations is the particle–particle particle–mesh (pppm) approach (Hockney and Eastwood 1981; Luty et al. 1994, 1995).

Classical Polarizable Electrostatical Models

In traditional classical molecular dynamics simulations with nonpolarizable force fields, the charge distribution is mimicked by the fixed partial charges. As a result the

electronic polarization effects are considered in a mean-field manner by optimizing the partial atomic charges such that they are representative of the condensed, typically aqueous, phase. In order to achieve a more accurate description of the response of the charge distribution to changes in the surrounding electrostatic field, models that explicitly account for electronic polarizability are essential.

There are several different approaches to including explicit electronic polarizability into classical force fields. The most computationally achievable methods to mimic the quantum-mechanical response of the electronic distribution within molecules to changes in the surrounding electric field is to extend the potential energy function such that it is capable of capturing this physics. There are three different general approaches most commonly used to do so and we will briefly discuss below: the *induced dipole model*, the *fluctuating charge model*, and the *classical Drude oscillator model*.

In the *induced dipole model*, generally an induced dipole, which is commonly calculated using a self-consistent field iterative procedure using isotropic atomic polarizabilities, is assigned to each atomic site (Warshel and Levitt 1976; Liu et al. 1998; Kaminski et al. 2002; Ren and Ponder 2002; Xie et al. 2007; Jorgensen et al. 2007; Shi et al. 2013). These induced dipoles are then used to calculate charge–dipole and dipole–dipole interactions, which are combined with the charge–charge interactions, to yield the electrostatic energy of the system. The induced dipole μ by an external electric field E from these models is calculated using $\mu = \alpha E$, where α is the polarizability of the atomic site.

The *fluctuating charge model* (Rick et al. 1994; Rick and Berne 1996; Stern et al. 2001; Patel and Brooks 2004; Patel et al. 2004) treats partial atomic charges as dynamical variables based on the electronegativity at each atomic site. Charges are propagated according to the principle of electronegativity equalization (Pauling and Yost 1932), and charge conservation constraints are assumed. Charges are generally allowed to only redistribute within molecules to avoid unphysical intermolecular charge transfer. During a molecular dynamics simulation, the charge variables used to model the fluctuating charges are usually propagated using an extended Lagrangian approach. In the fluctuating charge model, the induced dipole μ by an external electric field E is calculated by $\mu = (d^2/\eta)E$, where d is the distance between centers of two atoms and η is hardness of charge flow between them.

The *classical Drude oscillator model* (Lamoureux et al. 2003; Lamoureux and Roux 2003) is also commonly referred to as the shell (van Maaren and van der Spoel 2001) or charge-on-spring (Kunz and van Gunsteren 2009) model. In these models, a Drude particle or oscillator, which has a charge assigned to it, is attached to the center of the atom with which it is associated via a harmonic spring, and this setup is designed to mimic nuclear-electron motion (Dick and Overhauser 1958). In the Drude model, the induced dipole by an external electric field is calculated from $\mu = (q_D/k^2)E$, where q_D is the Drude charge and k is the spring constant of the harmonic spring that attaches the Drude particle to the center of its associated atom.

Each of these different models has been applied in various classical force fields in order to create polarizable versions of the force field. CHARMM has adopted the Drude model (Chowdhary et al. 2013; He et al. 2013; Patel et al. 2015; Savelyev

and MacKerell 2014; Lopes et al. 2013) and also has created a fluctuating charge model (Patel and Brooks 2004; Patel et al. 2004; Lucas et al. 2012; Zhong and Patel 2011). The induced dipole model has been used by the AMBER (Caldwell et al. 1990; Dang et al. 1991; Caldwell and Kollman 1995a, b) and AMOEBA (Ponder et al. 2010; Shi et al. 2013) force fields.

Bonded Interactions

The bonded interactions are needed to model the energetic penalty that will result from two covalently bonded atoms moving too close or too far away from one another. The most common functional form that is used to model the bond bending interactions is that of a harmonic term:

$$E_{\text{bond}} = \sum_{\text{bonds}} k_b (\ell_b - \ell_b^{(0)})^2 \quad (58)$$

where k_b is commonly referred to as the bond constant and is a measure of the bond stiffness and $\ell_b^{(0)}$ is the reference length or often referred to the equilibrium bond length. Each of these parameters will vary depending on the types of particles that the bond is joining.

Angle Bending Interactions

The angle bending interactions are also modeled in order to determine the energetic penalties of angles containing three different particles compressing or overextending such that they distort the geometry of a portion of a molecule away from its desired structure.

Again, the most common functional form to model the angle interactions is a harmonic expression:

$$E_{\text{angle}} = \sum_{\text{angles}} k_a (\theta_a - \theta_a^{(0)})^2 \quad (59)$$

where k_a is the angle constant and is a measure of the rigidity of the angle and $\theta_a^{(0)}$ is the equilibrium or reference angle.

Torsional Interactions

The torsional interactions are generally modeled using some form of a cosine series. The OPLS force-field uses the following expression for its torsional term:

$$E_{\text{dihed}} = \sum_{\text{dihedrals}} \frac{1}{2} K_d^{(1)} [1 + \cos(\phi)] + \frac{1}{2} K_d^{(2)} [1 - \cos(2\phi)] \\ + \frac{1}{2} K_d^{(3)} [1 + \cos(3\phi)] + \frac{1}{2} K_d^{(4)} [1 - \cos(4\phi)] \quad (60)$$

where $K_d^{(i)}$ are the force constants for each cosine term and ϕ is the measured dihedral angle. The CHARMM force field uses the following expression:

$$E_{\text{dihed}} = \sum_{\text{dihedrals}} K_d [1 + \cos(n\phi - d_d)], \quad (61)$$

where K_d is the force constant, n is the multiplicity of the dihedral angle ϕ , and d_d is the shift of the cosine that allows one to more easily move the minimum of the dihedral energy.

First-Principles Electronic Structure Methods

For the electronic ground state, i.e., $k = 0$, Kohn–Sham (KS) density functional theory is commonly used. In this case, the energy is given by

$$E_0 \approx E^{\text{KS}}[\rho] = T_s[\rho] + \int d\mathbf{r} v_{\text{ext}}(\mathbf{r})\rho(\mathbf{r}) + \frac{1}{2} \int d\mathbf{r} v_{\text{H}}(\mathbf{r})\rho(\mathbf{r}) + E_{\text{xc}}[\rho] \quad (62)$$

with the kinetic energy of *noninteracting electrons*, i.e., using a Slater determinant as a wave function ansatz,

$$\Psi^{\text{KS}} = \frac{1}{\sqrt{n!}} \begin{vmatrix} \psi_1(\mathbf{x}_1) & \psi_2(\mathbf{x}_1) & \cdots & \psi_n(\mathbf{x}_1) \\ \psi_1(\mathbf{x}_2) & \psi_2(\mathbf{x}_2) & \cdots & \psi_n(\mathbf{x}_2) \\ \vdots & \vdots & \ddots & \vdots \\ \psi_1(\mathbf{x}_n) & \psi_2(\mathbf{x}_n) & \cdots & \psi_n(\mathbf{x}_n) \end{vmatrix} \quad (63)$$

$$T_s[\rho] = -\frac{1}{2} \sum_i^n f_i \int d\mathbf{r} \psi_i(\mathbf{r}) \nabla^2 \psi_i(\mathbf{r}) \quad (64)$$

where f_i is the number of electrons occupying orbital ψ_i , the external potential including nucleus–nucleus repulsion and electron–nucleus attraction,

$$v_{\text{ext}}(\mathbf{r}) = \sum_{I=1}^{N-1} \sum_{J>I}^N \frac{Z_I Z_J}{|\mathbf{R}_I - \mathbf{R}_J|} - \sum_{I=1}^N \frac{Z_I}{|\mathbf{r} - \mathbf{R}_I|} \quad (65)$$

the Hartree potential (electron–electron interaction)

$$v_{\text{H}}(\mathbf{r}) = \int d\mathbf{r}' \frac{\rho(\mathbf{r}')}{|\mathbf{r} - \mathbf{r}'|} \quad (66)$$

the exchange–correlation energy, E_{xc} , and the electron density

$$\rho(\mathbf{r}) = \sum_i^n f_i |\psi_i(\mathbf{r})|^2 \quad (67)$$

The orbitals which minimize the total, many-electron energy (62) are obtained by solving self-consistently the 1-electron Kohn–Sham equations,

$$\left[-\frac{1}{2} \nabla^2 + v_{\text{ext}}(\mathbf{r}) + v_{\text{H}}(\mathbf{r}) + \frac{\delta E_{\text{xc}}[\rho]}{\delta \rho(\mathbf{r})} \right] \psi_i(\mathbf{r}) = \epsilon_i \psi_i(\mathbf{r}) \quad (68)$$

DFT is exact in principle, provided that $E_{xc}[\rho]$ is known, in which case E^{KS} (see Eq. (62)) is an exact representation of the ground state energy E_0 (see Eq. (8)). In practice, however, $E_{xc}[\rho]$ is not – and presumably never will be – known exactly; therefore, (semiempirical) approximations are used.

The starting point for most density functionals is the *local density approximation* (LDA), which is based on the assumption that one deals with a homogeneous electron gas. E_{xc} is split into an exchange term E_x and a correlation term E_c . Within the LDA the exchange functional is given exactly by Dirac (1930):

$$E_x^{\text{LDA}}[\rho] = \int \rho(\mathbf{r}) \epsilon_x^{\text{LDA}}(\rho(\mathbf{r})) d\mathbf{r} \quad (69)$$

where

$$\epsilon_x^{\text{LDA}}(\rho) = -\frac{3}{4} \left(\frac{3}{\pi} \right)^{\frac{1}{3}} \rho(\mathbf{r})^{\frac{1}{3}} \quad (70)$$

The LDA correlation functional, on the other hand, can only be approximated. We give here the most commonly used expression by Vosko et al. (1980), derived from Quantum Monte Carlo calculations:

$$E_c^{\text{LDA}}[\rho] = \int \rho(\mathbf{r}) \epsilon_c^{\text{LDA}}(\rho(\mathbf{r})) d\mathbf{r} \quad (71)$$

where

$$\epsilon_c^{\text{LDA}}(\rho) = A \left\{ \ln \left(\frac{x^2}{X} \right) + \frac{2b}{Q} \tan^{-1} \left(\frac{Q}{2x+b} \right) - \frac{bx_0}{X(x_0)} \left[\ln \left(\frac{(x-x_0)^2}{X} \right) + \frac{2(b2x_0)}{Q} \tan^{-1} \left(\frac{Q}{2x+b} \right) \right] \right\} \quad (72)$$

with $X = x^2 + bx + c$, $x = \sqrt{r_s}$, $r_s = \sqrt[3]{\frac{3}{4\pi\rho(\mathbf{r})}}$, $Q = \sqrt{4c - b^2}$, $x_0 = -0.104098$, $A = 0.0310907$, $b = 3.72744$, $c = 12.9352$.

This simplest approximation, LDA, is often too inaccurate for chemically relevant problems. A notable improvement is usually offered by so-called *semilocal* or *gradient corrected* functionals (*generalized gradient approximation* (GGA)), in which E_x and E_c are expressed as functionals of ρ and the first variation of the density, $\nabla\rho$:

$$E_x^{\text{GGA}}[\rho, \nabla\rho] = \int \rho(\mathbf{r}) \epsilon_x^{\text{GGA}}(\rho(\mathbf{r}), \nabla\rho) d\mathbf{r} \quad (73)$$

$$E_c^{\text{GGA}}[\rho, \nabla\rho] = \int \rho(\mathbf{r}) \epsilon_c^{\text{GGA}}(\rho(\mathbf{r}), \nabla\rho) d\mathbf{r} \quad (74)$$

Popular examples are the BLYP (Becke 1988; Lee et al. 1988), BP (Becke 1988; Polák 1986), and BPW91 (Becke 1988; Perdew et al. 1992) functionals. The expressions for $\epsilon_{xc}^{\text{GGA}}(\rho(\mathbf{r}), \nabla\rho)$ are complex and shall not be discussed here.

In many cases, accuracy can be further increased by using so-called *hybrid functionals*, which contain an admixture of Hartree–Fock exchange to KS exchange. Probably the most widely used hybrid functional is the three-parameter B3LYP functional (Becke 1993),

$$E_{xc}^{\text{B3LYP}} = aE_x^{\text{LDA}} + (1-a)E_x^{\text{HF}} + b\Delta E_x^{\text{B}} + (1-c)E_c^{\text{LDA}} + cE_c^{\text{LYP}} \quad (75)$$

where $a = 0.80$, $b = 0.72$, $c = 0.81$, and E_x^{HF} is the Hartree–Fock exchange energy evaluated using KS orbitals.

New functionals are constantly proposed in search of better approximations to the exact E_{xc} . Often functionals are designed to remedy a particular shortcoming of previous functionals. For systems in which van der Waals interactions are important, for instance, Grimme’s empirical D3 dispersion correction (Grimme et al. 2010) may be used in combination with a GGA or hybrid functional. The total energy is then simply the sum of the DFT energy E^{KS} and the dispersion correction E^{disp} ,

$$E^{\text{DFT-D3}} = E^{\text{KS}} + E^{\text{disp}} \quad (76)$$

where E^{disp} contains 2-body and 3-body terms,

$$E^{\text{disp}} = E^{(2)} + E^{(3)} \quad (77)$$

Becke and Johnson proposed the following form for the 2-body contributions (Becke and Johnson 2005; Johnson and Becke 2005, 2006):

$$E^{(2)} = - \sum_{I>J} \sum_{n=6,8} s_n \frac{C_n^{IJ}}{R_{IJ}^n + f(R_{IJ}^0)^n} \quad (78)$$

with the damping function

$$f(R_{IJ}^0) = a_1 R_{IJ}^0 + a_2 \quad (79)$$

to avoid near singularities at short interatomic distances R_{IJ} , and

$$R_{IJ}^0 = \sqrt{\frac{C_8^{IJ}}{C_6^{IJ}}} \quad (80)$$

The functional-dependent scaling factors s_n and coefficients a_1 and a_2 can be obtained from the website of the Grimme group (www.thch.uni-bonn.de/tc) together with the dispersion coefficients C_n^{IJ} .

The reader is referred to a number of excellent textbooks (Parr and Yang 1989; Dreizler and Gross 1990; Koch and Holthausen 2000; Fiolhais et al. 2003) and online resources (Burke <http://dft.uci.edu/doc/g1.pdf>; Rappoport et al.) on DFT for further details on the theory and on how to choose the right functional for a specific application.

Building the System/Collecting the Ingredients

Setting Up an AIMD Simulation

Building a Molecule

In many cases, the coordinates of a molecular structure are available for download on the Web, from crystallographic databases (Reciprocal Net www.reciprocalnet.org/edumodules/commonmolecules; Cambridge Crystallographic Data Centre www.ccdc.cam.ac.uk; RCSB Protein Data Bank www.rcsb.org/pdb; Inorganic Crystal Structure Database www.fiz-karlsruhe.de/icsd.html; Toth Information Systems www.tothcanada.com) or journal supplements. For relatively small molecules, an initial guess structure can be built using molecular graphics software packages such as Molden (www.cmbi.ru.nl/molden/molden.html) or Avogadro (Hanwell et al. 2012; www.avogadro.cc).

Plane Waves and Pseudopotentials

The most common form of AIMD simulation employs DFT (see section “First-Principles Electronic Structure Methods”) to calculate atomic forces, in conjunction with periodic boundary conditions and a plane-wave basis set. Using a plane-wave basis has two major advantages over atom-centered basis functions: (i) there is no *basis set superposition error* (Boys and Bernardi 1970; Marx and Hutter 2000) and (ii) the Pulay correction (Pulay 1969, 1987) to the Hellmann–Feynman force, due to basis set incompleteness, vanishes (Marx and Hutter 2000, 2009).

Plane Wave Basis Set

As a consequence of Bloch’s theorem, in a periodic lattice, the Kohn–Sham orbitals (see Eq. 68) can be expanded in a set of plane waves (Ashcroft and Mermin 1976; Meyer 2006),

$$\psi_{\mathbf{k},j}(\mathbf{r}) = \sum_{\mathbf{G}} c_{\mathbf{G}}^{\mathbf{k},j} e^{i(\mathbf{k}+\mathbf{G})\mathbf{r}} \quad (81)$$

where \mathbf{k} is a wave vector within the Brillouin zone, satisfying Bloch’s theorem,

$$\psi(\mathbf{r} + \mathbf{T}) = e^{i\mathbf{k}\mathbf{T}} \psi(\mathbf{r}) \quad (82)$$

for any lattice vector \mathbf{T} ,

$$\mathbf{T} = N_1\mathbf{a}_1 + N_2\mathbf{a}_2 + N_3\mathbf{a}_3 \quad (83)$$

N_1, N_2, N_3 being integer numbers, and $\mathbf{a}_1, \mathbf{a}_2, \mathbf{a}_3$ the vectors defining the periodically repeated simulation box.

In Eq. (81), the summation is over all reciprocal lattice vectors \mathbf{G} which fulfill the condition $\mathbf{G} \cdot \mathbf{T} = 2\pi M$, M being an integer number. In practice, this plane-wave expansion of the Kohn–Sham orbitals is truncated such that the individual terms all yield kinetic energies lower than a specified cutoff value, E_{cut} ,

$$\frac{\hbar^2}{2m} |\mathbf{k} + \mathbf{G}|^2 \leq E_{\text{cut}} \quad (84)$$

The plane-wave basis set thus has the advantage over other basis sets that convergence can be controlled by a single parameter, namely, E_{cut} . Which cutoff value is the best compromise between accuracy and computational cost depends on the specific system studied, on the properties of interest, and, crucially, on the choice of pseudopotentials (see below).

In this periodic setup, the electron density (see Eq. 67) can be approximated by a sum over a mesh of N_{kpt} \mathbf{k} -points in the Brillouin zone (Chadi and Cohen 1973; Monkhorst and Pack 1976; Moreno and Soler 1992),

$$\rho(\mathbf{r}) \approx \frac{1}{N_{\text{kpt}}} \sum_{\mathbf{k}} f_{\mathbf{k},j} |\psi_{\mathbf{k},j}(\mathbf{r})|^2 \quad (85)$$

Since the volume of the Brillouin zone, $V_{\text{BZ}} = (2\pi)^3/V_{\text{box}}$, decreases with increasing volume of the simulation supercell, V_{box} , only a small number of \mathbf{k} -points need to be sampled for large supercells. For insulating materials (i.e., large band gap), a single \mathbf{k} -point is often sufficient, typically taken to be $\mathbf{k} = 0$ (Γ -point approximation).

Pseudopotentials

While plane waves are a good representation of delocalized Kohn–Sham orbitals in metals, a huge number of them would be required in the expansion (81) to obtain a good approximation of atomic orbitals, in particular near the nucleus where they oscillate rapidly. Therefore, in order to reduce the size of the basis set, only the valence electrons are treated explicitly, while the core electrons (i.e., the inner shells) are taken into account implicitly through pseudopotentials combining their effect on the valence electrons with the nuclear Coulomb potential. This *frozen-core approximation* is justified as typically only the valence electrons participate in chemical interactions. To minimize the number of basis functions, the pseudopotentials are constructed in such a way as to produce nodeless atomic valence wave functions. Beyond a specified cutoff distance from the nucleus, R_{cut} the nodeless pseudo-wave functions are required to be identical to the reference all-electron wave functions.

Normconserving Pseudopotentials

are generated subject to the condition that the pseudo-wave function has the same norm as the all-electron wave function and thus gives rise to the same electron

density. Although normconserving pseudopotentials have to fulfill a (small) number of mathematical conditions, there remains considerable freedom in how to create them. Hence, several different recipes exist (Hamann et al. 1979; Bachelet et al. 1982; Kerker 1980; Vanderbilt 1985; Troullier and Martins 1990, 1991; Goedecker et al. 1996; Hartwigsen et al. 1998).

Since pseudopotentials are generated using *atomic* orbitals as a reference, it is not guaranteed that they are *transferable* to any chemical environment. Generally, transferability is the better the smaller the cutoff radius R_{cut} is chosen. However, the reduction in the number of plane waves required to represent a particular pseudo-wave function – i.e., the *softness* of the corresponding pseudopotential – increases as R_{cut} gets larger. So R_{cut} has to be chosen carefully and there is always a trade-off between transferability and softness. An upper limit for R_{cut} is given by the shortest interatomic distances in the molecule or crystal the pseudopotential will be used for: one needs to make sure that the sum of the two cutoff radii of any two neighboring atoms is smaller than their actual spatial separation.

For each angular momentum l a separate pseudopotential $V_l^{\text{PS}}(r)$ is constructed. The total pseudopotential operator is written as

$$\hat{V}^{\text{PS}} = V_{\text{loc}}^{\text{PS}}(r) + \sum_l V_{\text{nl},l}^{\text{PS}}(r) \hat{P}_l \quad (86)$$

where the nonlocal part is defined as

$$V_{\text{nl},l}^{\text{PS}}(r) = V_l^{\text{PS}}(r) - V_{\text{loc}}^{\text{PS}}(r) \quad (87)$$

and the local part $V_{\text{loc}}^{\text{PS}}(r)$ is taken to be the pseudopotential $V_l^{\text{PS}}(r)$ for one specific value of l , typically the highest one for which a pseudopotential was created. The pseudopotential (86) is called semi-local, since the projector \hat{P}_l only acts on the l -th angular momentum component of the wave function, but not on the radius r . (**Note:** a pseudopotential is called nonlocal if it is l -dependent.)

To achieve higher numerical efficiency, it is common practice to transform the semi-local pseudopotential (86) to a fully nonlocal form,

$$\hat{V}^{\text{PS}} = V_{\text{loc}}^{\text{PS}}(r) + \sum_{ij} |\beta_i \rangle B_{ij} \langle \beta_j| \quad (88)$$

using the Kleinman-Bylander prescription (Kleinman and Bylander 1982).

Vanderbilt Ultrasoft Pseudopotentials

An ultrasoft type of pseudopotential was introduced by Vanderbilt (1990; Laasonen et al. 1993) to deal with nodeless valence states which are strongly localized in the core region. In this scheme the normconserving condition is lifted and only a small portion of the electron density inside the cutoff radius is recovered by the pseudo-wave function, the remainder is added in the form of so-called augmentation

charges. Complications arising from this scheme are the nonorthogonality of Kohn–Sham orbitals, the density dependence of the nonlocal pseudopotential, and the need to evaluate additional terms in atomic force calculations.

How to Obtain Pseudopotentials?

There are extensive pseudopotential libraries available for download with the simulation packages CPMD (Hutter et al.), CP2K (Hutter et al.), QuantumEspresso (www.quantum-espresso.org), Abinit (www.abinit.org), or online (www.physics.rutgers.edu/~dhv/uspp/; <http://cp2k.web.psi.ch/potentials>; www.quantum-espresso.org; www.abinit.org). However, before applying any pseudopotentials, they should always be tested against all-electron calculations. Pseudopotentials used in conjunction with a particular density functional should have been generated using the same functional.

In many cases, the required pseudopotential will not be available in any accessible library; in this case it may be generated using freely downloadable programs (Vanderbilt www.physics.rutgers.edu/~dhv/uspp/; Atomic Pseudopotentials Engine <http://tddft.org/programs/APE>; Hamann www.mat-simresearch.com/oncepsp-2.1.1.tar.gz; Opium – pseudopotential generation project <http://opium.sourceforge.net>; Martins www.abinit.org/downloads/psp-links/psp-links/MARTINS2ABINIT.tgz; Fuchs and Scheffler http://cpc.cs.qub.ac.uk/summaries/ADKA_v1_0.html; Dacapo pseudopotential library http://wiki.fysik.dtu.dk/dacapo/Pseudopotential_Library).

How to Set the Plane-Wave Cutoff?

The number of plane-wave basis functions, i.e., the value of the cutoff energy E_{cut} , required for a sufficiently accurate DFT calculation sensitively depends on the choice of pseudopotential. For a calculation on H₂O with normconserving pseudopotentials of the Troullier–Martins type (Troullier and Martins 1990, 1991), for example, a cutoff energy of 70 Ry (= 35 a.u.) is typically used (see, e.g., Sprik et al. 1996), while 25 Ry is usually sufficient with ultrasoft pseudopotentials. Goedecker–Teter–Hutter normconserving pseudopotentials (Goedecker et al. 1996; Hartwigsen et al. 1998; Krack 2005) normally require a slightly higher cutoff than Troullier–Martins pseudopotentials (CPMD Manual www.cpmc.org:81/manual/node73.html).

Strictly speaking, the best cutoff energy should be determined for every new system and set of pseudopotentials by carrying out a series of single point calculations with different E_{cut} and analyzing the convergence of the total energy and the properties of interest.

Setting Up a Classical MD Simulation

There are two general stages that make up the preparation to conduct force-field molecular dynamics simulations: (1) gathering preliminary information and (2) building the actual system.

Gathering Preliminary Information

Gathering the preliminary information before conducting the simulation is mostly focused on making sure that the simulation is possible. First, it is important to identify the type and number of molecules that you wish to model. Then, it is necessary to find the force field that will allow you to most accurately model the molecules and physical system that you want to simulate. A brief synopsis of some of the larger classical force-field parameter sets is given in section "Classical Force Fields." These force fields and references may be good starting points in searching for the correct classical force field to use for a given system, but the best way to find a specific force field is to just conduct a search for research articles that may have been conducted on the same system. If no force-field parameters exist for the system of interest, then you can use configurations and energies from quantum simulations to parameterize a given force field for your system. A methodology for how a force field was parameterized originally is presented in the relevant paper; however, this is a complicated exercise and is probably best left to the experts.

Building the System

After identifying that a force field exists for the system you wish to model, the next step is to build the initial configuration of the molecules within the system. The initial configuration will consist of initial spatial coordinates of each atom in each given molecule. When building a large system consisting of several molecules of various types, it is easiest to write a computer code that contains or reads in the molecular structure and coordinates of each molecule present in the system and then have the code replicate each molecule however many times is necessary in order to build the entire system. Alternatively, most of the molecular dynamics simulation packages previously mentioned have capabilities to build systems from a pdb file; however, these tools are often useful for only certain systems and force fields. There is unfortunately no one tool which can be used to build any system with any force field.

These initial configurations can represent a minimum energy structure either from another simulation (i.e., a final structure from an energy minimization in a quantum or classical Monte Carlo simulation can be used as the starting state for classical simulations), from experimental observation (i.e., the pdb database for crystallographic structures of proteins) or building the initial coordinates based upon the equilibrium bond distances and bond angles from the force field.

The placement of the molecules within the simulation box can be done in a number of different ways as well. The molecules can be placed on the vertices of a regular lattice or in any other regularly defined geometry that may be useful for conducting your simulation (i.e., in simulating the structural properties of micelles oftentimes the surfactant molecules will initially be placed on the vertices of a bucky ball such that they are in a spherical configuration). Also, molecules can be placed at random positions within the simulation box. The one advantage of placing molecules at regularly spaced positions is that it is easier to insure that there is no overlapping of molecules, whereas with the randomly placed molecules it can be quite difficult to ensure that a placed molecule does not overlap with another

molecule in the box (particularly for large or highly branched molecules). For more complex geometries, there are several software packages and online resources which are very useful in generating initial configurations (most of these output xyz and/or pdb files and which are generally useable within the majority of molecular dynamics codes). These tools include Enhanced Monte Carlo (<http://montecarlo.sourceforge.net/emc/Welcome.html>), VMD TopoTools (<http://sites.google.com/site/akohlmeyer/software/topotools>), Avogadro (www.avogadro.cc), Packmol ([ch7-2:packmol-wwww](http://ch7-2.packmol-wwww.org)), and AtomsK (http://pierrehiel.info/codes_atomsk.php?lang=eng), which are all freely available. Then if you are interested in carrying out simulations with the CHARMM or MARTINI force fields, you can use the online resource – CHARMM-GUI (<http://www.charmm-gui.org/>) – to create a variety of systems by choosing the molecules and arrangement of molecules (i.e., bilayer, micelle, ...) and it will output a pdb file and result force field files for you.

In addition to containing the initial spatial coordinates of all of the molecules in the system, the initial configuration must also contain some additional information about the atoms and molecules in the systems. Each atom in the configuration must contain a label of what atomic species (i.e., carbon, nitrogen, etc.) it represents. This label will be different for each simulation code used, but all of them will have some type of label as it will inform the simulation code what force-field values to use to represent the interactions of that atom. A list of all of the covalent bonds, the bond angles, and the dihedrals in the system will also need to be included in the initial configuration. The lists of the bonds, angles, and dihedrals contain an identifier for each atom that make up the bond, angle, or dihedral and then an identifier for the type that informs the simulation package which parameters to use in calculating the energy of the bond, angle, or dihedral. The final component of the initial configuration of a classical simulation is a list of all of the various types of atoms, bonds, angles, and dihedrals in the system along with their corresponding force-field parameters (i.e., ϵ and σ for atom types to describe their nonbonded interactions, force constants, and equilibrium values for bond, angle, and dihedral types).

Finally, after building the initial configuration, the simulation is about ready to be performed. The last step is to choose the simulation variables and set up the input to the simulation package in order to convey these selections.

These options and the decision process behind choosing from the various options will be presented in the following sections.

Preparing an Input File

Optimization Algorithms

Optimization algorithms are often used to find stationary points on a potential energy surface, i.e., local and global minima and saddle points. It is often useful to carry out a geometry optimization before starting an MD simulation, in particular when the initial coordinates are likely to be far away from their realistic values. The only place where they directly enter MD is in the case of Born–Oppenheimer AIMD,

in order to converge the SCF wave function for each MD step. It is immediately obvious that the choice of optimization algorithm crucially affects the speed of the simulation.

Steepest Descent

The steepest descent method is the simplest optimization algorithm. The initial energy $E[\Psi_0] = E(\mathbf{c}_0)$, which depends on the plane-wave expansion coefficients \mathbf{c} (see Eq. 81), is lowered by altering \mathbf{c} in the direction of the negative gradient,

$$\mathbf{d}_n = -\frac{\partial E(\mathbf{c}_n)}{\partial \mathbf{c}} \equiv -\mathbf{g}_n \quad (89)$$

$$\mathbf{c}_{n+1} = \mathbf{c}_n + \Delta_n \mathbf{d}_n \quad (90)$$

where $\Delta_n > 0$ is a variable step size chosen such that the energy always decreases and n is the optimization step index. The steepest descent method is very robust; it is guaranteed to approach the minimum. However, the rate of convergence ever decreases as the energy gets closer to the minimum, making this algorithm rather slow.

Conjugate Gradient Methods

The Conjugate Gradient method generally converges faster than the steepest descent method due to the fact that it avoids moving in a previous search direction. This is achieved by linearly combining the gradient vector and the last search vector,

$$\mathbf{c}_{n+1} = \mathbf{c}_n + \Delta_n \mathbf{d}_n \quad (91)$$

where

$$\mathbf{d}_n = -\mathbf{g}_n + \beta_n \mathbf{d}_{n-1} \quad (92)$$

Different recipes exist to determine the coefficient β_n (Jensen 2007) among which the Polak–Ribière formula usually performs best for non-quadratic functions,

$$\beta_n = \frac{\mathbf{g}_n(\mathbf{g}_n - \mathbf{g}_{n-1})}{\mathbf{g}_{n-1}\mathbf{g}_{n-1}} \quad (93)$$

In the case of a general non-quadratic function, such as the DFT energy, conjugacy is not strictly fulfilled and the optimizer may search in completely inefficient directions after a few steps. It is then recommended to restart the optimizer (setting $\beta = 0$). Convergence can be improved by multiplying \mathbf{g}_n with a preconditioner matrix, e.g., an approximate inverse of the second derivatives matrix (Hessian in the case of geometry optimization) $\tilde{\mathbf{H}}$. The method is then called the preconditioned conjugate gradient (PCG). In the CPMD code, the matrix $\tilde{\mathbf{H}}$ is approximated by

$$\tilde{\mathbf{H}} = \begin{cases} H_{GG'}^{\text{KS}} & \text{for } G \geq G_{\text{cut}} \\ H_{G_{\text{cut}}G_{\text{cut}}}^{\text{KS}} & \text{for } G < G_{\text{cut}} \end{cases} \quad (94)$$

where $H_{GG'}^{\text{KS}}$ is the Kohn–Sham matrix in the plane-wave basis and G_{cut} is a cutoff value for the reciprocal lattice vector \mathbf{G} (set to a default value of 0.5 a.u.).

Direct Inversion of the Iterative Subspace

Having generated a sequence of optimization steps \mathbf{c}_i , the direct inversion of the iterative subspace (DIIS) method (Pulay 1980, 1982; Császár and Pulay 1984; Hutter et al. 1994) is designed to accelerate convergence by finding the best linear combination of stored \mathbf{c}_i vectors,

$$\mathbf{c}_{n+1} = \sum_{i=1}^n a_i \mathbf{c}_i \quad (95)$$

Ideally, of course, \mathbf{c}_{n+1} is equal to the optimum vector \mathbf{c}_{opt} . Defining the error vector \mathbf{e}_i for each iteration as

$$\mathbf{e}_i = \mathbf{c}_i - \mathbf{c}_{\text{opt}} \quad (96)$$

Equation (95) becomes

$$\sum_{i=1}^n a_i \mathbf{c}_{\text{opt}} + \sum_{i=1}^n a_i \mathbf{e}_i = \mathbf{c}_{\text{opt}} \quad (97)$$

Equation (97) is satisfied if

$$\sum_{i=1}^n a_i = 1 \quad (98)$$

and

$$\sum_{i=1}^n a_i \mathbf{e}_i = 0 \quad (99)$$

Instead of the ideal case Eq. (99), in practice one minimizes the quantity

$$\left\langle \sum_{i=1}^n a_i \mathbf{e}_i \mid \sum_{j=1}^n a_j \mathbf{e}_j \right\rangle \quad (100)$$

subject to the constraint (98), which is equivalent to solving the system of linear equations

$$\begin{pmatrix} b_{11} & b_{12} & \cdots & b_{1n} & -1 \\ b_{21} & b_{22} & \cdots & b_{2n} & -1 \\ \vdots & \vdots & \vdots & \vdots & \vdots \\ b_{n1} & b_{n2} & \cdots & b_{nn} & -1 \\ -1 & -1 & \cdots & -1 & 0 \end{pmatrix} \begin{pmatrix} a_1 \\ a_2 \\ \vdots \\ a_n \\ \lambda \end{pmatrix} = \begin{pmatrix} 0 \\ 0 \\ \vdots \\ 0 \\ -1 \end{pmatrix} \quad (101)$$

where

$$b_{ij} = \langle \mathbf{e}_i | \mathbf{e}_j \rangle \quad (102)$$

and the error vectors are approximated by

$$\mathbf{e}_i = -\tilde{\mathbf{H}}^{-1}(\mathbf{c}_{\text{opt}})\mathbf{g}_i \quad (103)$$

using an approximate Hessian matrix $\tilde{\mathbf{H}}$, e.g., Eq. (94).

Controlling Temperature: Thermostats

If understanding the behavior of the system as a function of temperature is the aim of your study, then it is important to be able to control the temperature of your system. The temperature of the system is related to the time average of the kinetic energy, which can be calculated by

$$\langle \frac{1}{2} \sum_I M_I V_I^2 \rangle_{NVT} = \frac{3N-6}{2} k_B T \quad (104)$$

if the system is in thermal equilibrium. The right-hand side of Eq. (104) can be approximated by $\frac{3N}{2} k_B T$ for a large number of particles.

Below we introduce specific thermostating techniques for MD simulations at thermodynamic equilibrium, e.g., for calculating equilibrium spatial distribution and time-correlation functions. However, when MD simulations are performed on a system undergoing some *nonequilibrium* process involving exchange of energy between different parts of the system, e.g., when an energetic particle, such as an atom or a molecule, hits a crystal surface, or there is a temperature gradient across the system, one has to resort to specially developed techniques, see, for example, Kantorovich (2008), Kantorovich and Rompotis (2008), and Toton et al. (2010). In these methods, based on the so-called generalized Langevin equation, the actual system on which MD simulations are performed is considered in contact with one (or more) heat bath(s) kept at constant temperature(s), and the dynamics of the system of interest reflects the fact that there is an interaction and energy transfer between the system and the surrounding heat bath(s).

Rescale Thermostat

One obvious way to control the temperature of a system is to rescale the velocities of the atoms within the system (Woodcock 1971). The rescaling factor λ is determined from $\lambda \sqrt{T_{\text{target}}/T_0}$, where T_{target} and T_0 are the target and initial temperatures, respectively. Then, the velocity of each atom is rescaled such that $V_f = \lambda V_i$. In practice, the inputs generally required to use a rescale thermostat include:

- T_0 – Initial temperature,
- T_{target} – Target temperature,
- τ - Damping constant, (i.e., frequency with which to apply the thermostat),
- δT – Maximum allowable temperature difference from T_{target} before thermostat is applied,
- f_{rescale} – Fraction of temperature difference between current temperature and T_{target} is corrected during each application of thermostat.

If it is desired to have a strict thermostat (i.e., when first starting a simulation that might have particles very near one another), then δT and τ should have values of $\sim 0.01 T_{\text{target}}$ and 1 time step, respectively, and f_{rescale} should be near 1.0. However, if you wish to allow a more lenient thermostat, then the value of δT should be of the same order of magnitude as T_{target} , τ should be $\sim 10^2 - 10^3$ time steps, and $f_{\text{rescale}} \sim 0.01 - 0.1$.

Berendsen Thermostat

Another way to control the temperature is to couple the system to an external heat bath, which is fixed at a desired temperature. This is referred to as a Berendsen thermostat (Berendsen et al. 1984). In this thermostat, the heat bath acts as a reservoir of thermal energy that supplies or removes temperature as necessary. The velocities are rescaled each time step, where the rate of change in temperature is proportional to the difference in the temperature in the system $T(t)$ and the temperature of the external bath T_{bath} :

$$\frac{dT(t)}{dt} = \frac{1}{\tau}(T_{\text{bath}} - T(t)) \quad (105)$$

which when integrated results in the change in temperature each time step:

$$\Delta T = \frac{\delta t}{\tau}(T_{\text{bath}} - T(t)). \quad (106)$$

In Eqs. 105 and 106, τ is the damping constant for the thermostat. In practice, the necessary inputs when using the Berendsen thermostat include:

- T_{bath} – temperature of the external heat bath,
- τ – damping constant for the thermostat.

Obviously the amount of control that the thermostat imposes on the simulation is controlled by the value of τ . If τ is large, then the coupling will be weak and the

temperature will fluctuate significantly during the course of the simulation, while if τ is small, then the coupling will be strong and the thermal fluctuations will be small. If $\tau = \delta t$, then the result will be the same as the rescale thermostat, in general.

Nosé–Hoover Thermostat

While the Berendsen thermostat is efficient for achieving a target temperature within your system, the use of a Nosé–Hoover thermostat properly reproduces a canonical ensemble once the system has reached a thermal equilibrium. The extended system method, which was originally introduced by Nose (1984a, b) and then further developed by Hoover (1985), introduces additional degrees of freedom into the Hamiltonian that describes the system, from which equations of motion can be determined.

The extended system method considers the external heat bath as an integral part of the system by including an additional degree of freedom in the Hamiltonian of the system that is represented by the variable s . As a result, the potential energy of the reservoir is

$$E_{\text{pot}} = (f + 1)k_B T \ln s, \quad (107)$$

where f is the number of degrees of freedom in the physical system and T is the target temperature. The kinetic energy of the reservoir is calculated by

$$E_{\text{kin}} = \frac{Q}{2} \left(\frac{ds}{dt} \right)^2, \quad (108)$$

where Q is a parameter with dimensions of energy \times (time)² and is generally referred to as the "virtual" mass of the extra degree of freedom s . The magnitude of Q determines the coupling between the heat bath and the real system, thus influencing the temperature fluctuations.

Utilizing Eqs. 107 and 108, and substituting the real variables for the corresponding

Nosé variables, the equations of motion are found to be as follows:

$$\ddot{\mathbf{R}}_I = \frac{\mathbf{F}_I}{M_I} - \gamma \dot{\mathbf{R}}_I, \quad (109)$$

$$\dot{\gamma} = \frac{f k_B}{Q} \left(T - T_{\text{target}} \right), \quad (110)$$

where $\gamma = \frac{\dot{s}}{s}$. quantity

$$\tau_{\text{NH}} = \sqrt{\frac{Q}{f k_B T_{\text{target}}}} \quad (111)$$

is an effective relaxation time or damping constant.

In practice, the inputs that are necessary when utilizing the Nosé–Hoover thermostat during a molecular dynamics simulation include:

- T_{target} – Target temperature,
- Q – Fictitious mass of the additional degree of freedom s .

The most significant variable in the above list is Q . Large values of Q may cause poor temperature control, with the infinite limit resulting in no energy exchange between the temperature bath and the real system, which is the case of conventional molecular dynamics simulations resulting in the microcanonical ensemble. However, if Q is too small, then the energy oscillates and the system will take longer in order to reach a thermal equilibrium. An in-depth discussion of the Nosé–Hoover thermostat can be found in Hunenberger (2005) and Tuckerman (2010), for example.

Nosé–Hoover Chains

The Nosé–Hoover thermostat discussed above has been demonstrated to run into ergodicity problems and does not generate the canonical ensemble in some pathological cases. To make the particle motion more “chaotic,” in the Nosé–Hoover chain thermostat, the simple Nosé–Hoover thermostat is itself coupled to another thermostat, which again can be coupled to a thermostat, and so forth. The equations of motion for a chain of m thermostats are given by (Martyna et al. 2002; Tuckerman 2010)

$$\ddot{\mathbf{R}}_I = \frac{\mathbf{F}_I}{M_I} - \gamma_1 \dot{\mathbf{R}}_I \quad (112)$$

$$\dot{\gamma}_1 = \frac{fk_B}{Q_1} [T - T_{\text{target}}] - \gamma_1 \gamma_2 \quad (113)$$

⋮

$$\dot{\gamma}_j = \frac{1}{Q_j} [Q_{j-1} \gamma_{j-1}^2 - kT] - \gamma_j \gamma_{j+1} \quad (114)$$

⋮

$$\dot{\gamma}_m = \frac{1}{Q_m} [Q_{m-1} \gamma_{m-1}^2 - kT] \quad (115)$$

The conserved quasi-Hamiltonian is

$$\tilde{H} = H + \sum_{j=1}^m \frac{Q_j}{2} \gamma_j^2 + 3NkT \int \gamma_1 dt + \sum_{j=2}^m kT \int \gamma_j dt \quad (116)$$

Compared to the input parameters required for the simple Nosé–Hoover thermostat, the user now needs to also specify the length m of the chain (e.g., $m = 4$ is the default value in the CPMD program).

Langevin Thermostat

The Langevin thermostat is a stochastic thermostat, in which the equations of motion of the particles in the system take the form:

$$M_I \ddot{\mathbf{R}}_I = \mathbf{F}_I + \mathbf{F}_{\text{friction}}(\dot{\mathbf{R}}_I). \quad (117)$$

Therefore, the force that a particle experiences is due to the gradient in the potential energy surface and a frictional force due to collisions of the particle with the particles in the thermal bath. This frictional force is defined as

$$\mathbf{F}_{\text{friction}}(\dot{\mathbf{R}}_I) = -\gamma_I M_I \dot{\mathbf{R}}_I + \boldsymbol{\eta}_I(t) \quad (118)$$

where γ_I is a proportionality constant, which is often referred to as the "friction coefficient." The term $\boldsymbol{\eta}_I(t)$ is a random force due to the stochastic collisions with the particles in the thermal bath, and it has a Gaussian probability distribution with no correlation to any past or present \mathbf{R} or $\dot{\mathbf{R}}$ and an autocorrelation function

$$\langle \eta_I(t) \eta_J(t') \rangle = 2\gamma_I k_B T_{\text{target}} \delta_{I,J} \delta(t - t'), \quad (119)$$

where k_B is Boltzmann's constant and T_{target} is the temperature of the thermal bath.

In practice, Eq. (117) is solved using a difference equation over a small time step δt , such that:

$$\Delta \mathbf{V}_I = \mathbf{A}_I(t) \delta t - \gamma_I \mathbf{V}_I(t) \delta t + \zeta \sqrt{2k_B T_{\text{target}} \gamma_I \delta t / M_I} \quad (120)$$

where ζ is a random number with unit variance.

When using a Langevin thermostat during a molecular dynamics simulation, the necessary inputs generally are:

- T_{target} – Target (or bath) temperature,
- γ – The friction coefficient.

The most significant variable in the above list is γ . Choosing too large a value of γ will result in the system becoming overdamped due to the friction term, and choosing too small a value of γ may result in too weak of a coupling between the thermal bath and the system and therefore poor temperature control.

Controlling Pressure: Barostats

It may be desired to study the behavior of the simulated system while the pressure is held constant (i.e., pressure-induced phase transitions). Many experimental measurements are made in conditions where the pressure and temperature are held constant and so it is of utmost importance to be able to accurately replicate these conditions in simulations.

One thing of note is that the pressure often fluctuates more than other quantities such as the temperature in an NVT molecular dynamics simulation or the energy in an NVE molecular dynamics simulation. This is due to the fact that the pressure is related to the virial term, which is the product of the positions of the particles in the system and the derivative of the potential energy function. These fluctuations will be observed in the instantaneous values of the system pressure during the course of the simulation, but the average pressure should approach the desired pressure. Since generally the temperature and number of atoms will also be held constant during constant pressure simulations, and the volume of the system will be allowed to change in order to arrive at the desired pressure. Therefore, less compressible systems will show larger fluctuations in the pressure than the systems that are more easily compressed.

Berendsen Barostat

Many of the approaches used for the controlling the pressure are similar to those that are used for controlling the temperature. One approach is to maintain constant pressure by coupling the system to a constant pressure reservoir as is done in the Berendsen barostat (Berendsen et al. 1984), which is analogous to the way temperature is controlled in the Berendsen thermostat. The pressure change in the system is determined by:

$$\frac{dP(t)}{dt} = \frac{1}{\tau_P}(P_0 - P(t)), \quad (121)$$

where τ_P is time constant of the barostat, P_0 is the desired pressure and $P(t)$ is the system pressure at any time t . In order to accommodate this change in pressure, the volume of the box is scaled by a factor of μ^3 each time step; therefore, the coordinates of each particle in the system are scaled by a factor of μ (i.e., $\mathbf{R}_I(t + \delta t) = \mu^{1/3}\mathbf{R}_I(t)$, where

$$\mu = \left[1 - \frac{\delta t}{\tau_P}(P - P_0) \right]^{\frac{1}{3}}. \quad (122)$$

In practice, the inputs for the Berendsen barostat will include:

- P_0 – Desired pressure,
- τ_P – Time constant of the barostat,

One other input that may be included in the use of the Berendsen barostat is to define which dimensions are coupled during the pressure relaxation. For example, you could define that the pressure is relaxed in a way that the changes in all three dimensions are coupled and therefore all of the dimensions change at the same rate. On the other hand, the pressure relaxation can be handled in an anisotropic manner, such that none of the dimensions are coupled and each dimension will have its own scaling factor that results from the individual pressure components.

Nosé–Hoover Barostat

Similar to the Nosé–Hoover thermostat, the extended system method has been applied to create a barostat (Hoover 1986) that is coupled with a Nosé–Hoover thermostat. In this case, the extra degree of freedom η corresponds to a “piston,” and it is added to the Hamiltonian of the system, which results in the following equations of motion:

$$\frac{d\mathbf{R}(t)}{dt} = \mathbf{V}(t) + \eta(t)(\mathbf{R}(t) - \mathbf{R}_{\text{COM}}), \quad (123)$$

$$\frac{d\mathbf{V}(t)}{dt} = \frac{\mathbf{F}(t)}{M} - [\chi(t) + \eta(t)]\mathbf{V}(t), \quad (124)$$

$$\frac{d\chi(t)}{dt} = \frac{1}{\tau_T^2} \left(\frac{T}{T_0} - 1 \right), \quad (125)$$

$$\frac{d\eta(t)}{dt} = \frac{1}{Nk_B T_0 \tau_P^2} V(t)(P - P_0), \quad (126)$$

$$\frac{dV(t)}{dt} = 3\eta(t)V(t) \quad (127)$$

where \mathbf{R}_{COM} are the coordinates of the center of mass of the system, η is the thermostat extra degree of freedom and can be thought of as a friction coefficient, τ_T is the thermostat time constant, χ is barostat extra degree of freedom and is considered a volume scaling factor, and τ_P is the barostat time constant. Equations 126 and 127 explicitly contain the volume of the simulation box, $V(t)$. Generally, this barostat is implemented using the approach described in Melchionna et al. (1993).

In addition to the variables that are a part of the equations of motion, there is a variable Q that represents the “mass” of the “piston.” This is analogous to the “mass” variable in the Nosé–Hoover thermostat. In practice, the required input for the Nosé–Hoover barostat will include:

- P_0 – Desired pressure,
- T_0 – Desired temperature,
- τ_P – Time constant of the barostat,
- τ_T – Time constant of the thermostat,
- Q – The “mass” of the piston.

Like in the case of the Nosé–Hoover thermostat, care must be taken when selecting the value of the variable Q . A small value of Q is representative of a piston with small mass and thus will have rapid oscillations of the box size and pressure, whereas a large value of Q will have the opposite effect. The infinite limit of Q results in normal molecular dynamics behavior.

Setting the Timestep

Born–Oppenheimer MD/Classical MD

Since BOMD is a classical MD in the sense that the nuclei are classical particles, the same rules concerning the choice of timestep apply to both BOMD and atomistic or coarse-grained force-field MD. The largest possible timestep, δt , is partially determined by the fastest oscillation in the system – in many molecules this would be a bond-stretching vibration involving hydrogen, e.g., CH, NH, or OH. It is immediately plausible that δt must be smaller than the shortest vibrational period in order to resolve that motion and for the numerical integrator (see section “Classical Molecular Dynamics”) to be stable. Let us assume a particular molecule has an OH vibration at $\omega' = 3500 \text{ cm}^{-1}$. Then corresponding to a period T can be calculated to be about 10 fs:

$$\omega' = \frac{\hbar\omega}{hc} = \frac{h\nu}{hc} = \frac{\nu}{c} = \frac{1}{cT} \quad (128)$$

where we have used $\nu = 1/T$ and c is the speed of light (remember to use c in cm/s if ω' is in cm^{-1}). Solving (128) for T , we get

$$T = \frac{1}{c\omega'} \quad (129)$$

According to the Nyquist–Shannon sampling theorem, the lowest allowed sampling frequency is twice the maximum oscillation frequency of the simulated system, which would mean for the present example that the maximum timestep is 5 fs.

Another important consideration is the stability limit of the numerical integrator used in the MD simulation (Sutmann 2006). For a one-dimensional harmonic oscillator, the propagation of nuclear position and momentum can be written in matrix form as

$$\begin{pmatrix} \omega R_{n+1} \\ V_{n+1} \end{pmatrix} = \mathbf{M} \begin{pmatrix} \omega R_n \\ V_n \end{pmatrix} \quad (130)$$

In order for the propagation to be stable, the eigenvalues λ of matrix \mathbf{M} , which are obtained from the secular equation,

$$\det(\mathbf{M} - \lambda\mathbf{1}) = 0 \quad (131)$$

must satisfy the condition $|\lambda| < 1$. This then defines the maximum timestep.

The velocity Verlet algorithm is usually implemented in the form

$$V_{n+\frac{1}{2}} = V_n + \frac{\delta t}{2M} F_n \quad (132)$$

$$R_{n+1} = R_n + \delta t V_{n+\frac{1}{2}} \quad (133)$$

$$V_{n+1} = V_{n+\frac{1}{2}} + \frac{\delta t}{2M} F_{n+1} \quad (134)$$

Using the force expression for harmonic oscillator,

$$F = -\omega^2 MR \quad (135)$$

we obtain

$$V_{n+\frac{1}{2}} = V_n - \frac{\omega^2 \delta t}{2} R_n \quad (136)$$

$$R_{n+1} = R_n + \delta t V_{n+\frac{1}{2}} \quad (137)$$

$$V_{n+1} = V_{n+\frac{1}{2}} - \frac{\omega^2 \delta t}{2} R_{n+1} \quad (138)$$

The total propagation matrix \mathbf{M} (see Eq. 130) can be written as the product of the three propagation matrices corresponding to steps (136–138),

$$\mathbf{M} = \begin{pmatrix} 1 & 0 \\ -\frac{\alpha}{2} & 1 \end{pmatrix} \begin{pmatrix} 1 & \alpha \\ 0 & 1 \end{pmatrix} \begin{pmatrix} 1 & 0 \\ -\frac{\alpha}{2} & 1 \end{pmatrix} = \begin{pmatrix} 1 - \frac{\alpha^2}{2} & \alpha \\ -\alpha(1 - \frac{\alpha^2}{4}) & 1 - \frac{\alpha^2}{2} \end{pmatrix} \quad (139)$$

where $\alpha = \omega \delta t$. The eigenvalues of \mathbf{M} are then given by

$$\lambda = 1 - \frac{\alpha^2}{2} \pm \alpha \sqrt{1 - \frac{\alpha^2}{4}} \quad (140)$$

The stability condition is satisfied if (Sutmann 2006)

$$\omega^2 \delta t^2 < 2 \quad (141)$$

Solving (141) for δt , we obtain

$$\delta t < \frac{\sqrt{2}}{\omega} = \frac{T}{\pi \sqrt{2}} \approx \frac{T}{4.44} \quad (142)$$

In our example of the OH vibration at 3500 cm^{-1} , this would dictate a maximum timestep of 2 fs. However, although such a choice guarantees numerical stability, it

results in deviations from the exact answer (Sutmann 2006). Therefore, in practice smaller timesteps – typically around 1 fs – are often used.

Car–Parrinello MD

Although in CPMD the nuclei are still treated as classical particles, the choice of timestep can no longer be based solely on the highest nuclear frequency ω_n^{\max} . We also need to consider the fictitious dynamics of the electronic degrees of freedom. In fact, the optimum simulation timestep is closely linked to the value of the fictitious electron mass μ as we will see in the following.

The fictitious mass μ has to be chosen small enough to guarantee adiabatic separation of electronic and nuclear motion. This means that the frequency spectrum of the electronic degrees of freedom (Marx and Hutter 2009; Pastore et al. 1991)

$$\omega_{ph} = \sqrt{\frac{2(\epsilon_p - \epsilon_h)}{\mu}} \quad (143)$$

must not overlap with the vibrational spectrum of the nuclear system. The above formula (143) can be derived assuming that the fictitious orbital masses behave like classical harmonic oscillators whose energy, ΔE , is equal to the energy difference between an unoccupied and an occupied orbital,

$$\Delta E = \epsilon_p - \epsilon_h = \frac{1}{2} \mu \omega^2 \quad (144)$$

It is important to realize that μ has the dimension kg m^2 , as this is required to give the fictitious kinetic energy term in the Car–Parrinello Lagrangian (16), $\sum_i \mu_i |\dot{\psi}_i|^2$, the dimension $\text{kg m}^2/\text{s}^2$ (i.e., energy). Hence, ΔE in (144) also has the correct dimension of $\text{kg m}^2/\text{s}^2$ (i.e., energy). Equation (143) can now be easily obtained by solving (144) for ω .

The lowest electronic frequency according to Eq. (143) is

$$\omega^{\min} = \sqrt{\frac{2(\epsilon_{\text{LUMO}} - \epsilon_{\text{HOMO}})}{\mu}} \quad (145)$$

The highest electronic frequency is determined by the plane-wave cutoff energy E_{cut} ,

$$\omega^{\max} \approx \sqrt{\frac{2E_{\text{cut}}}{\mu}} \quad (146)$$

Thus, the maximum oscillation period, which is inversely proportional to ω^{\max} , obeys the relation

$$T^{\max} = \frac{2\pi}{\omega^{\max}} \approx \pi \sqrt{\frac{2\mu}{E_{\text{cut}}}} \quad (147)$$

According to Eq. (147) the maximum oscillation period can be increased by simply increasing μ . However, this would also result in a lowering of ω_e^{\min} (see Eq. 145) and therefore in a smaller separation $\omega_e^{\min} - \omega_n^{\max}$ between the nuclear and electronic spectra.

Let us discuss the above using some realistic numbers. In the case of the H₂O molecule, for example, the HOMO–LUMO gap with the BLYP functional is about 5.7 eV. Assuming a typical value of 400 a.u. for μ , the minimum electronic frequency (Eq. 145) is ca. 6900 cm⁻¹. The highest energy molecular vibrational mode in a CPMD simulation using these parameter values is the asymmetric stretch at about 3500 cm⁻¹. This means that electronic and nuclear spectra are well separated. A basis set cutoff of $E_{\text{cut}} = 70$ Ry (= 35 a.u.), which is typical for simulations with normconserving pseudopotentials (see section "Pseudopotentials"), leads to a maximum electronic frequency (Eq. 146) of approximately 92,000 cm⁻¹ corresponding to a vibrational period of 15 a.u. According to (142), the maximum CPMD timestep is 3.4 a.u. In fact, for water, a timestep/fictitious mass combination of 4 a.u./400 a.u. has been shown to be a good compromise between efficiency and accuracy (Kuo et al. 2004). When ultrasoft pseudopotentials are employed, a smaller cutoff energy of 25 Ry is usually sufficient (see section "Pseudopotentials"). This increases the maximum electronic oscillation period to 25 a.u. (Eq. (147)) and the maximum simulation timestep to 5.6 a.u. (142).

If we were to increase μ to 1000 a.u., we could afford a larger timestep of about 6 a.u. (according to Eq. (147)). However, ω_e^{\min} (Eq. (145)) would become ca. 4500 cm⁻¹, dangerously close to ω_n^{\max} . A simple trick that is often used to be able to afford larger timesteps is to replace all hydrogen atoms by deuterium atoms thus downshifting ω_n^{\max} to about 2500 cm⁻¹. If the aim of the simulation is to learn about a particular reaction mechanism, changing the isotope mass does not affect the outcome. Dynamical properties, such as diffusion or vibrations, on the other hand, are mass dependent.

For systems with a small or even vanishing (e.g., metals) band gap, it is increasingly difficult or impossible to achieve adiabatic separation of electronic and nuclear degrees of freedom following the above considerations. A solution to this problem is the use of separate thermostats for the two subsystems (Marx and Hutter 2009; Sprik 1991).

Besides the numerical stability and adiabaticity issues discussed so far, one also has to bear in mind that the approximations made in the Car–Parrinello method do introduce deviations from a Born–Oppenheimer simulation that increase with the value of the fictitious mass μ . The physical explanation for this is that in CPMD, nuclear motion is dampened since they have to carry with them the heavy fictitious mass of the orbitals. This results, for instance, in a red-shifted vibrational spectrum. It has been suggested that this error can be compensated by a priori reduction of the nuclear masses used in a CPMD simulation (Pastore et al. 1991; Blochl 1994; Tangney and Scandolo 2002; Marx and Hutter 2009). In the rigid ion approximation, the difference in mass is (Tangney and Scandolo 2002)

$$\Delta M_I = \frac{2m_e}{3\hbar^2} \sum_{\eta} \mu_{\eta} T^{I,\eta} \quad (148)$$

where $T^{I,\eta}$ is the quantum-mechanical kinetic energy of an electron with the fictitious mass μ_η in orbital η of atom I . Vibrational frequencies obtained from a CPMD simulation can be corrected using this mass shift (Tangney and Scandolo 2002). For a system containing only a single element (e.g., a silicon crystal), a corrected frequency $\omega_{\text{corrected}}$ may be obtained from the CPMD frequency ω_{CP} using the relation (Tangney and Scandolo 2002)

$$\omega_{\text{corrected}} = \omega_{\text{CP}} \sqrt{1 + \frac{\Delta M}{M}} \quad (149)$$

Postprocessing

Data Analysis

Spatial Distribution Functions

For a system of N particles in a volume V at temperature T , the probability of molecule 1 being in the volume element $d\mathbf{R}_1$ around the position \mathbf{R}_1 , molecule 2 being in $d\mathbf{R}_2$, ..., molecule N being in $d\mathbf{R}_N$ is given by (McQuarrie 1992)

$$P^{(N)}(\mathbf{R})d\mathbf{R} = P^{(N)}(\mathbf{R}_1, \dots, \mathbf{R}_N)d\mathbf{R}_1, \dots, d\mathbf{R}_N = \frac{e^{-E(\mathbf{R})/kT}}{Z_N} \quad (150)$$

with the configuration integral

$$Z_N = \int_V e^{-E(\mathbf{R})/kT} d\mathbf{R} \quad (151)$$

where $E(\mathbf{R})$ is the potential energy of the system at configuration \mathbf{R} (cf. Eqs. 8 and 10).

For a subset of n molecules, the probability of molecule 1 being in $d\mathbf{R}_1$, ..., molecule n being in $d\mathbf{R}_n$ is

$$P^{(n)}(\mathbf{R}_1, \dots, \mathbf{R}_n) = \frac{\int \dots \int e^{-E(\mathbf{R})/kT} d\mathbf{R}_{n+1} \dots d\mathbf{R}_N}{Z_N} \quad (152)$$

The probability of *any* molecule being in $d\mathbf{R}_1$, ..., *any* molecule n being in $d\mathbf{R}_n$ is

$$\rho^{(n)}(\mathbf{R}_1, \dots, \mathbf{R}_n) = \frac{N!}{(N-n)!} P^{(n)}(\mathbf{R}_1, \dots, \mathbf{R}_n) \quad (153)$$

In a liquid the probability of finding any one molecule in $d\mathbf{R}_1$, $\rho^{(1)}(\mathbf{R}_1)d\mathbf{R}_1$, is independent of \mathbf{R}_1 . Therefore,

$$\frac{1}{V} \int \rho^{(1)}(\mathbf{R}_1)d\mathbf{R}_1 = \rho^{(1)} = \frac{N}{V} = \rho \quad (154)$$

The dependence of the molecules of a liquid on all the other molecules, in other words, their correlation, is captured by the *correlation function* $g^{(n)}(\mathbf{R}_1, \dots, \mathbf{R}_n)$, which is defined by

$$\rho^{(n)}(\mathbf{R}_1, \dots, \mathbf{R}_n) = \rho^n g^{(n)}(\mathbf{R}_1, \dots, \mathbf{R}_n) \quad (155)$$

Using Eq. (153) we can thus write

$$g^{(n)}(\mathbf{R}_1, \dots, \mathbf{R}_n) = \frac{V^n N!}{N^n (N-n)!} \frac{\int \dots \int e^{-E(\mathbf{R})/kT} d\mathbf{R}_{n+1} \dots d\mathbf{R}_N}{Z_N} \quad (156)$$

The two-body correlation function $g^{(2)}(\mathbf{R}_1, \mathbf{R}_2)$ is of particular interest as it can be determined in X-ray diffraction experiments. In the following we shall only consider the dependence of $g^{(2)}$ on the interparticle distance $R = R_{12} = |\mathbf{R}_1 - \mathbf{R}_2|$, i.e., we have averaged over any angular dependence, and call $g^{(2)}(R_{12}) = g(R)$ the *radial distribution function*. The quantity $\rho g(R) d\mathbf{R}_I$ is proportional to the probability of finding another particle, I , in $d\mathbf{R}_I$ if the reference particle is at the origin. Spherical integration yields

$$\int \rho g(R) 4\pi R^2 dR = N - 1 \approx N \quad (157)$$

showing that $\rho g(R) 4\pi R^2 dR$ is the number of particles in the spherical volume element between R and $R + dR$ about the central particle. The radial distribution function $g(R)$ is proportional to the local density $\rho(R) = \rho g(R)$ about a certain molecule. In a fluid, $g(R) \rightarrow 1$ as $R \rightarrow \infty$, i.e., there is no long-range order and we "see" only the average particle density. At very short range, i.e., $R \rightarrow 0$, $g(R) \rightarrow 0$, due to the repulsiveness of the molecules. Examples from a CPMD simulation of liquid water are shown in Fig. 3.

The radial distribution function $g(R)$ provides a useful measure of the quality of a simulation as it can be compared to experimental – X-ray or neutron diffraction – data obtained by Fourier transform of the structure factor

$$h(k) = \rho \int [g(R) - 1] e^{i\mathbf{k}\mathbf{R}} d\mathbf{R} \quad (158)$$

where \mathbf{k} is the wave vector.

In addition to characterizing the structure of a liquid, the radial distribution function may also be used to calculate thermodynamic properties such as the total energy,

$$E = \frac{3}{2} NkT + 2\pi N\rho \int_0^\infty u(R) g(R) R^2 dR \quad (159)$$

the pressure,

$$p = \rho kT - \frac{2}{3} \pi \rho^2 \int_0^\infty \frac{du(R)}{dR} g(R) R^3 dR \quad (160)$$

Fig. 3 Radial distribution function of liquid water from CPMD simulations at 900 and 1200 K, respectively

and the chemical potential,

$$\mu = kT \ln(\rho\Lambda^3) + 4\pi\rho \int_0^1 d\xi \int_0^\infty u(R)g(R, \xi)R^2 dR \quad (161)$$

where

$$\Lambda = \sqrt{\frac{h^2}{2\pi mkT}} \quad (162)$$

is the thermal de Broglie wavelength. By varying the coupling parameter ξ between 0 and 1 one can effectively take a molecule in and out of the system. It should be stressed that Eqs. (159)–(161) have been derived assuming a pairwise additive intermolecular potential $u(R)$.

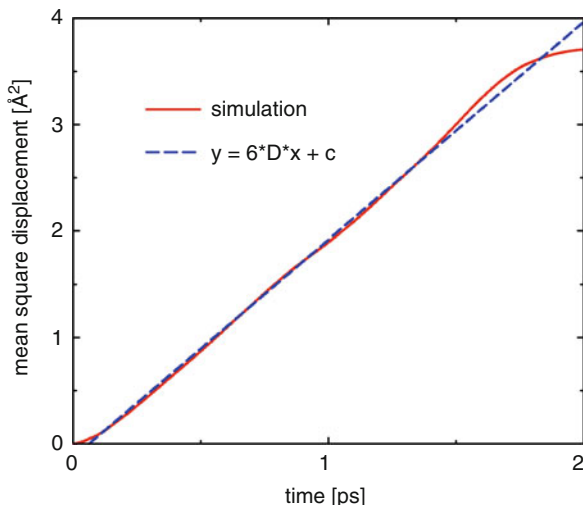

We now define the *potential of mean force*, i.e., the interaction between n fixed molecules averaged over the configurations of the remaining molecules $n + 1, \dots, N$, as

$$w^{(n)}(\mathbf{R}_1, \dots, \mathbf{R}_n) = -kT \ln g^{(n)}(\mathbf{R}_1, \dots, \mathbf{R}_n) \quad (163)$$

The mean force acting on molecule J is then obtained from

$$f_J^{(n)} = -\nabla_J w^{(n)} \quad (164)$$

Fig. 4 Mean square displacement of liquid water from CPMD simulations at 900 K and linear fit to determine the diffusion constant D using Eq. (168)

Time Correlation Functions

The classical *time autocorrelation function* of some vectorial function

$$\mathbf{A}(t) = \mathbf{A}(P(t), Q(t)) = \mathbf{A}(P, Q; t) \quad (165)$$

where $Q(t)$ and $P(t)$ are the generalized coordinate and momentum, respectively, is defined as

$$C(t) = \langle \mathbf{A}(0)\mathbf{A}(t) \rangle = \int \dots \int dP dQ \mathbf{A}(P, Q; 0)\mathbf{A}(P, Q; t) f(P, Q) \quad (166)$$

where $f(P, Q)$ is the equilibrium phase space distribution function.

From the velocity autocorrelation function, for example, one can calculate the diffusion coefficient as

$$D = \frac{1}{3} \int_0^{\infty} \langle \mathbf{V}_I(0)\mathbf{V}_I(t) \rangle dt \quad (167)$$

where \mathbf{V}_I is the velocity of particle I . Alternatively, one can obtain the diffusion coefficient for long times from the associated *Einstein relation*,

$$6tD = \langle |\mathbf{R}_I(t) - \mathbf{R}_I(0)|^2 \rangle \quad (168)$$

In practice, D is then determined from a linear fit to the *mean square displacement* (rhs of Eq. 168) as one sixth of the slope. An example is shown in Fig. 4.

Another common application of correlation functions is the calculation of IR absorption spectra. The line-shape function, $I(\omega)$, is given by the Fourier transform of the autocorrelation function of the electric dipole moment \mathbf{M} ,

$$I(\omega) = \frac{1}{2\pi} \int_{-\infty}^{\infty} \langle \mathbf{M}(0)\mathbf{M}(t) \rangle e^{-i\omega t} dt \quad (169)$$

Fig. 5 A snapshot of a micelle formed from DDAO molecules and oil molecules formed using the VMD software package (<http://www.ks.uiuc.edu/Research/vmd/>)

Visualization

Due to the nature of MD simulations, one of the most productive forms of analysis of a simulation is to be able to visualize the trajectory of the molecules of interest. This is particularly useful since experimental techniques are not able to produce visual pictures of atomistic interactions and therefore it is something that only simulations (at this point) are able to provide. In order to visualize a simulation trajectory, there are several different very powerful computer packages that are commonly used. These software packages include VMD (<http://www.ks.uiuc.edu/Research/vmd/>), PyMol (<http://pymol.sourceforge.net/>), RasMol (<http://rasmol.org/>), and several others (<http://www.umass.edu/microbio/rasmol/otherof.htm>). Figure 5 shows an example of the type of pictures that can be made using the visualization software.

Each of these codes will generally accept the trajectory in any number of standard inputs (i.e., pdb, xyz,...) and then will generate snapshots which can be rendered individually or as a movie. In addition to providing the visualization, these codes have become progressively powerful analysis codes in their own right. They now have the ability to measure bond lengths, angles, and dihedrals as a function of time and determine the solvent accessible surface area, hydrogen bond network, and many other useful structure-related and dynamic properties of the system.

Abstract

Single molecule force spectroscopy constitutes a robust method for probing the unfolding of biomolecules. Knowledge gained from statistical mechanics is helping to build our understanding about more complex structure and function of biopolymers. Here, we have review some of the models and techniques that have been employed to study force-induced transitions in biopolymers. We briefly describe the merit and limitation of these models and techniques. In this context, we discuss statistical models of polymer along with numerical techniques, which may provide enhanced insight in understanding the unfolding of biomolecules.

Introduction

Recent technological developments of experimental techniques, for example, optical tweezers, atomic force microscope, etc., made it possible to apply a force of the order of pN to manipulate the single biomolecules (Kumar and Li 2010; Rief et al. 1999, 1997; Tskhovrebova et al. 1997). Many interesting results, for example, structural, functional, and elastic properties of biomolecules, information about the kinetics of biomolecular reactions, and detection of molecular intermediates have been obtained (Bustamante et al. 2000; Cecconi et al. 2005; Smith et al. 1992, 1996). Moreover, these experiments also provided a platform to verify theoretical predictions based on the models developed in the framework of statistical mechanics (Bhattacharjee 2000; Giri and Kumar 2006; Kumar 2009; Kumar and Giri 2007; Kumar et al. 2005; Lubensky and Nelson 2000; Marenduzzo et al. 2001a; Zhou et al. 2006).

Many biological reactions involve large conformational changes which provide well-defined mechanical reaction coordinates, for example, the end-to-end distance of a polymer, that can be used to follow the progress of the reaction (Bustamante et al. 2004; Kumar et al. 2007). Such processes have been modeled by a simple two-state model (Bustamante et al. 2004). The applied force “tilts” the free energy surface along the reaction coordinate by an amount linearly dependent on the end-to-end distance. The kind of transitions induced by the applied force are the folding–unfolding transition of proteins, the stretching and unzipping transition of double-stranded DNA, or the ball–string transition of a polymer (Kumar and Li 2010). From thermodynamics point of view, the change in energy of system can be categorized into components related to the heat exchanged and the work done on or performed by the system. If the change in energy of the system is quite low then the system remains in quasi-static equilibrium. The aim of this chapter is to provide the concepts from statistical mechanics to describe the force-induced transitions of biopolymers. In section “[Models](#)”, we discuss some of the models of polymers, which have been used to study biopolymers in the presence of a force f . Section “[Methods and Techniques](#)” dwells with few techniques used in statistical mechanics for polymers. Among these techniques, we choose an exact enumeration technique to study force-induced desorption of polymer adsorbed on the surface in section “[Applications](#)”. The method developed for homo-polymers can also be extended to study the protein unfolding and DNA unzipping in quasi static equilibrium. The chapter ends with some results based on model studies which are interesting for future experiments in section “[Conclusions](#)”.

Models

Macromolecules from living organisms are called biopolymers which vary in their size, shape, and function. Polymers including biopolymers are made up of long chains of “monomer” units (de Gennes 1979; des Cloizeaux and Jannink 1990;

Grosberg and Khokhlov 1994; Vanderzande 1998). The monomers can be of different natures. In DNA and RNA they are called nucleotides, and amino acids in proteins. Building blocks of simple artificial polymers can be group of just a few atoms, for example, CH_2 in polyethylene or a complex structure in amino acids. The difference between polymers and biopolymers is in their structure. Biopolymers have generally well-defined structures. The most intensive theoretical study related to biomolecules can be performed with the help of all-atom simulations. All-atom models, which provide the most detailed description on the atomistic level, include the local interaction and interaction involved in non-bonded monomers. The later include the (6–12) Lennard-Jones potential, the electrostatic interaction, and the interaction with environment (Kumar and Li 2010). However, such study for a long chain is computationally demanding and is difficult to handle analytically. In order to get the key features, physicists attempt to simplify complex structures of biopolymers as much as possible. Such process is termed as coarse graining. They model polymer chains as threads or necklaces made of beads on a string which describes some essential properties of biopolymers (de Gennes 1979; des Cloizeaux and Jannink 1990; Grosberg and Khokhlov 1994; Vanderzande 1998) but not always. In the literature, coarse-grained models are divided into two broad categories: (1) Continuum models and (2) Lattice models, which are briefly discussed below.

Continuum Models

We briefly describe three models, namely, the Gaussian Chain model, Freely Jointed Chain (FJC) model, and Worm Like Chain (WLC) model, which have been extensively used to describe the force-extension curves of biopolymers. The advantages of these models come from their simplicity and allowing one to derive analytical expressions in a simple form. In these models a polymer chain consists of N beads (monomers) of contour length L . A point in d -dimensional space represents each monomer and the distance between two consecutive monomers is $R_{i-1} - R_i$ (see Fig. 1). The energy with force f (along x -direction) in Gaussian model is expressed as (Doi and Edwards 1986)

$$F = \frac{3k_B T}{2b} \int_0^{L=Nb} ds \left(\frac{\partial \mathbf{r}(s)}{\partial s} \right)^2 - f \hat{x}_0 \cdot \int_0^{Nb} ds \frac{\partial \mathbf{r}(s)}{\partial s}, \quad (1)$$

where b is the effective bond length known as the Kuhn length and $\mathbf{r}(s)$ describes the local state at arc-length point s . For example, in the case of a flexible Gaussian chain, \mathbf{r} is a three-dimensional position vector, whereas for WLC case it represents the unit tangent vector. k_B is the Boltzmann constant and T the temperature of the system. Using the path integral technique (Doi and Edwards 1986; Kleinert 1990), the end-to-end distance distribution function of a chain under the force can be written as

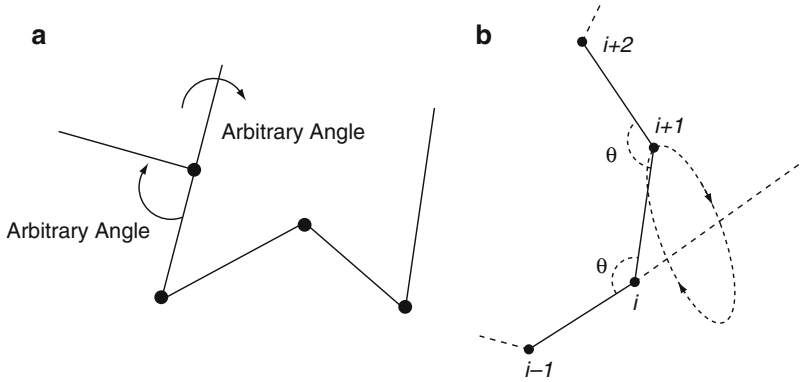

Fig. 1 (a) Schematic of a freely jointed chain. (b) Freely rotating chain with fixed bond angle. These models do not incorporate excluded volume effects in their description

$$P_N(\mathbf{R}, f) = \left(\frac{3}{2\pi N b^2} \right)^{(3/2)} \exp \left\{ -\frac{3}{2N b^2} \left(\mathbf{R} - \frac{N b^2 f \hat{x}_0}{3k_B T} \right)^2 \right\}. \quad (2)$$

The x-component of \mathbf{R} can be expressed as

$$\begin{aligned} P_N(R_x, f) &= \int dR_y dR_z P_N(\mathbf{R}, f) \\ &= \left(\frac{1}{2\pi N b^2} \right)^{(3/2)} \exp \left\{ -\frac{3}{2N b^2} \left(R_x - \frac{N b^2 f}{3k_B T} \right)^2 \right\}, \end{aligned} \quad (3)$$

which gives the expression for the extension x in the presence of applied force f (Dai et al. 2003)

$$x(f) = \frac{N b}{3} \frac{f b}{k_B T}. \quad (4)$$

This is a linear force relation. The model describes the response of a single polymer chain under low force. The major limitation of the model is the property that the distance between two monomers can be extended without any limit. This shortcoming of Gaussian chain is removed in the FJC model, where the distance between two consecutive monomers (bond length) is kept fixed while the rotational angle occurs with equal probability (Fig. 1b). The free energy of the system can be written as

$$F = -f \hat{x}_0 \cdot \sum_{n=1}^N \mathbf{r}_n, \quad (5)$$

where \mathbf{r}_n are bond vectors with constant length $|\mathbf{r}_n| = b$.

The distribution function of end-to-end vector \mathbf{R} in the presence of force f is defined as

$$P_N(\mathbf{R}, f) = \frac{\exp[\beta f \hat{x}_0 \cdot \mathbf{R}] P_N(\mathbf{R}, 0)}{\int d\mathbf{R} \exp[\beta f \hat{x}_0 \cdot \mathbf{R}] P_N(\mathbf{R}, 0)}, \quad (6)$$

where $\beta = 1/k_B T$ and $P_N(\mathbf{R}, 0)$ is the end-to-end distance distribution function in the absence of force f , which is given as

$$P_N(\mathbf{R}, 0) = \frac{1}{2^{N+1} (N-2)! \pi b^2 R} \sum_{n=0}^{[(N-R/b)/2]} (-1)^n \binom{N}{n} \times (N-2n-R/b)^{N-2}. \quad (7)$$

The component of end-to-end distance along the x -direction may be obtained by integrating Eq. 6 with respect to R_y and R_z as (Dai et al. 2003)

$$P_N(R_x, f) = \frac{\exp(\beta f R_x)}{[4\pi \sinh(\beta f b) / \beta f b]^N} P_N(R_x, 0), \quad (8)$$

where the value of $P_N(R_x, 0)$ can be obtained from Eq. 7.

The average extension along the force direction is

$$x(f) = bN \left[-\frac{1}{\beta f b} + \coth(\beta f b) \right]. \quad (9)$$

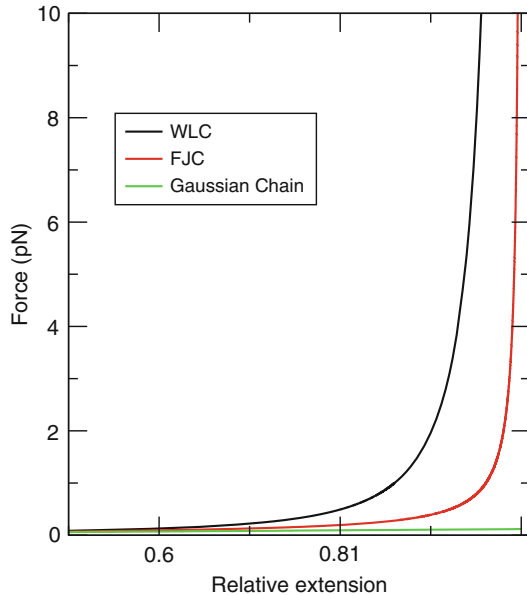

One of the important characteristics of biopolymers not described by the FJC model is the stiffness of the chain. A more realistic model for many systems is that of the Freely Rotating Chain, or Worm Like Chain (WLC), which includes stiffness in its description. This model builds an extension of the FJC model with the assumptions that the bond angles are fixed at certain angle, but are free to rotate. This gives rise to a uniform distribution of dihedral angles. The end-to-end distance within the WLC model can be calculated by transfer matrix methods, numerical simulations, etc. One can find variational expressions for x as a function of f (Chatney et al. 2004; Marko and Siggia 1995; Rosa et al. 2003a). The one used extensively in the literature is (Marko and Siggia 1995)

$$f = \frac{k_B T}{2b} \left[\frac{1}{(1-x/L)^2} - 1 + \frac{4x}{L} \right]. \quad (10)$$

This equation also reduces to the Gaussian chain result in the small force regime i.e., $f < k_B T/b$ and for large force $f > k_B T/b$, it acquires the form

$$x = L \left(1 - \sqrt{\frac{k_B T}{2fb}} \right). \quad (11)$$

Fig. 2 Force-extension curves for the Gaussian chain, FJC, and WLC models

One can see from this equation that the difference between the contour length L and the extension x varies as $f^{-0.5}$. The force-extension curves for the Gaussian chain, FJC and WLC are shown in Fig. 2. The behavior of a biopolymer subjected to a large force as described by the WLC model is contrary to the behavior as described by the FJC model, whereas at low force all models show identical behavior. The Kuhn length of the WLC model corresponds to twice the persistence length. One of the important shortcomings is that all these models have only one free parameter, known as the persistence length or Kuhn length, and hence are not suitable when it comes to describing the entire force-extension curve involving many intermediates.

It is important to recall that all these models ignore crucial excluded volume effect, i.e., the space occupied by a monomer is not available to other monomers (de Gennes 1979). Apart from these, in a polymer solution three types of interactions may be present (de Gennes 1979): (1) monomer–monomer interactions, (2) monomer–solvent interaction, (3) solvent–solvent interaction.

If monomer–monomer (or solvent–solvent) interaction is more than the monomer–solvent interaction in the solution, such solvent is known as a poor solvent. However, if monomer–solvent interaction favors in the solution, the solvent is referred as a good solvent. It is possible by lowering the temperature, one can go from the expanded coil state to a compact globule state and such transition is known as a coil–globule transition and transition point is called θ -point. Generally, force-induced transitions have been studied by these models where excluded volume effects and attractive interactions between chain segments have been ignored and is thus well suited only for modeling the stretching of polymers in a good solvent (Kumar and Li 2010).

Lattice Models

Any model designed to represent a polymer chain over a full range of physical conditions must include important effects such as excluded volume and attractive interactions as a starting point. In a simplified assumption, a linear biopolymer chain in a solvent can be described by a walk on a lattice in which a step or vertex of the walk represents a monomer. If the walk is allowed to cross itself without restriction such walk is referred as Random Walk, which is same as that of the Gaussian chain (de Gennes 1979; Vanderzande 1998). The excluded volume effect has been incorporated in the Random Walk model of polymer with a constraint that a lattice site cannot be visited more than once. This kind of walk is known as Self-Avoiding Walks (SAWs), which simulates a linear polymer chain in a good solvent (Fig. 3a). A polymer chain in a poor solvent is modeled by Self-Attracting Self-Avoiding Walks (SASAWs) by including self-attraction among non-bonded monomers. This model exhibits collapse transition including the existence of θ -point (de Gennes 1979; Vanderzande 1998). Various kinds of underlying lattices have been proposed in the literature to study the conformational properties of linear polymer chains. The choice of the lattice depends on the mathematical convenience, nature of the system,

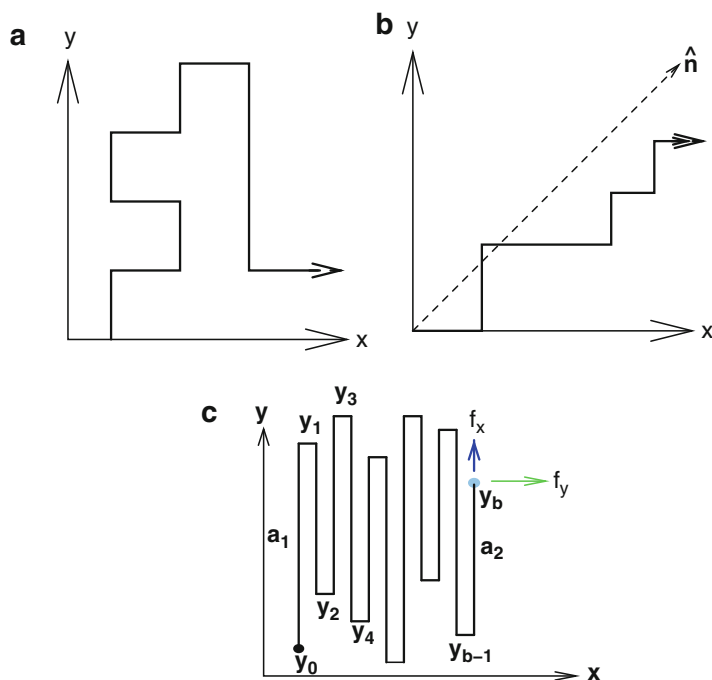

Fig. 3 Schematic diagrams of SASAW, DW, and PDSAW model. A force has been applied at one end (along x-axis) keeping other end fixed. In order to study the role of anisotropy, one may apply force along y-direction (Fig. 3c)

and the interactions present in the system. As far as universality is concerned, the nature of underlying lattice and the detail of interactions do not matter much and many important properties associated with polymers can be derived, which are in qualitative agreement with the experiments. Sometimes quantitative agreement has also been achieved particularly in determining the critical exponents (de Gennes 1979; Vanderzande 1998). Therefore, SAWs with suitable interactions on lattice has been studied extensively in describing the various properties of polymers and biopolymers.

In addition to self-avoidance, one can also introduce additional constraint on the walks, for example, certain direction(s) is (are) not accessible to the walker, such walks are called Directed Walks (DWs) (Privman and Svrakic 1989; Vanderzande 1998). To define a directed walk, a preferred direction \hat{n} on the lattice is assigned. Walkers are allowed to take only those steps in the non-negative direction of \hat{n} . The directed walk can be seen as a model of polymer that is subject to some external force in the direction of \hat{n} , for example, flow in which the polymer is immersed or an electric field acting on electrically charged polymers. If the direction \hat{n} is assigned as shown in Fig. 3b and walks in the non-negative projection of \hat{n} are not allowed then such walks are called Fully Directed Walks (FDWs). If the direction \hat{n} is assigned, say, along the x-axis (Fig. 3c), then the walks are said to be the Partial Directed Walks (PDSAWs). For example in two dimensions, the walker can take step in $\pm y$ directions but only in $+x$ direction. The major advantage of the directed walk model of polymer is that it can be solved analytically and many important results may be derived exactly. The drawback is that it is too far from the real chain.

Polymer and Critical Phenomena

It is known that the certain quantities associated with polymers modeled by SAWs for, example, number of distinct conformation (C_N), number of closed polygons (P_N), and end-to-end distance of chain (R_e) of N monomers scale as (de Gennes 1979)

$$\begin{aligned} C_N &\sim \mu^N N^{\gamma-1}, \\ P_N &\sim \mu^N N^{\alpha-3}, \\ R_e &\sim N^{\nu}, \end{aligned} \quad (12)$$

where μ is the connectivity constant giving the number of choices per step for an infinitely long walk. From the phase transition and critical phenomena, we also know that certain physical quantities like susceptibility (χ), specific heat (C), and correlation length (ξ) near the transition point T_C scale as

$$\begin{aligned} \chi &\sim \chi_0 \left| \frac{T - T_c}{T_c} \right|^{-\gamma}, \\ C &\sim C_0 \left| \frac{T - T_c}{T_c} \right|^{-\alpha}, \\ \xi &\sim \xi_0 \left| \frac{T - T_c}{T_c} \right|^{-\nu}. \end{aligned} \quad (13)$$

A relation between polymer statistics and phase transition was established by de Gennes (1979) and des Cloiseaux (1974) showing a correspondence between the polymer chain modeled by SAWs and the n -vector spin model of magnetization in the limit $n \rightarrow 0$. Similarities between correlation length (ξ) and the end-to-end distance (R_e) can be noticed by comparing Eqs. 12 and 13. Correspondence between $1/N$ and $\frac{T-T_c}{T_c}$ is viewed as $\frac{T-T_c}{T_c} \rightarrow 0$ and $N \rightarrow \infty$. This equivalence allowed polymer science to benefit from the vast knowledge accumulated in the study of critical phenomena. For example, the following relations, which are quite non-trivial to derive directly, are also valid here (de Gennes 1979):

$$\begin{aligned}\alpha + 2\beta + \gamma &= 2, \\ 2 - \alpha &= d\nu, \\ \gamma &= \nu(2 - \eta).\end{aligned}\tag{14}$$

Here, α , β , γ , and η are the critical exponents and d represents the dimensionality of the system. The above equivalence may serve an important role in describing the long range behavior of the polymers.

Methods and Techniques

Methods and techniques used in critical phenomena can also be applied to polymers and biopolymers to gain further insight of the system. In the following, we discuss some of the techniques of statistical mechanics which have been used in analyzing the results of single molecule force spectroscopy.

Generating Function Technique

The generating function technique is a very powerful technique, which may be adapted to study the conformational properties of biopolymers (Forgacs et al. 1995; Privman and Svrakic 1989). Here, we use a simple example to illustrate how the generating function approach can be applied and exact results can be derived. Let us consider a directed walk model of a polymer chain (Privman and Svrakic 1989; Vanderzande 1998). For simplicity, we consider partial directed walks (PDWs) in which the walker is allowed to move along x - and $\pm y$ -axes only (Fig. 3c). As discussed above biopolymers are in general semi-flexible. Stiffness is introduced into the polymer chain by putting an energy cost ε_b on every bend of the walk thus giving rise to an associated Boltzmann weight, $k = e^{-\frac{\varepsilon_b}{k_B T}}$. For $k = 1$ ($\varepsilon_b = 0$) the chain is said to be flexible, while for $0 < k < 1$, ($0 < \varepsilon_b < \infty$) the chain is said to be semi-flexible. The grand canonical partition function of such a chain can be written as (Mishra et al. 2003; Privman and Svrakic 1989)

$$\mathcal{Z}(z, k) = \sum_{N=0}^{\infty} \sum_{\text{all walks}} z^N k^{N_b}.\tag{15}$$

Fig. 4 The diagrammatic representations of the recursion relations Eqs. 16 and 17 for PDWs. The thick arrows X and Y denote all possible walks with the initial step (fugacity) along $+x$ and $\pm y$ directions

Here, z is the fugacity of the walk and N_b is the number of bends in a given configuration. In two dimensions, the grand canonical partition function defined by Eq. 15 may be expressed as a sum of two components of PDWs. The recursion relations for the case of a semi-flexible polymer chain are

$$X = z + z(X + 2kY), \tag{16}$$

and

$$Y = z + z(kX + Y). \tag{17}$$

Schematic representations of the above equations (for 2D) have been shown in Fig. 4. It may be noted that the first term of Eqs. 16 and 17 is the fugacity of the walk and remain constant as z . Solving Eqs. 16 and 17 we get

$$X = \frac{z + (2k - 1)z^2}{1 - 2z + z^2 - 2z^2k^2}, \tag{18}$$

$$Y = \frac{z + (k - 1)z^2}{1 - 2z + z^2 - 2z^2k^2}. \tag{19}$$

The partition function of the system can, therefore, be written as

$$\mathcal{Z}(z, k) = X + 2Y = \frac{(4k - 3)z^2 + 3z}{1 - 2z + z^2 - 2z^2k^2}. \tag{20}$$

The critical point for polymerization of an infinite chain is found from the relation

$$1 - 2z + z^2 - 2z^2k^2 = 0. \quad (21)$$

This leads to an expression for the critical value of the step fugacity as a function of k , $z_c = \frac{1}{(1+\sqrt{2k})}$. In the limit $k \rightarrow 1$, it reduces to the well-known value for the flexible polymer chain in 2D (Privman and Svrakic 1989). The approach has been successfully applied to study the DNA unzipping and unfolding of collapse polymer (Marenduzzo et al. 2001a, b; Rosa et al. 2003a, b).

Exact Enumeration Technique

The conformational properties of a polymer chain and phase transition phenomena can be understood if one has the complete information about the partition function of the chain. In the lattice model, the canonical partition function of a polymer chain is calculated (Domb and Lebowitz 1989) by enumerating all possible walks of a given length. For example, we show total number of conformations (C_N) for N step walk in Table 1. The grand canonical partition function defined in Eq. 15 can be written as

$$\mathcal{Z}(z) = \sum_N C_N z^N, \quad (22)$$

where z is the fugacity associated with each step of the walk. As the singularity of the partition function is associated with critical phenomena, the partition function defined in Eq. 22 will follow $\mathcal{Z}(z) \sim (1 - \mu z)^{-\gamma}$ in the thermodynamic limit. In

Table 1 Values of C_N for different N for the square lattice. The value of C_N can be obtained numerically or one may see the following webpage: <http://www.ms.unimelb.edu.au/iwan/saw/series/sqsaw.ser>

N	C_N	N	C_N
1	4	16	17245332
2	12	17	46466676
3	36	18	124658732
4	100	19	335116620
5	284	20	897697164
6	780
7	2172
8	5916
9	16268
10	44100
11	120292
12	324932
13	881500	53	99121668912462180162908
14	2374444	54	263090298246050489804708
15	6416596	55	698501700277581954674604

most of the cases, where model is not analytically solvable, one uses numerical techniques (Domb and Lebowitz 1989) to calculate the partition function. Once the partition function is known, other thermodynamic variables can be calculated.

Since in a system of finite size the true phase transition cannot take place, therefore, one has to use suitable extrapolation scheme to calculate C_N in the limit $N \rightarrow \infty$. For this purpose suitable techniques, for example, ratio method, Pade approximants, differential approximation, etc. (Domb and Lebowitz 1989) can be used. In ratio method, the approximate value of μ for $N \rightarrow \infty$ can be calculated by taking the ratios of consecutive terms of the series. These quantities should, for large N , be a linear function of $1/N$

$$\log \frac{C_{N+1}}{C_N} \simeq \log \mu + (\gamma - 1) \mathcal{O}(1/N), \quad (23)$$

where $\mathcal{O}(1/N)$ lower order correction. A simple fit then gives estimates for μ and γ (Domb and Lebowitz 1989). However, there is an odd-even effect in $\frac{C_{N+1}}{C_N}$. One can avoid this by using the square root of the successive ratios of C_N as $\mu = \sqrt{\frac{C_{N+2}}{C_N}}$ and extrapolate it to $N \rightarrow \infty$. Linear extrapolation of μ with $\frac{1}{N}$ is shown in Fig. 5.

Monte Carlo Simulation

The Monte Carlo (MC) technique is extremely simple in principle and has been greatly expanded and applied to a wide variety of problems (Binder 1995; Grass-

Fig. 5 Variation of connectivity constant (μ) with $1/N$ for SAW on square lattice. The linear extrapolation gives $\mu = 2.636$ which is quite close to the best estimated value

berger et al. 1999; Landau and Binder 2005). The typical goal of Monte Carlo simulations is first to find out the ground state of a given system (optimization problem) and then calculate ensemble averages through random sampling (equilibrium problem). The core of this approach is a set of predefined moves, which are traditionally on the lattice but may be defined in free space. At each time step a move is selected and may be accepted or rejected based on some criterion, for example, Metropolis method (Binder 1995), which has been used extensively, is defined as follows:

1. Start with some initial configuration I at a given temperature T
2. Define some rule to go from the present configuration to a new one
3. Compute the energy difference $\Delta E = E_{\text{new}} - E_{\text{old}}$, where E_{new} and E_{old} are energies of the system after and before the move
4. If $\Delta E < 0$, accept the move with new configuration. Otherwise, generate a random number r between 0 and 1 and accept the trial configuration if $\exp(-\beta\Delta E) > r$. Such choice of acceptance of move is known as Metropolis method
5. Repeat Steps 2–4 till enough configurations have been sampled
6. Repeat Steps 1–5 for different temperatures

The way in which temperature is decreased is known as the cooling process. Ideally one should try to devise an optimal way to find the annealing schedule, as the decrease rate and the number of MC steps per T can be varied during the numerical simulation. An important parameter to monitor during the annealing is the number of accepted moves that do not violate physical constraints. At high T , this number is very high but at low temperatures almost all moves may be rejected, and therefore, caution should be taken in sampling. One of the biggest advantages of the MC is that it can be very fast especially if the moves are selected carefully. The disadvantage is that it is not generally suitable for studying the dynamics since it is dependent on the move set, and method fails at low temperature. There are a number of good reviews and books available, and serious readers are advised to go through them (Binder 1997; Leckband and Israelachvili 2001; Muller et al. 2006; Muller-Plathe 1997).

Molecular Dynamics

One of the important tools that has been employed in statistical mechanics is the molecular dynamics (MD) simulations (Allen and Tildesley 1987; Frenkel and Smit 2002). Quite frequently, this technique has been used to study the biomolecules (Kumar and Li 2010). Before studying the structural and dynamical properties of biomolecules, it is important to note that these molecules exhibit a wide range of time scales over which specific processes take place. For example, local motion, which involves atomic fluctuation, side chain motion, and loop motion occurs in the length scale of 0.01–5 Å and the time involved in such process is of the order of 10^{-15} to 10^{-9} s. The motion of a helix, protein domain, or subunit falls under the

rigid body motion whose typical length scales are in between 1 Å and 10 Å and time involved in such motion is in between 10^{-9} and 1 s. Large-scale motion consists of helix–coil transition or folding–unfolding transition, which is more than 5 Å in length and, time involved is about 10^{-7} to 10^{-4} s. Hence the basic goal of molecular dynamics is to understand the role of different length and time scales involved in describing the physical phenomena. Since MD simulation provides information at microscopic level, it is desirable to use the basic concepts of statistical mechanics to derive the macroscopic observable like pressure, energy, heat capacity, etc.

In MD one generates a sequence of points in phase space $\Omega(p_i, q_i)$ where p_i is the momentum of the i th particle and q_i is the position as a function of time. These points belong to the same ensemble and correspond to different conformations (Allen and Tildesley 1987; Frenkel and Smit 2002). The ergodic hypothesis states that the ensemble average is equivalent to time average. Hence if one allows system to evolve in time indefinitely then system will pass through all possible states and thus corresponds to the time average. Therefore, the goal is to generate enough representative point such that equality is satisfied.

The method is based on Newton's second law of motion, that is, Frenkel and Smit (2002), Allen and Tildesley (1987)

$$\mathcal{F}_i = m_i \frac{d^2 r}{dt^2} = -\frac{dE_p}{dr_i}, \quad (24)$$

where \mathcal{F}_i is the applied force on the i -th particle of mass m_i and E_p is the potential energy of the system. The potential energy, in general, is a complicated function and there is no analytic solution to the equation of motion and therefore, one has to solve these equations numerically.

There are various algorithms/numeric schemes for integrating Newton's equations of motion (Allen and Tildesley 1987; Frenkel and Smit 2002). They are generally derived from the Taylor expansion. The expansion for the positions (\mathbf{r}), velocity (\mathbf{v}), and acceleration (\mathbf{a}) of the particles around some moment of time t are

$$r(t + \Delta t) = r(t) + v(t)\Delta t + \frac{1}{2}a(t)\Delta t^2 + \dots, \quad (25)$$

$$v(t + \Delta t) = v(t) + a(t)\Delta t + \frac{1}{2}b(t)\Delta t^2 + \dots, \quad (26)$$

$$a(t + \Delta t) = a(t) + b(t)\Delta t + \dots, \quad (27)$$

where Δt is the time step used in the simulation. In the following, we will discuss some of the common schemes of integration algorithm, which have been extensively used in literature.

- **Verlet algorithm:**

The Verlet algorithm uses positions and accelerations at time t and the positions from time $t - \Delta t$ to calculate new positions at time $t + \Delta t$. In order to derive the Verlet algorithm one can write

$$r(t + \Delta t) = r(t) + v(t)\Delta t + \frac{1}{2}a(t)\Delta t^2, \quad (28)$$

$$r(t - \Delta t) = r(t) - v(t)\Delta t + \frac{1}{2}a(t)\Delta t^2. \quad (29)$$

The sum of these equations gives

$$r(t + \Delta t) = 2r(t) - r(t - \Delta t) + a(t)\Delta t^2. \quad (30)$$

The algorithm does not use the explicit form of velocities. The usefulness of the algorithm are it is simple to implement, and does not require large memory. The algorithm is of moderate precision.

- **Leap Frog algorithm:**

In this algorithm, the velocities are first computed at time $t + \frac{\Delta t}{2}$ and then used to calculate the positions, r , at time $t + \Delta t$. The velocities leap over the positions and subsequently the positions leap over the velocities.

$$r(t + \Delta t) = r(t) + v\left(t + \frac{\Delta t}{2}\right)\Delta t, \quad (31)$$

$$v(t + \Delta t) = v\left(t - \frac{\Delta t}{2}\right) + a(t)\Delta t. \quad (32)$$

The approximate form of velocities at time t is given by

$$v(t) = \frac{1}{2}\left[v\left(t + \frac{\Delta t}{2}\right) + v\left(t - \frac{\Delta t}{2}\right)\right]. \quad (33)$$

The major gain in this process is that the velocities are explicitly calculated, however, the shortcoming of the algorithm is that velocities are not calculated at the same time as the positions.

- **The Velocity Verlet algorithm:**

It may be noted that in the Leap Frog algorithm, velocities are not defined at the same time as the positions. As a consequence kinetic and potential energies are also not defined at the same time, and hence one cannot directly compute the total energy in the Leap Frog algorithm. It is, however, possible to implement in the Verlet algorithm a form that uses positions and velocities computed at same instant of times.

$$r(t + \Delta t) = r(t) + v(t)\Delta t + \frac{1}{2}a(t)\Delta t^2, \quad (34)$$

$$v(t + \Delta t) = v(t) + \frac{1}{2}[a(t) + a(t + \Delta t)]\Delta t. \quad (35)$$

It has to be emphasized here that the Velocity Verlet algorithm is not memory consuming, because it is not required to keep track of the velocity at every time step during the simulation. Moreover, the long-term results of Velocity Verlet are equivalent to the Semi-implicit Euler method, and there is no compromise on precision.

- **Beeman's algorithm:**

This algorithm is related to the Verlet algorithm and yields the same trajectories. However, it provides better estimate of the velocities and looks different than the Verlet algorithm.

$$r(t + \Delta t) = r(t) + v(t)\Delta t + \frac{2}{3}a(t)\Delta t^2 - \frac{1}{6}a(t - \Delta t)\Delta t^2, \quad (36)$$

$$v(t + \Delta t) = v(t) + v(t)\Delta t + \frac{1}{3}a(t)\Delta t + \frac{5}{6}a(t)\Delta t - \frac{1}{6}a(t - \Delta t)\Delta t. \quad (37)$$

The advantage of this algorithm is that it gives accurate expression for the velocities and better energy conservation. The disadvantage is that because of the complex expressions computation is much more time-consuming.

The procedure for a molecular dynamics simulation is subject to many user-defined variables. However, one should consider certain criteria in choosing these algorithms. It should conserve energy, momentum and computationally efficient so that long time step integration can be performed. Because the evaluation of the atomic positions is not performed on a continuous basis, but at intervals of a femtosecond (fs). Since this is the time-scale of stretches of the bonds with hydrogen atoms, these stretches should be constrained in order to permit time steps of 2 fs. The algorithm that permits this increase in simulation speed is called SHAKE (Frenkel and Smit 2002). Application of constraints on all bond lengths and bond angles would increase the permitted time step even more, without too much loss of information. Since most of the computational time is spent on evaluating the non-bonded interactions between atoms, the evaluation time step for non-bonded atom pairs can be increased to a small extent. Using a cutoff distance beyond which atoms are no longer considered to interact can significantly reduce the amount of non-bonded atom pairs.

It may be noted that MD is a scheme for studying the time evolution of a classical system of N particles in volume V , where total energy is a constant of motion. As pointed out earlier, time averages are equivalent to ensemble averages, the observables, say A evolves according to constant energy simulation and hence,

$$\langle A \rangle_{N,V,E} = \lim_{\tau \rightarrow \infty} \int_0^\tau A(t) dt. \quad (38)$$

It is possible to run many NVE simulations with different energies and result could be used in a Boltzmann-weighted average as

$$\langle A \rangle_{NVT} = \sum_E \langle A \rangle_{NVE} e^{-\beta E}. \quad (39)$$

However, such process is not very practical, because simulations are quite expensive in terms of time. Moreover, we require a lot of E values to have enough statistics, and to conserve energy during simulation is a tough task. Thus, it is more appropriate to run simulation in constant temperature ensemble, that is, NVT. In the following, we will discuss some popular temperature control schemes (Allen and Tildesley 1987; Frenkel and Smit 2002).

1. Scaling velocities (Berendsen thermostat):

Since in the beginning, the system is not equilibrated and hence remains in the incorrect state. The potential energy is converted to thermal energy or thermal energy is being consumed during equilibration. In order to stop the temperature from drifting, one of the possible ways is to constrain instantaneous velocities scaled by a factor at each step

$$\mathbf{v}'_i = \sqrt{\frac{T_d}{T_i}} \mathbf{v}_i, \quad (40)$$

where T_d is desired temperature and T_i is instantaneous temperature given by $T_i = \frac{2}{3Nk_B} \sum_i^N \frac{p_i^2}{2m_i}$ after i -th step. This influences the dynamics severely and does not give correct canonical ensemble because it does not generate fluctuations in temperature which are also present in the canonical ensemble. The method is good for initialization of phase.

A weaker formulation of this approach is the Berendsen thermostat where to keep temperature constant, system is coupled to an external heat bath of temperature T_0 . The velocities are scaled in such a way that the rate of change of temperature is proportional to the difference in temperature between system and bath, that is,

$$\frac{dT}{dt} = \frac{T_0 - T(t)}{c}, \quad (41)$$

where c is coupling parameter of the system with a bath. The scaling factor for velocities is given by

$$\lambda = \sqrt{1 + \frac{\Delta t}{c} \left(\frac{T_0}{T(t - \Delta t/2)} - 1 \right)}. \quad (42)$$

2. Adding stochastic forces and/or velocities (Langevin thermostat):

This thermostat models the influence of a heat bath by adding to the velocity of each particle a small random (white) noise and a frictional force directly proportional to the velocity of that particle. These two factors are balanced to give a constant temperature. Since each particle is coupled to a local heat bath, the heat trapped in localized modes can be removed by using this model.

$$ma = -\xi v + f(r) + f'. \quad (43)$$

Here $f(r)$ and f' are conservative force and random force respectively. ξ is the friction coefficient. The drawback of this thermostat is that momentum transfer is destroyed. So, it is not advisable to use Langevin thermostat in the simulations where one wishes to study the diffusion processes.

3. Nosé–Hoover thermostat:

The Berendsen thermostat is quite efficient for relaxing a system to the target temperature. However, once your system has reached equilibrium, it is important to probe a correct canonical ensemble. The Nosé–Hoover thermostat is an extended-system method for controlling the temperature of simulated system (Huenenberger 2005; Thijssen 1999). It allows temperatures to fluctuate about an average value, and uses a friction factor to control particle velocities. This particular thermostat can oscillate when a system is not in equilibrium. Therefore, it is recommended to use a weak-coupling method for initial system preparation (e.g., Berendsen thermostat), followed by data collection under the Nosé–Hoover thermostat. This thermostat produces a correct kinetic ensemble.

In this context, molecular dynamics simulation of nucleic acids have been considered as a bigger challenge because of the negative backbone charge and the poly-electrolytes behavior. In oligonucleotide dynamics simulations, particular attention should be paid to the atomic charges. The negatively charged phosphate groups may very well influence the trajectory. In contrast with molecular mechanics where a structural minimum is the end result, molecular dynamics offers so much information that is hard to quantify. Excellent reviews on molecular dynamics and its use in biochemistry and biophysics are numerous (see, e.g., Adcock and McCammon 2006 and references therein).

Applications

FJC and WLC models have been used in analyzing the force-extension curve obtained from SMFS experiments. In this context, molecular dynamics and Monte Carlo simulations have been found to be quite useful in understanding the phenomena. Since there is a lot of good literature available in this subject, we are not going

Fig. 6 Schematic diagram of the polymer chain adsorbed on the surface under the application of external force

to discuss them here again. In this section, we shall illustrate that lattice model along with exact enumeration technique which may provide enhanced insight in the mechanism involved in the force-induced transitions because exact density of states are available and the entire phase diagram can be probed exactly for small chains.

We consider SAWs that start from a point on an impenetrable surface and experience a force f in a direction perpendicular to the surface at the other end as shown in Fig. 6. The applied force, because of its direction, favors desorption and one expects a critical force (f_c) for the desorption. At a given temperature (T) when the applied force f is less than $f_c(T)$ the polymer will be adsorbed, while for $f > f_c(T)$ the polymer will be desorbed. The curve $f_c(T)$, therefore, gives the boundary that separates the desorbed phase from the adsorbed phase in the force–temperature (f, T) plane (Mishra et al. 2005). Here, $C_N(N_s, h)$ corresponds to the number of SAWs of N steps having N_s number of monomers on the surface and h , the height of the end-monomer away from the surface. In this case, the partition function may be defined as

$$Z_N(\omega, u) = \sum_{N_s, h} C_N(N_s, h) \omega^{N_s} u^h, \quad (44)$$

where $\omega = e^{-\varepsilon_s/k_B T}$ and $u = e^{f/k_B T}$ are the Boltzmann weights for the surface interaction ($\varepsilon_s < 0$) and the applied force respectively. In the following, we set the Boltzmann constant $k_B = 1$ and $\varepsilon_s = -1$. For a fixed force f , we locate the adsorption–desorption transition temperature from the maximum of fluctuation in number of adsorbed monomers (i.e., $\langle N_s^2 \rangle - \langle N_s \rangle^2$) (see Fig. 7), where $\langle N_s \rangle$ and $\langle N_s^2 \rangle$ are defined as:

$$\langle N_s \rangle = \frac{1}{Z_N(\omega, u)} \sum_{N_s, h} N_s C_N(N_s, h) \omega^{N_s} u^h, \quad (45)$$

and

$$\langle N_s^2 \rangle = \frac{1}{Z_N(\omega, u)} \sum_{N_s, h} N_s^2 C_N(N_s, h) \omega^{N_s} u^h. \quad (46)$$

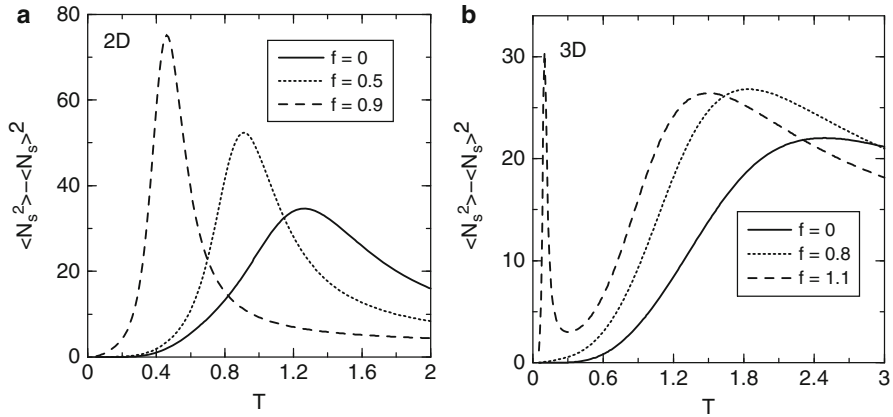

Fig. 7 The dependence of critical force $f_c(T)$ on T in (a) 2D and (b) 3D. The star corresponds to results obtained from the extrapolated values of the reduced free energy, and cross corresponds to the value obtained from finite size data of a step $N = 20$ (3D) and $N = 31$ (2D) respectively

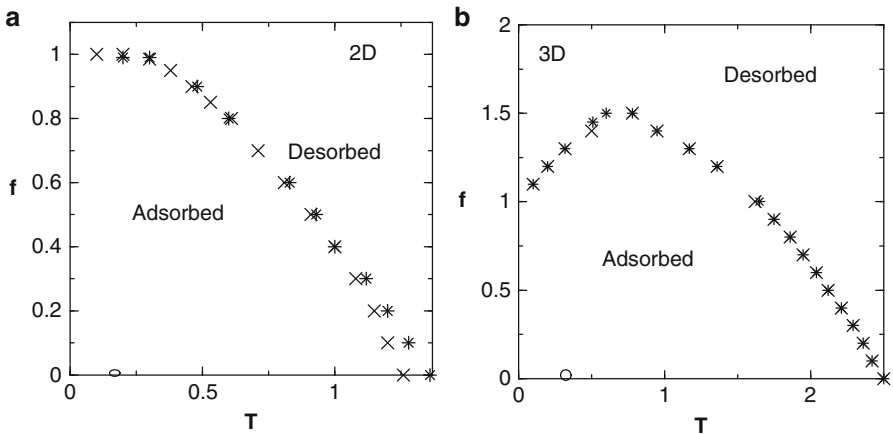

Fig. 8 The dependence of critical force $f_c(T)$ on T in (a) 2D and (b) 3D. The star corresponds to results obtained from the extrapolated values of the reduced free energy, and cross corresponds to the value obtained from finite size data of a step $N = 20$ (3D) and $N = 31$ (2D) respectively

The force–temperature phase diagram is shown in Fig. 8. The occurrence of two maxima in fluctuation curve gives the signature of re-entrance in 3D, but absent in 2D (Mishra et al. 2005). Using the phenomenological argument and the probability distribution analysis, it was shown that the ground state entropy is responsible for the re-entrance which is absent in 2D (Mishra et al. 2005).

It is possible to obtain better estimates of phase boundaries by extrapolating μ for the large N . The reduced free energy per monomer in this case is defined as

$$G(\omega, u) = \lim_{N \rightarrow \infty} \frac{1}{N} \log Z_N(\omega, u) = \log \mu_N(\omega, u). \quad (47)$$

$\mu_N(\omega, u)$ can be estimated from the partition functions found from the data of exact enumerations for finite N by extrapolating to large N . The fluctuation in terms of reduced free energy is given as $\frac{\partial^2 G}{\partial(\log \omega)^2}$.

The method described above has been applied to protein unfolding (Kumar and Giri 2005, 2007; Kumar et al. 2007), stretching of DNA (Kumar and Mishra 2008; Mishra et al. 2009), and unzipping of DNA (Giri and Kumar 2006; Kumar et al. 2005) and, many useful information about biomolecules have been derived which are in qualitative agreement with experiments.

Conclusions

We have discussed some basic models of biopolymers and few techniques which have been used extensively in the past to understand the mechanism involved in force-induced transitions. In particular, we showed that lattice model along with exact enumeration technique may be used to interpret the results of SMFS. It is important to point out here that all the single molecule experiments have been performed to understand the structure and function of biopolymers in vivo by analyzing it in vitro. As a result, the effect of cellular environment has been ignored in all these studies. It is known that the interior of the cell contains different kinds of biomolecules like sugar, nucleic acids, lipids, etc. These macromolecules occupy about 40% of the total volume with steric repulsion among themselves. This confined environment induces phenomena like “molecular confinement” and “molecular crowding” and has major thermodynamic and kinetic consequences on the cellular processes. Recently Singh et al. (2009a, b) have used exact enumeration technique and showed that the molecular crowding has significant impact on the force-induced transitions. In order to have better understanding of force-induced transitions, it is advisable to perform SMFS experiments in the environment similar to a cell.

Acknowledgments We would like to thank D. Giri, A. R. Singh, and G. Mishra for many helpful discussions. Financial assistance from the Department of Science and Technology, New Delhi is gratefully acknowledged.

Abstract

This chapter deals with two very important aspects of modern ab initio computational chemistry: the determination of molecular structure and the calculation, and visualization, of vibrational spectra. It deals primarily with the practical aspects of determining molecular structure and vibrational spectra computationally. Both minima (i.e., stable molecules) and transition states are discussed, as well as infrared (IR), Raman, and vibrational circular dichroism (VCD) spectra, all of which can now be computed theoretically.

Introduction

This chapter deals with two very important aspects of modern ab initio computational chemistry: the determination of molecular structure and the calculation, and visualization, of vibrational spectra. The two things are intimately related as, once a molecular geometry has been found (as a stationary point on a potential energy surface at whatever level of theory is being used) it has to be characterized, which usually means that it has to be confirmed that the structure is a genuine minimum. This of course is done by vibrational analysis, i.e., by computing the vibrational frequencies and checking that they are all real.

A large percentage of the total expenditure in CPU cycles devoted to computational chemistry (variously estimated at between 60% and 85%) is spent optimizing geometries. In order to calculate various molecular properties, one first needs a reliable molecular structure so this is perhaps not surprising. Algorithms for geometry optimization are now highly advanced and usually very efficient and most of the quantum chemistry programs available for general use have solid and reliable geometry optimization modules. They also nearly all have analytical second derivatives, at least for the most common theoretical methods, which makes it relatively straightforward to compute vibrational frequencies once a structure has been found.

In this chapter I deal primarily with the practical aspects of determining molecular structure and vibrational spectra computationally. I consider both minima (i.e., stable molecules) and transition states, as well as infrared (IR), Raman, and vibrational circular dichroism (VCD) spectra, all of which can now be computed theoretically. The program used to carry out the calculations presented here is the PQS package developed by Parallel Quantum Solutions (PQS 2010), although any modern general purpose package (e.g., Gaussian, Turbomole, GAMESS) would do just as well. As the name implies, all the major ab initio functionality of this package is fully parallel, including energies, gradients, and second derivatives. PQS was chosen because (a) it is the package I actually use in all my application work; and (b) I am one of its principal authors. A review of the capabilities and parallel efficiency of the PQS package was published recently (Baker et al. 2009).

I have elected to use a standard level of ab initio theory for all of the examples presented in this chapter, namely, density functional theory (Hohenberg and Kohn

1964; Kohn and Sham 1965) (DFT) using the B3LYP (Becke 1993) (see also Hertwig and Koch (1997)) functional and the 6-31G* (Ditchfield et al. 1971) basis set (B3LYP/6-31G*). DFT is now the method of choice for routine chemical applications, and B3LYP – despite the large number of functionals developed since – is still one of the most popular. Many of the techniques and pitfalls in locating stable geometries are essentially independent of method, although DFT has its own issues as a result of the numerical quadrature required to handle many of the integrals; this will be discussed in some detail later. DFT is so popular that Hartree–Fock theory, which used to be the standard approach throughout the 1980s, has now almost disappeared other than as a precursor for higher level post-SCF calculations. At the time of writing, the latter are beginning to make a bit of a comeback as the limitations of DFT are being reached, in particular its inability to systematically improve the wave function (and hence the results). A good introduction to DFT for those, like me, whose background is in traditional quantum chemistry is the now classic 1993 paper from (Johnson et al. 1993).

The Born–Oppenheimer approximation (Born and Oppenheimer 1927) (see also Wikipedia (2010)) is used throughout. This extremely important approximation, namely that electrons, being so much less massive, respond instantaneously to the motion of the nuclei, underpins the whole concept of the potential energy surface (PES). Stable arrangements of nuclei (stable or meta-stable molecules) correspond to local minima on the PES, first-order saddle points connecting two different minima correspond to transition states, and the “valleys” joining transition states to minima correspond to “reaction paths.” Electronic excitation is represented by a “jump” from one potential energy surface to another. We will be spending all of our time on the lowest energy (ground-state) PES.

Molecular Structure

From a theoretical point of view the determination of a “molecular structure” means determining the geometry (i.e., the positions of atoms relative to one another) at a minimum (the bottom of a well) on the ground-state potential energy surface. Although a prerequisite, locating a minimum does not automatically mean that you have found the structure of a stable molecule; this depends on the barrier height, i.e., the energy required to get out of the well. The barrier height can be determined by locating the transition state, which for our purposes is defined as the highest energy point on the lowest energy path between reactants and products. (In a barrierless reaction, this will effectively be the energy of the products, assuming the reactant is taken to have the lower energy.) As a rough rule of thumb, if the barrier height is less than about 12–15 kcal mol⁻¹, the system is kinetically unstable at room temperature.

Determining the geometry of a stable molecule therefore requires knowledge of both the minimum itself and the barrier height (i.e., effectively locating the transition state) for all possible decomposition reactions. Of course, the structures of many stable molecules can be derived from “chemical intuition” based on

preexisting knowledge, but for new structures in particular the transition state is equally important and the practicing theoretician must be able to find both. In this section we discuss the methods available to do so.

He₂²⁺: An Illustrative Example

The simplest possible molecular orbital approach to the bonding in the hydrogen molecule (H₂) would consider the overlap between two 1s atomic orbitals on each hydrogen producing two molecular orbitals (MOs), one of which is bonding (the in-phase combination) and the other antibonding (the out-of-phase combination). H₂ is stable because its two electrons occupy the bonding orbital, giving an overall energy lowering compared to two separate H atoms.

Similar considerations applied to helium would suggest, quite rightly, that He₂ would not be stable, since both the bonding and antibonding MOs would be occupied, giving no net bonding. (In fact, as is well known, the antibonding MO is more antibonding than the bonding MO is bonding.) What happens if the electrons in the antibonding MO are removed? On the one hand, there should be a strong bonding interaction, while on the other the resultant positive charge should cause the two nuclei to repel one another.

Figure 1 shows the ground-state PES of He₂²⁺. This was obtained via a potential scan, varying the He–He distance from 0.6 to 4.0 Å in steps of 0.01 Å and computing the energy at each scanned distance. (An optimized potential scan – scanning one particular variable or combination of variables while optimizing all remaining degrees of freedom – is a useful tool for locating transition states, as will be seen later.) The upper curve shows the energy at the restricted RB3LYP/6-31G* level, while the lower curve is the unrestricted equivalent (UBLYP/6-31G*). The two curves coalesce at He–He distances less than about 0.96 Å; at distances greater than this the restricted wave function is energetically unstable, i.e., a lower energy can be obtained by switching to the unrestricted formalism.

During the restricted (upper) scan full symmetry ($D_{\infty h}$) was maintained and the system is a pure singlet. For the unrestricted scan, symmetry was turned off and the highest occupied (HOMO) and lowest unoccupied (LUMO) MOs, both alpha and beta spin, were allowed to mix; this results – as can be seen – in an ultimately much lower energy, but the spin symmetry is lost and the system wave function is no longer a pure singlet. (Spin contamination gradually rises with increasing He–He distance until at 4.0 Å $\langle S^2 \rangle$ is 1.000 and the multiplicity is 2.236, i.e., the system is somewhat “greater” than a doublet.)

At B3LYP/6-31G* the energy of two separate He⁺ ions is $-3.9863 E_h$ and so, despite the spin contamination, the unrestricted curve gives a far better description of the dissociation of He₂²⁺ than the restricted one. This is a general feature of the dissociation of essentially all diatomic molecules and is well known.

The interesting feature from our point of view is that this simple, one-dimensional PES contains both a (local) minimum *and* a transition state, and both types of stationary point can be examined and discussed in relation to the *same*

Fig. 1 Energy versus He–He distance (Å) for He_2^+ (RB3LYP/6-31G* – upper curve; UB3LYP/6-31G* – lower curve)

potential energy curve. This is the only one-dimensional potential energy curve that I am aware of that has this feature.

The gradient is zero at both turning points – minimum and transition state – on the potential energy curve. The key difference between them is of course the sign of the energy second derivative (the rate of change of the gradient) which is positive for a minimum and negative for a transition state.

In this example, we have the complete energy curve between He–He distances of 0.5–4.0 Å available to us, but in general of course (in particular for anything more complicated than a diatomic molecule) this would not be the case, and if we wanted to search for, say, a local minimum we would have to provide an initial approximation for the geometry, i.e., a guess for the minimum structure. We would then calculate the energy, the gradient and either calculate, or provide a reliable estimate for, the second derivative and use this information to predict: (a) how far away we are on the PES from the nearest local minimum, and (b) the step to take (length and direction) in order to get there. Note that only in the one-dimensional case are the first and second derivatives single numbers; typically they would be vectors (with elements dE/dv_i , where v_i is the i -th variable) and matrices (with elements $d^2E/dv_i dv_j$), respectively.

Predicting the next step, i.e., how to change the current geometry to get to a new geometry that is closer to the desired stationary point than the old geometry was, is the job of the geometry optimization algorithm. For ab initio methods these algorithms can be very sophisticated as both the energy and the gradient are relatively expensive to compute (the second derivative is usually even more

expensive), and so additional manipulations in the optimization algorithm in order to reduce the number of optimization cycles (i.e., the number of costly energy and gradient calculations) is more than justified. Not so in molecular mechanics where the energy and gradient cost very little and a highly efficient – in terms of CPU time – optimization algorithm is required.

It is obvious that one of the factors that determines how quickly a given geometry optimization will converge is the starting geometry. In our He_2^{2+} example, in order to locate the metastable minimum, which occurs at a He–He distance of around 0.7 Å (shorter than in H_2 , making this the shortest bond distance known), any initial starting bond length greater than ca. 1.2 Å – the distance in the transition state on the lower, unrestricted, curve – will almost inevitably lead to dissociation (see Fig. 1). If you want to find the transition state then the closer you start to a He–He distance of around 1.2 Å the better off you will be.

The Newton–Raphson Step

Consider a starting He–He distance of about 1.0 Å, i.e., midway between the bound minimum and the transition state. This could probably go either way, toward the minimum or the transition state. Which way it does go is guided by the curvature of the surface around the local region, i.e., by the nature of the second derivative. If we do a standard Taylor series expansion about the current point, then we have

$$E(x+h) = E(x) + h \frac{dE}{dx} + \frac{h^2}{2} \frac{d^2E}{dx^2} + \frac{h^3}{6} \frac{d^3E}{dx^3} + \dots \quad (1)$$

In the region about a local minimum (or maximum) the potential energy curve is more-or-less parabolic, so assuming we are in or close to this region we can ignore all terms in the Taylor series expansion (Eq. 1) beyond the quadratic. Taking the derivative with respect to the displacement h gives

$$\frac{dE(x+h)}{dh} = \frac{dE}{dx} + h \frac{d^2E}{dx^2}. \quad (2)$$

At a stationary point $\frac{dE(x+h)}{dh} = 0$ and so the displacement h that achieves this is

$$h = -\frac{\frac{dE}{dx}}{\frac{d^2E}{dx^2}} \quad \text{or} \quad h = -\frac{g}{H}, \quad (3)$$

where g is of course the gradient and H is the energy second derivative.

Equation 3 is the well-known Newton–Raphson step in one dimension. The multidimensional equivalent of this is

$$\mathbf{h} = -\mathbf{H}^{-1} \mathbf{g}, \quad (4)$$

where \mathbf{h} is now a vector (a set of displacements for all variables), \mathbf{g} is the gradient vector, and \mathbf{H} is the second derivative matrix, commonly known as the Hessian matrix.

Going back to our He_2^{2+} example we see that the Newton–Raphson step is normally in the direction of minus the gradient (just like a steepest descent step) with a step length determined by the magnitude of the second derivative. If the second derivative is positive, the step will be downhill (opposite to the gradient) whereas if the second derivative is negative, the step will be uphill (in the same direction as the gradient). Thus at a He–He distance of 1.0 Å (see Fig. 1) the step taken will be uphill toward the transition state if the surface curvature is negative and downhill toward the minimum if it is positive.

In the multidimensional case, we can always find a unitary transformation that diagonalizes the Hessian matrix (which is symmetric about its diagonal), i.e.,

$$\mathbf{D} = \mathbf{U}\mathbf{H}\mathbf{U}^T, \quad (5)$$

where \mathbf{D} is a diagonal matrix and the superscript \mathbf{T} represents a matrix transpose. The vectors in \mathbf{U} are known as eigenvectors and the diagonal elements of \mathbf{D} are the corresponding eigen values. Both the displacement vector \mathbf{h} and the gradient \mathbf{g} can be transformed into this new (diagonal) representation as

$$\mathbf{g}' = \mathbf{U}^T\mathbf{g}; \quad \mathbf{h}' = \mathbf{U}^T\mathbf{h}. \quad (6)$$

Substituting Eq. 5 into Eq. 4 gives

$$\mathbf{h} = -(\mathbf{U}\mathbf{D}^{-1}\mathbf{U}^T)\mathbf{g}. \quad (7)$$

Multiplying both sides by \mathbf{U}^T and rearranging gives

$$\mathbf{U}^T\mathbf{h} = (\mathbf{U}^T\mathbf{U})\mathbf{D}^{-1}(\mathbf{U}^T\mathbf{g}), \quad (8)$$

$$\mathbf{h}' = \mathbf{D}^{-1}\mathbf{g}'. \quad (9)$$

Diagonalizing the Hessian matrix results in a set of mutually orthogonal directions on the PES (the vectors in \mathbf{U}) with the gradient along each direction given by the corresponding element in the vector \mathbf{g}' and the second derivative given by the corresponding diagonal matrix element in \mathbf{D} . Thus we see that the N -dimensional Newton–Raphson step is equivalent to N separate one-dimensional Newton–Raphson steps along the orthogonal directions given by the vectors in \mathbf{U} . If all the eigen values of the Hessian matrix (all the diagonal entries in \mathbf{D}) are positive, then the step taken will attempt to minimize along all directions on the PES (all degrees of freedom) and will head downhill to the nearest minimum. If one (and only one) of the Hessian eigen values is negative, then the Newton–Raphson step will attempt to maximize (head uphill in energy) along that direction, while simultaneously minimizing along all the other directions, i.e., it will move toward

a transition state. If the Hessian has two or more negative eigen values, then, left to its own devices, the optimization will head toward a second (or higher) order stationary point. As these are usually of much less interest than minima or transition states, the problem in these cases is normally how to take a decent optimization step when the Hessian signature (number of negative eigen values) is inappropriate for the stationary point being sought.

I have spent a lot of time on the Newton–Raphson step as it, or a modification thereof, forms the heart of virtually all advanced geometry optimization algorithms. It is usually a good step to take, particularly in the immediate region around the stationary point, and from a practical point of view it utilizes all the information that is likely to be available at the current point on the PES, i.e., first and second derivatives; there are very few codes that routinely compute derivatives higher than the second, and they would be prohibitively expensive in any case.

The Hessian Matrix and Hessian Updates

As I hope the above discussion has shown, the Hessian matrix plays a very important role in determining the step direction, which depends on the surface curvature in the local region of the PES. However, care must be taken with the step length. Hessian information is only local and only applies in the region immediately surrounding the current point. If the predicted step length is small, then you are probably near to a stationary point, in which case the step is best taken “as is”; however too large steps are usually not wise and you can easily get lost. Consequently it is a good idea to impose a limit on the step size – either an overall limit on the total step length or limits on the size of individual step components (or indeed both). Some algorithms attempt to define a “trust radius” which limits the step size dynamically depending on the local nature of the PES (usually determined by comparing the actual energy change from that predicted from the Hessian assuming quadratic behavior). In *PQS* a simple user-defined maximum step length is imposed (default 0.3 au).

Calculation of the exact Hessian for *ab initio* wave functions is expensive and in many cases it can be replaced by an approximation with little effect on the optimization itself, i.e., on the number of optimization cycles required to reach convergence. In some cases having the exact Hessian is a definite disadvantage. If you are fairly close on the PES to the stationary point being sought then, although an exact Hessian will likely get you there faster, the reduction in the number of optimization cycles will probably not be enough to offset the extra computational time required to compute the Hessian in the first place. (The exception is if the surface is fairly flat – long, weak bonds, or, especially, floppy systems with flat torsional potentials – in which case an exact Hessian will be a tremendous help.) A good quality Hessian will usually help the most when you are not really close to a stationary point, but within the region where the surface curvature is still appropriate, i.e., the Hessian matrix still has the correct signature (all positive eigen values for a minimum and one, and only one, negative eigen value for a transition state). Computing an exact Hessian will almost certainly be a waste of time if you

are a long way from where you finally end up; under these circumstances an exact Hessian will almost inevitably have more negative eigen values than required and the Newton–Raphson step alone will clearly be inappropriate. If you are searching for a minimum you will be far better off using an alternative for the Hessian matrix which has all positive eigen values (such a matrix is known as positive-definite) which should keep the energy going down until you get closer to the stationary point. If the gradient is large, then a few steepest descent steps, possibly with a line search, might be in order, simply to lower the energy and get to a more appropriate region of the PES.

In fact, other than in exceptional circumstances, when searching for a minimum you do not normally need to compute a full Hessian matrix at all. In most cases reasonably good starting geometries can be derived simply from “chemical intuition,” for example, C–H bond lengths (except in the rare cases of bridging hydrogens) are likely to be of the order of 1 Å, so there is no point in using a starting geometry with C–H distances differing much from this value. Very reasonable estimates of stretching, bending and also torsional force constants (diagonal Hessian elements) are readily available – for example, stretching force constants via Badgers rule (Badger 1934, 1935) (see also Schlegel 1984) – which are perfectly adequate in the vast majority of cases. Consequently you can normally come up with an approximate estimate for at least the diagonal elements of the Hessian matrix at the starting geometry using some simple empirical rules.

Once you have taken a step from one point on the PES to another (hopefully closer to the final stationary point), then you can compute an energy and a gradient at the new geometry. This information can be utilized, together with the energy, gradient, and anything else that might be to hand from the old point (or points), not only to work out a new step (the job of the geometry optimization algorithm) but also to improve (update) the original approximation for the Hessian matrix. You can think of this as similar to determining the surface curvature by finite difference on the gradient; you know the gradient where you started, you take a small step, calculate a new gradient, and determine the curvature by forward differences. Of course, updating a Hessian matrix on a multidimensional energy surface is a lot more approximate than this as typically the step taken is fairly large and you are attempting to get an update for the whole Hessian from a step in just one direction.

There are a number of different Hessian updating formulae, e.g., Murtagh and Sargent (1970) and Powell (1971), Broyden–Fletcher–Goldfarb–Shannon (BFGS) (Broyden 1970; Fletcher 1970, 1980; Goldfarb 1970; Shanno 1970), which can be used where appropriate depending on the nature of the stationary point being sought. (The exact details are not important.) For minimization the BFGS update is a popular one as, if you start out with a positive-definite Hessian matrix (with all positive eigen values), as needed for a minimum search, you are more likely to retain this desirable feature with BFGS than with the other updates. (You may see statements to the effect that the BFGS update *guarantees* retention of a positive-definite Hessian. This is not true. However, on those occasions – not too common, but they do occur – when the update fails in this regard, you can tell in advance that it is going to fail and either skip the update on that step or take a different one.)

Transition State Searches

For a minimum search then, computing an exact Hessian matrix is rarely required. Things are unfortunately not so straightforward for transition state searches. First of all transition state geometries are not as obvious as are the geometries of stable minima and so it is often quite difficult to come up with good starting structures. This can be a major problem in itself. Secondly, the correct Hessian eigen value structure is much more important for a transition state than it is for a minimum. For a transition state search, the Hessian must have one, and only one, negative eigen value, and furthermore the direction of negative curvature must correspond to that for the structure being sought; to the reaction coordinate if you will. Difficult transition state searches can be plagued with additional small negative Hessian eigen values continually reappearing which correspond to rotation of, e.g., methyl groups, way off the reaction path, i.e., on some side chain or other nowhere near the reaction center. These additional negative eigen values often interfere with the search algorithm making the final structure difficult to locate. And thirdly, there are no simple empirical rules generally available for estimating a reliable starting Hessian for transition state searches as there are for minima. All these factors make transition state searches more difficult than minimizations and in all but the simplest cases a good estimate of the Hessian for at least the region round the active center is essentially mandatory.

As is the case with minimization, once you are “on the right track,” it is not necessary to calculate fresh second derivative data at every optimization cycle, the Hessian matrix can be updated. Currently the best update for a transition state search is probably that proposed by Bofill (1994) which is a linear combination of the Powell (1971) and Murtagh and Sargent (1970) updates. This is a more flexible update than BFGS and allows the eigen value structure of the Hessian to change, which is obviously important if you get too close to a minimum. Unfortunately, unlike the case with minimization, there is no update that preserves the negative eigen value once you have it, and it is all too easy to find that the updated Hessian has either too few (zero) or too many (two or more) negative eigen values.

There are transition state search algorithms that do not require an initial starting structure; instead they take as input the two minima that you wish to connect and attempt to derive some kind of “reaction path” connecting the two. Depending on the nature of the algorithm, the maximum energy structure on this path is either the transition state itself, or a pretty good estimate for it which is subsequently refined. The original algorithm of this type was the Linear Synchronous Transit (LST) approach of Halgren and Lipscomb (1977) which mapped each atom in the reactant to a corresponding atom in the product and derived the best linear path between them in a least-squares sense. The maximum energy structure along this path provided an estimate (unfortunately often not a particularly good one) of the transition state geometry which was subsequently used as input into a standard search algorithm.

An improvement over this was Quadratic Synchronous Transit (QST) (Bell and Crighton 1984; Bell et al. 1981), which attempted to maximize along the line joining reactant and product while minimizing in all directions “orthogonal” (or conjugate) to this. One can easily see the rationale behind this approach: if the direction to be maximized could be reliably isolated from all other directions (imagine a Hessian matrix with what will become the direction of negative curvature having all zero off-diagonal matrix elements, i.e., H_{ij} ; all $H_{ij} = 0$) then it would be straightforward to maximize along the one direction while minimizing in the subspace of all the other variables. Unfortunately maintaining the orthogonality between the isolated direction and the rest of the space (i.e., keeping $H_{ij} = 0$, $j \neq i$) is rather difficult, and so the algorithm can often get lost. Nonetheless, there are several more modern algorithms based on these approaches, for example from Peng and Schlegel (1993) and Ionova and Carter (1993).

If the “reaction coordinate” can be reliably confined to just a couple of (ideally one) variables, then a very good starting geometry for a transition state search can be obtained from an optimized potential scan. Here the variable in question is scanned over a range of values (hopefully including the value the variable has in the transition state) and at each scanned value all other degrees of freedom are minimized. In effect this involves a series of constrained optimizations over the scanned variable. Once again, the transition state is taken to be the geometry at the highest energy found during the scan. (If the highest energy occurs at either of the scan endpoints then either the scan range needs to be extended or there is no transition state in the region of the PES that is being explored.) An optimized potential scan is easy to set up with *PQS* and is normally a very reliable method, albeit potentially time consuming, of obtaining an excellent transition state starting geometry provided that the principal reaction coordinate can be successfully identified.

Choice of Coordinates

In the discussion so far the choice of coordinates in which to carry out minimizations or transition state searches has not been specifically mentioned, although in certain cases – for example, when considering a potential scan – it is implicitly assumed that variables familiar to chemists, such as bond lengths and angles, have been employed. Virtually all quantities of interest that are actually computed in *ab initio* quantum chemistry, such as first (gradient) and second (Hessian) derivatives are calculated in terms of Cartesian coordinates and the molecular geometry, regardless of how it may be input, is stored and manipulated internally as a set of Cartesians. However, Cartesian coordinates are usually not the best choice when it comes to actually carrying out a geometry optimization, because they are generally too coupled. The only case where they are regularly used in the actual geometry optimization itself is in molecular mechanics.

In the late 1960s and early 1970s the so-called *Z*-matrix was widely used in quantum chemistry, initially simply as a means of inputting the molecular geometry,

but later as a means of defining a set of internal coordinates in which to carry out the optimization. With a *Z*-matrix, the geometry can be defined in terms familiar to a chemist using individual (primitive) bond lengths, bond angles, and torsions. The first atom defined in the *Z*-matrix is placed at the origin of a standard Cartesian axis system (i.e., at 0.0, 0.0, 0.0), the second is placed along the *Z* axis at a distance *R*₁, say, and the third in the *XZ* plane at a distance, *R*₂, from the second atom and making an angle, *A*₁, with the first atom (or vice versa). Thereafter the position of all subsequent atoms is given in terms of a bond distance, a bond angle and, say, a torsion, relative to three previously defined atoms. In the days before graphical user interfaces (GUI) and model builders, the *Z*-matrix became a regular way of defining and reading a molecular geometry into the program doing the actual calculation. Dummy atoms could be included in the *Z*-matrix (and were needed to help define linear arrangements of three or more atoms for which the torsion was undefined) and, once geometry optimizations were regularly performed in *Z*-matrix coordinates, the writing of a successful *Z*-matrix became almost an art form, with the aim of defining the *Z*-matrix variables so that the value of any one of them could be changed without changing the values of any of the others, the idea being to reduce the coupling between the variables to a minimum.

A well-defined set of internal coordinates usually performs better in a geometry optimization, i.e., converges in less optimization cycles, than the same optimization carried out in Cartesian coordinates. The playing field can be leveled, particularly for standard organic molecules, if the geometry is preoptimized in advance using a molecular mechanics force field (ensuring a reliable starting geometry) and if second derivative information – computed very cheaply during the mechanics minimization – is transferred to the *ab initio* optimization (Baker and Hehre 1991). However, as the system to be optimized gets larger and/or more complicated, Cartesian coordinates become less and less competitive with respect to a good set of internal coordinates.

The *Z*-matrix is rarely used today. With the increasing popularity of GUIs and model builders it is no longer needed as a means of geometry input, and *Z*-matrix coordinates have been superseded as a coordinate set for optimization, first by natural internal coordinates (Fogarasi et al. 1992; Pulay et al. 1979) and then by delocalized internal coordinates (Baker et al. 1996). The latter, which are linear combinations of stretches, bends, and torsions (as opposed to the individual primitive internals in a *Z*-matrix), are readily generated from an underlying set of Cartesian coordinates and decouple the coordinate set (in a linearized sense) to the maximum extent possible (Baker et al. 1996). In large systems, reductions in the number of optimization cycles to reach convergence by an order of magnitude or more compared to Cartesians can be readily achieved. There is an additional computational cost in using delocalized internal coordinates however, as the transformations required to convert the Cartesian gradient into the gradient over delocalized internals, and – in particular – to convert the new geometry in internals back into Cartesians for the next optimization step (the back-transformation), are expensive and increasingly so with increasing system size. They scale formally as $O(N^3)$, where *N* is a rough measure of the system size, although this can readily

be reduced to $O(N^2)$ (Baker et al. 1999). There have been attempts to reduce the scaling to $O(N)$ (Farkas and Schlegel 1998; Paizs et al. 2000), but I think it is fair to say that these have not been entirely successful. It is principally because of the unfavorable scaling in the coordinate transformations that internal coordinates have not been adopted in molecular mechanics.

The cost of the coordinate transformations and the overall complexity of the algorithm is not really a factor in ab initio methods and the majority of geometry optimizations in modern quantum chemistry packages are carried out in delocalized internals (Baker et al. 1996) or in some other set of redundant internal coordinates (Peng et al. 1996; Pulay and Fogarasi 1992).

The Modified Newton–Raphson Step

We have already seen that the Newton–Raphson step is a pretty good one provided that the eigen value structure of the Hessian matrix is appropriate to the stationary point being sought. What should you do if it is not? An early effort to take remedial action under these circumstances was due to Poppinger (1975) who proposed that, when searching for a transition state, if the negative eigen value was lost then take a step uphill in the direction of the lowest positive eigenvector, while if an additional (unwanted) negative eigen value appeared, then take a step downhill in the direction of the least negative eigenvector. While this approach should lead you back into the right region of the PES, it has at least two drawbacks. Firstly, unlike the Newton–Raphson step which, when appropriate, minimizes/maximizes along all directions on the PES (all Hessian modes) simultaneously, here you are minimizing/maximizing essentially along one direction only. Secondly, successive such steps following a particular Hessian mode tend to become linearly dependent, which degrades many of the standard Hessian updating procedures.

A much better step was subsequently proposed by Cerjan and Miller (1981) which involved modifying the standard Newton–Raphson step with a so-called shift parameter, λ . In terms of a diagonal Hessian representation, the Newton–Raphson step given by Eq. 4 can be written as

$$\mathbf{h} = \sum_i -\frac{F_i \mathbf{U}_i}{d_i}, \quad (10)$$

where \mathbf{U}_i is the i -th eigenvector, d_i is the corresponding eigen value, and $F_i = \mathbf{U}_i^T \mathbf{g}$ is the component of the gradient along the local eigen mode \mathbf{U}_i .

The modified Newton–Raphson step is given by

$$\mathbf{h} = \sum_i -\frac{F_i \mathbf{U}_i}{d_i - \lambda}, \quad (11)$$

where λ can be regarded as a shift parameter on the Hessian eigen values. A suitable choice of λ can guide the step in a particular direction; for example if λ is close to a

particular eigen value d_i , then the step taken will be predominantly in the direction of the corresponding eigenvector. In the early to mid-1980s, several groups were working on this topic, and several alternative transition state search algorithms were proposed differing only in the recipe used to determine the value of λ (Banerjee et al. 1985; Cerjan and Miller 1981; Simons et al. 1983).

The principal optimization algorithm in *PQS*, both for minima and transition states, is the eigenvector following (EF) algorithm developed in 1986 (Baker 1986). It is based on the Rational Functional Optimization (RFO) approach of Simons and coworkers (Banerjee et al. 1985) which was found at the time to provide the best recipe for determining the shift parameter, λ . In this approach, the energy on the PES following a step \mathbf{h} is written as (see Eq. 1):

$$E(x+h) = E(x) + \frac{\mathbf{g}^T \mathbf{h} + \frac{1}{2} \mathbf{h}^T \mathbf{H} \mathbf{h}}{1 + \mathbf{h}^T \mathbf{S} \mathbf{h}}. \quad (12)$$

In the original formalism, the matrix \mathbf{S} was a diagonal scaling matrix but in most practical implementations (certainly in the EF algorithm) it is taken as a unit matrix.

Applying the stationary condition $dE/dh = 0$ to Eq. 12 gives the RFO eigen value equation (Banerjee et al. 1985):

$$\begin{pmatrix} \mathbf{H} & \mathbf{g} \\ \mathbf{g}^T & \mathbf{0} \end{pmatrix} \begin{pmatrix} \mathbf{h} \\ 1 \end{pmatrix} = \lambda \begin{pmatrix} \mathbf{S} & \mathbf{0} \\ \mathbf{0} & \mathbf{1} \end{pmatrix} \begin{pmatrix} \mathbf{h} \\ 1 \end{pmatrix}. \quad (13)$$

The dimensionality of Eq. 13 is one more than the number of variables (n). As it is an eigen value equation, there are $(n+1)$ eigen values, λ ; normally the lowest one, λ_1 , is the one you need. Expanding out Eq. 13 gives

$$(\mathbf{H} - \lambda \mathbf{S}) \mathbf{h} + \mathbf{g} = \mathbf{0}, \quad (14)$$

$$\mathbf{g}^T \mathbf{h} = \lambda. \quad (15)$$

In terms of a diagonal Hessian representation, and with \mathbf{S} a unit matrix, Eq. 14 rearranges to Eq. 11, and substitution of Eq. 4 into the diagonal form of Eq. 15 gives

$$\Sigma_i - \frac{F_i^2}{\lambda - b_i} = \lambda, \quad (16)$$

which can be used to iteratively evaluate λ .

The eigen values, λ , of Eq. 13 have the following properties (Banerjee et al. 1985):

1. The $(n+1)$ eigen values of Eq. 13 bracket the n eigen values of the Hessian:
 $\lambda_i \leq d_i \leq \lambda_{i+1}$.

- At convergence to a minimum both \mathbf{g} and \mathbf{h} are $\mathbf{0}$. The lowest eigen value, λ_1 , of Eq. 13 is also zero and the other n eigen values are those of the Hessian at the minimum point, i.e., $\lambda_{i+1} = d_i$ for all i . Thus, near a local minimum, λ_1 is negative and approaches zero at convergence.
- For a saddle-point of order μ (i.e., a stationary point with μ negative eigen values) the zero eigen value of Eq. 13 at convergence separates the μ negative and $(n - \mu)$ positive Hessian eigen values.

The separability of the positive and negative Hessian eigen values led Simons and coworkers to suggest that the problem be reformulated into μ principal modes to be maximized and $(n - \mu)$ modes to be minimized. There would be two shift parameters, λ_p and λ_n , one for modes along which the energy is to be maximized and the other for which it is minimized. The RFO eigen value equation (Eq. 11) could thus be partitioned into two smaller P-RFO equations, and each one solved separately.

For a transition state, in terms of a diagonal Hessian representation, this gives rise to the two matrix equations:

$$\begin{pmatrix} d_1 & F_1 \\ F_1 & 0 \end{pmatrix} \begin{pmatrix} h_1 \\ 1 \end{pmatrix} = \lambda_p \begin{pmatrix} h_1 \\ 1 \end{pmatrix}, \quad (17)$$

$$\begin{pmatrix} d_2 & 0 & & F_1 \\ 0 & \ddots & & \vdots \\ & & d_n & F_n \\ F_2 & \dots & F_n & 0 \end{pmatrix} \begin{pmatrix} h_2 \\ \vdots \\ h_n \\ 1 \end{pmatrix} = \lambda_n \begin{pmatrix} h_2 \\ \vdots \\ h_n \\ 1 \end{pmatrix}. \quad (18)$$

λ_p is the highest eigen value of Eq. 17; it is always positive and approaches zero at convergence. λ_n is the lowest eigen value of Eq. 18; it is always negative and again approaches zero at convergence.

The above discussion assumes that, for a transition state search, the energy is to be maximized along the lowest Hessian mode, d_1 , and minimized along all the higher modes. However, as first pointed out by Cerjan and Miller (1981), it is possible to maximize along modes other than the lowest and in this way obtain transition states for alternative reactions and rearrangements from the same starting point. The ability of the algorithm to “walk” on the PES, maximizing along different Hessian eigen modes, is why the algorithm is known as Eigenvector Following. For maximization along the k -th mode, instead of the lowest, Eq. 17 would be replaced by

$$\begin{pmatrix} d_k & F_k \\ F_k & 0 \end{pmatrix} \begin{pmatrix} h_k \\ 1 \end{pmatrix} = \lambda_p \begin{pmatrix} h_k \\ 1 \end{pmatrix}, \quad (19)$$

and Eq. 18 would now exclude the k -th mode but include the lowest. Since what was originally the k -th mode is the mode along which the negative eigen value is required, if the search is to be successful this mode must eventually become the lowest mode. The mode that is actually followed during each optimization cycle is the mode which has the largest overlap with the mode followed on the previous cycle. In this way the same mode should hopefully be followed from cycle to cycle as it makes its way through the ranks from k -th position to first (lowest). Once the mode being followed has become the lowest, mode-following is switched off and it is always the lowest mode that is followed.

Although it was developed primarily for transition states, the EF algorithm is also a very powerful minimizer. For minimization the standard RFO-step is taken (requiring a single shift parameter) using Eq. 13. Mode following for transition state searches is useful if you want to explore the PES in detail, but it is likely to be expensive and requires reliable Hessian information to be effective. There will almost certainly be more variables, and hence more Hessian modes, for a given system than there are different transition structures associated with that system; furthermore it is not always obvious which mode to follow at any given point in order to locate a transition state of a desired type. Beware of low energy modes which if followed will lead to rotational barriers for torsions in side chains rather than to the transition state for the main reaction being sought.

GDIIIS

As well as the EF algorithm, the *PQS* package has another algorithm for structure minimization: GDIIIS (Csaszar and Pulay 1984). This is an extension of Pulay's ubiquitous DIIS (Direct Inversion in the Iterative Subspace) procedure for accelerating SCF convergence (Pulay 1980, 1982), only applied instead to geometry optimization.

The essence of the DIIS approach is that parameter vectors (in this case the geometry) generated in previous iterations $\mathbf{x}_1, \mathbf{x}_2, \dots, \mathbf{x}_m$ are linearly combined to find the best geometry in the current iteration. We can express each parameter vector in terms of its deviation from the final solution, \mathbf{x}_f : $\mathbf{x}_i = \mathbf{x}_f + \mathbf{e}_i$. If the conditions $\sum_i c_i \mathbf{e}_i = 0$ and $\sum_i c_i = 1$ are satisfied, then it is also the case that $\sum_i c_i \mathbf{x}_i = \mathbf{x}_f$. The true error vectors, \mathbf{e}_i , are of course unknown. However, they can be approximated by $\mathbf{e}_i = -\mathbf{H}^{-1} \mathbf{g}_i$ (i.e., by the Newton–Raphson step). Minimization of the norm of the residuum vector $\sum_i c_i \mathbf{e}_i$ taking into account the constraint equation $\sum_i c_i = 1$ leads to a system of m equations (Csaszar and Pulay 1984):

$$\begin{pmatrix} B_{11} & B_{12} & \dots & B_{1m} & 1 \\ B_{21} & B_{22} & \dots & B_{2m} & 1 \\ \vdots & \vdots & & \vdots & \vdots \\ B_{m1} & B_{m2} & \dots & B_{mm} & 1 \\ 1 & 1 & \dots & 1 & 0 \end{pmatrix} \begin{pmatrix} c_1 \\ c_2 \\ \vdots \\ c_m \\ -\lambda \end{pmatrix} = \begin{pmatrix} 0 \\ 0 \\ \vdots \\ 0 \\ 1 \end{pmatrix}, \quad (20)$$

Where $B_{ij} = \langle \mathbf{e}_i | \mathbf{e}_j \rangle$, the scalar product of the error vectors \mathbf{e}_i and \mathbf{e}_j , and λ is a Lagrange multiplier.

The coefficients, c_i , obtained from Eq. 20 are used to calculate an intermediate interpolated geometry:

$$\mathbf{x}'_{m+1} = \sum_i c_i \mathbf{x}_i, \quad (21)$$

and a corresponding interpolated gradient vector

$$\mathbf{g}'_{m+1} = \sum_i c_i \mathbf{g}_i. \quad (22)$$

A new, independent geometry is generated from the interpolated geometry by acting on the interpolated gradient with the (approximate) Hessian,

$$\mathbf{x}_{m+1} = \mathbf{x}'_{m+1} - \mathbf{H}^{-1} \mathbf{g}'_{m+1}. \quad (23)$$

Equations 20, 21, 22, and 23 constitute a complete cycle of the GDIIS method. Convergence can be tested for in the usual way (based on the gradient and the displacement from the previous step) or on the norm of the GDIIS residuum vector.

The size of the GDIIS subspace, m , increases by one after each optimization cycle. Experience with the method suggests that m should not be allowed to grow too large; once a predefined maximum size has been reached (say 20, the current default in *PQS*), the earliest vectors are dropped out as new vectors are added. Intermediate quantities (geometries and error vectors) within the GDIIS subspace need to be stored, so limiting the subspace size also limits the storage requirements of the method. (This is not really an issue with GDIIS, but is more important with DIIS, where potentially large-dimension Fock and possibly density matrices are stored.)

GDIIS was originally used in what is termed “static” mode, in which the original estimate for the Hessian matrix was used throughout the optimization procedure. In fact GDIIS performs very well with a simple unit matrix approximation for the Hessian. However, it certainly performs better if the Hessian matrix is updated. It is particularly important that the Hessian approximation remain positive definite, and so the BFGS update is strongly recommended with the update skipped if it is determined that this property is in danger of being lost.

Geometry Optimization and Symmetry

Many molecules have symmetry and it is definitely advantageous to utilize as much symmetry as possible during the calculation of the energy, the gradient and, if it is being computed, the Hessian. Various quantities, particularly the geometry and the gradient, can be symmetrized during the optimization step itself, thus removing numerical round-off error and resulting in a cleaner, and occasionally faster, optimization. Most programs can utilize at least Abelian point-group symmetry,

resulting in savings in computational time by up to a factor of 8, depending on the molecular symmetry.

If symmetry is utilized during a geometry optimization it obviously restricts the search on the PES to structures that retain the molecular symmetry, i.e., it excludes symmetry-breaking geometries. This can be particularly useful during a transition state search as, if it is known that the motion in the transition state breaks symmetry, then the transition state search can be replaced by a minimization within a symmetry-restricted subspace, usually a much simpler prospect. For example, consider ethane. The minimum, lowest energy structure has staggered C–H bonds and D_{3d} symmetry. The transition state for rotation about the C–C bond has eclipsed C–H bonds and D_{3h} symmetry. The latter can in fact be found by a simple minimization utilizing D_{3h} point-group symmetry as the path to the D_{3d} minimum is unavailable under the symmetry constraint. The minimum under D_{3h} symmetry is actually a transition state once the symmetry constraint is removed.

This illustrates another pitfall that occasionally catches out the novice: A structure that has been minimized under a symmetry constraint is not necessarily a true minimum and its identity should be confirmed by a full vibrational analysis. As a corollary to this, a transition state located under a symmetry constraint may not be a true transition state either; it could have one (or more) symmetry breaking modes with negative curvature.

Performance for Minimization

We have had a lot of theory. How well, for example, does the standard eigenvector following (EF) algorithm perform in practice? This is illustrated in Table 1 for a selection of ten organic molecules, selected at random from the fragments library in the graphical user interface *PQSMol* available for use with PQS (2010). These systems were all optimized using a molecular mechanics force field (it is not important which one) and symmetrized prior to being stored.

There have of course been a number of previous comparisons of the performance of various optimization algorithms. I mention two in particular, as I was involved in them myself. In 1991 Baker and Hehre compared the performance of the EF and GDIIS minimization algorithms, as implemented in the version of *Spartan* available at that time, on a test set of 20 organic molecules with a variety of structural motifs (Baker and Hehre 1991). The two algorithms performed similarly, but the main focus of this paper was to demonstrate that, provided reliable second derivative information was available, i.e., a good starting Hessian, then Cartesian coordinates were just as efficient as Z-matrix coordinates for routine geometry optimization. A later paper Baker (1993) did the same thing for Cartesians versus natural internal coordinates on a larger test set of 30 mainly organic molecules. This latter test set became a kind of “standard” for checking improved optimization algorithms and several papers showing minor enhancements in performance (as would be expected with the passage of time) for these 30 molecules were published subsequently (Bakken and Helgaker 2002; Eckert et al. 1997; Lindh et al. 1995; Swart and

^aStandard EF algorithm used with a maximum allowed step size in the optimization space of 0.3 au and a BFGS Hessian update; convergence criteria were the standard *PQS* defaults – maximum component of the gradient vector less than 0.0003 au and either a maximum predicted displacement of 0.0003 au or an energy change from the previous cycle of less than 10⁻⁶ Eh

^bStarting Hessian was a unit matrix

^cStarting Hessian was computed using PM3 by central-differences on the Cartesian gradient

^dDiagonal elements of the starting Hessian were estimated using simple empirical rules

^eConverged to higher energy local minimum

Bickelhaupt 2006). A similar test set is also available for transition structures (Baker and Chan 1996).

The conclusion in Baker (1993) was that with a reasonable starting geometry and a good initial Hessian, optimizations in Cartesian coordinates were as efficient as those employing natural internal coordinates. However, there were certainly signs that, as the system size increased, the use of natural internals became more and more advantageous even if a reliable starting Hessian was available, and it was further concluded that with no initial Hessian information, natural internals (for which read also delocalized internals which have more-or-less replaced them) were in general superior to both Cartesian and Z-matrix coordinates, and for unconstrained optimization were therefore the coordinates of first choice.

One of the issues with the published studies (Baker 1993; Baker and Hehre 1991) is that the size of the systems in both test suites (all molecules had less than 30 atoms, and most much less), although typical for the time (the early 1990s), is pretty small by today's standards. The molecules in Table 1 are about 50 % larger on the average, four of them have more than 30 atoms, with the largest having 48. The level of theory used, B3LYP/6-31G*, is also more typical of today. They are still only average-sized molecules, but nonetheless are representative as far as performance is concerned.

All the conclusions reached in the previous studies are fully supported by the results shown in Table 1. The use of a decent Hessian, even just an approximate one at the starting geometry (in this case computed by central differences using

the semiempirical PM3 method (Stewart 1989)), improves the performance of minimizations in Cartesian coordinates substantially, by up to a factor of almost 7 (cis-decalin) and by an average over all 10 molecules of around 3.5. Despite this, Cartesian coordinates are not really competitive with delocalized internals under the same conditions, taking about 45 % more cycles on the average to reach convergence. The performance of Cartesians is notably worse for large, floppy molecules with no symmetry (amp-5 and sucrose). Perhaps surprisingly, the performance of delocalized internals using the standard default Hessian (estimating diagonal matrix elements only using simple empirical rules) is even better, with the number of optimization cycles being the same or less than with the PM3 starting Hessian for all systems except one (alanine).

Of some surprise, at least to me, is the relatively poor performance of internal coordinates when no Hessian information (a unit matrix) is used. They are certainly better than Cartesian coordinates under the same conditions, which require about 75 % more cycles on the average to converge, but perform over three times worse than when the default diagonal Hessian is used, showing the advantages of even rudimentary information about the surface curvature.

One of the molecules in Table 1, bicyclo-2,2,2-octane, took significantly less optimization cycles to converge in Cartesian coordinates with a unit Hessian (12) than with the same optimization in delocalized internal coordinates (29); the reverse is the case for all of the other systems. This apparent anomaly is due to the fact that the Cartesian unit Hessian optimization converged to a higher energy local minimum than the other optimizations. This was not the only occasion when this occurred: higher energy local minima were also found for amp-5 and to a lesser extent for sucrose and alanine (although in the latter case the difference was only 40 μ H and may well be simply due to premature convergence, a fairly common occurrence for unit Hessian Cartesian optimizations (Baker et al. 1996)).

These results support another assertion made in Baker (1993), namely, that Cartesian optimizations tend to converge to the nearest local minimum whereas optimizations in natural (or delocalized) internals tend to converge more globally. This global tendency, and that is really all it is, with the internal coordinate optimizations is principally due to the fact that relatively small displacements in internal coordinates can lead to large changes when the geometry is converted back to Cartesian coordinates. For example a small change in a central bond angle can lead to a large Cartesian displacement at the end of a lengthy attached side chain; such large displacements enable internal coordinate optimizations to “jump over” local minima. (This phenomenon was first observed in the days of the Z-matrix.)

This is an appropriate point to emphasize that all the optimization algorithms discussed so far in this chapter are local methods, aimed at locating a single stationary point. Whether this is the lowest energy structure on the entire PES, i.e., the global minimum, is quite another matter. The number of (mainly conformational) minima a molecule has increases dramatically with system size and the problem of locating the one with the lowest energy quite quickly becomes almost insurmountable. Additionally, of course, unless the global minimum is noticeably lower in energy than other low-lying local minima, there will be a Boltzmann distribution at room

temperature with several different minima having appreciable population; under these circumstances to talk about a well-defined structure does not make a lot of sense.

Problems in locating global minima have only recently become an issue in *ab initio* calculations as the size of the systems that can be handled using these techniques has increased significantly in recent years. A number of global search algorithms are available, although none of them are bulletproof (i.e., absolutely guaranteed to locate the global minimum in a finite time). The problem of global minimization is outside the scope of this chapter and the interested reader is referred to the existing literature for more detail (Pardalos et al. 1995).

Minimization: An Example

Figure 2 shows the optimization output at each cycle in the standard default EF minimization of indole. There is more printout than normal for the first and last cycles as I have used a higher print flag in order to show more detail. The output is of course specific to *PQS* but would be similar – at least in terms of the quantities printed – in other programs.

At the beginning of each optimization cycle the current geometry is printed in Cartesian coordinates together with the point group (C_s) and the number of degrees of freedom (29). Indole is planar and is oriented in the *XY* plane; consequently all *Z*-coordinates are zero. Next comes the SCF energy at that geometry and the Cartesian forces (the gradient – not normally printed). The latter should fully reflect the symmetry of the system, which it does in this case, and so all *Z*-gradient components are zero.

This is followed by a symmetry analysis of the set of delocalized internal coordinates generated for indole which results in the elimination of all primitive torsions, all of which are fixed by symmetry. This analysis is typically done once only as thereafter the delocalized internal coordinates formed and used on the first cycle are retained unaltered throughout the optimization. One does not have to do this; several algorithms (e.g., Schlegel and coworkers (Peng et al. 1996)) effectively regenerate a set of active delocalized internals on each optimization cycle although in most cases this is not necessary and does not improve the overall performance.

There is then a statement as to how many Hessian modes (eigenvectors) are used during the construction of the optimization step – this does not have to be all of them, but is usually most, and cannot be more than the total number of degrees of freedom – followed by a listing of the corresponding Hessian eigenvalues (the curvature along each of the eigenvector directions). In this particular optimization, a diagonal Hessian in the underlying space of primitive internals (individual stretches, bends and torsions) is estimated using empirical rules, and is then transformed into the space of selected delocalized internal coordinates, \mathbf{U} , via $\mathbf{H} = \mathbf{U}^T \mathbf{H}_{\text{prim}} \mathbf{U}$ (Baker et al. 1996). The simple RFO step is then computed and taken, appropriate for minimization, resulting in a single shift parameter, λ (see

Fig. 2 *PQS* output for the minimization of indole

Eq. 16), with a value of -0.01172058 . The resulting step length of 0.174879 is below the default maximum of 0.3 and so no scaling of the step is required.

The parameter values, and their gradients and displacements are then printed out. As with the Cartesian forces, these are not normally printed, and are not particularly informative given that each coordinate is potentially a linear combination of all underlying primitive internals (minus the torsions in the case of indole). A persistently large gradient for a particular coordinate would suggest some problems with the overall coordinate set, suggesting that either the delocalized internals, the underlying primitives or likely both, should be regenerated.

The convergence criteria – current value, tolerance, and whether or not convergence is satisfied – are then printed, together with details of the back-transformation (conversion of the current geometry in internal coordinates back into Cartesians, again not normally printed). This constitutes a complete optimization cycle.

On subsequent optimization cycles, assuming that the system is converging, the energy, the gradient components (both Cartesian and internal) and the step size should all decrease, with the latter two tending to zero. This is exactly what occurs for indole (see Fig. 2) which converges smoothly to the minimum energy structure. Another quantity that should tend to zero is the shift parameter, λ , which

again clearly does so; its magnitude on the last cycle is 0.00000011. Note that, as previously stated (see the comments under Eq. 16) λ is always negative and so approaches zero from below. The closer λ is to zero, the closer is the step taken to the simple Newton–Raphson step.

After the initial estimate, the Hessian matrix is updated at the beginning of each new optimization step. This is done using the BFGS update, as appropriate for a minimization. Indole is a planar, rigid molecule and so, not surprisingly, convergence is achieved quickly taking just five optimization cycles. At final convergence the displacement criteria is not fully satisfied; this is not an error as the default convergence criteria in *PQS* allow for just one of the displacement and energy change criteria to be satisfied (see the footnotes under Table 1); this is to prevent wasteful cycles near the end of the optimization for excessively floppy molecules for which relatively large displacements result in only small changes in energy. If it is desired that the displacement criterion be rigorously satisfied, then the energy criterion should be reduced so that it is almost impossible to satisfy (for example to 10^{-8} Eh); Convergence can then only be achieved by satisfying the displacement criterion.

Transition State Searches: An Example

Figure 3 shows the optimization output at each cycle (truncated for the intermediate cycles) in the standard default EF transition state search for the reaction $\text{HCN} \leftrightarrow \text{HNC}$. This is a very simple reaction but is still instructive. Both reactant and product are linear. Reaction can be considered to occur essentially by motion of the hydrogen atom in a semicircle centered about the midpoint of the C–N bond, with the $\angle\text{HCN}$ angle going from 180° in HCN to 0° in HNC (CNH).

Consider the starting geometry. A first approximation to the transition state (TS) geometry might be to position the hydrogen atom directly vertically above the midpoint of the C–N bond. (The H–C distance of course has to be decided.) This corresponds to $\angle\text{HCN}$ a bit less than 90° . However, knowing the relative energetics (HNC is less stable than HCN, the reaction as written is endothermic), the Hammond postulate (Hammond 1955) suggests that the TS is likely to resemble HNC more than HCN, in which case $\angle\text{HCN}$ will very likely be noticeably less than 90° , i.e., relative to HCN we have a late transition state. Now this is only a simple consideration, but the use of “chemical intuition” in this way can potentially save several optimization cycles. In this particular example, it does not save much because the system as a whole only has three atoms and the transition state is fairly easy to locate, but starting with $\angle\text{HCN} = 85^\circ$ instead of 70° costs an extra optimization cycle, and starting with $\angle\text{HCN} = 130^\circ$ takes three more cycles. (The other starting parameters were $r\text{C} - \text{N} = 1.21 \text{ \AA}$ and $r\text{H} - \text{C} = 1.5 \text{ \AA}$.) As has already been mentioned, a good initial Hessian is almost mandatory for a TS search and a full Hessian at the starting geometry was computed at the semiempirical PM3 level (Stewart 1989) for the $\text{HCN} \leftrightarrow \text{HNC}$ reaction.

The output for a transition state search is of course similar to that for a minimization. Quantities such as the Cartesian geometry, the SCF energy, the forces, parameter values, and displacements are common to both TS searches and minimizations and are printed out in the same way. The first difference occurs in the treatment of the starting Hessian: for the indole minimization (Fig. 2) a default Hessian, diagonal in the underlying space of primitive internals, is used whereas the TS search started with a full, albeit approximate, Cartesian Hessian which needs to be transformed into internal coordinates. This transformation is done once only, on the first optimization cycle, as thereafter the Hessian will be updated.

Note the comment printed on cycle 1 that the Hessian transformation does not include the derivative of the \mathbf{B} -matrix. The \mathbf{B} -matrix (Wilson et al. 1955) formally relates a displacement in internal coordinates (q) to one in Cartesian coordinates (X), $\Delta q = \mathbf{B}\Delta X$, and it turns out that a full transformation of the Hessian to internal coordinates requires the derivative of the \mathbf{B} -matrix; the precise equation is Pulay (1977):

$$\mathbf{H}^{\text{int}} = \mathbf{B}^{\text{inv}} \left(\mathbf{H}^{\text{cart}} - \mathbf{g}^{\text{int}} \frac{d\mathbf{B}}{d\mathbf{X}} \right) (\mathbf{B}^{\text{inv}})^{\text{T}}, \quad (24)$$

Fig. 3 PQS output for the HCN \leftrightarrow HNC Transition State Search

where

$$\mathbf{B}^{\text{inv}} = (\mathbf{B}\mathbf{B}^{\text{T}})^{-1}\mathbf{B}, \quad (25)$$

and a superscript ^T represents a matrix transpose.

If you require an *exact* transformation of all quantities from Cartesian to internal coordinates, then the $d\mathbf{B}/d\mathbf{X}$ term must be included; however it is usually advantageous to leave it out as its inclusion often changes the Hessian eigen value structure. In general, Cartesian Hessian matrices with a known eigen value structure will retain that structure if the $d\mathbf{B}/d\mathbf{X}$ term is omitted; this is far from guaranteed when it is included. When starting off a geometry optimization (either a minimization or a TS search) using an optimized geometry and starting Hessian obtained from a previous calculation at a lower level of theory – a common occurrence – then the $d\mathbf{B}/d\mathbf{X}$ term should almost certainly be omitted. Note that for a Hessian transformation at a stationary point, the gradient is zero in any case and so the $d\mathbf{B}/d\mathbf{X}$ term will also be zero. For the HCN \leftrightarrow HNC TS search the starting Hessian has the correct eigen value structure, i.e., one negative eigen value, so our initial geometry was at least reasonable.

The other major difference from the indole minimization is with the shift parameter(s). A TS search uses the P-RFO step, as opposed to the simple RFO step used for minimization (see Eqs. 17, 18, and 19), and so there are *two* shift parameters instead of just one. As explained previously, one shift parameter maximizes along the TS mode (the eigenvector with the negative eigen value), while the other minimizes along all the other Hessian modes. The first shift parameter is positive

while the other is negative. On the first cycle the computed step length is initially greater than the default maximum of 0.3 and so the step is scaled down (by 0.888690).

As with a minimization, on subsequent optimization cycles the gradient components and the step size should both decrease, tending to zero if the structure is converging. The two shift parameters, λ , also both tend to zero, one from above and the other from below. On the last cycle they are both zero to all eight decimal places printed out. The energy may increase or decrease, depending on whether the increase in energy from maximization along the TS mode is greater or smaller than the decrease in energy from minimization along all the other modes; the change in energy however should of course again tend to zero. (Overall a decrease in energy is the more likely, especially as the system gets larger, as the number of modes which are minimized becomes far greater than the single mode along which the energy is maximized.)

The Hessian update, at the beginning of each new optimization step, is done using the Bofill formula (Bofill 1994), which is the default for a TS search. This is a linear combination of the Powell (1971) and Murtagh and Sargent (1970) updates, and the two mixing coefficients are printed out. They vary from cycle to cycle, as can be seen (Fig. 3). The final TS geometry is well converged (in six cycles), with the three convergence criteria all well below their respective tolerances.

Using Optimized Potential Scans in Transition State Searches

We turn now to a somewhat more complicated example, namely, a search for the transition state for the parent Diels–Alder reaction between *cis*-1,3-dibutadiene and ethylene to give cyclohexene. Here we use an optimized potential scan to obtain an initial approximation to the TS geometry. The starting geometry for the potential scan is shown in Fig. 4. This was obtained by building cyclohexene using *PQSMol*, the graphical user interface for PQS (2010), and then stretching the appropriate C–C bonds ($C_{10} - C_{13}$ and $C_7 - C_{16}$ as shown in Fig. 4) to separate off an ethylene fragment. The overall system symmetry (C_s) was maintained using the symmetrization tools available in *PQSMol*. The $\angle HCH$ angles in the ethylene fragment are likely to be too acute, but this will be rectified during the potential scan.

The $C_{10} - C_{13}$ and $C_7 - C_{16}$ distances in the starting geometry (see Fig. 4; the two distances are equivalent by symmetry) are 1.720 Å. What we are going to do is scan this distance over a range of (increasing) values, at each scanned value optimizing all the remaining degrees of freedom. If the scanned variable(s) is a good approximation to the reaction coordinate, and if the value of the variable at the transition state geometry lies within the scanned range, then what we should see is a maximum in the energy somewhere along the scan. The (optimized) geometry at this energy maximum should be a very good approximation to the transition state.

An optimized potential scan is effectively a series of constrained geometry optimizations, with the constraint being the scanned variable. *PQS* has powerful

Fig. 4 Starting structure for potential scan for Diels–Alder TS search

algorithms for constrained optimization using the method of Lagrange multipliers (Baker 1992, 1997; Baker and Bergeron 1993). Because of the symmetry of the system, the scanned variable is not a single distance but rather a linear combination (with equal weights) of the $C_{10} - C_{13}$ and $C_7 - C_{16}$ distances. The requested linear combination is normalized by the program and so the actual parameter scanned is $\frac{1}{\sqrt{2}} [(r_{C_{10} - C_{13}}) + (r_{C_7 - C_{16}})]$. The potential energy scan module in *PQS* is capable of scanning any linear combination of primitive internal coordinates selected by the user.

The optimized energies at $C_{10} - C_{13}$ and $C_7 - C_{16}$ distances from 1.720 Å to about 2.65 Å are shown in Table 2. Note that, although the final level of theory used in this chapter for all examples given is B3LYP/6-31G*, the scan was actually carried out using the smaller 3-21G (Binkley et al. 1980) basis set. This is simply to save computer time. I expect the B3LYP/3-21G energy surface to be very similar to the B3LYP/6-31G* one in this system, and since we are using the optimized scan to obtain a good, but still approximate, starting geometry for the proper TS search, there is no point using the larger basis set for the scan.

As can be seen in Table 2, there is a clear energy maximum at a parameter value somewhere around 8.75. The parameter printed out is the sum of the two scanned C–C distances (unnormalized) given in atomic units (bohr); the maximum is equivalent to a C–C distance of 2.315 Å. During the scan, the first energy (from

the starting geometry) took the most optimization cycles (12) to converge; thereafter each subsequent point typically converged in five to seven steps. Note that if the scanned range is insufficient to locate the maximum, it can simply be extended. For example, if the initial scan only went as far as 8.00 bohr (for the combined C–C distances), then it can be repeated for distances greater than this starting from the last optimized geometry found. That the scan needs to go to greater C–C distances is clear from the energy, which is increasing over the initial scan range; if it had been decreasing then one would need to go to shorter C–C distances.

The full B3LYP/6-31G* TS search commenced using the optimized geometry at the scan maximum with a full Hessian matrix computed at this geometry using the 3-21G basis (the same basis as used in the scan). Not surprisingly this starting Hessian had the desired one negative eigen value, and the search converged in just four optimization cycles, indicating just how good the geometry resulting from the scan was. A full vibrational analysis at the B3LYP/6-31G* level on the converged transition state structure indicated that it was indeed a genuine TS. The C₁₀–C₁₃ and C₇–C₁₆ distances in the final TS were 2.272 Å, very close to those in the structure at the scan maximum.

Comparison of Experimental and Theoretical Geometries

Before turning to the second part of this chapter, the computational simulation of vibrational spectra, I want to make a few comments on the accuracy of theoretically computed geometries. Direct comparison with reliable experimental data shows that theoretical geometries are now really very accurate indeed, particularly for “normal” organic molecules. The level of theory used here, B3LYP/6-31G*, is typically accurate for, say, bond angles to within a few degrees and bond lengths to within 0.02 Å at worst, and if any experimental bond distance differs by much more

than this from the theoretical value, it is more likely in my opinion for experiment to be in error rather than theory. One needs to bear in mind that none of the experimental methods commonly used in molecular structure determination, X-ray crystallography, microwave spectroscopy, nuclear magnetic resonance (NMR) etc., measure a bond distance directly; rather some kind of spectrum (or pattern) is obtained which has to be interpreted, and bond distances are extracted indirectly from this. It was fairly typical in the early 1970s (and even into the 1980s) for X-ray diffraction structures to be published, as a set of Cartesian coordinates, which resulted in quite ridiculous bond distances involving hydrogen. This was due principally of course to the difficulty in locating hydrogen atoms because of the much lower electron density surrounding hydrogen nuclei compared to heavier elements, and the fact that this density could easily be displaced in bonds involving more electronegative atoms. From the mid-1970s onward it became increasingly more common for theoretically computed bond distances involving hydrogen to be used in the fitting of X-ray data; this also resulted in much better agreement with heavy atom bond distances as well (Schäfer 1983).

Another factor to be considered is that theory and experiment do not quite measure the same thing. Within the Born–Oppenheimer approximation (Born and Oppenheimer 1927; Wikipedia 2010), theory ideally determines the geometry at the bottom of the well, at the energy minimum, whereas this geometry is inaccessible to experiment due to the existence of zero-point vibrational energy. Such differences, however, are usually minor.

Table 3 provides a comparison between optimized B3LYP/6-31G* and experimental geometrical parameters for a number of small, organic molecules. These results were taken from two papers published in the mid-1990s; a DFT study of some organic reactions (Baker et al. 1985) and a systematic DFT study of fluorination in methane, ethane, and ethylene (Muir and Baker 1996). The focus was mainly on the energetics, but many computed and experimental geometrical parameters were provided. The theoretical approaches did not include B3LYP, using instead a related functional (Becke's original ACM (Becke 1993; see also Hertwig and Koch 1997), better known today as B3PW91), but I have reoptimized all the geometries at the B3LYP/6-31G* level for compatibility with this chapter.

As can be seen from Table 3, the agreement between the computed and experimental geometrical parameters is excellent. The mean average deviation between the B3LYP/6-31G* and experimental bond lengths is just 0.006 Å, with a maximum error (for the C–N triple bond in HCN) of 0.022 Å. The mean average deviation for bond angles is only 0.8°. Such results are typical.

Included in Table 3 is the series of fluorine-substituted methanes: mono-, di-, tri-, and tetra-fluoromethane. These compounds exhibit a well-known substituent effect (the geminal effect) of decreasing C–F bond length (and increasing bond strength) with increasing fluorine substitution on the same carbon atom. This effect of fluorine (not seen with any of the other halogens) has been known for a long time (although there are still arguments about the explanation for it) and is very accurately reproduced by the theoretical calculations.

Geometry Optimization of Molecular Clusters

The situation at the time of writing is that molecular structures for stable or metastable minima are readily located theoretically using powerful optimization algorithms usually carried out in natural, delocalized or redundant internal coordinates. The resulting structural parameters (computed using B3LYP or better with a decent basis set) are typically in excellent agreement with experimental results where these are available. The location of transition states can be more difficult, but perseverance usually brings its reward. Theoretical calculations are essentially the only means for providing structural data on transition states as they are extremely difficult to study experimentally.

One area where standard natural or delocalized internal coordinates are not the best choice is for optimizing the geometry of molecular clusters. For larger clusters the problem of global versus local minimization becomes an issue, but even for relatively small clusters (containing half-a-dozen or so molecules) deriving a set of coordinates suitable for an efficient optimization from stretches, bends, and torsions alone usually results in poor optimization performance. One reason for this is that there are really two different types of forces involved in determining the structure of a molecular cluster: the normal, fairly strong intramolecular forces that determine the geometry of each individual molecule, and the weak intermolecular forces that determine the arrangement of each molecule relative to the others. The latter are best described in terms of scaled inverse distance coordinates (*not* standard distances) and an efficient algorithm which uses normal primitive internal coordinates to describe the geometry of each molecule in the cluster, and scaled inverse distances (with a cutoff) to describe the relative position of the cluster molecules with respect to each other (Baker and Pulay 2000) is available in *PQS*. The resulting set of coordinates, which are linear combinations of standard primitive internals and scaled inverse distances, are known as cluster coordinates.

Examples of geometry optimization of some small molecular clusters are shown in Table 4. Optimization performance using cluster coordinates ($1/R$ with a 5 Å cutoff) is compared with Cartesian coordinates. A modest level of theory was used (Hartree–Fock with the 3-21G basis set) and all optimizations were started with a unit Hessian matrix. In most cases the starting geometry was poor, and very far from the final converged structure. No comparisons with natural or delocalized internal coordinates are included in Table 4; with such poor starting geometries this is usually a waste of time as the large changes that occur in the relative positions of molecules in the cluster often result in individual bond angles, as defined, exceeding 180° causing problems with the various transformations, particularly the Cartesian backtransformation. This is yet another reason why standard internal coordinates are inappropriate for optimizing the geometry of molecular clusters. This is not a problem with inverse distance (or simple distance) coordinates as these are defined essentially from zero to infinity.

As shown in Table 4, cluster coordinates typically converge much faster than Cartesians (on average for the seven clusters shown by a factor of almost 5) and usually – but not always – to lower energy structures. (Five out of the seven

Table 4 Comparison of the performance of cluster coordinates and Cartesian coordinates for the optimization of some small molecular clusters

converged to lower energies than the corresponding Cartesian optimizations, two to higher.) The starting and final geometries are shown for the eight water molecule cluster in Fig. 5.

Geometry Optimization in the Presence of External Forces

I want to end this section by briefly mentioning a simple but relatively new technique which has proven to be very useful in deriving potentially new molecular structures. It was originally developed to study the geometrical changes inferred in atomic force microscopy and similar experiments (known collectively as mechano-chemistry) (Beyer and Clausen-Schaumann 2005), but can be applied as a general optimization tool which also has potential for the location of transition states. This is geometry optimization in the presence of external forces (Wolinski and Baker 2009) known as enforced geometry optimization (EGO). The force is applied along a straight line joining any two atoms in the molecule under study, either to push the two atoms together or to pull them apart. Whatever force is applied to one atom of the pair, an equal and opposite force is applied to the other. This ensures that there is no tendency for the molecule to translate or rotate; in essence it remains in place

under simulated pressure. Forces can be applied between as many pairs of atoms as desired, although calculations to date have typically involved only a single pair of atoms.

If you are applying an external force to, say, push two atoms together in a stable molecule there will be a tendency for a bond to form between the two atoms. If the applied force is insufficient to form a bond (or if a bond won't form anyway), there will be some minor geometrical changes as the system endeavors to compensate for the excess force. If the applied force is sufficient, then what you should see is the energy rise as the two atoms are pushed together, then fall as the bond forms and additional molecular rearrangement occurs. The final "optimized" geometry will still involve a structural arrangement under considerable strain, but if this structure is allowed to relax (by reoptimizing with the additional force removed) it could well converge to a new, stable geometry, different from the initial structure. If it does so, then the maximum energy structure found as the two atoms were pushed together is often a reasonable estimate for the transition state joining the original and the new structure.

The method as described above has been used to find seven previously unknown geometrical isomers of $C_{10}N_2H_8$, starting from the ground-state geometry of *cis*-azobenzene, at the B3LYP/6-31G* level by pushing together various pairs of atoms, one from each of the two benzene rings (Wolinski and Baker 2009). All of the new structures were classified by vibrational analysis, and all were found to be minimal. Transition states between each of the new structures and *cis*-azobenzene were also located and characterized. Additional calculations were carried out at MP2/6-311G** to ensure that the energetics remained stable. The technique overall shows considerable promise for the discovery of new chemistry and new chemical structures.

Molecular Vibrations

A molecular system containing N atoms nominally has $3N$ degrees of freedom. In Cartesian coordinates, one can consider each degree of freedom as separate X , Y , or Z displacements of each atom about its equilibrium position. This atomic motion can be induced for example by heat or by interaction with light or other electromagnetic radiation. Because the atoms in a molecule are connected by chemical bonds, the various atomic motions are coupled. In a classical treatment, it turns out that three of these motions involve overall translation of the system as a whole (along the X , Y , and Z directions of a standard Cartesian axis system), and three of them involve overall rotation of the system as a whole (about the same axes). These are known as rigid-body motions. The Cartesian axes pass through (they have their origin at) the center of mass of the system and the X , Y , and Z axes coincide with the principal axes of inertia of the undistorted molecule. Under these rigid-body motions the positions of the atoms in the molecule relative to each other remain unchanged, and so the potential energy of the system in a vacuum is also unchanged. The remaining $3N - 6$ coupled motions, which do affect the relative atomic positions and hence the

potential energy, are classified as molecular vibrations. (Note that a linear molecule has $3N - 5$ vibrations, not $3N - 6$, as one of the rotations – that about its own axis – cannot be observed, and is effectively ignored.)

To a reasonable approximation, at least for small displacements, the vibrations in a polyatomic molecule can be described as a kind of simple harmonic motion. This is essentially equivalent to considering a chemical bond between two atoms as a weightless spring that obeys Hooke's law (i.e., the force is proportional to the displacement). The simplest vibration is that in a diatomic molecule, and we can refer back to the potential energy curve for He_2^{2+} (Fig. 1) as an example. At the minimum, near the bottom of the well, the potential energy curve is indeed parabolic to a very good approximation.

The force/displacement equation for a diatomic molecule obeying Hooke's law is

$$F = -kq, \quad (26)$$

where F is the applied force, k is the so-called force constant, and q is the displacement from equilibrium. The negative sign indicates that the force exerted by the spring is in a direction opposite to that of the displacement. The potential energy stored in the spring (the integral of force over distance) is

$$E = \frac{1}{2}kq^2. \quad (27)$$

By Newton's second law of motion, the force can also be given by mass times acceleration

$$F = m \frac{d^2q}{dt^2}. \quad (28)$$

The two forces in Eqs. 26 and 28 are one and the same, and so the differential equation relating displacement, q , with time, t , for the harmonic oscillator is

$$m \frac{d^2q}{dt^2} + kq = 0. \quad (29)$$

The solution to Eq. 29 is

$$q(t) = A \cos(2\pi\nu t); \quad \nu = \frac{1}{2\pi} \sqrt{\frac{k}{m}}, \quad (30)$$

where A is the amplitude of the vibrational coordinate q and ν is the fundamental frequency of the vibration. The "mass," m , is actually the so-called reduced mass, μ , which for a diatomic molecule A–B, with atomic masses m_A and m_B , respectively, is given by

$$\frac{1}{\mu} = \frac{1}{m_A} + \frac{1}{m_B}. \quad (31)$$

Using the reduced mass ensures that the center of mass of A–B remains unchanged during the vibrational motion.

From Eq. 27 the force constant, k , is given by

$$k = \frac{d^2 E}{dq^2}. \quad (32)$$

The force constant in a one-dimensional system (a system with a single degree of vibrational freedom) is thus directly related to the curvature of the potential energy surface, i.e., the shape of the well. From the force constant, one can directly determine the fundamental frequency (via Eq. 30). In a polyatomic molecule the single $d^2 E/dq^2$ term is replaced by the Hessian matrix, \mathbf{H} (often called the force constant matrix). In Cartesian coordinates this is the same Hessian matrix introduced in Eq. 4 when discussing the Newton–Raphson step during a geometry optimization, and a classical treatment of molecular vibrations and the Newton–Raphson step both assume the same thing about the potential energy surface, namely that it is quadratic. The only major difference is that a vibrational analysis involves the atomic masses, whereas the potential energy surface is independent of mass. The fundamental vibrational frequencies for a polyatomic molecule can be extracted from the mass-weighted Hessian matrix, and the normal modes (the coupled motion of the atoms during the vibration) can be obtained by a suitable treatment of the Hessian eigenvectors. The precise steps involved are as follows:

1. Mass-weight the Cartesian Hessian matrix.

$$\mathbf{H}_{ij}^{\text{MW}} = \frac{\mathbf{H}_{ij}}{\sqrt{m_i m_j}}. \quad (33)$$

2. Project out the translations and rotations from the mass-weighted Hessian.

As discussed briefly above, the translational and rotational degrees of freedom can be separated out from the vibrations for a rigid body. This requires shifting the origin of the coordinate system to the center of mass, determining the principal moments and the rotation generators, setting up orthogonal coordinate vectors for translation and rotation about the principal axes of inertia, setting up a projection matrix \mathbf{P} from these vectors and using it to “remove” the translations and rotations from the Hessian matrix, leaving only the vibrational modes.

If the orthogonal set of vectors representing translation and rotation (there are six of them, each of length $3N$, where N is the number of atoms) are given by \mathbf{R} , then the projection matrix \mathbf{P} is formed by

$$\mathbf{P}_{ij} \ (i \neq j) = -\sum_k \mathbf{R}_{ik} \mathbf{R}_{jk}; \quad \mathbf{P}_{ii} = 1 - \sum_k \mathbf{R}_{ik} \mathbf{R}_{ik}, \quad (34)$$

and the projected Hessian is given by

$$\mathbf{H}^{\text{P}} = \mathbf{P} \mathbf{H}^{\text{MW}} \mathbf{P}^{\text{T}}. \quad (35)$$

3. Diagonalize the projected, mass-weighted Hessian matrix.

The effect of the projection leaves the eigenvectors of the Hessian corresponding to translations and rotations with exactly zero eigen values (or at least zero within numerical round-off error), allowing the $3N - 6$ nonzero vibrations to be separated out. These are converted to cm^{-1} prior to print out, and the corresponding eigenvectors are mass-weighted and normalized to become the normal modes. The mass-weighting uses isotopically averaged atomic masses based on the average isotopic abundance for each atom.

At first sight it might be surprising that the Hessian matrix, which after all in *ab initio* molecular orbital theory is inherently quantum mechanical, is amenable to a purely classical treatment. This is because the Born–Oppenheimer approximation (Born and Oppenheimer 1927; Wikipedia 2010) allows for a pretty good separation of the electronic and nuclear motion, allowing the latter to be treated classically. A quantum mechanical description of the simple harmonic oscillator leads to quantized energy levels given by

$$E_n = h\nu \left(n + \frac{1}{2} \right); \quad \nu = \frac{1}{2\pi} \sqrt{\frac{k}{m}}, \quad (36)$$

where the fundamental vibrational frequency, ν , is exactly the same as in a classical description (Eq. 30). The quantum number, n , takes integer values $0, 1, 2, \dots$ and so even in the vibrational ground-state ($n = 0$) there is a residual energy, $\frac{1}{2}h\nu$, known as the zero-point energy. This is a fundamental quantum mechanical property of all oscillators at the absolute zero of temperature (Einstein and Stern 1913).

A molecular vibration is excited when the system absorbs a quantum of energy, $h\nu$, corresponding to the vibrational frequency, ν , of one of its normal modes. This is commonly accomplished under standard conditions by interaction with infrared (IR) radiation. An IR spectrum can be recorded by passing a beam of infrared light covering a range of frequencies through the sample. This can be done by using a monochromatic beam which changes in wavelength over time, or by using a Fourier Transform instrument which effectively measures all wavelengths at once. From this a transmission (or absorbance) spectrum can be produced showing at which frequencies/wavelengths the sample absorbs.

Not all normal modes are IR active, i.e., result in the absorption of energy at the normal mode frequency. In order for a normal mode to be IR active, its motion must result in a change in the dipole moment of the vibrating molecule. For example, the totally symmetric C–H stretch in methane (in which all four C–H bonds are vibrating in the same way simultaneously) does not change the molecular dipole moment (which is zero in any case), and so this mode is IR inactive. Change one of the hydrogen atoms for a fluorine, however, and it is a different picture. In general, molecules with a permanent dipole moment in their ground-state geometries give rise to more intense signals in the IR spectrum (i.e., greater absorbance) than molecules in which a dipole moment is induced by the vibration itself.

Vibrational excitation can occur, and usually does, in conjunction with rotational excitations, resulting in vibration-rotation spectra. For straightforward IR vibrational spectra, the simultaneous rotational excitations result in broadening of the vibrational bands. Bands are additionally broadened if two (or more) normal modes have frequencies close to one another, as well as by instrument resolution and other experimental artifacts. Additional bands, other than those caused by vibrational fundamentals, can arise in the spectrum by the absorption of two or more quanta of energy simultaneously, giving rise to combination and overtone bands, and by further excitations from already vibrationally excited states which give rise to what are called hot bands.

It is worth noting at this point that although our analysis of vibrational motion derives from consideration of the simple harmonic oscillator, many common features observed in vibrational spectra are present precisely because the potential energy surface is not harmonic. For example, transitions between vibrational energy levels in the quantum harmonic oscillator formally allow the quantum number, n , to change only by 1 ($\Delta n = \pm 1$). As the vibrational energy levels are equally spaced (see Eq. 36), this means that light of only one frequency can be absorbed, that of the vibrational fundamental for each normal mode, and there are no overtone bands. The $\Delta n = \pm 1$ selection rule does not apply to an anharmonic oscillator and the observation of overtones is only possible because vibrations are anharmonic. A further consequence of anharmonicity is that the spacing between the vibrational energy levels decreases with increasing quantum number (eventually reaching a continuum allowing for vibrational dissociation) which results in the frequency of the first overtone being slightly less than twice the frequency of the vibrational fundamental.

IR spectroscopy is a very important method in molecular structure determination. Even though the normal modes depend on the whole molecule, certain structural motifs have very similar motions regardless of how many atoms the molecule contains. For example, virtually all molecules containing a carbonyl group give rise to an intense (because of the bond polarity) signal in the IR spectrum around $1,800\text{ cm}^{-1}$ due to excitation of the C = O stretch, thus allowing for the identification of this group. Theory can not only determine the fundamental frequencies and normal modes of a molecule, but by computing the dipole moment derivatives, it can reliably estimate the resulting band intensities as well, enabling the IR spectrum for the vibrational fundamentals to be predicted a priori.

Another technique used in vibrational spectroscopy is Raman scattering (Raman and Krishnan 1928). This normally uses visible light, which is typically scattered by the molecule. Most of the light is scattered elastically at the same frequency as the initial radiation (Rayleigh scattering), but a small amount interacts with the system, excites a vibrational mode, and is scattered inelastically at a lower frequency. If the system is already in a vibrationally excited state, then the scattered radiation can have a higher frequency than the initial radiation. These are known as Stokes and anti-Stokes Raman scattering, respectively. Raman scattering constitutes only a very small component of the total scattered radiation (only about one part in 10^7) and a major difficulty in Raman spectroscopy is to separate out the weak, inelastic

scattering from the intense Rayleigh scattered light. The frequency difference corresponds to, e.g., the frequency of one of the molecules normal modes.

As with IR spectroscopy, not all of a molecules vibrations are active in the Raman spectrum. In order for a vibrational mode to be Raman active, the motion must result in a change in the polarizability of the electron charge cloud surrounding the molecule. The degree of change determines the intensity of the band. Whether or not a band is Raman, or indeed IR, active can be determined in advance by a symmetry analysis of the normal modes. In molecules with no symmetry, all bands are potentially both IR and Raman active, but if the molecule has symmetry then vibrations of certain symmetry types may be inactive in either the Raman or the IR spectrum, or both. For example, in a molecule with a center of symmetry (such as trans-1,2-dichloroethylene; point group C_{2h}), the symmetric modes (a_g and b_g for C_{2h}) are Raman active but IR inactive, and vice versa for the unsymmetric modes. The intensity of a Raman band can be determined theoretically by calculating the molecule's polarizability derivatives.

The polarization of Raman scattered light also contains useful structural information. This property can be measured by using plane polarized light and a polarization analyzer. Spectra recorded with the analyzer set both parallel and perpendicular to the excitation plane can be used to calculate the depolarization ratio of each vibrational mode. This provides insight into molecular orientation and the symmetry of the vibrational modes, as well as information about molecular shape. It is often used to determine macromolecular orientation in crystal lattices, liquid crystals, or polymer samples.

Yet another spectroscopic method that can be used to help determine molecular structure is vibrational circular dichroism (VCD). This technique detects differences in attenuation of left and right circularly polarized light passing through the sample. VCD is sensitive to the mutual orientation of groups of atoms in a molecule and provides three-dimensional structural information. It is especially important in the study of chirality and molecular conformation. Only chiral molecules have a VCD spectrum. In particular, molecules that have either a plane of symmetry or a center of symmetry are VCD inactive.

The differential absorption of polarized light in vibrational circular dichroism is proportional to the rotational strength, a quantity that depends on both the electric and magnetic dipole transition moments. For a vibrational transition from the ground (g) to an excited vibrational state (e), this is given by

$$R(g \rightarrow e) = \text{Im}(\langle g | \mu_{\text{el}} | e \rangle \langle e | \mu_{\text{mag}} | g \rangle), \quad (37)$$

where μ_{el} and μ_{mag} are the electric and magnetic dipole operators, respectively. These quantities can be calculated theoretically, enabling VCD intensities to be computed. For details see the review by Stephens and Lowe (1985). Modern computational approaches use so-called gauge-invariant atomic orbitals (GIAOs) for the magnetic component (Bak et al. 1995) (as does *PQS*) which are particularly efficient, and the computation of VCD rotational strengths as part of a vibrational analysis is now almost routine.

IR, Raman, and VCD spectroscopy all excite the same vibrational fundamentals. The respective vibrational spectra are different because the mechanism by which light is absorbed is different in each case, the amount of absorption depending on changes in the dipole moment, the polarizability and the rotational strength, respectively. All these quantities are amenable to computation, and modern *ab initio* theory can reliably predict the frequencies of a molecule's vibrational fundamentals as well as the intensity of the signal in IR, Raman, and VCD spectra. The latter in particular are greatly assisted by electronic structure calculations; comparison of experimental and theoretical VCD spectra enable absolute molecular conformations to be determined.

1,2-Dichloroethane: An Illustrative Example

Figure 6 shows the *PQS* output for a full vibrational and thermodynamic analysis of *trans (anti)* 1,2-dichloroethane following a geometry optimization under C_{2h} symmetry at the B3LYP/6-31G* level of theory. It includes IR and Raman intensities obtained from the dipole moment and polarizability derivatives, respectively. (Because of its symmetry the system is not VCD active.) In *PQS*, dipole moment derivatives are computed analytically along with the Hessian matrix and atomic axial tensors (for VCD rotational strengths) (Bak et al. 1995) are computed in the same module that calculates NMR chemical shifts. Polarizability derivatives are obtained numerically by finite difference on the force (gradient) in the presence of a series of external electric fields. The number of applied fields varies with the molecular symmetry but requires a maximum of 12 separate single-point energy plus gradient calculations in the worst case (when the system is C_1).

Fig. 6 PQS vibrational frequency output for trans-1,2-dichloroethane

The first thing printed out is the name of the file containing the Hessian matrix. In *PQS* a vibrational and thermodynamic analysis is done independently of the Hessian computation enabling a full vibrational analysis of isotopomers to be carried out from the same Hessian matrix simply by changing the atomic masses. Analysis is done on any matrix read from the Hessian file, including partial and/or approximate Hessians (e.g., an updated Hessian left over from a geometry optimization), so care must be taken that the source of the Hessian matrix is known. A vibrational analysis of an approximate Hessian will of course, at best, be only approximate; in particular an analysis based on a geometry optimized at one level of theory and a Hessian matrix computed at another (lower) level of theory is, strictly speaking, invalid.

Then comes a list of the vibrational frequencies in atomic units after the translations and rotations have been projected out. This is simply a printout of the eigen values of the projected mass-weighted Hessian (see Eq. 35); as can be seen, the six eigen values corresponding to the translations and rotations are all zero. The remaining eigen values are all positive, showing that the optimized structure of trans-1,2-dichloroethane is a genuine minimum. As any decent chemist should know, 1,2-dichloroethane has two stable conformations, trans and gauche; the former is the more stable by around $1.5 \text{ kcal mol}^{-1}$ (El Youssoufi et al. 1998a, b). This energy difference is sufficiently small that both conformers will be present, certainly at room temperature, and experimental vibrational spectra of 1,2-dichloroethane, unless recorded at very low temperature, will contain bands from the gauche as well as the more abundant trans conformer. This will be discussed in more detail later in this chapter.

This is followed by a list of all symmetry types possible for the vibrational modes. This is simply a list of the irreducible representations present in the character table for the molecule's symmetry point group; for trans-1,2-dichloroethane, having C_{2h} symmetry, this is a_g, b_g (symmetric motions) and a_u, b_u (antisymmetric).

All $3N - 6$ normal modes (Cartesian displacements for each atom) are then listed, together with as much information for each mode as is available, depending on which, if any, of the dipole derivatives, the polarizability derivatives or the rotational strengths have been computed for the molecule in question. For trans-1,2-dichloroethane all these quantities are available except the latter, so listed for each mode is its symmetry type, its frequency in wavenumbers (cm^{-1}), whether or not the mode is IR active, the corresponding IR intensity, the X, Y and Z dipole derivatives with respect to the motion in each normal mode, whether the mode is Raman active, its corresponding Raman intensity and its Raman depolarization ratio. If the molecule were VCD active, its rotational strength (relative intensity in a VCD spectrum) would also be printed.

As already noted, whether a mode is IR or Raman active can be determined in advance (although its intensity cannot) by group theoretical considerations and depends on its symmetry type. For trans-1,2-dichloroethane (because of its point group symmetry) each mode is *either* IR active *or* Raman active, but not both, and so IR and Raman spectroscopy excite completely different vibrational fundamentals. In the Raman spectrum, only bands of a_g and b_g symmetry will appear. These can be distinguished experimentally by measuring the depolarization ratio; according to theory (Wilson et al. 1955), the depolarization ratio of totally symmetric modes (a_g under C_{2h}) is less than 0.75 (these are called polarized bands) whereas that of all other modes is 0.75 (depolarized bands). (See the depolarization ratios calculated for trans-1,2-dichloroethane in Fig. 5.)

The vibrational analysis is followed by a standard, classical statistical thermodynamic analysis at 298.18 K (25 °C) and 1 atm pressure. (For details, see McQuarrie (2000)). Computed quantities include the principal axes and moments of inertia, the rotational symmetry number and symmetry classification, and the translational, rotational, vibrational, and total enthalpy and entropy, respectively.

Fig. 7 Simulated IR and Raman spectra using data derived from Fig. 6: (a) IR Spectrum, (b) Raman Spectrum

Both the temperature and pressure can be altered from standard conditions and/or scanned across a requested range of values. The total zero-point energy at 0 K is given by $\sum_v \frac{1}{2} h\nu$, summed over all real frequencies (converted to kcal mol⁻¹; see Eq. 36).

The predicted IR and Raman spectra, based on the data printed out from the vibrational analysis in Fig. 6 are shown in Fig. 7. These are direct “screen captures” from *PQSVIEW*, which is the job output and visualization component of the *PQSMol* GUI (PQS 2010). For each spectrum, the frequency range (horizontal axis), the intensity range (vertical axis), and the band half-width (fitted using a Lorentzian band profile) can be varied; it is also possible to “zoom in” on selected regions of the spectrum.

So how good are the results? First of all it should be noted that we would not expect theory to be able to exactly reproduce experimental vibrational spectra as factors such as intensity and bandwidth depend strongly on experimental conditions (as to some extent do the frequencies themselves). Also, most importantly, the theoretical analysis assumes harmonic behavior, whereas the real spectrum is of course anharmonic. So we would expect the calculated vibrational fundamentals to deviate from experiment simply because they are harmonic, without even considering other sources of error (such as incomplete basis set and approximate treatment of electron correlation). For the level of theory used here, B3LYP/6-31G*, the average (mean) error between computed (harmonic) vibrational fundamentals and experimentally observed (anharmonic) values is around 50 cm⁻¹. For example, in a study of 900 individual vibrational fundamentals from 111 different small molecules using B3LYP and a polarized-valence triple-zeta basis, Schlegel and coworkers (Halls et al. 2001) found an average absolute deviation between theory and experiment of 44.69 cm⁻¹.

Agreement with experiment can be much improved by scaling. This has been done since the early days of Hartree–Fock theory, when all computed HF/6-31G* frequencies were regularly scaled by a factor of around 0.89. Optimized Hartree–Fock bond lengths are typically too short compared with experiment; hence computed frequencies are almost uniformly too high. Single scale factors, applied directly to computed vibrational fundamentals, have since been derived for a range of other wave functions, including post-HF and DFT. A recent paper from Radom and coworkers derived least-squares fitted scale factors for more than 100 different levels of theory (varying both the methodology and the basis set) (Merrick et al. 2007). Scale factors for DFT-based methods are much closer to unity than scale factors derived using Hartree–Fock (which completely neglects electron correlation) showing that the raw (unscaled) results are simply better. The scale factor for B3LYP/6-31G* is 0.9614 (Merrick et al. 2007).

Scaled Quantum Mechanical Force Fields

Although scaling of the computed vibrational frequencies using a single, global, scale factor is common, the first scaling methods applied to ab initio force constants used several different scale factors to correct for systematic errors in different types of molecular deformations, e.g., stretches, bends, or torsions. This procedure requires the transformation of the molecular force field (the Hessian matrix) into chemically meaningful internal coordinates and scales the resulting Hessian elements themselves. It cannot be applied directly to the calculated frequencies. It is thus less convenient than global scaling using a single scaling factor. Largely because of its simplicity, global scaling became popular, but using multiple scale factors yields much better results as was convincingly demonstrated by Blom and Altona in a series of papers starting in the mid-1970s (Blom and Altona 1976, 1977a, b; Blom et al. 1976). Their method forms the basis of the scaled quantum mechanical (SQM) procedure which has been in widespread use for over 25 years (Pulay et al. 1983).

In the original SQM procedure, the molecular geometry was expressed in terms of a full set of nonredundant natural internal coordinates (Fogarasi et al. 1992; Pulay et al. 1979). On the basis of chemical intuition, the natural internal coordinates of all molecules under consideration (there can be more than one) are sorted into groups sharing a common scale factor, and factors for each group are determined by a least-squares fit to experimental vibrational frequencies. Force constants, originally calculated in Cartesian coordinates, are transformed into the internal coordinate representation, and scaling is applied to the elements of the internal force constant matrix (not to the individual vibrational frequencies) according to

$$\mathbf{F}_{ij} \text{ (scaled)} = \sqrt{s_i s_j} \mathbf{F}_{ij}, \quad (38)$$

where s_i and s_j are scaling factors for internal coordinates i and j , respectively.

The accuracy obtained by selective scaling in this way is naturally greater than if just a single global scaling factor were used. Additionally, scaling the force constant matrix also affects the resultant normal modes, and hence the calculated intensities (which are unaffected if only the frequencies are scaled), leading to better agreement with experimental intensities. Furthermore the vibrational frequencies derive directly from the (scaled) Hessian matrix, and are thus fully consistent with it; not the case at all if the frequencies are scaled directly.

The SQM procedure has been widely used in the interpretation of vibrational spectra. A further important role is the development of transferable scale factors which can be used to modify calculated force constants and so predict the vibrational spectrum *a priori*.

The SQM module in *PQS* uses a modified scaling procedure involving the scaling of individual valence coordinates (Baker et al. 1998) (not the linear combinations present in natural internal coordinates). This has immediate advantages in terms of ease of use, as no natural internals need to be generated (a procedure which may fail for complicated molecular topologies), and it simplifies the classification and presorting of the coordinates. In addition, the extra flexibility involved in the scaling of individual primitive internals generally leads to an increase in accuracy and to more transferable scale factors. On typical organic molecules one can expect average differences between predicted SQM and experimental fundamentals of around 10 cm^{-1} with maximum errors of about 30 cm^{-1} or so (Baker and Pulay 1998). In my experience, if differences greatly exceed this maximum, it is more likely that the observed experimental peaks have been misassigned than the predicted SQM frequency is wrong.

1,2-Dichloroethane: A Further Analysis

We are going to apply the SQM method to the existing Hessian matrix for trans-1,2-dichloroethane in order to improve the agreement with experiment; furthermore, we will also need to consider the gauche conformer which will almost certainly contribute to the experimental vibrational spectra at room temperature.

The results of a vibrational analysis of gauche-1,2-dichloroethane, optimized at the B3LYP/6-31G* level, are shown in Fig. 8. This is direct printout from the corresponding *PQS* log file (not the output file). In addition to the full output, *PQS* produces a summary output – the log file – which contains only data that is of direct interest to the user and omits all intermediate printout (such as integral and timing data, intermediate steps in an optimization etc.). As can be seen, the log file reproduces the thermodynamic analysis that is printed in the full output file, but provides only a summary of the vibrational analysis and completely omits the normal modes.

Gauche-1,2-dichloroethane has C_2 symmetry and formally all of its vibrational fundamentals are both IR and Raman active. (Additionally, unlike the trans conformer, it is also potentially VCD active.) However, several modes have only relatively low intensity and may therefore be difficult to see in the experimental

spectrum, especially given that the *gauche* is the higher energy conformer and is only expected to comprise about 13–25 % of the total at room temperature (El Youssefi et al. 1998a, b). The computed B3LYP/6-31G* energy difference between the *gauche* and *trans* conformers is 1.5 kcal mol⁻¹, including (minor) zero-point energy effects.

In the paper that introduced the scaling of individual primitive internals into the SQM method (Baker et al. 1998), a set of 11 scale factors were derived from a test set of 30 molecules containing C, H, O, N and Cl at the B3LYP/6-31G* level. These scale factors will be used “as is” to scale the raw Hessian data for both *trans* and *gauche*-1,2-dichloroethane. The seven scale factors appropriate for use with 1,2-dichloroethane as shown in Table 5.

There have been several experimental studies of the vibrational spectra of 1,2-dichloroethane. Of note are the 1975 IR and Raman measurements on the solid, liquid, and gaseous *trans* and *gauche* conformers from Mizushima and coworkers (1975), and the combined theoretical and FT-IR study of El Youssefi et al. already referred to (El Youssefi et al. 1998a, b). These results are summarized, together with the unscaled, scaled using a single scale factor (Merrick et al. 2007), and the SQM predicted fundamentals in Table 6.

^aRef. Mizushima et al. (1975)^bRef. El Youssofi et al. (1998a, b)^cReported as 3,040 cm⁻¹ in the solid^dOmitting the two highest fundamentals, maximum deviation in parentheses (see text)

The first thing to note from Table 6 is that the order and the symmetry assignments of the fundamentals is predicted to be exactly the same theoretically as found experimentally. The actual assignments as to the type of motion for each vibrational mode can be readily checked by animating the mode and observing it visually. In this regard, theory is far easier to interpret than experiment. When you determine a vibrational fundamental computationally you automatically get its normal mode, its symmetry type, its IR and Raman intensities, its depolarization ratio, indeed the whole vibrational analysis, so there is absolutely no dispute as to the bands assignment. Additionally, it is possible to do an energy distribution analysis (Pulay and Torok 1966) of the normal modes which determines which primitive internals have more than a given weight (typically 3 %) to each mode, often enabling the principal motion in the mode (assuming there is one) to be found without having to animate it.

The two sets of experimental fundamentals are for the most part in excellent agreement with each other and typically differ by 1–2 cm^{-1} only. However, there are more serious discrepancies for the two highest frequencies. These are C–H stretches which, primarily due to tunneling, often show large differences from harmonic behavior, and both the position and the intensity of these bands in the experimental spectrum can deviate significantly from theoretical predictions. They are also often difficult to determine experimentally. In this case the highest frequency for the *gauche* conformer differs by 35 cm^{-1} between the two sets of experimental values: 3,005 and 3,040 cm^{-1} . Additionally, although the agreement in this region for the *trans* conformer looks fine, Mizushima and coworkers (1975) report a value for the a_u C–H antisymmetric stretch in the solid of 3,040 cm^{-1} , compared to 3,009 cm^{-1} in the gas phase, a substantial difference. Because of these experimental differences, we have omitted the two highest frequency C–H stretches from our error analysis, and the mean average (unsigned) and maximum errors between theory and experiment is reported over 16 vibrational fundamentals (not 18).

The largest errors are of course found for the raw, unscaled frequencies, which show average differences from experiment for the two conformers of around 40 cm^{-1} (and maximum errors of about 140 cm^{-1}). These are in line with the average errors reported by Schlegel (Halls et al. 2001) previously mentioned. Despite the large average differences, even the unscaled B3LYP/6-31G* frequencies are helpful in assigning the experimental spectrum as the order is the same as that found experimentally, even if the positions are off.

Scaling even using just a single scaling factor significantly improves the comparison with experiment, reducing the average error by well over 50 %. However, the SQM results are by far the best and are genuinely predictive. Results for the *trans* conformer are typical for this approach (average error 9.3 cm^{-1} , maximum error 30 cm^{-1}) and those for the *gauche* are even better (average error 5.4 cm^{-1} , maximum error 14 cm^{-1}). In the latter case, they are three times better than using a single scaling factor, both on the average and for the maximum deviation.

A recently published SQM reappraisal of the vibrational spectrum of toluene (Baker 2008) showed a similar average deviation from the 2005 experimental study of Keefe and coworkers (Bertie et al. 2005) of 5.3 cm^{-1} (maximum error 17 cm^{-1})

Fig. 9 Predicted SQM IR spectra for 1,2-difluoroethane: (a) IR spectrum for *trans*-1,2-dichloroethane, (b) IR spectrum for *gauche*-1,2-dichloroethane, (c) IR spectrum for 1,2-dichloroethane at room temperature

and convincingly proposed that three observed bands either unassigned or assigned as combination bands were in fact fundamentals. In their 1998 SQM study of the vibrational spectra of several small fluorocarbons, Baker and Pulay (1998) proposed several reassignments to previously published experimental spectra and predicted the fundamental frequencies and IR intensities of nine other fluorocarbons for which there was, at that time, no experimental data. A subsequent jet-cooled FT-IR investigation by McNaughton and coworkers (Jiang et al. 2002) essentially confirmed all of the theoretical predictions.

The final SQM-predicted IR and Raman Spectra for 1,2-dichloroethane are shown in Fig. 9 and 10, respectively. In each case individual spectra for the *trans* and *gauche* conformers are given followed by a combined spectrum assuming a room-temperature distribution of 85 % *trans* and 15 % *gauche*.

Not surprisingly, because of its dominance at room temperature, the observed IR spectrum of 1,2-dichloroethane is predicted to look very much like that for the *trans*-conformer alone. However there are some peaks due to the *gauche* form that should be visible in room-temperature spectra and their intensity should increase at higher temperature. In particular, the CH₂ wag. at $\sim 1,300\text{ cm}^{-1}$ should have sufficient intensity to be seen in the IR spectrum and the CH₂ twist at $1,211\text{ cm}^{-1}$ should be visible in the Raman spectrum.

Fig. 10 Predicted SQM Raman spectra for 1,2-dichloroethane: (a) Raman spectrum for *trans*-1,2-dichloroethane, (b) Raman spectrum for *gauche*-1,2-dichloroethane, (c) Raman spectrum for 1,2-dichloroethane at room temperature

In addition to their results for normal 1,2-dichloroethane, Mizushima et al. also reported the experimental vibrational fundamentals for the fully deuterated isotopomer ($\text{CD}_2\text{ClCD}_2\text{Cl}$) (Mizushima et al. 1975). These are compared with the SQM scaled frequencies (using the same scaling factors as for $\text{CH}_2\text{ClCH}_2\text{Cl}$) in Table 7. (As the Hessian matrix is independent of mass, the vibrational fundamentals for all possible isotopomers can be derived from a single Hessian matrix simply by changing the mass weighting.) The agreement is again excellent, with average errors (mean average deviation) of just over 7 cm^{-1} and maximum errors around 20 cm^{-1} for both deuterated conformers. There is one frequency for the *gauche* conformer where there is significant disagreement between theory and experiment (see Table 7); this is a *b* mode observed experimentally at 707 cm^{-1} but predicted theoretically at 752 cm^{-1} . In Table 3 in Mizushima et al. (1975) this frequency is in parentheses (the only one to be thus treated) which suggests that its value is uncertain. The *trans* conformer shows an intense band at precisely this frequency (707 cm^{-1}) which is predicted to be the most intense band in the entire IR spectrum of deuterated 1,2-dichloroethane, and it may well be that a *gauche* mode was assumed to lie hidden under this intense band. The prediction here is that this is not the case, and there is an unassigned feature in the IR spectrum around 752 cm^{-1}

which should be assigned as a *gauche* fundamental. Because of the possible experimental misinterpretation, this mode was omitted from the error analysis.

As noted, *gauche*-1,2-dichloroethane is potentially VCD active. The two chiral forms of this molecule are shown in Fig. 11 together with their simulated VCD spectra. (They are denoted by *gauche*1 and *gauche*2, respectively; the rotational strengths given in Fig. 8 correspond to *gauche*1.) The VCD spectra for the two chiral conformers are precisely the opposite of each other; where one form has a positive rotational strength, the other has exactly the same magnitude but with a negative sign. In any real mixture of *gauche*-1,2-dichloroethane, however, both forms will be present in equal amounts, i.e., it will be a racemic mixture, and so overall there will be no observable VCD spectrum as everything will cancel. However, this clearly shows the potential of VCD spectroscopy to determine the absolute molecular configuration of a pure, chiral conformer.

Finally Table 8 compares optimized geometrical parameters for *trans*-1,2-dichloroethane with experimental electron diffraction data from Kvesethi as reported in El Youssoufi et al. (1998a, b).

I hope that the above has demonstrated just how useful modern theory can be for the prediction and interpretation of molecular vibrational spectra and the

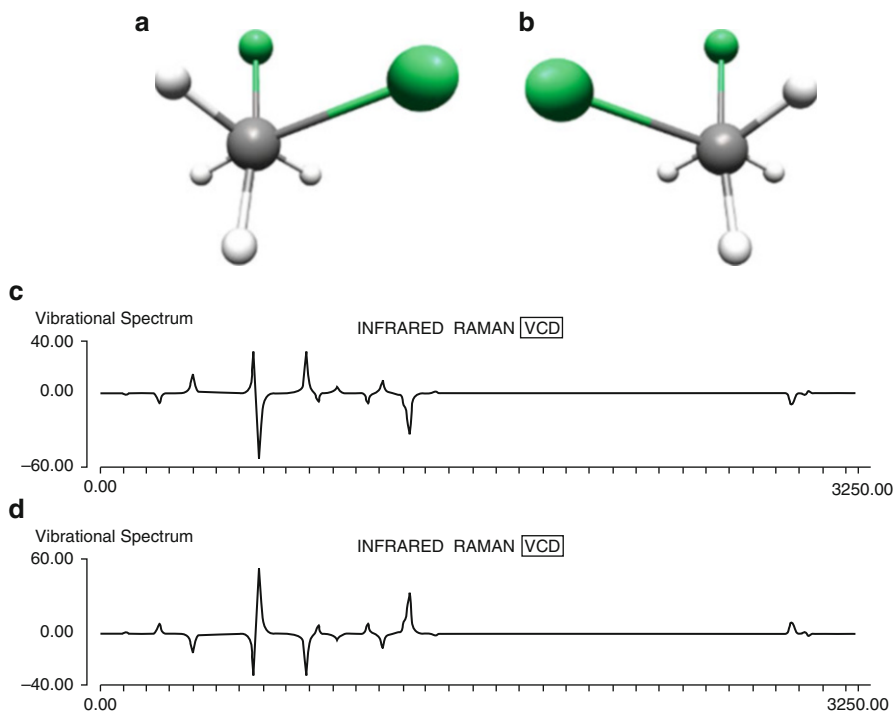

Fig. 11 Predicted VCD spectra for the two chiral forms of *gauche*-1,2-dichloroethane: (a) *gauche*1, (b) *gauche*2, (c) simulated VCD spectrum of *gauche*1, (d) simulated VCD spectrum of *gauche*2

identification and assignment of vibrational fundamentals. I have attempted to show this with a fairly extensive theoretical study (carried out especially for this chapter) on one particular molecule, 1,2-dichloroethane, rather than merely summarizing the results of previous studies.

Density Functional Theory and Weight Derivatives

Before concluding, I would like to comment on the use of weight derivatives in DFT calculations. As will be discussed, this has important ramifications for the reliable computation of DFT vibrational frequencies. Following Pople and coworkers (Johnson et al. 1993), we can write the DFT exchange-correlation energy as

$$E_{XC} = \int f(\rho) dr, \quad (39)$$

Table 8 Comparison of experimental and theoretical (B3LYP/6-31G^{*}) geometrical parameters for *trans*-1,2-dichloroethane

^bFrom Ref. Kveseth (1974), standard deviation in parentheses

where ρ represents all the density dependence, of whatever form, in the density functional $f(\rho)$. This integral is too complicated to be evaluated analytically and numerical integration has to be used. Virtually all DFT programs employ an atomic partitioning scheme pioneered by Becke (1988) to evaluate this integral, which separates the molecular integral into atomic contributions which may then be individually treated using single-center techniques.

If this is done, we can replace Eq. 39 by

$$E_{XC} = \sum_A \sum_i \omega_{Ai} f(\rho; \mathbf{r}_{Ai}), \quad (40)$$

where the first summation is over all atoms, A , and the second is over the numerical quadrature grid points, i , for the current atom. The ω_{Ai} are quadrature weights and the grid points, \mathbf{r}_{Ai} are given by $\mathbf{r}_{Ai} = \mathbf{R}_A + \mathbf{r}_i$, where \mathbf{R}_A is the position of nucleus A and \mathbf{r}_i represents a suitable quadrature grid centered on A .

Because the grid points are atom-centered they are not fixed in space, but “move with” the atom. This means that the derivative of Eq. 40 (needed for the DFT contribution to the gradient) formally has two parts:

$$\nabla_A E_{XC} = \sum_B \sum_i [\omega_{Bi} \nabla_A f(\rho; \mathbf{r}_{Bi}) + (\nabla_A \omega_{Bi}) f(\rho; \mathbf{r}_{Bi})]. \quad (41)$$

The first term in Eq. 41 looks like the numerical integral of the exchange-correlation contribution to the total energy gradient, and is the only term in a fixed grid, but the second term is formally needed and the implementation in Johnson et al. (1993) was the first time that this term – the weight derivative – was properly included.

The error in neglecting the weight-derivative term can be reduced to virtually zero by taking a large enough number of grid points, but for smaller grids its omission is not justified (Johnson et al. 1993). I suspect that the hope was that if the second term in Eq. 41 were properly included, then small grids would no longer give unreliable results, but if this was indeed the hope, it was quickly dashed when it was shown that small grids which included weight derivatives often gave worse results than calculations in which they were omitted (Baker et al. 1994). Basically you have to have a decent quadrature grid to get reliable gradients; if the grid is not

good enough using weight derivatives will not save you, if it is good enough then you probably do not need weight derivatives. At least this is typically the case for the gradient.

One clear advantage of including weight derivatives is that the gradient zero coincides essentially exactly (for minimization) with the energy minimum. If the weight derivative term is omitted and grid quality is poor then there is a strong tendency for the energy to rise near the end of a geometry optimization as the gradient supposedly decreases. This was a common occurrence with many early DFT codes almost entirely due to sloppy numerical integration.

The kind of errors in geometries seen when the DFT integration grid gets increasingly worse is shown in Table 9 which gives geometrical parameters for BLYP/6-31G* optimizations of hydrogen peroxide with a range of decreasing quality grids. The table is taken from Baker et al. (1994) for which see for more details. Results are shown with and without inclusion of the weight derivative term. As can be seen from Table 9, the HOOH torsion changes substantially with grid quality, as do some of the other parameters with the poorest quality grid. If anything, results with weight derivatives are worse than those without as grid quality worsens. The actual optimization for the poorest quality grid (grid 5) converged smoothly when weight derivatives were included, with the energy decreasing on every optimization cycle; it was only when examining the final geometry that one realizes that something is badly wrong.

The situation as far as the first energy derivative (the gradient) is concerned is that for reliable results you need a good quality grid, but if you have that then you don't really need to include weight derivatives (although there is no harm in doing so of course). For the second energy derivative (the Hessian matrix and hence vibrational frequencies) things are somewhat different. As convincingly

demonstrated by Malagoli and Baker (2003), weight derivatives are essentially *de rigueur* for the reliable computation of vibrational frequencies, particularly if heavier elements (beyond the first row) are involved. However, the reason for this is not what you might think.

It turns out that there is a potential, major difficulty in integrating derivatives of basis functions that represent core electrons on their own atomic grid. Such basis functions have large exponents and their contribution to the electron density consequently dies off very rapidly with increasing distance from the nucleus. Exponents of the order of a million or more are not at all uncommon, especially if the core – as is often the case – is represented by a contracted function, and such exponents only increase in magnitude with increasing atomic number. In order to accurately integrate a Gaussian function that dies off so rapidly a high density of points are needed near the nucleus. The numerical inaccuracy does not matter very much at all for the exchange-correlation energy, but for the gradient and especially for the second derivative, then a basis function $\exp(-\omega r^2)$ which has a small value at some grid point near the nucleus, has a magnitude $2\omega \exp(-\omega r^2)$ for its gradient and $4\omega^2 \exp(-\omega r^2)$ for its second derivative. With ω of the order of 10^6 , then the contribution of this function to the second derivative has a magnitude four trillion r^2 times its contribution to the energy at that particular grid point, i.e., it has changed from something fairly small to something potentially large, as well as having a greater radial extent. Consequently it requires a far more accurate numerical integration than it previously had.

It is possible to ameliorate this inaccuracy by increasing the grid quality, but eventually with a large enough exponent, you will simply be swamped and it will not be possible to accurately integrate the function on any viable radial grid. The tremendous advantage of including the weight derivative term (as opposed to ignoring it and in effect assuming a fixed grid) is that, when considering any derivative term, because a grid “moves with” its atom there is no need to take the derivative of any basis function centered on that atom. Thus the highly inaccurate integration of basis functions with large exponents on their own atomic center no longer needs to be carried out. In other words, the inclusion of weight derivatives is so important for reliable frequencies with DFT, not because of anything inherent in the weight derivative term itself, but because, by including them, one can completely avoid a highly inaccurate numerical integration.

If you are using DFT code which does *not* have weight derivatives, then consider carrying out any vibrational analysis with a Hessian matrix computed numerically. As noted above, the gradient is normally reliable even without weight derivatives provided the quadrature grid is of sufficient quality. The calculation will almost certainly take longer compared to computing a fully analytical Hessian, but at least it should give reasonable results.

Table 10 shows the effects of not including weight derivatives in analytical Hessian matrices on the computed B3LYP/m6-31G* harmonic vibrational frequencies for Fe(CO)₅. (The m6-31G* basis (Mitin et al. 2003) is a modified version of the 6-31G* basis for first-row transition metals (Rassalov et al. 1998) that corrects deficiencies in the latter due to the lack of a sufficiently diffuse *d*-function in the

^aFrom Malagoli and Baker (2003)

3 *d*-shell.) This Table, taken from Malagoli and Baker (2003), shows analytical frequencies computed both with and without weight derivatives using the standard grid in *PQS* (which is perfectly adequate for DFT energies and gradients) as well as a much better quality grid; additionally it gives numerical frequencies derived from a Hessian obtained via central differences on the (analytical) gradient using the standard grid.

As can be seen, all computed frequencies are in excellent agreement with one another (all agreeing within 1 cm^{-1}) except for those computed with the standard grid without weight derivatives. These results are terrible. Apart from the high frequency C–O stretches (above $2,000 \text{ cm}^{-1}$), all the e' modes show significant errors, as do the a_2'' . The low frequencies are completely wrong, the order of the fundamentals is incorrect, and there are two imaginary frequencies even though the geometry was minimized. All this is solely due to integration error.

Conclusions

Modern ab initio theory can compute a large number of molecular properties, particularly those for individual molecules – such as geometries and spectroscopic data – that are of direct relevance for experimental studies. This chapter has

concentrated on molecular structure and vibrational spectroscopy where theory can be tremendously helpful to experimentalists. Theoretical data – for example, bond lengths involving hydrogen – are now regularly used as an aid when fitting X-ray and microwave data in order to extract geometrical parameters. IR, Raman and VCD spectra can readily be simulated theoretically, with reliable estimates of both band positions and intensities, especially if the raw data is scaled via an SQM treatment. I have tried to illustrate the latter in particular by concentrating for the most part on an extensive study of a single system using a standard level of theory (B3LYP/6-31G^{*}) rather than attempting to summarize results on a large number of molecules using a variety of theoretical methods.

Thirty years ago I was attending scientific meetings and conferences in which the theoretical chemists in the audience were often attempting to justify their existence to their experimental colleagues. At that time calculations were not especially helpful to the experimentalist. The standard level of theory for most applications was Hartree–Fock, with perhaps some higher level post-HF single-point energies to hopefully improve the energetics. Computed geometries were not particularly good, computed frequencies were typically much too high (indeed, the paper introducing one of the first useable analytical Hartree–Fock second derivative codes (Pople et al. 1979) had only just been published), reaction energetics were fairly poor and barrier heights were simply not reliable. All that has changed. Today the experimentalist who refuses to consider any input from theory is just making things harder for him/herself. This is especially the case in the field covered by this chapter.

Abstract

The theory and applications of *ab initio* methods for the calculation of molecular properties are reviewed. A wide range of properties characterizing the interactions of molecules with external or internal sources of static or dynamic electromagnetic fields (including nonlinear properties and those related to nuclear and electron spins) is considered. Emphasis is put on the properties closely connected to the parameters used to describe experimentally observed spectra. We discuss the definitions of these properties, their relation to experiment, and give some remarks regarding various computational aspects. Theory provides a unified approach to the analysis of molecular properties in terms of average values, transition moments, and linear and nonlinear responses to the perturbing fields. Several literature examples are given, demonstrating that theoretical calculations are becoming easier, and showing that computed *ab initio* molecular properties are in many cases more accurate than those extracted from experimentally observed data.

Introduction

The term “molecular properties” is generally used to denote properties characterizing the interactions of molecules with internal or external sources of static or dynamic electromagnetic fields. In the description of a complex quantum-mechanical system consisting of a molecule and a field it is convenient,

both in theory and in experiment, to introduce an approximation that separates the molecule, the field, and the molecule–field interaction. One can then introduce an additional approximation and analyze the effects of the interaction only for the molecule, assuming a passive role of the interaction-induced changes in the field. In this way we can describe the interaction between the field and the molecule in terms of what we can consider intrinsic properties of the molecule.

Most spectroscopic methods assume that the experiment can be described in terms of these molecule–field interactions. There is, therefore, often a very close connection between the parameters used to describe the experimental spectra and the molecular properties that describe the molecule–field interactions probed by the experiment. The set of properties describing the influence of external electric and magnetic fields – static and time-dependent, spatially uniform or nonuniform – can be used to determine parameters that enter into the analysis of different experimental spectra. In particular, optical properties describe the interactions of a molecule with an external electromagnetic radiation field, and characterize both linear and nonlinear responses to the fields. Other sets of molecular properties describe the interactions of external magnetic fields and the magnetic fields due to the spins of all particles – that is, nuclear spins (specific for each nuclear isotope) and electron spin. These properties determine the parameters entering the analysis of Nuclear Magnetic Resonance (NMR) and Electron Spin Resonance (ESR) experiments. Additional fields can be created by the presence of neighboring molecules, and various effects due to weak long-range intermolecular interactions can also be described in terms of molecular properties. The treatment of molecular vibrational properties is in many cases based on the same principles as the formalism explored here; however, the calculation of such properties differs quite substantially from that of electronic properties due to the different quantum-mechanical treatments of the electronic and nuclear motions, and for this reason we will not consider vibrational properties in this chapter.

The Molecular Hamiltonian

Our starting point for electronic structure calculations of molecules is the time-independent, field-free nonrelativistic Schrödinger equation for the electronic degrees of freedom of a molecule

$$\hat{H}^{(0)}\Psi = E\Psi, \quad (1)$$

where Ψ is the wave function describing the electronic state of the molecule, E the energy of this state, and $\hat{H}^{(0)}$ the Hamiltonian operator for the system, given by

$$\hat{H}^{(0)} = \frac{1}{2m_e} \sum_i \hat{p}_i^2 - \frac{e^2}{4\pi\epsilon_0} \sum_{iK} \frac{Z_K}{r_{iK}} + \frac{e^2}{8\pi\epsilon_0} \sum_{i \neq j} \frac{1}{r_{ij}} + \frac{e^2}{8\pi\epsilon_0} \sum_{K \neq L} \frac{Z_K Z_L}{R_{KL}}, \quad (2)$$

where the first term corresponds to the kinetic energy of the electrons, $\mathbf{p}_i = -i\hbar\nabla_i$ is the linear momentum operator of particle i , the second term is the attractive

potential between the electrons and the nuclei, the third term the electron–electron repulsion potential, and the last term the repulsive potential for the interaction between the nuclear point charges. In Eq. 2, e is the elementary charge, $Z_K e$ is the charge of nucleus K , ϵ_0 is the electric constant (electric permittivity of vacuum), and m_e the mass of the electron. We use \mathbf{r}_i and \mathbf{R}_K to denote the vectors giving the position of electron i and nucleus K with respect to a chosen origin of the molecular frame. If needed, for a specific frame of interest, we use the notation

$$\mathbf{r}_{iO} = \mathbf{r}_i - \mathbf{O} \quad (3)$$

to emphasize that the positions are given relative to an origin \mathbf{O} . We define vectors between two different points in space with the directional convention

$$\mathbf{R}_{KL} = \mathbf{R}_K - \mathbf{R}_L, \quad (4)$$

corresponding to a vector pointing from nucleus L to nucleus K . In the summations over electrons or nuclei, we always assume – unless explicitly stated otherwise – that the summation runs over all the particles of a given type in the molecule. Whenever needed, we shall use for vector and tensor coordinates the following subscripts:

- Greek symbols for unspecified molecular frame coordinates; for these coordinates the Einstein summation convention is applied
- x, y, z for specific molecular frame coordinates (for instance, determined by molecular symmetry)
- X, Y, Z for laboratory frame coordinates
- 1, 2, 3 when the tensor is specified using its own principal axes and values
- a, b, c for coordinates defined by the moment of inertia \mathbf{I}

where $\mathbf{I} = \sum_K M_K \mathbf{R}_K \mathbf{R}_K^T$ and M_K is the mass of nucleus K .

The Hamiltonian in Eq. 2 does not take into account the interactions with external electric or magnetic fields. Moreover, so far we have neglected numerous other interactions, related to the existence of the electron and nuclear spins (and the corresponding magnetic moments), their interactions with external fields, and relativistic effects. Thus, for the study of molecular properties which depend on these interactions we need to consider a more general approach, based for instance on the Breit–Pauli Hamiltonian (Dyall and Faegri 2007; Moss 1973). In many cases the contributions to molecular properties due to the additional terms appearing in the Breit–Pauli Hamiltonian can be estimated using the available solutions of the (nonrelativistic) Schrödinger equation and perturbation theory.

The Molecular Breit–Pauli Hamiltonian

There are several ways to introduce and justify the use of the Breit–Pauli Hamiltonian. One can start from the Dirac equation which involves the relativistic

Hamiltonian for the free electron, and extend it by applying various approximations to many electrons in the field generated by the nuclei. We will not discuss here the steps taken in the reduction of the Dirac Hamiltonian to the Breit–Pauli Hamiltonian (Dyall and Faegri 2007; Moss 1973). Instead, we only list the various contributions appearing in the Breit–Pauli Hamiltonian. The approximate form of the Breit–Pauli Hamiltonian we will discuss is accurate to order α_{fs}^2 , where α_{fs} is the fine structure constant, and higher-order corrections are not considered at this stage (we will include later selected terms of the order α_{fs}^4 needed for the calculation of response properties in the presence of magnetic fields). Finally, even though some of the operators appearing in the electronic Breit–Pauli Hamiltonian are of little interest from the point of view of molecular properties, they are included here for completeness.

The purely electronic contributions to the Breit–Pauli Hamiltonian can be written as (Bethe and Salpeter 1957, p. 170; Moss 1973):

$$\hat{H}_{\text{el}}^{\text{BP}} = \sum_i \left(\frac{\pi_i^2}{2m_e} - e\phi \right. \quad (5)$$

$$\left. - \mathbf{m}_i \cdot \mathbf{B} \right. \quad (6)$$

$$\left. + \frac{\alpha_{\text{fs}}^2}{4m_e} \mathbf{m}_i \cdot (\pi_i \times \mathbf{F} - \mathbf{F} \times \pi_i) \right. \quad (7)$$

$$\left. + \frac{e\hbar^2 \alpha_{\text{fs}}^2}{8m_e^2} (\nabla \cdot \mathbf{F}) \right. \quad (8)$$

$$\left. - \frac{\alpha_{\text{fs}}^2}{8m_e^3} \pi_i^4 \right. \quad (9)$$

$$\left. + \frac{\alpha_{\text{fs}}^2}{2m_e^2} (\mathbf{m}_i \cdot \mathbf{B}) \pi_i^2 \right. \quad (10)$$

$$\left. + \frac{1}{4\pi\epsilon_0} \sum_{j \neq i} \left\{ \frac{e^2}{2} \frac{1}{r_{ij}} \right. \right. \quad (11)$$

$$\left. - \frac{e^2 \alpha_{\text{fs}}^2}{4m_e^2} \left[\frac{\pi_i \cdot \pi_j}{r_{ij}} + \frac{(\pi_i \cdot \mathbf{r}_{ij})(\mathbf{r}_{ij} \cdot \pi_j)}{r_{ij}^3} \right] \right. \quad (12)$$

$$\left. + \frac{e\alpha_{\text{fs}}^2}{2m_e} \frac{\mathbf{m}_i \cdot (\mathbf{r}_{ij} \times \pi_i)}{r_{ij}^3} \right. \quad (13)$$

$$\left. - \frac{e\alpha_{\text{fs}}^2}{m_e} \frac{\mathbf{m}_i \cdot (\mathbf{r}_{ij} \times \pi_j)}{r_{ij}^3} \right. \quad (14)$$

$$+ \frac{\alpha_{\text{fs}}^2}{2} \left[\frac{\mathbf{m}_i \cdot \mathbf{m}_j}{r_{ij}^3} - \frac{3(\mathbf{m}_i \cdot \mathbf{r}_{ij})(\mathbf{r}_{ij} \cdot \mathbf{m}_j)}{r_{ij}^5} - \frac{8\pi}{3} \delta(\mathbf{r}_{ij}) \mathbf{m}_i \cdot \mathbf{m}_j \right] \quad (15)$$

$$- \frac{\pi e^2 \hbar^2 \alpha_{\text{fs}}^2}{2m_e^2} \delta(\mathbf{r}_{ij}) \left. \vphantom{\frac{\pi e^2 \hbar^2 \alpha_{\text{fs}}^2}{2m_e^2} \delta(\mathbf{r}_{ij})} \right\}, \quad (16)$$

where $\delta \mathbf{r}_{ij}$ is the Dirac delta function

$$\delta(\mathbf{r}_{ij}) = 0 \quad \text{for} \quad \mathbf{r}_{ij} \neq \mathbf{0}; \quad \int_V \delta(\mathbf{r}_{ij}) d^3 \mathbf{r} = 1. \quad (17)$$

In addition to these purely electronic contributions, we must also consider the interactions that involve simultaneously one of the electrons and one of the nuclei:

$$\hat{H}_{\text{eN}}^{\text{BP}} = \frac{1}{4\pi\epsilon_0} \sum_{iK} Z_K \left[-\frac{e^2}{r_{iK}} \right. \quad (18)$$

$$+ \frac{e\alpha_{\text{fs}}^2}{2m_e} \frac{\mathbf{m}_i \cdot (\mathbf{r}_{iK} \times \boldsymbol{\pi}_i)}{r_{iK}^3} \quad (19)$$

$$\left. + \frac{\pi e^2 \hbar^2 \alpha_{\text{fs}}^2}{2m_e^2} \delta(\mathbf{r}_{iK}) \right]. \quad (20)$$

Finally, we have the contributions arising from the nuclei only

$$\hat{H}_{\text{nucI}}^{\text{BP}} = \sum_K \left[Z_K e \phi_K - \mathbf{m}_K \cdot \mathbf{B} \right. \quad (21)$$

$$\left. + \sum_{L \neq K} \frac{e^2}{8\pi\epsilon_0} \frac{Z_K Z_L}{R_{KL}} \right]. \quad (22)$$

We have omitted in these equations all the terms dependent on the (inverse) masses of the nuclei. In the purely electronic and purely nuclear parts we have not included the rest mass of the particles. In the above equations we have introduced the mechanical momentum

$$\boldsymbol{\pi}_i = \mathbf{p}_i - q_i \mathbf{A}(\mathbf{r}_i), \quad (23)$$

where $\mathbf{A}(\mathbf{r}_i)$ is the magnetic vector potential experienced by electron i , and q_i is the charge of the particle, which for an electron is $-e$. The corresponding magnetic field induction is \mathbf{B} (see below). ϕ represents the external scalar electrostatic potential, and the electric field due to this external potential is $\mathbf{F} = -\nabla\phi$. We have also

introduced the magnetic moment of the electron \mathbf{m}_i , which is related to the electron spin through

$$\mathbf{m}_i = -g_e \frac{e\hbar}{2m_e} \mathbf{s}_i = -g_e \mu_B \mathbf{s}_i, \quad (24)$$

where g_e is the electron g factor and the Bohr magneton μ_B is the unit for magnetic moments. In a similar manner, \mathbf{m}_K is the nuclear magnetic moment, related to the nuclear spin \mathbf{I}_K as

$$\mathbf{m}_K = \hbar \gamma_K \mathbf{I}_K = \mu_N g_K \mathbf{I}_K, \quad (25)$$

where γ_K is the nuclear magnetogyric ratio, $\mu_N = e\hbar/2m_p$ is the nuclear magneton, m_p the proton mass, and g_K is the g factor of nucleus K , unique for each isotope. For a detailed description of the different terms appearing in the Breit–Pauli Hamiltonian we refer to Moss (1973). The Breit–Pauli Hamiltonian, Eqs. 5, 6, 7, 8, 9, 10, 11, 12, 13, 14, 15, 16, 17, 18, 19, 20, 21, and 22, does not contain explicitly any coupling between the nuclear magnetic moments \mathbf{m}_K and the magnetic moments of the electrons \mathbf{m}_i . In sections “The Magnetic Vector Potential” and “Small Terms Due to the Vector Potential in the Hamiltonian,” we introduce these interactions by establishing a magnetic vector potential for the nuclear magnetic moments in a similar manner to the magnetic vector potential for the external magnetic field induction. These interactions, important for determining the observable NMR and ESR spectra, will thus appear through the couplings arising when we expand π_i^2 (and the spin–Zeeman term leading to Eq. 6) using the full mechanical momentum operator given in Eq. 23.

The Breit–Pauli Hamiltonian describes a number of contributions that can be considered small compared to the nonrelativistic Hamiltonian given in Eq. 2. These contributions are thus ideally suited to be treated by perturbation theory, at least as long as we do not consider the heaviest atoms of the periodic table, where the relativistic effects become substantial and the lack of a variational bound for the Breit–Pauli Hamiltonian makes any perturbation approach fail. For the energy of molecules consisting of light atoms, the relativistic effects can to a first approximation often be treated considering only the mass-velocity (Eq. 9) and one-electron Darwin (Eq. 20) terms.

Some of the terms included in the Breit–Pauli Hamiltonian also describe small interactions that can be probed experimentally by inducing suitable excitations in the electron or nuclear spin space, giving rise to important contributions to observable NMR and ESR parameters. In particular, for molecular properties for which there are interaction mechanisms involving the electron spin, also the spin-orbit interaction (Eqs. 13 and 14) becomes important. The Breit–Pauli Hamiltonian in Eqs. 5, 6, 7, 8, 9, 10, 11, 12, 13, 14, 15, 16, 17, 18, 19, 20, 21, and 22, however, only includes molecule–external field interactions through the presence of a scalar

electrostatic potential ϕ (and the associated electric field \mathbf{F}) and the appearance of the magnetic vector potential in the mechanical momentum operator (Eq. 23). In order to extract in more detail the interaction between the electronic structure of a molecule and an external electromagnetic field, we need to consider in more detail the form of the scalar and vector potentials.

Small Terms Due to the Scalar Potential in the Hamiltonian

Let us begin with the simplest example, the interaction of a molecule with a static electric field. This interaction can be described by the Hamiltonian

$$\hat{H} = \hat{H}^{(0)} - e \sum_i \phi(\mathbf{r}_i) + e \sum_k Z_K \phi(\mathbf{R}_K), \quad (26)$$

where we have neglected the spin-orbit and relativistic terms given in Eqs. 7 and 8. We can expand the potential around a common origin

$$\phi(\mathbf{r}_i) = \phi(0) + \frac{\partial \phi}{\partial r_{i\alpha}} r_{i\alpha} + \frac{1}{2} \frac{\partial^2 \phi}{\partial r_{i\alpha} \partial r_{i\beta}} r_{i\alpha} r_{i\beta} + \dots \quad (27)$$

with a similar expansion for the potential at the position of the nuclei, $\phi(\mathbf{R}_K)$. Recalling that the electric field due to the external potential is $\mathbf{F} = -\nabla\phi$, we can rewrite Eq. 26 in terms of electric multipole operators

$$\hat{H} = \hat{H}^{(0)} + Q\phi(0) + \hat{H}^{\mathbf{F}} \cdot \mathbf{F} + \hat{H}^{\nabla\mathbf{F}} \cdot \nabla\mathbf{F} + \dots, \quad (28)$$

where Q is the total charge of the molecule. We note that the multipole operators are defined with respect to the chosen common origin. For a neutral system, the first two contributions describing the field effects are given by the:

- External electric field perturbation:

$$\hat{H}^{\mathbf{F}} = -\boldsymbol{\mu}, \quad (29)$$

where the electric dipole operator is

$$\hat{\mu}_\alpha = -e \sum_i \hat{r}_{i\alpha} + e \sum_K Z_K R_{K\alpha}. \quad (30)$$

- External electric field gradient perturbation:

$$\hat{H}^{\nabla\mathbf{F}} = -\frac{1}{3}\Theta, \quad (31)$$

where the electric quadrupole operator in its traceless form is

$$\hat{\Theta}_{\alpha\beta} = -\frac{e}{2} \sum_i (3\hat{r}_{i\alpha}\hat{r}_{i\beta} - \hat{r}_i^2\delta_{\alpha\beta}) + \frac{e}{2} \sum_K Z_K (3R_{K\alpha}R_{K\beta} - R_K^2\delta_{\alpha\beta}). \quad (32)$$

The interaction due to the external field gradient can also be expressed in terms of the second moments (traced form)

$$\hat{q}_{\alpha\beta} = -e \sum_i \hat{r}_{i\alpha}\hat{r}_{i\beta} + e \sum_K Z_K R_{K\alpha}R_{K\beta}. \quad (33)$$

Later we shall discuss also the effects due to the:

- Electric field gradient at the nucleus K:

$$\begin{aligned} \hat{V}_{\alpha\beta}^K &= \frac{1}{4\pi\epsilon_0} e \sum_i \frac{3\hat{r}_{iK,\alpha}\hat{r}_{iK,\beta} - \hat{r}_{iK}^2\delta_{\alpha\beta}}{r_{iK}^5} \\ &\quad - \frac{1}{4\pi\epsilon_0} e \sum_{L \neq K} Z_L \frac{3R_{LK,\alpha}R_{LK,\beta} - R_{LK}^2\delta_{\alpha\beta}}{R_{LK}^5}, \end{aligned} \quad (34)$$

since we will need it to describe the interaction with the nuclear quadrupole moments, \mathbf{Q}_K , described by the interaction Hamiltonian

$$\hat{H}^{VK} = -\frac{1}{2} \sum_K \mathbf{V}^K \mathbf{Q}_K. \quad (35)$$

The Magnetic Vector Potential

We consider a molecule in which the magnetic field arises from two primary sources, an external magnetic field induction and the permanent magnetic moments of nuclei possessing a spin. In the minimal coupling approximation, the mechanical momentum operator (Eq. 23) is given as

$$\pi_i = \mathbf{p}_i + e\mathbf{A}^{\mathbf{B}}(\mathbf{r}_i) + e \sum_K \mathbf{A}^{\text{m}K}(\mathbf{r}_i), \quad (36)$$

where the superscripts indicate the different sources of the magnetic vector potential. In Eq. 36 we have explicitly indicated that we are interested in the magnetic vector potential at the positions of the electrons.

The magnetic vector potential is not uniquely defined, and we have to choose the gauge (Jackson 1998). In the Coulomb gauge, that is, where the magnetic vector potential is divergence free at all points in space,

$$\nabla \cdot \mathbf{A}(\mathbf{r}) = 0, \quad (37)$$

we may choose the vector potential describing the interaction with the external magnetic field induction and with the magnetic moments of the nuclei in the form

$$\mathbf{A}(\mathbf{r}_i) = \frac{1}{2}\mathbf{B} \times \mathbf{r}_{iO} + \alpha_{fs}^2 \sum_K \frac{\mathbf{m}_K \times \mathbf{r}_{iK}}{r_{iK}^3}. \quad (38)$$

It can easily be verified that the magnetic vector potential (Eq. 38) is divergence free. Since the magnetic field induced by the magnetic vector potential is given by

$$\mathbf{B} = \nabla \times \mathbf{A}^{\mathbf{B}}(\mathbf{r}_i), \quad (39)$$

we can add any scalar differentiable potential $\nabla\Lambda$ to the magnetic vector potential in Eq. 38 without changing the description of the magnetic field induction experienced by the molecule (since $\nabla \times (\nabla\Lambda) = 0$). There are, therefore, multiple definitions of the magnetic vector potential that describe the same magnetic field induction, and thus the same physical situation. This invariance with respect to the choice of magnetic vector potential may be lost in approximate calculations. This in turn leads to what is known as the gauge dependence of computed magnetic properties, an undesirable feature of approximate calculations – the results depend on an arbitrary factor in the calculation. In practice, when interactions with external magnetic fields are considered, special computational methods are introduced to bypass this problem and to obtain reliable and unambiguous gauge-origin independent results. We will return to this point when we consider magnetic properties in section “[Magnetic Properties](#).”

Small Terms Due to the Vector Potential in the Hamiltonian

Having now established the form of the vector potential, we return to the molecular Hamiltonian. In the presence of magnetic fields, the kinetic energy is defined by the mechanical momentum operator, Eq. 23 (instead of the linear momentum operator), and in addition we need to consider the Zeeman term, Eq. 6. We can expand all the terms appearing in the kinetic energy, using the vector potential in the mechanical momentum, and introduce the magnetic field induction in the Zeeman term. This yields the following form of the Hamiltonian:

$$\hat{H} = \hat{H}^0 - i \frac{e\hbar}{m_e} \sum_i \mathbf{A}(\mathbf{r}_i) \cdot \nabla_i + \frac{e^2}{2m_e} \sum_i \mathbf{A}^2(\mathbf{r}_i) + \sum_i \mathbf{m}_i \cdot (\nabla_i \times \mathbf{A}(\mathbf{r}_i)), \quad (40)$$

where \hat{H}^0 indicates the Hamiltonian in Eq. 2. In this equation we have taken advantage of the commutator relation $[\mathbf{A}(\mathbf{r}_i), \nabla_i] = 0$ (this relation holds true for our choice of the Coulomb gauge, see Eq. 37). Inserting the magnetic vector potential, Eq. 38, into Eq. 40 we get

$$\hat{H} = \hat{H}^0 + \hat{H}^{\text{B}}\mathbf{B} + \sum_K \hat{H}^{K(\text{PSO})}\mathbf{m}_K \quad (41)$$

$$+ \mathbf{B}^T \hat{H}^{\text{B},\text{B}}\mathbf{B} + \sum_K \mathbf{B}^T \hat{H}^{B,K}\mathbf{m}_K + \frac{1}{2} \sum_{K \neq L} \mathbf{m}_K^T \hat{H}^{K,L(\text{DSO})}\mathbf{m}_L \quad (42)$$

$$+ \sum_i \mathbf{m}_i \hat{H}^{\text{s},\text{B}}\mathbf{B} + \sum_{iK} \mathbf{m}_i \hat{H}^{K(\text{FC})}\mathbf{m}_K + \sum_{iK} \mathbf{m}_i \hat{H}^{K(\text{SD})}\mathbf{m}_K. \quad (43)$$

The summation over the nuclear magnetic moments in the last term of Eq. 42 should include contributions quadratic in \mathbf{m}_K , but since these contributions do not correspond to any measurable quantity, we have restricted the summation to different nuclei. We note also that these neglected terms are divergent, which shows the limitations of the applied theory.

Let us analyze the explicit expressions for the different operators in Eqs. 41, 42, and 43, which are obtained by inserting the magnetic vector potential Eq. 38 into Eq. 40. The contributions in Eq. 41 arise from the unperturbed Hamiltonian and from the term linear in $\mathbf{A}(\mathbf{r}_i)$. The operators involved are:

- Magnetic dipole operator

$$\hat{H}^{\text{B}} = \frac{e}{2m_e} \sum_i \mathbf{l}_{iO} = \frac{\mu_B}{\hbar} \sum_i \mathbf{l}_{iO} = -i \mu_B \sum_i (\mathbf{r}_{iO} \times \nabla_i) = -\mathbf{m}. \quad (44)$$

The magnetic dipole moment is proportional to the angular momentum, the coefficient of proportionality being the magnetogyric ratio $\gamma_e = e/2m_e$. The orbital angular momentum of electron i is defined as

$$\mathbf{l}_{iO} = \mathbf{r}_{iO} \times \mathbf{p}_i = -i\hbar \mathbf{r}_{iO} \times \nabla_i. \quad (45)$$

The magnetic dipole operator describes the magnetic moment induced by the angular momentum of the electrons arising from the orbital motion, in contrast to the magnetic moment arising from the electron spin which we discuss when we consider the spin-Zeeman interaction.

- Paramagnetic spin-orbit operator

$$\hat{H}^{K(\text{PSO})} = \alpha_{\text{fs}}^2 \frac{2\mu_B}{\hbar} \sum_i \frac{\mathbf{l}_{iK}}{r_{iK}^3}. \quad (46)$$

The paramagnetic spin-orbit interaction, often called the orbital hyperfine interaction, describes the interaction of the magnetic moment induced by the orbital motion of the electrons with the nuclear magnetic moments.

The contributions in Eq. 42 arise from the term quadratic in $\mathbf{A}(\mathbf{r}_i)$ in Eq. 40. They involve the following operators:

- Diamagnetic magnetizability operator

$$\hat{H}^{\text{B,B}} = \frac{e^2}{8m_e} \sum_i (r_{iO}^2 \mathbf{1} - \mathbf{r}_{iO} \mathbf{r}_{iO}^T), \quad (47)$$

where $\mathbf{1}$ is a 3×3 unit matrix. This operator is closely related to the second moment of the electronic charge, and thus reflects the size of the electron density distribution. The diamagnetic magnetizability tensor is a symmetric 3×3 tensor operator, and has, therefore, in general six independent tensor operator elements.

- Diamagnetic shielding operator

$$\hat{H}^{\text{B,K}} = \alpha_{\text{fs}}^2 \frac{e^2}{2m_e} \sum_i \frac{(\mathbf{r}_{iO} \cdot \mathbf{r}_{iK}) \mathbf{1} - \mathbf{r}_{iO} \mathbf{r}_{iK}^T}{r_{iK}^3}. \quad (48)$$

The diamagnetic shielding tensor describes the interaction of the magnetic field induction with the nuclear magnetic moment, mediated by the orbital motion of the electrons. We note that the diamagnetic shielding tensor is a 3×3 nonsymmetric tensor operator, and thus in general has nine independent elements.

- Diamagnetic spin-orbit operator

$$\hat{H}^{\text{K,L(DSO)}} = \alpha_{\text{fs}}^4 \frac{e^2}{2m_e} \sum_i \frac{(\mathbf{r}_{iK} \cdot \mathbf{r}_{iL}) \mathbf{1} - \mathbf{r}_{iK} \mathbf{r}_{iL}^T}{r_{iK}^3 r_{iL}^3}. \quad (49)$$

The diamagnetic spin-orbit operator describes the direct interaction between the two orbital magnetic moments induced in the electron density by the presence of the magnetic moments of nuclei K and L . As for the diamagnetic shielding operator, this is a 3×3 nonsymmetric tensor operator, with in general nine independent elements.

Finally, the terms in Eq. 43 arise from the spin–Zeeman term, the last term in Eq. 40.

- Spin–Zeeman operator

$$\hat{H}^{\text{s,B}} = -\mathbf{1}. \quad (50)$$

The spin–Zeeman operator describes the direct interaction of an electron spin with the external magnetic field induction, and does not act on the spatial coordinates of the electrons, acting only in spin space (this contribution thus vanishes for closed-shell systems). We note that it is customary to describe this term in the Hamiltonian using the electron spin explicitly rather than the electron magnetic moment.

- Fermi contact (FC) operator

$$\hat{H}^{\text{K(FC)}} = -\alpha_{\text{fs}}^2 \frac{8\pi}{3} \sum_i \delta(\mathbf{r}_{iK}) \mathbf{1}. \quad (51)$$

The Fermi contact operator acts both in the spin and in the spatial space of the electronic coordinates, often leading to a very different behavior of the response properties than for instance the $\hat{H}^{K(\text{PSO})}$ operator. The Fermi contact operator represents the direct interaction of the electron spin-magnetic moment with the nuclear magnetic moment at the position of the nucleus, and can also be considered to be a measure of the spin-polarization at the nucleus.

- Spin–dipole (SD) operator

$$\hat{H}^{K(\text{SD})} = -\alpha_{\text{fs}}^2 \sum_i \frac{3\mathbf{r}_{iK}\mathbf{r}_{iK}^T - r_{iK}^2\mathbf{1}}{r_{iK}^5}. \quad (52)$$

The spin–dipole operator is in the form of a classical dipole–dipole interaction between the magnetic dipole of the nucleus and the magnetic dipole of the electron.

For the contributions involving the electronic spin operators through the electron spin-magnetic moment \mathbf{m}_i — that is, $\hat{H}^{K(\text{FC})}$ and $\hat{H}^{K(\text{SD})}$ — we need to keep track of the electron spin index and of the nuclear spin index. Due to the nature of the Dirac delta function appearing in the operator for $\hat{H}^{K(\text{FC})}$, this operator is diagonal in the two tensor indices, that is

$$\hat{H}_{\alpha\beta}^{K(\text{FC})} = \hat{H}_{\text{iso}}^{K(\text{FC})} \delta_{\alpha\beta}. \quad (53)$$

Both the Fermi contact and the spin–dipole operators can be derived considering the magnetic field induction created by the vector potential describing the nuclear magnetic moment

$$\begin{aligned} \nabla \times \mathbf{A}^{\mathbf{m}_K}(\mathbf{r}_i) &= \alpha_{\text{fs}}^2 \nabla \times \frac{\mathbf{m}_K \times \mathbf{r}_{iK}}{r_{iK}^3} \\ &= \alpha_{\text{fs}}^2 \left(\sum_i \frac{3\mathbf{r}_{iK}\mathbf{r}_{iK}^T - r_{iK}^2\mathbf{1}}{r_{iK}^5} + \frac{8\pi}{3} \sum_i \delta(\mathbf{r}_{iK}) \mathbf{1} \right) \mathbf{m}_K, \end{aligned} \quad (54)$$

which can be derived using standard vector product formulas.

We shall in later sections also discuss the effects of the spin-orbit interaction. The total spin-orbit (SO) interaction operator (McWeeny 1992) can be defined combining the terms included in Eqs. 13, 14, and 19 as

$$\begin{aligned} \hat{H}^{\text{SO}} &= -\frac{e}{8\pi\epsilon_0 m_e} \alpha_{\text{fs}}^2 \left[\sum_{iK} Z_K \frac{\mathbf{m}_i \cdot \mathbf{1}_{iK}}{r_{iK}^3} - \sum_{i \neq j} \frac{(\mathbf{m}_i + 2\mathbf{m}_j) \cdot \mathbf{1}_{ij}}{r_{ij}^3} \right] \\ &\equiv \hat{H}^{\text{SO}(1)} + \hat{H}^{\text{SO}(2)}. \end{aligned} \quad (55)$$

The corrections to the \hat{H}^{SO} operator, Eq. 55, which account for the presence of magnetic fields, arise through the angular momentum operators (Fukui et al. 1996):

$$\mathbf{l}_{iK} = \mathbf{r}_{iK} \times [-i\hbar\nabla_i + e\mathbf{A}(\mathbf{r}_i)] \quad (56)$$

$$\mathbf{l}_{ij} = \mathbf{r}_{ij} \times [-i\hbar\nabla_i + e\mathbf{A}(\mathbf{r}_i)]. \quad (57)$$

The first part of the vector potential, related to the external magnetic field, causes the \hat{H}^{SO} operator to contain two contributions

$$\hat{H}^{\text{SO,B}} = \hat{H}^{\text{SO,B(1)}} + \hat{H}^{\text{SO,B(2)}}, \quad (58)$$

$$\hat{H}^{\text{SO,B(1)}} = -\frac{e^2}{16\pi\epsilon_0 m_e} \alpha_{\text{fs}}^2 \left[\sum_{iK} Z_K \mathbf{m}_i \cdot \frac{(\mathbf{r}_{iO} \cdot \mathbf{r}_{iK}) \mathbf{1} - \mathbf{r}_{iO} \mathbf{r}_{iK}^T}{r_{iK}^3} \cdot \mathbf{B} \right], \quad (59)$$

$$\hat{H}^{\text{SO,B(2)}} = \frac{e^2}{16\pi\epsilon_0 m_e} \alpha_{\text{fs}}^2 \left[\sum_{i \neq j} (\mathbf{m}_i + 2\mathbf{m}_j) \cdot \frac{(\mathbf{r}_{iO} \cdot \mathbf{r}_{ij}) \mathbf{1} - \mathbf{r}_{iO} \mathbf{r}_{ij}^T}{r_{ij}^3} \cdot \mathbf{B} \right]. \quad (60)$$

Similarly, the second part of the vector potential related to the magnetic moment of nucleus K leads to

$$\hat{H}^{\text{SO,K}} = \hat{H}^{\text{SO,K(1)}} + \hat{H}^{\text{SO,K(2)}}, \quad (61)$$

$$\hat{H}^{\text{SO,K(1)}} = -\frac{e^2}{8\pi\epsilon_0 m_e} \alpha_{\text{fs}}^4 \left[\sum_M Z_M \sum_i \mathbf{m}_i \cdot \frac{(\mathbf{r}_{iK} \cdot \mathbf{r}_{iM}) \mathbf{1} - \mathbf{r}_{iK} \mathbf{r}_{iM}^T}{r_{iK}^3 r_{iM}^3} \cdot \mathbf{m}_K \right], \quad (62)$$

$$\hat{H}^{\text{SO,K(2)}} = \frac{e^2}{8\pi\epsilon_0 m_e} \alpha_{\text{fs}}^4 \left[\sum_{i \neq j} (\mathbf{m}_i + 2\mathbf{m}_j) \cdot \frac{(\mathbf{r}_{iK} \cdot \mathbf{r}_{ij}) \mathbf{1} - \mathbf{r}_{iK} \mathbf{r}_{ij}^T}{r_{iK}^3 r_{ij}^3} \cdot \mathbf{m}_K \right]. \quad (63)$$

Response Theory

Molecular Response: Definitions, Symbols

The formalism we use to compare theory with experiment is based on the analysis of the expectation value of some operator of interest. We denote the time-dependent reference state as $|\tilde{0}(t)\rangle$ and consider hermitian (in general time-dependent) perturbing operators. The response functions correspond to the Fourier coefficients in the expansion of the time-dependent expectation value of an operator A (Olsen and Jørgensen 1995):

$$\begin{aligned}
\langle \tilde{0}(t) | A | \tilde{0}(t) \rangle &= \langle 0 | A | 0 \rangle + \int_{-\infty}^{\infty} \langle \langle A; V^{\omega_1} \rangle \rangle e^{-i\omega_1 t} d\omega_1 \\
&+ \frac{1}{2} \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} \langle \langle A; V^{\omega_1}, V^{\omega_2} \rangle \rangle e^{-i(\omega_1 + \omega_2)t} d\omega_1 d\omega_2 \\
&+ \frac{1}{6} \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} \langle \langle A; V^{\omega_1}, V^{\omega_2}, V^{\omega_3} \rangle \rangle e^{-i(\omega_1 + \omega_2 + \omega_3)t} d\omega_1 d\omega_2 d\omega_3 + \dots,
\end{aligned} \tag{64}$$

where each V^{ω_i} represents a time-dependent perturbation operator. We have omitted the infinitesimal factors, which ensure that the perturbations are switched on adiabatically and vanish for $t = -\infty$.

In the analysis of the different terms in Eq. 64 for the case of exact electronic states, the zeroth-order response function is the expectation value of the operator A in the reference state $|0\rangle$, $\langle 0 | A | 0 \rangle$. The first-order, or linear, response function and its residue are given in the sum-over-states form by Olsen and Jørgensen (1995) and Sasagane et al. (1993):

$$\begin{aligned}
\langle \langle A; B \rangle \rangle_{\omega_1} &= -\frac{1}{\hbar} \sum_P \sum_n \frac{\langle 0 | A | n \rangle \langle n | B | 0 \rangle}{\omega_n - \omega_1} \\
&= -\frac{1}{\hbar} \sum_n \left[\frac{\langle 0 | A | n \rangle \langle n | B | 0 \rangle}{\omega_n - \omega_1} + \frac{\langle 0 | B | n \rangle \langle n | A | 0 \rangle}{\omega_n + \omega_1} \right].
\end{aligned} \tag{65}$$

The poles correspond to the excitation energies of the system. In addition, from the residues:

$$\lim_{\omega_1 \rightarrow \omega_e} \hbar (\omega_1 - \omega_e) \langle \langle A; B \rangle \rangle_{\omega_1} = \langle 0 | A | e \rangle \langle e | B | 0 \rangle, \tag{66}$$

$$\lim_{\omega_1 \rightarrow -\omega_e} \hbar (\omega_1 + \omega_e) \langle \langle A; B \rangle \rangle_{\omega_1} = -\langle 0 | B | e \rangle \langle e | A | 0 \rangle, \tag{67}$$

we can extract information about the transition matrix elements. The second-order, or quadratic, response function is defined as

$$\langle \langle A; B, C \rangle \rangle_{\omega_1, \omega_2} = -\frac{1}{\hbar^2} \sum_P \sum_{m, n} \frac{\langle 0 | A | m \rangle \langle m | B | n \rangle \langle n | C | 0 \rangle}{(\omega_m - \omega_\sigma) (\omega_n - \omega_2)}. \tag{68}$$

In Eq. 68 and in the expressions given below, ω_σ equals the sum of the other frequencies ($\omega_\sigma = \sum_i \omega_i$) and P permutes the operators and the associated frequencies. For example, in Eq. 68, P permutes $A(-\omega_\sigma)$, $B(\omega_1)$, $C(\omega_2)$. We note that different expressions for nonlinear response functions, involving operators of the form $\bar{B} = B - \langle 0 | B | 0 \rangle$, are obtained when the state $|0\rangle$ is omitted from the summations (see, e.g., Sasagane et al. 1993).

For the quadratic and cubic response functions there is a variety of residues, and we present only expressions for the residues that are of practical interest. A single residue of a quadratic response function is

$$\lim_{\omega_2 \rightarrow \omega_f} \hbar (\omega_2 - \omega_f) \langle\langle A; B, C \rangle\rangle_{\omega_1, \omega_2} = -\frac{1}{\hbar} \left[\sum_P \sum_m \frac{\langle 0 | A | m \rangle \langle m | B | f \rangle}{(\omega_m - \omega_\sigma)} \right] \langle f | C | 0 \rangle. \quad (69)$$

This type of residue is used for instance to evaluate two-photon transition amplitudes, the B term in magnetic circular dichroism or the transition moments in phosphorescence. A double residue of the quadratic response function, given by

$$\begin{aligned} \lim_{\omega_1 \rightarrow -\omega_f} \hbar (\omega_1 + \omega_f) \lim_{\omega_2 \rightarrow \omega_e} \hbar (\omega_2 - \omega_e) \langle\langle A; B, C \rangle\rangle_{\omega_1, \omega_2} \\ = -\langle 0 | B | f \rangle \langle f | (A - \langle 0 | A | 0 \rangle) | e \rangle \langle e | C | 0 \rangle, \end{aligned} \quad (70)$$

allows us to determine (from a knowledge of the reference state $|0\rangle$ only) the transition moment between two other states, $|e\rangle$ and $|f\rangle$.

For the particular choice of $|e\rangle = |f\rangle$, we obtain

$$\begin{aligned} \lim_{\omega_1 \rightarrow -\omega_e} \hbar (\omega_1 + \omega_e) \lim_{\omega_2 \rightarrow \omega_e} \hbar (\omega_2 - \omega_e) \langle\langle A; B, C \rangle\rangle_{\omega_1, \omega_2} \\ = -\langle 0 | B | e \rangle (\langle e | A | e \rangle - \langle 0 | A | 0 \rangle) \langle e | C | 0 \rangle, \end{aligned} \quad (71)$$

which allows us to extract the expectation value $\langle e | A | e \rangle$. In this way, using a double residue of the quadratic response function from the reference state function we can compute first-order properties of another state.

Finally, the third-order, or cubic, response function can be expressed as

$$\langle\langle A; B, C, D \rangle\rangle_{\omega_1, \omega_2, \omega_3} = -\frac{1}{\hbar^3} \sum_P \sum_{m, n, q} \frac{\langle 0 | A | m \rangle \langle m | B | n \rangle \langle n | C | q \rangle \langle q | D | 0 \rangle}{(\omega_m - \omega_\sigma) (\omega_n - \omega_2 - \omega_3) (\omega_q - \omega_3)}. \quad (72)$$

From the discussed residues, we can determine properties explicitly dependent on different electronic states, for instance all the transition moments coupling the reference state $|0\rangle$ and other states $|e\rangle$ (from linear response residues) and all the one-photon transition moments coupling other pairs of states (from quadratic response double residues). In addition, from single residues of the second- and third-order response functions we can identify two- and three-photon transition matrix elements.

The frequency(time)-independent properties are a special case of the response functions ($\omega_1 = \omega_2 \cdots = 0$) and correspond to energy derivatives. We shall use a simplified notation omitting the subscripts indicating the (zero) frequencies for these properties. The response function, is therefore, in this case written as $\langle\langle A; B, C, D \dots \rangle\rangle$.

For time-dependent oscillatory perturbations, the response functions can be related to the derivatives of the time-averaged quasienergy (Christiansen et al. 1998; Saue 2002). The derivation, based on a time-dependent variational principle and the time-dependent Hellman–Feynman theorem, shows explicitly the symmetry of the response functions with respect to the permutation of all the operators.

We do not describe in this chapter the standard basis sets and wave function models in use in quantum chemistry, referring instead the interested reader to other chapters in this handbook and to a recent textbook (Helgaker et al. 2000). We only note that response theory has been formulated and corresponding programs have been implemented for most of the standard approximations, such as:

- RHF, the restricted Hartree–Fock model
- MCSCF, the multiconfigurational self-consistent field model
- DFT, density-functional theory
- MP2, the Møller–Plesset second-order perturbation theory, which in the case of frequency-dependent perturbations has to be replaced by an iterative optimization of the perturbation amplitudes, as described by the CC2 model (Christiansen et al. 1995)
- CCSD, the coupled-cluster singles-and-doubles model
- CCSD(T), CCSD with a noniterative perturbative treatment of the triples correction, which in the case of frequency-dependent response functions has to be replaced by an iterative triples correction, as described by the CC3 model (Koch et al. 1997)
- FCI, full configuration-interaction theory

There are also a couple of models designed primarily for the purpose of calculating response functions – that is, they cannot be derived in terms of energy or quasienergy derivatives of the energy expression for an electronic structure method. We note here the second-order polarization propagator approximation [SOPPA (Enevoldsen et al. 1998; Nielsen et al. 1980)], SOPPA using CCSD correlation amplitudes [SOPPA(CCSD) (Sauer 1997)], as well as the equation-of-motion CCSD model [EOM-CCSD (Perera et al. 1994a; Stanton and Bartlett 1993)].

In general, the accuracy of the computed molecular properties reflects the accuracy of the approach used for the unperturbed reference state. There is, however, one significant difference between variational and perturbative, nonvariational approximations which should be kept in mind in the calculation of properties. The response equations which hold for the exact wave function are in general not fulfilled for nonvariational wave function models, even in the limit of a complete basis set. For instance, in the MP2 and coupled-cluster approximations, the static first-order properties, which should be computed as the first energy derivatives, do not correspond to simple expectation values – corrections arising from orbital relaxation must in general be taken into account. Similarly, in the calculation of higher-order molecular properties when the basis set depends explicitly on the applied perturbations (such as geometrical distortions, or magnetic field perturbations described using London atomic orbitals), orbital relaxation corrections should

be included (Gauss and Stanton 1995). We note, however, that as the excitation level is increased (triple excitations, etc.), the importance of orbital relaxation is reduced, since in the limit of the full CI wave function, which is exact, no orbital relaxation is necessary.

Expansions of Energy and Multipole Moments

The static properties can be defined by an expansion of the total energy

$$\begin{aligned}
 E = E^{(0)} &- \mu_\alpha F_\alpha - \frac{1}{2} \alpha_{\alpha\beta} F_\alpha F_\beta - \frac{1}{6} \beta_{\alpha\beta\gamma} F_\alpha F_\beta F_\gamma - \frac{1}{24} \gamma_{\alpha\beta\gamma\delta} F_\alpha F_\beta F_\gamma F_\delta + \dots \\
 &- \frac{1}{3} \Theta_{\alpha\beta} F_{\alpha\beta} - \frac{1}{3} A_{\alpha,\beta\gamma} F_\alpha F_{\beta\gamma} - \frac{1}{6} C_{\alpha\beta,\gamma\delta} F_{\alpha\beta} F_{\gamma\delta} + \dots \\
 &- \frac{1}{2} \xi_{\alpha\beta} B_\alpha B_\beta - \frac{1}{2} \zeta_{\gamma,\alpha\beta} B_\alpha B_\beta F_\gamma - \frac{1}{4} \eta_{\gamma\delta,\alpha\beta} B_\alpha B_\beta F_\gamma F_\delta + \dots \\
 &+ \sigma_{K,\alpha\beta} B_\alpha m_{K,\beta} + \dots
 \end{aligned} \tag{73}$$

For a molecule in a radiation field, the definitions of the frequency-dependent properties are related to the induced (in general also frequency-dependent) multipole moments. Let us consider a small harmonic perturbation of angular frequency ω from a plane-wave radiation field. We then have (Barron 2004):

- The induced electric dipole moment μ

$$\mu_\alpha = \alpha_{\alpha\beta} F_\beta + \frac{1}{\omega} G'_{\alpha\beta} \dot{B}_\beta + \frac{1}{3} A_{\alpha,\beta\gamma} F_{\beta\gamma} + \dots \tag{74}$$

$$+ \frac{1}{\omega} \alpha'_{\alpha\beta} \dot{F}_\beta + G_{\alpha\beta} B_\beta + \frac{1}{3\omega} A'_{\alpha,\beta\gamma} \dot{F}_{\beta\gamma} + \dots, \tag{75}$$

- The induced electric quadrupole moment Θ

$$\Theta_{\alpha\beta} = A_{\gamma,\alpha\beta} F_\gamma - \frac{1}{\omega} D'_{\gamma,\alpha\beta} \dot{B}_\gamma + C_{\alpha\beta,\gamma\delta} F_{\gamma\delta} + \dots \tag{76}$$

$$- \frac{1}{\omega} A'_{\gamma,\alpha\beta} \dot{F}_\gamma + D_{\gamma,\alpha\beta} B_\gamma + \frac{1}{\omega} C'_{\alpha\beta,\gamma\delta} \dot{F}_{\gamma\delta} + \dots, \tag{77}$$

- The induced magnetic dipole moment m'

$$m'_\alpha = \xi_{\alpha\beta} B_\beta + \frac{1}{3\omega} D'_{\alpha,\beta\gamma} \dot{F}_{\beta\gamma} - \frac{1}{\omega} G'_{\beta\alpha} \dot{F}_\beta + \dots \tag{78}$$

$$+ \frac{1}{\omega} \xi'_{\alpha\beta} \dot{B}_\beta + \frac{1}{3} D_{\alpha,\beta\gamma} F_{\beta\gamma} + G_{\beta\alpha} F_\beta + \dots, \tag{79}$$

where \dot{F} and \dot{B} denote the time derivatives of the fields and we have considered only linear response properties.

The properties we have included are the electric multipole polarizabilities – $\alpha_{\alpha\beta}$, dipole–dipole, $A_{\alpha, \beta\gamma}$, dipole–quadrupole; and $C_{\alpha\beta, \gamma\delta}$, quadrupole–quadrupole – as well as the mixed polarizabilities – $G_{\alpha\beta}$, electric dipole-magnetic dipole, $D_{\gamma, \alpha\beta}$, magnetic dipole-electric quadrupole and the magnetizability (magnetic dipole-magnetic dipole polarizability) $\xi_{\alpha\beta}$. The frequency-dependent response properties labeled with a prime vanish for $\omega = 0$, and the properties specified in the second rows of the equations (Eqs. 75, 77, 79) are zero for reference states described by real wave functions (in practice, closed-shell nondegenerate systems).

We note that in the expansion of the induced dipole moment, higher-order corrections may also be important, in particular in connection with electric-field perturbations. For instance, considering only electric dipole contributions, it is customary to also include contributions to μ_{α} arising from frequency-dependent hyperpolarizabilities (see Eq. 84 below).

Electric Properties

In this section we consider molecular properties which characterize the interactions with static and/or frequency-dependent electric fields. The electric properties of a molecule determine the electric properties of the bulk sample, such as the relative permittivity (dielectric constant) and the refractive index. In addition, the electric properties can be used to describe intermolecular forces.

Only static and dynamic molecular properties involving electric dipole and quadrupole operators will be discussed below. However, electric properties related to higher-order electric multipole operators can also be determined in a similar manner to the properties described here, in terms of expectation values, linear and nonlinear response functions. Nevertheless, it should be kept in mind that although the same formalism is applied in the calculation of response functions involving octupole, hexadecapole, and higher moments, in practice it may be difficult to obtain accurate results for these moments and related molecular properties. For instance, significantly larger basis sets with more polarization and diffuse functions may be required than for the properties involving lower-order electric moments.

Most theoretical results are obtained in atomic units (a.u.), whereas experimental data often are given in SI or esu units. In Table 1 some useful conversion factors are given.

Electric Multipole Moments

The permanent multipole moments characterize the charge distribution in a molecule. The zeroth-order (monopole) moment corresponds to the total charge, the first moment to the dipole, the second to the quadrupole, and so on. The multipole

^bThe nuclear quadrupole moments, needed to compare the calculated NQCC with experiment (section “[Electric Field Gradient at the Nucleus, Nuclear Quadrupole Coupling Constant](#)”), are usually given in barn; 1b = 10^{-28} m^2

moments can be computed as expectation values of the multipole moment operators discussed in section “[Small Terms Due to the Scalar Potential in the Hamiltonian.](#)” As for the operators, we can use the primitive or traceless forms for the quadrupole and higher-order moments. The traceless multipole moments describe the deviation from an isotropic charge distribution. For instance, the traceless quadrupole moment vanishes for a spherical charge distribution when the center of the sphere coincides with the origin, since the transformation from the primitive (traced) quadrupole moment $q_{\alpha\beta}$ to the traceless quadrupole moment $\Theta_{\alpha\beta}$ eliminates the isotropic contribution. The traceless multipole moment of order n is defined by $2n + 1$ components, whereas the traced tensor involves $(n + 2)(n + 1)/2$ independent quantities. A tabulation of nonzero symmetry-independent elements of multipole moments (μ = dipole, Θ = quadrupole, Ω = octupole, and Φ = hexadecapole) for different point groups is given by Kielich (1972).

In general, when the multipole expansion of the potential is used to describe the influence of a static electric field, only the first nonzero moment is unambiguously defined. The next, higher-order multipole moments depend on the choice of origin, and when computed with respect to the origin of the coordinate system, they depend on the position of the molecule in space. This can be seen from Eq. 30, where a shift of the chosen common origin for the expansion of the potential by a vector \mathbf{D} for a molecule with the total charge Q leads to a change of $Q\mathbf{D}$ in the dipole moment; similarly, for a neutral molecule with a nonzero dipole moment, the quadrupole moment will change.

Dipole and Quadrupole Moments

From the multipole expansion of the energy in the presence of a static electric field, Eq. 73, we find that the α -component of the static permanent dipole moment is defined as the electric field derivative of $E(\mathbf{F})$

$$\mu_\alpha = - \left. \frac{\partial E(\mathbf{F})}{\partial F_\alpha} \right|_{\mathbf{F}=\mathbf{0}}. \quad (80)$$

For wave functions that fulfill the Hellman–Feynman theorem we can compute the dipole moment as the expectation value

$$\mu_\alpha = \langle 0 | \hat{\mu}_\alpha | 0 \rangle, \quad (81)$$

where $\hat{\mu}_\alpha$ is the α -component of the dipole moment operator defined in Eq. 30. Obviously, the expectation value expression is correct for the exact wave function. Furthermore, for most approximate wave functions it is much easier to compute the expectation value than to calculate the energy derivative. However, the results differ when the method used does not fulfill the Hellman–Feynman theorem. In this case, one can either derive the analytic expressions which reproduce the correct definition of the electric field derivative of $E(\mathbf{F})$ (see for instance the discussion of the coupled cluster approach in Helgaker et al. 2000) or use the finite field method and numerical differentiation.

The finite-field method appears to be very simple and has been often applied, but it has some drawbacks. First, the values of $E(\mathbf{F})$ depend not only on the dipole moment, but also on the polarizability and hyperpolarizabilities, and high accuracy of the computed values of $E(\mathbf{F})$ is required to perform the numerical differentiation accurately. Moreover, the presence of the finite electric field may lower the symmetry of the system, making the calculations much more time-consuming.

Figure 1, taken from Bak et al. (2000), illustrates the accuracy of equilibrium geometry dipole moments calculated for a series of small molecules. In Bak et al. (2000), the dipole moments of 11 molecules were studied at various levels of approximation using a sequence of basis sets, with the CCSD(T)/aug-cc-pVQZ results providing the benchmark values. The normal distribution of errors with respect to the reference values, shown in Fig. 1, demonstrates the systematic improvements of the computed results with increasing basis set and improved treatment of electron correlation effects.

The expectation value of $\hat{\Theta}$, that is, the traceless electric quadrupole operator as defined in Eq. 32 following Buckingham (1967),

$$\Theta_{\alpha\beta} = \langle 0 | \hat{\Theta}_{\alpha\beta} | 0 \rangle = -3 \frac{\partial E(\nabla\mathbf{F})}{\partial F_{\alpha\beta}}, \quad (82)$$

can be related to the expectation values of second moments, $q_{\alpha\beta} = \langle 0 | \hat{q}_{\alpha\beta} | 0 \rangle$, by a simple linear transformation, the same as that connecting the corresponding operators, Eqs. 32 and 33. Both Θ and \mathbf{q} are rank two, symmetric tensors.

For molecules with an n -fold rotation axis with $n \geq 3$:

$$\Theta \equiv \Theta_{zz} = -2\Theta_{yy} = -2\Theta_{xx}, \quad (83)$$

where z coincides with the rotation axis. In experiment, two diagonal components of Θ are measured.

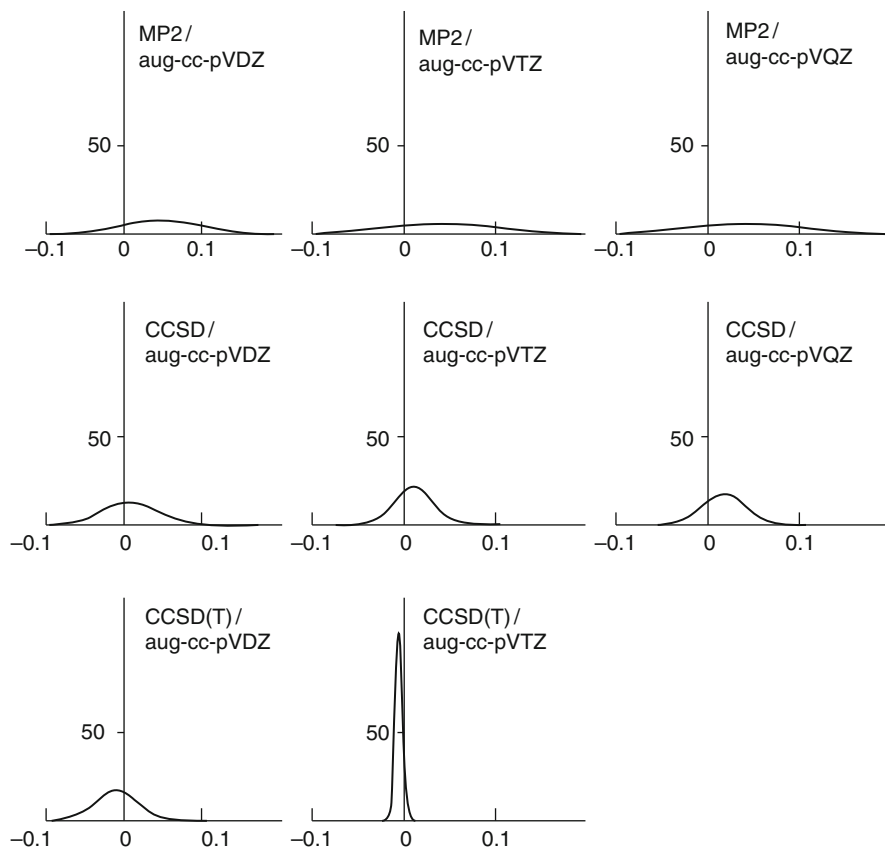

Fig. 1 Correlation and basis set dependence of the dipole moment – normal distribution of errors (in Debye) (Reproduced by permission from Bak et al. (2000))

The Origin of the Frequency-Dependent Electric Dipole Polarizability and Hyperpolarizabilities

The electric dipole moment $\tilde{\mu}$ in the presence of an applied spatially homogeneous non-monochromatic electric field $\sum_i \mathbf{F}^{\omega_i}$ (where ω_i indicates the circular frequency) can be written as

$$\begin{aligned}
 \tilde{\mu}_\alpha^{\omega_\sigma} &= \mu_\alpha \delta(\omega_\sigma = 0) + \alpha_{\alpha\beta}(-\omega_\sigma; \omega_1) F_\beta(\omega_1) \\
 &+ \frac{1}{2} \sum_{\omega_1, \omega_2} \beta_{\alpha\beta\gamma}(-\omega_\sigma; \omega_1, \omega_2) F_\beta(\omega_1) F_\gamma(\omega_2) \\
 &+ \frac{1}{6} \sum_{\omega_1, \omega_2, \omega_3} \gamma_{\alpha\beta\gamma\delta}(-\omega_\sigma; \omega_1, \omega_2, \omega_3) F_\beta(\omega_1) F_\gamma(\omega_2) F_\delta(\omega_3) + \dots,
 \end{aligned} \tag{84}$$

where μ_α is the unperturbed electric dipole moment. In this phenomenological expansion (which we use to describe elastic light scattering processes) the summations over optical frequencies will be restricted in order to preserve a constant ω_σ equal to the sum of optical frequencies

$$\omega_\sigma = \sum_i \omega_i. \quad (85)$$

Equation 84 defines the components of the dynamic electric dipole polarizability tensor, $\alpha_{\mu\nu}(-\omega_\sigma; \omega_1)$, those of the first electric dipole hyperpolarizability, $\beta_{\mu\nu\eta}(-\omega_\sigma; \omega_1, \omega_2)$, and those of the second electric dipole hyperpolarizability $\gamma_{\mu\nu\eta\xi}(-\omega_\sigma; \omega_1, \omega_2, \omega_3)$. The combination of frequencies and the presence or absence of static fields characterize various nonlinear processes. The calculations can be done for any combination of frequencies satisfying Eq. 85, but only selected examples of the most commonly studied optical phenomena will be discussed below (see, e.g., Willets et al. 1992 and Bogaard and Orr 1975 for more details).

Figure 2 shows how some of these processes can be interpreted in terms of electronic transitions between ground and excited states. The excited states can be treated as virtual states, but if one of the excitation energies is close to the frequency of the light, the contribution of that state is often dominant. Simplified models that include in the analysis only a few excited states can be used when these computed states describe well the real, physical states of the molecule which are relevant for the property studied. However, it is important to emphasize that even though these few-states models in many cases may give qualitative insight into the electronic processes, the convergence of the sum-over-states expansion for the (hyper)polarizabilities (see Eqs. 65, 68, and 72) with respect to the number of excited states included in the summation is in general very slow (Wiberg et al. 2006). We should also keep in mind that if an excitation energy equals a frequency, we have a very different situation in which we have to consider the finite lifetime of the excited state and also deal with the absorption process.

In experiment, the molecule is often perturbed by a combination of a static and a dynamic electric field. We then have, assuming a monochromatic dynamic field,

$$F_\alpha(t) = F_\alpha^0 + F_\alpha^\omega \cos(\omega t), \quad (86)$$

and therefore the time dependence of the polarization can be described as

$$\mu_\alpha(t) = \mu_\alpha^0 + \mu_\alpha^\omega \cos(\omega t) + \mu_\alpha^{2\omega} \cos(2\omega t) + \mu_\alpha^{3\omega} \cos(3\omega t) + \dots, \quad (87)$$

where $\mu_\alpha^{n\omega}$ are the Fourier amplitudes to be determined. In order to compare the measured polarization at a certain frequency to the theoretical expressions, we insert Eq. 86 into Eq. 84 and use the relations between $\cos^n(\omega t)$ and $\cos(n\omega t)$. We obtain

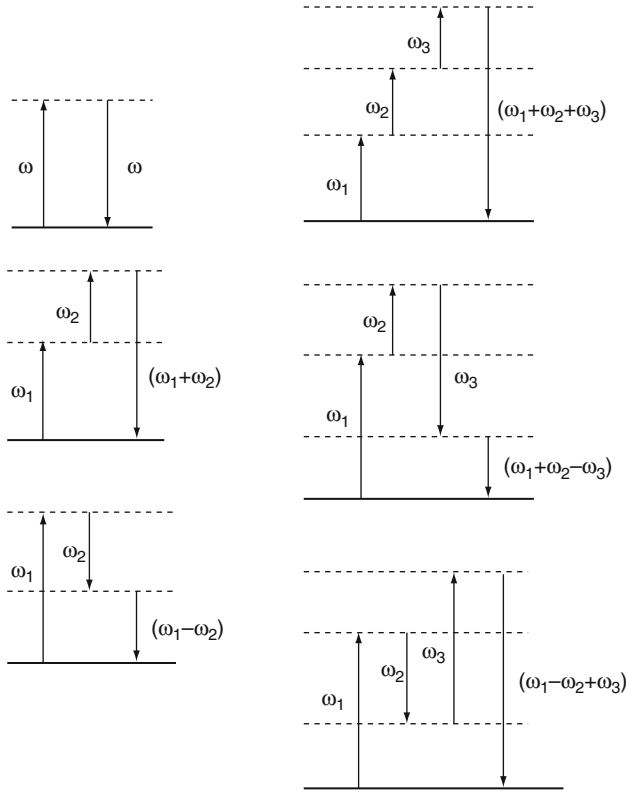

Fig. 2 Linear and nonlinear optical properties – a schematic illustration of the involved transitions for (left, top to bottom): $\alpha(-\omega; \omega)$; $\beta(-(\omega_1 + \omega_2); \omega_1, \omega_2)$; and $\beta(-(\omega_1 - \omega_2); \omega_1, -\omega_2)$; (right, top to bottom) $\gamma(-(\omega_1 + \omega_2 + \omega_3); \omega_1, \omega_2, \omega_3)$; $\gamma(-(\omega_1 + \omega_2 - \omega_3); \omega_1, \omega_2, -\omega_3)$, and $\gamma(-(\omega_1 - \omega_2 + \omega_3); \omega_1, -\omega_2, \omega_3)$

$$\begin{aligned} \mu_\alpha^0 &= \mu_\alpha + \alpha_{\alpha\beta}(0; 0) F_\beta^0 + \frac{1}{2}\beta_{\alpha\beta\gamma}(0; 0, 0) F_\beta^0 F_\gamma^0 + \frac{1}{8}\gamma_{\alpha\beta\gamma\delta}(0; 0, 0, 0) F_\beta^0 F_\gamma^0 F_\delta^0 \\ &+ \frac{1}{4}\beta_{\alpha\beta\gamma}(0; -\omega, \omega) F_\beta^\omega F_\gamma^\omega + \frac{1}{4}\gamma_{\alpha\beta\gamma\delta}(0; 0, -\omega, \omega) F_\beta^0 F_\gamma^\omega F_\delta^\omega, \end{aligned} \quad (88)$$

$$\begin{aligned} \mu_\alpha^\omega &= \alpha_{\alpha\beta}(-\omega; \omega) F_\beta^\omega + \beta_{\alpha\beta\gamma}(-\omega; \omega, 0) F_\beta^\omega F_\gamma^0 \\ &+ \frac{1}{2}\gamma_{\alpha\beta\gamma\delta}(-\omega; \omega, 0, 0) F_\beta^\omega F_\gamma^0 F_\delta^0 + \frac{1}{8}\gamma_{\alpha\beta\gamma\delta}(-\omega; \omega, -\omega, \omega) F_\beta^\omega F_\gamma^\omega F_\delta^\omega, \end{aligned} \quad (89)$$

$$\mu_\alpha^{2\omega} = \frac{1}{4}\beta_{\alpha\beta\gamma}(-2\omega; \omega, \omega) F_\beta^\omega F_\gamma^\omega + \frac{1}{4}\gamma_{\alpha\beta\gamma\delta}(-2\omega; \omega, \omega, 0) F_\beta^\omega F_\gamma^\omega F_\delta^0, \quad (90)$$

$$\mu_\alpha^{3\omega} = \frac{1}{24}\gamma_{\alpha\beta\gamma\delta}(-3\omega; \omega, \omega, \omega) F_\beta^\omega F_\gamma^\omega F_\delta^\omega, \quad (91)$$

where we have truncated the expansions at $\cos(3\omega t)$. Using the expansions given above and the expansion in Eq. 84 we can compare the experimentally measured polarization and the theoretical estimates.

Dipole Polarizability

The frequency-dependent electric dipole polarizability is, next to the dipole moment, the most important effect characterizing the response of a molecule to electromagnetic radiation. It is a second-order symmetric tensor determined by the linear response function

$$\alpha_{\alpha\beta}(-\omega; \omega) = -\langle\langle \hat{\mu}_\alpha; \hat{\mu}_\beta \rangle\rangle_\omega. \quad (92)$$

The frequency dependence of the polarizability may be described using the Cauchy moments (section “[Cauchy Moments](#)”).

For the static dipole polarizability $\alpha(0;0)$ we have

$$\alpha_{\alpha\beta}(0;0) = -\left. \frac{\partial^2 E(\mathbf{F})}{\partial F_\alpha \partial F_\beta} \right|_{\mathbf{F}=\mathbf{0}}, \quad (93)$$

and the energy derivative can be evaluated using the finite-field approach (i.e., computing numerically the differences between $E(\mathbf{F})$ and $E(0)$).

Numerous molecular properties which describe nonlinear effects, such as the Kerr effect (section “[Second Dipole Hyperpolarizability](#)”) or magnetic circular dichroism (section “[Magnetic Circular Dichroism](#)”), arising in the presence of radiation and additional electric or magnetic fields, are interpreted as derivatives of the dipole polarizability (Michl and Thulstrup 1995). They can be calculated as higher-order response functions. Similarly, relativistic corrections to the polarizabilities for heavy atoms can be estimated from higher-order response functions including the mass-velocity and Darwin operators, Eqs. 9 and 20, as additional perturbations (Kirpekar et al. 1995).

In isotropic fluids, the experimentally measured quantity is usually the scalar component of the α tensor given by the isotropic average, defined as

$$\alpha_{\text{iso}} = \frac{1}{3} \alpha_{\eta\eta}. \quad (94)$$

The polarizability anisotropy may be defined as

$$(\alpha_{\text{anis}})^2 = \frac{(3\alpha_{\mu\nu}\alpha_{\mu\nu} - \alpha_{\mu\mu}\alpha_{\nu\nu})}{2}, \quad (95)$$

which, using the components of the diagonalized tensor, leads to

$$\alpha_{\text{anis}} = 2^{-1/2} \left[(\alpha_{xx} - \alpha_{yy})^2 + (\alpha_{yy} - \alpha_{zz})^2 + (\alpha_{zz} - \alpha_{xx})^2 \right]^{1/2}. \quad (96)$$

For linear molecules, α_{anis} reduces to the difference between the parallel and perpendicular components,

$$\alpha_{\text{anis}} = \alpha_{\parallel} - \alpha_{\perp}. \quad (97)$$

The macroscopic property related to the molecular polarizability α is the dielectric constant ε , defined by the ratio of the permittivity of the medium to the electric constant, ε_0 . It is also related to the refractive index n ($n = \sqrt{\varepsilon}$, assuming the vacuum magnetic permeability to be equal to 1). The quantity measured in a dielectric constant experiment is

$$\tilde{\alpha} = \left(\frac{\tilde{\mu}_Z^F}{F} \right)_{F \rightarrow 0} = \langle \alpha_{II} \rangle_{\Omega} + \frac{\mu_z^2}{3kT}, \quad (98)$$

where we use the notation $\langle \dots \rangle_{\Omega}$ for the average over all the orientations, k is the Boltzmann constant, and T is the temperature. The temperature-dependent term is proportional to the square of the dipole moment, the temperature-independent term is the isotropic average of the polarizability (using Eq. 94 we can obtain a corresponding expression in terms of properties calculated in the molecular frame of reference).

The anisotropy of the electric dipole polarizability can be determined in Rayleigh scattering experiments, where the observed depolarization of the incident light is a function of $(\alpha_{\text{anis}})^2$ (Bonin and Kresin 1997).

The static electric dipole polarizability of the He atom has been studied in more detail than any other response property of any other atomic or molecular system. Not only is the nonrelativistic value known accurately, and the relativistic corrections computed, but – in a recent benchmark calculation – the quantum-electrodynamic corrections have also been analyzed and numerous effects related to the nuclear mass have been taken into account (Łach et al. 2004).

Standard energy-optimized basis sets are not suitable for accurate calculations of electric polarizabilities. The simplest solution – adding the necessary polarization and diffuse functions – makes the basis sets too large to enable efficient calculations for large molecules. Significantly smaller basis sets, designed considering the electric-field dependence of the orbitals (Benkova et al. 2005; Sadlej 1988), provide results of similar or better quality at lower computational cost.

A practical problem that may be encountered in calculations using very extended basis sets is the appearance of linear dependencies in the basis set. This may make the response equations (as well as the equations determining the molecular energy/density) ill-conditioned and the calculations slowly convergent; in exceptional cases it may even be impossible to converge the equations. The problem is normally resolved by removing the linear dependencies in the basis set, or by removing manually the most diffuse basis functions from the basis set.

Electron correlation effects on the isotropic polarizability are in general moderate, being at the most 5–10 % of the uncorrelated value and for nondipolar systems

always leading to an increased polarizability. Correlation effects are usually larger on the individual tensor components than on the isotropic polarizability, and can, therefore, be expected to be more important for the polarizability anisotropies. In general, Hartree–Fock polarizability anisotropies cannot be considered accurate enough to allow for a quantitative comparison with experimental observations, or for the interpretation of the ellipticity arising in some birefringences, where the polarizability anisotropies often constitute an important (and dominant) orientational contribution.

DFT in general reproduces quite well correlation effects in the polarizability of small molecular systems. In particular, polarizability anisotropies calculated using DFT will usually be in better agreement with experiment. However, due to the local nature of the exchange–correlation functionals and the lack of general implementations of current density functionals, DFT does not perform so well for extended conjugated systems (Champagne et al. 2000). We will return briefly to this point when discussing calculations of hyperpolarizabilities.

First Dipole Hyperpolarizability

The first electric dipole hyperpolarizability, given by the quadratic response function

$$\beta_{\alpha\beta\gamma}(-\omega_{\sigma}; \omega_1, \omega_2) = -\langle\langle \hat{\mu}_{\alpha}; \hat{\mu}_{\beta}, \hat{\mu}_{\gamma} \rangle\rangle_{\omega_1, \omega_2}, \quad (99)$$

has physical meaning only when $\omega_{\sigma} = \omega_1 + \omega_2$.

The static dipole hyperpolarizability $\beta(0;0,0)$ can be obtained evaluating the third derivative of the energy. When we consider dynamic fields, the processes of particular interest are:

Second Harmonic Generation (SHG)	$\beta_{\mu\nu\eta}^{\text{SHG}}(-2\omega; \omega, \omega) = -\langle\langle \hat{\mu}_{\mu}; \hat{\mu}_{\nu}, \hat{\mu}_{\eta} \rangle\rangle_{\omega, \omega},$
dc-Pockels Effect (dc-P) or	
Electro-Optic Pockels Effect (EOPE)	$\beta_{\mu\nu\eta}^{\text{EOPE}}(-\omega; \omega, 0) = -\langle\langle \hat{\mu}_{\mu}; \hat{\mu}_{\nu}, \hat{\mu}_{\eta} \rangle\rangle_{\omega, 0},$
Optical Rectification (OR)	$\beta_{\mu\nu\eta}^{\text{OR}}(0; \omega, -\omega) = -\langle\langle \hat{\mu}_{\mu}; \hat{\mu}_{\nu}, \hat{\mu}_{\eta} \rangle\rangle_{\omega, -\omega}.$

According to Eqs. 88, 89, 90, and 91, in these processes we deal with a perturbation of frequency ω (and a static field in the Pockels effect) and we consider the resulting dipole moment oscillating with frequency 2ω , frequency ω or static, respectively.

The general definition of the quadratic response function, Eq. 68, indicates its symmetry with respect to permutation of operators. Thus, for all the dipole hyperpolarizabilities we have

$$\beta_{\mu\nu\eta}(-\omega_{\sigma}; \omega_1, \omega_2) = \beta_{\mu\eta\nu}(-\omega_{\sigma}; \omega_2, \omega_1). \quad (100)$$

Also the relation

$$\beta_{\mu\nu\eta}(-\omega_\sigma; \omega_1, \omega_2) = \beta_{\nu\mu\eta}(\omega_1; -\omega_\sigma, \omega_2) \quad (101)$$

holds, and we have, for instance, $\beta_{\mu\nu\eta}^{\text{OR}}(0; \omega, -\omega) = \beta_{\eta\nu\mu}^{\text{EOPE}}(-\omega; \omega, 0)$. We note that this relation does not hold for macroscopic samples due to the differences in the local fields experienced by the molecule in these two different experimental setups.

In the case of the first hyperpolarizability, the measured quantity is the vector component of β in the direction of the permanent dipole moment μ , defining the molecular z axis. The relevant averages are given by:

$$\beta_{\parallel} = \frac{1}{5} (\beta_{z\eta\eta} + \beta_{\eta z\eta} + \beta_{\eta\eta z}), \quad (102)$$

$$\beta_{\perp} = \frac{1}{5} (2\beta_{z\eta\eta} - 3\beta_{\eta z\eta} + 2\beta_{\eta\eta z}), \quad (103)$$

where the same sequence of optical frequencies (not given explicitly) is used for the laboratory axes and the molecular axes.

The number of independent nonzero tensor elements depends on the nonlinear optical process and on the symmetry of the molecule, see for instance Bogaard and Orr (1975). For example, β^{SHG} is symmetric with respect to the permutation of the second and third indices (see Eq. 100) and this can be used to simplify the equations for the parallel and perpendicular components. For nonzero frequencies, the number of independent tensor components to be computed decreases when Kleinman's symmetry (Kleinman 1972) is assumed – that is, we assume that we can permute the indices of the incoming light without changing the corresponding frequencies,

$$\beta_{\mu\nu\eta}(-\omega_\sigma; \omega_1, \omega_2) \approx \beta_{\mu\eta\nu}(-\omega_\sigma; \omega_1, \omega_2). \quad (104)$$

Although for $\omega_1 \neq \omega_2$ this is only an approximation and these two tensor components are not equal, Kleinman's symmetry is often applied for low frequencies, where it is usually found to be a reasonable approximation.

The basis set requirements for the calculation of first hyperpolarizabilities are much the same as for the linear polarizability. However, as the first hyperpolarizability probes even higher-order electric-field-perturbed densities of the molecule, care should be exercised to ensure that the basis set is sufficiently saturated with respect to diffuse polarizing functions. Special basis sets have been developed for the calculation of hyperpolarizabilities by Pluta and Sadlej (1998), though the same basis sets that can be used for polarizabilities in most cases give reliable estimates also for first hyperpolarizabilities.

Due to the fact that the first hyperpolarizability involves multiple virtual excited states (Eq. 68), the property has proven to be more sensitive to electron correlation effects than the polarizability (Christiansen et al. 2006). Molecules with push-pull

conjugated structures are often characterized by large first hyperpolarizabilities. Due to the problems facing many commonly used local exchange-correlation functionals, DFT has been shown to have difficulties describing correctly nonlinear optical properties such as the first hyperpolarizability for extended systems (Champagne et al. 2000). The recently introduced Coulomb-attenuated B3LYP functional (CAM-B3LYP), see Yanai et al. (2004) has, in contrast, shown quite good performance also for rather extended systems (Paterson et al. 2006).

Second Dipole Hyperpolarizability

The second dipole hyperpolarizability is described by the cubic response function

$$\gamma_{\alpha\beta\gamma\delta}(-\omega_\sigma; \omega_1, \omega_2, \omega_3) = -\langle\langle \hat{\mu}_\alpha; \hat{\mu}_\beta, \hat{\mu}_\gamma, \hat{\mu}_\delta \rangle\rangle_{\omega_1, \omega_2, \omega_3}, \quad (105)$$

where $\omega_\sigma = \omega_1 + \omega_2 + \omega_3$.

Similarly to the lower-order static polarizabilities, the hyperpolarizability $\gamma(0;0,0,0)$ corresponds to an energy derivative and can be computed using the finite-field approach. Among the possible frequency-dependent third-order processes, the most relevant are:

Electric Field – Induced Second Harmonic Generation (dc-SHG, ESHG, EFISH)	
$\gamma_{\mu\nu\eta\xi}^{\text{ESHG}}(-2\omega; \omega, \omega, 0)$	$= -\langle\langle \hat{\mu}_\mu; \hat{\mu}_\nu, \hat{\mu}_\eta, \hat{\mu}_\xi \rangle\rangle_{\omega, \omega, 0}$
Third Harmonic Generation (THG)	
$\gamma_{\mu\nu\eta\xi}^{\text{THG}}(-3\omega; \omega, \omega, \omega)$	$= -\langle\langle \hat{\mu}_\mu; \hat{\mu}_\nu, \hat{\mu}_\eta, \hat{\mu}_\xi \rangle\rangle_{\omega, \omega, \omega}$
Electro-optical or dc-Kerr effect (EOKE, dc-Kerr)	
$\gamma_{\mu\nu\eta\xi}^{\text{dc-Kerr}}(-\omega; \omega, 0, 0)$	$= -\langle\langle \hat{\mu}_\mu; \hat{\mu}_\nu, \hat{\mu}_\eta, \hat{\mu}_\xi \rangle\rangle_{\omega, 0, 0}$
Optical or ac-Kerr effect (OKE, ac-Kerr)	
$\gamma_{\mu\nu\eta\xi}^{\text{ac-Kerr}}(-\omega_1; \omega_1, \omega_2, -\omega_2)$	$= -\langle\langle \hat{\mu}_\mu; \hat{\mu}_\nu, \hat{\mu}_\eta, \hat{\mu}_\xi \rangle\rangle_{\omega_1, \omega_2, -\omega_2}$
Intensity-Dependent Refractive Index or Degenerate Four Wave Mixing (IDRI or DFWM)	
$\gamma_{\mu\nu\eta\xi}^{\text{IDRI}}(-\omega; \omega, \omega, -\omega)$	$= -\langle\langle \hat{\mu}_\mu; \hat{\mu}_\nu, \hat{\mu}_\eta, \hat{\mu}_\xi \rangle\rangle_{\omega, \omega, -\omega}$
dc Optical Rectification (dc-OR, EFior)	
$\gamma_{\mu\nu\eta\xi}^{\text{dc-OR}}(0; \omega, -\omega, 0)$	$= -\langle\langle \hat{\mu}_\mu; \hat{\mu}_\nu, \hat{\mu}_\eta, \hat{\mu}_\xi \rangle\rangle_{\omega, -\omega, 0}$

The experimentally measured quantities in isotropic fluids are usually the scalar components of the tensor γ given by the isotropic average:

$$\gamma_{\parallel} = \frac{1}{15} (\gamma_{\xi\eta\eta\xi} + \gamma_{\xi\eta\xi\eta} + \gamma_{\xi\xi\eta\eta}), \quad (106)$$

$$\gamma_{\perp} = \frac{1}{15} (2\gamma_{\xi\eta\eta\xi} - \gamma_{\xi\xi\eta\eta}), \quad (107)$$

where the same sequence of optical frequencies, not given explicitly above, is used for the laboratory axes and the molecular axes.

As for the first hyperpolarizability, the number of independent nonzero tensor elements depends on the optical process and on the symmetry of the molecule. For example, γ^{THG} is symmetric with respect to the second, third, and fourth indices, and this can be used to simplify Eqs. 106–107. For instance, the average value that should be compared with the experimental THG parallel component becomes

$$\gamma_{\parallel}^{\text{THG}} = \frac{1}{5} \gamma_{\xi\xi\eta\eta}^{\text{THG}}. \quad (108)$$

Experimentally, if all fields have parallel polarization, one can measure the parallel components of the first and second hyperpolarizabilities which take into account the classical orientational averaging. In the case of ESHG, with the optical field polarized perpendicular to the static field, one measures the perpendicular components, and in the case of a dc-Kerr experiment, the differences between the parallel and perpendicular components.

In the ESHG experiment a laser beam passes through the sample in a static electric field and a weak, collinear, frequency-doubled beam is detected. Absolute values for the hyperpolarizabilities cannot be extracted; the signal from the sample is compared to that of a known buffer gas (ultimately helium, for which there are accurate theoretical values (Bishop and Pipin 1989)) or a solid. In analogy with the derivation for $\tilde{\alpha}$, the classical thermal averaging yields

$$\tilde{\gamma}^{\text{ESHG}} = \left(\tilde{\beta}_{ZZZ}^F / F \right)_{F \rightarrow 0} = \langle \gamma_{ZZZZ} \rangle_{\Omega} + \frac{\mu_z \langle \beta_{ZZZ} \rangle_{\Omega}}{3kT}. \quad (109)$$

The molecular hyperpolarizabilities γ^{ESHG} and β^{SHG} can be obtained in this experiment. For non-centrosymmetric molecules a series of measurements over a range of temperatures has to be performed, whereas for centrosymmetric molecules $\beta = 0$ and thus a single measurement at one temperature is sufficient.

The majority of existing experimental data on hyperpolarizabilities are derived from ESHG and dc-Kerr measurements (Shelton and Rice 1994). The dc-Kerr effect differs from the other nonlinear optical processes as it allows for absolute measurements without the need for a reference measurement. The measured molar Kerr constant is (Shelton and Rice 1994):

$$A^{\text{dc-Kerr}} = \frac{N_A}{81\epsilon_0} \left[\frac{3}{2} (\langle \gamma_{ZZZZ} \rangle_{\Omega} - \langle \gamma_{ZXXZ} \rangle_{\Omega}) + \mu_z (\langle \beta_{ZZZ} \rangle_{\Omega} - \langle \beta_{XZX} \rangle_{\Omega}) / kT \right. \\ \left. + \frac{3}{10kT} \left(\alpha_{\alpha\beta} \alpha_{\alpha\beta}^0 - \langle \alpha_{ZZ} \rangle_{\Omega} \langle \alpha_{ZZ} \rangle_{\Omega} \right) + \frac{1}{kT} \mu_z^2 (\alpha_{zz} - \langle \alpha_{ZZ} \rangle_{\Omega}) \right], \quad (110)$$

where N_A is Avogadro's number, and it involves both dynamic hyperpolarizabilities ($\gamma^{\text{dc-Kerr}}$ and β^{EOPE}) as well as static (superscript 0) and dynamic polarizabilities.

The computational requirements for the second hyperpolarizability are more or less the same as for the first hyperpolarizability. Although the number of studies that analyze the importance of electron correlation effects (not including here DFT) is rather limited, the available results confirm in general the findings made for the first hyperpolarizabilities (Christiansen et al. 2006).

Cauchy Moments

Response functions for a system in its electronic ground state are analytic functions of the frequency arguments, except at the poles that occur when a frequency or a sum of frequencies is equal to an excitation energy. Thus, for frequencies below the first pole, the linear, quadratic, or cubic response functions can be expanded in power series (Hättig and Jørgensen 1998). Let us consider in more detail the simplest case when only electric dipole operators are involved and the frequency dependence of the (hyper)polarizabilities is of interest. The Cauchy series – that is, the power series expansion of the frequency-dependent polarizability – is usually written as:

$$\alpha(-\omega; \omega) = \sum_{k=0}^{\infty} \omega^{2k} S(-2k-2) = S(-2) + \omega^2 S(-4) + \omega^4 S(-6) + \dots, \quad (111)$$

where $S(-2) = \alpha(0; 0)$. This expansion is valid also for purely imaginary frequency arguments.

Similar expansions may be applied to describe the dispersion effects for hyperpolarizabilities. Often, the power series expansion in the frequency arguments may be truncated at second order leading to:

$$\alpha_{\text{iso}}(-\omega_{\sigma}; \omega_1) = \alpha_{\text{iso}}(0; 0) [1 + \mathcal{A}^{\alpha} (\omega_{\sigma}^2 + \omega_1^2) + \mathcal{O}(\omega_i^4)], \quad (112)$$

$$\beta_{\parallel}(-\omega_{\sigma}; \omega_1, \omega_2) = \beta_{\parallel}(0; 0, 0) [1 + \mathcal{A}^{\beta} (\omega_{\sigma}^2 + \omega_1^2 + \omega_2^2) + \mathcal{O}(\omega_i^4)], \quad (113)$$

$$\gamma_{\parallel}(-\omega_{\sigma}; \omega_1, \omega_2, \omega_3) = \gamma_{\parallel}(0; 0, 0, 0) [1 + \mathcal{A}^{\gamma} (\omega_{\sigma}^2 + \omega_1^2 + \omega_2^2 + \omega_3^2) + \mathcal{O}(\omega_i^4)]. \quad (114)$$

Each expansion contains only a single second-order dispersion coefficient \mathcal{A} . Since these coefficients for different optical processes of a given order are equivalent (Bishop 1995), they express the dispersion of frequency-dependent properties in a way that is transferable between different optical processes, for instance \mathcal{A}^{β} describes both the second-harmonic generation and the (dc-)electro-optic Pockels effect.

Long-Range Dispersion Interaction Coefficients

For neutral, closed-shell weakly interacting systems, one of the dominant contributions to the interaction energy at large intermolecular distances is the dispersion energy. It can be analyzed using perturbation theory, and for two atoms or molecules A and B , we find (McWeeny 1992):

$$E_{\text{disp}}^{AB} = -\frac{1}{\hbar} \sum_{n \neq 0}^A \sum_{m \neq 0}^B \frac{\left| \langle 0^A 0^B | \hat{V}^{AB} | n^A m^B \rangle \right|^2}{\omega_{n0}^A + \omega_{m0}^B}, \quad (115)$$

where \hat{V}^{AB} denotes the intersystem interaction, $|0^A\rangle$ and $|n^A\rangle$ represent the ground and excited states of system A , ω_{n0}^A is the excitation energy, and similarly for system B .

We would like to express the dispersion energy in terms of response properties of molecules A and B since this allows for a physical interpretation of the dispersion interaction. Such an expression is obtained applying an integral transform to avoid the summation of the A and B excitation energies in the denominator of Eq. 115 and using the multipole expansion of the perturbing operator \hat{V}^{AB} .

For the second-order dispersion interaction between closed-shell atoms A and B we have:

$$E_{\text{disp}}^{AB}(R) = -\frac{C_6^{AB}}{R^6} - \frac{C_8^{AB}}{R^8} - \frac{C_{10}^{AB}}{R^{10}} - \dots, \quad (116)$$

where the coefficient for the dipole–dipole term can be written as (Langhoff et al. 1971):

$$C_6^{AB} = \frac{\hbar}{(4\pi\epsilon_0)^2} \frac{3}{\pi} \int_0^\infty \alpha^A(-i\omega; i\omega) \alpha^B(-i\omega; i\omega) d\omega. \quad (117)$$

This equation is known as the Casimir–Polder formula. The polarizability at imaginary frequencies, $\alpha(-i\omega; i\omega)$, can be obtained for instance using Eq. 111 with an imaginary value of ω . The C_n^{AB} , $n > 6$ coefficients depend on similar higher-order multipole polarizabilities of one or both atoms. The same approach can be applied for atom–molecule and molecule–molecule interactions considering individual tensor components of the required polarizabilities. It can also be used for three-body interactions, and to describe the dispersion contributions to the pair polarizability function (Fowler et al. 1994).

To determine the long-range dispersion coefficients we need the values of $\alpha(-i\omega; i\omega)$ for the whole range of imaginary frequencies, whereas the radius of convergence of the power series expansion of the polarizability (Eq. 111) is determined by the lowest excitation energy. However, using analytic continuation of the Cauchy expansion (Langhoff and Karplus 1970) we can obtain all the required values of $\alpha(-i\omega; i\omega)$ and thus we can determine accurate values of the dispersion interaction

coefficient C_6^{AB} . The polarizabilities at imaginary frequencies can also be obtained directly, solving the complex linear response equations (Norman et al. 2003).

Qualitatively correct estimates of the dispersion energy are obtained in the perturbational approach even using the dispersion coefficients C_n calculated at the DFT level. It has been shown that a successful description of intermolecular forces for large molecules may be obtained in this manner (Misquitta et al. 2005; Podszwa and Szalewicz 2008).

Electric Field Gradient at the Nucleus, Nuclear Quadrupole Coupling Constant

The *electric field gradient* (EFG) tensor at the nucleus $K - V_{\alpha\beta}^K$ – corresponds to the expectation value (Baker et al. 1989; Fowler et al. 1989) of the EFG operator \hat{V}^K given by Eq. 34:

$$V_{\alpha\beta}^K = \langle 0 | \hat{V}_{\alpha\beta}^K | 0 \rangle, \quad (118)$$

where the traceless form of the operator \hat{V}^K is used. The components of the diagonalized EFG tensor, given in its own (EFG) principal axis system, fulfill therefore the equation

$$V_{zz}^K + V_{yy}^K + V_{xx}^K = 0. \quad (119)$$

They are by definition arranged so that

$$|V_{zz}^K| \geq |V_{yy}^K| \geq |V_{xx}^K|. \quad (120)$$

For the asymmetry parameter η_K defined as

$$\eta_K = \frac{V_{xx}^K - V_{yy}^K}{V_{zz}^K}, \quad (121)$$

we thus have $0 \leq \eta_K \leq 1$.

On the other hand, for comparison with experimental data derived from the hyperfine structure of rotational spectra, tensor components defined in the principal axes of inertia system must be used.

For quadrupolar nuclei – that is, nuclei for which the nuclear spin quantum number $I_K \geq 1$, the *nuclear quadrupole coupling* tensor is defined as $-eQ_K \mathbf{V}^K / \hbar$, where eQ_K is the electric quadrupole moment of the nucleus. There is an interaction of the nuclear quadrupole moment tensor with the EFG at the nucleus, mediated by the nuclear spin \mathbf{I}_K and described by the operator:

$$\mathcal{H}^{\text{Nq}} = \frac{1}{2} \sum_K \frac{-eQ_K}{I_K(2I_K - 1)} \mathbf{I}_K^T \mathbf{V}^K \mathbf{I}_K. \quad (122)$$

The *nuclear quadrupole coupling constant* (NQCC) is defined as $-e Q_K V_{zz}^K / \hbar$. The EFG at the nucleus affects the NMR relaxation processes, thus it is relevant in the analysis of the linewidths of NMR signals. The linewidth is proportional to the inverse relaxation time (Abragam 1961), that is:

$$\Delta\nu_{1/2} \propto \frac{1}{T_q} = \frac{3}{40} \frac{2I_K + 3}{I_K^2 (2I_K - 1)} \left(1 + \frac{\eta_K^2}{3}\right) \left(\frac{e Q_K}{\hbar} V_{zz}^K\right)^2 \tau_c, \quad (123)$$

where $\Delta\nu_{1/2}$ is the width of the peak at half of the maximum intensity and τ_c is the correlation time for the quadrupole coupling relaxation.

From the formal $1/r_K^3$ dependence of the operator in Eq. 34, we realize that the basis used to calculate this property must be flexible in the core region and the outer-core/inner-valence region. This is an important requirement, as many modern basis sets are quite heavily contracted in these regions (since the orbitals do not change much in this region when going from the atomic to the molecular system). In general, much of the same basis set requirements as those arising in the calculation of nuclear shielding constants (and to some extent also the spin–spin coupling constants) apply, and we refer to section “[Nuclear Spin–Related Properties](#)” for further discussion.

An important application of theoretically calculated electric field gradients at the nucleus is in the determination of nuclear quadrupole moments. The interaction between the nuclear quadrupole moments and the electric field gradient at the nucleus can be measured with unprecedented accuracy (compared to other experimental approaches for determining nuclear quadrupole moments) in microwave spectroscopy. These interactions give rise to the fine structure in the rotational spectrum of the molecule. Highly accurate estimates for the electric field gradient at the nucleus can often be calculated theoretically (since this is a first-order molecular property). By combining these theoretical results with experimental observations, accurate values of the nuclear quadrupole moments can be obtained, and this approach has been used to revise previously estimated nuclear quadrupole moments (see, e.g., Kellö and Sadlej 1998).

One-Photon Absorption, Excitation Energies, and Transition Moments

Calculations of one-photon absorption enable the determination of the extinction coefficient ε , describing the attenuation of the intensity of an incoming light beam when passing through a sample of absorbing species. In the lowest-order perturbative expansion of the interaction between light and matter, ε is related to the excitation energy and $\langle 0 | \hat{\mu} | n \rangle$, the transition moment between the ground $| 0 \rangle$ and excited $| n \rangle$ electronic states. The derived quantities are the dipole strength

$${}^n D_{\alpha\beta} = \langle 0 | \hat{\mu}_\alpha | n \rangle \langle n | \hat{\mu}_\beta | 0 \rangle, \quad (124)$$

and the oscillator strength. In the length gauge, the latter can be written as

$$f_{0n}^r = \frac{2m_e\omega_{0n}}{3\hbar e^2} \langle 0 | \hat{\mu}_\alpha | n \rangle \langle n | \hat{\mu}_\alpha | 0 \rangle = \frac{2m_e}{3e^2} \lim_{\omega \rightarrow \omega_{0n}} (\omega - \omega_{0n}) \omega \langle \langle \hat{\mu}_\alpha; \hat{\mu}_\alpha \rangle \rangle_\omega. \quad (125)$$

Using the hypervirial relationship

$$\langle 0 | \hat{p}_\alpha | n \rangle = i m_e \omega_{0n} \langle 0 | \hat{r}_\alpha | n \rangle, \quad (126)$$

we obtain in the velocity gauge

$$f_{0n}^v = \frac{2}{3\hbar m_e \omega_{0n}} \langle 0 | \hat{p}_\alpha | n \rangle \langle n | \hat{p}_\alpha | 0 \rangle = \frac{2}{3m_e} \lim_{\omega \rightarrow \omega_{0n}} (\omega - \omega_{0n}) \omega^{-1} \langle \langle \hat{p}_\alpha; \hat{p}_\alpha \rangle \rangle_\omega, \quad (127)$$

and in the mixed length-velocity gauge

$$f_{0n}^{rv} = -\frac{2i}{3\hbar e} \langle 0 | \hat{\mu}_\alpha | n \rangle \langle n | \hat{p}_\alpha | 0 \rangle = -\frac{2i}{3e} \lim_{\omega \rightarrow \omega_{0n}} (\omega - \omega_{0n}) \langle \langle \hat{\mu}_\alpha; \hat{p}_\alpha \rangle \rangle_\omega, \quad (128)$$

respectively (Hansen and Bouman 1980).

To illustrate the differences between oscillator strengths computed in different approaches, we present in Table 2 the results for the $1^1\Sigma_g^+ \rightarrow 1^1\Pi_u$ singlet transition in the N_2 molecule. The HF results and the results for the hierarchy of coupled-cluster approximations (CCS, CC2, CCSD and CC3) show the role of the wave function model. In addition, the role of the basis set is shown in the sequence of the results for the d-aug-cc-pV XZ correlation-consistent basis sets (Kendall et al. 1992), with $X = D, T, Q,$ and 5 , abbreviated in the table as daDZ, daTZ, daQZ, and da5Z, respectively. At the HF level the hypervirial relationship (Eq. 126) is fulfilled in complete basis sets and the differences between computed oscillator strengths are only due to the incompleteness of the basis set. We observe that all the HF results converge with X , and the da5Z values are almost identical. In the CC methods, in addition to the differences arising due to basis set incompleteness, $f_{0n}^r, f_{0n}^v,$ and f_{0n}^{rv} may differ even for a complete basis set since Eq. 126 is not satisfied. This difference should be diminishing as we approach the full CI limit, and in fact for a given one-electron basis the differences between $f_{0n}^r, f_{0n}^v,$ and f_{0n}^{rv} follow the sequence $CCS > CC2 \approx CCSD > CC3$. Finally, we note that for evaluating the accuracy of the results the gauge invariance of a calculated oscillator strength is a necessary, but not sufficient requirement. Gauge invariance has been obtained for large basis sets both at the HF and at the CC3 level, whereas the correlated values differ significantly from the HF results, and only the CC3 results can be expected to be of high accuracy.

Table 2 Oscillator strength and excitation energy (ω_{0n} , in eV) for the singlet transition $1^1\Sigma_g^+ \rightarrow 1^1\Pi_u$ of N_2 ; results taken from Pawłowski et al. (2004)

Model	Basis set	f_{0n}^r	f_{0n}^v	f_{0n}^{rv}	$f_{0n}^r - f_{0n}^v$	ω_{0n}

The Thomas–Reiche–Kuhn (TRK) sum rule, which can be written in terms of the dipole oscillator strengths as

$$\sum_n f_{0n} = N_{e1}, \quad (129)$$

where N_{e1} is the total number of electrons, can be used as another test of the accuracy of the calculations.

Of particular concern are Rydberg states, characterized by a very diffuse orbital occupied by the excited electron. DFT in general fails to properly describe Rydberg-excited states, as many of the common exchange-correlation functionals do not display the correct asymptotic behavior for the $-1/r$ operator. This deficiency of modern exchange-correlation functionals can be partially rectified by introducing the correct asymptotic behavior for the exchange-correlation functional (Tozer and Handy 1998). It is worth noting that the time-dependent Hartree–Fock (TDHF) theory does not display the same problems in describing Rydberg states, due to use of the exact exchange operator. However, the lack of electron correlation effects in TDHF may limit the applicability of this approach for excited states in general.

To account for the broadening of the experimental spectrum (related not only to the finite lifetime of the electronic state, but also to the rovibrational structure,

collisions, and other aspects of the interaction between light and matter), and in particular to investigate whether certain bands may be hidden in the experimental spectrum due to overlapping bands, simple Lorentzian line broadening is often added in the form

$$L(\nu) \approx \frac{\tilde{\Gamma}}{\pi} \left[\frac{1}{(\nu_0 - \nu)^2 + \tilde{\Gamma}^2} \right], \quad (130)$$

where $\tilde{\Gamma}$ is related to the lifetime of the excited state, and ν_0 is the frequency of the electronic excitation. Assuming an isolated absorption band, $\tilde{\Gamma}$ is equal to half the width of the absorption band at half height (the value of $\tilde{\Gamma}$ is often adjusted in the calculations to fit the experimental data). It is common also to employ a Gaussian function to reproduce the line broadening

$$L(\nu) = \frac{2}{\Gamma\sqrt{2\pi}} e^{-2(\nu-\nu_0)^2/\Gamma^2}, \quad (131)$$

and we have $\tilde{\Gamma} = \Gamma\sqrt{(\ln 2)/2}$.

Finally, we recall that the transition moment between two excited states $\langle m | A | n \rangle$ can be obtained using only the reference state wave function from a double residue of the quadratic response function Eq. 70 (and if $|m\rangle = |n\rangle$ we may in this way determine the expectation value of A in the excited state).

Two-Photon Absorption

In experimental studies of two- and multi-photon absorption processes, the multi-photon transition strength, a function of all the frequencies of all photons absorbed, is analyzed. For two laser sources of circular frequency ω_1 and ω_2 with associated wavelengths λ_1 and λ_2 , the two-photon transition strength $\delta(\omega_1, \omega_2)$ for the transition between states $|0\rangle$ and $|n\rangle$ in isotropic samples is given by, see e.g., Craig and Thirunamachandran (1984):

$$\begin{aligned} \delta_{0n}^{\text{TPA}}(\omega_1, \omega_2) = & \mathbf{F} \mathcal{S}_{\alpha\alpha}^{0n}(\omega_1, \omega_2) \mathcal{S}_{\beta\beta}^{0n,*}(\omega_1, \omega_2) + \mathbf{G} \mathcal{S}_{\alpha\beta}^{0n}(\omega_1, \omega_2) \mathcal{S}_{\alpha\beta}^{0n,*}(\omega_1, \omega_2) + \\ & + \mathbf{H} \mathcal{S}_{\alpha\beta}^{0n}(\omega_1, \omega_2) \mathcal{S}_{\beta\alpha}^{0n,*}(\omega_1, \omega_2), \end{aligned} \quad (132)$$

where \mathbf{F} , \mathbf{G} , and \mathbf{H} are numbers depending on the polarization state of the two photons and on the geometrical setup (mutual direction of the laser beams) (Craig and Thirunamachandran 1984; McClain 1974) and, in the dipole approximation,

$$\mathcal{S}_{\alpha\beta}^{0n}(\omega_1, \omega_2) = \frac{1}{\hbar} \sum_m \left\{ \frac{(\hat{\mu}_\alpha)_{0m}(\hat{\mu}_\beta)_{mn}}{\omega_{m0} - \omega_1} + \frac{(\hat{\mu}_\beta)_{0m}(\hat{\mu}_\alpha)_{mn}}{\omega_{m0} - \omega_2} \right\} \quad (133)$$

is the second-rank, two-photon tensor. In Eq. 133 the summation runs over the whole set of excited states, the energy conservation relation $\omega_1 + \omega_2 = \omega_{n0}$ applies, and off-resonance conditions are implied – that is, the frequencies ω_1 and ω_2 are sufficiently far off the values at which the denominators vanish. The tensor is nonsymmetric in the exchange of the two frequencies except for $\omega_1 = \omega_2$. For the special case of a one-color beam – that is, a monochromatic light source – the transition matrix is symmetric and (using $\omega = \omega_1 = \omega_2$)

$$\delta_{0n}^{\text{TPA}}(\omega) = S_{\lambda\lambda}^{0n}(\omega) S_{\mu\mu}^{0n,*}(\omega) + 2S_{\lambda\mu}^{0n}(\omega) S_{\lambda\mu}^{0n,*}(\omega) \quad (134)$$

for linear polarization of the incident light and

$$\delta_{0n}^{\text{TPA}}(\omega) = -S_{\lambda\lambda}^{0n}(\omega) S_{\mu\mu}^{0n,*}(\omega) + 3S_{\lambda\mu}^{0n}(\omega) S_{\lambda\mu}^{0n,*}(\omega) \quad (135)$$

for circular polarization, respectively.

It can be shown that the two-photon absorption transition rate (cross section) can be obtained from the single residue of the cubic response function (Hättig et al. 1998a). Two-photon absorption transition amplitudes $S_{\alpha\beta}^{0n}(\omega_1, \omega_2)$, Eq. 133, can also be extracted from the single residue of a quadratic response function, see Eq. 69 above.

The following relations hold for the matrix elements of the two-photon transition tensor

$$S_{\alpha\beta}^{0n}(\omega) = S_{\beta\alpha}^{0n}(\omega_{n0} - \omega), \quad (136)$$

$$S_{\alpha\beta}^{0n}(\omega) = S_{\alpha\beta}^{n0}(-\omega)^*, \quad (137)$$

For methods which do not fulfill Eq. 137 (such as the coupled cluster approach), one can instead use the two-photon transition strength (Hättig et al. 1998b):

$$F_{\alpha\beta,\gamma\delta}^{0n}(\omega) = \frac{1}{2} \left\{ S_{\alpha\beta}^{0n}(-\omega) S_{\gamma\delta}^{n0}(\omega) + S_{\gamma\delta}^{0n,*}(-\omega) S_{\alpha\beta}^{0n,*}(\omega) \right\}, \quad (138)$$

where $S_{\alpha\beta}^{0n}(\omega)$ and $S_{\alpha\beta}^{n0}(\omega)$ are the left and right transition moments.

Three-photon absorption has been described through the single residue of the cubic response function (Cronstrand et al. 2003). Similarly to two-photon absorption, one can discuss the third-order (left and right) transition moments and strengths (Hättig et al. 1998a) and define the three-photon transition strengths in this manner for nonvariational wave functions. There has been a rather limited number of theoretical studies of three-photon absorption processes and these will therefore not be discussed any further here.

In general, the computational requirements for the calculation of molecular properties from the residues of the response functions inherit the requirements from the response functions themselves; that is, the selection of the basis sets has to

be done considering the operators appearing in the expression for the transition moments and excited-state properties. However, as the residues are connected to specific excited states, the nature of the probed excited state also needs to be considered.

Magnetic Properties

Let us now consider perturbations involving external static magnetic fields only. In this case, the number of observable molecular properties that arise is rather limited. This is due in part to the fact that the strength of the magnetic field perturbation of the molecular energy is much smaller than the electric field perturbational strength, but also because only even-order interactions will survive for closed-shell molecules. This is normally referred to as quenching of the induced magnetic moment, and can also be seen as an explanation why there are no permanent magnetic dipoles in such systems. The quenching of the magnetic moment in closed-shell molecules can easily be understood by considering that for any orbitally nondegenerate state, one can always choose the wave function to be real. For such a state, the expectation value of the magnetic moment is given as

$$\langle 0 | \hat{H}_\alpha^B | 0 \rangle = \langle 0 | \hat{H}_\alpha^{B*} | 0 \rangle^* = -\langle 0 | \hat{H}_\alpha^B | 0 \rangle^* = 0, \quad (139)$$

since the magnetic dipole operator is Hermitian and purely imaginary (see Eq. 44).

Magnetizability

The magnetizability yields the first nonvanishing (second order in the external magnetic field) contribution to the energy of interaction between an external magnetic field and a closed-shell molecule

$$\Delta E(\mathbf{B}) = -\frac{1}{2} B_\alpha \xi_{\alpha\beta} B_\beta, \quad (140)$$

where ξ is a symmetric tensor of rank two with a total of six independent elements. For isotropic samples, the magnetizability is expressed in the principal axis system in which the tensor is diagonal, and in addition to the isotropic magnetizability defined in a standard manner as

$$\xi_{\text{iso}} = \frac{1}{3} \xi_{\alpha\alpha}, \quad (141)$$

two anisotropies:

$$\xi_{\text{anis1}} = \xi_{33} - (\xi_{11} + \xi_{22}) / 2, \quad (142)$$

$$\xi_{\text{anis2}} = \xi_{11} - (\xi_{22} + \xi_{33}) / 2, \quad (143)$$

Table 3 Unit conversion factors for magnetizability

	1 a.u.	SI		CGS	
ξ	$(e\hbar/m_e)^2 E_h^{-1}$	7.89104×10^{-29}	JT^{-2}	4.7521	$\text{ppm cgs/ppm cm}^3 \text{ mol}^{-1}$

are usually defined, with $|\xi_{33}| \leq |\xi_{22}| \leq |\xi_{11}|$. However, results reported in the literature often do not follow these definitions, and care should be exercised when comparing with experiment to ensure that the same conventions are used for defining the anisotropies. For unit conversion factors, see Table 3.

Two contributions to the magnetizability appear in the nonrelativistic electronic Hamiltonian in the presence of a magnetic vector potential Eq. 40. One arises as an expectation value of the diamagnetic magnetizability operator, see Eq. 47. The second involves a linear response contribution arising from the interaction of the magnetic dipole operator Eq. 44 with itself. We can, therefore, calculate the magnetizability from the expression:

$$\xi_{\alpha\beta} = -2 \left\langle 0 \left| \hat{H}_{\alpha\beta}^{\text{B,B}} \right| 0 \right\rangle - \left\langle \left\langle \hat{H}_{\alpha}^{\text{B}}, \hat{H}_{\beta}^{\text{B}} \right\rangle \right\rangle = - \left. \frac{\partial^2 E(\mathbf{B})}{\partial B_{\alpha} \partial B_{\beta}} \right|_{\mathbf{B}=0}, \quad (144)$$

where the last equality shows that the magnetizability can be obtained as an energy derivative and it holds because the magnetic fields discussed here are static.

A negative magnetizability corresponds to an induced magnetic moment of the molecule opposing the applied magnetic field, and is experimentally manifested by the molecule trying to get away from the poles of a magnet and thus align itself across the applied magnetic field, an effect that is referred to as *diamagnetism*. The opposite effect, where the induced magnetic moment enforces the magnetic field, is referred to as *paramagnetism*, and in this case the molecule will seek to orient itself in the direction of the poles of the magnet and therefore along the magnetic field.

The diagonal elements of the first contribution to the magnetizability in Eq. 144 are negative since

$$\xi_{\alpha\beta}^{\text{dia}} = -2 \left\langle 0 \left| \hat{H}_{\alpha\beta}^{\text{B,B}} \right| 0 \right\rangle = - \frac{e^2}{4m_e} \left\langle 0 \left| \hat{r}_O^2 \delta_{\alpha\beta} - \hat{r}_{O,\alpha} \hat{r}_{O,\beta} \right| 0 \right\rangle, \quad (145)$$

and this part is for this reason referred to as the diamagnetic contribution. The linear response function contribution to the magnetizability (including the negative sign, see Eq. 144) is always positive and is therefore referred to as the paramagnetic contribution. For closed-shell molecules, the expectation value almost always dominates, and these molecules are therefore diamagnetic. Exceptions occur for molecules for which there are near degeneracies in the electronic ground state. Then the denominator of the linear response function (65) may become small, leading to such an increase of the magnitude of the paramagnetic term that the overall magnetizability becomes positive. A well known and often studied example is the BH molecule (Ruud et al. 1995; Sauer et al. 1993).

Although the expression for the magnetizability in Eq. 144 is conceptually simple and can in principle be used straightforwardly, the gauge origin problem turns out to be difficult. In order to ensure gauge-origin independent magnetizabilities, as well as significantly improve the basis set convergence, London atomic orbitals should be used when calculating magnetizabilities.

A London orbital is obtained from a conventional basis function by multiplying it by an imaginary phase factor

$$\omega_\mu(\mathbf{B}, \mathbf{R}_M) = \exp\left(-\frac{i}{\hbar}e\mathbf{A}_M \cdot \mathbf{r}\right) \chi_\mu(\mathbf{R}_M). \quad (146)$$

χ_μ is here an ordinary basis function, such as a Gaussian or a Slater-type basis function. The magnetic vector potential appearing in the imaginary phase factor is defined as

$$\mathbf{A}_M = \frac{1}{2}\mathbf{B} \times \mathbf{R}_{OM} = \frac{1}{2}\mathbf{B} \times (\mathbf{R}_M - \mathbf{O}). \quad (147)$$

The effect of this complex phase factor is to move the global gauge origin \mathbf{O} to the “best” gauge origin for the basis function located at center \mathbf{R}_M , namely, the nucleus M to which the basis function is attached.

When London atomic orbitals (LAOs, known also as gauge-including atomic orbitals – GIAOs) are used, the definition of dia- and paramagnetic contributions to the magnetizability in Eq. 144 can no longer be used. We can instead define (Ruud and Helgaker 1997):

$$\xi_{\alpha\beta}^{\text{dia}}(\mathbf{O}) = -2\left\langle 0 \left| \hat{H}_{\alpha\beta}^{\text{B,B}}(\mathbf{O}) \right| 0 \right\rangle, \quad (148)$$

$$\xi_{\alpha\beta}^{\text{para,Lon}}(\mathbf{O}) = \xi_{\alpha\beta}^{\text{Lon}} - \xi_{\alpha\beta}^{\text{dia}}(\mathbf{O}). \quad (149)$$

This partitioning leads to dia- and paramagnetic contributions that display the correct gauge origin dependence also for finite basis sets, since the diamagnetic contribution, $\xi_{\alpha\beta}^{\text{dia}}$ in Eq. 148, is an expectation value, and therefore it has the correct origin dependence. Furthermore, expectation values in general show fast basis set convergence. Therefore the significant improvement in convergence of both the total magnetizability and the diamagnetic magnetizability ensures fast basis set convergence also for the paramagnetic contribution, Eq. 149.

To illustrate the importance of using London orbitals when calculating magnetizabilities, we consider in Table 4 the magnetizability (and rotational g tensor, vide infra) of the PF_3 molecule. We note that the isotropic magnetizability calculated using the aug-cc-pVDZ basis set and without London atomic orbitals is wrong by a factor of almost three compared to the estimated Hartree–Fock limit. As shown in Table 4, even when the aug-cc-pV5Z basis containing more than 500 basis functions is used, the results obtained using Eq. 144 are still more than 10 % off

Table 4 Basis set convergence of the SCF magnetizability (in a.u.) and rotational g tensor of PF_3 calculated without and with London atomic orbitals, Ruud and Helgaker (1997)

	aug-cc-pVDZ		aug-cc-pVTZ		aug-cc-pVQZ		aug-cc-pV5Z	
	No-Lon	Lon	No-Lon	Lon	No-Lon	Lon	No-Lon	Lon

g_{\parallel}	0.0845	-0.0618	0.0159	-0.0636	-0.0181	-0.0643	-0.0461	-0.0649
g_{\perp}	0.0890	-0.0378	0.0162	-0.0380	-0.0181	-0.0383	-0.0274	-0.0385

the results obtained with London atomic orbitals, which can be expected to be very close to the Hartree–Fock limit considering the excellent basis set convergence of the London atomic orbital magnetizabilities. In contrast, all the calculations using London orbitals are within 3 % of the LAO aug-cc-pV5Z results. More importantly, the anisotropy is off by an order of magnitude at the aug-cc-pVDZ level, and even has the wrong sign at the aug-cc-pVQZ basis (containing 345 basis functions) if London orbitals are not used.

Computational studies have shown that unless the ground electronic state is nearly degenerate with the lowest excited states, electron correlation effects on the isotropic magnetizability are in general negligible. All published results of correlated calculations of the magnetizability of closed-shell molecules without close-lying excited states have found electron correlation effects to be less than 3 % in most cases, much smaller than any uncertainty in experimentally determined magnetizabilities for such molecular systems. Results within 1–2 % of the Hartree–Fock limit can be obtained using the very modest-sized aug-cc-pVDZ basis set of Woon and Dunning (1994). The important point in the construction of a suitable basis set is the inclusion of diffuse polarizing functions in order to ensure highly accurate magnetizabilities.

Commonly adopted exchange-correlation functionals (e.g., B3LYP, BLYP) are in general less efficient in recovering correlation effects on molecular magnetic properties than they are in recovering correlation effects on vibrational spectra or electric properties. Indeed, in many cases DFT may perform worse than Hartree–Fock in the calculation of isotropic magnetizabilities. A set of new functionals designed specifically for the calculation of magnetic properties has been developed by Keal and Tozer (2003). However, recent CCSD benchmark calculations indicate that the results obtained with one of these functionals deteriorate when vibrational corrections and solvent effects are taken into account (Lutnæs et al. 2009).

The isotropic magnetizabilities are in general very little affected by nonelectronic contributions such as zero-point vibrational corrections, dielectric medium effects, or weak intermolecular forces. The situation is very different for the magnetizability anisotropy, which may display both fairly large electron correlation effects as well as sizeable contributions from nonelectronic contributions.

Although highly accurate theoretical calculations using coupled-cluster wave functions have demonstrated that correlation effects are in general small (Gauss

et al. 2007), and that nonelectronic contributions are small as noted above, agreement with experimentally determined magnetizabilities is in general poor. Part of the reason for this is the general lack of experimental gas-phase magnetizabilities. However, more important for the apparent disagreement between theory and experiment may be the fact that isotropic magnetizabilities are almost exclusively determined *relative* to the magnetizability of reference compounds. It has been suggested that the reference values used to determine experimental magnetizabilities are inaccurate (Ruud et al. 2000).

Rotational g Tensor

The magnetizability describes the magnetic moment induced in a molecule by an external magnetic field induction, and how this induced magnetic moment in turn can interact with the external magnetic field and lead to an energy correction. A molecule also has its own source of a magnetic moment, arising from the rotational motion. Since the molecule consists of charged particles, the nuclei, and the electrons, the overall rotation of these particles will generate a small magnetic moment. In the case of the external-field-induced magnetic moment, the vector potential and the electron magnetogyric ratio determine the form of the magnetic dipole operator in Eq. 44. For the magnetic moment induced by the molecular rotation, the magnitude of the rotational angular momentum \mathbf{J} is determined by the rotational quantum numbers of the molecule, giving rise to a rotationally induced magnetic moment

$$m_a^J = \frac{\mu_N}{\hbar} \sum_{a,b} g_{ab}^J J_b, \quad (150)$$

where μ_N is the nuclear magneton and the rotational g tensor (also called the molecular g factor) is defined as

$$g^J = g^{J,\text{nucl}} + g^{J,\text{el}} = m_p \mathbf{I}^{-1} \sum_K Z_K (R_{K,\text{CM}}^2 \mathbf{1} - \mathbf{R}_{K,\text{CM}} \mathbf{R}_{K,\text{CM}}^T) - \frac{4m_p m_e}{e^2} \mathbf{I}^{-1} \xi^{\text{para}}(\mathbf{R}_{\text{CM}}). \quad (151)$$

In Eq. 151 we have introduced the moment of inertia tensor \mathbf{I} and we have used the definition of ξ^{para} as given in Eq. 149, which is applicable both when using London orbitals and when using conventional basis sets. Both the nuclear positions and magnetic dipole operators are defined with respect to the center of mass of the molecule, as this is the point about which the molecule rotates.

There are two contributions to the rotationally induced magnetic moment, one arising from the rotation of the nuclear framework, and one arising because of the rotation of the electron density, and these contributions are opposite in sign because

the linear response function ξ^{para} in Eq. 151 is positive. This rotationally induced magnetic moment is an example of a nonadiabatic effect. If the electrons were able to adjust their positions and momenta instantaneously to any change in the nuclear configuration, the magnetic moment created by the electrons and the nuclei would have the same magnitude but opposite sign, due to the different charges of the particles. However, this description, corresponding to the Born–Oppenheimer approximation, is not exact, and in fact a small permanent magnetic moment will arise from the decoupling of the electronic and nuclear rotation.

The rotational magnetic moment can interact with either internal or external sources of magnetic moments or magnetic fields. If the rotational magnetic moment interacts with the nuclear magnetic moment it gives rise to a contribution to the energy, discussed in more detail in section “[Nuclear Spin Rotation Constants](#),” which involves the nuclear spin–rotation constant. If we apply an external magnetic field and consider the interaction of this field with the magnetic moment created by the molecular rotation, the interaction energy is (Flygare 1974; Gauss et al. 1996):

$$\Delta E = -\frac{\mu_N}{\hbar} \sum_{a,b} B_a g_{ab}^J J_b, \quad (152)$$

where J_a is the rotational quantum number along the principal rotational axis a .

The rotational g tensor is a tensor of rank two with in principle nine independent elements. The rotational magnetic moment is only well defined in the principal rotational axis system, where the moment of inertia tensor is diagonal, and only the diagonal elements of g^J in this principal axes system contribute to the rotational Zeeman effect (Flygare 1974; Gauss et al. 1996).

We also note that if we can determine both the magnetizability and the rotational g factor, we can indirectly determine the molecular quadrupole moment from the equation:

$$q_{cc} = \frac{2m_e}{e} (\xi_{aa} + \xi_{bb} - 2\xi_{cc}) + \frac{e}{2m_p} (g_{aa}^J I_{aa} + g_{bb}^J I_{bb} - 2g_{cc}^J I_{cc}). \quad (153)$$

This relation shows that microwave Zeeman spectroscopy can be an important source of molecular quadrupole moments. From a theoretical point of view, this equation does not provide any additional information compared to calculating the molecular quadrupole moment directly as an expectation value, since the relationship (Eq. 153) is fulfilled exactly for any wave function.

The electronic contribution to the rotational g factor is important in high-resolution microwave spectroscopy even in the absence of an external magnetic field. In Eq. 150 we introduced the magnetic moment induced by the rotation of the molecular framework. Instead of letting this induced magnetic moment interact with an external magnetic field induction, we can let it interact with the rotational moment of the molecule. This gives a correction to the molecular energy which is quadratic in the rotational quantum number J . In ordinary microwave spectroscopy, the leading energy contribution is related to the moment of inertia tensor and is

also quadratic in J . Therefore, the energy correction related to g^J can be treated as a correction to the moment of inertia tensor, and it is customary to introduce an effective inverse moment of inertia tensor defined as (Flygare 1974):

$$\mathbf{I}_{\text{eff}}^{-1} = \mathbf{I}^{-1} \left(\mathbf{1} - \frac{m_e}{m_p} g^{J,\text{el}} \right). \quad (154)$$

When comparing highly accurate theoretical estimates of moments of inertia directly with the results observed in high-resolution microwave spectroscopy, it is essential to take into account these nonadiabatic corrections. It is particularly noteworthy that the experimental determination of the equilibrium geometry involves the estimation of the effects of the rotational g tensor on the moment of inertia tensor, and that it is currently possible to calculate these effects with an accuracy much higher than obtainable from experimental data alone. Therefore, the use of highly accurate experimental data, for instance from rotational spectra, combined with highly accurate calculations of small corrections to these quantities, is currently the most accurate way to obtain experimental equilibrium geometries (Stanton et al. 2001) (for a related analysis of diatomic systems, see Sauer et al. 2005).

As the rotational g tensor includes a linear response function involving two magnetic dipole operators, similar computational requirements apply for this property as for the magnetizability. We can therefore expect that the direct calculation of the rotational g tensor using Eq. 151 will display very slow basis set convergence. However, London orbitals are very efficient in getting fast basis set convergence, as illustrated for PF_3 in Table 4.

In microwave or molecular beam experiments, all of the three diagonal elements of the rotational g tensor are determined. As for the magnetizability, the individual tensor components show some dependence on electron correlation effects, and in order to allow for the calculated results to be within the very tight experimental errors bars for the rotational g tensor elements, electron correlation and the effects of zero-point vibrational corrections need to be included. This is illustrated for the water molecule in Table 5.

Table 5 Electron correlation effects and zero-point vibrational corrections to the rotational g tensor components of H_2O . The molecule is located in the xz -plane with the dipole moment along the z -axis (g^J is dimensionless)

Birefringences and Dichroisms

The consequences of the fact that an electromagnetic wave has both a frequency-dependent electric field component and a frequency-dependent magnetic field component have so far not been discussed. The two components are perpendicular to each other, as well as perpendicular to the direction of the propagation of the light beam. Moreover, we have not discussed the implications of the possible polarization of the light beam. Light experienced in everyday life is mostly nonpolarized – that is, the tip of the electric or magnetic field vectors moves randomly in the plane perpendicular to the propagation direction. With the use of appropriate tools, unpolarized light can be turned into a wide variety of polarization states, becoming linearly, elliptically, or circularly polarized. In these cases, the tip of the field vector(s) oscillates in the plane containing the direction of propagation (linear polarization) or rotates along a circle (circular polarization) or an ellipse (elliptical polarization) in the plane perpendicular to it. The polarization of light plays an important role in the interactions of light with a molecule.

Birefringences and dichroisms are two aspects of this interaction which are closely related to the polarization status of light. They arise through a variety of different mechanisms and interactions between the electromagnetic field and the molecule, but they are all characterized by the simultaneous measurements of the refractive (birefringences) or absorptive (dichroisms) index of light along two directions, different with respect to some predefined laboratory or molecular frame. The difference in the dispersion or absorption in these two directions is described by a quantity of a specific sign and magnitude. All these properties give detailed information about the molecular structure, and in particular some of them can distinguish between a sample and its mirror image. Distinguishable mirror images can occur naturally, in chiral molecules where the mirror image of the molecule cannot be superimposed on the original molecule itself – that is, for so-called enantiomers – or they can occur by introducing an asymmetry in the experimental setup that makes the mirror image of the experimental design impossible to superimpose on the original setup. In the latter case, since the experimental design is itself chiral, the observed effect does not vanish even if the molecule is not chiral. We note that only molecules possessing no improper or rotation-reflection axes may be chiral.

It is instructive to start by giving some examples of birefringences, before discussing the details of the most important birefringences and dichroisms. Let us consider first an isotropic liquid sample subject to a strong external static electric field. The refractive index n_{\parallel} experienced by the component of the polarization vector aligned parallel to the direction of the external field \mathbf{F} in this case differs from the index of refraction n_{\perp} for the component aligned perpendicular to the direction of the vector \mathbf{F} (Kerr 1875a, b). As a consequence, the initially linearly polarized light beam will exit the region of the sample with an ellipticity. This is an example of a *linear birefringence*

$$\Delta n^{\text{lin}} = n_{\parallel} - n_{\perp}, \quad (155)$$

and the effect is known as electric-field-induced optical birefringence or more often as the Kerr (electro-optical) effect. It exhibits a quadratic dependence on the strength of the applied electric field. Its existence is due mainly to the fact that the external electric field, in a system possessing an anisotropic electric dipole polarizability tensor, tends to align the molecules preferentially in its direction.

Other mechanisms in general also contribute to the emergence of an anisotropy, the most important being the effect of electronic rearrangements. They play a role through the higher-order polarizabilities of the system, in particular through the second electric-dipole hyperpolarizability γ and, in the presence of permanent electric dipoles, through the first electric-dipole hyperpolarizability β (Kerr 1875a, b). Other examples of linear birefringences are the Cotton–Mouton and Buckingham effects, briefly discussed below, and the Jones and magneto-electric birefringences, which occur when linearly polarized light goes through an isotropic fluid perpendicularly to both static electric and magnetic fields.

Circular birefringence is observed when the two circular components of a linearly polarized beam propagate with different circular velocities, and therefore an anisotropy arises between the two refractive indices n_+ and n_- :

$$\Delta n^{\text{circ}} = n_+ - n_- \quad (156)$$

The net result is a rotation of the plane of polarization. An example of a circular birefringence is *optical activity*, which is observed when a medium composed of chiral molecules (with an excess of one enantiomer) is subject to linearly polarized electromagnetic radiation. The dependence of the corresponding anisotropy on the wavelength is described by the optical rotatory dispersion (ORD). The Faraday effect, discussed below, is another well-known example of a circular birefringence.

An *axial birefringence* occurs with unpolarized light, and an example is the so-called magnetochiral birefringence (Barron and Vrbancich 1984; Kalugin et al. 1999). It can be seen in isotropic samples composed of chiral molecules, and it is observed when a static magnetic induction field is switched on parallel to the direction of propagation of the unpolarized probe beam. The refractive index experienced by the beam propagating parallel to the external magnetic field, $n_{\uparrow\uparrow}$, becomes different from that experienced by a beam propagating antiparallel to the field, $n_{\uparrow\downarrow}$

$$\Delta n^{\text{ax}} = n_{\uparrow\uparrow} - n_{\uparrow\downarrow} \quad (157)$$

The corresponding anisotropy has a different sign for the different enantiomers.

An external field will have an orientational effect on the molecules of the sample, and this is a mechanism responsible for the emergence of birefringences. In the presence of external fields the sample becomes anisotropic, and the extent to which this happens depends on the temperature. Indeed, the general form of the optical anisotropy (for measurements taken at a fixed pressure) is usually of the form

$$\Delta n \propto A_0 + \frac{A_1}{T} + \frac{A_2}{T^2} + \dots, \quad (158)$$

where the term A_0 includes all contributions arising from the reorganization of the electrons due to the action of the external field(s), whereas the terms A_1, A_2, \dots are connected to different mechanisms of reorientation of the molecules, involving the interaction of the field(s) with permanent electric or magnetic multipole moments. The temperature-dependent terms vanish for systems of spherical symmetry; the contributions exhibiting a nonlinear dependence are usually connected to the presence of permanent electric or magnetic dipole moments, or higher-order processes involving more complicated interactions between fields and multipoles.

When the inducing field is time dependent, the birefringence is said to be “optically induced.” In general, the information provided by birefringences induced by static fields can differ from that obtained observing the corresponding optically induced phenomena. For example, in the static Kerr effect of dipolar molecules, an important role is played by the permanent dipoles, which tend to be aligned by the static field. This contribution vanishes for dynamic inducing fields, where the birefringence arises only from the rearrangement of the anisotropy of the electric dipole polarizability. The contribution resulting from the interaction with permanent multipoles averages over time to zero.

Optical Rotation

The first contribution to the induced electric dipole moment in Eq. 74 from the time dependence of the magnetic field, $\omega^{-1}G'$, gives rise to two different observable properties. In the dispersive region, this property determines the optical rotatory power, or just optical rotation (OR) for short, and in the absorptive region it determines the rotational strength observed in electronic circular dichroism (ECD).

There are no terms bilinear in the electric and magnetic fields in the Hamiltonian, therefore G' , the mixed electric dipole–magnetic dipole polarizability (see also Eq. 74), can be expressed as a linear response function:

$$G'_{\alpha\beta}(-\omega; \omega) = -\frac{2\omega}{\hbar} \sum_{n \neq 0} \mathcal{I}m \frac{\langle 0 | \hat{\mu}_\alpha | n \rangle \langle n | \hat{m}_\beta | 0 \rangle}{\omega_n^2 - \omega^2} = -\mathcal{I}m \langle \langle \hat{\mu}_\alpha; \hat{m}_\beta \rangle \rangle_\omega. \quad (159)$$

We note that G' vanishes if the electromagnetic field is static ($\omega = 0$), see the discussion in section “[Expansions of Energy and Multipole Moments](#).” For unit conversion factors, see Table 6.

Measurements of optical rotation are almost exclusively carried out on liquid samples (though gas-phase measurements recently became possible (Müller

Table 6 Unit conversion factors for electric dipole–magnetic dipole polarizability

	1 a.u.	SI	CGS
G'	$e^2 a_0^3 \hbar^{-1}$	$3.60702 \times 10^{-35} \text{ C}^2 \text{ m}^3 \text{ J}^{-1} \text{ s}^{-1}$	$1.08136 \times 10^{-27} \text{ Fr cm G}^{-1}$

et al. 2000)) and we will, therefore, be concerned primarily with the rotational average of the G' tensor, which is described by the quantity ${}^{\text{ORD}}\beta$ defined as

$${}^{\text{ORD}}\beta = -\frac{1}{3\omega} G'_{\alpha\alpha}. \quad (160)$$

The most common experimental setup involves the determination of the rotation of plane-polarized light as it passes through a sample in which there is an excess of one enantiomer. The standard optical rotation $[\alpha]_D^{25}$, proportional to ${}^{\text{ORD}}\beta$, is reported for light with a frequency corresponding to the sodium D-line (589.3 nm) at a temperature of 25 °C.

Because the mixed electric dipole–magnetic dipole polarizability involves the magnetic dipole operator, in approximate calculations G' carries an origin dependence. Indeed, the individual tensor elements of G' are origin dependent. The trace of G' must be origin independent, since the optical rotation is an experimental observable. In non-isotropic media, contributions to the optical rotation tensor arise from the mixed electric dipole–electric quadrupole polarizability A ,

$$A_{\alpha,\beta\gamma}(-\omega; \omega) = -\left\langle\left\langle \hat{\mu}_{\alpha}; \hat{\Theta}_{\beta\gamma} \right\rright\rangle_{\omega}, \quad (161)$$

(see the last term in Eq. 74), and it is the combination of the G' and A contributions that is gauge-origin independent for exact wave functions. The contribution from A vanishes in isotropic samples, since this mixed electric dipole–electric quadrupole polarizability is traceless.

For approximate variational wave functions, the origin independence of the trace of G' is only achieved in the limit of a complete basis set. One way to overcome this problem is to introduce local gauge origins by using London atomic orbitals (Helgaker et al. 1994).

The dispersion of the optical rotation was for a long time also the focus of much experimental attention through optical rotatory dispersion measurements. Even after it became customary to restrict the optical rotation measurements to a single frequency, ORD served as an important tool for determining excitation energies in chiral molecules, although it has now been surpassed by electronic circular dichroism for these purposes (see section “Circular Dichroism”).

At the sodium frequency, the optical rotation is rather small for most molecules. However, the individual diagonal elements of the mixed electric dipole–magnetic dipole polarizability may be fairly large in absolute value, often canceling each other in the trace. This is illustrated for a few selected molecules in Table 7. Consequently, the optical rotation is highly sensitive to numerical errors in the tensor components, because small residual errors in the individual tensor components, arising from the solution of the linear response equations, may lead to substantial errors in ${}^{\text{ORD}}\beta$. Another consequence of this cancellation is that ${}^{\text{ORD}}\beta$ is very sensitive to the choice of molecular geometry, as well as zero-point vibrational effects (Ruud et al. 2001), since the small changes introduced by these effects in the molecular charge

^bThe optical rotations were calculated for the B3LYP/6-311++G** geometries

^cAn energy minimum corresponding to a **B**-like conformer could not be found

distribution, and thus on the different diagonal elements of G' , can give rather large effects on $^{\text{ORD}}\beta$.

The sensitivity of the optical rotation is perhaps most clearly illustrated in the case of conformationally flexible molecules – that is, molecules that have a significant population of multiple stable minima. As exemplified for paraconic acid (a substituted γ -butyrolactone) in Table 8, different molecular conformations can have optical rotations that differ by orders of magnitude and even in sign. A thorough conformational search is therefore mandatory before the absolute sign of the optical rotation (or any birefringence or dichroism for that matter) is determined from theoretical calculations for conformationally flexible molecules. The optical rotation of the flexible molecule can then be determined by Boltzmann averaging over the dominant molecular conformations.

In order to ensure reasonably well-converged results for the optical rotation, basis sets of polarized valence double-zeta quality are required, and sets such as the aug-cc-pVDZ of Woon and Dunning (1994), or the polarized triple-zeta basis of Sadlej (1988) have been shown to perform well for calculations of optical rotation. Most importantly, diffuse p functions in the outer regions of the electron density, which in most cases is described by the electron density of hydrogen atoms, are required to ensure qualitatively correct results (Zuber and Hug 2004).

Since the optical rotation is very sensitive even to small changes in the electron density, electron correlation effects should also be taken into account in order to get accurate results. Due to the fact that chiral molecules in general have very low symmetry, if any symmetry at all, the only viable approach for calculating electron correlation effects in chiral molecules is currently density functional theory (Ruud et al. 2003; Stephens et al. 2001). Methods such as MP2 and CCSD could also be used to describe electron correlation, but due to their nonvariational nature it is not ensured that gauge-origin independent results can be obtained in the conventional length-gauge formulation even in the limit of a complete basis set. In principle, the use of the dipole velocity gauge will ensure that the calculated results are independent of the gauge origin. For all but the smallest basis sets, the differences between the velocity and the length gauges are not very large, with the length gauge in general performing better. However, in the case of the optical rotation an additional complication arises: whereas G' given by Eq. 159 will vanish in the limit of a static field, this is not the case for the dipole-velocity analogue of the optical rotation. It has been suggested that the much slower basis set convergence of the optical rotation compared to other properties calculated using the velocity-gauge formulation can be improved by subtracting the static-limit value of the corresponding response function (Pedersen et al. 2004), such that

$$G' \propto \left\langle \left\langle \hat{p}_\alpha; \hat{l}_\beta \right\rangle \right\rangle_\omega - \left\langle \left\langle \hat{p}_\alpha; \hat{l}_\beta \right\rangle \right\rangle_0. \quad (162)$$

Since there are no empirical rules relating the stereochemistry of a molecule to the observed sign of the optical rotation, an important area of application for optical rotation calculations would be the combined theoretical and experimental determination of absolute configurations. However, this is a difficult task due in part to the large variations with geometry in the optical rotation of conformationally flexible molecules, and in part because of the small magnitude of $^{\text{ORD}}\beta$. These factors make the sign of the optical rotation hard to determine with confidence. One way to increase the predictive power of the calculations is to change the frequency of the incident light to shorter wavelengths. The magnitude of the optical rotation increases dramatically as the frequency approaches that of a resonance. Thus, if both theory and experiment could determine the optical rotation at frequencies closer to electronic excitation energies, theoretical calculations could provide a much more reliable proof of the absolute configuration of the molecule (Giorgio et al. 2004).

Circular Dichroism

Natural (Electronic) Circular Dichroism

Let us now turn to the lowest-order absorption process involving mixed electric and magnetic perturbations. This property, which is the absorptive analogue of the optical rotation, is known as *electronic circular dichroism* (ECD) or just CD for short.

The differential absorption of circularly polarized light, corresponding to the difference between the absorptive index of the two circular components of linearly polarized light, is proportional to the rotational strength, which is normally calculated as the residue of the linear response mixed electric dipole–magnetic dipole polarizability:

$$\lim_{\omega \rightarrow \omega_{n0}} \hbar (\omega - \omega_{n0}) \langle\langle \hat{\mu}_\alpha; \hat{m}_\beta \rangle\rangle_\omega = \langle 0 | \hat{\mu}_\alpha | n \rangle \langle n | \hat{m}_\beta | 0 \rangle. \quad (163)$$

Since this expression corresponds to the infinite lifetime approximation for the excited state, only a single number will be obtained at the frequency of the electronic excitation.

In general ${}^n R$, the rotatory strength for the transition $|0\rangle \rightarrow |n\rangle$, includes an electric dipole–magnetic dipole contribution

$${}^n R_{\alpha\beta}^m = -\frac{3ie^2}{4m_e} \left(\delta_{\alpha\beta} \langle 0 | \mathbf{r} | n \rangle \langle n | \mathbf{I}^T | 0 \rangle - \langle 0 | \hat{r}_\beta | n \rangle \langle n | \hat{l}_\alpha | 0 \rangle \right), \quad (164)$$

and an electric dipole–electric quadrupole contribution

$${}^n R_{\alpha\beta}^Q = -\frac{3\omega_{n0}e^2}{4} \epsilon_{\alpha\gamma\delta} \langle 0 | \hat{r}_\gamma | n \rangle \langle n | \hat{q}_{\delta\beta} | 0 \rangle. \quad (165)$$

For randomly oriented molecules, the averaging leaves only the electric dipole–magnetic dipole contribution and the scalar rotatory strength is given by

$${}^n R = -\frac{ie^2}{2m_e} \langle 0 | \mathbf{r}^T | n \rangle \langle n | \mathbf{I} | 0 \rangle, \quad (166)$$

corresponding to Eq. 163. These expressions are given in the length gauge. In the velocity gauge

$${}^n R_{\alpha\beta}^m = \frac{3e^2}{4m_e^2\omega_{n0}} \left(\delta_{\alpha\beta} \langle 0 | \mathbf{p} | n \rangle \langle n | \mathbf{I}^T | 0 \rangle - \langle 0 | \hat{p}_\beta | n \rangle \langle n | \hat{l}_\alpha | 0 \rangle \right), \quad (167)$$

and

$${}^n R_{\alpha\beta}^Q = \frac{3e^2}{4m_e^2\omega_{n0}} \epsilon_{\alpha\gamma\delta} \langle 0 | \hat{p}_\gamma | n \rangle \langle n | \hat{T}_{\delta\beta}^+ | 0 \rangle, \quad (168)$$

where \mathbf{T}^+ indicates the “velocity” form of the electric quadrupole operator

$$\mathbf{T}^+ = -(\mathbf{rp} + \mathbf{pr}). \quad (169)$$

This form has an advantage in comparison to the length form. Although with a translation of the reference frame the magnetic dipole and electric quadrupole components change, the total tensor in the velocity gauge is invariant to such a

change of origin. For the length gauge, this invariance depends in addition on the fulfillment of the hypervirial relation, Eq. 126.

Two-Photon Circular Dichroism

Two-photon circular dichroism (Tinoco 1975) arises in chiral systems due to the differential absorption of two photons, of which at least one is circularly polarized (De Boni et al. 2008). In this sense it can be seen as the nonlinear extension of ECD. The observable, the anisotropy of the two-photon transition strength, is proportional to the two-photon rotatory strength (Jansík et al. 2005; Rizzo et al. 2006; Tinoco 1975):

$${}^n R^{\text{TPCD}}(\omega) = -b_1[\mathcal{B}_1(\omega)]_{0n} - b_2[\mathcal{B}_2(\omega)]_{0n} - b_3[\mathcal{B}_3(\omega)]_{0n}, \quad (170)$$

where b_1 , b_2 , and b_3 are numbers, simple combinations of the analogous polarization and setup-related coefficients \mathbf{F} , \mathbf{G} , and \mathbf{H} given for two-photon absorption in Eq. 132. The molecule-related parameters \mathcal{B}_1 , \mathcal{B}_2 , and \mathcal{B}_3 take the form:

$$[\mathcal{B}_1(\omega)]_{0n} = \frac{1}{\omega^3} \mathcal{M}_{\rho\sigma}^{\text{p},0n}(\omega) \mathcal{P}_{\rho\sigma}^{\text{p}*,0n}(\omega), \quad (171)$$

$$[\mathcal{B}_2(\omega)]_{0n} = \frac{1}{2\omega^3} \mathcal{T}_{\rho\sigma}^{+,0n}(\omega) \mathcal{P}_{\rho\sigma}^{\text{p}*,0n}(\omega), \quad (172)$$

$$[\mathcal{B}_3(\omega)]_{0n} = \frac{1}{\omega^3} \mathcal{M}_{\rho\rho}^{\text{p},0n}(\omega) \mathcal{P}_{\sigma\sigma}^{\text{p}*,0n}(\omega), \quad (173)$$

and they are, therefore, appropriate contractions of generalized two-photon second-rank tensors, like the one given in Eq. 133. Indeed, these tensors are defined (for the general case of two photons of different frequency) as follows:

$$\mathcal{P}_{\alpha\beta}^{\text{p},0n}(\omega_1, \omega_2) = \frac{1}{\hbar} \sum_m \left\{ \frac{(\hat{\mu}_\alpha^{\text{p}})_{0m} (\hat{\mu}_\beta^{\text{p}})}{\omega_{m0} - \omega_1} + \frac{(\hat{\mu}_\beta^{\text{p}})_{0m} (\hat{\mu}_\alpha^{\text{p}})_{mn}}{\omega_{m0} - \omega_2} \right\}, \quad (174)$$

$$\mathcal{M}_{\alpha\beta}^{\text{p},0n}(\omega_1, \omega_2) = \frac{1}{\hbar} \sum_m \left\{ \frac{(\hat{\mu}_\alpha^{\text{p}})_{0m} (\hat{m}_\beta)_{mn}}{\omega_{m0} - \omega_1} + \frac{(\hat{m}_\beta)_{0m} (\hat{\mu}_\alpha^{\text{p}})_{mn}}{\omega_{m0} - \omega_2} \right\}, \quad (175)$$

$$\mathcal{T}_{\alpha\beta}^{+,0n}(\omega_1, \omega_2) = \frac{1}{\hbar} \varepsilon_{\beta\rho\sigma} \sum_m \left\{ \frac{(\hat{T}_{\alpha\rho}^+)_{0m} (\hat{\mu}_\sigma^{\text{p}})_{mn}}{\omega_{m0} - \omega_1} + \frac{(\hat{\mu}_\sigma^{\text{p}})_{0m} (\hat{T}_{\alpha\rho}^+)_{mn}}{\omega_{m0} - \omega_2} \right\}, \quad (176)$$

where we have introduced the velocity form of the dipole operator,

$$\hat{\mu}_\alpha^{\text{p}} = -\frac{e}{m_e} \sum_i \hat{p}_{i\alpha}. \quad (177)$$

Within the formalism of response theory, the second-rank tensors of interest are obtained from the single residues of appropriate quadratic response functions, see Eq. 69. The quadratic response functions of relevance for two-photon circular dichroism are:

$$\left\langle\left\langle\hat{\mu}_{\alpha}^{\text{P}};\hat{\mu}_{\beta}^{\text{P}},V^{\omega_n}\right\rright\rangle_{\omega_1,\omega_2}\Rightarrow\mathcal{P}_{\alpha\beta}^{\text{P},0n}(\omega_1,\omega_2),\quad(178)$$

$$\left\langle\left\langle\hat{\mu}_{\alpha}^{\text{P}};\hat{m}_{\beta},V^{\omega_n}\right\rright\rangle_{\omega_1,\omega_2}\Rightarrow\mathcal{M}_{\alpha\beta}^{\text{P},0n}(\omega_1,\omega_2),\quad(179)$$

$$\varepsilon_{\beta\rho\sigma}\left\langle\left\langle\hat{T}_{\alpha\rho}^{+};\hat{\mu}_{\sigma}^{\text{P}},V^{\omega_n}\right\rright\rangle_{\omega_1,\omega_2}\Rightarrow\mathcal{T}_{\alpha\beta}^{+,0n}(\omega_1,\omega_2),\quad(180)$$

where V^{ω_n} is an arbitrary operator (corresponding to the excitation vector to the state n). Single residues of quadratic response functions are efficiently and accurately computed nowadays with a number of wave function models. Nevertheless, DFT has been used almost exclusively in the few theoretical studies of two-photon circular dichroism that have been published (Jansík et al. 2007, 2008).

Faraday Effect

In 1846, Faraday observed that when a static magnetic field was applied with its direction parallel to the direction of propagation of linearly polarized light traversing a transparent sample (glass, liquid, gas), the plane of polarization of the beam was rotated (Faraday 1846a, b). It was the first ever experimental evidence of a birefringence phenomenon, and in particular of a circular birefringence, and the effect is often referred to as the *Faraday effect* or magnetic field-induced optical rotation. The rotation is proportional to the optical anisotropy, see Eq. 156, and this depends linearly on the strength of the applied magnetic induction field. The mechanisms governing this effect involve the interaction of the static external magnetic induction field with the oscillating electric field of the light wave and with the electric multipoles of the sample. The term “magnetic optical rotatory dispersion” (MORD) is often used to denote the frequency dispersion of the Faraday effect, and thus of the corresponding circular birefringence.

For a fluid sample, the rotation with respect to the molecular frame becomes (Barron 2004; Buckingham and Stephens 1966):

$$\phi = V(\omega) B_z l \propto \omega \varepsilon_{\alpha\beta\gamma} \left(\alpha'_{\alpha\beta,\gamma}^{\text{B}} + \frac{1}{kT} \langle 0 | \hat{m}_{\gamma} | 0 \rangle \alpha'_{\alpha\beta} \right) B_z l, \quad(181)$$

where l is the path length, we have introduced the Verdet constant $V(\omega)$, and α'^{B} denotes the magnetic field derivative of α' , the antisymmetric electric dipole polarizability. The second term in the parentheses vanishes for closed-shell systems, as the magnetic dipole is quenched, $\langle 0 | \hat{m}_{\gamma} | 0 \rangle = 0$.

Table 9 Unit conversion factors for the Verdet constant

	1 a.u.	SI	CGS
$V(\omega)$	$\text{rad } e a_0 \hbar^{-1}$	$8.03961 \times 10^4 \text{ rad T}^{-1} \text{ m}^{-1}$	$2.76382 \times 10^2 \text{ min G}^{-1} \text{ cm}^{-1}$

The Verdet constant of a closed-shell system, free of orbital degeneracies both in the ground and in the excited state, is therefore obtained from the response function (Jaszuński et al. 1994; Parkinson and Oddershede 1997):

$$V(\omega) \propto i\omega \varepsilon_{\alpha\beta\gamma} \langle \langle \hat{\mu}_\alpha; \hat{\mu}_\beta, \hat{m}_\gamma \rangle \rangle_{\omega,0}. \quad (182)$$

This contribution is sometimes referred to as the *B* term contribution to the Verdet constant. For molecules containing orbital degeneracies additional contributions arise (the *A* and *C* terms), in analogy with the closely related phenomenon – magnetic circular dichroism, discussed in section “[Magnetic Circular Dichroism](#).” For unit conversion factors, see Table 9.

Hypermagnetizabilities, Cotton–Mouton Effect

The *Cotton–Mouton effect* (CME) is a magnetic induction field-induced linear birefringence, observed in the presence of a strong magnetic induction field \mathbf{B} with a component perpendicular to the direction of propagation of the beam. It is mainly due to the tendency of both the electric field associated with the light beam and the magnetic induction field to align the molecules exhibiting both an anisotropic electric dipole polarizability and an anisotropic magnetizability tensor (according to the Langevin–Born theory (Born 1918; Langevin 1910)). The rearrangement of the electron density again plays a part through the mixed electric and magnetic hyperpolarizabilities, or hypermagnetizabilities.

The experimental quantity connected to the hypermagnetizability is the molar Cotton–Mouton constant ${}_mC$. Semiclassically, for fluids composed of closed-shell systems (Buckingham and Pople 1956; Fowler and Buckingham 1989; Jamieson 1991):

$${}_mC = \frac{2\pi N_A}{27} [\Delta\eta + Q(T)], \quad (183)$$

where $\Delta\eta$ is the hypermagnetizability anisotropy

$$\Delta\eta = \frac{1}{15} (3\eta_{\alpha\beta,\alpha\beta} - \eta_{\alpha\alpha,\beta\beta}), \quad (184)$$

and

$$Q(T) = \frac{1}{15kT} (3\alpha_{\alpha\beta}\xi_{\alpha\beta} - \alpha_{\alpha\alpha}\xi_{\beta\beta}). \quad (185)$$

In Eq. 185, α is the (frequency-dependent) electric polarizability tensor, and ξ the magnetizability tensor. The two contributions to the molar Cotton–Mouton constant in Eq. 183 are, therefore, a temperature-independent term related to the hypermagnetizability $\eta_{\alpha\beta,\gamma\delta}$ and a temperature-dependent molecular orientational part – the “Langevin term.”

When the magnetizability is expressed as a power series in the perturbing electric field:

$$\xi_{\alpha\beta}(\mathbf{F}) = \xi_{\alpha\beta} + \zeta_{\gamma,\alpha\beta} F_\gamma + \frac{1}{2} \eta_{\gamma\delta,\alpha\beta} F_\gamma F_\delta + \dots, \quad (186)$$

the expansion coefficients $\zeta_{\gamma,\alpha\beta}$ and $\eta_{\gamma\delta,\alpha\beta}$ define the molecular first and second hypermagnetizability. The first indices of ζ and η refer to the electric field and the last two to the magnetic field. In fluids, the experimentally measured property is related to the anisotropy of η . From the expansion above it can be seen that the static hypermagnetizability η corresponds to the fourth derivative of the molecular energy:

$$\eta_{\alpha\beta,\gamma\delta} = - \left. \frac{\partial^4 E(\mathbf{F}, \mathbf{B})}{\partial F_\alpha \partial F_\beta \partial B_\gamma \partial B_\delta} \right|_{\mathbf{F}, \mathbf{B} = \mathbf{0}}. \quad (187)$$

It can also be expressed in terms of $\xi(\mathbf{F})$ – the magnetizability dependent on \mathbf{F} :

$$\eta_{\alpha\beta,\gamma\delta} = \left. \frac{\partial^2 \xi_{\gamma\delta}}{\partial F_\alpha \partial F_\beta} \right|_{\mathbf{F} = \mathbf{0}}, \quad (188)$$

or $\alpha(\mathbf{B})$ – the polarizability dependent on \mathbf{B} :

$$\eta_{\alpha\beta,\gamma\delta}(\omega) = \left. \frac{\partial^2 \alpha(-\omega; \omega)_{\alpha\beta}}{\partial B_\gamma \partial B_\delta} \right|_{\mathbf{B} = \mathbf{0}}, \quad (189)$$

and we have indicated in the latter equation that it holds also for the frequency-dependent polarizability.

The hypermagnetizability is given as a sum of paramagnetic and diamagnetic contributions:

$$\eta_{\alpha\beta,\gamma\delta}(\omega) = \eta_{\alpha\beta,\gamma\delta}^{\text{para}}(-\omega; \omega, 0, 0) + \eta_{\alpha\beta,\gamma\delta}^{\text{dia}}(-\omega; \omega, 0), \quad (190)$$

corresponding to a sum of a cubic response and a quadratic response function (Rizzo et al. 1997):

$$\eta_{\alpha\beta,\gamma\delta}^{\text{para}}(-\omega; \omega, 0, 0) = - \left\langle \left(\hat{\mu}_\alpha; \hat{\mu}_\beta, \hat{m}_\gamma, \hat{m}_\delta \right) \right\rangle_{\omega, 0, 0}, \quad (191)$$

$$\eta_{\alpha\beta,\gamma\delta}^{\text{dia}}(-\omega; \omega, 0) = \left\langle \left(\hat{\mu}_\alpha; \hat{\mu}_\beta, \hat{\xi}_{\gamma\delta}^{\text{B,B}} \right) \right\rangle_{\omega, 0}, \quad (192)$$

where (see for comparison Eq. 145) the “diamagnetic magnetizability operator” in the second term is

$$\hat{\xi}_{\alpha\beta}^{\text{B,B}} = -2\hat{H}_{\alpha\beta}^{\text{B,B}}. \quad (193)$$

We recall here that the magnetic dipole moment and diamagnetic magnetizability operators, and thus the partitioning of the hypermagnetizability into para- and diamagnetic components, may depend on the chosen gauge origin.

Finite field approaches corresponding to Eqs. 188 and 189 have been used (Rizzo et al. 1997). In these calculations $\eta_{\alpha\beta,\gamma\delta}$ is obtained combining the available analytic linear response methods with the numerical finite difference approach. The frequency-dependent electric dipole polarizability can be computed in the presence of a magnetic induction field, and the hypermagnetizability is obtained by numerical differentiation. This approach (Cybulski and Bishop 1994; Tellgren et al. 2008) in general requires complex algebra as the perturbation is purely imaginary, whereas most electronic structure codes use real wave functions. In the more often used finite field approach based on Eq. 188, one computes the magnetizability ξ with and without an external electric field perturbation. However, in this approach only the static value of the required hypermagnetizability is obtained. Analytic calculations of the quadratic and cubic responses Eqs. 192 and 191 also including London orbitals to ensure gauge origin independence can nowadays be carried out (Thorvaldsen et al. 2008). The effect of the London orbitals on improving the basis set convergence appears to be small.

For atoms, choosing the origin of the gauge at the nucleus automatically makes the dependence on the gauge vanish, and there is no advantage in using LAOs. Moreover, the evaluation of $\Delta\eta$ may be reduced to the calculation of the Cauchy moments $S(-2n)$ and of the dipole–dipole–quadrupole hyperpolarizability frequency dispersion coefficients (Coriani et al. 1999a; Rizzo et al. 1997). For unit conversion factors, see Table 10.

Electric-Field-Gradient-Induced Birefringence

As a magnetic induction field can give rise to an optical anisotropy through its interaction with the anisotropic magnetizability of a molecule, so can an electric field gradient, through its coupling with a permanent molecular quadrupole moment. The corresponding birefringence (Buckingham 1959; Buckingham and Disch 1963) is commonly called *electric-field-gradient-induced birefringence*, more recently *Buckingham birefringence*, and it exhibits a linear dependence on the strength of the electric field gradient. Besides the orientational Langevin-Born-type effect, acting on quadrupolar molecules and due to both the electric field associated with the light

Table 10 Unit conversion factors for hypermagnetizability

	1 a.u.	SI	CGS
η	$(ea_0^2)^2 (e\hbar/m_e)^2 E_h^{-3}$	$2.98425 \times 10^{-52} \text{ C}^2 \text{ m}^2 \text{ J}^{-1} \text{ T}^{-2}$	$2.68211 \times 10^{-44} \text{ cm}^3 \text{ G}^{-2}$

wave and to the static external field gradient, it also involves the rearrangement of the electron density as a consequence of the electron interaction with the electric and magnetic wave vectors associated with the beam and with the externally applied electric field gradient. In this case, mixed electric-dipole, electric-quadrupole, and magnetic-dipole hyperpolarizabilities play their role in determining the strength of the effect. Buckingham birefringence has been often employed for the determination of molecular quadrupole moments (Buckingham 1959; Buckingham and Disch 1963).

For an ideal gas at constant pressure, for light propagating along the Z axis

$$\Delta n = n_X - n_Y = \frac{N_A \nabla F}{15V_m \varepsilon_0} s = \frac{3 \nabla F}{2V_m} mQ(\omega, T), \quad (194)$$

$$mQ(\omega, T) = \frac{2N_A}{45\varepsilon_0} s, \quad (195)$$

Where V_m is the molar volume, ∇F is the external electric field gradient arranged so that $\nabla F = \nabla F_{XX} = -\nabla F_{YY}$ and $\nabla F_{ZZ} = 0$. Equation 195 introduces the Buckingham constant mQ , which depends through the quantity s on the circular frequency of the light and on the temperature. For non-dipolar systems, where the quadrupole moment does not depend on the choice of origin,

$$s = b(\omega) + \frac{1}{kT} \Theta_{\alpha\beta} \alpha_{\alpha\beta}(-\omega; \omega), \quad (196)$$

Involving the molecular quadrupole moment $\Theta_{\alpha\beta}$ and the frequency-dependent electric dipole polarizability $\alpha_{\alpha\beta}(-\omega; \omega)$. The temperature-independent contribution is

$$b(\omega) = B_{\alpha\beta, \alpha\beta}(-\omega; \omega, 0) - \mathcal{B}_{\alpha, \alpha\beta, \beta}(-\omega; \omega, 0) - \frac{5}{\omega} \varepsilon_{\alpha\beta\gamma} J'_{\alpha, \beta, \gamma}(-\omega; \omega, 0), \quad (197)$$

And is a combination of three mixed hyperpolarizabilities:

$$B_{\alpha, \beta, \gamma\delta}(-\omega; \omega, 0) = \left\langle \left\langle \hat{\mu}_\alpha; \hat{\mu}_\beta, \hat{\Theta}_{\gamma\delta} \right\rangle \right\rangle_{\omega, 0}, \quad (198)$$

$$\mathcal{B}_{\alpha, \beta\gamma, \delta}(-\omega; \omega, 0) = \left\langle \left\langle \hat{\mu}_\alpha; \hat{\Theta}_{\beta\gamma}, \hat{\mu}_\delta \right\rangle \right\rangle_{\omega, 0}, \quad (199)$$

$$J'_{\alpha, \beta, \gamma}(-\omega; \omega, 0) = i \left\langle \left\langle \hat{\mu}_\alpha; \hat{M}_\beta, \hat{\mu}_\gamma \right\rangle \right\rangle_{\omega, 0}, \quad (200)$$

The expressions are somewhat more complex for dipolar fluids (Buckingham and Longuet-Higgins 1968), where the quadrupole moment becomes origin dependent. The formal expressions for s , Eq. 196, does not change provided that we refer to a

frequency-dependent origin for the quadrupole operator, commonly labeled as the “effective quadrupole center” (Rizzo and Coriani 2005; Rizzo et al. 2007). For any other choice of the origin we have

$$s = b(\omega) + \frac{1}{kT} \left\{ \Theta_{\alpha\beta\alpha\beta}(-\omega; \omega) - \mu_\alpha \left[A_{\beta,\alpha\beta}(-\omega; \omega) + \frac{5}{\omega} \varepsilon_{\alpha\beta\gamma} G'_{\beta\gamma}(-\omega; \omega) \right] \right\}. \quad (201)$$

The effective quadrupole center is defined as the point in space where the last term in Eq. 201, involving the molecular dipole moment μ_α and the mixed polarizabilities $A_{\alpha,\beta\gamma}(-\omega; \omega)$ and $G'_{\alpha\beta}(-\omega; \omega)$, vanishes.

Magnetic Circular Dichroism

For a medium that is isotropic in the absence of magnetic fields, the Faraday A , B , and C terms determining the MCD of a transition from the electronic state to the electronic state $|n\rangle$ are defined as (Buckingham and Stephens 1966; Schatz and McCaffery 1969; Stephens 1976):

$$A(0 \rightarrow n) = \frac{1}{2} [\langle n | \mathbf{m} | n \rangle - \langle 0 | \mathbf{m} | 0 \rangle] \cdot \mathcal{I}m(\langle 0 | \boldsymbol{\mu} | n \rangle \times \langle n | \boldsymbol{\mu} | 0 \rangle), \quad (202)$$

$$B(0 \rightarrow n) = \mathcal{I}m \left\{ \sum_{k \neq 0} \frac{\langle k | \mathbf{m} | 0 \rangle}{\omega_{k0}} \cdot \langle 0 | \boldsymbol{\mu} | n \rangle \times \langle n | \boldsymbol{\mu} | k \rangle + \sum_{k \neq n} \frac{\langle n | \mathbf{m} | k \rangle}{\omega_{kn}} \cdot \langle 0 | \boldsymbol{\mu} | n \rangle \times \langle k | \boldsymbol{\mu} | 0 \rangle \right\}, \quad (203)$$

$$C(0 \rightarrow n) = \frac{1}{2} \langle 0 | \mathbf{m} | 0 \rangle \cdot \mathcal{I}m(\langle 0 | \boldsymbol{\mu} | n \rangle \times \langle n | \boldsymbol{\mu} | 0 \rangle), \quad (204)$$

where an average over the molecular orientations has been made. These tensors correspond to the single residues of the tensors that determine the Verdet constant of the Faraday effect (section “Faraday Effect”). With the convention used here, the Faraday terms given in Eqs. 202, 203, and 204 are three times those of Buckingham and Stephens (1966). The A term exists only if either $|0\rangle$ or $|n\rangle$ is degenerate, whereas the C term is nonvanishing only if $|n\rangle$ is degenerate.

The B terms exist in all cases, independently of the appearance of any ground- and excited-state degeneracies. We can rearrange Eq. 203 recalling that $(\hat{\mu}_\alpha)_{lm}^* = (\hat{\mu}_\alpha)_{lm}$, $(\hat{m}_\alpha)_{lm}^* = -(\hat{m}_\alpha)_{lm}$, and $\mathcal{I}m(z) = -i(z - z^*)/2$ we find that the $B(0 \rightarrow n)$ term can be written in terms of a single residue of a quadratic response function (Coriani et al. 1999b; Olsen and Jørgensen 1985) as:

$$B(0 \rightarrow n) = i \varepsilon_{\alpha\beta\gamma} \left(\lim_{\omega \rightarrow \omega_{n0}} \hbar(\omega - \omega_{n0}) \langle \langle \hat{\mu}_\gamma; \hat{m}_\beta, \hat{\mu}_\alpha \rangle \rangle_{0,\omega} \right). \quad (205)$$

By analogy to the spectral representation expression for the single residue we may also write (Olsen and Jørgensen 1985):

$$\lim_{\omega \rightarrow \omega_{n0}} \hbar (\omega - \omega_{n0}) \langle \langle \hat{\mu}_\gamma; \hat{m}_\beta, \hat{\mu}_\alpha \rangle \rangle_{0,\omega} = M_{\mu_\alpha}^{0 \leftarrow n} M_{m_\beta \mu_\gamma}^{n \leftarrow 0}(0), \quad (206)$$

where $M_{\mu_\alpha}^{0 \leftarrow n}$ and $M_{m_\beta \mu_\gamma}^{n \leftarrow 0}(0)$ indicate specific one- and (formally) two-photon transition matrix elements between state $|0\rangle$ and state $|n\rangle$, respectively.

In a recent experimental study of the ethylene MCD spectrum (Snyder et al. 2004), the assignment of the transitions was revised. The proposed new assignment is in agreement with earlier ab initio calculations of the *B* term in ethylene (Coriani et al. 1999b). Recently, also calculations of the *A* term of magnetic circular dichroism appeared (Seth et al. 2004). We also note that both the *A* and *B* terms come out directly from calculations using the complex polarization propagator approach (Solheim et al. 2008).

Nuclear Spin-Related Properties

In the electronic Schrödinger equation defined by the Hamiltonian of Eq. 2, there are no terms dependent on the isotopic species of the nuclei. The electron–nucleus and nucleus–nucleus interactions are described only as interactions of point charges. In particular, no hyperfine interactions dependent on the nuclear magnetic moments are included. To determine molecular properties dependent on the nuclear magnetic dipole moments we thus considered an extension of this Hamiltonian, Eqs. 41, 42, and 43, assuming that the magnetically active nuclei are represented by point magnetic dipoles. The related properties of the nucleus – its spin and magnetogyric constant – enter the definitions of the molecular properties as known, constant factors.

All the effects which determine the existence of nuclear magnetic resonance (NMR) spectra are due to the magnetic moments of the nuclei. Each magnetically active nucleus contributes to the magnetic field through the magnetic vector potential Eq. 38. In the NMR spectrum we observe the effects due to the interaction of this locally induced magnetic field with the applied external magnetic field and with other magnetically active nuclei in the molecule. The richness of the NMR spectrum arises from the dependence of both these interactions on the electronic structure. Within a molecule, each nucleus is shielded by the electrons, and due to this shielding the effective, local magnetic field differs for different nuclei. Similarly, the interaction of two magnetic dipole moments – determining the spin–spin coupling in NMR spectra – depends not only on the distance between two nuclei, but also on the electronic structure of the molecule. Moreover, in contrast to the direct dipole–dipole interaction, this electron-mediated contribution – the indirect spin–spin coupling tensor – does not vanish in isotropic media. We focus in this section on the calculation of the linear response properties that determine these effects.

Due to the importance of NMR spectroscopy in modern chemical research, the shielding and spin–spin coupling constants are undoubtedly the most important properties which depend on the nuclear spin. Nevertheless, we analyze here also other phenomena proportional to the magnetic moment of a nucleus. The existence of an external magnetic field affects the rotational spectrum; similarly, splittings in the rotational spectrum will also appear due to the field associated with the nuclear magnetic dipole moment and these splittings are described by the nuclear spin–rotation constant (NSRC). Indeed, in high-resolution molecular beam and microwave spectroscopies, the effective Hamiltonians describing the rotational spectrum include the contributions to the rotational energy levels due to the presence of the spin–rotation interactions, as well as the interactions between two nuclear spin–magnetic moments, and the electric field gradients at the nuclei (see Vaara et al. (2002) and references therein for more details).

NMR Effective Spin Hamiltonian

Let us first consider the standard interpretation of the NMR spectrum. The parameters used to define it – the shielding constants and spin–spin coupling constants – are obtained from an effective NMR Hamiltonian \mathcal{H}^{NMR} . This operator acts in the space defined by all possible arrangements of the nuclear spins. The eigenvalues of \mathcal{H}^{NMR} determine the transition energies as the differences between different nuclear spin states in the molecule, and the eigenvectors determine the arrangement of the nuclear spins with respect to the external field. The effective NMR Hamiltonian is written as (Abragam 1961):

$$\mathcal{H}^{\text{NMR}} = -\sum_K \mathbf{B}^T (1 - \sigma_K) \mathbf{m}_K + \frac{1}{2} \sum_{K \neq L} m_K^T (\mathbf{D}_{KL} + \mathbf{K}_{KL}) \mathbf{m}_L, \quad (207)$$

where σ_K is the shielding tensor (see section “Nuclear Magnetic Shielding”) and \mathbf{K}_{KL} is the reduced indirect spin–spin coupling tensor (see section “NMR Indirect Spin–Spin Coupling”). We recall that the nuclear magnetic dipole moment is related to the nuclear spin, $\mathbf{m}_K = \mu_N g_K \mathbf{I}_K$, see Eq. 25. Finally, \mathbf{D}_{KL} is the direct interaction of the magnetic dipoles. The effective Hamiltonian does not include the \mathcal{H}^{Nq} operator, Eq. 122, which describes the interactions due to the quadrupole moment of the nucleus and the electric field gradient at the nucleus (as discussed in section “Electric Field Gradient at the Nucleus, Nuclear Quadrupole Coupling Constant,” \mathcal{H}^{Nq} can be related to the contributions quadratic in \mathbf{I}_K). The reason for this is that in isotropic media the nuclear quadrupole interaction does not contribute to the nuclear spin energy levels, but only to the relaxation processes in the nuclear spin system – thus, it only affects the shapes of the spectral lines, and not their positions.

The effective NMR Hamiltonian \mathcal{H}^{NMR} has no explicit dependence on the electronic structure. It includes two electron-independent contributions, the nuclear Zeeman term $-\mathbf{B}^T \cdot \mathbf{m}_k$ and the classical direct dipolar coupling of the nuclear magnetic moments $\mathbf{m}_K^T \mathbf{D}_{KL} \mathbf{m}_L$. All the effects of the electronic structure are

incorporated in the nuclear magnetic shielding tensors σ_K , and the reduced indirect nuclear spin–spin coupling tensors \mathbf{K}_{KL} .

In order to calculate the shielding and indirect spin–spin coupling tensors, we employ the perturbation expansion of the molecular Hamiltonian, discussed in section “[The Molecular Hamiltonian](#).” As indicated by Eq. 207, in the perturbation expansion of the Schrödinger equation we have to consider all contributions that are either linear or bilinear in \mathbf{B} and \mathbf{m}_K for the shielding constants, and those linear or bilinear in \mathbf{m}_K and \mathbf{m}_L for the indirect spin–spin coupling constants. Since the perturbing operators are time independent, both the shielding and spin–spin coupling tensors can be expressed as energy derivatives.

For a rotating molecule in an isotropic medium, the NMR spin Hamiltonian may be written as (assuming the external magnetic field is directed along the Z axis):

$$\mathcal{H}_{\text{iso}}^{\text{NMR}} = -\sum_K B (1 - \sigma_K) m_{K,Z} + \frac{1}{2} \sum_{K \neq L} K_{KL} \mathbf{m}_K^T \cdot \mathbf{m}_L. \quad (208)$$

The direct spin–spin couplings D_{KL} are purely anisotropic and vanish in the rotational averaging, while for the shielding and indirect spin–spin coupling tensors the averaging leads to what is commonly referred to as the nuclear shielding constants σ_K and the reduced indirect nuclear spin–spin coupling constants K_{KL} :

$$\sigma_K = \frac{1}{3} \text{Tr} \sigma_K, \quad (209)$$

$$K_{KL} = \frac{1}{3} \text{Tr} \mathbf{K}_{KL}. \quad (210)$$

The name “scalar coupling” is sometimes used for the indirect spin–spin interaction; this is rather unfortunate, and one should keep in mind that we discuss a tensor even when the individual components are not observed.

The numerical values of the shielding and indirect spin–spin coupling constants are determined in experiment by fitting the solutions of the nuclear spin equation with the effective Hamiltonian Eq. 208 to the observed spectrum. The NMR spin Hamiltonian is usually not expressed in terms of the reduced indirect spin–spin coupling tensors \mathbf{K}_{KL} , but rather in terms of the indirect spin–spin coupling tensors \mathbf{J}_{KL} , which are related to the reduced tensors as:

$$\mathbf{J}_{KL} = \frac{1}{h} \mu_N g_K \mu_N g_L \mathbf{K}_{KL}. \quad (211)$$

The reduced coupling tensors \mathbf{K}_{KL} are independent of the nuclear g factors, and therefore, in contrast to \mathbf{J}_{KL} , can be used to compare the strengths of the couplings between nuclei with different g_K values.

An example of an NMR spectrum is shown in Fig. 3. The positions of the three groups of peaks are determined by the shielding constants and the fine structure within each group of peaks is determined by the spin–spin coupling constants. Both

Fig. 3 Simulated 500 MHz proton NMR spectra of C_2H_3F . *Top* – ab initio, *bottom* – experimental values of shielding and spin–spin coupling constants. The labels define the position of the relevant proton with respect to the fluorine. The shielding constants and the Fermi contact contributions to the coupling constants were computed at the CCSD level, the other theoretical values are taken from Helgaker et al. (1997), where the experimental data were also discussed

proton spectra have been simulated assuming no coupling to C atoms (i.e., for ^{12}C). We note here that the changes in the energy levels due to the screening of the nuclear magnetic moments, reflected in the magnetic shielding constants, depend on the external magnetic field induction, whereas the changes induced by the spin–spin coupling constants (the splitting within each group of lines) are independent of the external magnetic field induction.

Nuclear Magnetic Shielding

The nuclear magnetic shielding tensor σ_K can be determined from the equation:

$$\left. \frac{\partial^2 E(\mathbf{B}, \mathbf{m}_K)}{\partial \mathbf{B} \partial \mathbf{m}_K} \right|_{\mathbf{B}=0, \mathbf{m}_K=0} = \sigma_K - \mathbf{1}, \quad (212)$$

where the second term represents the direct Zeeman interaction between the nucleus and the field. From the form of the energy derivative, as well as the bilinear nature of the interaction described by the shielding tensor appearing in the effective NMR Hamiltonian, it is clear that in the molecular Hamiltonian the terms that are linear and bilinear in the external magnetic field induction and the nuclear magnetic

moments should be considered. Collecting them and writing the contributions in terms of expectation values and response functions, we find for closed-shell systems:

$$\sigma_{K,\alpha\beta} = \left\langle 0 \left| \hat{H}_{\alpha\beta}^{B,K} \right| 0 \right\rangle + \left\langle \left\langle \hat{H}_{\alpha}^B; \hat{H}_{\beta}^{K(\text{PSO})} \right\rangle \right\rangle = \sigma_{K,\alpha\beta}^{\text{dia}} + \sigma_{K,\alpha\beta}^{\text{para}}. \quad (213)$$

As for the magnetizability, there are two contributions to the shielding: the so-called diamagnetic contribution σ_K^{dia} , which is obtained as the expectation value $\langle 0 | \hat{H}^{B,K} | 0 \rangle$ and the paramagnetic contribution σ_K^{para} , calculated as a linear response function $\langle \langle \hat{H}^B; \hat{H}^{K(\text{PSO})} \rangle \rangle$.

The shielding tensor is a nonsymmetric tensor of rank two. The principal axis system (PAS) is determined by the diagonalization of the symmetric part of the tensor. The shielding constant, already introduced in Eq. 209, is defined as the isotropic part; we can also define the anisotropy (Smith et al. 1992)

$$\sigma_{\text{anis}} = \sigma_{33}^{\text{PAS}} - \frac{1}{2} (\sigma_{11}^{\text{PAS}} + \sigma_{22}^{\text{PAS}}), \quad (214)$$

as well as the asymmetry:

$$\eta_{\text{asym}} = \frac{(\sigma_{22}^{\text{PAS}} - \sigma_{11}^{\text{PAS}})}{(\sigma_{33}^{\text{PAS}} - \sigma_{\text{iso}})}, \quad (215)$$

where it is assumed for the principal axis components of the shielding tensor that $\sigma_{33}^{\text{PAS}} \geq \sigma_{22}^{\text{PAS}} \geq \sigma_{11}^{\text{PAS}}$. Unfortunately, there are different conventions for the ordering of the principal shielding axes which can lead to much confusion when comparing literature values of anisotropies and asymmetries. To circumvent these problems it has been proposed that shielding tensor results should be reported in terms of the span and the skew, defined as (Mason 1993):

$$\Omega_{\text{span}} = \sigma_{33}^{\text{PAS}} - \sigma_{11}^{\text{PAS}}, \quad (216)$$

$$\kappa_{\text{skew}} = \frac{3(\sigma_{\text{iso}} - \sigma_{22}^{\text{PAS}})}{\Omega_{\text{span}}}. \quad (217)$$

The antisymmetric part does not affect the standard NMR spectrum (that is why the rank-1 tensor has been disregarded above); however, it affects the relaxation rates (Anet et al. 1990).

Since the magnetic dipole operator appears in the expression for the paramagnetic contribution to the shielding tensor, the calculated quantity will depend on the choice of a global gauge origin. Similarly, for the diamagnetic contribution an origin dependence can easily be seen from the definition of the operator $\hat{H}^{B,K}$ in Eq. 48. Hence, the partitioning of the nuclear shielding into dia- and paramagnetic contributions depends on the choice of global gauge origin. Any

interpretation attributed to the individual contributions is, therefore, limited to the applied computational approximation – in particular, care should be exercised when results for different nuclei in different molecules are compared. When the gauge origin is chosen to be the nucleus of study, the paramagnetic contribution to the shielding tensor is related to the electronic contribution to the nuclear spin-rotation constant; see Eq. 231 below. We note, however, that this relation is true only in a nonrelativistic approach.

The dependence of the dia- and paramagnetic contributions to the shielding on a global gauge origin means that in approximate calculations the nuclear magnetic shielding tensors will display a dependence on a gauge origin. This can be avoided through the introduction of local gauge origins, as described in section “Magnetic Properties.” In addition to the London orbital approach other methods have also been applied to enable the calculation of origin-independent nuclear magnetic shielding constants, such as the individual gauge for localized orbitals (IGLO) method developed by Kutzelnigg (1980; Schindler and Kutzelnigg 1982) and various continuous transformation of the origin of the current density (CTOCD) methods developed by Lazzeretti, Malagoli, and Zanasi (Lazzeretti and Zanasi 1996; Lazzeretti et al. 1994; Zanasi et al. 1995).

The shielding constant is dimensionless, and is expressed in ppm (parts per million). This unit reflects the role of the shielding in comparison to the electron-independent direct Zeeman interaction of the nuclear magnetic moment with the external field (Eq. 208). We can get a physical understanding of the nuclear shielding by considering that the electrons in the molecule create an additional magnetic field, acting as a correction proportional to the external field and leading to the local magnetic field

$$\mathbf{B}_K^{\text{loc}} = (\mathbf{1} - \sigma_K) \mathbf{B}. \quad (218)$$

When σ_K is positive, it means that the presence of electrons leads to a decreased local magnetic field experienced by the nuclear magnetic moments – that is, the electron density shields the nuclear magnetic moments from the external magnetic field, a concept that explains the origins of the term shielding constant (we note that shielding constants can also be negative). The values of the shielding constants for various elements differ widely, as do their variations with molecular structure. In general the variation of the shielding constants increases with increasing atomic number – ranging from 10–10² ppm for light atoms to $\approx 10^4$ ppm for Pb (see also Table 11). The range of shielding constants for a particular nucleus is relevant when we compare the computed and experimental spectra, for instance to assign the peaks in the NMR spectrum to specific nuclei. The required accuracy for the shielding of hydrogen may be ≈ 0.1 ppm, whereas for carbon or nitrogen nuclei it may be sufficient to obtain results accurate to ≈ 5 ppm.

Let us also briefly consider the shielding constants in paramagnetic molecules. In this case we have a total electron spin S which implies a set of $2S + 1$ degenerate spin states. These different states will be split when an external magnetic field is applied to the sample. The ensemble average of the projection of the spin operator

along the Z axis can be obtained in much the same way as the magnetization induced in a molecular sample containing unpaired electrons as:

$$\langle S_Z \rangle = -\frac{g_e}{2} \frac{S(S+1)}{3kT} B_Z. \quad (219)$$

The total magnetic moment of the electrons becomes directly proportional to the external magnetic field induction, and thus additional contributions to the nuclear shielding constant arise, since we need to consider new terms linear and bilinear in the nuclear and electronic magnetic moments. From the terms in the molecular Hamiltonian introduced in section “[Small Terms Due to the Vector Potential in the Hamiltonian](#)” we see that these are the hyperfine interactions involving the Fermi contact and spin–dipole operators, $\hat{H}^{K(\text{FC})}$ and $\hat{H}^{K(\text{SD})}$ given in Eqs. 51 and 52, respectively. Using the ensemble average for the spin–projection given in Eq. 219, we find that the contributions to the nuclear shielding constants due to these hyperfine interactions are (Rinkevicius et al. 2003):

$$\sigma_{K,\alpha\beta}^{\text{con,FC}} = \frac{4\mu_B^2}{3kT} S(S+1) \left\langle 0 \left| \hat{H}_{\alpha\beta}^{K(\text{FC})} \right| 0 \right\rangle, \quad (220)$$

$$\sigma_{K,\alpha\beta}^{\text{con,SD}} = \frac{4\mu_B^2}{3kT} S(S+1) \left\langle 0 \left| \hat{H}_{\alpha\beta}^{K(\text{SD})} \right| 0 \right\rangle. \quad (221)$$

These contributions are closely related to the hyperfine interactions observed in ESR spectroscopy (see section “[ESR Hyperfine Coupling Tensors](#)”). The above expressions have been derived assuming kT to be much larger than the separation

of the different electronic spin states. We have also for simplicity ignored higher-order corrections arising from the spin-orbit interaction, which for many open-shell species can be quite significant.

It is worth noticing that the so-called contact contributions to the nuclear shielding tensor, Eqs. 220 and 221, are temperature dependent, and thus behave differently than the orbital contributions. Experimentally, the contact contributions are often quite large and assumed to vary much more with molecular structure than the dia- and paramagnetic contributions, and thus these latter two terms are often assumed constant in different chemical species or taken to be identical to closely related closed-shell molecules. However, theoretical studies have shown that this is a rather crude approximation, and it may fail to correctly describe the total shifts due to the contact and orbital terms (Rinkevicius et al. 2003).

A direct comparison of calculated shielding constants with experiment is hampered by the difficulty in experimentally determining the absolute shielding constants calculated by theory. The lack of experimental data for absolute shielding constants has many origins: first, the shielding constant is defined as a correction to the direct interaction between the external magnetic field induction and the bare nuclear magnetic moment. However, it is impossible to experimentally determine this direct interaction. Moreover, determining the magnetic field induction of an NMR spectrometer with sufficient accuracy is difficult.

The shielding constant can be considered as a measure of the local field experienced by a nuclear magnetic moment due to the shielding of the external magnetic field by the electron density. The *relative* difference in the local magnetic fields around different nuclei provides similar information and for this reason experimental NMR studies report the *chemical shift* δ_K defined as:

$$\begin{aligned}\delta_K &= \frac{\sigma_K(\text{reference}) - \sigma_K(\text{sample})}{1 - \sigma_K(\text{reference})} \\ &\cong \sigma_K(\text{reference}) - \sigma_K(\text{sample})\end{aligned}\quad (222)$$

The trends for the absolute shielding are thus reversed to those for the chemical shift – that is, $\delta_K < \delta_L$ means that the nucleus K is more shielded than nucleus L . The chemical shifts are taken relative to the shielding in a selected molecule (see Table 11); for instance, liquid tetramethylsilane (TMS) is used as a standard reference for ^{13}C . Unfortunately, large molecules in solution or in condensed phase are chosen for many nuclei to define experimental chemical shifts. It is not yet possible to perform benchmark calculations for these standard systems; moreover, it is often not even possible to compute the shielding in these reference compounds at the same level of accuracy as for smaller molecules that are of interest.

There is a semi-experimental approach for determining absolute shielding scales, based on the relationship between the paramagnetic shielding constant and the nuclear spin-rotation constants, as indicated in Eq. 231 below. The absolute shielding constants have been used to obtain the magnetic dipole moments of bare nuclei from NMR spectra – in this case, it is not sufficient to measure the chemical shifts. Similarly to the electric quadrupole moments, improved values of the nuclear

magnetic dipole moments can now be determined applying increasingly accurate absolute shielding constants obtained in *ab initio* calculations for small molecules (Jaszuski and Jackowski 2008).

The use of perturbation-dependent basis sets is mandatory in theoretical studies of nuclear shielding constants. This is particularly important in order to ensure that the calculated shielding constants are independent of the choice of gauge origin. At the same time, for smaller basis sets, the use of perturbation-dependent basis sets improves basis set convergence compared to calculations only employing conventional basis sets. Moreover, the convergence may be significantly improved by applying property-optimized basis sets, such as the pcS-*n* basis sets optimized by Jensen for DFT calculations of the shielding constants (Jensen 2008).

For atomic systems, theory can determine rather accurately the absolute shielding constants. First, fairly large nonelectronic contributions such as the zero-point vibrational corrections are absent. Secondly, because of symmetry only the diamagnetic term – an expectation value, which is much easier to compute than an accurate value of the response function – contributes. For instance, for the hydrogen atom the nonrelativistic shielding constant can be calculated as:

$$\sigma^{\text{dia}} = \alpha_{\text{fs}}^2 \frac{e^2}{3m_e} \left\langle 0 \left| \frac{1}{r_{iK}} \right| 0 \right\rangle = 17.750454 \text{ ppm.} \quad (223)$$

In a similar manner, explicitly correlated calculation of the $1/r_{iK}$ expectation value leads to an absolute shielding constant for the helium atom of 59.9367794 ppm (Drake 2006) (the most accurate value obtained in a recent study including relativistic, quantum-electrodynamic, and nuclear mass effects is $\sigma_{\text{He}} = 59.96743$ ppm (Rudziński et al. 2009)). For all the rare-gas atoms the shielding constants have been computed using a four-component relativistic approach (Vaara and Pyykkö 2003). The calculations were performed within the Dirac–Hartree–Fock approximation and, if we assume that the electron correlation effects are small, they provide the shielding scale for the rare gas atoms.

The development of efficient methods – using perturbation-dependent basis sets and highly correlated wave functions for the calculation of nuclear magnetic shieldings – has allowed in practice to reach high accuracy also for shielding constants in molecules (see the reviews by Gauss and Stanton 2002 and Helgaker et al. 1999). For instance, the use of carefully chosen basis sets with the CCSD(T) method has enabled calculations of the equilibrium shielding constants with an accuracy of about 1–3 ppm for ^{13}C shieldings in a range of molecules (Auer et al. 2003). Most importantly, it has been demonstrated that systematic convergence of the results with improvement in the level of the calculation can be achieved. In order to obtain highly accurate shielding constants comparable with experiment, in addition to the effects of electron correlation, vibrational effects also have to be considered. The latter are obviously mandatory to estimate the isotopic substitution effects, since for a fixed molecular geometry the shielding constants are independent of the nuclear masses. The most accurate and reliable results are presently obtained

in this manner – within the CCSD(T) approach, applying GIAOs and taking into account the vibrational effects [see for instance a recent ^{19}F shielding study (Harding et al. 2008a)]. CCSD(T) shielding constants may be computed for increasingly large molecules, as shown by benzene calculations with basis sets including up to 474 functions (Harding et al. 2008b). Higher-order coupled-cluster methods have also been developed, but so far their application has been limited to small molecules (Kállay and Gauss 2004). At the HF or DFT level, shielding constants may nowadays be computed for molecules with more than 1000 atoms, with basis sets including over 10,000 functions (Kussmann and Ochsenfeld 2007; Ochsenfeld et al. 2004).

In practice, care should be exercised when using the data of Table 11 to analyze experimental chemical shifts and computed absolute shielding values. The differences between various levels of approximation in the theory are often difficult to foresee, and variations of the experimental conditions may also lead to unpredictable changes in the shielding. When a particular approximation is used in a sequence of calculations, a comparison of the calculated chemical shifts with the corresponding experimental data might be more appropriate. Moreover, whereas there is no guarantee that zero-point vibrational effects or changes due to intermolecular interactions will be identical for nuclei of interest in two molecules (or even within a single molecule), one may expect that these effects partly cancel out for two nuclei (Ruud et al. 2001), and thus that higher accuracy may be achieved for chemical shifts than for absolute shielding constants.

To obtain the shielding constants in ppm, the computed values in a.u. are multiplied by $10^6 \times \alpha_{\text{fs}}^2 \cong 53.25136$.

Shielding Derivatives

The nuclear shielding depends, as does the molecular energy itself, on additional sources of perturbations, such as electric and magnetic fields. Assuming these perturbations to be static, we may perform a Taylor expansion of the nuclear shielding tensor in the presence of the additional perturbations. As the simplest example, let us mention the perturbation-induced changes in the shielding in the presence of a static electric field. They can be described in terms of so-called shielding polarizabilities (a review was given by Raynes 1996), where for instance the first shielding polarizability is given by:

$$\left. \frac{\partial \sigma_K(\mathbf{F})}{\partial \mathbf{F}} \right|_{\mathbf{F}=\mathbf{0}} = \left. \frac{\partial^3 E(\mathbf{B}, \mathbf{m}_K, \mathbf{F})}{\partial \mathbf{B} \partial \mathbf{m}_K \partial \mathbf{F}} \right|_{\mathbf{B}, \mathbf{m}_K, \mathbf{F}=\mathbf{0}} = \left\langle \left\langle \hat{H}^{\text{B},K}; \boldsymbol{\mu} \right\rangle \right\rangle + \left\langle \left\langle \hat{H}^{\text{B}}; \hat{H}^{\text{K(PSO)}} \right\rangle, \boldsymbol{\mu} \right\rangle. \quad (224)$$

We note that there is a route to origin-independent shielding polarizabilities, as the combination of origin-independent linear response calculations of the shielding constant in the presence of a finite electric field can be used in a finite-field procedure. This allows for the calculation of origin-independent shielding polarizabilities using for instance London atomic orbitals (Rizzo and Gauss 2002).

Spin-Orbit Corrections to Nuclear Magnetic Shielding

The formalism presented above for calculating the nuclear shielding constants works well for molecules containing elements from the first two or three rows of the periodic table. However, when the molecule contains heavier nuclei, this formalism may fail to reproduce correctly even the qualitative features of all the shielding constants, also for light elements such as hydrogen or carbon in a molecule. A classic example of this failure of Eq. 213 is shown in Fig. 4, which illustrates the hydrogen shielding in the hydrogen halides. Whereas the hydrogen shielding observed experimentally increases strongly with increasing atomic number, only a small increase is observed when Eq. 213 is used to calculate the shielding constants. The reason for this failure can be traced to relativistic effects, and in the case of the hydrogen shielding in Fig. 4 to the effects of the spin-orbit interactions.

Some of the most important relativistic effects – such as the discussed spin-orbit contributions to the shielding of light elements bonded to heavy atoms – can be calculated using perturbation theory, beginning with the nonrelativistic treatment and considering the spin-orbit operator as an additional perturbation representing one of the relativistic corrections. The spin-orbit operator provides a coupling between the orbital magnetic moment of the electron, in the case of NMR induced by an external magnetic field induction, and either its own or another electron's spin-magnetic moment. This induced spin-magnetic moment may in turn interact with the nuclear magnetic moments through the Fermi contact (Eq. 51) or spin-dipolar (Eq. 52) mechanism. These contributions involve three perturbing

Fig. 4 The proton shielding constants (in ppm) in the HX series (X = F, Cl, Br, I) calculated with and without spin-orbit coupling contributions. Also included are the available experimental data. The theoretical data are CASSCF results from Vaara et al. (1998)

operators, and they are thus proportional to quadratic response functions such as $\langle\langle \hat{H}^{K(\text{FC})} + \hat{H}^{K(\text{SD})}; \hat{H}^{\text{SO}}, \hat{H}^{\text{B}} \rangle\rangle$.

In addition, in the presence of an external magnetic field there is a term in the spin-orbit operator which is proportional to the external magnetic field induction (we recall here the discussion of the general form of the spin-orbit operators in section “[Small Terms Due to the Vector Potential in the Hamiltonian](#),” Eqs. 58, 59, and 60). The operator $\hat{H}^{\text{SO,B(n)}}$ can in turn interact with the Fermi contact and spin-dipole operators, leading to second-order contributions to the shielding tensor which are proportional to triplet linear response functions (Vaara et al. 1999) of the form $\langle\langle \hat{H}^{K(\text{FC})} + \hat{H}^{K(\text{SD})}; \hat{H}^{\text{SO,B(n)}} \rangle\rangle$.

For the shielding constants of the heavy elements themselves, relativistic effects arising from the other terms in the Breit–Pauli Hamiltonian (see section “[The Molecular Breit–Pauli Hamiltonian](#)”) are in general found to be more important than the spin-orbit corrections (Manninen et al. 2003). In general, relativistic effects on the heavy-atom shielding are due to a large number of contributions (Fukui et al. 1996; Ruiz de Azúa et al. 2003) in contrast to the hydrogen shieldings in molecules containing heavy elements, which are dominated by the spin-orbit corrections. Although there have been several studies of scalar relativistic effects on shielding, yielding results in good agreement with four-component Dirac–Hartree–Fock methods, the Breit–Pauli Hamiltonian is not variationally bound and thus the perturbation theory approach may fail for heavy elements.

Nuclear Spin Rotation Constants

The interaction between the nuclear magnetic dipole and the effective magnetic field of a rotating molecule at that nucleus leads to a splitting in the rotational spectrum (Flygare 1974; Gauss et al. 1996). This splitting is usually expressed in terms of the nuclear spin \mathbf{I}_K and the total rotational angular momentum \mathbf{J} as

$$\Delta E_K = -\mathbf{I}_K^T \mathcal{M}_K \mathbf{J}, \quad (225)$$

where $\mathcal{M}_K = \mathcal{M}_K^{\text{el}} + \mathcal{M}_K^{\text{nucl}}$ is the nuclear spin–rotation tensor in the Born–Oppenheimer approximation. More precisely, the energy shift depends on the nuclear magnetic moment interacting with the magnetic field induced by the molecular rotation, so we shall proceed from the equivalent equation,

$$\Delta E_K = -\frac{2\pi}{\mu_{\text{N}} g_K} \mathbf{m}_K^T \mathcal{M}_K \mathbf{J}. \quad (226)$$

The electronic contribution $\mathcal{M}_K^{\text{el}}$ is a second-order property

$$\mathcal{M}_K^{\text{el}} = -\frac{\mu_{\text{N}} g_K}{2\pi} \left. \frac{\partial^2 E^{\text{el}}}{\partial \mathbf{m}_K \partial \mathbf{J}} \right|_{\mathbf{m}_K, \mathbf{J}=0}, \quad (227)$$

and thus it can be obtained from the linear response function $\mathbf{I}^{-1} \langle \langle \hat{H}^{K(\text{PSO})}; \hat{I}_K \rangle \rangle$, where \mathbf{I} is the moment-of-inertia tensor and the angular momentum is evaluated with respect to nucleus K . The nuclear contribution is

$$\mathcal{M}_K^{\text{nucI}} = \alpha_{\text{fs}}^2 \mu_{\text{NG}K} \sum_{L \neq K} Z_L \frac{R_{LK}^2 \mathbf{1} - \mathbf{R}_{LK} \mathbf{R}_{LK}^T}{R_{LK}^3} \mathbf{I}^{-1}. \quad (228)$$

The principal axes of the nuclear spin–rotation tensor are determined by the molecular moment of inertia. Indeed, the magnetic moment induced by the rotational motion is well defined only in the rotation frame. Spin–rotation constants are related to the difference between the total shielding (for instance obtained using LAOs) and the diamagnetic part of the shielding derived from a conventional calculation with \mathbf{R}_K as the global gauge origin, $\sigma_K^{\text{dia}}(\mathbf{R}_K)$,

$$\mathcal{M}_K^{\text{el}} = \mathcal{M}_K - \mathcal{M}_K^{\text{nucI}} = \frac{\hbar}{\mu_{\text{B}}} \frac{\mu_{\text{NG}K}}{2\pi} [\sigma_K - \sigma_K^{\text{dia}}(\mathbf{R}_K)] \mathbf{I}^{-1} \quad (229)$$

in analogy with our definition of the paramagnetic magnetizability, Eq. 149. Hence, $\mathcal{M}_K^{\text{el}}$ is related to the correspondingly defined paramagnetic shielding:

$$\sigma_K^{\text{para}}(\mathbf{R}_K) = \langle \langle -\mathbf{m}(\mathbf{R}_K); \hat{H}^{K(\text{PSO})} \rangle \rangle, \quad (230)$$

as (Flygare 1974):

$$\sigma_K^{\text{para}}(\mathbf{R}_K) = \frac{\mu_{\text{B}}}{\hbar} \frac{2\pi}{\mu_{\text{NG}K}} \mathcal{M}_K^{\text{el}} \mathbf{I}. \quad (231)$$

The additional contributions to the spin–rotation constants arising in paramagnetic molecules have been discussed by Minaev et al. (2003).

As the spin–rotation interaction splits lines in the rotational spectrum, the unit of the spin–rotation constant is kHz.

NMR Indirect Spin–Spin Coupling

The interaction of the magnetic dipoles of two nuclei, including also the classic dipolar interaction between the bare nuclei, can be determined (compare section “NMR Effective Spin Hamiltonian”) from perturbation theory as the second derivative of the energy

$$\left. \frac{\partial^2 E(\mathbf{m}_K, \mathbf{m}_L)}{\partial \mathbf{m}_K \partial \mathbf{m}_L} \right|_{\mathbf{m}_K=0, \mathbf{m}_L=0} = \mathbf{K}_{KL} + \mathbf{D}_{KL}, \quad (232)$$

where \mathbf{K}_{KL} is the reduced indirect spin–spin coupling tensor given as the derivative of $E^{\text{el}}(\mathbf{m}_K, \mathbf{m}_L)$, and \mathbf{D}_{KL} describes the direct interaction of two nuclear dipoles. The reduced spin–spin coupling constants, independent of the nuclear magnetogyric ratios, should be used (for instance) to compare the strength of the coupling between pairs of different nuclei, and to analyze relative accuracies of calculated constants.

In standard gas- or liquid-phase NMR spectra the interaction of magnetic dipoles leads to a splitting of the lines of the spectrum, described by the NMR indirect spin–spin coupling constant J_{KL} . This constant is the trace of the tensor (Eq. 211):

$$\mathbf{J}_{KL} = \frac{1}{h} \mu_{\text{N}} g_K \mu_{\text{N}} g_L \mathbf{K}_{KL}.$$

The total spin–spin coupling tensor includes (see, e.g., Vahtras et al. 1992b) the so-called diamagnetic spin-orbit contribution $-\langle 0 | \hat{H}^{K,L(\text{DSO})} | 0 \rangle$ – obtained as the expectation value of the corresponding operator (Eq. 49), and a sum of linear response terms $\langle \langle \hat{H}^{K(\text{PSO})}; \hat{H}^{L(\text{PSO})} \rangle \rangle$ and $\langle \langle \hat{H}^{K(\text{FC})} + \hat{H}^{K(\text{SD})}; \hat{H}^{L(\text{FC})} + \hat{H}^{L(\text{SD})} \rangle \rangle$.

The paramagnetic spin-orbit operator $\hat{H}^{K(\text{PSO})}$ (Eq. 46) does not depend on electron spin, whereas the Fermi contact $\hat{H}^{K(\text{FC})}$ and spin–dipole $\hat{H}^{K(\text{SD})}$ operators (Eqs. 51 and 52) are electron-spin dependent. Therefore, as shown for instance by the sum-over-states description, in the calculation of the PSO term only singlet excited states have to be considered. In contrast, the FC–FC, SD–SD, and mixed FC–SD contributions depend on the triplet excited states. This leads to computational difficulties when the reference state function is not stable with respect to triplet perturbations. For instance, when the HF approximation is used to describe the reference state, completely meaningless results may be obtained.

\mathbf{J}_{KL} is an asymmetric tensor, and the different terms (DSO, PSO, SD, FC, and mixed SD–FC) yield contributions of different symmetry. For example, the term $\langle \langle \hat{H}^{K(\text{FC})}; \hat{H}^{L(\text{FC})} \rangle \rangle$ is fully isotropic, whereas the terms $\langle \langle \hat{H}^{K(\text{FC})}; \hat{H}^{L(\text{SD})} \rangle \rangle$ are fully anisotropic. Therefore, if we are only interested in the isotropic value of the spin–spin coupling constant, we can express it as the sum of four contributions:

$$J_{KL} = J_{KL}^{\text{DSO}} + J_{KL}^{\text{PSO}} + J_{KL}^{\text{SD}} + J_{KL}^{\text{FC}}, \quad (233)$$

and we do not need to compute the SD–FC terms. They have to be included when all the tensor components are required (see Buckingham and Love (1970), Buckingham et al. (1982), Jameson (1987) for details).

In addition to NMR spectra, microwave spectra also may provide information on the spin–spin coupling (Vaara et al. 2002). In particular, for diatomic molecules accurate data can be obtained from molecular beam electric and magnetic resonance when the splitting of a single rotational–vibrational state can be observed. One of the parameters of this splitting (usually called c_4) is equal to the isotropic value of the indirect spin–spin coupling tensor, another one (c_3) depends both on the direct coupling ($\propto R_{KL}^{-3}$) and on the anisotropy of the tensor.

In contrast to the shielding constants, London orbitals are neither needed nor used in any calculation of spin–spin coupling constants. There is no dependence

Table 12 The Fermi contact contribution to the spin–spin coupling constant of HD (in Hz), calculated using the CCSD Polarization Propagator Approximation (Oddershede et al. 1988)

14s6p2d	150,000	39.93
15s6p2d	500,000	39.94

^aGaussian-type functions. The effects of additional functions of *p*- and *d*-type symmetry are negligible

of the perturbing operators on the external magnetic field and thus no gauge origin problem.

The basis-set dependence of the Fermi contact term has been often a source of problems in the calculation of spin–spin coupling constants. To describe properly the response to the $\delta(\mathbf{r}_{iK})$ perturbation we need a basis set which is sufficiently flexible in the region of the nucleus. An illustration of the slow convergence of computed J^{FC} values for the simplest example – the HD molecule – is given in Table 12. We can see that practically only the last added function does not affect the result, whereas there are very few other properties where an *s*-type function with so high exponents as 150,000 would be needed for the H atom.

In general, two modifications of the standard energy-optimized basis sets are needed: the standard functions should be uncontracted and tight *s*, *p*, and *d* functions should be added. The *s*-type functions are of particular importance for the Fermi contact contribution, whereas other functions may be more relevant for the other contributions. Various basis sets constructed in this way have been successfully used in ab initio and DFT calculations; further improvement of convergence with the basis set extension is achieved reoptimizing the exponents and contraction coefficients (Benedikt et al. 2008; Jensen 2006).

In Table 13 we present, as an example, the different contributions to all the coupling constants in acetylene. The dominant role of the FC term is typical for many molecules, in particular for large coupling constants in organic compounds. The SD contribution is often small, and therefore (being most expensive to calculate) it is sometimes neglected or analyzed at a lower level of accuracy than the other terms. In some cases such an approach is, however, not possible. For instance, the FC, PSO, and SD terms, respectively, dominate for different coupling constants in ClF_3 (Jaszuński 2004).

To illustrate the accuracy of the results that may be achieved for small molecules, we present in Table 14 the values for all the coupling constants in acetylene. The comparison with experimental data clearly demonstrates that it is necessary to consider the effects of vibration and rotation (zero-point vibrations and temperature).

Finally, we note that J_{KL} is very sensitive to variations in the molecular geometry. It has been repeatedly observed that the best results are obtained when the same approximation (for instance DFT functional and basis set) is used for geometry

optimization and for the following calculation of spin-spin coupling constants. We refer to the recent reviews discussing the calculation of spin-spin coupling constants (Aucar 2008; Helgaker et al. 2008; Krivdin and Contreras 2007) for a discussion of many practical issues and numerous examples of successful applications.

The unit of J is Hz; K is given in $\text{kg m}^{-2} \text{s}^{-2} \text{A}^{-2} = \text{N A}^{-2} \text{m}^{-3} = \text{T}^2 \text{J}^{-1}$ (Raynes 1992).

Electron Spin-Related Properties

Electron spin resonance (ESR) and NMR are in principle very similar from a theoretical point of view, involving excitations and de-excitations in the electron and nuclear spin space, respectively. Thus, the effective Hamiltonians have much the same appearance in ESR and NMR theory, and the structure of the interactions is also very similar from a purely theoretical point of view.

However, from a computational viewpoint, there is a large difference between electron and nuclear spin interactions. In the case of the nuclear spin interactions, the Born-Oppenheimer approximation allowed us to decouple the nuclear spin wave function from the electronic wave function. This is not possible for the electron spin; indeed, the change in the electron spin state directly affects also the spatial part of the total electronic wave function. This is in principle not a problem. In *spin-unrestricted* approaches, the α and β electrons are treated separately, and changes

of electron spin through perturbation theory expressions can quite straightforwardly be included. However, since the spatial part of the orbitals of the α and β spins may differ, the total electron spin is no longer necessarily a good quantum number (as required for the exact wave function), giving rise to what is often referred to as *spin contamination*. Spin contamination can be avoided forcing the spin to be a good quantum number, for instance by demanding that the spatial orbitals for the α and β electrons are the same and writing the wave function as a fixed linear combination of Slater determinants referred to as configuration-state functions (CSFs). We also note that many open-shell wave functions of low and intermediate spin have strong multireference character, putting severe constraints on the wave function models that can be used. An alternative approach to address low and intermediate spin states is through the use of broken symmetry states (Noodleman 1981).

We recall that the Hamiltonian, Eq. 2, does not involve the electron spin. Spin-restricted implementations of electronic structure methods, therefore, only optimize the wave function parameters of the same spin symmetry as the reference wave function. Since operators that change the spin symmetry are known not to contribute to the ground-state energy (at least in the nonrelativistic picture in which spin-orbit effects are ignored), such spin-breaking wave function parameters are left undefined. This has the consequence that average values of triplet-perturbing operators cannot be accurately calculated in spin-restricted approaches, and an alternative approach to circumvent this problem has been proposed (Fernandez et al. 1992). Furthermore, in the calculation of second-order properties, such as for instance spin–spin coupling constants discussed in section “NMR Indirect Spin–Spin Coupling,” triplet instabilities in the wave function may occur. We have discussed this problem in section “NMR Indirect Spin–Spin Coupling” and we will not dwell further on this here. We only note that these considerations apply to all properties discussed in the following sections.

Spin-Orbit Coupling Constants

The spin–orbit coupling constant is obtained from the single residue of a triplet linear response function:

$$\lim_{\omega \rightarrow \omega_f} \hbar (\omega - \omega_f) \langle \langle \hat{H}^{\text{SO}}; V^{\omega_f} \rangle \rangle_{\omega}, \quad (234)$$

where V^{ω_f} is an arbitrary operator (corresponding to the excitation vector). There are two terms in the spin-orbit interaction operator \hat{H}^{SO} (Eq. 55); the contribution to the spin-orbit coupling from the two-electron part is usually smaller than the one-electron contribution, though it is as large as 30% for the spin–orbit coupling constant in triplet O₂ (Vahtras et al. 1992c).

The two-electron spin-orbit integrals calculated using the operators in Eqs. 13 and 14 of the Breit–Pauli Hamiltonian have three spatial components and lower symmetry than conventional two-electron repulsion integrals, and the cost of

calculating these integrals is therefore very high. In order to reduce the costs of computations of spin-orbit effects, building on the observation that the one-electron contribution dominates, either scaled one-electron spin-orbit approximations are used (in which an effective nuclear charge is introduced) (Kosegi et al. 1995) or atomic mean-field approaches are utilized (Hess et al. 1996). In the latter approach, the two-electron interactions are included in a mean-field sense, in principle similar to the way the two-electron repulsion is included in a mean-field sense in Hartree–Fock calculations.

The spin-orbit coupling is the major intramolecular interaction mechanism responsible for intersystem crossings, such as singlet–triplet transitions. It should be kept in mind that, in contrast to, for example, external fields, \hat{H}^{SO} does not describe a perturbation which has a well-defined physical meaning and arbitrarily modified strength. It is our description of the system which provides first a set of singlet and triplet states and only next includes \hat{H}^{SO} and yields the values of the spin-orbit coupling constants. Indeed, within a relativistic framework, the spin-orbit interaction appears naturally and is included variationally in the optimization of the wave function. The spin-orbit effects often differ quite substantially in their behavior from the scalar relativistic effects (as for instance illustrated in the case of the hydrogen shielding constants in molecules containing heavy elements). It is therefore important, in order to get physical insight into the role of various relativistic effects, that spin-orbit effects can be addressed separately from other effects in a four-component framework, and an approach for achieving such a decomposition of the relativistic effects at the four-component level has been proposed (Visscher and Saue 2000).

The spin-orbit coupling constant is normally reported in cm^{-1} .

Phosphorescence

When the spin-orbit operator \hat{H}^{SO} is taken into account, the ground and excited state, which we assume here to be of singlet and triplet spin multiplicity, respectively, are no longer pure spin states – $|^1 0^{(0)}\rangle$ and $|^3 f^{(0)}\rangle$ – but are contaminated by, to first order in perturbation theory:

$$|^3 0^{(1)}\rangle = -\sum_{3_n} \frac{|^3 n^{(0)}\rangle \langle ^3 n^{(0)} | \hat{H}^{\text{SO}} | ^1 0^{(0)}\rangle}{\omega_n}, \quad (235)$$

$$|^1 f^{(1)}\rangle = \sum_{1_n} \frac{|^1 n^{(0)}\rangle \langle ^1 n^{(0)} | \hat{H}^{\text{SO}} | ^3 f^{(0)}\rangle}{\omega_f - \omega_n}. \quad (236)$$

Including these first-order corrections to the ground- and excited-state wave functions in the expression for the dipole transition moment, we find that the first-order nonvanishing contribution to the dipole transition moment between a singlet and a

triplet state may be written in terms of a residue of a quadratic response function (Olsen and Jørgensen 1995; Vahtras et al. 1992a):

$$\langle {}^1 0 | \boldsymbol{\mu} | {}^3 f \rangle^{(1)} = \lim_{\omega \rightarrow \omega_f} \hbar (\omega - \omega_f) \left\langle \left\langle \boldsymbol{\mu}; \hat{H}^{\text{SO}}, V^\omega \right\rangle \right\rangle_{0, \omega} / \langle {}^3 f | V^\omega | {}^1 0 \rangle, \quad (237)$$

where V^ω is an arbitrary triplet operator (determining the excitation vector) and ω matches the singlet-triplet excitation energy.

The phosphorescent radiative lifetime τ_k of the k th triplet spin component of state $|{}^3 f\rangle$ is obtained from the relation:

$$\frac{1}{\tau_k} = \frac{4\omega_f^3 \alpha_{\text{fs}}^3}{3\hbar} \sum_{\nu} \left| \langle {}^1 0 | \hat{\mu}_\nu | {}^3 f_k \rangle \right|^2, \quad (238)$$

and thus depends not only on the transition moment from the ground to the excited state, but also on the excitation energy. The transition moments may vary for different polarizations of the light, and the average phosphorescent lifetime is dominated by the shortest lifetime, corresponding to the polarization with the largest partial transition rate. The total transition rate is given in s^{-1} , the total lifetime being its inverse.

ESR Effective Spin Hamiltonian

The effective ESR Hamiltonian, including also contributions from the nuclear spins and nuclear quadrupole moments (the latter primarily observable in electron-nuclear double resonance – ENDOR – spectroscopy), may be written as (Harriman 1978):

$$\mathcal{H}^{\text{ESR}} = \mathcal{H}^{\text{ex}} + \mathcal{H}^{\text{SZ}} + \mathcal{H}^{\text{ZFS}} + \mathcal{H}^{\text{hf}} + \mathcal{H}^{\text{nZ}} + \mathcal{H}^{\text{Nq}}. \quad (239)$$

Like the NMR effective Hamiltonian, the ESR effective Hamiltonian contains no reference to the electronic structure of the molecule, and the different contributions to the ESR Hamiltonian thus describe phenomenologically the interactions present in the molecule.

The first term in Eq. 239, \mathcal{H}^{ex} , contributes to the overall energy of interaction between electronic spin states, but the energy differences are in general too large to be observed by ESR spectroscopy. This exchange contribution accounts for the difference in energy between states of different multiplicity, and the Hamiltonian

$$\mathcal{H}^{\text{ex}} = -2\mathcal{J} \mathbf{s}_1 \cdot \mathbf{s}_2, \quad (240)$$

is often referred to as the Heisenberg Hamiltonian. It is important in the analysis of the spin states in open-shell species. However, since to a large extent it defines an intrinsic relation between different electronic states of a molecule, we do not consider it to describe a molecular property in the sense we have defined, and we will, therefore, not discuss this contribution any further.

The second term in Eq. 239, \mathcal{H}^{sZ} , is the electron spin–Zeeman interaction describing the interaction between the spin-magnetic moment of the electron and the external magnetic field induction

$$\mathcal{H}^{sZ} = \mu_B \mathbf{S}^T \mathbf{g} \mathbf{B}, \quad (241)$$

where \mathbf{g} is the electron g tensor. We use here \mathbf{S} to indicate the total effective spin of the system. For a free electron, the strength of this interaction would be determined by Eq. 6 and thus be given by the free electron g factor ($g_e \approx 2.0023193$, in which the quantum-electrodynamic corrections to the electron g factor are included). However, unpaired electrons in a molecule experience a local magnetic field, arising from a partial shielding (or deshielding) due to the other electrons in the molecule, which leads to a shift relative to g_e , and therefore:

$$\mathbf{g} = g_e \mathbf{1} + \Delta \mathbf{g}. \quad (242)$$

\mathcal{H}^{ZFS} is the spin–spin interaction:

$$\mathcal{H}^{ZFS} = \mathbf{S}^T \mathbf{D} \mathbf{S}, \quad (243)$$

which gives rise to the zero-field splitting of the ESR spectrum, since it can be observed even without an external magnetic field. It is described by the dipole interaction between the spin-magnetic dipoles of two unpaired electrons, and is thus only present in states with more than one unpaired electron, such as for instance triplet states. This term will in general lead to a splitting of the different spin sublevels in the triplet state.

The electronic g tensor and the electron spin–spin interactions (if present) are in most cases the dominating contributions to the ESR spectrum. The interactions of the spin-magnetic moments of the electrons with the nuclear magnetic moments give rise to hyperfine interaction in the ESR spectrum described by \mathcal{H}^{hf} :

$$\mathcal{H}^{hf} = \sum_K (A_K^{fc} \mathbf{S}^T \cdot \mathbf{I}_K + \mathbf{S}^T \mathbf{A}_K^{sd} \mathbf{I}_K). \quad (244)$$

There are thus hyperfine interactions arising from all nonzero nuclear magnetic moments. We note from Eq. 244 that the hyperfine interactions in general can be divided into two contributions. The first term is purely isotropic and has the form of a contact interaction, whereas the second term A_K^{sd} corresponds to the dipolar interaction of the electron spin-magnetic moment and the nuclear magnetic moment, and is purely anisotropic. The isotropic hyperfine interaction measures the spin density at a given nucleus.

The last terms in Eq. 239 are in general not observable in ESR spectroscopy, because of the increased linewidths due to the presence of the unpaired electrons. The nuclear Zeeman interaction is given by:

$$\mathcal{H}^{nZ} = -\mu_N \sum_K g_K \mathbf{B}^T \cdot \mathbf{I}_K, \quad (245)$$

and is analogous to the interaction included in the NMR effective Hamiltonian Eq. 207, where the shift with respect to the nuclear g factor was described in terms of the shielding constant. The final term, the nuclear quadrupole interaction \mathcal{H}^{Nq} , also only involves the two nuclear spins and has already been discussed in section “Electric Field Gradient at the Nucleus, Nuclear Quadrupole Coupling Constant.”

ESR Electronic g -Tensor

In this section we concentrate on the part of the ESR effective Hamiltonian describing the interaction between the electron spin and the external magnetic field, Eq. 241. In the case of molecules with a single open-shell electronic doublet state, as well as high-spin radicals in the strong field limit, the energy difference between the eigenvalues of the effective ESR Hamiltonian can be written as

$$\Delta E = \mu_{\text{B}} \sqrt{\mathbf{B}^{\text{T}} \mathbf{G} \mathbf{B}}, \quad (246)$$

where we have introduced the so-called symmetric \mathbf{G} tensor, measured in experiment, and defined as $\mathbf{G} = \mathbf{g} \cdot \mathbf{g}^{\text{T}}$. The shift in the g factor may be anisotropic, and thus the \mathbf{g} tensor is a 3×3 nonsymmetric tensor. Both \mathbf{G} and \mathbf{g} tensors provide the same information and are thus suitable for analyzing EPR data. We emphasize that the effective Hamiltonian employed here requires the use of degenerate perturbation theory for a proper analysis, since we consider states that are degenerate in the absence of the perturbation. We do not discuss these aspects in detail here, referring instead to Löwdin and Goscinski (1999) for a general introduction to this topic, and to Rinkevicius et al. (2008) for the g tensor in particular.

Within degenerate perturbation theory at the nonrelativistic level, there are in principle two contributing terms arising from expectation values of the spin–Zeeman (Eq. 50) and the magnetic dipole operator (Eq. 44), respectively. The latter can be shown to be zero, and the effect of the spin–Zeeman operator is to recover the free-electron g factor, g_{e} . Thus, within a purely nonrelativistic picture, there would be no effect of the electronic structure of the molecule on the interaction between an external magnetic field and the magnetic moment of the unpaired electron.

Including relativistic effects to order α_{fs}^2 leads to three corrections to the electronic g tensor (we consider here only the shift Δg relative to the free-electron value):

$$\Delta \mathbf{g} = \Delta \mathbf{g}^{\text{SO}} + \Delta \mathbf{g}^{\text{RMC}} + \Delta \mathbf{g}^{\text{GC}} + \mathcal{O}(\alpha_{\text{fs}}^4). \quad (247)$$

Of these three contributions, the linear response contribution arising from the spin-orbit operator interacting with the orbital magnetic dipole operator is in most cases dominating, giving corrections to the g tensor of the form:

$$\Delta g_{\alpha\beta}^{\text{SO}} = \frac{2}{\langle S_Z \rangle} \left\langle \left\langle \hat{H}_{\alpha}^{\text{B}}, \hat{H}_{\beta}^{\text{SO}} \right\rangle \right\rangle, \quad (248)$$

where $\langle S_Z \rangle$ is the expectation value of the z component of the total electron spin. The relativistic mass correction Δg^{RMC} and gauge correction Δg^{GC} contributions are obtained as expectation values:

$$\Delta g_{\alpha\beta}^{\text{RMC}} = \frac{2}{\langle S_Z \rangle} \langle 0 | \hat{H}_{\alpha\beta}^{\text{SZ/KE}} | 0 \rangle, \quad (249)$$

$$\Delta g_{\alpha\beta}^{\text{GC}} = \frac{2}{\langle S_Z \rangle} \langle 0 | \hat{H}_{\alpha\beta}^{\text{GC}} | 0 \rangle. \quad (250)$$

Here, $\hat{H}^{\text{SZ/KE}}$ is the kinetic energy correction to the spin–Zeeman term given in the Breit–Pauli Hamiltonian (Eq. 10), whereas $\hat{H}^{\text{GC}} = \hat{H}^{\text{SO,B(1)}} + \hat{H}^{\text{SO,B(2)}}$ is the sum of the one- and two-electron magnetic-field corrections to the spin-orbit operator, Eqs. 59 and 60. Higher-order relativistic corrections have also been derived (Rinkevicius et al. 2008). We note, however, that the electron g tensor is a property for which a two- or four-component relativistic framework provides the most elegant expression, with the g tensor being reduced to a simple expectation value of the orbital magnetic dipole operator (see for instance van Lenthe et al. (1997)).

As for other open-shell properties, most calculations employ unrestricted approaches, in which conventional response-theory methodology can be used to calculate the relevant quantities if performed starting from a nonrelativistic wave function and using perturbation theory to include the relativistic corrections, as applied in Geurts et al. (1980), Noodleman and Baerends (1984). Spin-restricted approaches have also been applied, though it is important in this case to ensure that the triplet-perturbing operators acting on an open-shell reference state properly take all possible excitations into account (Rinkevicius et al. 2008). We also note that multireference CI and MCSCF wave functions have been used to calculate the g tensor of small molecules (see, e.g., Engström et al. (1998), Lushington and Grein (1996)).

The computed electronic g tensor will in general also be origin dependent in approximate calculations, since it depends on the external magnetic field. The origin dependence of the orbital magnetic dipole operator is canceled by the origin dependence of the gauge-correction term for exact states and wave functions. This means that in approximate calculations, care should be exercised to ensure gauge origin independence, for instance using London atomic orbitals (Ciofini et al. 2004). In general, however, electronic g tensors appear to be less sensitive than other properties to the choice of gauge origin (see for instance Kacprzak and Kaupp 2004), although exceptions have been observed.

Zero-Field Splitting

In degenerate perturbation theory, the ZFS of a spin-degenerate state ${}^{2S+1}\Psi_0$ is evaluated from the eigenvalues of the matrix

$$|\mathcal{H}_{ij}^{\text{ZFS}} - W\delta_{ij}| = 0, \quad (251)$$

where

$$\mathcal{H}_{ij}^{\text{ZFS}} = \frac{\langle 2S+1\Psi_0^i | \hat{H}^{\text{S,S}} | 2S+1\Psi_0^j \rangle - \sum_{n,\lambda} \sum_k \frac{\langle 2S+1\Psi_0^i | \hat{H}^{\text{SO}} | \lambda\Psi_n^k \rangle \langle \lambda\Psi_n^k | \hat{H}^{\text{SO}} | 2S+1\Psi_0^j \rangle}{\lambda E_n - E_0}}{1} \quad (252)$$

In these expressions, ${}^\lambda\Psi_n^k$ is the zeroth-order wave function, λ is the multiplicity of the state, S is the total spin quantum number, and the indices $i, j, k = M_S$ determine the projection of the total spin (Minaev et al. 2003; Vahtras et al. 2002). As the operator couples two electron spins, ZFS will only occur in molecules with at least two unpaired electrons.

As for many other properties, the zero-field splitting has two distinct contributions. The first contribution in Eq. 254 is an expectation value of the two-electron spin–spin dipole–dipole coupling operator,

$$\hat{H}^{\text{S,S}} = \frac{\alpha_{\text{fs}}^2}{2} \sum_{j \neq i} \left[\frac{\mathbf{m}_i \cdot \mathbf{m}_j}{r_{ij}^3} - \frac{3(\mathbf{m}_i \cdot \mathbf{r}_{ij})(\mathbf{r}_{ij} \cdot \mathbf{m}_j)}{r_{ij}^5} \right], \quad (253)$$

whereas the other term is the indirect interaction between the spin-magnetic moments of two electrons, mediated through the interaction between the orbital magnetic moments in the spin-orbit operator. For transition-metal complexes, the spin-orbit effects, often dominated by a few close-lying electronic states, can be included in a limited sum-over-states expansion (Bolvin 2006) or using ligand-field theory (Neese and Solomon 2003). The electron spin–spin interaction can, however, be dominant in molecules with weak spin-orbit interactions, such as triplet states of organic molecules (Vahtras et al. 2002).

We can represent the zero-field splitting as

$$\mathcal{H}^{\text{ZFS}} = \mathbf{S}^T \mathbf{D} \mathbf{S}, \quad (254)$$

and in a basis that diagonalizes \mathbf{D} , it is customary to write

$$\mathcal{H}^{\text{ZFS}} = D \left[S_z^2 - \frac{1}{3} S(S+1) \right] + E \left[S_x^2 - S_y^2 \right], \quad (255)$$

in which $D = D_{zz} - \frac{1}{2}(D_{xx} + D_{yy})$ and $E = \frac{1}{2}(D_{xx} - D_{yy})$, and there are thus only two independent parameters for the spin–spin coupling constants. There is in principle a contribution involving the total spin multiplied by the isotropic value of D , but since it does not contribute to the splitting of the electron spin levels, it does not affect the ESR spectrum.

There have not been too many studies, in particular using highly correlated wave functions, of the basis set and correlation requirements for the direct spin–spin

interaction to the zero-field splitting. For the spin-orbit contribution, the basis set requirements follow to a large extent those applicable for the spin-orbit correction to the g tensor. Otherwise, an accurate description of the relevant electronic excited states contributing to the spin-orbit contribution is required, which by itself may be a challenge in the case of transition-metal complexes (Bolvin 2006).

ESR Hyperfine Coupling Tensors

The ESR hyperfine splitting constants A_K appear in the ESR spin Hamiltonian Eq. 239 in the term \mathcal{H}^{hf} dependent on $\mathbf{S}^T \mathbf{A}_K \mathbf{I}_K$. This contribution couples the electron and nuclear magnetic moments, and thus provides very detailed information about the structure of radicals, in much the same manner as shielding constants do in NMR spectroscopy. To compute this correction, we thus need to select in the perturbation expansion all the terms bilinear in \mathbf{S} and \mathbf{m}_K .

Considering the expansion of the spin–Zeeman term in Eq. 40, when we insert the magnetic vector potential arising due to the nuclear magnetic moments, we find two contributions that are bilinear in the electron spin and nuclear magnetic moments, namely:

$$\mathbf{A}_K = \mathbf{A}_K^{\text{fc}} + \mathbf{A}_K^{\text{sd}}. \quad (256)$$

The purely isotropic contribution to the hyperfine interaction $\mathbf{A}_K^{\text{fc}} = A_K^{\text{fc}} \mathbf{1}$ and the purely anisotropic contribution \mathbf{A}_K^{sd} (Fernandez et al. 1997) in Eq. 256 are due to the Fermi contact (Eq. 51) and the spin–dipole (Eq. 52) operators, respectively. Both contributions can in principle be calculated as expectation values of the respective operators, using the spin-density matrix $\mathbf{D}^{\alpha-\beta}$ (i.e., the difference between the density matrices for α and β spin):

$$A_K^{\text{fc}} = -\frac{1}{2} g_K g_e \mu_B \mu_N \langle S_Z \rangle^{-1} \sum_{\mu\nu} \langle \phi_\mu | \hat{H}^{K(\text{FC})} | \phi_\nu \rangle D_{\mu\nu}^{\alpha-\beta}, \quad (257)$$

$$A_K^{\text{sd}} = -\frac{1}{2} g_K g_e \mu_B \mu_N \langle S_Z \rangle^{-1} \sum_{\mu\nu} \langle \phi_\mu | \hat{H}^{K(\text{SD})} | \phi_\nu \rangle D_{\mu\nu}^{\alpha-\beta}. \quad (258)$$

There are also contributions of the order α_{fs}^4 – a linear response contribution $\langle\langle \hat{H}^{\text{SO}}; \hat{H}^{K(\text{PSO})} \rangle\rangle$ due to relativistic effects caused by the spin-orbit operator and expectation values $\langle 0 | \hat{H}^{\text{SO},K(1)} | 0 \rangle$ and $\langle 0 | \hat{H}^{\text{SO},K(2)} | 0 \rangle$, Eqs. 62 and 63 (see Neese (2003), Arbuznikov et al. (2004)).

The ESR hyperfine coupling is determined by triplet perturbations. Thus, in principle one should use an unrestricted wave function to describe the reference state. However, it is also possible to use a spin-restricted wave function (Fernandez et al. 1992) and take into account the triplet nature of the perturbation in the definition of the response. Within such a (e.g., SCF or MCSCF) restricted-unrestricted approach,

first-order properties are given as the sum of the usual expectation value term and a response correction that takes into account the change of the wave function induced by the perturbation (of the type $\langle 0^{(1)} | H^0 | 0 \rangle$). This restricted-unrestricted approach has also been extended to restricted Kohn–Sham density functional theory (Rinkevicius et al. 2004).

In general, the most severe basis set requirements come from the isotropic hyperfine interactions, the anisotropic contribution in general being well converged with basis sets that perform well for the isotropic contribution. We mention in particular that there are basis sets specifically designed for calculations of hyperfine coupling constants (EPR-III) using density functional theory (Barone 1995). In general, for main-group elements, DFT does not display a particularly strong sensitivity on the choice of exchange–correlation functional, and provides results in quite good agreement with CCSD(T) (Perera et al. 1994b).

Even though the majority of calculations of hyperfine coupling constants are performed using unrestricted approaches, the importance of spin contamination and its effect on the hyperfine coupling constants remains somewhat unclear, in particular in DFT calculations. Whereas restricted and unrestricted approaches give more or less identical results for simple radicals, the situation is less clear in the case of transition metal compounds, and a few examples of the differences between restricted and unrestricted approaches are collected in Table 15, based on the results reported by Rinkevicius et al. (2004). We note that the differences between restricted and unrestricted approaches in general are small for the same functional, but that

Table 15 Calculated isotropic hyperfine coupling constants (in MHz) of transition metal compounds and their dependence on the exchange–correlation functionals; results taken from Rinkevicius et al. (2004)

^aNot available

these differences become significant when spin contamination can be a problem, for instance for TiF_3 and MnO_3 .

The hyperfine coupling constants are usually reported in MHz; the contributions evaluated in a.u. need to be multiplied by $g_K g_e \mu_B \mu_N$.

Conclusions

We end this discussion of molecular properties with some additional comments related both to theory and to experiment. First of all, we have mainly discussed nonrelativistic methods, since these are still dominant in practical applications. The approach starting with a nonrelativistic description of the molecular system and introducing relativistic effects as a correction/perturbation has obviously some limitations and cannot be applied in highly accurate studies of molecules containing heavy elements. There are different approaches that start from a relativistic description of the unperturbed molecule (using one-, two-, or four-component wave functions), and we refer for a discussion of relativistic methods applied in the theory of molecular properties to Reiher and Wolf (2009) and Saue (2002). There is an increasing number of successful applications of these methods, for example, in the study of NMR shielding constants (Autschbach 2007; Kaupp 2004; Maldonado and Aucar 2009) and spin–spin coupling constants (Autschbach 2008).

Secondly, we have not discussed in any detail the effects of nuclear motion. Methods used to calculate these vibrational corrections, for both zero-point vibrational effects and temperature effects, have been described elsewhere in this book. There are, however, other effects that should also be considered. We have not discussed the role of the purely vibrational contributions to molecular (electric) properties (Bishop 1990), which in certain cases can be as large as the electronic contributions (Kirtman et al. 2000). Moreover, in conformationally flexible molecules one has to consider the effects of large nuclear motions. For instance, for a proper comparison with experiment, it may not be sufficient to perform an *ab initio* calculation for a single molecular structure. In experiment one will always observe the average value of the different thermally accessible isomers (rotamers, conformers), and in order to allow for a direct comparison with these experimental observations, a Boltzmann average of the properties of these isomers must be computed. This is particularly important when the properties of the isomers are very different, possibly even differing in sign (Pecul et al. 2004).

Finally, most experimental data are not obtained in the gas phase. Therefore, in order to have a faithful comparison with experiment, the effects of the solvent must be considered. There is an increasing number of studies of molecular properties in the presence of a solvent; we refer to a recent review for more details (Mennucci and Cammi 2007). Molecular dynamics or Monte Carlo procedures can be used when it is necessary to describe the nuclear dynamics in more detail, for example, for a better description of solvent effects or when considering sophisticated isomerization processes (Böhme et al. 2007; Møgelhøj et al. 2008, 2009).

The theory of molecular properties has for a long time provided a precise description of the interactions of a molecule with external and internal fields. In the last years, progress in the development and implementation of computational methods has enabled increasingly accurate calculations of such properties, often yielding results more accurate than experimental data. We note here that a molecular property is always defined as a quantity characterizing an isolated molecule, in a particular state, subject to particular perturbation(s) – conditions not easily achieved in experiment.

Theoretical calculations may thus provide insight into the electronic origins of the behavior of a molecule in the presence of electromagnetic fields, and help disentangle the contributions of solvents, vibrational effects, molecular rotation, and other small perturbations to the experimental observation. By combining the information obtainable in experiment with the tools of analysis offered by quantum-chemical calculations, a better understanding of the interactions between molecules and electromagnetic fields can be achieved, which in turn may facilitate for instance the design of molecules and functional materials with specific responses to external perturbations.

Acknowledgments We are grateful to Dr. Stephan Sauer and to Dr. Olav Vahtras for many helpful comments. We are indebted to Dr. Anna Kaczmarek-Kędziera for help in the editing of the manuscript.

Abstract

Weak intermolecular interactions, which are ubiquitous in biological and materials chemistry, are fast becoming more routinely and accurately investigated owing to the increased performance of computational methods being actively developed. A vast array of pragmatic methods have been proposed using

M. Waller (✉) • S. Grimme

empirical, semi-empirical, density functional theory, and ab initio approaches, which all serve to widen the scope of feasible problems. Especially for the calculation of the important London dispersion interactions, significant progress has been achieved. Herein, we present a general overview on a number of illustrative strategies used to routinely investigate structures and energies of such systems. The composition and advantages/disadvantages of different benchmark sets, which have been found to be of crucial importance in assessing such a wide range of methods is discussed. Finally, a number of experience-based perspectives are provided in relation to the scaling and accuracy of the “more popular” methods used when investigating non-covalent interactions.

A present trend in quantum chemistry is on cheap and reliable methods that effectively solve present-day problems in biological and materials chemistry. Quantum chemistry now confidently looks beyond small polyatomic molecules and toward large supramolecular complexes; this represents an area on the cutting edge of simulation sciences.

This chapter deals with weak intermolecular (non-covalent) interactions between molecules in the gas phase. These interactions are essential for the quantitative description and understanding of complex molecular aggregates in physics (e.g., surface science), chemistry, and molecular biology. The same interactions also occur in an intramolecular fashion between atoms or groups in one molecule. One of the big advantages of the supermolecular approach described herein is that it can handle both situations on an equal footing. Just for convenience and due to space limitations, we will consider here only intermolecular cases (complexes of at least two molecules). The reader should, however, keep in mind that much of what we are saying about quantum chemical methods similarly holds for the quantum chemical simulation of protein folding.

The following chapter is a pragmatic overview on “current” methods that are useful in obtaining reliable data from quantum chemical calculations, with a strong focus on methods used (and developed) primarily to study such non-covalent interactions. Weak intermolecular interactions in the solid or solution phase are almost completely neglected here, this is by no means a reflection on their importance, rather a way of restricting the scope of this chapter to a particular stream of research. A thorough description of the underlying theory of molecular interactions is presented in Volume I written by Alston Misquita. Only a succinct overview of weak intermolecular interactions is given below to “*set the scene.*”

Introduction

The individual stabilization of weak interactions is to a good approximation additive and is, therefore, extremely important. Weak molecular interactions are characterized by stabilization energies of typically less than $\Delta E < -30$ kJ/mol (Suresh and Naik 2000) per pair of interacting atoms (fragments). Therefore, in normal physiochemical environments, there is a continuous formation and breaking

of such molecular interactions. The resultant combined interaction energies can be responsible for some substantial effects on, e.g., molecular conformation and reactivity. However, one should keep in mind that due to additive property, complexes made out of about 100 atoms can have non-covalent (gas phase) interaction energies more resembling that of covalent bonds (i.e., 300–500 kJ/mol).

In chemistry and biochemistry, weak interactions are a hot topic of interest, especially within the emerging areas of molecular recognition (Desiraju and Steiner 1999), self-assembly (Hyla-Kryspin et al. 2004), supramolecular chemistry, and general host–guest interactions (Arunan and Gutowsky 1993; Desiraju and Steiner 1999; Hyla-Kryspin et al. 2004; Kim et al. 2000; Sharma et al. 2009; Sinnokrot et al. 2002; Steed et al. 1979; Tsuzuki and Luthi 2004; Tsuzuki et al. 1994). Weak interactions are fundamental in many aspects of biology with the quintessential example being the elegant double helix of Weak intermolecular interactionsDNA, resulting from a subtle interplay of weak interactions (Antony and Grimme 2008), see Fig. 1.

Furthermore, the secondary and tertiary structure of proteins, membrane structures, and complex intracellular particles such as ribosomes are all maintained by a variety of weak interactions (Wong 2009). Structure-based drug design is therefore dependent upon an understanding of the geometric and energetic aspects of these abundant interactions. Since pharmaceutical agents often bind to biological targets under the control of weak interactions, deconvolution of such host-receptor interactions into separate quantifiable interactions enables drug designers to make subtle modifications and then predict the consequences using modeling techniques.

Fig. 2 The Watson and Crick (interstrand) adenine-thymine hydrogen-bonded base pair

Hydrogen-Bonded Complexes

The electron distribution in covalent bonds is frequently polarized due to electronegativity differences of the atoms involved. The lone pair(s) on electron-rich atoms such as oxygen or nitrogen are attractive targets for terminal electron-poor atoms such as hydrogen on adjacent molecules. A hydrogen bond develops wherever a LP-bearing electronegative atom (acceptor) and a hydrogen atom that is bound covalently to another electronegative atom (donor) are sufficiently near, see Fig. 2.

Hydrogen bonds are typically strong if the atoms (donor, hydrogen, and acceptor) are collinear. The strength of their interactions reduces drastically for H-bonds which depart significantly from collinearity. The length of hydrogen bonds depends on the type of the constituent groups, but is typically 2.5–3.5 Å (between donor and acceptor nuclei) (Desiraju and Steiner 1999). Molecules may develop both inter- and intramolecular hydrogen bonds. So-called weak H-bonding, e.g., between C–H and fluorine atoms (with interactions in the range 3–10 kJ/mol) are a current topic of research (Hyla-Kryspin et al. 2004).

Aromatic $\pi \dots \pi$ Stacking

When aromatic rings are oriented favorably, they may develop a stabilizing interaction known as “ $\pi \dots \pi$ stacking” (i.e., involving the π electrons). The $\pi \dots \pi$ interaction is known to influence reactions, stabilize complexes, and influence structure. It follows that the estimation of the energetic and structural features

Fig. 3 The (intrastrand) adenine–thymine stacked base pair

of these interactions would be extremely useful in understanding many important chemical phenomena (Fig. 3).

A myriad of experimental and theoretical methods have been employed to investigate $\pi \dots \pi$ -stacking interactions. State-of-the-art electronic structure methods such as Møller–Plesset perturbation and coupled-cluster methods (see below) show that dispersive forces play the primary stabilizing role in π -stacked complexes (Arunan and Gutowsky 1993; Kim et al. 2000; Sinnokrot et al. 2002; Steed et al. 1979; Tsuzuki and Luthi 2004; Tsuzuki et al. 1994), while the electrostatic forces are responsible for details of the geometrical arrangements. Dispersion is a result of electron correlation, therefore methods that ignore electron correlation cannot be used at all and those that make drastic approximations to it must be carefully validated. The challenge of adequately describing the dispersion interaction is a major focus of the following chapter.

The non-covalent interactions in biological systems are of significant interest, e.g., in purine riboswitches binding sites (Sharma et al. 2009). The interactions of benzene and polycyclic aromatic hydrocarbons (PAHs) can be extended to real-world applications such as investigating the interaction of stacked graphene-nucleobase complexes (Antony and Grimme 2008). Concave buckyball catchers (Wong 2009) were investigated using sophisticated computational methods (e.g., DFT-D and SCS-MP2) explained later within this chapter. Fullerenes and carbon nanotubes (CNT) (Dappe et al. 2009), self-assembled of molecular tweezers formed by discrete biomolecular π -stacks (Lohr et al. 2009), and C_{60} -derived nanobaskets (dos Santos et al. 2009) were all investigated in 2009 using methods directly developed to model dispersion in an efficient manner. An interesting question was raised by Grimme, asking whether “special $\pi \dots \pi$ -stacking interactions really exist?” (Grimme 2008).

Other Interaction Types

The “weak” interaction energy discussed in detail below can be decomposed into various physically meaningful components, i.e., attractive electrostatic, polarization, and dispersion interactions and the repulsive Pauli exchange term. The sum of dispersion and Pauli repulsion is often called van der Waals interaction. In the various types of non-covalent interactions, these contributions are contained to a different degree. For example, there is a continuous transition from a purely dispersion bound van der Waals complex like the methane dimer to the ammonia dimer which already has partial H-bonding character to the water dimer as the H-bonding prototype complex. The typical H-bond has strong electrostatic and polarization contributions but only small (but non-negligible) dispersion forces. Pauli-repulsion is always present and mainly determined by the distance (wave function overlap) between the fragments. The benzene dimer on the other hand would be unbound when one could switch off the dispersion term. From the above, it is clear that only an accurate account of all these physically important contributions will lead to a consistent description of non-covalent interactions in general.

Interaction Energy

The interaction energy can be calculated with any of the methods outlined within this chapter, to a varying degree of accuracy. Adopting a “*Supramolecular approach*,” the interaction energy is defined as

$$\Delta E^{\text{int}} = E(AB) - E(A) - E(B), \quad (1)$$

where $E(A)$, $E(B)$, and $E(AB)$ are the electronic energies of the monomers A , B , and of the complex AB , respectively. This concept of interaction energy can be extended to a general multi-body regime:

$$\Delta E^{\text{int}} = E(A_1, A_2, A_3, \dots, A_N) - \sum_{i=1}^N E(A_i). \quad (2)$$

When investigating multi-body effects, the question of cooperative and anti-cooperative interactions can become an additional consideration of the utmost importance.

When one adopts a supermolecular approach using ab initio methods, one has to be mindful of the strengths, and limitations, of a given method:

- (a) Is a particular method size-consistent?
- (b) Does a particular method provide an adequate description of electron correlation?
- (c) Is the use of a particular finite basis set sufficient?

- (d) Does the method inherently have problems in the description of the electronic structure of *A* or *B*?

Within this chapter, we shall seek to answer such questions in a general overarching fashion.

An alternative to the supermolecular approach is symmetry adapted perturbation theory (SAPT) that computes the interaction energy directly (Chipman and Hirschfelder 1980; Jeziorski et al. 1978, 1980). The SAPT method has been shown to be suitable for studying weak intermolecular interactions and, in general, provides results similar to the current “gold standard” CCSD(T) (see below). Although this method has been instrumental to the understanding of weak intermolecular interactions, we have omitted details to rein in the scope of the chapter.

Methods

A general overview of the methods, in particular those developed to particularly address weak intermolecular interactions, will be given. The in-depth theoretical details of the underlying methods are given in other parts of this handbook and shall not be restated here in any depth. This should ensure that readers of different levels (and background) could gain some insight into how such calculations may be performed.

Ab initio methods are naturally more computationally expensive than empirical or semiempirical methods. However, they have the obvious advantage that no parameters need to be derived beforehand, which is often laborious and time consuming. The advantage of semiempirical methods are obviously speed, compared to their fully ab initio brethren. A discussion on describing weak intermolecular interactions would be obviously incomplete without an overview of the classical methods.

A strong disclaimer is that we cannot possibly cover all methods derived to compute weak intermolecular interactions, and the methods that we choose to cover shall inevitably date rather quickly. Neither of these considerations is avoidable within such a large and dynamic field of research, and this should hardly be taken as a negative.

Coupled Cluster

Coupled cluster with singles and doubles excitations (CCSD) is a size-consistent post-HF electron correlation method. The wavefunction, Ψ , in coupled cluster theory is formulated in terms of a cluster (exponential) expansion including the single and double excitation operators \hat{T}_1 and \hat{T}_2 . The effect of triple excitations (T) is calculated with perturbation theory.

CCSD(T) has become, and remains, the “gold-standard” for studying weak intermolecular interactions in the gas phase. The accuracy of this method in general

surpasses that of experimental determination and marks the limit of what is feasible using current computing resources.

Quantum Monte Carlo

Quantum Monte Carlo (QMC) effectively solves the many-body problem by a random walk through the electronic configuration space; it has been shown to be a promising method in quantum chemistry. One of the major advantages of QMC is the ability to perform massively parallel calculations, which can effectively increase the scope of what is computationally tractable by distributing the work over hundreds or even thousands of processors. QMC is a general method and, therefore, also has been applied recently to the computation of non-covalent interactions (e.g., the S22 data set) (Korth et al. 2008).

Møller–Plesset Perturbation theory

Møller–Plesset second-order perturbation theory (MP2) is a common method used in computational chemistry to include electron correlation as an extension to Hartree–Fock (HF) theory which neglects Coulomb correlation and thus also misses all dispersion effects. The perturbation is the difference between the Fock-operator and the exact electronic Hamiltonian.

In general, MP2 is a substantial improvement upon Hartree–Fock for all types of non-covalent interactions. The largest advantage of using second-order perturbation is, however, the inclusion of dispersion interactions. The method in general overestimates such an interaction; however, a number of strategies have been developed to address this problem. For example, Hobza et al. was the first to show that MP2/6-31G(0.25)* (i.e., with spatially expanded polarization functions) works well in a number of cases due to error compensation (Hobza and Šponer 1996).

Local (truncated) correlation methods, for example, LMP2, have the advantage of superior scaling behavior of the computation time with system size. In addition, they remove to large extent the basis set superposition error (explained below in section “CounterpoiseCorrection”). Such local methods have been applied to weak intermolecular interactions in combination with density fitting approximations (Goll et al. 2008; Hill and Platts 2008).

A further way to correct for the overestimation of MP2 for dispersion bound complexes is MP2.5 (Pitonák et al. 2009). This is a sum of MP2/CBS (complete basis set limit) interaction energies and a scaled third-order energy contribution obtained in small or medium size basis sets. MP2.5 results agree very closely with the estimated CCSD(T)/CBS interaction energies for weak intermolecular interactions. In particular, a very balanced treatment of hydrogen-bonded compared to stacked complexes is achieved with MP2.5. The main advantage of the approach is that it employs only a single empirical parameter and is thus based on two rigorously defined, asymptotically correct ab initio methods, MP2 and MP3.

The method is an accurate and computationally feasible alternative to CCSD(T) for the computation of the properties of various kinds of non-covalently bound systems.

Spin Component Scaled MP2

The total MP2 correlation energy is partitioned into parallel- and antiparallel-spin components that may be separately scaled. The two parameters p_s and p_t (scaling factors), whose values can be justified by basic theoretical arguments, were optimized on a thermochemical benchmark set (Grimme 2003).

$$E^{\text{corr}}(\text{SCS-MP2}) = p_s E_{\uparrow\downarrow} + p_t E_{\uparrow\uparrow+\downarrow\downarrow}. \quad (3)$$

It was shown, that the new method performs significantly better than standard MP2. Significant improvements are especially observed for cases which are usually known as MP2 pitfalls, while cases already described well with MP2 remain almost unchanged. Also, for difficult systems including strong (nondynamical) correlation effects, the improved MP2 method clearly outperforms DFT(B3LYP) and yields results of QCISD or sometimes QCISD(T) quality (QCISD is a variant of CCSD). The uniformity with which the new method improves upon MP2, thereby rectifying many of its problems and suggests it as a valuable quantum chemical method for the investigation of weak intermolecular interactions.

In an effort to simplify and reduce the scaling of the SCS-MP2 method, Head-Gordon has proposed a scaled opposite-spin (SOS) method. The SOS-MP2 method completely neglects the antiparallel-spin contribution to the MP2 energy and scales the parallel contribution by a factor of 1.3 (Jung et al. 2004). The Head-Gordon group has also developed a method, termed modified opposite-spin (MOS), in an attempt to provide a better description of long-range interactions (Lochan et al. 2005). The SCS(MI)-MP2 (MI: molecular interaction) was specifically designed to treat intermolecular interactions (Distasio and Head-Gordon 2007).

SCSN-MP2 is another parameterization of the spin scaling parameters which completely neglects the contribution from antiparallel-spin electron pairs to the MP2 energy while scaling the parallel contribution by 1.76 (Hill and Platts 2007). These spin-component scaled for nucleobases (SCSN) parameters were obtained by minimizing, with respect to SCS parameters, the RMS interaction energy error relative to the best available literature values, over a set of ten stacked nucleic acid base pairs. The applicability of this scaling to a wide variety of non-covalent interactions is verified through evaluation of a larger set of model complexes, including those dominated by dispersion and electrostatics.

One disadvantage of all SCS variants (except when the scaling factors add to a value of two) is that asymptotically (for large interfragment distances) the correct dispersion energy is not obtained. Although this is of less importance in many complexes, one should keep this in mind when very extended systems are considered.

Hartree–Fock

Hartree–Fock theory is a well-established method in computational chemistry. Therefore, no details on the method or implementation are given here. It suffices to say that Hartree–Fock theory is adequately accurate for hydrogen-bonding interactions (with, however, significant underbinding) in organic first-row compounds. Hartree–Fock, however, fails spectacularly for dispersion bound complexes. A dispersion corrected Hartree–Fock method (HFD) was proposed (Hepburn et al. 1975) and has seen some applications. Its main further disadvantage is the systematic overestimation of dipole moments and underestimation of the fragment polarizability. These two issues are much better described by DFT (at the same cost) so that Hartree–Fock can be considered as being more or less completely outdated.

Density Functional Theory

Density functional theory (DFT) has gained huge popularity due to its ability to provide good accuracy, and due to its favorable scaling, in a timely fashion. Although it has been shown, and is commonly known, that an exact exchange correlation functional is possible, it remains ever elusive. To make matters worse, “traditional” (Kohn–Sham) DFT in present approximations does not provide a correct description of the dispersion interactions.

Density functional theory still remains “plagued” by an abundance of functionals developed with a plethora of design goals. Some grouping of functionals was proposed by Perdew and Schmidt (2001) using the “Jacob’s ladder” metaphor. In this metaphor, functionals may be grouped according to their formulation:

- First-rung functionals are only dependent upon the density and are known as local density approximation (LDA). Although LDA does overestimate the interaction energies in some dispersion bound systems (but for the wrong reasons), its accuracy can only be described as sporadic, and therefore its application in intermolecular interactions is NOT recommended.
- Second-rung functionals utilize in addition the gradient of the density, known as generalized gradient approximation (GGA). They typically show repulsive behavior for dispersion bound complexes similar to Hartree–Fock.
- Third-rung functionals further include the kinetic energy density or Laplacian (second derivative) of the density. These functionals show only marginal improvements over their second-rung counterparts.
- Fourth-rung functionals include Hartree–Fock exchange and are known as hybrid-GGAs. A number of hybrid functionals have been intentionally parameterized using datasets that include dispersion bound complexes, e.g., M05 (Zhao et al. 2005, 2006) and M06 (Zhao and Truhlar 2006a, b, 2008) (and variants thereof) from Truhlar and coworkers. The BHandH (Becke 1993) has been shown to give reasonable answers for particular problems of interest, but should be used with extreme caution (Swart et al. 2007; Waller et al. 2006).

Fig. 4 Schematic description of possible methods arising from different combinations of HF exchange and PT2 mixing parameters. The *dashed areas* I and II can be excluded by physical reasoning. B-LYP is a second-rung GGA and in HF-LYP the correlation energy is mixed with Hartree-Fock

- Fifth-rung functionals include the occupied and virtual orbitals simultaneously and are known as double hybrid functionals. They offer a superior description of long range-dispersion, while maintaining some quantum mechanical rigor. By their very nature, the current implementations are fundamentally semiempirical. A general *ansatz* for a combination of Kohn-sham DFT and perturbation theory is based on the following expression for the exchange-correlation energy E_{xc} :

$$E_{xc} = (1 - a_x) E_x^{\text{GGA}} + a_x E_x^{\text{HF}} + (1 - c_c) E_c^{\text{GGA}} + c_c E_c^{\text{PT2}}. \quad (4)$$

If $c_c = 0$ and $a_x \neq 0$, then a fourth-rung functional; If $c_c = 0$ and $a_x = 0$, then a second-rung functional is recovered, see Fig. 4.

The details of many “garden variety” density functionals are not discussed in this chapter, rather only recently developed schemes that specifically address shortcomings of density functionals in accurately describing weak intermolecular interactions.

DFT-D

An empirical method to account for dispersive interactions in practical calculations with the density functional theory (termed DFT-D) (Grimme 2006) has been tested for a wide variety of molecular complexes. As in previous schemes, the dispersive energy is described by a damped interatomic potential of the form $C_6 R^{-6}$. The use of pure (non-hybrid), gradient-corrected density functionals (e.g., BLYP or PBE), together with the resolution-of-the-identity (RI) approximation for the Coulomb integrals, allows for an efficient computation of large systems (as is often required for supramolecular chemistry).

By using a global scaling factor for the atomic C_6 coefficients, the functional dependence of the results could be strongly reduced. The double counting of correlation effects for strongly bound complexes is found to be insignificant if steep damping functions are employed. For stacked aromatic systems and the important base pairs, the DFT-D(BLYP) model seems to be even superior to standard MP2 treatments (which are known to systematically overbind). The good results obtained, in a variety of diverse examples, suggest that the DFT-D approach is a practical tool for describing weak intermolecular interactions. Furthermore, the DFT-D data may be used to calibrate much simpler (e.g., force-field) potentials. Alternatively, the optimized structures may be used as input for more accurate ab initio calculations of the interaction energies (Grimme 2006b).

The dispersive correction term in DFT-D is given by

$$E_{\text{disp}} = -s_6 \sum_{i=1}^{N_{\text{at}}-1} \sum_{j=i+1}^{N_{\text{at}}} \frac{C_6^{ij}}{R_{ij}^6} f_{\text{dmp}}(R_{ij}), \quad (5)$$

where N is the number of atoms in the system, C_6^{ij} denotes the dispersion coefficient for atom pair ij , s_6 is a global scaling factor (see below), and R_{ij}^6 is the interatomic distance. The damping function is

$$f_{\text{dmp}}(R) = \frac{1}{1 + e^{-\alpha(R/R_0-1)}}, \quad (6)$$

where R_0 is the sum of atomic respective van der Waals (cut-off) radii, see Fig. 5.

Fig. 5 Dispersion correction (Eq. 5) for two carbon and two fluorine atoms ($s_6 = 1.0$) separated by a distance R . The *solid line* shows the undamped potential for comparison

This simple approach has recently been improved regarding accuracy, less empiricism (the most important parameters R_0 and C_6 are computed *ab initio*), and general applicability to most elements of the periodic table (Grimme et al. 2010). An important change in this so-called DFT-D3 method is that the C_6 dispersion coefficients are dependent on the molecular structure which accounts for subtle effects, e.g., the hybridization state of an atom changes.

The DFT-D method does not only work for molecular complexes and intramolecular dispersion effects but is rather general, and Sauer and coworkers extended this correction to periodic systems (Kerber et al. 2008).

Range Separated and Dispersion Functionals

An alternative method is the nonlocal van der Waals density functional (vdW-DF) of Langreth and Lundqvist and coworkers (Andersson et al. 1996; Lundqvist et al. 1995). In vdW-DF, the nonlocal correlation is calculated explicitly in a non-empirical manner. It is typically used with standard GGAs like PBE or revPBE which introduces some inconsistency, as this results in an unbalanced treatment of computed interaction energies and equilibrium distances. The overall quality of vdW-DF results for typical non-covalent complexes is not better than with DFT-D but requires substantially more computation time.

The range-separated hybrid (RSH+MP2) (Ángyán et al. 2005; Gerber and Ángyán 2007) employs MP2 to account for the dispersion interaction, HF for long-range exchange, and, finally, LDA for short-range exchange and correlation. The method provides promising results for rare gas complexes but has not thoroughly been tested on standard benchmark sets (see section “[BenchmarkSets](#)”). The basic idea is similar to that of double-hybrid functionals.

Dispersion Calibrated Effective Potentials

A Dispersion-Corrected Atom-Centered Potential (DCACP) is a novel approach whereby the “missing” dispersion effect in traditional DFT is introduced using a suitably engineered effective core potential (ECP) (von Lilienfeld et al. 2004). The fitted atom–electron potentials in the DCACP method have been shown to perform well for weak intermolecular interactions (Arey et al. 2009; Tapavicza et al. 2007). Importantly, for practical purposes, the parameterized DCACPs are somewhat transferable to atoms in a wide range of different chemical environments (Lin and Rothlisberger 2008; Lin et al. 2007a, b; von Lilienfeld et al. 2005). This approach, however, has the same disadvantage as standard DFT-D in that the atomic parameters do not change with the electronic environment.

SemiEmpirical Methods

Traditionally, it has been generally believed that semiempirical methods are not particularly well suited to hydrogen bonding problems. In order to overcome these

limitations, the PM6 method has been re-parameterized and additional empirical terms were added to increase the accuracy of this semiempirical hamiltonian for describing weak intermolecular interactions (PM6-DH) (Řezáč et al. 2009) and the second generation corrections scheme PM6-DH2 (Korth et al. 2010). Such empirical corrections for the semiempirical methods brings about a new frontier in large simulations.

Another approach was proposed by Tuttle and Thiel (2008), starting with the OM x family of methods and adopting the dispersion correction of Grimme (2004). This particular combination was referred to as OM x -D. The authors found it necessary to rescale the empirical s_6 parameter (see above). Similarly, Hillier et al. (McNamara and Hillier 2007) proposed the AM1-D and PM3-D to alleviate some of the shortcomings of some more traditional semiempirical Hamiltonians.

The RM1_{BH} method (Feng et al. 2009) was constructed by adding Gaussian functions to the core–core repulsion items in the original AM1 formula. It was demonstrated that RM1_{BH} provides good agreement with the values of both high-level calculations and experiments for the binding energies of biological hydrogen-bonded systems.

Somewhat removed is the density functional based tight-binding method (DFTB), which is based on a second-order expansion of the Kohn-Sham total energy, employing a self-consistent redistribution of Mulliken charges (SCC-DFTB) (Elstner et al. 1998). It also employs dispersion corrections similar to the DFT-D method and has successfully been applied, e.g., to nuclear-base stacking problems (Elstner et al. 2001).

Molecular Mechanics

The empirically fitted force-fields such as CHARMM (Brooks et al. 1983), AMBER (Case et al. 2008), and GROMOS (Scott et al. 1999) perhaps perform better than one might originally imagine. Most importantly for the focus of this chapter are the noncovalent interactions, as naturally the interaction energy of a supramolecular complex should be dominated by the non-covalent terms. Therefore, a good description of such noncovalent interactions requires a balanced description of the electrostatic and van der Waals energies. Typically standard force-fields utilize the Coulomb's law for the electrostatic part and do not consider polarization. By judicious adjustment of the partial charges, one may strive to effectively model hydrogen-bonded interactions. Furthermore, one recognizes that the expression for the van der Waals interaction is normally represented as a Lennard-Jones potential. The r^{-12} term describing the Pauli repulsion and the r^{-6} term describing the long-range attractive dispersion forces. The vdW parameters may also be fitted to reproduce experimentally derived structures.

Basis Sets

Most *ab initio* and DFT schemes employ the LCAO method. The molecular orbitals are expanded using an orbital basis set – a collection of mathematical functions used to model the spatial variation of the orbitals. Historically, Slater-type orbitals were used due to their geometric similarity to the hydrogenic orbitals. They also remain a common choice in semiempirical MO theory. However, they do have a significant drawback in that there are no general and numerically stable solutions for the many-center integrals involving Slater-type orbitals. Consequently, most practitioners of quantum chemistry turned to Gaussian type orbitals.

Larger basis sets give rise to more accurate representations of the MOs. Practical considerations have dictated the need for optimization of basis sets to best describe molecular properties within a sensible computational time. This has led to the development of various basis sets each with differing characteristics reflecting their intended applications. The use of such optimized finite basis sets does produce reasonably accurate geometries (as the particular choice of a basis set does not strongly influence computed structures). However, energies are much more basis set dependent.

One may use two contracted GTOs per atomic orbital, as in the so-called double-zeta basis sets (Lochan et al. 2005), as this provides much greater flexibility. Split-valence basis sets partition the atomic orbitals into core and valence regions. The core AO's are assigned a minimal basis, while the valence orbitals are described at the double-zeta level.

The Pople style basis sets (Binkley et al. 1980; Dobbs and Hehre 1986; 1987a, b; Gordon et al. 1982; Hehre et al. 1969; Pietro et al. 1982) have received widespread use in the computational community. They may be described as: $X - YZg$ where X is the number of primitive Gaussians used to describe the core atomic orbitals. The valence orbitals are composed of a linear combination of Y and Z primitive Gaussian functions, respectively. Split-valence triple- and quadruple-zeta basis sets are also used, denoted as $X - YZWg$, $X - YZVWg$, etc.

The correlation consistent (cc) basis sets devised by Dunning (1989) were designed to converge systematically to the complete-basis-set (CBS) limit when used in conjunction with extrapolation techniques, see below. They may be described as: cc-pVNZ where $N = D, T, Q, 5, 6, \dots$ ($D =$ double zeta, $T =$ triple zeta, etc.).

Alternatively, the Ahlrichs style split-valence basis sets (Schaefer et al. 1992) are also ubiquitous in computational chemistry. Practically, extended AO basis sets of polarized TZV or QZV quality should be employed. Because the Ahlrichs basis sets have been carefully optimized variationally, the basis set superposition error (described below) is much smaller than with Pople or Dunning sets of about the same size. These expansions are consistently available for all elements of the periodic table.

Diffuse functions, denoted in Pople-type sets by a plus sign, +, and in Dunning-type sets by “aug” (abbreviation of “augmented”), are shallow Gaussian basis functions with large exponents. The diffuse functions are essential for the “tail” portion of the atomic orbitals, which are distant from the atomic nuclei. The diffuse basis functions are important when considering intermolecular complexes (a) to effectively span the intermolecular region and (b) to accurately describe the fragment polarizabilities. So-called polarization functions are also necessary for weak interactions to improve the flexibility of the wave function. These are functions with higher angular momentum than in the occupied ground state atomic orbitals.

The RI approximation is a method to approximate four-index two electron integrals without having any significant effect on the accuracy of results (Eichkorn et al. 1995). It requires specific auxiliary basis functions, which are available for many standard basis sets. The method is most efficient in GGA and MP2 calculations where it saves a factor of 10–20 in computation time for larger systems. It is also available in hybrid-GGA and Hartree–Fock treatments, but the savings are less (about a factor of 2–3). RI (also called density fitting) is strongly recommended in all treatments of larger complexes and is available in many major quantum chemistry codes.

Extrapolation schemes are employed to relieve the errors associated by using a truncated basis set. It is most often used to improve the computed correlation energy but also Hartree–Fock or DFT energies can be extrapolated. A number of schemes have been proposed and routinely used within the literature, a brief survey of some of the more popular schemes in chronological order: Martin (1996) and later Martin and Taylor (1997), Helgaker et al. (1998), Truhlar (1998), and Lee (2005) correction scheme. In the mostly employed standard scheme, two computations with basis sets of systematically improved quality (e.g., Dunning sets with $X = 2$, $Y = 3$ or $X = 3$, $Y = 4$) are required. The correlation energy is obtained by

$$E_{XY}^{\infty} = \frac{E_X^{\text{corr}} X^3 - E_Y^{\text{corr}} Y^3}{X^3 - Y^3}. \quad (7)$$

Basis set extrapolation also reduces considerably the basis set superposition error (see below).

Counterpoise Correction

The basis set superposition error (BSSE) arises as a direct result of basis set truncation. This truncation for a dimer or complex is less severe as it is for the monomer as the dimer basis set is the union of the two-monomer basis sets. This leads to an artificial energy lowering of the dimer compared to the monomers and leads to a too low (negative) interaction energy. The so-called *counterpoise correction* (CP) is the standard procedure for calculating an interaction energy using a supermolecular approach. The counterpoise corrected interaction energy is

$$\Delta E^{\text{CP}} = E_{AB}(AB) - E_{AB}(A) - E_{AB}(B), \quad (8)$$

where $E_{AB}(A)$ and $E_{AB}(B)$ denote the total energies of monomers A and B , respectively, computed with the dimer basis set of AB , i.e., in the calculation of monomer A including the basis set of the B monomer (but neglecting the nuclear charges and electrons of B). In this way, the basis set for each monomer becomes of about the same size as for the dimer thereby creating a more balanced description.

The counterpoise correction typically overestimates the BSSE since the monomer basis set is enhanced not only by empty orbitals of the other fragment, but also by orbitals occupied by electrons of the other monomer molecule which are excluded by the Pauli principle. Thus, if CP-corrected and uncorrected interaction energies are plotted as function of basis set size, they approach from above and below, respectively, the true interaction energy at the complete basis set (CBS) limit. CP corrections are mandatory for all double-zeta calculations and with MP2 or CCSD(T) also for triple-zeta basis treatments. In triple-zeta basis set (e.g., cc-pVTZ or TZVPP) DFT calculations, the BSSE is typically less than 5–10 % of the interaction energy which makes the laborious CP correction unnecessary. If sets of valence quadruple-zeta are used, it seems as if the error of the CP procedure is often similar to the (uncorrected) BSSE, but this is system-dependent and more definite conclusions about this issue requires further work.

Benchmark Sets

The importance of validating and assessing the relative strengths, and pitfalls, of a given theoretical method is often achieved using validation against standardized data sets. This circumvents the need to meta-analyze inhomogeneous studies (different basis sets, density functionals, etc.) of diverse molecular systems. Computational chemistry should ideally be predictive, and by having a clear and widely accepted set of references, one can preempt the magnitude of expected errors.

The development of force fields, semiempirical parameters, or even indeed density functionals, are reliant upon such carefully constructed datasets. What is needed is a good balance of diversity and relevance, when creating such a benchmark set. A benchmark set should ideally be able to expose systematic errors for different methods.

The BEDGB dataset (Řezáč et al. 2008) contains a number of subsets; S22 (Jurecčka et al. 2006) has been used extensively in benchmarking weak intermolecular interactions, see Fig. 6; S26 (Riley and Hobza 2007) augments four extra molecules into the S22 dataset; Small Halogen Bonding Complexes (Riley and Hobza 2008) contains six complexes calculated at the CCSD(T)/aug-cc-pVTZ CP level of theory; JSCH-2005 (Jurecčka et al. 2006) is a larger benchmark of non-covalent complexes; Set of five small peptides (Valdes et al. 2008) contains aromatic side chains and includes the P26 set; SCAI (Berka et al. 2009) – representative interactions of amino acid side chains.

The Minnesota non-covalent interaction databases were compiled by Truhlar et al. Benchmark Database of Noncovalent Interactions (2006): HB6/04 (Zhao et al. 2006; Zhao and Truhlar 2005a, b) is a hydrogen bond database that consists of

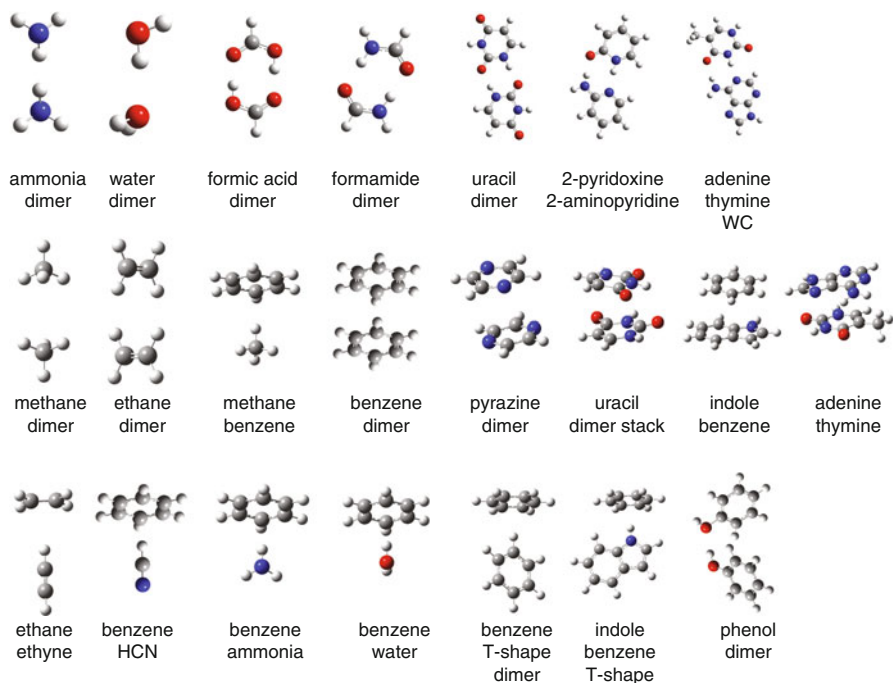

Fig. 6 The S22 dataset

the equilibrium binding energies of six hydrogen bonding dimers; DI6/04 (Zhao et al. 2006; Zhao and Truhlar 2005a, b,) database contains the binding energies of six dipole interaction complexes; WI7/05 (Zhao et al. 2005; 2006; Zhao and Truhlar 2005a) database consists of the binding energies of seven weak interaction complexes; PPS5/05 (Zhao et al. 2005; Zhao and Truhlar 2005a) database consists of binding energies of five $\pi \dots \pi$ -stacking complexes; CT7/04 (Zhao et al. 2005, 2006; Zhao and Truhlar 2005b) database consists of binding energies of seven charge transfer complexes.

When a collection of the different constituents of the Minnesota non-covalent interaction databases is made (HB6/04, DI6/04, WI7/05, PPS5/05, and CT7/04) the superset contains 31 complexes with many dimers in common with the S22 dataset. As these two databases are rather similar, for the remaining chapter, we will focus on the S22 dataset, see Fig. 5, to assess performance.

Performance Considerations

The methods were, more or less, presented above in order of decreasing accuracy. The higher-level ab initio methods are more accurate than the lower methods, as expected. The density functionals tend to roughly follow the Jacob's ladder

Fig. 7 The normal error distribution (in kcal/mol) for Møller-Plesset (MP), density functional theory (DFT), semiempirical (SE), molecular mechanics (MM)

analogy in terms of accuracy for the S22 dataset. Less accurate, for the S22, are the semiempirical methods with the empirical ones performing even worse. In order to provide a visual indication of the relevant methods Fig. 7 displays plots of the normal error distributions. One can immediately note that most methods are shifted to the right of the y-axis with CCSD(T) being the reference values. The higher-level methods again tend to be more narrow in their error distribution.

The dramatic gains in accuracy when one investigates weak intermolecular interactions at the DFT and MP2 levels of theory (with and without corrections) are displayed in Fig. 8.

Timing considerations (typically scaling) are important when one considers computational efficiency. Diminishing returns does occur with ab initio methods, and one must remain mindful of the desired accuracy and computational resources on hand. Such a delicate balancing act is crucial for practitioners of computational chemistry.

The computation time $t(cpu)$ required to execute a given quantum chemical method to obtain the energy follows a power law with respect to the number of electrons in the system, i.e.,

$$t(cpu) = a(N_{el})^b, \quad (9)$$

where a and b are constants which are characteristic for each method and its implementation. While b determines how fast the computation time increases with increasing system size (often abbreviated by the term “order n ”, i.e., an “order n ” method means $b = n$), the prefactor a measures how efficiently the given

Fig. 8 The individual errors (in kcal/mol) for (a) DFT (b) DFT-D (c) MP2 (d) MP2.5 across the entries of the S22 dataset

Table 1 Computation times (in seconds on one Intel CoreDuo T9300 2.50 GHz CPU) for two non-covalently bound complexes with different quantum chemical methods

Method	Formal scaling exponent b	Water dimer ($N_{el} = 20$)	Benzene dimer ($N_{el} = 84$)
AM1	3	0.5	0.6
DFT(semi-local)	3	12.7	78.3
Hartree–Fock	4	5.6 (10.8)	278
RI-MP2	5	7.2 (12.5)	301
CCSD	6	11.7 (47.7)	17,284
CCSD(T)	7	14.1 (72.9)	25,810

Except for AM1, all calculations have been performed with a small cc-pVDZ (oraug-cc-pVDZ in parentheses) AO basis set and using the ORCA programpackage

combination of hard- and software performs the task. Although in general methods with small b are preferred, it is important to mention that to some extent a large value of b can be compensated by a small a so that formally “expensive” methods can sometimes be a better choice. Because the prefactor is very strongly influenced by many technical parameters, we present in Table 1 the computation times (single-point energy only) for two examples ordered according to formal scaling behavior.

It is seen (Table 1) that a realistic evaluation of the performance requires consideration of not too small systems and basis sets. The aug-cc-pVDZ results for the water dimer and the cc-pVDZ values for the benzene dimer, however, nicely illustrate the steep increase of the computation time with the level of sophistication. While RI-MP2 is not much more costly than HF (and even DFT), higher-level correlation methods (in particular CCSD(T)) already for medium-sized systems

lead to a substantial increase in computation time. The timings for the two systems also allow to check if the formal scaling laws hold. For example, for the water and benzene dimers, the system size increases by about a factor of four which translates for $b = 4$ to a computation time ratio of $4^4 = 256$ which is worse than the actually observed factor of about 50. The timings also show that already for a medium-sized system like the benzene dimer, CCSD(T) calculations with reasonable basis sets (at least aug-cc-pVDZ) are prohibitive in routine applications.

Concluding Remarks and Recommendations

The aim of developing a diverse set of well-balanced methods that can treat weak and strong inter- and intramolecular interactions continues to be a dominant area of computational chemistry. The ubiquitous nature of the weak intermolecular interactions in “state-of-the-art” materials and biomedical sciences ensures that work in this direction shall continue unabated.

The nature of fundamental intermolecular interactions were briefly introduced; a general impression of the relative strengths and weaknesses of different methods; basis sets; basis set extrapolation schemes; counterpoise correction schemes; and benchmark sets was presented. The chapter has concluded with overarching summary for the expected accuracy of the particular methods.

We finally want to make some general recommendations how “weak interactions” should be treated by quantum chemical methods:

1. Whenever possible, simple, approximate methods that are unavoidable in many practical applications should be checked or benchmarked against large (or complete) basis set CCSD(T) results. Often one can identify the main interactions and construct suitable model systems for this task. If the one-particle basis set issues and the basis set superposition error are carefully considered, CCSD(T) errors are $<5\%$ of the true interaction energies.
2. The simpler CCSD and MP3 *ab initio* methods are much less reliable (but still computationally expensive) and should not be used. In the “wave function world,” MP2 can (with some faults) also be recommended because the cost/performance ratio is rather good. MP2 should not be used for unsaturated or more strongly correlated (metallic) cases for which SCS-MP2 is a reliable alternative. If the systems are not too large (<50 atoms), MP2.5 can be used as well.
3. An interesting *ab initio* alternative when the system can be separated into chemically meaningful fragments is symmetry adapted perturbation theory (SAPT) that is complementary to the here-described supermolecular approach. Its main advantage is that it is free of BSSE and that it provides a natural partitioning of the interaction energy into physically meaningful components.
4. When the issue of London dispersion interactions is carefully considered with DFT, this yields a similar or often even better performance than MP2. Of the several approaches in this area, the DFT-D method has proven as an accurate

and robust computational tool. The main advantage of DFT-based approaches is that they can be applied also in electronically complicated situations (e.g., metal-containing systems) when MP n -based methods fail.

5. The biggest problem in DFT is the choice of the functional approximation. In many cases, computationally cheap (meta-)GGAs (e.g., BLYP, PBE, or TPSS) can be recommended. Such functionals should not be used when the self-interaction error (e.g., in charged open shell systems) plays a role. Then, hybrid functionals are required which also have less tendency for over-polarization. The currently highest level of approximation in DFT is represented by double-hybrid functionals (e.g., B2PLYP) that also perform very well for non-covalent interactions.
6. An important performance issue, that is unfortunately occasionally overlooked, is the tremendous computational savings gained by applying the resolution of the identity (RI) approximation when evaluating the two-electron integrals. This approximation, in combination with the development of well-performing “auxiliary” basis sets, has dramatically opened up new frontiers in large-scale calculations. We do not wish to comment on the accuracy of the various RI approximations, but we have experienced particularly good performance with the implementations in TURBOMOLE, ORCA, MOLPRO and Q-CHEM.
7. Semiempirical methods (and this also holds for many forcefields) mainly suffer from a poor description of the electrostatic interactions which, e.g., is demonstrated by their notoriously bad performance for hydrogen-bonded systems (for which even the simplest GGAs work very well). Because also their description of polarization (induction) contributions to binding is deficient, these methods can only be recommended for nonpolar systems or as parts in ONIOM-type approaches to describe the outer regions of a quantum chemical system.

Abstract

This chapter provides an introduction to the calculation of thermochemical data for chemical reactions using quantum chemical methods. The basic procedure is first described, namely, obtaining molecular structures and electronic energies of reactants and products, followed by vibrational frequency calculations and evaluation of thermal corrections. Since it is harder to obtain a given accuracy for some types of reactions than others, some discussion is provided on classes of reactions (e.g., isodesmic reactions) for which a given accuracy is easier to achieve than for a general reaction. Three examples illustrate different aspects of thermochemical calculations. The first example, the formation of ammonia from its elements, illustrates a variety of basis set and correlation effects on calculated data. The second example is concerned with calculations on small fluorine-oxygen species and a systematic side-by-side comparison of coupled-cluster and density-functional methods, including the use of isodesmic reactions.

The third example describes the use of high-level coupled-cluster calculations to predict the standard enthalpy of formation of $S(OH)_2$.

Introduction

The term “chemical reactions” obviously covers a wide range of phenomena. The purpose of this chapter is to address some of the basic issues that one faces when using quantum chemical methods to calculate thermodynamic properties of chemical reactions. The focus here is more on the electronic problem than the nuclear problem, i.e., more on the potential energy surface than on motion thereon. The emphasis also is on gas-phase processes.

Fundamentally, the quantities to be calculated in thermochemical studies are the changes in enthalpy, entropy, and Gibbs free energy for a chemical reaction. From the standard Gibbs free energy change, the equilibrium constant may be obtained. At the most basic level, thermochemical data must be calculated for the reactants and products. This necessitates the calculation of minimum energy structures for all reactant and product species, followed by the calculation of harmonic vibrational frequencies, and thermal corrections. Very often one will seek to improve the results by high-level single-point energy calculations at the geometries obtained at lower-level methods, and using thermal corrections from a lower-level method. Another point is that the ultimate goal in a thermochemical study is often not the ΔH , ΔS , or ΔG of the reaction(s) directly studied. Rather, these quantities for one reaction are to be combined with data for another reaction, leading ultimately, for example, to an estimate of the standard heat of formation for a particular species. Sometimes experimental data may be incorporated in some way, and one often has some freedom in choosing which reactions to employ. The choices one makes can have a significant effect on the accuracy of the final answer, and hence the overall success of the project.

It is appropriate to mention a few monographs at this point. These provide a wide range of information on studying the thermochemistry of reactions by quantum chemical methods. The first of these is by Hehre et al. (1986). It summarizes a lot of studies using the theoretical-model chemistry approach pioneered by John A. Pople, as well as providing information on background theory and what have come to be called the Pople-type basis sets. Although this book is almost 25 years old, it is still a useful source. Hehre's book (Hehre 2003), which is provided as part of the Spartan software, is in some respects an update of (Hehre et al. 1986), providing new data, including data from various density-functional theory (DFT) methods. A different type of book is that by Helgaker et al. (2000). Most of it is devoted to a thorough and advanced presentation of the theory behind quantum chemical methods, but it also presents some numerical results on enthalpy changes using very large basis sets. A volume edited by Irikura and Frirup (1998) covers a range of issues in computational thermochemistry. Finally, a textbook by Lewars (2003) is very readable and has useful material on thermochemistry.

The plan of this chapter is as follows. The next section first addresses some general aspects of performing calculations and some points to be considered when

planning a project that will yield thermochemical data. Afterwards, it looks at some points concerning the accuracy of results obtained. The third and final section is split into a discussion of three types of studies that involve thermochemical calculations. The first examines in some detail the formation of (gaseous) ammonia from its elements. Various effects of basis set and method are illustrated. The second is concerned with obtaining accurate heats of formation on fluorine-oxygen species, especially using DFT methodology. The third is concerned with obtaining an accurate heat of formation of H_2SO_2 , for which experimental thermochemical data are lacking.

General Aspects of Thermochemical Calculations

Calculating the ΔH , ΔS , and ΔG for a Chemical Reaction

We consider a general gas-phase chemical reaction $aA(g) + bB(g) \rightarrow cC(g) + dD(g)$. In quantum chemical calculations, the enthalpy change for this reaction is calculated from the enthalpies of the species involved:

$$\Delta H^0 = cH_C + dH_D - [aH_A + bH_B].$$

This equation differs from the calculation of ΔH^0 from standard enthalpies of formation (ΔH_f^0), although it is equivalent to it. We return to the issue of obtaining ΔH_f^0 in theoretical methods later. At first sight, the notion of the enthalpy of a substance (H_A , H_B , H_C , and H_D) might be confusing: there is after all no such thing as an “absolute enthalpy.” The quantities H_A , H_B , H_C , and H_D are relative enthalpies, but they are enthalpies of substances *relative to the so-called quantum chemical standard state*. The quantum chemical standard state consists of infinitely separated electrons and nuclei of a substance. For example, the quantum chemical enthalpy of the water molecule is the enthalpy relative to an O nucleus, two protons, and ten electrons, all infinitely separated. The quantum chemical standard state is the zero of the potential energy in the usual quantum chemical Hamiltonian. To make a parallel with experimental thermochemistry, the ΔH_f^0 of a substance is its molar enthalpy relative to the enthalpy of its elements in their standard states.

Next we consider how the enthalpies are calculated. The quantum chemical enthalpy of a substance has electronic, nuclear, and PV contributions. The nuclear contribution consists of translational, rotational, and vibrational contributions. Hence:

$$H_A = E(A)_{\text{elec}} + E(A)_{\text{trans}} + E(A)_{\text{rot}} + E(A)_{\text{vib}} + PV.$$

The electronic contribution is the quantum chemical energy, that is, the energy of the stationary, nonrotating, non-vibrating system relative to the quantum chemical standard state; it is sometimes referred to as the bottom-of-the-well energy. The translational energy is the classical kinetic energy of a gas, and just depends on temperature. The rotational energy depends on the molecular structure, and the vibrational energy depends on the vibrational levels of the molecule. The

rotational and vibrational contributions depend on the temperature. In practice, the rotational and vibrational contributions are usually evaluated using the rigid-rotor and harmonic oscillator models. Equations for the various contributions are given in many places, for example, the textbook by McQuarrie and Simon (1999). A technical note on the Gaussian Web site by Ochterski (2000) is also recommended. Along with the equations, a sample output from the Gaussian software is explained. Calculating the enthalpy of a species thus requires a geometry optimization to obtain the molecular structure and a vibrational frequency calculation. The electronic energy is the energy at the optimized geometry.

The first step is to select a particular method and basis set that will be used to optimize the geometry and obtain vibrational frequencies. Several factors will be considered in this choice:

1. The method and basis set selected should give a satisfactory geometry and vibrational frequencies that are not *qualitatively* different from the true results.
2. The required computational resources should be available for the geometry optimization and frequency calculation. This is not a trivial matter: a geometry optimization involves several force calculations, and each force calculation typically requires 2–3 times the time required for an energy calculation. In addition to more processor time, further resources may be needed, for example, additional disk space. Even more resources are needed for frequency calculations. If vibrational frequencies are calculated by finite differences of gradients, calculations at lower symmetries than the molecule's symmetry are needed, and these require substantially more resources.
3. Ideally the method and basis set will be capable of providing reasonably accurate electronic energy differences, that is, $\Delta E_{\text{elec}} = cE(C)_{\text{elec}} + dE(D)_{\text{elec}} - [aE(A)_{\text{elec}} + bE(B)_{\text{elec}}]$. In practice, however, it is very common to use a higher-level method and/or basis set to provide an improved estimate for ΔE_{elec} by performing “single-point” energy calculations at the geometries obtained with a smaller basis set. ΔE_{elec} is the major contribution to ΔH , and it is more sensitive to quantum chemical method and basis set than are the other components of H . In conclusion, then, the method chosen for the geometry and frequency calculations is frequently not the method used for refined ΔE_{elec} calculations, especially in high-accuracy work. In fact, in high-accuracy work, it is also common to employ extrapolation techniques to estimate higher-level corrections.

Preliminary Comments on Accuracy

Naturally, one of the key questions concerns the level of theory needed to obtain a particular accuracy. There is no simple answer, but a few general comments are appropriate at this point (Hehre 2003; Hehre et al. 1986). The more similar are the reactants and products, the easier it should be to obtain accurate results. Similar in this sense means having similar chemical environments and bonding patterns in reactants and products. If the reactants and products are “similar” it

might be anticipated that the errors in the calculations on reactants and products are similar and to a significant degree cancel out. On the other hand, when there is less similarity, such cancelation is not expected, and higher-level calculations are likely to be needed for the same accuracy. For example, in the reaction $\text{N}_2 + 3\text{H}_2 \rightarrow 2\text{NH}_3$, the reactants and products are rather dissimilar: the reactants have an N–N triple bond and an H–H single bond, while the products have N–H single bonds. Another view is that the hybridization states of the N in reactants and products are different. Accurately calculating the ΔH^0 for the above “simple” reaction in fact is not at all an easy task. Both large basis sets and a high-level treatment of electron correlation are needed. Some numerical data to illustrate these points will be presented. It has long been known (Hehre et al. 1986) that it is especially difficult to obtain accurate results for reactions that have different numbers of unpaired electrons in reactants and products, for example, homolytic dissociation reactions.

Several classes of reactions have been defined that display some degree of similarity in reactants and products. These include isogyric, isodesmic, and homodesmotic reactions. In isogyric reactions (Pople et al. 1983), the numbers of pairs of electrons in reactants and products is the same (and hence so is the number of unpaired electrons). For example, the following are isogyric processes:

Isogyric reactions constitute a very large group of reactions and it should not be assumed that it is easy to calculate the ΔH^0 of a general isogyric reaction. However, overall it tends to be easier to obtain an accurate ΔH^0 for an isogyric reaction than for a non-isogyric reaction. Any reaction that involves closed-shell reactants and products, such as the formation of ammonia from elements, is isogyric. Isodesmic and homodesmotic reactions are more restricted. In isodesmic reactions (Hehre et al. 1970), the number of bonds of each type and the number of lone pairs of each type are the same in reactants and products. For example:

Homodesmotic reactions (George et al. 1975) are a subset of isodesmic reactions. For organic compounds, the reactants and products have equal numbers of carbon atoms with the same hybridization. In addition, there are equal numbers of carbon atoms with each number of C–H bonds in reactants and products. Two examples, taken from a IUPAC document (Minkin 1999), are as follows:

It is expected and has been amply verified (Hehre 2003; Hehre et al. 1986) that calculating ΔH for isodesmic and homodesmotic reactions is less demanding than for reactions in which reactants and products are less similar. Of course, this is of no apparent help if the target reaction is not one of these types. However, in a significant number of cases, it is possible to take advantage of (say) an isodesmic reaction in calculating a particular quantity of interest, such as a heat of formation.

A term commonly used in theoretical thermochemistry is “chemical accuracy.” This normally means an accuracy of 1 kcal mol^{-1} or about 4 kJ mol^{-1} . Achieving this accuracy is certainly not easy, and a lot of effort has been expended in trying to do so for reactions of relatively small molecules.

Examples

Case Study

In this section we discuss the calculation of the ΔH^0 of this reaction by different methods and basis sets. Although many other choices could have been made, this example illustrates many important points that are likely to apply to other cases. We begin by considering the calculation of the change in electronic energies, ΔE_{elec} . In fact, an experimental value of ΔE (the elec subscript is omitted hereafter in this section) can be derived by starting from the observed ΔH^0 and using known molecular structures and vibrational frequencies to obtain an “experimental” ΔE . Thus, we shall be assessing the ability of theoretical methods to calculate the experimental ΔE . Hehre et al. estimated this value to be $-37 \text{ kcal mol}^{-1}$ (Hehre et al. 1986, p. 283), but the later estimate of $-39.5 \text{ kcal mol}^{-1}$ (Helgaker et al. 2000, p. 866) by Helgaker et al. is probably more reliable. The ΔH^0 is $-22.1 \text{ kcal mol}^{-1}$.

Small Basis Set Study

We begin with results of calculations at geometries obtained with the Hartree–Fock (HF) method and the $6\text{-}31\text{G}^*$ basis set. In Table 1 we report ΔE values from the HF method and several correlated methods. The correlated methods used are second- and third-order perturbation theory (MP2 and MP3), fourth-order perturbation theory including single, double, and quadruple excitations (MP4SDQ), fourth-order perturbation theory including single, double, triple, and quadruple excitations (MP4), coupled-cluster singles-and-doubles (CCSD), and CCSD with noniterative treatment of triple excitations (CCSD(T)). Two well-known DFT treatments, namely, the BLYP and B3LYP functionals, are also used. Five basis sets are used. These are the $6\text{-}31\text{G}^*$ basis set and four extensions thereof, namely, $6\text{-}31\text{G}^*$, $6\text{-}31 + \text{G}^*$, $6\text{-}31 + \text{G}^*$, and $6\text{-}31++\text{G}^{**}$. The $6\text{-}31\text{G}^*$ basis set is a double-zeta valence basis set augmented with a set of d polarization functions on Li and heavier atoms. The $6\text{-}31 + \text{G}^*$ set adds a set of diffuse s and p functions to Li and heavier atoms to the $6\text{-}31\text{G}^*$ basis set. The $6\text{-}31\text{G}^{**}$ set includes a set of p polarization

Table 1 Calculated ΔE values for $3\text{H}_2(\text{g}) + \text{N}_2(\text{g}) \rightarrow 2\text{NH}_3(\text{g})$ (units are kcal mol^{-1})

BLYP	-20.5	-27.8	-29.9	-37.4	-36.3
B3LYP	-29.2	-35.9	-37.0	-43.9	-43.3

functions on H atoms. The 6-31 + G* extends 6-31G** by adding a set of diffuse s and p functions to Li and heavier atoms. Finally, the 6-31++G** set has a diffuse s set on H atoms. References for these basis sets are given in (Hehre et al. 1986). The basis sets considered here are not expected to give very high accuracy. However, they are a convenient starting point and the results illustrate several important points. The results with the 6-31G* and 6-31 + G* basis sets can be discounted since these basis sets are not adequate for use with correlated methods for this example: in the calculations on H_2 these basis sets do not include any polarization functions. For the MP and CC methods, one can see a large change in ΔE on going from 6-31G* to 6-31G**. Likewise, there is a significant effect on going from 6-31 + G* to 6-31 + G**. Both show the importance of polarization functions on H.

Several features are shown by the data in Table 1. Looking at basis set effects first, we see that for all methods there is an appreciable effect on going from the 6-31G** to the 6-31 + G** basis set. This is the effect of adding diffuse functions to the N atom: it is $4.6 \text{ kcal mol}^{-1}$ for the HF method and slightly more for the correlated methods. Adding the H diffuse s functions, that is, going from 6-31 + G** to 6-31++G**, has a smaller effect. It decreases ΔE for the HF, MP, and CC methods, but increases it for BLYP and B3LYP. It should be borne in mind that effects of diffuse functions depend on the size of the rest of the basis set, but here they are definitely important. These results illustrate that diffuse functions can be important even when all species are neutral.

Several trends among the different correlated methods are noteworthy. The MP2 results are much closer to the MP4 or MP4SDQ results than to the MP3 results. In fact, the MP3 results seem to be somewhat exceptional. This underscores the widely held view that MP3 calculations rarely offer any benefits: they demand considerably more resources than MP2 calculations but do not usually improve MP2 results. This is certainly the case here. For all basis sets, the MP2 results are between the MP4SDQ and MP4 results. This is not to be expected in general, but is nonetheless noteworthy. There are close parallels between CCSD and MP4SDQ and between CCSD(T) and MP4. CC methods can be viewed as summing certain classes of terms in the perturbation series to infinite order. CCSD includes all of the

contributions in MP4SDQ to infinite order, along with certain other terms. There is a similar relationship between CCSD(T) and MP4. The closeness the CC and MP methods suggests relatively minor importance of infinite-order effects. Again, this is certainly not true in all cases, especially difficult cases, for which the CC methods are expected to perform better than the MP methods. The effect of connected triple excitations, that is, the difference between MP4SDQ and MP4 or between CCSD and CCSD(T), is about 3 kcal mol⁻¹, and so triple excitations are necessary for “chemical accuracy.”

It is premature to make judgments about accuracy based on the data in Table 1 since the basis sets are relatively small. A few noteworthy trends are apparent, however. The MP2, MP4, and CCSD(T) results seem to be getting closer to the experimental value as the basis set size increases. The HF result with the largest basis set is actually quite close to experiment, but this cannot generally be counted on. The two DFT sets of results show contrasting behavior. BLYP performs better for the larger basis sets, but this is not true for B3LYP for this example. It should be remembered that the effects of basis set and correlated methods are not additive. Differences between a pair of methods can depend on the basis set being used.

Study with Extended “Pople-Type” Basis Sets

We now examine the results when a set of larger Pople-type basis sets is used. These are based on a triple-zeta valence description. The effects of adding diffuse functions and using multiple sets of polarization effects are considered. The 6-311G** basis set is a triple-zeta valence basis set, augmented with a set of polarization functions for all atoms. 6-311++G** includes in addition a set of diffuse functions on all atoms. In the 6-311++G(2df,2pd) and 6-311++G(3df,3pd), multiple sets of polarizations are used on all atoms.

Comparing the 6-311G** results with the 6-31G** data in Table 1, one sees a change of about 1 kcal mol⁻¹, but not in the same direction for all methods. At the HF, MP2, CCSD, and CCSD(T) levels, the magnitude of ΔE decreases, while it increases for BLYP and B3LYP on going from 6-31G** to 6-311G**. Adding diffuse functions to 6-311G** again has a significant effect, 4 kcal mol⁻¹ for HF, about 5 kcal mol⁻¹ for MP2, CCSD, and CCSD(T), and about 6 kcal mol⁻¹ for BLYP and B3LYP. As in Table 1, diffuse functions make ΔE more negative. The effect of expanding the polarization space illustrates a significant difference between methods. For the HF method, the effect is comparatively small, and it decreases the magnitude of ΔE . For the conventional correlated methods, that is, MP2, CCSD, and CCSD(T), expanding the polarization space increases the magnitude of ΔE by about 7 kcal mol⁻¹, making it more negative. There is a comparatively small difference between the two largest polarization spaces. For BLYP and B3LYP there is little effect on ΔE on going beyond the 6-311++G** basis set. The comparative insensitivity of the DFT methods to polarization is rightly cited as an advantage of these methods over conventional wave function-based correlation methods. It is well known that the results of the latter converge more slowly with respect to basis set expansion.

Table 2 Calculated ΔE values for $3\text{H}_2(\text{g}) + \text{N}_2(\text{g}) \rightarrow 2\text{NH}_3(\text{g})$ using extended Pople-type basis sets (units are kcal mol^{-1})

	6-311G**	6-311++G**	6-311++G(2df,2pd)	6-311++G(3df,3pd)
HF	-32.4	-36.4	-35.1	-34.5
MP2	-27.3	-32.9	-40.7	-40.3

CCSD(T)	-27.0	-32.2	-40.2	-39.9
BLYP	-28.6	-35.5	-36.5	-36.3
B3LYP	-36.3	-42.3	-42.9	-42.6

Table 3 Effect of geometries on ΔE

HF	MP2	CCSD	CCSD(T)	BLYP	B3LYP
-34.5	-40.3	-41.2	-39.9	-36.3	-42.6
-34.2	-38.6	-40.7	-39.1	-35.9	-42.4

The basis set is 6-311++G(3df,3pd). The first row data are for the HF/6-31G* geometry. The second row data are for the optimized geometries of the different methods with the 6-311++G(3df,3pd) basis set. Units are kcal mol^{-1}

One difference between Tables 1 and 2 is that the effect of triple excitations is slightly smaller with the larger basis sets used in Table 2. As observed in Table 1, the MP2 method seems to perform very well since its results are between those of CCSD and CCSD(T). Concerning agreement with experiment ($-39.5 \text{ kcal mol}^{-1}$ (Helgaker et al. 2000)), results with the largest basis set show best agreement for CCSD(T). Of course, the effects of several additional factors need to be assessed. These include further basis set extensions and the effect of using the actual minimum energy geometries for the respective methods.

Effect of Geometry

Geometries of all species were calculated using the 6-311++G(3df,3pd) basis set for six methods (HF, MP2, CCSD, CCSD(T), BLYP, and B3LYP), and the ΔE values were calculated. The results are shown in Table 3 below, along with the ΔE values obtained with the same basis set and the HF/6-31G* geometries.

The data in Table 3 show that the effect of geometry in this case is comparatively small, just under 1 kcal mol^{-1} for CCSD(T), for example. This is not to say that using a low-level geometry such as HF/6-31G* is generally recommended. Rather, the choice of geometry should be carefully considered, with factors such as desired accuracy and available resources being considered. Certainly, with extended basis sets, obtaining a CCSD(T) geometry can be very time consuming, and this has to be weighed against benefits. In practice, it is advisable to study the effect of geometry on the final results using both some low-level and intermediate-level geometries before obtaining a very high-level geometry.

Results from Correlation-Consistent Basis sets

Within the family of so-called Pople-type basis sets, 6-311++G(3df,3pd) is the largest standard set. Even though this basis set is quite large, it is not a complete basis set for correlated methods. Better basis sets for the systematic description of electron correlation, the so-called correlation-consistent (cc) basis sets, were developed some years later, the first being published in 1989 (Dunning 1989). The largest of such sets are recognized as providing a pathway to basis set completeness. At the same time, these basis sets are quite large, and basis set completeness for wave function-based correlated methods generally requires the use of an extrapolation. The cc basis sets were developed in such a way as to permit reasonably reliable extrapolation to the complete basis set result. Of course, the larger the basis sets used in the extrapolation, the more reliable the extrapolation is likely to be. Helgaker et al. (2000) discuss the convergence and performance of the cc sets quite extensively.

We have calculated the ΔE using two series of the cc basis sets. The first series used the cc-pVDZ, cc-pVTZ, and cc-pVQZ basis sets. The cc-pVDZ set is a valence double-zeta set with one set of polarization functions (p for H, d for Li-Ar). In terms of contracted functions, it is equivalent to 6-31G**. The cc-pVTZ and cc-pVQZ sets are valence triple- and quadruple-zeta sets. They have multiple sets of polarization functions (2p1d and 2d1f for cc-pVTZ; 3p2d1f and 3d2f1g for cc-pVQZ). In the second series, we have used the augmented sets, namely, aug-cc-pVDZ, aug-cc-pVTZ, and aug-cc-pVQZ. These contain a set of diffuse functions for each angular momentum, for example, there are diffuse s, p, and d sets in cc-pVDZ. In terms of contracted functions, the cc-pVTZ set is the same size as 6-311G(2df,2pd). The aug-cc-pVTZ set would be expected to be similar in accuracy to 6-311++G(2df,2pd). The next table shows the results from the cc-pVDZ, cc-pVTZ, and cc-pVQZ basis sets (Table 4).

At the HF level, there is a small change as the basis set is extended, as observed with the other basis sets considered in this section. For MP2, CCSD, and CCSD(T), there is a considerable change from cc-pVDZ to cc-pVTZ (over 10 kcal mol⁻¹), followed by a much smaller change on going to cc-pVQZ. The changes for BLYP and B3LYP are smaller. It is natural to wonder how well converged are the cc-pVQZ results. Larger basis sets in the cc series have been defined, and one could employ these in calculation on these systems (Helgaker et al. 2000). An alternative,

Table 4 Calculated ΔE values for $3\text{H}_2(\text{g}) + \text{N}_2(\text{g}) \rightarrow 2\text{NH}_3(\text{g})$ using the cc-pVXZ (X = D, T, Q) basis sets (units are kcal mol⁻¹)

	cc-pVDZ	cc-pVTZ	cc-pVQZ
HF	-32.4	-34.0	-34.9
MP2	-23.6	-34.2	-37.3
CCSD	-26.7	-36.9	-39.7
CCSD(T)	-24.0	-34.8	-37.9
BLYP	-26.1	-30.9	-33.3
B3LYP	-34.1	-38.5	-40.6

mentioned above, is to use an extrapolation formula to estimate the complete basis set result. For example, to use the L^{-3} extrapolation the formula (Halkier et al. 1998; Helgaker et al. 2000):

$$W(\infty) = \frac{M^3 W(M) - N^3 W(N)}{M^3 - N^3}$$

could be applied to a pair of ΔE values for a method. In this formula, M and N are the highest angular momentum quantum numbers of two basis sets, while $W(M)$ and $W(N)$ are the values of the quantity being extrapolated with the two corresponding basis sets. For example, suppose we extrapolate the CCSD(T) results with the cc-pVTZ and cc-pVQZ basis sets: $M = 3$ (for the f functions in cc-pVTZ), $W(3) = -34.8$, $N = 4$ (for the g functions in cc-pVQZ), and $W(4) = -37.9$. Applying the extrapolation formula, the result is -40.2 kcal mol $^{-1}$. Applying the extrapolation formula to the cc-pVDZ and cc-pVTZ data for CCSD(T) yields -39.3 kcal mol $^{-1}$. In this case, both extrapolations give quite similar results. This will not always be the case. The larger the basis sets used in the extrapolation, the more reliable the result should be. The next set of results to consider are those with the augmented cc basis sets. These are shown in the Table 5.

Going from cc-pVTZ to aug-cc-pVTZ the ΔE decreases by about 4 kcal mol $^{-1}$ for the correlated methods and just over 2 kcal mol $^{-1}$ for HF. The effect of adding diffuse functions to cc-pVQZ is smaller, namely, about 1.5 kcal mol $^{-1}$ for the correlated methods. The diffuse functions in aug-cc-pVTZ effectively make up for some the valence basis set incompleteness in cc-pVTZ, while cc-pVQZ is more complete, so the effect of the diffuse functions is smaller. The difference between the aug-cc-pVTZ and aug-cc-pVQZ results is very small in this case.

Finally, based on the data in Table 5 and an experimentally derived value of ΔE of -39.5 kcal mol $^{-1}$ (Helgaker et al. 2000), one can see the CCSD(T) results approaching chemical accuracy for this problem. MP2 also performs very well in this case, but this is not always the case. Helgaker et al. (2000) report an extrapolated CCSD(T) result from cc-pcV5Z and cc-pcV6Z values of -39.6 kcal mol $^{-1}$. The cc-pVXZ basis sets include additional functions to account for core correlation effects that are not included in the cc-pVXZ sets.

Table 5 Calculated ΔE values for $3\text{H}_2(\text{g}) + \text{N}_2(\text{g}) \rightarrow 2\text{NH}_3(\text{g})$ using the aug-cc-pVXZ (X = T, Q) basis sets (units are kcal mol $^{-1}$)

Thermochemistry of Species with F–O Bonds

Species containing F–O bonds have provided a significant challenge for theoretical methods over the years. The most celebrated case is fluorine peroxide, the theoretical structure of which is arguably an unsolved problem, as is its heat of formation. As far as thermochemistry is concerned, getting reliable, chemically accurate heats of formation for several fundamental species (e.g., FO, F₂O, HOF, FOO, and F₂O₂) is very difficult. For some of these species (FOO and F₂O₂) additional difficulties are possible uncertainties in experimental data, which make it more difficult to assess the quality of theoretical data. One theoretical strategy is to use the most advanced theoretical methods (e.g., CCSD(T)) and large basis sets, perhaps including attempted extrapolation to the (estimated) basis set limit. Such calculations place severe demands on resources and are applicable only to relatively small species, but they should be capable of chemical accuracy when carried far enough. Another strategy is to use DFT methods. These are much less demanding computationally and thus can be applied to much larger species. The key issue is their accuracy: can they provide sufficient accuracy on small species to be applied with confidence on larger species? A study by Ventura et al. (1999) involves a comparative study of two functionals and the CCSD(T) method for species with F–O bonds, which we now discuss.

Ventura et al. undertook this study since there were conflicting reports on the suitability of DFT methods for systems containing F–O bonds. Their first goal was to provide a systematic, side-by-side comparison of two functionals, namely, B3LYP and B3PW91, and the CCSD(T) method using the same large atomic natural orbital basis set. The basis set chosen was an uncontracted 14s9p4d3f set (for N, O, and F) combined with an uncontracted 8s4p3d set for H. Two strategies were used to calculate heats of formation: (a) calculating the enthalpy changes for the defining equations of ΔH_f^0 (referred to hereafter as the direct method) and (b) calculating the enthalpy changes for appropriate isodesmic equations and then using experimental data on all but one species to calculate the enthalpy of formation of the unused species. For example, approach (a) would use the following equations for FO and F₂O:

The isodesmic approaches for FO and F₂O used the equations

To calculate the heat of formation of FO, for example, one would calculate the ΔH^0 of the first equation and then combine this result with experimental standard enthalpies of formation of H₂O, HOF, and OH:

$$\Delta H_f^0(\text{FO}) = \Delta H_f^0(\text{HO}) + \Delta H_f^0(\text{HOF}) - \Delta H_f^0(\text{H}_2\text{O}) - \Delta H^0.$$

DFT and CCSD(T) approaches were used to obtain a series of standard enthalpies of formation using both the direct (referred to by the authors as the diatomic approach) and isodesmic approaches. The species with F–O bonds studied were FO, HOF, and F₂O. In addition, the authors calculated heats of formation of the H, N, O, and F atoms, the OH and NO radicals, and H₂O.

The general findings of Ventura et al. can be summarized as follows. The DFT methods performed better using the isodesmic method than they did for the direct method. For the CCSD(T) method, however, the reverse was true. For the isodesmic method, the DFT methods perform better than the CCSD(T) method, but CCSD(T) performs better than the DFT methods for the direct method. Overall the performance of all methods is generally very good. Representative data are shown in the table below (Table 6).

Two values are given for the isodesmic method for FO and HOF, one for each of the two equations given above. Whether the isodesmic or direct method is used for the DFT approaches, the results are impressive, especially considering that the time required for these calculations is a fraction of that needed for CCSD(T). The CCSD(T) results would likely be improved slightly with larger basis sets, while the effect is likely to be much smaller for the DFT methods.

Another instructive aspect of the work of Ventura et al. (1999) comes from the use of the 6-31G* basis set. Such a basis set is obviously not expected to be accurate enough for a direct calculation of the heat of formation of a molecule. However, as the following data show, when the isodesmic approach is used, very promising results are obtained (Table 7).

For HOF in particular, one can see that the isodesmic approach is a major improvement over the direct method for all methods. This illustrates the potential value of isodesmic approaches. The good result obtained for CCSD(T) for FO with

Table 6 Calculated and experimental ΔH_f^0 of FO, HOF, and F₂O (units are kcal mol⁻¹; the data are from Ventura et al. 1999)

	Experiment	B3PW91		B3LYP		CCSD(T)	
		Iso	Direct	Iso	Direct	Iso	Direct
FO	26.06	25.75	24.93	26.50	24.31	28.01	26.42
		26.42		26.29		27.20	
HOF	-20.60	-20.30	-18.84	-21.05	-19.20	-22.56	-20.83
		-20.41		-20.36		-19.45	
F ₂ O	5.86	5.67	5.78	5.62	5.48	4.71	6.52

Table 7 Calculated and experimental ΔH_f^0 of FO and HOF using the 6-31G* basis set (units are kcal mol⁻¹; the data are from Ventura et al. 1999)

	Experiment	B3PW91		B3LYP		CCSD(T)	
		Iso	Direct	Iso	Direct	Iso	Direct
FO	26.06	26.44	23.08	27.04	24.53	30.28	26.24
HOF	-20.60	-20.99	-13.60	-21.56	-13.47	-24.83	-13.16

the 6-31G* is no doubt fortuitous. Ventura et al. (1999) do not report results for F₂O using the 6-31G* basis set.

One cautionary comment worth making here concerns the use of experimental data in schemes with isodesmic reactions. The success of such schemes obviously depends on the reliability of the experimental data, certainly requiring chemical accuracy in the experimental data. For FO, HOF, and F₂O, this appears to be the case. As mentioned above, this is probably not true for all F–O containing species. Some theoretical studies (Feller and Dixon 2003; Karton et al. 2009) have found a disagreement between high-quality calculated data and experimental data for FOO and F₂O₂ and recommend revision and/or a new determination of experimental data for these species.

Calculating the Heat of Formation of H₂SO₂

In a recent study (Napolion et al. 2008), isomers of H₂SO₂ were investigated theoretically using the CCSD(T) and other methods. Part of that study was calculating the standard heat of formation of the lowest energy isomer, namely, the C₂ conformer of sulfoxylic acid, S(OH)₂. This species has been detected experimentally, but no structural, spectroscopic (e.g., infrared), or thermochemical data have been measured. There had been some prior theoretical estimates, but the variations were significant. In 1978, using bond energy estimates, Benson (Benson 1978) estimated ΔH_f^0 to be -69.3 ± 4.1 kcal mol⁻¹. Wang and Zhang (2002) calculated ΔH_f^0 in two ways using the G3B3 and G3//MP2 procedures. First, they calculated the enthalpy change for dissociation to atoms. Then they used the experimental ΔH_f^0 values of atoms to obtain a ΔH_f^0 for S(OH)₂. With this approach they obtained values of -65.2 (G3B3) and -65.9 kcal mol⁻¹ (G3//MP2), which are at the lower end of Benson's estimate. However, Wang and Zhang were concerned about possible inaccuracies in the atomization procedure, so they also used a procedure that involved isodesmic reactions. This gave estimates of -69.5 kcal mol⁻¹ (G3B3) and -68.3 to -70.0 kcal mol⁻¹ (G3//MP2). Wang and Zhang's preferred value was -69.3 kcal mol⁻¹. Our strategy was to use the CCSD(T) method with extended basis sets, including correlation-consistent basis sets and L⁻³ extrapolation.

A direct approach to calculating the ΔH_f^0 was not possible since the standard state of sulfur is solid sulfur. Instead, two schemes were devised, each of which involved calculating the ΔH^0 of a reaction that could be combined with experimental data to yield an estimate of the required ΔH_f^0 . In the limit of an exact calculation, both schemes will give the same final result. Hence, the closeness of the two estimates is to some extent a measure of the accuracy. The two schemes are as follows.

Scheme 1 The standard enthalpy change for the reaction S(OH)₂ (g) → SO₂ (g) + H₂ (g) was calculated. The ΔH_f^0 was then calculated from

$$\Delta H_f^0 = \Delta H_f^0(\text{SO}_2) + \Delta H_f^0(\text{H}_2) - \Delta H_{rxn}^0 = -70.9 \text{ kcal mol}^{-1} - \Delta H_{rxn}^0,$$

using the calculated ΔH_{rxn}^0 and experimental data for SO₂ and H₂.

Scheme 2 The standard enthalpy change for the reaction $\text{S}(\text{OH})_2(\text{g}) \rightarrow \text{H}_2\text{S}(\text{g}) + \text{O}_2(\text{g})$ was calculated. The ΔH_f^0 was then calculated from

$$\Delta H_f^0 = \Delta H_f^0(\text{H}_2\text{S}) + \Delta H_f^0(\text{O}_2) - \Delta H_{rxn}^0 = -4.8 \text{ kcal mol}^{-1} - \Delta H_{rxn}^0,$$

using the calculated ΔH_{rxn}^0 and experimental data for SO_2 and H_2 . The difference

$$\Delta H_f^0(\text{Scheme 1}) - \Delta H_f^0(\text{Scheme 2})$$

is equal to $\Delta H^0(\text{Expt.}) - \Delta H^0(\text{Calc.})$ for the reaction $\text{H}_2\text{S}(\text{g}) + \text{O}_2(\text{g}) \rightarrow \text{SO}_2(\text{g}) + \text{H}_2(\text{g})$. For our most complete calculations (see below), the difference is only $-0.6 \text{ kcal mol}^{-1}$, which is within chemical accuracy. This is a significant achievement since it is well known to be very difficult to obtain accurate thermochemical data on SO_2 . This suggests that our strategy is suitable for calculating the ΔH_f^0 of $\text{S}(\text{OH})_2$.

The results of our calculations are shown in Tables 8 and 9 (see below). Each table shows three quantities. ΔE is the energy change of the reaction for stationary nuclei at 0 K. ΔH^0 is the calculated standard enthalpy change of the reaction at 298.15 K, obtained from ΔE and the unscaled CCSD(T)/6-311++G(2d,2p) thermal correction (-6.4 and $-5.4 \text{ kcal mol}^{-1}$ for Schemes 1 and 2, respectively). ΔH_f^0 is the calculated standard enthalpy of formation of $\text{S}(\text{OH})_2$ at 298.15 K, obtained as indicated above.

Before discussing the data, a note on the cc basis sets used is needed. When the cc basis sets for third-row elements such as sulfur were first developed, the numbers of polarization functions used were the same as in the basis sets for the second-row elements (e.g., 1d for cc-pVDZ, 2d1f for cc-pVTZ, and so on). It was subsequently found that the d set for third-row elements was inadequate and needed to be expanded by adding a set of “tight” d functions. The resulting basis sets are referred to as cc-pV(X+d)Z and aug-cc-pV(X+d)Z. For H and second-row

^bExtrapolation based on the aug-cc-pVTZ and aug-cc-pVQZ results

elements, these sets are the same as the original cc-pVXZ and aug-cc-pVXZ sets, but for third-row elements they have an extra set of d functions.

Looking at Table 8, one sees that there are quite small differences between the triple- and quadruple-zeta results, the largest being 1.1 kcal mol⁻¹ between the aug-cc-pV(T + d)Z and aug-cc-pV(Q + d)Z results. Consequently, the extrapolated results differ little from the cc-pV(Q + d)Z and aug-cc-pV(Q + d)Z values. Also, the two extrapolated results differ by only 0.3 kcal mol⁻¹. The 6-311++G(3df,3pd) basis set performs fairly well overall. The cc-pV(D + d)Z and aug-cc-pV(D + d)Z results are not as good, especially the latter.

The data in Table 9 show greater sensitivity to basis set than do those in Table 8, no doubt a reflection of the demands on the basis set in calculations on SO₂. In Table 9, one can see much larger differences between the triple- and quadruple-zeta results. Not surprisingly, the extrapolation has a larger effect than in extrapolation has a larger effect than in Table 8. However, the two extrapolations give ΔH_f^0 values that differ by only 0.1 kcal mol⁻¹. The 6-311++G(3df,3pd) basis set is seen not to perform as well in Table 9 as in Table 8. The deficiencies of the smaller basis sets are more apparent in Table 9 than in Table 8.

A measure of the quality of the results can be obtained by comparing the ΔH_f^0 values in Tables 8 and 9. Even for the aug-cc-pV(Q + d)Z basis set, there is a 2.9 kcal mol⁻¹ difference, which is not within chemical accuracy, of course. However, the corresponding extrapolated values in the two tables differ by less than 1 kcal mol⁻¹, which is within chemical accuracy. Our best results for ΔH_f^0 , then, are 1–2 kcal mol⁻¹ above Benson's mean value and in the range of values obtained by Wang and Zhang by isodesmic reactions, rather than their estimates based on dissociation reactions. Our reaction enthalpies predict that decomposition of S(OH)₂ to SO₂ + H₂ is slightly exothermic, while decomposition to H₂S + O₂ is strongly endothermic.

Acknowledgments This work was supported in part by the National Science Foundation. Calculations performed in this work on the formation of NH_3 were run on a QS4-2800C computer from Parallel Quantum Solutions, LLC using the Gaussian 2003 software.

Abstract

Excited states participate in photoinduced events as well as in thermally activated reactions, even in many cases in which only the ground state is believed to be involved. Life on Earth also depends, both directly and indirectly, on the influence that light has on chemistry. The energy of the Sun's visible and ultraviolet radiation promotes processes that not only permit the continued existence of life on the planet, but which are keys for evolution by means of mutations. To study a system in an excited state, far away from its optimum situation, is a challenge for chemists, both experimentalists and theoreticians. This chapter is focused on the practical aspects related to the calculation of excited states in molecular systems by using quantum-chemical methods, a type of study that escapes in many cases from the well-established computational strategies used for the molecular ground states, both because of the complexity of the problem itself and for the methodological requirements. A short review of the spectroscopic and photochemical panorama will be provided first in order to explain which are the main parameters and processes to be determined, followed by a compact description of the most relevant and employed quantum-chemical methods and computational strategies for excited states. A number of applied examples of actual calculations on paradigmatic excited state problems will be provided in the different subchapters, followed in each case by comments on practical issues occurring in the calculations. With these cases we will try to demonstrate that in the last years the quantum-chemical studies on excited states have reached the required maturity to interpret and predict, at a molecular level, different types of chemical situations.

Introduction

Computing electronic excited states with quantum chemical methods is much more complex than doing it for ground states, because it implies not only coping with higher solutions of the electronic Hamiltonian with diverse character and therefore requiring more complex methods, but also to solve a plethora of new situations, such as hypersurface crossings and coupling between the states, that usually requires to abandon convenient approximations like Born–Oppenheimer (see Szabo and Ostlund 1996), for instance.

Molecules, consisting of electrically charged nuclei and electrons, may interact with the oscillating electric and magnetic fields of light. Spectroscopic experiments demonstrate that energy can be absorbed or emitted by molecules (and atoms) in discrete amounts, corresponding to precise changes in energy of the molecule (or atom) concerned. As matter, light is a form of energy that exhibits both wave- and particle-like properties. Absorption of the relevant frequencies from incident radiation raises molecules from lower to higher levels. Electrons in molecules occupy molecular orbitals (MOs) with precise energy levels. Transitions from lower, filled orbitals, to upper (higher energy), empty orbitals usually involve absorption of radiation in the UV and visible parts of the spectrum. Much smaller quantities of

energy are linked to changes in the vibrational and rotational energy of the molecule. The understanding of the spectroscopic phenomena in the light of molecular orbital theory has opened new avenues in the comprehension of the photoinduced events.

The molecule in excited state is often prone to react in an easier way than in the ground state. The excess energy of an excited species can alter its reactivity and is particularly significant in the case of electronic excitation because of the energies involved are of similar order of magnitude as bond energies. Electronic excitations can then have a considerable effect on the structure of a species. Accordingly, the energies correspond roughly with typical activation energies for many reactions, which are too high to be reached from the ground but not from the excited state. The new electronic rearrangement may be also the key of the reactivity since the molecule in an excited state may exhibit nucleophilic or electrophilic properties different than those of its ground state.

Three modern developments have been produced in the last years that are the key for the comprehension of the photophysics and photochemistry of many chemical and biochemical phenomena: (1) rapid advances in quantum-chemical methods allow to study the excited states with high accuracy; (2) improved molecular beams techniques permit studies of isolated molecules, despite their sometimes low vapor pressure and propensity for thermal decomposition, and (3) the revolutionary impact that femtosecond laser and multiphoton techniques have had on the study of the electronic energy relaxation processes. Indeed, now it is possible to get information about reaction intermediates at very short times from femtochemical techniques, and, more than ever, the participation of quantum chemistry to interpret such findings has become crucial. A constructive interplay between theory and experiment can provide an insight into the chemistry of the electronic state that cannot be easily derived from the observed spectra alone.

From the theoretical viewpoint, the calculation of excited states is still a very complex task. Considering the many different electronic structure situations occurring in the potential energy hypersurfaces (PEHs) of the excited molecular systems, the only methods generally applicable to all of them are the multiconfigurational approaches. The application of these procedures requires a lot of skill and experience, and the limitations on the size of the problem are noticeable. Single-reference (black-box) methods only work in certain regions of the PEHs. In general, the excited state problem can be considered heavily multiconfigurational. New tools and strategies are required for excited states at the highest levels of calculation: optimization of minima, transition states, hypersurface crossings (conical intersections), and reaction paths, whereas states couplings (nonadiabatic, electronic, spin-orbit) need to be computed. This solves only the first part of the problem, that is, the solution of the time-independent Schrödinger equation. Once the potential represented by the PEHs is obtained, time-dependent equations have to be solved to finally determine reaction rates, states lifetimes, or populations. Coupling at the proper level those two types of calculations, static and dynamic approaches representing the electronic structure and reaction dynamics problems, respectively, is still a task under development.

Spectroscopy Overview

The concept of PEHs comes from the Born–Oppenheimer approximation, based on the separation of electronic and nuclear motion due to the large difference in mass between these particles, and assumes that the electrons follow the nuclei instantaneously during the motion of the latter. Therefore, an electronic and a nuclear Hamiltonian can be defined. Solving the electronic Schrödinger equation provides us a description of the movement of electrons, whereas we consider the rotation, vibration, and translation of the molecule solving the nuclear counterpart. The solution of the electronic Schrödinger equation is the energy of a particular nuclear configuration. The total energy for fixed nuclei must also include the constant (within this approximation) nuclear repulsion potential. The value of this total potential energy for every possible nuclear configuration is specifically the potential energy hypersurface. Photophysical and photochemical processes take place through interactions between PEHs. For the specific case of close degeneracies between the surfaces, where ultrafast energy transfers occur, the Born–Oppenheimer approximation breaks down and special methods in order to localize, optimize, and study the crossing structures are required.

The absorption of photons for a molecule is hardly a static problem. After the absorption (ABS) of one photon, a state of the same multiplicity as the ground state is mainly populated. Direct absorption to states of different multiplicity are only possible if the states heavily interact, for instance, by spin-coupling effects. Actually, in the general case, the energy goes to a vibrational excited state of an electronic excited state of the molecule. Straight afterward, a non-radiative decay occurs, with emission of heat (IVR, intramolecular vibrational relaxation), toward more stable structures of the state PEH, in many cases the state minimum. It might frequently happen that along the decay other states cross and, if appropriately coupling, the system can evolve toward other electronic states of the same multiplicity via a non-radiative internal conversion (IC). Finally, the molecule arrives to the lowest-lying singlet excited state, S_1 , from which the molecule may emit (F, fluorescence) and return to the ground state. Alternatively, a non-radiative transition between two states of different multiplicity is also possible (ISC, intersystem-crossing). By successive internal conversions the system reaches the lowest-lying triplet excited state, T_1 , from which the molecule may emit (P, phosphorescence).

Figure 1 contains a simplified Jablonski diagram summarizing the main photophysical and photochemical effects undergone by a molecular system. It is common to reserve the word photophysics to processes not involving the generation of new photospecies, that is, just to decays leading to emission or returns to the ground state. However, nonradiative internal conversions or intersystem crossing are also considered photochemical processes, therefore the use of both terms is somewhat loose. A proper nomenclature for excited states is not easy to establish. The less ambiguous (and less informative too) form is purely enumerative: S_0 , S_1 , T_1 , T_2 , where S represents a singlet state and T stands for the triplet states, and the states are ordered by energy. In symmetric systems, it is convenient to use the labels

Fig. 1 Jablonski's diagram, lifetimes of the basic photophysical processes and deexcitation pathways from the lowest-lying excited states of a molecule

derived from group theory. A state is then described in terms of the behavior of the electronic wave function under the symmetry operations of the point group which the molecule belongs to $1^1A_g, 2^3B_{3u} \dots$, including the energy ordering, multiplicity, and symmetry label. Classical nomenclatures, such as those developed by Mulliken (N, V, T), Kasha ($^1\pi\pi^*$, $^3\sigma\pi^*$), and Platt (1L_a , 3B_b), highlighting the type of orbitals implied in the excitation, can be useful in different cases.

The basic information required to rationalize a photoinduced phenomenon is the energy levels of the excited solutions and the probability of energy (population) transfer from one state to the other. In the semiclassical treatment of the interaction radiation-matter, whereas we treat the molecule quantum-mechanically, the radiation field is seen as a classical wave obeying Maxwell's equations.

The electric and magnetic fields of the radiation will interact with the atomic or molecular electrons giving a time-dependent perturbation. Solving the time-dependent Schrödinger equation provides us the comprehension of absorption and stimulated emission, whereas to explain spontaneous emission we need the machinery of quantum electrodynamics. The resonance condition provided by the energy differences between the different PEHs of the corresponding states relates to the absorbed or emitted energy quanta. Regarding the transfer probability, it is related with the strength of the interaction between the time-dependent field and the multipolar (the dipole, d , approach is usually enough) charge distribution of the

Fig. 2 Vertical energies and band origins. Vibrational states are labeled with the greek character ν

molecular system. Such strength is proportional to the transition dipole moment (TDM) (Fig. 2).

As an initial feature, the electronic states produce a superposition of bands which characterize the absorption spectrum. The range of absorbed energies fluctuates between the vertical absorption energy, E_{VA} (difference between the minimum of the ground state and the excited state at the same geometry, that is, the Franck–Condon transition), and the adiabatic transition or band origin, T_e (difference between the excited state and the ground state at their respective optimized equilibrium geometries): it is the minimal energy difference allowed in absorption if the assumption that all excitations begin from the relaxed ground state is considered, as well as the largest energy emitted from the relaxed excited state. In many cases, the determination of T_e provides enough information to assign band origins; however, the zero-point vibrational energy (ZPE) has to be included in both initial and final states to get the vibrational band origin, T_0 , which can be directly compared to the experimental value, at least that obtained in the gas phase or in molecular beams. In addition, there is another magnitude named vertical emission energy, E_{VE} , which is the difference between the excited state and the ground state at the relaxed geometry of the former. The Franck–Condon principle stipulates that the vertical absorption can be related with the experimental band maximum. In fact, this is hardly the case, except when the ground and excited states have very similar geometries, and in this case the T_0 transition ($S_0\nu'' = 0 \rightarrow S_1\nu' = 0$) yields the most intense peak. The vertical excitation has, however, no experimental counterpart, whereas to get a true band maximum, the band vibrational profile must be computed. The only direct comparison relates the theoretical and experimental band origins, T_0 actually. Trying to assess the quality of a theoretical approach by comparing theoretical vertical excitations and experimental band maxima is one of the most frequent mistakes seen in the literature.

Regarding the transfer probability, far from the conical intersection regions the Fermi's Golden Rule is employed, in which the one-photon (optical) transition probability between two states $|n\rangle \rightarrow |m\rangle$ is proportional to the square of the

TDM between such states: $\text{TDM} = \langle m | d | n \rangle$. Two- and higher-order multiphoton probabilities can be also obtained. Based on symmetry considerations, selection rules for electronic transitions have been developed because only the totally symmetric matrix elements yield allowed nonzero probabilities (at first order). Using the so-computed electronic TDM, it is useful to estimate the electronic oscillator strength as $f = (2/3) E_{VA} \text{TDM}^2$, with E_{VA} being the vertical energy difference. The oscillator strength is a classically derived magnitude that represents the relative area of the electronic transition band and that it can be compared with the experimental estimation based in shapes and bandwidths. On the other hand, the vibrational contributions to the band intensity (or, in general, the strength of the transfer) can be obtained by computing the TDM between vibrational states. If belonging to the same electronic states, infrared or Raman intensities can be produced, otherwise electronic band vibrational profiles can be obtained. The vibrational TDM is proportional to the vibrational overlap term between the electronic states, $\langle v_m | v_n \rangle$, which are called the Franck–Condon factors (the probability of transition is proportional to its square). The vibrational profiles are basically related to the differences in geometry existing from the initial to the final electronic state and, therefore, the most intense progressions proceed through the normal modes which trigger the aforesaid changes. Within the harmonic approach, the complete TDM with respect the nuclear coordinates Q_i is defined as the Herzberg–Teller expansion:

$$\begin{aligned} \text{TDM} = & \text{TDM}(Q_0) \langle v_m(Q) | v_n(Q) \rangle \\ & + \sum_K \left(\frac{\partial \text{TDM}(Q)}{\partial Q_K} \right)_{Q_0} \langle v_m(Q) | Q_K | v_n(Q) \rangle + \dots \end{aligned}$$

Each one of the terms has an electronic and a vibrational component. The neglect of all terms except the first one is known as the Condon approximation, a usual way to proceed but only applicable for the one-photon dipole-allowed transitions. Otherwise, $\text{TDM}(Q_0)$ is zero by symmetry and the first term vanishes. Nonetheless, this approximation is valid only when the Born–Oppenheimer approximation is also valid. Otherwise, the phenomenon of vibronic coupling arises, which gives rise to other approximations (the term vibronic should be reserved to solutions obtained in non-Born–Oppenheimer cases, although is frequently used improperly). From the calculation of transition dipole moments, radiative lifetimes can also be obtained, both in fluorescence and phosphorescence by using the Einstein coefficients (A_{21}) and the Strickler–Berg relationships (Strickler and Berg 1962):

$$A_{21} = \frac{1}{\tau_{\text{rad}}} = 2.142005 \cdot 10^{10} E_{VE}^3 \text{TDM}_{1 \rightarrow 2}^2 \quad (1)$$

where τ_{rad} is the radiative lifetime measured in s^{-1} . The use of T_e instead of E_{VE} is more representative of the energy of the emission.

To study photophysical and photochemical processes on theoretical grounds, we need to determine the topography of the potential surfaces of the implied states (see Fig. 3). According to the different reaction paths through what a system

Fig. 3 Scheme of the main photophysical and photochemical molecular events. Notice that the order of the states changes along the nuclear coordinate, Q

might evolve, one can normally make the following classification that defines the photochemical panorama: adiabatic and non-adiabatic photochemistry. In an adiabatic reaction path, once vertical absorption takes place, the system proceeds along the hypersurface of the excited state to reach a local (or absolute) minimum leading in some cases to an emitting feature. On the contrary, in a non-adiabatic photochemical reaction, one part of the reaction takes place on the higher-state hypersurface and after a nonradiative jump at the surface crossing (or funnel) continues on the lower-state hypersurface. In a typical closed-shell ground-state molecule, the reaction usually begins on the potential energy surface of the excited state (S_1 or higher) at the Franck–Condon geometry (i.e., at the ground-state equilibrium geometry) and evolves either to the S_1 state minimum, from which it might emit, or to a crossing region with the ground state. Depending on the properties of such crossing, the process will end up on the reactant minimum or a new photoproduct minimum on the ground-state surface (S_0). The crossings between the excited state relevant from the photochemical view and the ground state are frequent, and they represent the basis of the spectroscopic phenomena. Therefore, a molecule evolving through the PEH of an excited state may well enter in a crossing region between two hypersurfaces during the lifetime of such an excited state. Hence, the lifetime of excited states is determined by the barriers that separate the excited states at the Franck–Condon geometry from the low-lying crossings. There are two types of crossings: conical intersections (CI), when the two interacting hypersurfaces have the same multiplicity, and (within the nonrelativistic approximation) singlet-triplet crossings (STC) or any other crossing between states

Fig. 4 Description of a conical intersection. The vectors x_1 and x_2 span the branching space. They are called the gradient difference (GD) vector and the derivative coupling (DC) vector. The DC vector measures the distortion of the system providing the maximum coupling between the electronic states involved in the crossing. The GD vector measures the distortion of the system leading to the largest variation of the energy difference between the two electronic states involved in the crossing

that have different multiplicity (Bearpark and Robb 2007; Domcke et al. 2004; Herzberg and Longuet-Higgins 1963; Robb et al. 1996; Teller 1937). Therefore, internal conversions take place through CIs, and intersystem crossings through STCs. The name of conical intersection (see Fig. 4) reflects the fact that a cone-shaped crossing is obtained when the energy of the states is plotted against the two privileged coordinates, the gradient differential vector, x_1 , and the nonadiabatic coupling vector, x_2 . Thus the total coordinate space F -dimensional is divided in two: the intersecting space (of dimension $F - 2$), in which both states are degenerated, and the branching space (of two dimensions). The most pronounced difference between the slopes of both hypersurfaces occurs along x_1 , whereas along x_2 the optimum nuclear displacement which mixes the two adiabatic wave functions in the CI point takes place. Actually, the intersection space is an hyperline that consists of an infinite number of CI points, i.e., a $(F - 2)$ -dimensional intersection space. To locate a CI point is equivalent to minimize the energy in the intersection space. In the case of STCs (if the nonrelativistic Hamiltonian is considered), we have only one privileged coordinates since the nonadiabatic coupling vector vanishes. Therefore we should refer this feature as an hyperplane, since we are moving along a $(F - 1)$ -dimension space.

As the Born–Oppenheimer approximation is not valid in regions where the electronic states become too close, it is logical that the nonadiabatic transfer is faster than the radiative relaxation. In essence, the former is based on the structure of the vibronic states. Certainly, the smaller is the gap between the states, the larger is the transfer probability.

Conical intersections may be peaked or sloped (see Atchity et al. 1991; Ben-Nun and Martínez 2000, and Fig. 5).

Fig. 5 Scheme of the limit characters displayed by the conical intersections. For a peaked CI, the two minima lie on the two different sides of the CI point and the gradients of the two intersecting PEHs are directed toward different directions. Conversely, for a sloped CI, the excited-state and ground-state minima lie on the same side (the gradients of the two PEHs point in the same direction), then the probability of re-crossing is higher and the efficiency of funneling is lower

If the connection between the two surfaces is sloped, the funnel may well be more efficient. In addition, the degeneracy at a crossing point can also be lifted at second order. As a consequence, we can choose a coordinate system in which to mix the branching and intersection space coordinates to remove this splitting and preserve the degeneracy to second order. These new coordinates give the curvature of the conical intersection hyperline and determine whether one has a minimum or a saddle point on it. These studies may also provide the vibrational modes that must be stimulated in order to enhance nonradiative decay because they decrease the energy gap and can lead to a CI (see Paterson et al. 2004; Sicilia et al. 2007).

A computational strategy can be designed, namely the Photochemical Reaction Path approach, in which the mechanism of the photoinduced process is accounted for by determining the fate of the energy on the populated state by computing the reaction profile. The whole process can be described by computing Minimum Energy Paths (MEPs), describing the lowest-energy, and therefore most favorable, although not unique, path for energy decay. The MEP is often built as steepest descent paths, guaranteeing the absence of barriers along the path. Each step requires the minimization of the PEH on a hyperspherical cross-section of the hypersurface centered on the initial geometry and characterized by a predefined radius. The optimized structure is taken as the center of a new hypersphere of the same radius, and the procedure is iterated until the bottom of the energy surface is reached. Mass-weighted coordinates are used, therefore the MEP coordinate corresponds to the so-called Intrinsic Reaction Coordinate (IRC), measured in a.u., that is, $\text{bohr} \cdot (\text{amu})^{1/2}$. The end of the path and the states crossed along the computed profile will inform about the fate of the energy, and, in particular, of the location of possible radiative minima and surface crossings, CIs and STCs. More crucial than

the presence of a crossing is its accessibility. The path of available energy should reach the crossing region to take place. Otherwise, if a too high energy barrier hinders the access to the crossing, the feature could be totally ineffective.

Electronic Structure Calculations

The development of Quantum Mechanics was spread over by Erwin Schrödinger, Werner Heisenberg, and Paul Dirac in the 1920s. The wave and particle aspects of matter are reconciled by the Schrödinger equation for stationary states, $\mathbf{H}\Psi = E\Psi$. The Hamiltonian operator, \mathbf{H} , is associated to the total energy of a physical system and is the sum of the kinetic energy and the potential energy operators associated with electrons and nuclei ($\mathbf{H} = \mathbf{T}_e + \mathbf{T}_N + \mathbf{V}_{NN} + \mathbf{V}_{Ne} + \mathbf{V}_{ee}$). This is an eigenvalue problem, in which wave functions Ψ are the eigenfunctions of \mathbf{H} and E stands for the corresponding eigenvalues (energies). The main challenge in Quantum Chemistry is that we cannot solve exactly the Schrödinger equation, except for one-electron systems, due to the electron repulsion term present in the Hamiltonian. Quantum-chemical methods look for approximate solutions of the equation, employing computational numerical methods typically based on the variational principle and perturbation theory. A point worth bearing in mind is that none of these models is applicable under all circumstances. Actually, we should get the best method in order to find what it has been wisely defined as “the right answer for the right reason.”

The physics of electron correlation is hidden in the Hamiltonian itself. The Coulomb repulsion given by the term r^{-1} present in the \mathbf{V}_{ee} energy, the inverse distance between two electrons, increases enormously in the regions close to $r_{ij} = 0$, preventing that two electrons may occupy the same space. Therefore, the motion of any two electrons is not independent but it is correlated. The phenomenon is known as electron correlation. Moreover, the statement that two electrons are correlated is equivalent to express that the probability of finding two electrons at the same point in space is zero. The instantaneous position of electron i forms the center of a region that electron j will avoid. For this reason, it is stated that each electron, as described by the exact wave function Φ , is surrounded by a Coulomb hole. However, electron correlation is not taken into account properly by many approximate methods. The effect of neglecting electron correlation partly in approximate quantum-chemical approaches has great impact in the computed molecular spectroscopic properties of interest.

General Overview

We can group computational–chemical methods in three basic categories (see for instance Atkins and Friedman 1997; Helgaker et al. 2004):

- Ab initio methods, in which the complete Hamiltonian is used, all the integrals are solved numerically, and no essential parametrization is employed

- Semiempirical methods, in which a simpler Hamiltonian is used or integrals are adjusted to experimental values or *ab initio* results
- Molecular mechanics, in which we solve Newton's equation of motion, only valid for situations where no bonds are broken or formed, i.e., conformational changes

Obviously, the larger is the system under study, the less accurate is the available method. Despite their inherent drawbacks, classical semiempirical methods are still employed in large systems, whereas modern semiempirical methods, based on the Density Functional Theory, have a widespread use. A combined approach, QM/MM (Quantum Mechanics/Molecular Mechanics) treats an internal part of the problem with QM methods, whereas the surroundings or a large part of a macromolecule (for instance, a protein) is introduced using classical mechanics.

According to the number of configurations used to build the reference wave function, the *ab initio* methods can be classified in the following two categories (see Fig. 6):

- *Single-configuration methods.* They are typically based in the single Hartree–Fock (HF) reference, which determines the optimal ground-state energy and MOs (molecular orbitals). Post-HF methods introduce the electron correlation usually at the Configuration Interaction (CI), Coupled-Cluster (CC) or perturbative (PT) Møller–Plesset (MP, or PT in general) levels. The coupled-cluster methods with singly and doubly excited configurations, including the effect of triple excitations by perturbation theory CCSD(T), as well as related approaches, yield accurate results in well-defined ground-state situations and are considered as benchmark

Fig. 6 *Ab initio* methods

results for small to medium molecules. In general, the applicability of the methods in this group is restricted to situations where a single reference wave function is adequate for the description of a chemical process, something not generally true for bond-breaking cases, degeneracies, and excited states

- *Multiconfigurational methods.* Part of the electronic correlation is already included in the reference wave function, normally by using a Multiconfigurational Self-Consistent-Field (MCSCF) wave function, which determines a set of MOs. The remaining electron correlation effects are accounted for by MRCI, MRCC, or MRPT techniques, where MR stands for multireference. They have a more ample range of applicability (ground state, excited states, transition states) than single-reference methods

The variation principle states that given a normalized wave function that satisfies the appropriate boundary conditions, then the expectation value of the Hamiltonian is an upper bound to the exact ground-state energy. In the linear variational problem, the trial function is a linear combination of basis functions, in general using the Linear Combination of Atomic Orbitals (LCAO) approach. On the other hand, in perturbation theory, the total Hamiltonian of the system is divided into two pieces: a zeroth-order part, which has known eigenfunctions and eigenvalues, and a perturbation part. The exact energy and wave function are then expressed as an infinite sum of contributions of increasing complexity. If we have chosen the zeroth-order Hamiltonian wisely, then the perturbation is small and the expansion (i.e., the sum of the 1st-, 2nd-, . . . , n th-order energies) converges quickly.

The simplest wave function to describe a many-electron system is a Slater determinant built by orthogonal one-electron wave functions. Electrons are fermions and accordingly they have to be described by an antisymmetric wave function. For an N -electron system, the Slater determinant has the form:

$$\Psi(x_1, x_2, \dots, x_N) = (N!)^{-1/2} \begin{vmatrix} \chi_i(x_1) & \chi_j(x_1) & \dots & \chi_k(x_1) \\ \chi_i(x_2) & \chi_j(x_2) & \dots & \chi_k(x_2) \\ \vdots & \vdots & \ddots & \vdots \\ \chi_i(x_N) & \chi_j(x_N) & \dots & \chi_k(x_N) \end{vmatrix} = |\chi_i \chi_j \dots \chi_k| \quad (2)$$

without specifying which electron is in which orbital. To simplify the notation, a normalized Slater determinant is represented by only showing the diagonal elements of the determinant. The constant $(N!)^{-1/2}$ is a normalization factor. The wave function for an electron that describes both the spatial distribution and its spin is called spin orbital, $\chi_i(x_i)$. Since the Hamiltonian employed does not depend on the electronic spin, each spin orbital can be expressed by multiplying the spatial orbital, $\psi_j(r_i)$, by the spin function, ω (α – spin up and β – spin down): $\chi_i(x_i) = \psi_j(r_i) \cdot \omega$. A complete set for describing the spin of an electron consists of two orthogonal functions $\alpha(\omega_i)$ and $\beta(\omega_i)$.

A single-determinant wave function has several interesting properties. Firstly, it is worth noting that spin orbitals must be linearly independent, otherwise the value

of the determinant is zero. It is obvious that interchanging two rows of the Slater determinant, which is equivalent to interchanging the coordinates of two electrons, changes the sign of the determinant. The requirement of the antisymmetry principle is automatically fulfilled. Having two columns of the determinant identical, that is, two electrons occupying the same spin orbital, makes the determinant zero. Thus, no more than one electron can occupy a spin orbital (Pauli exclusion principle). When a linear transformation of the set $\{\chi_i\}$ is carried out, $\chi'_i = \sum_j \chi_j \cdot A_{ji}$, where A_{ji} is an element of the matrix \mathbf{A} of dimension $N \times N$, with a value for its determinant, $\det(\mathbf{A})$, different from zero, then $\Psi' = \det(\mathbf{A}) \Psi$. The wave functions Ψ' and Ψ differ just in a constant and, therefore, represent the same physical situation. Since the set of spin orbitals is linearly independent, we can always choose a transformation matrix \mathbf{A} so that the resulting spin orbitals χ'_i become orthonormal. Therefore, no restriction at all is imposed when we choose from the beginning an orthonormal set of spin orbitals. It just makes the computation of the Hamiltonian matrix elements involving Slater determinants easier. A Slater determinant is completely specified by the spin orbitals used to build it, and any unitary transformation of them is equally valid. Two sets of spin orbitals related by a unitary transformation ($\mathbf{A}^\dagger = \mathbf{A}^{-1}$), which keeps the orthonormality of the spin orbitals, yield the same Slater determinant. Slater determinants formed from orthonormal spin orbitals are normalized and N -electron Slater determinants that have different spin orbitals are orthogonal. In other words, a Slater determinant is completely specified by the spin orbitals used to build it and any unitary transformation of them is equally valid (each result of such a linear transformation represents the same physical situation).

There are two types of spin orbitals: restricted spin orbitals, which are constrained to have the same spatial function for α and β spin functions; and unrestricted spin orbitals, which have different spatial functions for α and β spins. A restricted set of spin orbitals has the form: $\chi_i(x) = \psi_j(r) \cdot \alpha(\omega) // \psi_j(r) \cdot \beta(\omega)$, whereas an unrestricted set has the form: $\chi_i(x) = \psi_j^\alpha(r) \cdot \alpha(\omega) // \psi_j^\beta(r) \cdot \beta(\omega)$.

Essentially, all practical calculations for generating solutions to the electronic Schrödinger equation are performed with molecular orbital methods: the zeroth-order wave function is constructed as one or two Slater determinants and the MOs are expanded in a set of atomic orbitals, the basis set. In a subsequent step, the wave function may be improved by adding electron correlation by either CI, MP, or CC methods. Nevertheless, there is another equivalent theory to get approximate solutions of this eigenvalue equation: the valence bond (VB) theory. The main drawback is that this theory leads to awkward calculations. On the positive side, conceptually it is much closer to the experimentalist's language since it may be regarded as a quantitative version of the resonance structure of electronic structure, with ionic structures and covalent structures of molecules. The VB method assumes that the wavefunction of a molecule may be written as a linear superposition of mathematical functions which represent canonical electronic structures: structures in which electrons are assigned to specific atoms and then paired (spinwise) leading to covalent and ionic structures, the combination of which represents the wave

function. The VB description of a bond as the result of two overlapping and localized orbitals is in contrast to the MO approach where a bond between two atoms arises as a sum over (small) contributions from many delocalized orbitals.

Classical valence bond theory is very successful in providing a qualitative explanation for many aspects. One of the great merits of VB theory is its pictorially institutive wave function that is expressed as a linear combination of chemically meaningful structures. It is this feature that has made VB theory so popular in the 1930–1950s. However, VB theory was “defeated” by MO theory for two main reasons: (1) mathematical simplicity and (2) several “failures” of the VB theory (actually due to misuse of very simplified versions of the theory). Currently, VB theory is coming of age in all the branches of theoretical chemistry (excited states, dynamics, environmental effects, and so on), with the development of faster, and more accurate *ab initio* VB methods, and with generation of new post-Pauling concepts. The Renaissance of VB theory is marked by surge in the following two-pronged activity: (1) creation of general qualitative models based on VB theory and (2) development of new methods and softwares that enable applications to moderate sized molecules.

Methods, Advantages, and Drawbacks

The Hartree–Fock method is the simplest *ab initio* approach. We can equate closed-shell HF theory to single determinant theory, and we are thus interested in finding a set of spin orbitals $\{\chi_a\}$ such that the single determinant formed from them, $|\Psi_0\rangle = |\chi_1\chi_2\chi_3\dots\chi_a\chi_b\dots\chi_N\rangle$ is the best possible approximation to the ground state of the N -electron system described by an electronic Hamiltonian \mathbf{H} . The expectation value of the energy, $E_0 = \langle\Psi_0|H|\Psi_0\rangle$, is a linear combination of one-electron integrals, $\langle i|h|j\rangle$ and two-electron integrals, $\langle ij|kl\rangle$. According to the properties of a Slater determinant, electrons are not uncorrelated in a HF wave function. At least the probability of finding two electrons with parallel spins at the same point in the space is zero, the so-called exchange correlation, which is incorporated by the antisymmetric condition of the wave function for fermions. The phenomenon is known as the Fermi hole. We are, therefore, facing a model of independent particles where the behavior of certain electrons is not fully independent because the Fermi hole simulates somehow the Coulomb hole. Consequently, only Fermi correlation is accounted for by the HF wave function.

By minimizing E_0 with respect to the choice of spin orbitals $\{\chi_a\}$, varying them with the only restriction that they remain orthonormal, $\langle\chi_a|\chi_b\rangle = \delta_{ab}$, one can arrive to the Hartree–Fock conditions. In doing so, one obtains an equation that defines the best spin orbitals, the ones that minimize E_0 . This equation for the best (Hartree–Fock) spin orbitals is the Hartree–Fock integro-differential equation $f|\chi_a\rangle = \varepsilon_a|\chi_a\rangle$, for the N -occupied spin orbitals. Each of the solutions $\{\chi_j\}$ has a spin orbital energy ε_j . The N spin orbitals with the lowest orbital energies are just the spin orbitals occupied in $|\Psi_0\rangle$ for which we use the indices a, b , etc. The remaining

infinite number of spin orbitals with higher energies are the virtual spin orbitals, which we label with the indices r, s , etc.

The Fock operator f is the sum of a core-Hamiltonian operator $h(1)$, which is the kinetic energy and potential energy for attraction to the nuclei of a single electron, and an effective one-electron potential called the Hartree–Fock potential $v^{\text{HF}}(1)$, which contains the Coulomb term (the total averaged potential acting on the electron in χ_a , arising from the $N - 1$ electrons in the other spin orbitals) and the exchange term (which arises because of the antisymmetric nature of the determinantal wave function). This is the essence of the HF approximation: to replace the complicated many-electron problem by a one-electron problem in which electron–electron repulsion is treated in an average way. What is more, since the Fock operator has a functional dependence, through the coulomb and exchange operators, on the solutions $\{\chi_a\}$ of the pseudo-eigenvalue equation, Hartree–Fock equations are actually nonlinear equations and will need to be solved by iterative procedures. The matrix representation of the Fock operator in the basis of spin orbitals eigenfunctions is diagonal with diagonal elements equal to the orbital energies.

The exact solution to this integro-differential equation corresponds to the “exact” HF spin orbitals. In practice, it is only possible to solve this equation exactly (i.e., as an integro-differential equation) for atoms. In practice, for molecules, the spin orbitals are expanded as a combination of one-electron atomic base functions and the set of matrix equations are solved. Only as the basis set approaches completeness, i.e., as one approaches the HF limit, will the spin orbitals be the exact HF orbitals.

It can be shown that any single determinant wave function $|\Psi_0\rangle$ formed from a set of spin orbitals $\{\chi_a\}$ retains a certain degree of flexibility in the spin orbitals; the spin orbitals can be mixed among themselves without changing the expectation value $E_0 = \langle \Psi_0 | H | \Psi_0 \rangle$. Furthermore, for a single determinant wave function, any expectation value is invariant to an arbitrary unitary transformation of the spin orbitals, since a transformed single determinant $|\Psi'_0\rangle$ can at most differ from the original determinant $|\Psi_0\rangle$ by a phase factor and, obviously, any observable property depends on $|\Psi|^2$, as we stated before. Thus the spin orbitals that make the total energy stationary are not unique, and no particular physical significance can be given to a particular set of spin orbitals. Localized spin orbitals, for instance, are not more “physical” than delocalized spin orbitals. Indeed, there exist a set of spin orbitals for which the eigenvalue matrix is diagonal, and we obtain just the equation $f | \chi_a \rangle = \varepsilon_a | \chi_a \rangle$, and this set is called “canonical spin orbitals.” The canonical spin orbitals, which are a solution to this equation, will generally be delocalized and form a basis for an irreproducible representation of the point group of the molecule.

It was in 1951 that Roothaan published his equations (see Roothaan 1951), considering molecular orbitals that were restricted to be linear combinations of a set of three-dimensional one-electron functions, ϕ_μ . Thus, ψ_i is a linear combination of these functions ϕ_μ (basis set): $\psi_i = \sum C_{\mu i} \cdot \phi_\mu$. If the set $\{\phi_\mu\}$ was complete, this would be an exact expansion, and any complete set $\{\phi_\mu\}$ could be used. Unfortunately, this one is always restricted, for practical computational reasons,

to a finite set of N basis functions. As the basis set becomes more and more complete, this expansion leads to more and more accurate representations of the “exact” molecular orbitals, which are eigenfunctions of the Fock operator. For any finite basis set, we will obtain molecular orbitals which are exact only in the space spanned by the aforesaid finite basis. In addition, since the electronic energy (the output of the quantum mechanical calculation) is variational, the better the basis set, the lower the total energy. As the basis set becomes more and more complete, the total energy approaches the Hartree–Fock limit. Of course, by the variational principle, the Hartree–Fock-limit energy is still above the “exact” energy, which here can be taken as the energy obtained from an exact solution to the nonrelativistic Schrödinger equation in the Born–Oppenheimer approximation.

Variation of the total energy was then carried out respect to the coefficients $C_{\mu i}$ of such a linear combination. This leads to a set of algebraic equations which can be written in matrix form, $\mathbf{FC} = \mathbf{SCE}$, where \mathbf{F} is the matrix representation of the Fock operator (which can be divided into the core-Hamiltonian matrix, that is, integrals involving the one-electron operator $h(i)$ describing the kinetic energy and nuclear attraction of the electron i , plus the two-electron terms), \mathbf{C} is the matrix of coefficients, \mathbf{S} is the overlap matrix, and \mathbf{E} is the diagonal energy matrix. The columns of \mathbf{C} describe the molecular orbitals, i.e., the coefficients describing ψ_1 are in the first column, with the corresponding energy ε_1 , those describing ψ_2 are in the second column, and so on. If \mathbf{S} is the unit matrix (i.e., if we have an orthonormal basis set), then we would have $\mathbf{FC} = \mathbf{CE}$, and Roothaan’s equations would just have the form of the usual matrix eigenvalue problem. Increasing the flexibility of the one-electron basis set $\{\phi_{\mu}\}$, the HF energy E_0 will progressively reach the Hartree–Fock limit.

The approximation has its limitations, in particular the lack of electronic correlation energy. For instance, Restricted Hartree–Fock (RHF) solution predicts incorrectly the dissociation of molecules into open-shell fragments (like $\text{H}_2 \rightarrow 2\text{H}$) given that both electrons are forced to occupy the same spatial molecular orbital (MO), when they should belong to infinitely separated atoms in the dissociated solution. This means that some electron–electron repulsion remains even at infinity, which is the source of a spurious term in the total energy (different from twice the energy of two hydrogen atoms). Alternatively, the products of dissociation are not just $2\text{H}\cdot$, but also include, incorrectly, H^- and H^+ . However, the poor behavior of closed-shell RHF calculations upon dissociation to open-shell products does not detract from their utility as reference function in the region of equilibrium: the potential surface obtained from a closed-shell RHF calculation will not be parallel in regions of the surface characterizing dissociation limit, but it will be reasonably parallel near the region of the equilibrium geometry. It is worth mentioning that the VB wave function for H_2 , $\Psi = C_{\text{cov}}\Psi_{\text{cov}} + C_{\text{ion}}\Psi_{\text{ion}}$, with the covalent and ionic counterparts, contains “left-right” correlation which is necessary for a correct description of dissociation of the H_2 molecule.

Within the HF approach, a slight improvement can be achieved in dealing with open-shell systems with the restricted open-shell (ROHF) and the unrestricted Hartree–Fock (UHF) procedures. In the former, all electrons, except those that

are explicitly required to occupy open-shell orbitals, occupy closed-shell MOs. In the latter, electrons of different spin, in general, are described by different sets of spatial orbitals, although the obtained wave function is typically contaminated with higher spin state solutions. The approximation leads to two integro-differential eigenvalue equations which are coupled and cannot be solved independently. The introduction of a basis leads to the Pople–Nesbet equations, $\mathbf{F}^\alpha \mathbf{C}^\alpha = \mathbf{S}^\alpha \mathbf{C}^\alpha \mathbf{E}^\alpha$ and $\mathbf{F}^\beta \mathbf{C}^\beta = \mathbf{S}^\beta \mathbf{C}^\beta \mathbf{E}^\beta$. $\mathbf{N}^\alpha = \mathbf{N}^\beta$, a restricted solution to the Roothaan equations is a solution to the unrestricted Pople–Nesbet equations. In general those approaches, which can serve as reference for post-HF methods in ground-state cases, are not accurate enough to compute excited states.

The lack of correlation is the actual source of all errors. In particular, a Slater determinant incorporates exchange correlation, i.e., the motion of two electrons with parallel spins is correlated (the so-called Fermi correlation). Unfortunately, the motion of electrons with opposite spins remains uncorrelated. It is common to define correlation energy, E_{corr} , as the difference between the exact nonrelativistic energy of the system, ε_0 , and the Hartree–Fock energy, E_0 , obtained in the limit that the basis set approaches completeness: $E_{\text{corr}} = \varepsilon_0 - E_0$. The simplest manner to understand the inclusion of the correlation effects is through the method of configuration interaction (CI). The basic idea is to diagonalize the N-electron Hamiltonian in a basis of N-electron functions: we represent the exact wave function as a linear combination of N-electron trial functions and use the linear variational method.

$$|\Phi\rangle = C_0 |\Psi_0\rangle + \sum_{ra} C_a^r |\Psi_a^r\rangle + \sum_{a<b;r<s} C_{ab}^{rs} |\Psi_{ab}^{rs}\rangle + \dots \quad (3)$$

If the basis were complete, we would obtain the exact energies of all the electronic states of the system. In spite of providing the exact solution of a many-electron problem, we can handle only a finite set of N-electron trial functions. As a result, the CI method provides only upper bounds to the exact energies. Specifically, the lowest eigenvalue, ε_0 , will be an upper bound to the ground-state energy of the system. When all the N-electron wave functions are taken into account, the calculation is named full configuration interaction (FCI) and the corresponding eigenvalues and eigenvectors computed are exact within the space spanned by the finite basis set. Despite the great advances in FCI technology in the last few years, the size of the eigenvalue problem becomes rapidly too large to be handled by modern computers. As a result, FCI solutions are only available for very small molecular systems. In contrast to HF, the FCI energy of H_2 properly describes the dissociation. However, within a minimal basis set approach, the FCI potential curve does not agree very well with the exact one provided by Kolos and Wolniewicz due to the lack of flexibility of such a basis set. The truncation of both N-electron basis and one-electron basis is the main source of inaccuracies in quantum-chemical calculations (Fig. 7).

As mentioned earlier, for computational reasons, we have to truncate the full CI matrix or equivalently the CI expansion for the wave function, considering only those configurations which differ from the HF ground-state wave function

$$\begin{aligned}
 & \text{N-electron basis set} \\
 \langle \Phi \rangle &= C_0 |\Psi_0\rangle + \sum_{ra} C_a^r |\Psi_a^r\rangle + \sum_{a<b; r<s} C_{ab}^{rs} |\Psi_{ab}^{rs}\rangle + \dots \\
 & \text{1-electron basis set} \\
 \langle \Phi_i \rangle &= |\chi_i \chi_j \dots \chi_N\rangle \quad \chi_i = \phi_i \vec{\omega} / \vec{\omega} = \alpha, \beta \\
 \phi_i(\vec{r}) &= \sum_{\mu=1}^K C_{\mu i} \phi_{\mu}(\vec{r}) \quad \phi_{\mu}(\vec{r}) = \sum_K d_{K\mu} g_K
 \end{aligned}$$

Fig. 7 Many-electron expansion (CI) and one-electron expansion (basis set). The total wave function, Φ , is a linear combination of N-electron wave functions Ψ_0, Ψ_a^r , etc. Each one of these functions is an antisymmetrized and normalized product of spin orbitals, χ_l . Each of them is constituted by a one-electron wave function, ψ_l , and a spin function, ω . Each one-electron wave function is defined as a linear combination of a set of basis functions, ϕ_{μ} , which are used to be contracted gaussian functions, CGTFs (linear combinations of a set of primitive functions, g_{κ})

by no more than a predetermined number of spin orbitals. The simplest version of this scheme is to deal with single and double excitation out of $|\Psi_0\rangle$: a SDCI calculation. SDCI and, in fact, all forms of truncated CI deteriorate as the number of electrons increases. The truncation of the CI expansion leads to problems of size-extensivity. For instance, in a DCI calculation, by definition the wave function of each monomer contains double excitations within the monomer. If we restrict the supermolecule trial function to double excitations, we exclude the possibility that both monomers are simultaneously doubly excited, since this represents a quadruple excitation in the supermolecule. It is now common to differentiate size-extensivity and size-consistency. The latter was originally employed by Pople as a criterion for a well-constructed quantum-chemical method, indicating that the energy computed for two noninteracting molecules should be exactly twice that calculated for only one isolated molecule, that is, a property that described the additive separability of the wave function. Recently, the concept has been extended to include not only the fragmentation limit but the entire process, that is, qualitatively all regions of the potential energy hypersurface must be qualitatively correct. For instance, both RHF and UHF wave functions are size consistent in the first sense, considering that they properly describe a separated H_2 dimer system, but for a closed-shell molecule dissociating into open-shell fragments the RHF descriptions fails, and therefore does not conform to the broader size-consistency concept. On the other hand, size extensivity, analogously to the extensivity concept in thermodynamics, refers to the correct, linear, scaling of a method with the number of electrons, and its fulfillment leads to methods in which calculations with differing number of electrons can be compared, like those related to ionization processes. Otherwise, the error of the method increases with the size of the system. At the noninteracting limit size extensivity implies size consistency, but this latter property has the requirement of correct fragmentation, which does not depend on the mathematical scaling. Therefore, RHF and UHF approaches are always size extensive, but RHF does not provide

proper dissociation in open-shell cases, and it is therefore non-size-consistent, as any other method such as single-reference coupled-cluster (CC) or perturbation approaches (PT) which use RHF as reference wave function. On the other hand any truncated configuration interaction approximation is not size extensive, whereas CC and PT are. In the case of the multiconfigurational methods, the size-consistency depends on the selected reference – generally they are size consistent – and the size extensivity varies with the approach. MRCI is formally a truncated CI approach and therefore is not size extensive, as CASPT2 – multiconfigurational complete active space perturbation theory up to second order – and similar methods, which are formally not size extensive either, but in practice the effects are irrelevant, in particular for the most common implementation (see Taylor 2007).

It is worth mentioning that using a better-variational method only ensures to get a better variational energy, but a priori we cannot say nothing regarding properties other than the energy. For instance, the dipole moment of CO is ca. zero, and to obtain the correct sign of the vector (actually, greater than zero: +0.044 a.u. experimentally) is a tricky problem. A DCI calculation with the 200 most important double excitations has a lower energy than a SDCI procedure with 138 doubles + 62 singles. Still, the DCI calculation predicts the wrong sign of the dipole moment (−0.072 a.u.), just the contrary that the SDCI calculation (+0.030 a.u.). To improve the result it is necessary to employ CCSD(T) (+0.047 a.u.) (Paschoal et al. 2009).

There is another clever way to introduce in the wave function enough correlation effects to get a good account of the nature of the chemical problem, for instance, in a dissociation path of a diatomic molecule. Such procedure implies to improve the reference wave function by including more than one determinant or electronic configuration in its description. Adding more than one configuration means to get their weights in a linear combination. Therefore, the central idea of a multiconfigurational self-consistent field (MCSCF) calculation is to build the wave function as a truncated CI expansion

$$|\Psi_{\text{MCSCF}}\rangle = \sum_I c_I |\Psi_I\rangle, \quad (4)$$

in which both the expansion coefficients and the orthonormal orbitals contained in $|\Psi_I\rangle$ are optimized simultaneously. For a closed-shell system, if only one determinant is included in such an expansion, the MCSCF and HF methods become identical. In the minimal basis set description of H_2 , Ψ_{MCSCF} is identical to the FCI wave function. However, if an extended basis set is used, the MCSFC energy will be above and nearly parallel to the FCI energy but below the energy obtained from any two-configuration CI expansion based on canonical HF MOs.

The correlation energy introduced in a MCSCF wave function is usually named nondynamic, static, or large-range correlation energy, and the corresponding wave function must be build in such way that includes most of near-degenerate electronic configurations, that is, all those which basically contribute to define the reference function along the chemical process under study. An example is a bond breaking. A proper MCSCF description should include both the bonding and antibonding dis-

tribution of the electrons, and the corresponding MOs. The optimization procedure at each region of the PEH will determine the relative weight of each configuration at that point and the proper MOs. Improving the reference in such manner helps to the post-HF approaches to account for the remaining correlation effects, named dynamic or short-range. It is like starting the race from a more advantageous position.

One of the most successful and systematic procedures to account for the correlation energy, which is not variational but is size extensive at each order, is the perturbation theory. Using different zeroth-order Hamiltonians, Møller–Plesset perturbation theory (MPPT), also named many-body perturbation theory (MBPT), yields the energy and the wave function corrected up to n order following a Taylor series expansion. Although, in general, higher perturbation orders improve the result, it has been proved that it leads to divergences at infinite order. Second- and fourth-order perturbation (MP2, MP4) results are much better than the SCF and SDCI ones. The most recent family of methods based on a single reference is that based on the coupled-cluster (CC) approach, in which the correlation energy is introduced size-extensively by increasing the excitation level. CC methods for the ground state, especially when including up to triple excitations, have become, in practice, the most accurate quantum-chemical approaches for many systems.

No matter how good is the quality of the post-HF method for the inclusion of the correlation energy, when based on a single HF reference, the accuracy of the results largely decreases in many situations, like those related with dissociations, degeneracies, and excited states. For instance, regarding the dissociation problem, the potential curve calculated at any level based on a RHF reference is not satisfactory at long range. The problem is the starting point: the exact wave function at large R cannot be described by a single determinant. The results largely improve its accuracy when a multiconfigurational or multireference (MR) wave function is used as a reference, for instance, in the MRCI, MRCC, or MRMP approaches. Recovering correlation energy does not require so large effort in this case, for instance, lower perturbation (MP) or excitation (CC) levels. As a drawback, the complexity of the methods increases.

On the other hand, the semiempirical DFT approach has become the most widespread quantum-chemical method in the last years. It allows us to treat large systems in a relatively short time taking into account electron correlation. The basic idea is that the energy of an electronic system can be written in terms of the electron density, ρ . For a system of N electrons, $\rho(\mathbf{r})$ denotes the total electron density at a particular point in space \mathbf{r} . The electronic energy E is said to be a functional of the electron density, denoted $E[\rho]$, in the sense that for a given function $\rho(\mathbf{r})$, there is a single corresponding energy. It is not necessary to compute a wave function, but, unfortunately, the Hohenberg–Kohn theorem does not inform about the form of the functional dependence of energy on the density: it confirms only that such a functional exists. So the procedures should resort to approximate derivations with adjustable parameters. This is the reason why functionals proliferate to hundreds in the literature. Some of them, like the Becke3–Lee–Yang–Parr (B3LYP) functional, is the most popular in the literature, not because its overall accuracy but of its balance

and its controlled flaws. There is no systematic way to improve a functional, just to derive another one with different parameters. It is typical to use one functional per each situation, something that makes the predictability of the results somewhat questionable. On the contrary, *ab initio* calculations, if allowed by the size of the problem, can be hierarchically improved in a known direction enlarging the N -electron and/or the one-electron basis.

Basis Sets

The choice of the one-particle space is a most important decision when setting up any calculation, and there is no point in trying to improve the result if the selection of the one-electron basis set is not adequate. This is especially true for the calculation of excited states, in which states of very different nature (for instance, compact and diffuse) have particular requirements that must be fulfilled simultaneously when selecting the basis set. In a strict mathematical sense, many different types of basis set functions $\{\phi_\mu\}$ can be used. Gaussian-type functions (GTFs, $g \propto e^{-\alpha r^2}$) are the more widespread in spite of being ill-behaved in both close and far away of the nuclei. Nevertheless, four-center integrals (that is, two-electron repulsion integrals) are very easy to evaluate with GTFs, and, in addition, the basis set can be improved by employing contracted Gaussian functions, CGTFs, which are linear combinations of primitive GTFs. To build a CGTFs, the primitive functions have to be optimized, both exponents and contraction coefficients. According to the number of basis functions, it is common to distinguish among minimal basis set (a single basis function per occupied atomic orbital), double- ζ (two basis functions per atomic orbital), triple- ζ , split-valence (duplication only affects to valence layer whereas minimal basis set is used for core orbitals), etc.

Ground-state calculations have made extensive use of the so-called Pople basis sets: STO-G, 3-21G, 6-31G. These basis sets are built using segmented contraction, which means that each primitive functions contributes to one or a limited number of contracted function only. Exponents and coefficients were optimized using the HF approach. Valence basis sets are too limited to get accurate results, and therefore additional functions have to be added, named polarization functions (6-31G* or 6-31G(d), which means that polarization functions are added to second-period atoms; and 6-31G** or 6-31G(d,p), which means that, additionally, polarization functions are added to hydrogen atoms). These are functions of higher angular momentum than those of valence type and are necessary in order to describe the changes of the electronic density of an atom in the molecule. Diffuse functions (6-31+G, 6-31++G) can be also added which are more extended in the space, that is, with smaller exponents, to describe better situations such as anions or Rydberg states. A 6-31G basis set for the C atom ($1s^2 2s^2 2p^2$) is described as (10s4p)/[3s2p], i.e., 10 primitives s and 4 primitives p (22 primitives: $1s \times 6 + 2s \times 3 + 2s \times 1 + 2p \times 3 + 2p \times 1$) are contracted to three combined functions s and two combined functions p (nine contracted functions: $1s, 2s, 2s'$,

2p, 2p'). The basic flaw of Pople's basis sets is that they have been built with a method lacking correlation energy. The consequence is that they are very poor in recovering correlation effects in post-HF methods. In order to get better values, more polarization of diffuse functions have to be added to compensate the lack of flexibility of these basis set.

If the ultimate goal is to perform correlated calculations, it would seem preferable to include correlation in the construction of the basis set. For correlated calculations, the basis set requirements are different and more demanding since we must also provide a virtual orbital space capable of recovering a large part of the correlation energy. It is often sufficient to correlate only the valence electrons. This is the case for correlation consistent (cc) or Atomic Natural Orbitals (ANO) basis sets. Correlation consistent basis sets are designed so that functions which contribute in similar amounts of correlation energy are included at the same stage, independently of the function type. We can add polarization functions (cc-pVDZ) or diffuse functions (augmented, aug). They need fewer primitives than ANOs, and each contracted basis comes from a different primitive set and the exponents of polarization functions are optimized by correlated calculations within a segmented contraction scheme.

On the other hand, ANO-type basis sets arise as eigenfunctions of the first-order reduced density matrix of the atom. They give the most rapidly convergent CI expansion, and to obtain a given accuracy one requires fewer configurations formed from NOs than configurations formed from any other orthonormal basis. The occupation number is a reference of its significance in the wave function and the truncation of the orbital space by elimination of the ANOs whose occupation numbers are small produces the least possible error on the wave function. The coefficients of ANOs obtained in a correlated calculation of the ground state of the atom represent the coefficients of the basis functions within a general contraction scheme (all primitives on a given atom and of a given angular momentum enter all the contracted functions having that angular momentum, but with different contraction coefficients, which improves the flexibility). This yields basis of any size with a unique calculation with the primitive set, and since the same primitive set for all contractions is used, a smaller basis is always a subset of a larger basis. In other words, we can enlarge our basis set without changing of vector space (Almlöf and Taylor 1986, 1991). An improvement of the original scheme takes into account an average density matrix to build the basis set (including ground state, excited state, cation, anion, atom into an electric field, see Widmark et al. (1990)). In general, ANO basis set will require less contracted functions than the other basis to get the same results. Recently, all electron ANO basis sets, including correlation effects for all periodic system elements, have been generated (Roos et al. 2005). It has also been observed that for extremely accurate calculations, only ANO basis sets can provide the best answer (see, e.g., Martin et al. 1997).

A final type of approach regarding the one-electron basis sets is the combination of inner-shell pseudopotentials (including typically relativistic effects) with valence basis sets and the use of embedded potentials to represent atomic environments.

Methods for Excited States

Based on the methods described in the previous section, specific algorithms to deal with electronic excited states have been developed. In this section, the most commonly employed approaches will be briefly summarized (see also Merchán and Serrano-Andrés 2005; Serrano-Andrés and Merchán 2005).

Starting by the single-configurational methods that use the HF solution as reference wave function, an approach which has lost popularity because of its poor performance is the method named Configuration Interaction-Singles (CIS). The essence of the method is to consider that an excited state can be described by a singly excited determinant formed by replacing, with respect to the reference wave function, an occupied spin orbital with a virtual spin orbital. The drawbacks of such a description may be partially compensated if a linear combination of all possible single excited determinants is used to build the excited state wave function. In general, the CIS excitation energies are largely overestimated due to the absence of correlation energy effects. It is more common to find in the literature cases in which CIS yields the wrong order and state nature than the proper ones, simply because the differential correlation energy affects the excited states unevenly and because the intrinsic character of the states is multiconfigurational (Foresman et al. 1992).

In the light of the previous discussion, the logical method to deal with excited states should be multireference CI (MRCI) (Buenker et al. 2000). Consider a wave function of CI type expanded in a many-electron basis set of determinants. As in the H_2 molecule, it is possible to select a number of determinants to describe the correct dissociation limit. When the energy is minimized with respect to the coefficients of the expansion, the configuration interaction (CI) method is employed. It should be kept in mind that actual calculations are performed using either spin-adapted Configuration State Functions (CSFs: appropriate linear combination of Slater determinants) or determinants as a N -electronic basis set (Slater determinants lead to more efficient CI algorithms), whereas CSFs lead to shorter CI expansions and, obviously, spin eigenfunctions, i.e., singlet, doublet, triplet states . . .). In case that the expansion contains more than one configuration, the process is denoted as MRCI. The wave function $|\Psi\rangle$ is a multireference function and, at least, the singly and doubly excited determinants generated from each reference determinant $|m\rangle$ are taken into account. Unfortunately, MRCI-based approaches are restricted to molecular systems of small molecular size (containing up to 6–7 atoms), where dynamic correlation can be fully retrieved. Otherwise, truncation of the many-electron functions involved in the MRCI expansion might easily lead to large errors in the computed excitation energies.

Another type of methods applied to the calculation of excited states are the propagator approaches (Oddershede 1987). The underlying technique, also called Green's function approach, equation-of-motion or linear response theory in its different forms, can be applied to various types of methodologies: single- or multi-reference configuration interaction, coupled-cluster, or density functional.

The essentials of the technique consider that once a molecule is subjected to a linear time-dependent electric field fluctuating with frequency ω , a second-order property as the frequency-dependent ground-state polarizability of the system is well approximated by

$$\alpha_{\omega} = \sum_{i \neq 0}^{\text{states}} \frac{|\langle \Psi_0 | r | \Psi_i \rangle|^2}{\omega - \Delta E_i}, \quad (5)$$

where the denominator of the expression involves the frequency of the field and the excitation energies (ΔE_i) characterizing the excited states (Eq. 1), while the numerator of each term is the square of the transition dipole moment between the ground and the corresponding excited state. Using complex function analysis, it is possible to obtain the poles of the expression, that is, the values for which the frequency corresponds to the excitation energies and the denominator goes to zero, while the residues provide the numerators, in this case, the one-photon absorption matrix elements. The peculiarity of the propagator approaches is that the wave functions of the individual states are not necessarily computed to obtain excitation energies and transition probabilities, while its quality relies on the type of reference wave function. Except for very elaborated implementations, usual propagator approaches have also the same problems as all single-reference procedures.

The family of methods CCS, CC2, and CC3 is based on response theory (Koch and Jørgensen 1990). The CCS approach is equivalent to the single excited configuration interaction or Tamm–Dancoff approach. The iterative hybrid CC2 and CC3 procedures introduce approximations to account for the level of excitation. They have been defined for systems with closed-shell ground-states, although some Equation of Motion EOM-CC procedures also deal with open-shell ground state cases. In order to get accurate excitation energies and properties, the single-configuration coupled-cluster methods should include high excitation levels to compensate both the poor reference wave function and the multiconfigurational character of the excited states. CC-based methods are, up-to-date and in practice, the most accurate methods to compute excited states in small to medium size molecules with closed-shell ground states, but only for those states which are well described by singly excited configurations, in systems where the ground state has a clear single-configuration character, and close to the equilibrium geometry. Triple excitations have to be anyway included in the cluster expansion if accuracy is intended. The precision of the single-reference CC methods decreases in systems with open-shell ground states and vanishes (up to several eVs of error) for multiconfigurational cases, like the $2^1 A_1$ state of ozone. The inclusion of quadruple excitations, unpractical so far, would improve some of those results, although the only solution in prospect to beat in accuracy the lower level and less expensive multireference perturbation approaches such as CASPT2, is to use multireference coupled-cluster (MRCC) methods, in which the required excitation level will be expected lower. However, the development of such methods is still in their infancy, and the initial results are not very promising.

Before continuing with the *ab initio* procedures, in particular the MRMP theory most employed in this chapter, the use of DFT approaches for excited states will be discussed. The implementation, known with the unfortunate name of Time-Dependent DFT (TD-DFT) approach (no time-dependency is accounted for) should be expected to be able to deal with large systems were *ab initio* methods become too expensive. Unfortunately, these methods fail dramatically in too many situations: charge transfer states, multiconfigurational states, doubly or highly-excited states, and even introduce large and systematic errors in valence states of large π extended systems. In some cases, the deviations can be as large as 5–6 eV, especially in cases in which the ground state is poorly defined by the HF configuration. Even when many different parameterizations have been tried and different functionals developed in order to correct the flaws of the method, so far no single functional is able to solve most of them simultaneously. Much worse than that (and this is common for all single-configurational approaches), they cannot describe at all degenerate situations like conical intersections, which are the core of the quantum-chemical description of the excited states.

An hybrid derivation, known as DFT/MRCI is unarguably the best DFT-based procedure for excited states. It consists of an MRCI expansion with multiconfigurational wave functions replacing the HF orbitals with Kohn–Sham orbitals in the building of CSFs. The Hamiltonian, however, is heavily modified with empirical parameters, and only a few situations can be handled. The objective is to recover dynamic correlation by means of DFT and static correlation by means of MRCI. In this way, severe size-extensivity problems can be avoided even for systems with many valence electrons. Currently, optimized parameter sets for the effective DFT/MRCI Hamiltonian are available in combination with the B3LYP functional. The accuracy in energy is about 0.2–0.3 eV, and other properties are well balanced as well. Additionally, it is very appropriate to compute SOC, including a spin-dependent Hamiltonian (Grimme and Waletzke 1999; Kleinschmidt et al. 2001).

As already mentioned, a multiconfigurational description of the reference wave function helps enormously to recover the overall correlation effects. Starting from a good reference, the method used for such a recovery does not need to be extremely elaborated. That is why multiconfigurational second-order Møller–Plesset theory, the CASPT2 method, based on a Complete Active Space SCF (CASSCF) zeroth-order wave function, has become the most successful method for excited states. As this is the procedure in which most of the examples of the chapter will be based on, a more detailed description of the procedure will be given. Nowadays, the CASPT2//CASSCF methodology has proved the best ratio quality of the results/computational cost. At the CASSCF level (a particular case of MCSCF), both the many-electron-function coefficients of the MCSCF expansion and the coefficients included in the expansion of each molecular orbital are optimized simultaneously (see Eq. 3). Their variations are considered as rotations in an orthonormalized vector space. In the CASSCF method, the orbitals are classified in three categories, depending on the role they play in building the N -electron wave function: inactive, active, and secondary orbitals. Inactive and active orbitals are occupied in the wave functions, whereas the remaining of the orbital space, given by

the size of the one-electron basis set employed, is constituted by secondary orbitals, also called external or virtual. Inactive orbitals are doubly occupied in all the CASSCF configurations. The rest of the electrons (called active electrons) occupy active orbitals. The CASSCF wave function is formed by a linear combination of all the possible configurations that can be built by distributing the active electrons among the active orbitals and are consistent with a given spatial and spin symmetry. That is, in the configuration space spanned by the active orbitals, the CASSCF function is complete (CAS-CI space, equivalent to FCI). Inactive orbitals are also optimized in the variational process, but they are treated as in the restricted HF function. The CASSCF energy is invariant to rotations among the active orbitals (Roos et al. 1979).

Essentially, we construct for a given state a multiconfigurational wave function which includes all configurations generated by a set of active orbitals and active electrons that fulfils spin and spatial symmetry requirements. This provides the nondynamic correlation effects due to configurations which are very close in energy. Several states that belong to a same symmetry are usually computed by means of a State-Average (SA) CASSCF calculation, where a functional of energy is defined as average of a number of states, that, if required, although it is not recommended, can be weighted. From a SA-CASSCF calculation, a single set of average orbitals and a number of orthogonal wave functions equal to the number of roots used in the average process are obtained. In this manner, it is sometimes possible to overcome the problem of “root flipping,” that is, the interchange of roots along the CASSCF optimization procedure. For a given spatial and spin symmetry, the treatment of excited states is preferably performed by using SA-CASSCF calculations. In principle, it is also possible to make a single CASSCF calculation for higher roots, optimizing just one state. Nevertheless, experience shows that in most cases it can only be achieved for the second root of a given irreducible representation. Wave functions obtained in a SA-CASSCF calculation are orthogonal among them, whereas those obtained from different CASSCF calculations are not. In the latter cases, the wave function is rather poor and cannot be used for a further correlated calculations, although sometimes it may be useful to perform CASSCF optimizations.

On the other hand, the Restricted Active Space Self-Consistent Field (RASSCF) method is a more general extension of the CASSCF method. Now, there are three subspaces within the active orbitals: RAS1 (orbitals that are doubly occupied except for a maximum number of holes allowed in this orbital subspace), RAS2 (in these orbitals, all possible occupations are allowed), and RAS3 (orbitals that are unoccupied except for a maximum number of electrons allowed in this subspace). CASSCF calculations can be performed by allowing orbitals only in the RAS2 space. A single reference SDCI wave function is obtained by allowing a maximum of two holes in RAS1 and a maximum of two electrons in RAS3, while RAS2 is empty (Malmqvist et al. 1990; Olsen et al. 1988; Fig. 8).

Either by using CASSCF or RASSCF, the active space provided by the user of a CASSCF calculation represents a key point to obtain accurate theoretical predictions once dynamic correlation has subsequently been taken into account,

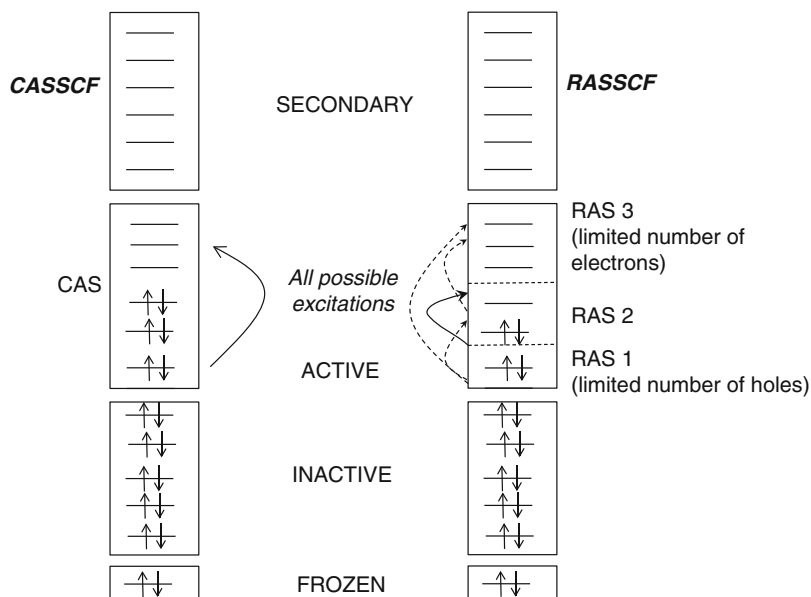

Fig. 8 CASSCF and RASSCF methods

for instance, at the CASPT2 or RASPT2 levels. The properties of a CASSCF wave function depend on the active space. Thus, a valence CASSCF is size-extensive (the computed energy within a given methods scales linearly with the number of particles) and the corresponding CASPT2 results become also nearly size-extensive (formally the CASPT2 method is not size-extensive, but it is in practice, in particular the MOLCAS implementation). As in any quantum-chemical approach, one has to make sure that the method has enough flexibility, i.e., the active space is the appropriate one, to describe the chemical process under consideration. It is important to mention here the power of the CAS State Interaction (CASSI) approach, which provides orthogonal wave functions and transition densities from CASSCF or RASSCF wave functions optimized independently for a number of excited states of whatever symmetry (Malmqvist and Roos 1989).

Valence-bond methods have increased its applicability recently. One example is the CASVB (complete active space valence bond) method. A CASVB wave function can be obtained simply by transforming a canonical CASSCF function and readily interpreted in terms of the well-known classical VB resonance structures. The total CASVB wave function is identical to the canonical CASSCF wave function. In other words, the MO description and the VB description are equivalent, at least at the level of CASSCF. The CASVB method provides an alternative tool for describing the correlated wave functions.

The CASPT2 (complete active space perturbation theory to second order) method (Andersson et al. 1992) includes the remaining dynamic correlation due to short-range electronic interactions. This method can be seen as a conventional non-

degenerate perturbation theory, that is, a single state is independently considered, with the particularity that this zeroth-order wavefunction is multiconfigurational (CASSCF). The wave function is corrected up to first order and, consequently, the energy is corrected up to second order. The set of functions required to compute the first-order correction of the wave function is formed by those that interact with the zeroth-order wave function through the Hamiltonian in the Rayleigh–Schrödinger perturbation theory, and it is known as the first-order interacting space. Taking into account the one and two particle nature of the Hamiltonian, the first-order interaction space, called hereafter V_{SD} , comprises the functions generated by singly and doubly excited configurations from the zeroth-order (CASSCF) wave function. As a matter of fact, the configurational space is divided in four subspaces: V_0 (one-dimension space expanded by the reference function $|0\rangle$ of the studied states), V_K (orthogonal to $|0\rangle$ in the restricted FCI subspace used to generate the CAS function), the aforesaid V_{SD} (space expanded by the singles and doubles replacements from $|0\rangle$), and $V_{TQ} \dots$ (space that contains the excitations of higher order). Regarding orbitals, they are classified into frozen (doubly occupied, not correlated), inactives (doubly occupied in the reference function), actives (with any occupation, between 0 and 2, in the reference function) and secondary (empty in the reference function). Recently, a new shifted zeroth-order Hamiltonian named IPEA has been designed and set up with a value 0.25 a.u. into the default for the MOLCAS implementation (Ghigo et al. 2004). The new formulation solves previous effects for open-shell cases in which the correlation effects were overshoot. The net effect of this correction is to slightly increase the excitation energies. In any case care has to be taken when comparing present with previous CASPT2 results.

The normalized wave function is corrected up to first order. The weight of the reference function, C_0^2 , can be used as a simple and rapid criterion of quality for the perturbation treatment carried out. Ideally, in order to get a fast convergence in the perturbation series, the weight should be close to unity. Nevertheless, its value depends on the number of correlated electrons. Thus, upon enlarging the molecular system the reference weight decreases. The electronic excited states considered should have a similar magnitude for the weight as compared to the ground state, employing the same active space. Sometimes intruder states appear in the second-order calculation, which are normally related to the occurrence of large coefficients in the first-order expansion, leading to a low value for the reference weight. Analysis of the states with large coefficients (intruder states) may give a hint about the type of reformulation in the perturbation partition necessary to overcome the problem. Thus, a new CASSCF calculation might be designed comprising in the active space the MOs implied in the description of the previous intruder states. It is the proper action to be taken when intruder states are strongly interacting with the CASSCF reference wave function, because it points out to obvious deficiencies in the choice of the active space. Intruder states are often present in the treatment of excited states of small organic compounds when the active space does not include the full π valence system. Thus, the low weight for the zeroth-order wave function in such a case just tells us that the active space has to be enlarged in a way that previous intruder states would be treated variationally, that is, they should be moved to the

active space. It is also frequent to find calculations where the reference weight of the excited state is “somewhat low” compared to that of the ground state, but a particular state cannot be identified as intruder in the first-order wave function, which is instead characterized by a large number of low-energy minor contributions. It occurs often in the simultaneous computation of valence and Rydberg states, where the one-electron valence basis set has been augmented with Rydberg-type functions. This is a typical case when using large and diffuse basis sets like ANOs. We have to face then accidental near-degeneracy effects, implying weakly interacting intruder states, and the level-shift (LS) technique is especially useful in order to check the validity of the perturbation treatment performed. The level-shift CASPT2 (LS-CASPT2) method removes efficiently weak intruder states by the addition of a shift parameter ε , to the zeroth-order Hamiltonian and a subsequent back correction of its effect to the second-order energy.

Many times, one has to apply both strategies: enlargement of the active space to overcome the problem of severe intruder states, and, with the enlarged active space, the LS technique is applied in order to minimize the effect of weakly interacting intruder states. Since a constant added to a linear and Hermitian operator (like \mathbf{H}) does not affect its eigenfunctions but it is added to its eigenvalues (let k be a constant; as long as $\mathbf{H}\Psi = E\Psi$, then $(\mathbf{H} + k)\Psi = \mathbf{H}\Psi + k\Psi = E\Psi + k\Psi = (E + k)\Psi$), the energies of the states may be altered, but this is a price that must be paid. However, it is desirable that the shift parameter is as small as possible. For instance, results at $\varepsilon = 0.0$ (standard CASPT2), 0.1, 0.2, 0.3, and 0.4 a.u. are sufficient to establish the proper behavior of the LS-CASPT2 results. It is extremely dangerous to rely on just one result because the appearance of an accidental near degeneracy might lead to large errors in the excitation energies. In order to demonstrate the proper performance of the LS-CASPT2 technique, calibration calculations of that type always have to be carried out. The best choice for ε is the lowest possible value capable of removing intruder states. In order to avoid singularities, currently the technique so-called imaginary level-shift should be employed. The dependence of the energy on the imaginary level-shift parameter is of minor relevance (see Forsberg and Malmqvist 1997; Roos et al. 1996).

Finally, the multistate CASPT2 (MS-CASPT2) procedure has to be mentioned. It represents an extension of the CASPT2 method for the perturbation treatment of chemical situations that require two or more reference states. The procedure implies the use of an effective Hamiltonian in which the diagonal terms are the single-root, and non-orthogonal, CASPT2 solutions, whereas the interacting terms form the off-diagonal components. The diagonalization of the Hamiltonian, after symmetrization, provides a set of MS-CASPT2 energies and orthogonal states ready to describe situations such as avoided crossings and near-degeneracy of valence and Rydberg states, which cannot be fully accounted for by just using a single-reference perturbation treatment. A new wave function, named Perturbatively Modified CAS-CI (PMCAS-CI), is obtained built as a combination of the previous SA-CASSCF states, which has been in many cases improved from the previous set. This approach is not free of problems, as it will be discussed along this chapter (Finley et al. 1999; Serrano-Andrés et al. 2005).

The CASPT2 approach, especially when combined with ANO-type basis set functions, has proved to give a balanced and accurate description of all types of excited states and electronic structure cases, independently of their nature. The energy and the wave function are treated in general in an unbiased way. As all other quantum-chemical methods, the results heavily rely on the proper determination of the structural parameters, that is, the geometry optimizations. Because of their computational cost, geometries are obtained at lower levels of calculations than energies. In many cases, analytical gradients, more convenient for optimization processes, are not available at the highest level of calculation (they are, for instance, at the MRCI level, see Shepard et al. (1992) or for CASPT2 applicable to small molecules, see Celani and Werner (2003)). This is why most of the calculations use the mixed strategy, for instance, CASPT2 energies and CASSCF geometries (CASPT2//CASSCF), but also MRCI//CASSCF or CC3//CC2. Some problems related with this inconsistency will be discussed during the chapter.

It can be finally commented that, recently, the RASPT2 approach, in which a RASSCF wave function is used as reference for multiconfigurational perturbation theory has been made available, using all tools related with CASPT2, for instance allowing MS-RASPT2 calculations (Malmqvist et al. 2008). Benchmark studies are currently under way in order to determine the best partition schemes for the RASSCF active spaces. Prospectively, the approach will largely extend the applicability of the MRMP calculations.

How to Compute Excited States

How to Start: Selection of Goals, Methods, Geometries

Quantum-chemical methods provide information for excited states directly applicable to explain and predict the spectroscopy, photophysics, and photochemistry of molecular systems. A balanced description of the different electronic states is required in order to obtain the initial, basic data, that is, energy differences and transition probabilities, in an accurate way. This goal is a much more difficult task for excited states as compared to the ground state. First, one has to deal with many classes of excited states, each one showing different sensitivity to the amount of electronic correlation energy and, also, flexible one-electron basis functions able to describe all effects simultaneously are required, in general larger than that used in ground-state quantum chemistry. Then, it is necessary to compute extremely complicated potential energy hypersurfaces where the number of minima, transition states, and surface crossings like conical intersections, is multiplied. Because of the inherent complexity of the problems, the methods and algorithms to compute excited states are not as widespread as for ground states or are still under development.

In this section, we are going to illustrate different examples for the calculation of excited states using presently available quantum-chemical techniques. In each subsection, we will proceed in the same manner, first, by describing an actual

example taken from the literature, and, after, practical aspects which explain the choices made. The results obtained will be then discussed, including new cases if necessary.

Before introducing the first example, let's make some comments on the initial way to tackle the problem. Our goal, in principle for a typical ground-state closed-shell case, will be focused in the lowest-lying singlet and triplet excited states of the molecule. Most of the interesting spectroscopy and photochemistry will take place in the low-lying states, although higher states are relevant in other contexts. Properties of interest provided by static electronic structure quantum-chemical calculations that help to rationalize the photophysical and photochemical processes in a molecule are: molecular structures, charge and spin distributions, electronic and vibrational energies, oscillator strengths, dipole and transition moments and their directions, radiative lifetimes, nonadiabatic, vibronic, spin-orbit, and electronic couplings. In a second step, in reaction dynamics calculations, reaction rates, lifetimes, and population distributions can be provided.

Which method is the most appropriate for the purpose of that research? The initial questions to answer is what is the goal of the study, how far can it go, how many questions can be solved, and, especially, which is the accuracy required in the study. All this depends in most cases on the complexity and the size of the system. Of course, the best ratio quality/CPU time should be looked for, but it is useless to carry out calculations, no matter how cheap they are, with methods that cannot provide accuracy to make conclusive predictions. Apart from checking carefully the literature, calibrations will be typically necessary. Both methods and basis sets should be tested, and several steps to approach to the problem are maybe necessary. We can start by using less expensive semiempirical classical or TD-DFT methods in order to understand the problem and its requirements, and then move to more sophisticated coupled-cluster or multiconfigurational approaches, depending on the goals of the research. The same with basis sets. 6-31G-type basis sets are practical because of their reduced time requirements, but they are less accurate and in many cases using them may degrade too much our results. Calibrating the obtained values with fully correlated methods or higher-quality basis sets like Dunning's correlation consistent or ANO-type basis sets is always a requirement. Obviously the program package we should use has to balance all aspects we have mentioned. Normally a combination of them will be necessary: versatile programs, such as GAUSSIAN, GAMESS, or QCHEM; packages specialized in DFT implementations, like ADF, TURBOMOLE, or NWCHEM; suites focused on CC algorithms such as DALTON or ACES II; or programs especially designed for multiconfigurational methods like MOLCAS or MOLPRO, these more generally applicable to the calculation of excited states.

A point to bear in mind is that there are different types of excited states, and each of them has different theoretical requirements. A valence state can be viewed as a promotion from one occupied molecular orbital to a virtual one. On the other hand, a Rydberg state, in a simple MO theory, is the result of exciting one electron from one occupied molecular orbital to an atomic-like orbital of higher quantum number. Valence excited states are more compact than the diffuse Rydberg states. A valence

state can be denoted as covalent or zwitterionic according to the type of valence bond (VB) structures. Covalent and zwitterionic states are described by hole-hole and hole-pair VB structures, respectively. What is more, the label ionic is reserved to states with an actual charge separation. On the other hand, if a pair of nearly degenerated nonbonding orbitals is occupied with a total of two electrons in the ground state, the molecule is called biradical. In addition, there are charge transfer states, in which an electron is transferred from one occupied orbital of a molecule to a virtual orbital of another molecule (or the same molecule, if it is intramolecular).

Excited states can be also classified according to the main types of configurations involved in their description, in relation to the ground state: singly excited states, doubly excited states, and so on. Rydberg states are usually well described by only one singly excited configuration. Multiconfigurational singlet excited states with a large contribution of doubly excited configurations are normally covalent. Singlet excited states of zwitterionic character are described by one or several singly excited configurations. In anionic systems, new types of excited states are present, such as the resonance states or the multipole-bound (dipole, basically) states, where the bonding energy is the result of the interaction between the additional electron and the multipole moments of the molecule.

Molecular Photophysics: Computing Absorption and Emission Spectra

An Application Example: Psoralen

The simplest approach to the electronic state problem is the determination of the photophysics of an isolated molecule, that is, to reproduce its absorption and emission spectra. As mentioned, let's first describe in its full extent a case, the psoralen molecule, and later the choices made can be analyzed (see Serrano-Pérez et al. 2006, 2008a, b, c, d).

Furocoumarins (also named psoralens, see Fig. 9) are a class of heterocyclic compounds with a known phototherapeutic activity. These systems have been found to possess mutagenic properties when applied in conjunction with near UV-A light (320–400 nm) exposure. The technique so-called PUVA therapy (psoralen + UV-A) has been specifically designed to treat different skin disorders such as psoriasis and vitiligo. It is generally assumed that there is an oxygen-independent mechanism, which implies a [2 + 2]-photocycloaddition of psoralen and a pyrimidine DNA base monomer, and there is also an oxygen-dependent mechanism, in which energy transfer between the furocoumarin and molecular oxygen present in the cellular environment is produced generating cytotoxic singlet molecular dioxygen. It is believed that the state protagonist of the photosensitizing action, in both cases, is the lowest-lying triplet excited state of psoralen. Initially, our main goal is to describe the absorption spectrum of the molecule, and we do it by computing the lowest-lying singlet and triplet states at the optimized structure of the ground state (i.e., those distances, angles, and dihedral angles which make the energy minimum), what is

Fig. 9 Psoralen labeling.

The *arrow* defines the positive angles of both the dipole moment and electronic transition moment directions with respect to the pseudosymmetry long axis

typically known as the Franck–Condon geometry. Later, the mechanisms for triplet state population can be determined.

Using CASSCF multiconfigurational wave functions as reference, the second-order perturbation theory through the CASPT2 method was employed to include dynamic correlation energy in the calculation of the electronic excited states. The imaginary level-shift technique was employed in order to prevent the effect of intruder states. A shift parameter of 0.3 a.u. was selected by checking the stability in the excitation energies. The molecular symmetry was constrained to the C_s point group. An atomic natural orbital (ANO-L)-type basis set, contracted to C,O [4s3p1d]/H [2s1p] was used throughout. The carbon and oxygen 1 s core electrons were kept frozen in the second-order perturbation step. Geometries were obtained by computing analytical gradients at the RASSCF level of calculation for the ground and the lowest singlet and triplet excited states. In the optimization of the A' states, an active space of 14 a'' active orbitals and 16 electrons, i.e., the full π system of the molecule, has been employed, and up to quadruple excitations were considered (eight orbitals in RAS1 space and six orbitals in RAS3 space). Within the irreducible representations (a' , a'') of the C_s group, this active space can be labeled as (0, 14). An additional oxygen lone-pair orbital was included in the active space (1, 14) in order to optimize the lowest A'' excited state. In all the remaining calculations, CASSCF wave functions were generated as state-average (SA) CASSCF roots of a given symmetry. Based on preliminary RASSCF calculations and using the criterion of the largest natural orbitals occupations for the states of interest, the CASSCF active space was reduced to include 12 active electrons and 12 active orbitals (0, 12) for A' roots and 14 active electrons and 13 active orbitals (1, 12) for A'' roots. The CAS state interaction method (CASSI) was used to compute transition properties, including the spin-orbit coupling (SOC) elements between selected states.

At the Franck–Condon (FC) geometry, the lowest singlet excited states $2^1A'(\pi\pi^*)$, $1^1A''(n\pi^*)$, and $3^1A'(\pi\pi^*)$ lie at 3.98, 5.01, and 5.03 eV, respectively (see Table 1). Whereas the transition to the $n\pi^*$ state is predicted with negligible intensity, the $\pi\pi^*$ states have related oscillator strengths of 0.027 and 0.107. Unlike other states, the $3^1A'$ state has a high dipole moment, 8.70 D, differing by more than 2.5 D from that of the ground state, and therefore the associated transition is expected to undergo a red shift (bathochromic effect) in polar environments. The recorded absorption spectra in different solvents, from cyclohexane to water,

Table 1 Computed excitation energies ΔE (eV) at CASPT2 level, oscillator strengths f , dipole moments $\mu(D)$, dipole moment directions μ_{dir} (deg), and transition dipole moment directions TDM_{dir} (deg) for the low-lying electronic transitions of psoralen

State	ΔE	f	μ	μ_{dir}	TDM_{dir}
$1^1A'$	—	—	6.25	128	—
$2^1A'(\pi\pi^*)$	3.98	0.027	6.50	132	4
$1^1A''(n_o\pi^*)$	5.01	0.000	2.07	130	—
$3^1A'(\pi\pi^*)$	5.03	0.107	8.72	132	5
$4^1A'(\pi\pi^*)$	5.22	0.064	7.07	−23	−10
$5^1A'(\pi\pi^*)$	5.30	0.331	7.07	−37	102
$6^1A'(\pi\pi^*)$	5.70	0.091	7.37	−37	30
$1^3A'(\pi\pi^*)$	3.27	—	5.40	124	—
$2^3A'(\pi\pi^*)$	3.55	—	5.35	125	—
$3^3A'(\pi\pi^*)$	4.08	—	5.48	127	—
$1^3A''(n\pi^*)$	4.85	—	2.15	111	—

display a weak and structured band ranging from 360 to 270 nm (3.44–4.77 eV). Depending on the band resolution and the environment, one or two maxima near 330 and 280 nm (3.76 and 4.43 eV, respectively) have been described. The present computed results suggest that this set of features can be better assigned just to the $2^1A'(\pi\pi^*)$ transition, with the weak $n\pi^*$ band lying beneath. In that case, the observed band profile should be attributed to vibrational structure. This explanation is not unlikely, considering that a noticeable rearrangement of the molecular bond distances occurs at the $2^1A'$ minimum.

Although less relevant regarding the phototherapeutic properties, we will describe the higher-energy region of the absorption spectrum. Transitions to the $4^1A'$ (5.22 eV) and $5^1A'$ (5.30 eV) ($\pi\pi^*$) excited states have oscillator strengths of 0.064 and 0.331, respectively. The recorded spectra show a single and sharp band peaking near 248 nm (5.00 eV) in cyclohexane and 240 nm (5.16 eV) in ethanol and water. In principle, the observed feature can be assigned to transition to the $3^1A'$ state at 5.03 eV. Moreover, taking into account our computed results, an additional and more intense band can be expected at higher energies (5.30 eV). The measured band is probably a combination of both transitions.

Three other $^3A'\pi\pi^*$ states are next in energy at 3.55, 4.08, and 4.66 eV. The nature of the low-lying transitions of each symmetry, which are those basically responsible for the photophysical properties of psoralen, can be graphically described by computing the differential electron density plots as displayed in Fig. 10. Transition to the $S_1\pi\pi^*$ state is mainly benzene-like, with the charge migration concentrated in the central benzenoid ring. On the contrary, that related to the $T_1\pi\pi^*$ state has its major contributions in the pyrone ring, with high participation of the carbonyl oxygen and a shift in the density away from the pyrone ring C_3 – C_4 bond, which will be later discussed as an essential feature of the photophysics of the system. Also in Fig. 10, we find the expected differential density plots of the $n\pi^*$ states centered on the carbonyl group. Transition dipole moment directions (TDM_{dir}) indicate that the three lowest $\pi\pi^*$ features have nearly parallel polarizations, that is, they are aligned with the long axis of the molecule, while

Fig. 10 Differential electron density for the main valence transitions in psoralen computed at the ground-state optimized geometry. The electron density is shifted upon light-induced excitation from *darker* to *lighter* regions

transition to the $5^1A'$ state has essentially perpendicular polarization. Regarding the vertical excitations to the triplet states, the $1^3A'\pi\pi^*(T_1)$ state lies at 3.27 eV, near 0.7 eV below the $2^1A'(S_1)$ state.

Fluorescence has been reported for psoralen in polar solvents starting (T_0) at 350 nm (3.54 eV) with a maximum at 409 nm (3.03 eV). Phosphorescence has also been recorded in solution with band origin at 456 nm (2.72 eV) and a maximum between 460 and 490 nm (2.7–2.5 eV).

The fluorescence and phosphorescence quantum yields were measured in ethanol as $\Phi_F = 0.019 - 0.02$ and $\Phi_P = 0.13$, respectively. The obtained ratio Φ_F/Φ_P is approximately 7.1. The total phosphorescence decay time (τ_P) has been reported 1.1 s in glycerol-water and 0.66 s in ethanol. With those data, the phosphorescence radiative lifetime $\tau_{\text{rad}} (= \tau_P \cdot \Phi_P)$ can be therefore expected between 8 and 5 s.

The low-lying singlet excited state $2^1A'(\pi\pi^*)$ is responsible for the lowest-energy absorption and emission fluorescence bands (see Table 2). Vertically, at the ground-state geometry, the transition energy is computed to be 3.98 eV and, upon relaxation of the geometry, the band origin (T_e) decreases to 3.59 eV. This means that the range of absorption goes from 3.59 to 3.98 eV, well within the PUVA action. A similar relaxation is observed experimentally between the lowest-energy absorption band maximum and the band origin. The structural changes of the computed equilibrium geometries for the ground (S_0) and the $2^1A'(\pi\pi^*)$ states affect the bond alternation of the system, mainly in the central ring (cf. Figs. 10 and 11), as expected from the differential charge density plots. By using the Strickler–Berg relationship, a fluorescence radiative lifetime of 74 ns is calculated for the S_1 state. The low-lying $1^1A''(n\pi^*)$ state (vertically S_2) becomes relaxed by more than

Table 2 Computed and experimental excitation energies (eV) and emission radiative lifetimes (τ_{rad}) relevant for the photophysics of psoralen

Theoretical (CASPT2)

Fig. 11 Spin density for the low-lying triplet states in psoralen computed at the ground-state optimized geometry

1 eV upon geometry optimization. Although the $1^1A''(n\pi^*)$ minimum belongs to the S_1 hypersurface, the final T_e value is about 0.3 eV higher in energy than the computed and measured band origin for $2^1A'(\pi\pi^*)$. Therefore the $n\pi^*$ state is not a plausible candidate for the fluorescence, which is better attributed to the $\pi\pi^*$ state.

The $1^3A'(\pi\pi^*)$ state is the clear protagonist of the phosphorescence. The computed band origin at 2.76 eV perfectly relates to the observed value in solution at 2.72 eV. The relaxation energy is about 0.5 eV. The largest structural change is produced in the C_3 – C_4 bond of the pyrone ring, which enlarges by near 0.13 Å from the ground-state value. The computed spin population, displayed in Fig. 11,

is mainly placed on each of the carbon atoms forming the bond. In that way, psoralen becomes highly reactive in its lowest triplet state through its pyrone C₃–C₄ bond. This finding is the cornerstone of the photophysics of psoralen, which has been repeatedly proposed to take place through a reactive triplet state. The computed phosphorescence radiative lifetime is 28 s, somewhat higher than those estimated experimentally from the quantum yield and the total relaxation time, 5 and 8 s. For the $2^3A'(\pi\pi^*)$ state, the spin population is placed mainly on the carbon atoms forming both C=C bonds, that is, C₃–C₄ (pyrone) and C₄, –C₅, (furan).

Practical Aspects

Selection of Geometries

Any quantum-chemical calculation starts with the definition of the molecular geometry. As mentioned in section “[Methods, Advantages, and Drawbacks](#),” we can safely assume that the absorption spectrum is initiated at the ground state equilibrated geometry. An optimization is therefore required, in principle at the highest reasonable level of theory. DFT (with a proper functional) works well for most closed-shell cases, and it is a fully correlated method. Other ab initio methods that also include all correlation energy will be more accurate, but also more computationally expensive: MP2, CCSD, CASPT2 (with numerical gradients for small molecules). Although the best choice is not to use any symmetry restriction and let the system to find the lowest-energy solution, it is possible to make approximations and, for instance, let the system to be planar (C_s point group), like in the case of psoralen and save computational time, especially if experiment give some indication along these lines. In order to confirm that the obtained point is a true minimum, it would be desirable to perform a frequency analysis, although computing Hessians (second derivatives) is an expensive task. If too demanding, maybe is feasible to compute the Hessian at lower levels of theory and check the outcome. Of course, if possible, one should compare the result with experimental (X-ray or electron diffraction, for instance) data. To compute emission, we have to optimize excited states too, a more difficult task than for ground states only at reach of few methods: CASSCF, RASSCF, CASPT2, and CCSD, to mention the most reliable ones (the two latter only for small systems). If the ground state is optimized with a better method than the ground state, some unbalance in the results may occur. It can be a good idea to get the different states optimized at the same level, like CASSCF or RASSCF. The choice of RASSCF in the psoralen example is motivated by the impossibility of including all π space into a CASSCF calculation. Although safe in many cases, the exclusion of some MOs, like, for instance, the lowest-energy nodeless π orbital, may lead to problems if the excluded orbital, instead of becoming delocalized and having then no biased effect, tends to localize unbalancing the calculations. It is worth noticing that CASSCF (RASSCF) gives very good geometries in π -conjugated systems, probably because of some compensation between the obtained single and double bonds lengths.

Accuracy of the Excitation Energies and How to Compare with Experiment

It is time to decide if the method and strategy employed is accurate enough to solve the problem. In principle, the accuracy should be established by previous experience if the electronic structure problem is under control. We cannot expect a TD-DFT calculation to be more accurate than 0.5–0.4 eV, much less if the problem has no closed-shell ground state or a charge transfer character (except for specific functionals like CAMB3LYP, see Peach et al. (2008)). Choosing one functional for each molecule makes theoretical chemistry useless as a predictive tool. It is much better to stick into one procedure and know their limitations. Coupled-cluster results, EOM-CC(T) or CC3, are much more accurate, sometimes near 0.2–0.1 eV if pushed to the limit, but this also relies on being far from degenerate situations or multiconfigurational ground states (see Grein (2009), 1^1B_2 state of ozone: CCSD(T) 1.81 eV vs. best estimation 4.11 eV, or Kowalski (2005), 2^1A_1 state of ozone: EOMCCSD 9.82 eV vs. best estimation 4.33 eV). Multiconfigurational calculations, CASPT2 in particular, can reach also 0.2–0.1 eV in most cases, although the result may degrade if the reference is not well described. More important that all we have said: accuracy with respect to what? Many studies discussing the precision of a method for excited states compare their vertical excitation energies with what experiment initially offers, absorption maxima. This is wrong and misleading. A vertical excitation energy computed at the electronic ground-state equilibrium geometry is a purely theoretical concept without experimental counterpart. The Franck–Condon principle relates such value with the absorption (not emission) maximum, but this approximation will be true only in the case that the ground and excited minima take place at the same geometry. Apart from that, an experimentally determined absorption maximum depends on the concentration of the sample, the apparatus, the environment, the temperature, the pressure, etc. In the most favorable case, vertical absorption and emission maximum will differ by near 0.1 eV from an experimental gas-phase or molecular beam maximum. Typically, those cases display as maximum feature the band origin or T_0 transition. Indeed, the true experimental data to compare with this band origin, that theory computes as the energy difference between the states minima, also named the adiabatic energy difference, T_e if it is just electronic energies or T_0 – the true comparable value – if the zero-point energy correction has been included. The situation is even worse for the emission, where the FC principle is hardly fulfilled. In the psoralen example, a good agreement has been obtained for the band origins: computed T_e 3.57 and 2.76 eV and measured T_0 3.54 and 2.7 eV for fluorescence and phosphorescence, respectively. In most cases, T_e and T_0 differ by close to 0.1 eV. On the other hand, the vertical emission is typically much lower than the emission maxima.

How to Deal with Symmetry

Unfortunately, the topic is too extensive to be treated here. For practical cases, the reader is referred to the advances examples in the MOLCAS program manual (see <http://www.teokem.lu.se/molcas>). Group theory may be very useful in a calculation on excited states, especially because it allows dividing the states in each one

of the irreducible representations (since a symmetry operation leaves a molecule unchanged) and consequently reduce the computational effort. Unfortunately, the molecular symmetry is typically only found for ground states, and most of the photochemistry takes place at distorted asymmetric structures, especially for organic systems. Linear molecules or many inorganic complexes can however be studied making an extensive use of the symmetry, as well as other systems if absorption, and sometimes emission, spectra are studied. Symmetry is particularly useful in multiconfigurational calculations to reduce the active space requirements. Also, symmetry permits prediction of intensities when following selection rules or analysis of the polarization or dipole moment directions. Normally, one should have at hand the character tables and also the Wigner–Witmer rules, as those found in Herzberg books. Finally, it is necessary to warn about symmetry breaking problems, in which a bad selection of the method or the active space may lead to find spurious lower-energy solutions.

How to Obtain Intensities and Band Shapes: Vibrational Contributions

Apart from the energies, computing electronic oscillator strengths, f , provides information about the relative intensity of the different transitions, initially for those states allowed in one-photon (optical) spectroscopy. Group theory indicates that one-photon allowed transitions of the molecule are those in which the direct product of the symmetries of the initial state, the corresponding dipole moment component (x , y or z), and the final state belong to the totally symmetric irreducible representation of the point group of the molecule:

$$\int \psi_m^* \hat{d}_{el} \psi_n d\tau_{el} \Rightarrow \Gamma(\psi_m) \otimes \Gamma(\hat{d}_{el}) \otimes \Gamma(\psi_n). \quad (6)$$

For instance, in the case of a C_S molecule like psoralen (in the XY plane), the allowed transitions are those in which the aforesaid direct product is A' . Otherwise, the transition is forbidden. In other words, from the ground state A' , the accessible states are A' if the light is x -polarized or y -polarized, and A'' if the light is z -polarized. If the light is x -polarized, for instance, the transition $A' \rightarrow A'$ is allowed, whereas the transition $A' \rightarrow A''$ is forbidden. The magnitude of the adimensional f has to be compared to the area beneath the band representing the transition, not to the height. Frequently, especially in gas-phase spectra, weak bands such as the Rydberg transitions are the highest because they sit on top of the more intense, although broader, valence bands. Notice that the range of energies of a band depends on the length of the vibrational progressions, which, in turn, relies on the difference in geometries with the ground state. The larger is the difference, the broader and extended will be the band. Flexible systems like NH_2 or $C=O$ -based spectra like that of formaldehyde extends their valence bands and spread their intensity by several eVs. In many occasions it may be required to compute the vibrational profile of different electronic bands and plot them together. This is an expensive task because, requires the calculation of Hessians, FC factors, and sometimes the derivatives of such factors and of TDMs in order to obtain vibrational TDMs. This is, however,

the only procedure to elucidate complex cases, for instance, that of the lowest single valence 5.5–6.5 eV band of pyrrole, which contains two valence and four Rydberg bands which have all to be resolved (see Roos et al. 2002). Ideally, and in order to get all actual excitation bands, calculations on vibrational TDMs should be complemented with the inclusion of vibronic couplings, in which more than one electronic state is considered at the same time (breaking the Born–Oppenheimer approach), an example of what can be found in the pioneering studies of Domcke and coworkers on the pyrazine molecule (Domcke et al. 1993).

How to Add Environmental Effects

Adding the effects of the environment for excited states accurately is, if possible, even more complex than for the ground state. Usual procedures use cavity models such as Onsager's or the Polarized Continuum Model (PCM), with the additional consideration of the non-equilibration of the electronic response for the excited states that leads to divide the reaction field in slow, inertial, and fast, optical, parts. Results obtained with cavity models cannot be expected to be as accurate as those for the isolated system when compared with gas-phase results, among other things, because using large basis sets as those required for excited states will force the charge to leave the cavity and provide non-physical results. In many cases, the information yielded by the dipole moment of the states will be informative enough for qualitative purposes. In the psoralen example, it was discussed how states with dipole moments larger than that of the ground state were expected to stabilize in polar solvents (and undergo a spectral red-shift) than those with smaller dipole moments (blue-shift), typical case of the $n\pi^*$ states, which, additionally, tend to directly interact with protic solvents forming hydrogen bonds and pushing the excitation energy up in energy, sometimes even 0.5 eV. These interactions cannot be included by the cavity models and specific molecules have to be applied, even several solvation shells. Careful microhydration experiments allow nowadays comparison with such type of calculations.

Solvation is a very dynamical phenomenon which requires also the inclusion of statistical effects. More sophisticated studies require the employment of dynamical approaches making use of statistical mechanics, such as Monte Carlo type of calculations. Solvent molecules can be then simulated by point charges (like in QM/MM approaches as it will be discussed later) and dynamical time shots with their positions taken for a subsequent quantum chemical calculation. The required property will be obtained as an average of the different conformations, as some studies on 2-aminopurine reported recently have shown.

Active Spaces for Multiconfigurational Methods

As a large part of studies on excited states, and especially in photochemistry, employ multiconfigurational approaches, it is necessary to understand the process of selection of an appropriate active space (AS) for such computations. An active space should contain all orbitals and electrons relevant for the chemical process under study. The size and nature of the AS define the type of states and processes the multiconfigurational method will compute. Obviously, there is no single choice,

and the size is limited to 14–15 or 30–30 orbitals/electrons in CASSCF and RASSCF calculations, respectively, depending on the type of partitions made. It is important to emphasize that the selection depends on the problem. If one is only interested in low-lying excited states, maybe a small AS is enough for that purpose. On the other hand, more states imply larger ASs. In photochemistry the situation is worse, because the AS must be flexible enough to include all MOs participating in the process in all different regions of the PEHs which are chemically relevant. For instance, each bond that breaks means that the AS should contain both the corresponding bonding and antibonding MOs. In the psoralen example above the highest-lying $\pi\pi^*$, MOs plus one lone-pair MO from the carbonyl oxygen were selected because the purpose was to compute the low-lying spectra. The selection was a combination of experience and use of tools like performing a RASSCF calculation on several roots with enlarged active spaces to analyze the MOs participation in the different states and eliminate those orbitals with occupation numbers <0.05 and >1.95 in all roots of interest. If Rydberg states were to be computed, they should be added into the active space too. Making a TD-DFT calculation also helps to select the AS. As a general rule, it is wise to have in the AS one “virtual correlating” MO for each heavily occupied MO, for instance, each π MO with its corresponding “correlating” π^* MO. This is not necessary for lone-pair orbitals. Other well-known requirements relates to the need to include a second “correlating” d shell (4d) when computing the excited states of first-row transition metals, or more specific rules for very heavy elements. One big advantage of using symmetry in the calculations is the possibility of splitting the AS following the symmetry requirements, always when the energy differences are computed between states computed with the same AS size. The reader is referred to the specialized literature and the MOLCAS manual.

The recently developed RASPT2 method has opened the field to the use of larger RASSCF ASs. Special care has to be taken in the proper distribution of the MOs into the three RAS subspaces, and in the inclusion of an excitation level high enough (triples typically) from and to RAS1/RAS3 to get accurate results. The method is still under calibration, but it is a big step forward for the application of the methodology to larger and more complex systems. Typical improvements include the placement of Rydberg MOs or the second d-shell into the RAS3 space.

Computing Rydberg States

An Application Example: Water

How do we understand a Rydberg state? If we extract one electron from each of the MOs of a neutral molecule, the system becomes positively charged. An electrostatic interaction is therefore established between the molecular cation and the negative electron up to the moment that this ends up as a free electron, that is, at the energy named ionization potential (IP). While the electron leaves the molecule many metastable situations, the Rydberg states, take place, one series from each of the MOs converging to the respective IPs. Obviously, the electrons will be located

relatively far from the molecule, therefore the Rydberg states will differ in extension from the compact valence ones and will require basis sets that generate large and diffuse orbitals able to represent them. Typically, the Rydberg states are labeled, and even represented, in the united-atom approach, that is, by using atomic-type orbitals, because they “see” the molecule as a single atom. The Rydberg states are of interest in gas-phase photochemistry; because of their diffuseness, they are strongly affected by external fields and solvation. Solution chemistry does not contain Rydberg transitions.

Treating simultaneously valence and Rydberg states is not that simple. It requires methods able to deal with the mixing of configurations and orbitals in the wave function. In the past, the literature has been plagued with discussions about how physical is the effect of the valence-Rydberg mixing. In most cases, such mixing was just a consequence of the lack of electron correlation in the calculation of the wave function. Then, both valence and Rydberg orbitals and configurations mix, and valence states, become more diffuse and Rydberg states more compact, with specially dangerous consequences for the valence states, which are extremely sensitive to the mixing. Therefore, if a calculation does not provide clear and compact valence states the result is always suspicious.

Not always the mixing is spurious. One intriguing case is the water molecule. A comprehensive *ab initio* study performed in 1974 by Goddard and Hunt characterized all the computed states below 11.7 eV as having Rydberg nature, a result supported at the configuration interaction (CI) level. The electronic spectrum of water in the gas phase is currently interpreted as composed either of different Rydberg series or implying excited states with a significant Rydberg character at the ground-state equilibrium geometry. The lowest-energy band of the gas-phase electronic spectrum of water is broad (6.8–8.2 eV), with poorly defined vibrational progressions, and has its maximum absorption around 7.4 eV. There is a unanimous agreement in assigning the lowest-energy band to the 1^1B_1 state, but the valence, Rydberg or mixed valence-Rydberg, nature of the state is still under debate.

In C_{2v} symmetry, the ground state of the water molecule is mainly described by the electronic configuration $(1a_1)^2(2a_1)^2(1b_2)^2(3a_1)^2(1b_1)^2$. The latter orbital is nonbonding. The valence orbitals comprise the four highest occupied MOs listed above and two unoccupied orbitals of a_1 and b_2 symmetries ($4a_1$ and $2b_2$ orbitals). The valence excited states can interact with the corresponding Rydberg states of the same symmetry and close in energy. For instance, the valence singly excited $1b_1 \rightarrow 4a_1$ configuration could be mixed with the $1b_1 \rightarrow 3s$, $1b_1 \rightarrow 3p_z$, $1b_1 \rightarrow 3d_{x^2-y^2}$, and $1b_1 \rightarrow 3d_{z^2}$ Rydberg states.

The properties of the lowest-lying electronic states were studied in the light of CASPT2//CASSCF procedure (see Rubio et al. 2008). The coupling of the CASSCF wave functions via dynamic correlation was dealt by using the MS-CASPT2 method. In this way, all the states of a given symmetry are allowed to interact under the influence of dynamic correlation, and the possible erratic valence-Rydberg mixing can be removed. Properties of the states were determined from the PMCAS-CI wave functions.

Table 3 Computed MS-CASPT2 vertical transition energies (ΔE , eV), oscillator strengths (f), and orbital extensions ($\langle r^2 \rangle$, a.u.) from the PMACAS-CI wave functions for the lowest-lying singlet states of the water molecule at the ground-state equilibrium geometry

State	ΔE	f	$\langle r^2 \rangle$
1^1A_1			13
$1^1B_1 (1b_1 \rightarrow 3s/4a_1)$	7.50	0.033	30
$1^1A_2 (1b_1 \rightarrow 3p_y/2b_2)$	9.27	Forbidden	43
$2^1A_1 (3a_1 \rightarrow 3s/4a_1)$	9.86	0.032	45

The next table lists some properties of the low-lying electronic states of the water molecule, employing (after calibration) a one-electron basis set O[5s4p2d1f]/H[3s2p1d] + (2s2p2d), being the diffuse 2s2p2d set, located at the oxygen atom only, necessary to properly describe Rydberg states. Indeed, if no Rydberg orbital is included into the active space, the CASSCF calculation will only yield roots corresponding to valence states. Rydberg and valence orbitals must be treated simultaneously, and this is not possible if there is no Rydberg orbital in the active space. The full valence active space comprises six orbitals with eight electrons and corresponds to (3120), labels that represents each one of the irreducible representations of the point group ($a_1 b_1 b_1 a_2$).

Regarding the first excited state, 1^1B_1 , it has a diffuse nature according to the value of $\langle r^2 \rangle$, more than twice that of the ground state, but appreciably lower than that obtained for a pure Rydberg state as the $2^1B_1 (1b_1 \rightarrow 3pz)$ state ($\langle r^2 \rangle = 64$ a.u.). As the state is mainly described by the singly excited $1b_1 \rightarrow 3s/4a_1$ configuration (75 % in the PMCAS-CI wave function), the valence-Rydberg character of the state arises mainly from the nature of the excited orbital, labeled here as $3s/4a_1$ to highlight its intermediate character valence ($4a_1$)-Rydberg (3s), and not from configurational mixing (Table 3).

We can get further insight into the nature of such a state analyzing its evolution with respect to the O–H internuclear distance. For the sake of simplicity, we have considered the symmetrical stretching of both O–H bonds, preserving thus the C_{2v} symmetry of the system. MS-CASPT2 calculations were performed for the three lowest roots of 1^1B_1 symmetry using the O[5s4p1d]/H[2s1p] + (2s2p2d) basis set (since now we will use the same basis sets for each state, one for vertical transitions, another for potential curves analysis) and the (5120) active space (full valence active space plus two extra Rydberg orbitals of a_1 symmetry). The bond angle was kept fixed at 104.5° .

The second and third 1^1B_1 states have Rydberg character at all distances examined since they show high values of $\langle r^2 \rangle$ in comparison with the ground state. However, the situation is clearly different for the 1^1B_1 state. The evolution of the computed $\langle r^2 \rangle$ with the O–H distance shows that the state is getting more and more valence character when stretching the O–H bond as a result mainly of the changes undergone by the virtual orbital: the energy of the antibonding $4a_1$ orbital decrease when lengthening the O–H distance separating this orbital from the related 3 s-Rydberg orbital. In other words, the nature of the 1^1B_1 state evolves from a valence-Rydberg

mixing type ($1b_1 \rightarrow 3s/4a_1$) at the ground-state equilibrium geometry to a valence character ($1b_1 \rightarrow 4a_1$) at O–H bond lengths around 1.25 Å and longer, which corresponds only to a symmetrical bond stretching of 0.3 Å from the ground-state equilibrium value. Accordingly, the second 1B_1 root becomes the Rydberg state ($1b_1 \rightarrow 3s$) at O–H distances longer than 1.32 Å. This state constitutes an example of MO Rydbergization postulated by Mulliken. The reason for such behavior is probably that both valence and 2 s Rydberg MOs share the same energy and position in space, yielding therefore a common mixed state (Fig. 12).

A similar analysis of the 1A_2 state shows another example of Rydbergization, as its nature evolves from ($1b_1 \rightarrow 3p_y/2b_2$), with a 73 % weight at PMCAS-CI wave function at geometries close to the ground-state equilibrium geometry to

Fig. 12 Symmetrical stretching of the O–H bonds in the ground and low-lying 1B_1 states of the water molecule. Potential energy curves referred to the corresponding ground-state minimum (*left*) and computed $\langle r^2 \rangle$ values

($1b_1 \rightarrow 2b_2$) at O–H distances longer than ~ 1.217 Å, where the second 1A_2 state becomes the $1b_1 \rightarrow 3p_y$ Rydberg state. Indeed, the diffuse nature of the 1A_2 state decreases when increasing the O–H distance. Calculations of the stretching potential energy curves were performed using the active space (3141) with eight active electrons.

On the other hand, the 2A_1 state is characterized mainly by means of the $3a_1 \rightarrow 3s/4a_1$ configuration, with a weight of 70 % at the PMACAS-CI wave function, and by $1b_1 \rightarrow 3p_x$, with a weight of 28 %. This state is closely related to the 3A_1 state, which is characterized by the same configuration but in different proportion (69 % and 28 %, respectively). Since the $1b_1 \rightarrow 3p_x$ one-electron promotion is a pure Rydberg excitation, its contribution increases the configurational mixing of the state. Calculations carried out using the active space (4220) show that the valence character of the state increases with the stretching the O–H bonds due to the increment of the weight of the singly excited $3a_1 \rightarrow 3s/4a_1$ configuration in the PMACAS-CI wave function of the state together with the transformation of the excited orbital toward a valence $4a_1$ orbital. To sum up, the 2A_1 state is a valence-Rydberg state at the ground-state equilibrium geometry and the mixing is not only due to the nature of the excited orbital ($3s/4a_1$), but also to configurational mixing involving the Rydberg $1b_1 \rightarrow 3p_y$ excitation.

In the light of these results, it is concluded that the electronic spectrum of gas-phase water has a predominant Rydberg character at the Franck–Condon geometry, in line with the general view, although a certain degree of valence character has been shown to exist in the three lowest singlet states, a property that increases far from the FC region.

Practical Aspects

How to Solve Valence-Rydberg Mixing

Many methods are unable to solve properly the valence-Rydberg mixing because they do not include enough correlation effects in the calculation of the wave function, for instance, TD-DFT, CASSCF, RASSCF, or even CC2. In many cases, the problem is aggravated by the use of excessively diffuse basis set functions. For instance, aug-cc- or 6-31++G-type basis sets are already too diffuse, becoming even more when atom-centered and combined in the LCAO approach. The excess of uncontracted diffuse functions has been found necessary to compensate the poor recovery of the correlation energy of the underlying valence basis sets. A procedure to reduce the mixing problems and even to make the obtained Rydberg solutions identifiable is to employ molecule-centered uncontracted functions, as explained in the previous example. Typically, orbitals, excitations, and even population analysis are more clearly represented in such cases.

If the mixing persists, and it can be observed by comparing the orbital extension (second Cartesian moment $\langle r^2 \rangle$) of the valence state with that of the ground state, which should be similar and different from that of the Rydberg state, the only solution is to increase the level of correlation used to compute the wave

function. In the CC treatments, it might mean to include the triple excitations. For multiconfigurational studies, it means to make the CASPT2 states to interact and display orthogonal solutions via the MS-CASPT2 method. Ethene is the most paradigmatic case. A CASPT2(2e,9MOs)/ANO-L C[5s4p2d]/H[3s2p] + 1s1p1d calculation yielded an expected $^1B_{1u}$ valence and Rydberg states at 8.45 and 8.93 eV with orbital extensions $\langle x^2 \rangle$ 52 and 50 a.u., and with related oscillator strengths 0.261 and 0.166, respectively (see Finley et al. 1998; Müller et al. 1999). Several errors plague these results. First, the ground state extension was 12 a.u., therefore none of the two states seemed to have proper valence character. Also, Rydberg states cannot have oscillator strength values close to those of valence states. Second, the correct energetic values are known to be ~ 8.0 and 9.33 eV, respectively, leading then to deviations of ± 0.4 eV. A clear mixing of states was obtained at the CASSCF level (in which our wave function was obtained) that CASPT2 could not solve properly for the energies. Using the multistate MS-CASPT2 method makes both states to interact. By diagonalization of the effective interaction Hamiltonian, a new set of states is obtained. The new wave functions, PM-CASCI, are linear combination of the previous SA-CASSCF references built with the eigenvectors of the MS treatment. The new results provide two new solutions for the $^1B_{1u}$ valence and Rydberg states at 7.98 and 9.33 eV with orbital extensions $\langle x^2 \rangle$ of 20 and 82 a.u., and with related oscillator strengths 0.360 and 0.051, respectively, leading to a proper interpretation of the spectrum.

A proof that the valence-Rydberg mixing problem is just a problem of lack of correlation in the wave function is obtained when performing RASSCF/RASPT2 calculations on the ethene molecule. When a calculation including all valence σ , π , π^* , σ^* and Rydberg orbitals in the RAS active spaces is carried out, the mixing vanishes even at the RASSCF level and compact valence and diffuse Rydberg states are obtained separated. The RASPT2 step, without the need of a multistate treatment, produces already the correct results.

Focusing on the Valence States

Is it possible to ignore the Rydberg states and focus on the valence spectrum? Logically, this depends on the system and also on our goals. A system with a solvated or proteinic environment perturbs so much the diffuse transitions that it is safe to ignore the Rydberg solutions. For isolated systems, the simultaneous treatment of valence and Rydberg states seems unavoidable, for instance, in pyrrole, where the lowest-energy excited single state is of Rydberg character. Using poor basis sets like 6-31G* type or excluding in general the diffuse functions from the basis set or the Rydberg orbitals from an active space may seem a solution (the Rydberg states cannot be represented in such case), but the obtained “valence” solutions will most probably be of mixed type.

For larger systems the, exclusion of the Rydberg orbitals from the basis or the active space may be less dangerous. Valence states decrease much more in energy with the enlargement of the molecule or the complexity of the chromophore than Rydberg states. It is unusual to find Rydberg series below 4.5–5.0 eV. Therefore, if one is interested in computing low-lying valence states in a large molecule, it

might be safe to first estimate where the lowest-energy Rydberg state is placed and consider that valence states below such energy are treated accurately with compact basis sets. From one to other molecule, this estimation can be done using the respective IPs, which are a good measure of where the Rydberg series are being located energetically. On the other hand, the geometry of the Rydberg states tends to be similar to that of the molecular cation, typically different from that of the valence states. A way to simplify the calculations in many systems may be to use a compact valence basis set to get the geometry of valence states that, far from the FC region, might not suffer of mixing with the Rydberg states. A recent example can be found in the literature for 1,1'-bicyclohexyliden (see Pérez-Hernández et al. 2008).

Electronic States of Anionic Systems

An Application Example: p-benzosemiquinone Radical Anion

When computing excited states in anionic systems, several cautions should be taken into account. In some molecules, certain states in the anion may lie below the ground state of the neutral system, for instance, those in which the actual electron affinity is positive. Most of the electronic states in anions, including in many cases the ground state, are, however, higher in energy than the ground state of the neutral system and represent temporary anion states, which means that they are unstable with respect to electron detachment. They are typically named Temporary Negative Ion (TNI) states, resonances, or anionic valence-bound states. Conventional quantum-chemical techniques cannot be applied in general to the study of these temporary states since they lie in the continuum of the neutral species plus the free electron. It has been shown that it is, however, possible to obtain well-localized solutions with *ab initio* methods such as CASSCF and others. Those eigenvalues can be regarded as discrete representations of the TNI or anion resonance states. The metastable states of anions can be classified as either shape or core-excited resonances. From the electronic structure standpoint, shape resonances originate in the attachment of the electron to a virtual orbital of the neutral ground state. Alternatively, they can be viewed as the result of the promotion of the unpaired electron of the LUMO to higher-lying virtual orbitals. Core-excited resonances can be seen, on the other hand, as arising from the attachment of an extra electron to an excited state of the neutral molecule. They can be divided into Feshbach and core-excited shape resonances, depending on their energetic position with respect to the excited state of the neutral molecule involved. The former lie below the parent state of the neutral, whereas the latter are located above.

The theoretical treatment of temporary negative ions can proceed via the use of scattering theory or the employment of modified bound-state quantum chemical techniques. The latter requires the use of stabilization methods for the obtained solutions, for instance, by decreasing the exponents of the diffuse functions. It is of general knowledge that any quantum chemical calculation in anions requires a basis set including extra diffuse functions. Besides the discrete valence TNI states, also named valence-bound (VB) anion states, diffuse states described by a singly

excited configuration involving a diffuse orbital can be also obtained, and they have been sometimes erroneously interpreted as Rydberg states. Singly excited Rydberg states are not present on monoanions because there is no specific direct electrostatic interaction between the neutral molecule and the electron; doubly excited Rydberg states would be instead present at high energies. Then, if not Rydberg states, what is the nature of the diffuse states that a quantum-chemical calculation finds interleaved between the valence excited states of the anion? In the cases where the neutral system has a dipole moment larger than a critical value established between 1.26 and 2.50 D, metastable solutions known as dipole-bound (DB) anion states should be found consequence of the interaction between the additional electron and the dipole moment of the neutral system. These states will have small binding energies (i.e., they will be more stable than the neutral ground state), but in some cases, they may appear higher than the neutral state because of deficiencies of the quantum-chemical treatment. Upon improvement of the level of the calculation, they should end up with a positive binding energy. In systems with smaller dipole moments, however, spurious diffuse solutions are also present together with the VB and DB states, but they are an artificial consequence of the calculation, in particular of the structure of the one-electron basis set, which forces a confinement effect (known as the basis set cage effects) leading to erroneous results. In the low dipole moment molecules, these diffuse solutions for the excited states of the anion try to simulate the neutral molecule plus a free electron by placing the extra electron into the most diffuse orbital available. The computed energy for these states strongly depends on the diffuseness of the basis set employed. In practice, the only way to check if the obtained result is correct is to analyze the stability of the energy, for instance, with the increase of the diffuseness of the basis set, as it will be discussed below.

We have a hint of how to analyze ionic systems in the monodeterminant HF approach. The Koopman's theorem stated that given an N -electron HF single determinant $|\Psi_0\rangle = |\chi_1\chi_2\cdots\chi_c\cdots\chi_N\rangle$, the ionization potential (IP) to produce and $(N-1)$ -electron single determinant by removing an electron from spin orbital χ_c , and the electron affinity (EA) to produce and $(N+1)$ -electron single determinant by adding an electron to spin orbital χ_r , are just $\text{IP} = E_c - E_0 = -\varepsilon_c$ and $\text{EA} = E_0 - E_r = -\varepsilon_r$, respectively; that is, the corresponding orbital energies of the protagonist spin orbitals. This "frozen orbital" approximation assumes that the spin orbitals in the $(N \pm 1)$ -electron states are identical with those of the N -electron state, neglecting the relaxation of the spin orbitals in the ionized states. As a result, Koopman's theorem calculations tend to produce too positive IPs and too negative EAs. In addition, we should take into account the correlation effects, which one obtains in going beyond the HF approximation, which will produce further corrections. In general, Koopman's ionization potentials are reasonable first approximations to the experimental ones. On the contrary, Koopman's electron affinities are often inaccurate. Obviously, correlated methods are needed to determine quantitatively such properties.

The ground state of the anion can be then lower (positive EA) or higher (negative EA) in energy than the ground state of the neutral system. How about the excited states of the anion? They will lie in general higher than the neutral ground state,

in the continuum region. As mentioned, it is possible to obtain discrete solutions of the Hamiltonian corresponding to the valence-bound states of the anion, but, because of the confinement effect of the basis set functions, other solutions in which the electrons are placed in the diffuse orbitals will be also present. In a series of calculations on the *p*-benzosemiquinone radical anion (pBQ^- , nonpolar in the neutral form), a number of experiments were performed (see Pou-Amérgo et al. 2000). Apart from the clearly localized valence-bound anionic states, a number of supposedly diffuse states were obtained interleaved with the valence states. What are those solutions? They are spurious solutions caused by the cage effect of the basis set. By decreasing the orbital exponents in the C and O basis sets, it was observed that, while the valence states remained in energy, the “diffuse” solutions started to decrease their absolute energy. The instability remained until their energy converged to the energy of the neutral system, while the electron becomes free and detached from the molecule, an effect that is observed because it always ends up on the most diffuse orbital available. Once identified, the stable solutions above the neutral ground state energy can be TNI states or anion resonances, whereas the instable solutions can be neglected as spurious. The apolar character of pBQ^- prevents the molecule to have dipole bound anion states (although it has quadrupole-bound states).

The CASPT2 study on pBQ^- used a basis set of ANO-L type C[4s3p1d]/H[2s1p] plus a set of 1s1p1d diffuse functions centered in the molecule and an active space of 9 MOs of valence $\pi\pi^*$ type, (03010301), distributed into the D_{2h} irreducible representations ($a_g b_{3u} b_{2u} b_{1g} b_{1u} b_{2g} b_{3g} a_u$). The adiabatic electroaffinity (AEA), obtained as the difference between the ground states of the neutral and anion pBQ at their respective geometries was computed as -0.33 eV (CASSCF) and 2.01 eV (CASPT2), as compared to the 1.9 eV measured in experiment. The result clearly highlights the fundamental role of the correlation effects. Two series of calculations on the excited states were performed to analyze the spectrum of the system at the geometries of neutral and anion pBQ . The former results can be compared with those obtained from photodetachment measurements, whereas the latter are better related to the electron attachment or electron transmission spectroscopy (ETS). Table 4 summarizes the results.

Whereas most of the assignments, made to $\pi\pi^*$ valence-bound states, seem to be explained, the observed band near 2.7 – 2.9 eV in the pBQ^- absorption spectrum could not be initially resolved because the degeneracy of the 1^2B_{3u} and 1^2A_u states, both leading to one-photon allowed transitions. This broad band had two main peaks at 2.7 and 3.1 eV, which could be attributed to one or other states. In principle, the transition to the 1^2A_u was computed with larger oscillator strength, but that does not guarantee that the highest peaks correspond to such a state. The vibrational profile of the transitions to both states was therefore computed at the CASPT2//CASSCF level of calculation by obtaining vibrational energies and TDMs, which required geometries optimizations and Hessians for both states and resolution of the vibrational Hamiltonian. As a result, it was confirmed that the two highest bands at 2.7 and 3.1 eV corresponded to the initial quanta in the vibrational progression of the breathing mode in the 1^2B_{3u} state, whereas the 1^2A_u transition,

even when broader, extended to higher energies displaying a larger band area but not so high peaks. Such result proves the danger implicit in the use of vertical excitation energies matching band maxima to assign molecular spectra.

Practical Aspects

Basis Sets and Spurious Solutions in Anions

Closely controlling the quality of our basis set and its effects on our states will confirm the validity of our results. Let us illustrate this aspect with another example. Neutral nitromethane (CH₃NO₂) has a dipole moment of 3.46 D. A standard ANO-L C,N [4s3p2d]/H[3s1p1d] basis set is used supplemented with a set of 1 s diffuse functions (eight primitives) with exponents for the diffuse functions explicitly optimized to deal with Rydberg states. At the CASSCF optimized geometry for the neutral molecule, the lowest state of the anion is 0.530 eV above the neutral ground state at the MS-CASPT2 level. Just by scaling the exponents of the diffuse functions by a factor 0.5 in both the neutral ground state and the lowest anion state, the energy difference decreases to 0.250 eV. Scaling instead the exponents by 0.1 leads to an energy difference of -0.022 eV, that is, the lowest state of the anion has converged below the energy of the neutral system. Increasing further the diffuseness of the basis set does not vary the result, which corresponds to a dipole-bound state of the anion with a small binding energy of 0.022 eV (experimental value 0.012 eV). The lowest valence-bound anion state is computed, adiabatically, 0.23 eV below the neutral ground state of the molecule at the CCSD(T) level. This state remains basically stable with the increase of the diffuseness of the basis set and it is, in general, better represented by using diffuse functions localized in the positive sites of the molecule. To test the stability of the solutions obtained, other techniques have

been developed, such as increasing the effective positive nuclear charge, adding specific counter ions to fix the negative charge, or using penalty functions or electric fields, such the dielectric continuum cavities, which will highly perturb the diffuse solutions.

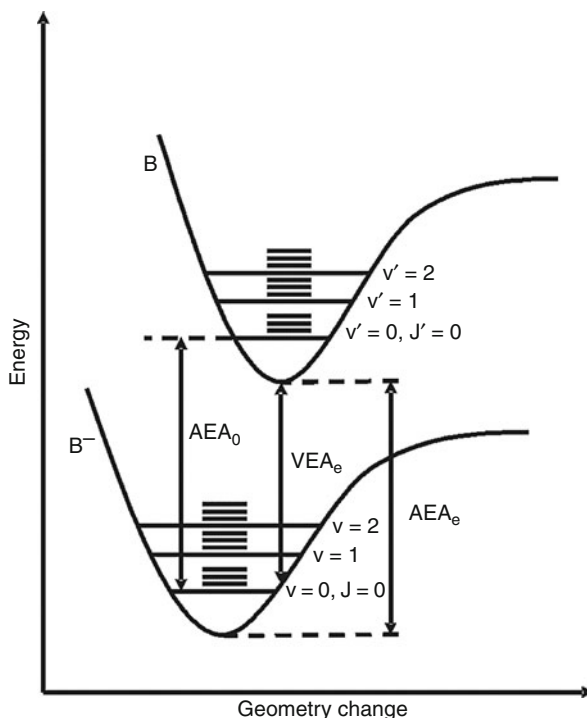

Negative Electron Affinities

Ionization potentials and electron affinities are intrinsic properties of the DNA and RNA nucleic acid bases (NABs) whose determination enables a deep understanding of all phenomena related to the electron donor and acceptor abilities of the NABs, such as those involving charge transfer and transport along the DNA strand. Determination of the EAs of NABs is difficult both experimentally and theoretically, and the uncertainties range up to several eV, including also changes in the sign of the energies, because both VB and DB anions may be located within a small range of energies, and therefore determination of accurate EAs is uncertain, especially because the type of anion formed may vary with the different experimental conditions. Apart from that, new difficulties interfere the experimental determination of EAs of nucleobases as the presence of different tautomers of the nucleobases which are close in energy in the gas phase. In particular, the canonical (keto) form of guanine, which is the biologically relevant tautomer, has a very low concentration in the vapor, and there is no direct experimental value reported for the corresponding EA.

The electron affinity of a neutral molecule is the energy required for detaching an electron from a singly charged negative ion, or equivalently, the energy released when an electron is attached to the neutral system. Thus, the electron affinity of a neutral molecule can be defined as the energy difference between the ground state of the neutral system and that of the anion. A positive EA implies that the anion is more stable than the neutral species. As in the case of the ionization potential, three theoretical magnitudes (see Fig. 13) are used for describing this transition: the vertical electronic energy difference (VEA_e or VEA) between the ground states of the neutral system and the anion at the equilibrium geometry of the neutral molecule, the adiabatic energy gap (AEA_e) between the minima of the neutral and anion molecule ground states, and the corrected adiabatic property (AEA_0 or AEA) with the addition of the zero-point vibrational energy correction (ZPE). Thus, positive $VEAs$ indicate that the molecule acts as a trap for an excess electron, with an attachment energetically favored and, therefore, the anion can be created spontaneously. In this case, positive $AEAs$ follows, and the system becomes stable, that is, it does not undergo autodetachment and can take part in chemical reactions. On the other hand, negative values for $VEAs$ and $AEAs$ represent the TNI states, existing in short periods of time and becoming prone to photodetachment.

Analysis of the experimental literature on nucleobase EAs shows an extremely confuse situation, ranging from clearly negative values (-0.56 eV) up to largely positive energies (1.51 eV), and including EAs close to 0 eV. In general, determination of EAs represents a technical challenge, especially when they have negative values, and in many cases it is based on indirect measurements. Negative electron affinities can be experimentally measured by electron transmission spectroscopy.

Fig. 13 EA diagram ($B + 1e^- \rightarrow B^-$). Definitions of the theoretical magnitudes related to EA are graphically shown through the electronic, vibrational, and rotational potential energy levels. Those magnitudes are VEA_e (vertical electronic electron affinity, from the neutral ground-state minimum), AEA_e (adiabatic electronic electron affinity, from minimum to minimum), and AEA_0 (adiabatic electron affinity including the zero-point vibrational corrections of the minima)

The technique is able to detect negative ion resonance states, which are energetically unstable with respect to electron autodetachment. It is unclear when the experiment is measuring vertical (VEA) or adiabatic (EAs) attachments, or if the indirectly obtained data truly represent the molecular EAs. In general, however, ETS is the only direct experimental technique which is expected to provide actual VB anions in the region of the resonance states. In particular for gas-phase NABs (except G, which cannot be isolated), ETS measurements report EAs values clearly in the negative region (from -0.22 to -0.54 eV).

In order to compute accurate theoretical results for the VEA and AEA of NABs different levels of theory were taken into account, employing the MP2, CCSD, and CCSD(T), and the CASSCF and CASPT2 methods, in conjunction with the 6-31G*, cc-pVDZ, aug-cc-pVDZ, ANO-L C,N,O[4s3p1d]/H[2s1p] (hereafter ANO-L 431/21), and ANO-L C,N,O[4s3p2d1f]/H[3s2p1d] (hereafter ANO-L 4321/321) basis sets. Methods and basis sets were selected to obtain the most accurate values from preliminary calculations on atomic systems, in which the required levels of highly flexible enough basis sets and strongly correlated methods to obtain predictive EAs were determined. Geometry optimizations of both neutral and anionic NABs were carried out at the MP2/6-31G(d), MP2/aug-cc-pVDZ, CASSCF/cc-pVDZ, CASSCF/ANO-L 431/21, and CCSD/aug-cc-pVDZ levels of theory. No symmetry restrictions (C_1 symmetry) were imposed, whereas all minima

were characterized by computing second derivatives at the same level, except in the case of CCSD/aug-cc-pVDZ where the geometries were tested comparing with the optimized parameters at the other levels of theory. At the respective equilibrium structures, additional CASPT2 and CCSD(T) calculations were performed to account for the most accurate energy values. ZPE corrections were included at different levels using the harmonic approach. The active space for the CASSCF calculations in geometry optimizations comprises the full π -valence system, except the molecular orbital localized mainly on the nitrogen atom of the NH_2 group in the case of cytosine, adenine, and guanine, whose occupation number is very close to two. This MO is further included in conjunction with the lone pair electrons and orbitals of the heteroatoms in the final CASSCF and CASPT2 calculations of VEAs and AEAs, except when the large ANO-L 4321/321 basis set was employed (see Roca-Sanjuán et al. 2006, 2008a).

The analysis of the results shows that neither DFT procedures nor the MP2 method have the required accuracy, either by the known problems of DFT to deal with negative centers or by the spin contamination problem that affects MP2. CCSD(T)//CCSD/aug-cc-pVDZ and CASPT2(IPEA)/ANO-L 4321/321//CASSCF/ANO-L 431/21 will be established as the most accurate procedures, both for vertical and adiabatic EAs. It must be emphasized here that the main factor to achieve accurate results for the VEA of NABs by using ab initio methods is the employment of atomic one-electron basis sets flexible enough to describe both the spatial distributions of electrons and their correlation effects and including functions decaying slowly with the radial distance. The CASPT2//CASSCF strategy has the advantage to compute several states of the system, and it is possible to easily distinguish between the different solutions. Single-reference methods are not free of problems, because they can only obtain the lowest solution. For instance, at the corresponding geometry of the neutral species, adenine and guanine, in which the VB anion state lies much higher than other diffuse states, the CCSD and CCSD(T) computations lead initially to a diffuse and low-energy spurious solution in which a delocalized electron is located far from the molecule in a diffuse orbital. Finally, the sequence of stable solutions obtained for the VEAs of NABs using the reference CCSD(T) and CASPT2(IPEA) levels of theory is established as $U \approx T > C > A > G$, ranging from -0.61 eV (U) to -1.14 eV (G). Therefore, for guanine is less favorable to accept an electron at the neutral molecule geometry.

Regarding gas-phase adiabatic EAs, those for uracil and thymine were determined very close to zero, whereas cytosine has a small negative AEA. The sequence of AEAs for isolated NABs can be established as $0 \text{ eV} \sim U \sim T > C > G > A$. Purines are much less favorable than pyrimidines to retain the electron attached to the neutral nucleobase, and after geometry relaxation adenine becomes the poorest electron acceptor of all NABs, in contrast to what occurred for the vertical EAs, in which guanine had the more negative value. To understand the differences among these compounds, it can be also analyzed how the inductive effect (and the number of stable resonance structures) makes more or less stable the new center of negative charge created by the addition of the new electron. It should not be forgotten

that the accepting properties of the systems will largely change in solvated or biological environments. For instance, a recent calculation performed for the EAs of the cytosine molecule within a chain of oligomers, $dC_{18} \times dG_{18}$, employing a CASPT2/MM approach led the AEA of cytosine to change from -0.26 eV in vacuo to 0.69 eV in the biological surrounding, becoming therefore the molecule a strong electron acceptor.

Photochemistry: On the Trail of the Energy

An Application Example: Thymine

The energy absorbed by a molecule can be released radiatively, that is, slowly emitted via fluorescence or phosphorescence, or nonradiatively. In that case, it can give rise to productive photochemistry, yielding photoproducts different from the initial species, or it can become unproductive, meaning that it is dissipated to the environment through the vibrational degrees of freedom, ending in some cases in the initial ground state of the system. Photophysics and photochemistry is typically a combination of all such processes. From the theoretical viewpoint, the best initial strategy to understand the photochemical processes is trying to follow closely the path of the energy from the initially populated states at the FC region toward favorable regions of the PEHs. That means to trace the lowest-energy possible pathway until reaching an energy barrier, that is, a minimum, or a transition state, or a hypersurface crossing, in particular conical intersections (CIs), the protagonists of the ultrafast radiationless nonadiabatic energy transfers between PEHs. The only strategy that guarantees finding PEH points along the lowest-energy path is the computation of a minimum energy path (MEP), that is, a steepest-descendent pathway. The procedure is performed generally in mass-weighted coordinates, and it is equivalent to the Intrinsic Reaction Path approach. Once localized, the crossings and CIs, the estimation of their accessibility, and the calculation of the interstate couplings (like the SOC between singlet and triplet states) and transfer probabilities will help understand and predict favorable IC and ISC processes. The described strategy is named as the Photochemical Reaction Path approach, and it can be applied to solve a large number of photochemical problems.

An interesting example of nonproductive photochemistry can be found in important compounds such as the DNA/RNA natural nucleobases, which were determined a long time ago as basically nonfluorescent. Modern femtochemical techniques have determined fluorescence decay times in the DNA/RNA nucleobase monomers, nucleosides, and nucleotides in different media to be ultrafast. In particular, molecular beam measurements reported two main decay lifetimes near 100 fs and few ps in all five natural NABS: thymine, uracil, cytosine, adenine, and guanine (Crespo-Hernández et al. 2004). Finding ultrafast decays in a molecule suggests the presence of extremely efficient internal conversion channels, and therefore the presence of accessible conical intersections, in particular one connecting the initially populated bright spectroscopic $\pi\pi^*$ singlet and the ground state, yielding therefore nonfluorescent species. The ultrashort lifetime of nucleobases

Fig. 14 Evolution of the ground and lowest singlet excited states for thymine from the FC geometry along the $^1(\pi\pi^*HL)$

is an intrinsic molecular property as it has been proved in recent years both from theory and experiment. Indeed, such photoprotective properties may well be very important at the beginning of life in our planet given that there are evidences that point out that life began on Earth millions of years before the development of the ozone layer. The ultrafast decay channels of the nucleobases may have favored photostable natural nucleobases against less stable derivatives (Serrano-Andrés and Merchán 2009). This type of photochemical mechanisms may have been operative as natural selection processes reaching in that way the genomic stability until the development of the ozone layer and complexes mechanisms of reparation of DNA.

Thymine photophysics is here selected as an illustration of the computational strategies mentioned above (see Merchán et al. 2006; Serrano-Pérez et al. 2007b). Figure 14 displays the CASPT2 energies of the lowest-lying singlet and triplet states of thymine along the MEP calculated for thymine on the bright $^1(\pi\pi^*HL, \text{HOMO} \rightarrow \text{LUMO})$ state from the FC geometry. The level of the calculation was CASPT2//CASSCF(14e⁻,10MOs)/ANO-S C,N,O[3s2p1d]/H[2s1p]. Apart from the radius of the hypersphere controlling the distance from the initial geometry, not any other restriction was imposed to the calculations.

From thymine ground state and upon near-UV absorption at the FC region, most of the population reaches initially singlet excited states, and in particular, it is the transition to the $^1(\pi\pi^*HL)$ excited state at 4.89 eV which has the largest oscillator strength up to 6 eV, that is, 0.167. The ultrafast nonradiative decay undergone by thymine in the femtosecond range can be rationalized by the barrierless character of the path leading from the FC region toward a CI seam with

the ground state, $(\text{gs}/^1\pi\pi^*)_{\text{CI}}$. Unlike simple geometry optimizations, the use of the MEP technique guarantees the absence of energy barriers along the lowest-energy path. The structure of the CI at the end of the MEP can be characterized as ethene-like, a diradical species (as many CI are) involving combined stretching and twisting of the ethylenic bond and leading to a screw-boat (S) conformation $^5\text{S}_6$ for the six-membered ring. The presence of an accessible CI explains also the low fluorescence quantum yield ($\sim \phi_F = 10^{-4}$) detected for thymine with band origin at 4.5 eV in water. This weak emission can be related to the presence of a high-lying planar $^1(\pi\pi^*HL)$ minimum computed adiabatically from the ground state at 4.49 eV, whereas a nonfluorescent $^1(n_o\pi^*)$ minimum is found at 4.05 eV with a minor contribution to the emissive properties. As recently estimated by means of reaction dynamics, the near 100 fs decay detected in natural nucleobases can be related to the barrierless path from the FC to the CI region. Although other slower singlet decay pathways could be estimated proceeding through the low-lying $n_o\pi^*$ state, that crosses the MEP at high energies and has its own CI with the ground state, still the main relaxation path for the energy runs along the computed $^1(\pi\pi^*HL)$ barrierless MEP, which will transfer most of the energy toward the ground state and back to the original species. Such behavior means that the systems are largely photostable, as it has been proved for natural and methylated nucleobases, and that the mechanism can be considered an intrinsic property of the systems. Figure 15 illustrates such mechanism for the pyrimidine nucleobases, thymine, uracil, and cytosine, although the basics also hold true for the purine systems, adenine and guanine (Merchán et al. 2006; Serrano-Andrés et al. 2006, 2008; ?). Further insight can be only obtained when reaction dynamic calculations are performed on larger regions of the PEHs (see, for instance, Szymczak et al. (2009)).

The decay along the singlet manifold is not the only procedure for energy relaxation. Efficient population of the triplet manifold can also take place, essentially through intersystem crossing (ISC) processes taking place along the main decay process on $^1(\pi\pi^*HL)$ or via photosensitization from endogenous or exogenous species. Triplet states are frequent intermediates in different types of photoinduced reactions. Both their usual diradical character and long lifetimes make them reactive species prone to interact with other systems. Among the most important reactions involving triplet states, those related to DNA/RNA purine and pyrimidine nucleobases have undoubtedly attracted more attention, in particular the photodimerization of pyrimidine nucleobases, considered to be the most frequent DNA lesion taking place after UV light irradiation. Through their triplet states, DNA/RNA nucleobases may not be as photostable as expected. As seen in Fig. 14, along the $^1(\pi\pi^*HL)$ state, MEP is clear that two singlet-triplet crossings (STC) are accessible, and therefore two ISC processes may take place: at 4.8 eV with the $^3(n_o\pi^*)$ triplet state, $(^3n_o\pi^*/^1\pi\pi^*)_{\text{STC}}$, and at 4.0 eV, further along the relaxation path and near the ethene-like CI with the ground state, directly with the lowest $(^3\pi\pi^*)T1$ triplet state, $(^3\pi\pi^*/^1\pi\pi^*)_{\text{STC}}$, a structure displaying the same type of screw-boat puckered geometry with a stretched and twisted double bond $\text{C}_5=\text{C}_6$ as at the $(\text{gs}/^1\pi\pi^*)_{\text{CI}}$ CI. Efficient ISC requires both small singlet-triplet energy gaps and large spin-orbit coupling elements at the regions of degeneracy.

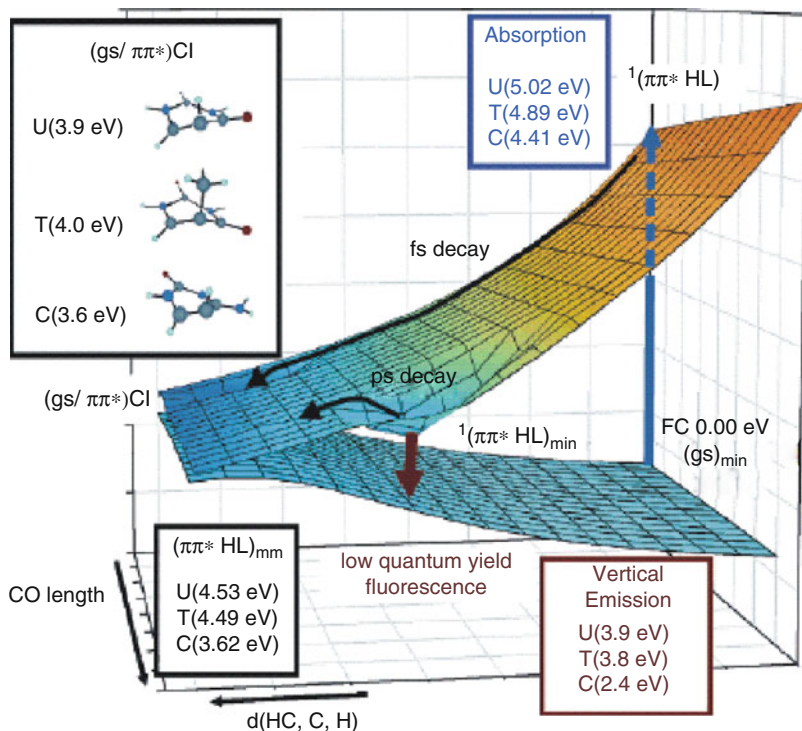

Fig. 15 Global scheme of the photochemistry of uracil (U), thymine (T) and cytosine (C) as suggested by the CASPT2 calculations

As compared to IC, taken place essentially in small zones where the seam of CIs becomes accessible, the regions of the potential energy hypersurfaces for effective ISC are more extensive.

Figure 16 includes a scheme describing the population of T_1 based on our CASPT2 calculations, and three are the suggested competitive mechanisms from the initially populated singlet state by means of STC processes:

Regarding the higher-energy ISC process, the ${}^3(n_o\pi^*)$ triplet state can be populated from ${}^1(\pi\pi^*)$ in the STC crossing region, in which a high SOC of 8 cm^{-1} has been computed favoring the process. From such region, a MEP on the ${}^3(n_o\pi^*)$ state leads directly to its energy minimum, ${}^3(n_o\pi^*)_{min}$, placed at 3.93 eV adiabatically from the ground state. Basically degenerated, we have located a conical intersection connecting the triplet states ${}^3(n_o\pi^*)$ and ${}^3(\pi\pi^*)$, facilitating the population switch

Fig. 16 Scheme, based on CASPT2 results, of the photochemistry of thymine focused on the population of the lowest-energy triplet state

toward the lowest ${}^3(\pi\pi^*)$ state. Another computed MEP on the T_1 hypersurface leads from $({}^3n_O\pi^*/{}^3\pi\pi^*)_{CI}$ to the ${}^3(\pi\pi^*)$ state minimum. A second ISC channel also relates with an $n\pi^*$ state. In our results, as well as in previous theoretical studies, the presence of the low-lying ${}^1(n_O\pi^*)$ state is confirmed, lying almost isoenergetic with the lowest ethene-like $(gs/{}^1\pi\pi^*)_{CI}$ CI near 4.0 eV. The ${}^1(n_O\pi^*)$ state may then be related to the observed dark state in pyrimidine nucleobases in solution. Additionally, we have found that, as both singlet and triplet ${}^{1,3}(n_O\pi^*)$ states have almost parallel hypersurfaces because of the typical small singlet-triplet splitting of $n\pi^*$ -type states, near degeneracy structures with the lowest ${}^3(\pi\pi^*)$ state are equal to both states. Therefore, close to the $({}^3\pi\pi^*/{}^3n_O\pi^*)_{CI}$ CI, we have found a singlet-triplet crossing $({}^3\pi\pi^*/{}^1(n_O\pi^*))_{STC}$. The extremely large computed SOC terms, $\sim -61\text{ cm}^{-1}$, guarantee also an efficient ISC process in the region, confirming this mechanism as relevant for the overall process. In principle, in different environments such as in polar solvents, it is expected that the $n\pi^*$ -type excited state will destabilize with respect to $\pi\pi^*$ -type excited states. Despite those effects, both singlet and triplet $n_O\pi^*$ -type states are estimated to lie in the solvent below the ${}^1(\pi\pi^*HL)$ state at the FC geometry, confirming the existence of the STC crossing upon decay along the ${}^1(\pi\pi^*HL)$ state. Finally, a third ISC channel directly connecting the lowest $\pi\pi^*$ states is found at low energies with SOC values ranging 5–8 cm^{-1} . The profile of the computed MEP in Fig. 16 suggests that the lowest-energy ISC mechanism may enhance its efficiency with respect to the other nucleobases resulting in larger quantum yields because the region for the energy transfer near to the end of the MEP seems to be much more extended. The presence of three basic ISC funnels in thymine (occurring also in uracil and adenine but not in guanine and cytosine where the higher-energy $n\pi^*$ -mediated channels are

absent) successfully explains for the first time the wavelength dependence on the measured ISC quantum yield (ϕ_{ISC}) reported in thymine (uracil and adenine too) on the basis of the location and accessibility of the two STC crossing regions upon the initial excitation conditions. In the case of thymine, the ϕ_{ISC} value increases from 3.9×10^{-3} at 280 nm (4.43 eV) to 5.2×10^{-2} at 240 nm (5.17 eV). At low excitation energies, only the lowest-lying ISC computed to take place close to 4.0 eV will be activated. At higher-energies, however, the channels near 4.8 eV will be additionally activated, increasing the overall triplet formation yield.

From any of the STC or CI regions, the lowest triplet state is populated by any of the previous ISC processes and reaches its minimum, as proved by the computed MEPs. The high reactivity attributed to this triplet state originates from its partial diradical character on C₅ and C₆. The minimum is placed at 2.87 eV, adiabatically from the ground state optimized minimum. As a final aspect of the evolution along the triplet manifold in thymine, we have located the singlet-triplet crossing connecting the $^3(\pi\pi^*)$ and the ground state, and mapped the MEP leading from such STC toward $^3(\pi\pi^*)_{min}$. The crossing is placed at near 3.0 eV from the ground state minimum, what means that there is a relatively small barrier of 0.13 eV ($3.0 \text{ kcal mol}^{-1}$) to reach $(gs/^3\pi\pi^*)_{STC}$ from $^3(\pi\pi^*)_{min}$. The computed electronic SOC is, however, somewhat low, $\sim 2 \text{ cm}^{-1}$, predicting for the triplet state a long lifetime and a slow relaxation, becoming therefore prone to undergone reactivity (Merchán et al. 2005; Serrano-Pérez et al. 2007b).

Practical Aspects

Reaction Paths: MEP Verses Other Approaches

Computing minimum energy paths (MEP) is an expensive procedure in which each point of the MEP is obtained from individual optimizations. Special care is required in the selection of active spaces, which should be flexible enough and appropriate along the whole path, and the radius of the hypersphere, which should be not too small or too large. When the steepest-descendent MEP ends finding an energy barrier, for instance, as frequently in the minimum of the state, other procedures should be employed. It must occur also that the calculation of the MEP is too expensive. It is possible to continue using the MEP algorithm upward, that is, by increasing the hypersphere radius increasing energy paths can be computed. Other procedure is to search for a transition state (TS) along the path that represents the energy barrier. More general strategies are normally required to map the full profile of the reaction linking two predefined regions of the PEHs. One possibility is performing a relaxed scan, that is, varying by specific amounts one internal coordinate which is expected to be the leading structural modification along the path and, at each selected value, to perform a restricted geometry optimization in which only such coordinate is frozen. Relaxed scans are extremely dangerous and should be used with caution, because they often produce unconnected and useless paths. There is no guarantee that the lowest-energy value for each of the selected frozen-coordinate structures belongs to a connected path. In many cases, the results will

jump from one region of the PEH to another along a profile that should represent a reaction path but does not at all. In general, the only relatively safe case in which a relaxed path can be used is that leading to a dissociation of an atom, because in this case the path has a descendent character while the bond length is increased.

Instead of a relaxed scan is preferable to make a linear interpolation in internal coordinates (LIIC). This is a predefined path in which each structure is generated from the previous one by adding linearly to each internal coordinate the geometrical change of the initial and final structures divided by the number of steps. The advantage of this profile is that the points belong to a connected path. The disadvantage is that it will most probably give rise to too high energy barriers, although they will always be upper bounds of the actual barrier. For instance, in a study of the photophysics of psoralen, it was determined that the MEP from the FC region led the system to the minimum of the initially populated $S_1^1(\pi\pi^*)$ state. Psoralen is a strongly emitting system, especially by phosphorescence (in a ratio 7/1 with respect to fluorescence). Emission from the $S_1^1(\pi\pi^*)$ minimum explains the fluorescence of the system, but, what about phosphorescence? The population of the triplet manifold seems not to take place close to the FC region, and no relevant STC crossing takes place soon along the MEP. Therefore, an effective triplet formation has to take place by depopulating the singlet state minimum by an accessible STC. The $T_1(T_\pi)$ state lies much lower in energy than the $S_1(S_\pi)$ state, both vertically (~ 0.6 eV) and adiabatically (~ 1.2 eV). Direct interaction between the singlet and triplet vertical excited states is unlikely, and therefore another mechanism has to be found, involving most probably population of higher-energy triplet states and subsequently internal conversion toward T_1 . The qualitative El-Sayed rules indicate that the spin-orbit coupling is large between states of $\pi\pi^*$ and $n\pi^*$ types and small between states of the same character. In addition, it is known that the ISC process is enhanced in molecules with heavy atoms (the heavy-atom effect) because the SOC terms increase. There are two necessary conditions to be fulfilled for an effective ISC to take place: low energy gap and high spin-orbit coupling between a singlet and a triplet state. Thus, the nonradiative decay to a triplet state should occur along the relaxation pathway of S_π , starting from the Franck–Condon region, and in close vicinities of a singlet-triplet crossing. A LIIC profile was computed (see Fig. 17) from $(S_\pi)_{\text{MIN}}$ to the minimum of the $1^1A''$, $(S_n)_{\text{MIN}}$, a path considered to be appropriate to find the singlet-triplet crossing, since both S_n and T_n states share the same basic structure and energetics (see Serrano-Pérez et al. 2007a). At half of the path the S_π and $T_n^3(n\pi^*)$ states cross, and the SOC value is high enough (9 cm^{-1}) to guarantee an efficient ISC. A barrier of 0.4 eV, surely an upper bound, has to be overcome to reach the T_n state.

The geometry closer to the crossing point was used as initial geometry to initiate a search at the CASSCF level for a singlet-triplet crossing (STC) between S_π and T_n , that is, $(S_\pi/T_n)_X$. As expected, the main change in geometry from the minimum of S_π to the optimized structures of S_n or T_n is related to the length of the C=O bond, much larger (~ 0.15 Å) than the ground state value for the $n\pi^*$ states. It is not surprising that the STC structure displays an intermediate value of 1.220 Å. The

Fig. 17 LIIC path for psoralen. The crossing region between S_1 and T_n is highlighted with a square

SOC term in STC is computed as 6.4 cm^{-1} . As displayed in Fig. 18, the barrier from $(S_\pi)_{\text{MIN}}$ to $(S_\pi/T_n)_X$ was computed 0.36 eV at the CASPT2 level. This is still a large energy barrier; however, the crossing is now below the energy of the S_π state at the FC geometry, and therefore the system has enough excess energy to access the STC region and make the ISC process to take place.

Once the T_n state is efficiently populated through a favorable ISC mechanism, it will quickly evolve toward the nearby energy minimum, $(T_n)_{\text{MIN}}$, placed 0.11 eV below $(S_\pi/T_n)_X$. At those geometries, T_n is the second-energy excited triplet state and can be expected that the energy follows a pathway for favorable internal conversion (IC) toward the low-lying T_π state. Actually, a conical intersection has been found, $(T_n/T_\pi)_{\text{CI}}$, placed isoenergetic with $(T_n)_{\text{MIN}}$. An efficient IC will therefore take place transferring the population to T_π , which will subsequently evolve to its own minimum, $(T_\pi)_{\text{MIN}}$, from where phosphorescence (P) will take place. Additionally, the molecule may react with thymine or transfer its energy to the molecular oxygen exerting the photosensitizing action. The family of furocoumarins (8-MOP, 5-MOP, khellin, TMP, and 3-CPS) was studied at the same grounds showing that all the compounds share the same mechanism of population of T_π . The differences in the values of the barriers (to reach the crossing regions on the hypersurfaces), besides the values of SOC, are actually the key points in considering the photosensitizing ability of each compound.

A final remark should be introduced. Considering that $n\pi^*$ states tend to destabilize in polar solvents, the (T_n) -mediated mechanism here proposed will surely decrease its importance in polar media, remaining a plausible candidate for the efficient population of the low-lying T_π triplet state in the gas phase. Indeed, the relevance of out-of-plane displacements for the relaxation of the S_π state has been emphasized recently at DFT/MRCI level of theory, together with the enhancement

Fig. 18 Scheme of the gas-phase photochemistry of psoralen based on quantum-chemical CASPT2 calculations. Energies are referred to $(S_{\pi})_{\text{MIN}}$

of the SOC terms between low-lying S_{π} and T_{π} states by vibronic coupling effects involving out-of-plane modes, as an alternative mechanism for efficient ISC.

How to Compute Conical Intersections

There is hardly any good recipe to make the calculation of CIs more efficient, in particular those relating the ground and excited states that are usually the most relevant features for the photochemistry of the systems. Experience orientates toward certain types of CIs common in organic compounds, like the so-named ethane- or methanamine-like CIs, taking place by the stretching and twisting of $C=C$ and $N=C$ bonds, respectively, or situations of $C=O$ stretching, in both cases creating an almost diradical species. In many other cases, one has to let the computational algorithm to find the right path. One initial approach is trying to find the minimum energy CI (MECI), considered to be the most relevant for the photochemical process. Technically, it is easier to look for MECIs, because one can simply search for the lowest-energy crossing point fulfilling the nonadiabaticity rules. Calculation of nonadiabatic terms, the so-called branching space, is complex. Time-consuming projected-gradient or Barry's phase algorithms have to be used to guarantee the true CI nature. In practical cases, there are some implementations

available at a high level of theory, like that at the MRCI level in the COLUMBUS code (see Lischka et al. 2004).

In many cases, however, it is safe enough just to compute the minimum energy crossing point (MECP), discarding the calculation of nonadiabatic coupling, because the obtained solution already defines the crossing region accurately enough. Even when the MECI (or MECP) is found, nothing guarantees that this is going to be the relevant structure from the photochemical viewpoint. It might happen that the MECI is placed in a region that it cannot be easily accessed from the main energy decay paths of the molecule. Therefore, the accessibility of the region is the key point making a CI (or a seam of CIs) relevant for the photochemistry. The next example can properly illustrate this idea. In the same manner as described for thymine, the MEP from the FC region on the bright $^1(\pi\pi^*\text{HL})$ state was computed for guanine at the CASPT2//CASSCF (14e⁻,12MOs)/ANO-S C,N,O[3s2p1d]/H[2s1p] level of calculation (see Fig. 1, top), leading, through a barrierless path, to a crossing with the ground state at the end of the MEP. Independently, a MECI search was carried out to find the lowest-energy CI (Fig. 19, bottom, right), which provided a geometry somewhat different from that obtained at the end of the MEP. To solve the problem, a CASSCF path was computed along the seam of CIs (Fig. 19, bottom). The points of this profile have been computed to belong to the seam, that is, both the ground and the $^1(\pi\pi^*)$ states are degenerated, and by successive optimizations in which the radius of the hypersphere has been increased from the initial MECI structure. It is clear that the MECI energy is lower than any other point of the seam, but also that a barrier separates that structure from a CI which is higher in energy but accessible from the end of the MEP (the actual source of the energy) and whose structure is quite similar to that of the end of the MEP (Fig. 19, bottom, left). That CI is the relevant funnel for the photochemistry of guanine.

Other serious problems can be found when computing PEHs crossings, although it is as general issue in quantum chemistry. Determination of molecular structures is one of the most time-consuming steps in computational chemistry. It is therefore a typical strategy to use lower-level methodologies to locate singular-point geometries (minima, transition states, conical intersections . . .) and correct then the energetics by employing higher-level methods. Implicit in this procedure is the problem of the differential correlation effects. We shall check this issue in the case of the location of conical intersections (or any other hypersurface crossing). A usual protocol employed for that purpose is named CASPT2//CASSCF, meaning that geometries have been determined at the CASSCF level and, at those structures, the energies have been computed at the CASPT2 level. CASSCF includes the static or long-range correlation effects and provides wave functions which describe qualitatively the electronic states and form the reference for subsequent calculations. The remaining short-range correlation effects, dynamical electron correlation, are included by means of a second-order perturbative treatment, CASPT2. Depending on the nature of the state, the effects of the static and dynamical correlation energies differ, affecting directly to the description of the hypersurface. Figure 20 summarizes what we have called the differential correlation effects on the location of surface crossing within the CASPT2//CASSCF protocol. It is important to recall that this problem

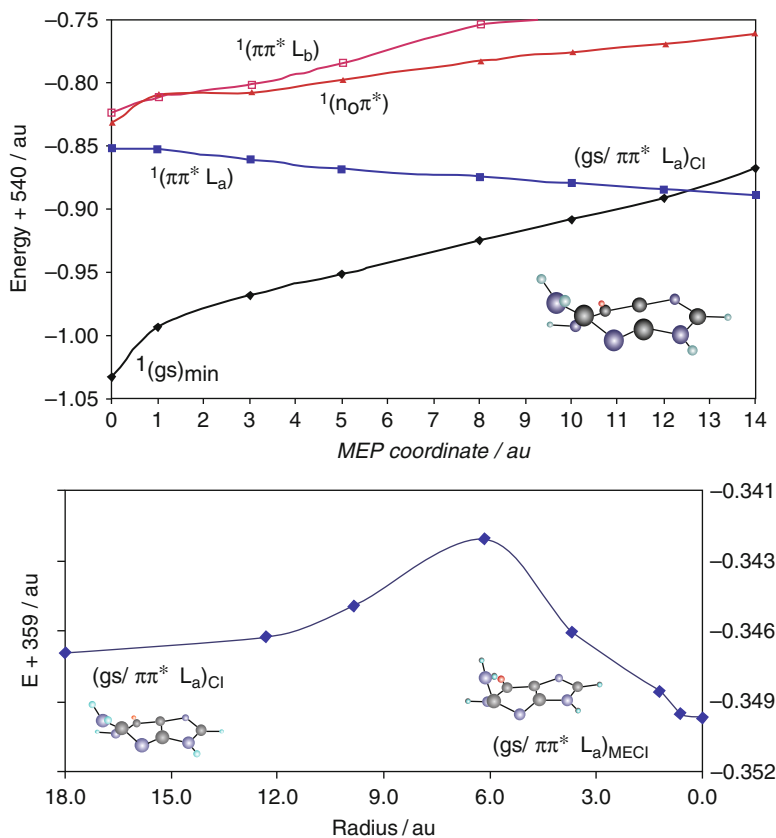

Fig. 19 CASPT2 low-lying singlet states along the MEP from the FC region on the $1(\pi\pi^*HL)$ state in guanine (*top*) and seam of CIs (*bottom*) computed from the MECI structure (*bottom, right*) to the CI close to the end of the MEP (*bottom, left*)

is general in quantum chemistry if two levels of theory are being used to compute geometries and energies, e.g., CCSD(T)//CCSD or MRCI//CASSCF.

Turning to our example, two main situations do actually occur. In cases where the PEHs computed at the CASSCF and CASPT2//CASSCF levels behave approximately parallel (Case A), the CASSCF optimized geometries will be in general correct, despite they have been computed at a lower level of theory. It means that the dynamical correlation contributions are quite regular and similar for the two states in ample regions of the PEH. In these situations, two-step computational strategies like CASPT2//CASSCF can be confidently applied. When dynamical correlation is markedly different for the states considered and varies significantly along the PEH of interest, geometry optimization has to be carried out at the highest correlated level (Case B). Otherwise, the uneven contributions of dynamical correlation may lead to unphysical crossings and interactions between the two electronic states.

Fig. 20 Different effects of correlation within the CASPT2//CASSCF protocol

The crossing can be then placed at a different geometry or it may never occur! Normally, states of ionic (in the valence-bound sense) nature have larger amounts of dynamical correlation in contrast to covalent states, in which the static correlation is able to recover large fractions of the total correlation energy. When both types of states are involved in a crossing, it is clear that a CASSCF description will give an unbalanced picture of the hypersurfaces and, obviously, of the crossing, which can be recovered only by inclusion of the dynamical correlation, with CASPT2 for instance, even in the searching of states crossing. In difficult cases, it can be convenient to map a grid of CASPT2 points in the region of the CASSCF CI to find the degeneracy at the highest level, or, if possible, to compute the CI with CASPT2, more specifically, with MS-CASPT2, considering that CASPT2 provides non-orthogonal and therefore mixed solutions. This is a tricky issue that was studied recently and requires careful consideration.

Figure 21 displays the result of CASPT2/MS-CASPT2/ANO-L Li [4s2p]/F [4s3p1d] calculations on the lowest-lying $^1\Sigma^+$ states of the LiF molecule along its dissociation path (see Serrano-Andrés and Merchán 2005). The lowest state has ionic and covalent character at short and long distances, respectively, because the lowest dissociation channel leads to the ground states of the neutral atoms, whereas the opposite occurs for the second state. At intermediate distances, the lowest ionic and next covalent states interact and change their character smoothly thanks to the multiconfigurational treatment. According to the non-crossing rule for states of the same spin and spatial symmetry that holds true for diatomic molecules, the two curves cannot become degenerate and instead an avoided crossing should take place. In the sample calculations, the results of three different active spaces and two levels of calculation, CASPT2 and MS-CASPT2, have been displayed. In cases A and B, the CASPT2 curves (dotted lines) incorrectly cross or touch. The reason is that in a single-state perturbation theory each root is not orthogonal to the others.

Neglecting the state interaction leads to unphysical crossing situations. On the contrary, the multistate treatment of MS-CASPT2 (solid lines) makes the two states

Fig. 21 CASPT2 (dotted lines) and MS-CASPT2 (solid lines) calculations on the lowest-lying $^1\Sigma^+$ states of the LiF molecule

to interact. The corresponding orthogonal solutions display therefore a “correct” avoided crossing. In case A the employed AS is the minimal one (one 2s orbital from Li and three 2p orbitals from F). Although the MS-CASPT2 solution yields a formally correct avoided crossing, the state interaction is overestimated, giving rise to a large energy splitting at too short distances (as compared to higher-level MS-CASPT2 or MRCI calculations) because of the too large value of the off-diagonal elements in the multistate effective Hamiltonian. A better treatment is obtained for enlarged active spaces in B and, especially, C, in which the increased space allows for angular correlation in the AS and the CASPT2 and MS-CASPT2 solutions match, undoubtedly because the initial CASPT2 states were including most of the interaction effects. Unfortunately in most cases the enlargement of the active space will not be possible. A good strategy is testing different spaces to check the stability of the results. The right solution seems to be between the CASPT2 and the MS-CASPT2 ones. In the worst case, the CASPT2 result is generally not so bad after all.

Table 5 compiles the results of CASPT2 and MS-CASPT2 calculations on the two lowest singlet states of the C_{2h} ethylene dimer using a cc-pVDZ basis set computed at the MECP point upon the increase of the AS (see Serrano-Andrés and Merchán 2005). In order to provide a proper multistate treatment, the off-diagonal

elements of the effective Hamiltonian have to be small and similar, otherwise the matrix symmetrization will be erroneous, whereas the energy split undergone by the original states once diagonalized the matrix will be excessive. Indeed, although the CASPT2 energy differences between the states remained always small (<3.35 kcal mol⁻¹), the splitting largely increases at the MS-CASPT2 level, especially when the off-diagonal elements H_{12} and H_{21} most differ. It is only with the largest active space (angular $\sigma - \pi$ correlation has been included in the active space in this case, 4,242) that the elements become smaller and the MS-CASPT2 reduces. Values close to 2 kcal mol⁻¹ can be considered small enough to identify such feature as a CI point within the accuracy of the method. What happens when a CI search is performed blindly using MS-CASPT2 solutions? Typically, it occurs that the obtained solutions are too separated and, apparently, the closest-energy solutions correspond to an avoided crossing. This is probably a wrong answer derived from that fact that the active space is too small and the MS-CASPT2 method is overshooting the interaction of the CASPT2 solutions. If it is not possible to increase the AS (may be MS-RASPT2 is a solution), it is better trusting in the CASPT2 energies.

Setting the Path for Dynamics

Mapping the PEHs of the molecular systems is not but the initial stage of the calculations. Once the topography of the hypersurfaces is obtained by solving the time-independent Schrödinger equation, the evolution of the nuclei on that potential must be described. Studying the reaction dynamics (RD) of the system implies considering time dependence and the statistical distribution on a sample of molecules. Several procedures can be followed, from the most expensive approach, solving the time-dependent Schrödinger equation, typically along specific reaction coordinates, to the semiclassical approaches, in which quantum-chemical information is used to solve the classical Newton equations. When properly averaged, the obtained data yield, in principle, predictive data for reaction rates, state lifetimes, and population distribution. We will not discuss dynamical calculations here, but will simply try to emphasize that the quality of a RD calculation, no matter how sophisticated, strongly relies on the quality of the underlying quantum-chemical description of the PEHs.

In other words, the dynamics is always as good as the quantum chemistry employed to describe the PEH. Expensive RD calculations tend to use analytical potentials fitted with quantum-chemical parameters, a technique filled with problems. The other approach is known as direct or “on the fly” reaction dynamics, meaning that the quantum-chemical information is obtained at each of the points of a trajectory and passed to the RD step. The basic difficulty stays: how good is the description of the PEHs and how this affects to the RD results?

In the study of thymine described above, it was found that when using lower levels of calculation, for instance, a 6-31G* basis set or a small active space, the CASSCF MEPs run in wrong regions of the PEHs, something that only occurred in thymine and uracil, not in purine bases. The MEP FC¹ ($\pi\pi^*$) leads in this case to the high-energy planar minimum and not to the low-lying CI with the ground state, an outcome obtained only when increasing the quality of the calculation by using ANO-type basis sets, larger active spaces or CASPT2 gradients. It is obvious that the RD description will be strongly affected by the quality of the underlying quantum-chemical description. As an illustration, Fig. 22 includes two sample trajectories computed in the guanine molecule on the lowest-energy ¹($\pi\pi^*$) state starting near the FC region. The calculations used a Verlet-type algorithm for the classical part (which gives the solution of the equations of motion, i.e., how position, velocity, and acceleration change over time) and CASSCF(12,10) or CASPT2(12,10)/6-31G(d,p) quantum-chemical energies and gradients computed “on the fly” at intervals of 5 fs. In this preliminary study, most of the computed trajectories starting close to the FC region were shown to follow a similar path than the MEP, that is, leading to the region of CI with the ground state, and this is done in times close to 100 fs, explaining the ultrafast lifetime measured for the molecule in molecular beams (see Serrano-Andrés et al. 2008). From that point, the complications continue with the selection of the surface hopping algorithm for the population transfer, the diabatic description of the crossing regions, the re-evaluation of the reaction step, etc. (see, just as one of the many examples the use of the NEWTON-X reaction dynamics approach (Barbatti et al. 2007)).

Photoinduced Reactions in Bimolecular Systems

The theoretical description of photoinduced bimolecular reactions requires specific strategies and procedures that will be illustrated here with two examples. First, the cytosine dimer, which forms an excimer in the ground state and it is also able to react yielding a photoadduct in the ground state. Second, the energy transfer reaction between psoralen and molecular oxygen, in which the lowest-energy triplet states are the protagonists.

An Application Example of Reactivity: Cytosine Dimer

One intriguing aspect of UV-irradiated DNA is the appearance of red-shifted long-lived emissive states not found in base monomers, whereas the DNA absorption spectra closely resemble that of the monomers. This phenomenon is called excimer

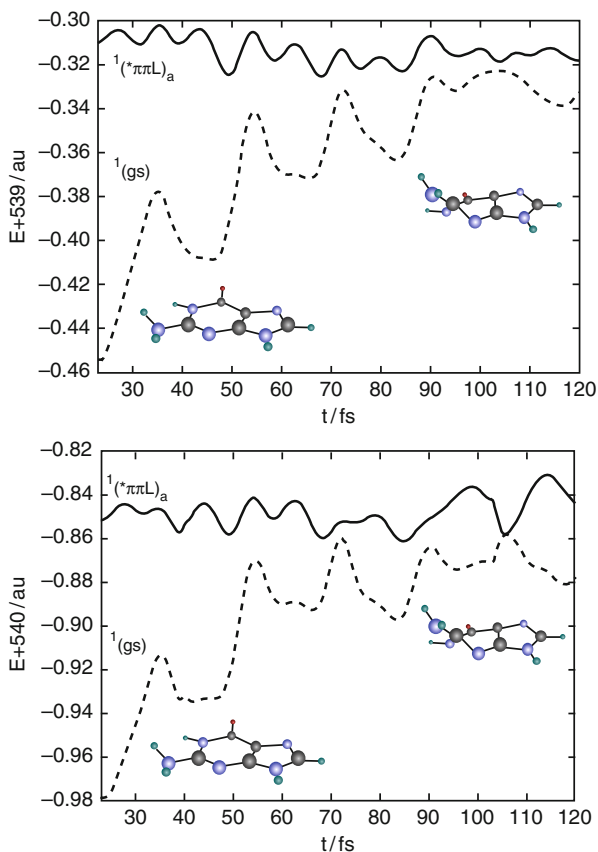

Fig. 22 Sample CASSCF (*top*) and CASPT2 (*bottom*) semiclassical trajectories run on the lowest-energy $^1(\pi\pi^*)$ state of guanine from the FC region

fluorescence, reflecting the relevant role assumed to be played by the corresponding excited dimer (excimer) of the biopolymer, given the similarity between the emission from dinucleotides and polynucleotides (Eisinger and Shulman 1968). Recent experimental results in the light of time- and wavelength-resolved fluorescent techniques using 80 picoseconds (ps) excitation pulses make readily apparent the longer-decay components and red-shifted emission that it was assumed to arise from excimer formation. Because of the slow rate of energy relaxation, these long-lived states associated to excimer-like states have been suggested as the precursors of the DNA photolesions, including photodimers (Schreier et al. 2007).

Classically, an excimer (homodimer) or exciplex (heterodimer) is defined as a dimer system which is bound in the excited state and dissociative in the ground state (see Fig. 23). The existence of excimers between DNA nucleobases was proven theoretically by means of CASPT2(12,12)/ANO-S C,N,O [3s2p1d]/H [2s1p] calculations (see Olaso-González et al. 2006). Potential energy curves (PECs)

Fig. 23 (a) The nonexcited molecule (or a set of molecules; notice that A and B can be both atoms or molecules) is in a bound state; once excited, the molecules evolve to a dissociative state. (b) An excimer is a combination of atoms (or molecules) such that it is bound only in the excited state, and then it dissociates as soon as the system relaxes

Fig. 24 Labeling for the cytosine dimer. Bond distances (in Å) correspond to the ground-state equilibrium geometry of the monomer. The homodimer system displays C_s symmetry, being the mirror symmetry plane represented by a *dashed line* in the side-view inset

with respect to the intermolecular separation (R) of two cytosine molecule kept at the ground-state geometries were built (see Fig. 24). The structure allows for an effective and natural interaction of two cytosine molecules in the biologically relevant *cis-syn* stereoisomer. The ground-state PEC is repulsive at the CASSCF level, whereas the lowest singlet excited state is weakly bound. In contrast, at the CASPT2 level (see Fig. 25), when dynamic correlation is taken into account, the ground-state S_0 and the three lowest singlet excited states (S_1 , S_2 , and S_3) have well defined minima with binding energies of a few tenths of an eV.

The Basis Set Superposition Error (BSSE) is corrected by means of the counterpoise procedure, an important aspect that will be discussed later. In the figure energies are referred to two ground-state cytosine molecules separated about 20 a.u. In the asymptotic limit, S_1 and S_2 become degenerate, which is consistent with the

Fig. 25 BSSE-corrected CASPT2 (12,12) potential energy curves built with respect to the distance cytosine-cytosine arranged in a face-to-face disposition

fact that they are related to the equivalent situations $C + C^*$ and $C^* + C$, where C and C^* stand for the ground-state cytosine and its lowest singlet excited state, respectively. The absorption $S_0 \rightarrow S_1$ calculated at 20 a.u. (4.41 eV) corresponds to the monomer absorption. On the other hand, the vertical emission from the minimum of S_1 is calculated at 3.40 eV, and it can be considered the source of emission observed in DNA or oligomer samples. In particular, the fluorescence maximum was reported in aqueous solution for the dimer $d(C)_2$ and the 15-mer $d(C)_{15}$ at 3.22 eV, considerably red-shifted as compared to that of the monomer (3.96 eV).

Since that theoretical determination, the existence of excimers in DNA and their role as precursors for phenomena like the red-shifted DNA emission, charge transports in the DNA strand, the formation of nucleobase photoadducts, and, in general, the control of the decay dynamics of excited DNA has been determined both theoretically and experimentally. Crespo-Hernández et al. (2004), for instance, have shown by using femtosecond transient absorption spectroscopy that excimers are formed in high yields in a variety of synthetic DNA oligonucleotides and conclude that excited-state dynamics of A · T DNA is controlled by base stacking. CASPT2 calculations explained also the dynamics of the adenine dimer by the presence of the excimers.

As an illustration of bimolecular reactions, the formation of pyrimidine nucleobase adducts in the excited state will be presented here (see Roca-Sanjuán et al. 2008b; Serrano-Pérez et al. 2008d). Among the possible photoreactions that pyrimidine (Pyr) bases of nucleic acids may undergo upon ultraviolet (UV) irradiation, cyclobutane thymine dimers ($T < > T$ or CBT) formed by intrastrand adjacent thymine bases (see Fig. 26) constitute one of the major photoinduced lesions, particularly in cellular DNA, in spite of the direct repair by a light-activated mechanism (DNA photolyase) in which abnormal bonds are cleaved. Unrepaired or misrepaired thymine or cytosine dimers and the resultant mutations

Fig. 26 Photocycloaddition between two adjacent molecules of thymine is a particular class of perycyclic [2 + 2] reaction allowed photochemically and not thermally. It is one of the most usual lesion on DNA. In this picture, taken from a structure obtained in the Protein Data Bank and visualized by Jmol program, the cyclobutane ring is highlighted

may well lead to the development of skin cancer. The major of Pyr < > Pyr photoproducts. The relatively smaller degree of flexibility of A-DNA compared to B-DNA to achieve the right orientations that become prone to react has been related to the greater resistance of A-DNA to Pyr < > Pyr formation.

Dimerization seems to occur only for thymine residues that are already in a reactive arrangement at the instant of excitation because the rate of formation by favorably oriented thymine pairs is much faster than the rate of orientation change. The dimerization reaction occurs both in the singlet and triplet manifolds (see Bosca et al. 2006; Cadet et al. 1992). Focusing on the singlet states, a CI must drive the ultrafast formation of the cycloadduct. Figure 27 displays an scheme of the energy levels of the cytosine dimer in its lowest-lying singlet states based on CASPT2(12,12)/ANO-S C,N,O[3s2p1d]/H[2s1p] results (BSSE corrected). The lines connecting the different solutions represent the different evolution paths followed by the system.

Initially, upon absorption of UV-light radiation in the 4.4 eV region, the system can undergo two types of processes. Nearly unstacked pairs will localize its excitation in one of the monomers and evolve in a ultrafast way toward the ground state via the CI of the monomer, located at 3.6 eV. Other pairs will form an excimer through the stacking interaction of the π clouds of the nucleobases, displaying much larger lifetimes, as it has been already determined experimentally. The binding interaction in the excimer will depend on the conformational arrangement of the

Fig. 27 Scheme based on CASPT2 calculations of the dimerization photochemistry of the cytosine dimer after UV-light absorption

nucleobase pair. Whereas the most common DNA confirmation, B-DNA, displays a very small interaction, strongly overlap situations like the face-to-face parallel arrangement yields the largest binding energy. The cytosine dimer has an excimer structure even lower than the CI leading the system to the formation of the ground state photoadduct CBT. This peculiarity and the presence of both S_0/S_1 CIs, that of the monomer and the one related to CBT, almost isoenergetic and therefore competitive, makes the yield of formation of CBT adducts much smaller than in the case of the thymine dimer, where the CI of the adduct is the lowest and easily accessible feature.

An Application Example of Energy Transfer: Psoralen + O_2

Photomedicine applies the principles of photobiology, photochemistry, and photo-physics to the diagnosis and therapy of diseases. One of the most active research areas in this field is photodynamic therapy (PDT), in which the affected living tissue is treated with a combination of a photosensitizer, activated by UV light, and molecular oxygen in its ground triplet state, $^3\Sigma_g^-$. Oxygen is present in the cellular environment ready to transform into singlet oxygen 1O_2 ($^1\Delta_g$), which is a strong electrophilic species that reacts with different compounds including some components of the cellular membrane causing cell death by apoptosis. An energy transfer (ET) process triggered by electronic coupling between a molecule in an excited state, the donor (D^*), and a molecule, the acceptor (A) or quencher within a

collision complex, is the mechanism through what the reaction takes place, a process that strongly depends on the inter-fragment distance. In general, ET processes, at large separation between the moieties (20–30 Å or even larger), the electronic coupling arises from the Coulomb interaction between electronic transitions that, under the dipole approximation, reduces to the known Förster's dipole–dipole coupling. The process is actually a nonradiative transfer of energy occurring whenever the emission spectrum of D overlaps with the absorption spectrum of A (although no intermediate photon takes part on it). It is the electric field around D*, behaving like a field generated by a classical oscillating dipole, the cause of the excitation of A. At larger separations than Förster's, fluorescence resonance ET (with photon emission by D* and subsequent absorption by A) becomes more efficient than excitation ET. At shorter interfragment distances, however, the so-called Dexter exchange coupling predominates, arising from the exchange integrals that account for the indistinguishability of the electrons in many-electron wave functions. This factor decreases steeply with separation. If the interaction is assumed weak and overlap between D* and A wave functions is produced, Fermi's Golden Rule for coupled transitions can be applied. Such processes have been studied theoretically in depth in recent years, in particular for singlet–singlet ET processes implying an exchange of electrons of the same spin but different energies, that is, the spin state of each fragment is conserved. In PDT, the actual mechanism is, on the other hand, an intermolecular triplet–triplet energy transfer (TET), that is, a process of exchanging both spin and energy between a pair or molecules or molecular fragments. These reactions are commonly used to efficiently populate the triplet states of many organic molecules.

TET processes can be therefore understood as two simultaneous ETs with spin exchange between the interacting fragments and it is similar to the Dexter coupling for singlet–singlet ET, in particular because, as it depends on an electron exchange mechanism, it only takes place at short donor–acceptor distances (<10 Å). In TET the Förster's mechanism will not contribute, because at short distances the dipole approximation breaks down and because the transitions are dipole forbidden. The electronic coupling is not the only key factor that determines the efficiency of the ET process, but also the resonance condition, that is, the energy available in the donor must be at least equal or higher than that required to populate the excited state of the acceptor. If this is the case, the process is usually controlled by diffusion and described as exothermic. In the opposite situation, that is, if the energy of the acceptor is lower than that of the donor, the process becomes thermally activated and lies in the endothermic region. That means that there is an energy barrier whose height will depend on the nature of the acceptor, either classical (for rigid systems) or nonclassical (flexible systems which might find conformations for efficient, non-vertical TET), with a corresponding larger or smaller, respectively, decay in the process rate.

Besides the reaction with DNA nucleobases, psoralen can also interact with molecular oxygen to exert its photosensitizing action. Singlet oxygen and other reactive species of oxygen induce photooxidation of lipids and are considered responsible for cell membrane damaging effects, causing also the appearance of

Fig. 28 Scheme of the oxygen-dependent PUVA mechanism

erythema and pigmentation activity in the human skin. In particular, the TET process taking place between psoralen and molecular oxygen is (see also Fig. 28):

where activated psoralen behaves as a donor in its lowest triplet state, and triplet ground-state oxygen is the acceptor. The lowest excited singlet state of molecular oxygen (${}^1\Delta_g$) is located at 0.97 eV. Furocoumarins (psoralen, 8-MOP, 5-MOP, khellin, TMP, and 3-CPS) have their lowest-lying triplet T_1 state energy at least 1.4 eV higher than the oxygen singlet state, what makes the TET exothermic and diffusion-controlled, with molecular oxygen behaving as a rigid, classical acceptor.

A recent study (see Serrano-Pérez et al. 2009) performed employing the CASPT2/ANO-LC,O[4s3p1d]/H[2s1p] methodology estimated the electronic coupling at some specific disposition of the moieties (psoralen and O_2). Looking for an appropriate arrangement yielding the most effective TET process is nontrivial and, in general, not even relevant, in particular in diffusion-controlled systems which may form a collision complex at short distances. It is important, however, to estimate reaction rates and lifetimes at different intermolecular distances. Furthermore, $\text{M}-\text{O}_2$ interaction potentials are very weak, and the potential surfaces are generally characterized by multiple shallow minima. Hence, it is necessary to consider different orientations when approaching M and O_2 through a basic interfragment coordinate, here the distance R. Previous studies on systems composed by two ethylene molecules (Et–Et), by the methaniminium cation and ethylene (MetN^+-Et), and by ethylene and molecular oxygen ($\text{Et}-\text{O}_2$), show that the face-to-face (FF) arrangement is the most appropriate orientation (see Fig. 29).

The geometries of both psoralen and molecular oxygen were kept fixed at the CASSCF optimized triplet excited (T_1) state structure and the triplet ground

Fig. 29 Psoralen- O_2 supermolecule. The molecular oxygen was placed parallel to the reactive pyrone double bond of psoralen

($^3\Sigma_g^-$) state experimental geometry, respectively. The active space employed was 14 electrons/11 orbitals (8/7 located in the furocoumarin and 6/4 located in O_2). The active space was validated after comparing the results with previous findings in the isolated psoralen and control calculations on the oxygen molecule with larger active spaces and basis sets. The four lowest singlet states and the three lowest triplet states of the supermolecule were computed. The molecule behaves as a donor in its triplet state, and it is capable to transfer its energy to molecular oxygen in its triplet ground state to generate the singlet ground state furocoumarin and excited singlet oxygen ($^1\Delta_g$). The energy of the triplet state of the furocoumarin is much higher than the energy of the oxygen $^1\Delta_g$ state (computed 1.09 eV, experimental 0.97 eV), and the process falls clearly into the exothermic regime, expected to be controlled by diffusion. Figure 30 displays the potential energy curves of the lowest-lying singlet and triplet states of the supermolecule psoralen- O_2 in a FF arrangement with respect to the $C_3=C_4$ bond of the pyrone ring (the reactive bond in the triplet state, where the spin density is basically located at different intermolecular distances). The states of the supermolecule protagonist of the TET are 4^1A (T_1 of psoralen + $^3\Sigma_g^-$ of O_2), as initial energy level, and 1^1A (S_0 of psoralen + $^1\Delta_g$ of O_2), as the final outcome of the process in which both moieties have changed spin and energy. Within the present approach, the electronic coupling (H') is obtained as half the difference $|\epsilon_\infty - \epsilon_i|$, where ϵ_∞ and ϵ_i are the energy gaps between the states 4^1A and 1^1A at infinite distance (at 10 Å in the current computation) and at the different interfragment distances, respectively. In this way, the coupling represents the perturbation introduced in each state due to the interaction within the dimer. It is important to notice how advantageous that definition is, because the results are in practice independent of the number of states considered. Notice that the BSSE problem does not affect the results of the coupling, which uses energy differences between states computed at the same geometry. As a result, the BSSE correction vanishes when the energy gap is computed. In other cases, known as non-vertical TET systems, the geometry of the acceptor can be distorted to better accept the photosensitization from the donor. In such situations, the search for regions of state degeneracy with enhanced effectiveness for the ET transfer may be convenient. This is not the case for the present example, in which the acceptor is a rigid oxygen molecule and the process is basically diffusion controlled.

Fig. 30 Potential energy curves of the low-lying excited states of the supermolecule psoralen-molecular oxygen along the interfragment distance (R). The energy coupling H' is obtained as half of the energy difference $|\epsilon_\infty - \epsilon_i|$ between the initial 4^1A (T_1 of psoralen and ${}^3\Sigma_g^-$ of O_2) and final 1^1A (S_0 of psoralen and ${}^1\Delta_g$ of O_2) states of the supermolecule at infinite distance (ϵ_∞ , zero coupling situation) and at each of the distances (ϵ_i)

2.25	0.3833	1.40×10^{14}	7.13×10^{-15}

Table 6 compiles the values of the electronic coupling computed at the different internuclear distances, related with the ET rates and lifetimes. In the weak coupling regime in which the electronic interaction is smaller than the vibrational reorganization energy, the rate for triplet–triplet energy transfer (k_{TET}), and the corresponding lifetime (τ_{TET}), between the donor and the acceptor can be estimated using Fermi's Golden Rule:

$$k_{\text{TET}} = \frac{1}{\tau_{\text{TET}}} = \frac{4\pi^2}{h} \left| \langle \psi_i | \hat{H} | \psi_j \rangle \right|^2 \rho_E = \frac{4\pi^2}{h} (H')^2 \rho_E, \quad (8)$$

where the matrix element of the Hamiltonian, H' , is the electronic part of the energy transfer (i.e., the electronic coupling) and ρ_E is the density of vibrational states in the

initial and final states and their spectral overlap. The inverse of the rate is the lifetime of energy transfer. To obtain the TET rates, we have taken values of $\rho_E = 200 \text{ eV}^{-1}$ and $(4\pi^2/h) = 9.554 \times 10^{15} \text{ eV}^{-1} \text{ s}^{-1}$. This order of magnitude for the value of the density of states was used previously as a good estimation in systems of this size.

The whole process of generation of singlet oxygen from psoralen does not only depend on the efficiency of the TET from the triplet state of the photosensitizer, but also on the rate of formation of the triplet state itself. As shown previously, in psoralen the crucial step to populate the triplet manifold in the gas phase is the intersystem crossing (ISC) process between the initially populated singlet $S_\pi (\pi\pi^*)$ state and the lowest-lying triplet $T_n (n\pi^*)$ state. The latter state evolves subsequently toward the lowest triplet $T_1 (\pi\pi^*)$ state via a corresponding (and essentially barrierless and ultrafast) internal conversion (IC).

In a similar manner as for Eq. 8, the estimation of the rate constant, here for nonradiative ISC (k_{ISC}), can be obtained as:

$$k_{\text{ISC}} = \frac{4\pi^2}{h} |H_{\text{SO}}|^2 \rho_E, \quad (9)$$

where H_{SO} stands for the spin-orbit coupling terms for the nonradiative transition $S_\pi (\pi\pi^*) \rightarrow T_n (n\pi^*)$. An estimated value of 200 eV^{-1} will be employed for ρ_E as used for psoralen in studies explicitly computing vibronic factors.

The ISC nonradiative process corresponds to the transfer $S_\pi (\pi\pi^*) \rightarrow T_n (n\pi^*)$ in each furocoumarin donor, a process which will take place more efficiently in the region of the (S_π/T_n) STC singlet-triplet crossing, and that subsequently will give rise to an ultrafast population of the lowest $T_\pi (\pi\pi^*)$ by internal conversion in the triplet manifold. The spin-orbit coupling factors near the crossing point between S_π and T_n , along the LIIC performed in a previous study, is 9.2 cm^{-1} (see Fig. 17). As a result, the k_{ISC} rate computed was $3.58 \times 10^9 \text{ s}^{-1}$. Additionally, to the H_{SO} strength, the presence of energy barriers in the potential energy hypersurfaces may strongly affect the value of the rate constants, which can be corrected using the Arrhenius exponential term in the framework of the transition state theory. As a qualitative estimation of these effects, a corrected ISC rate (k'_{ISC}) can be obtained from:

$$k'_{\text{ISC}} = k_{\text{ISC}} e^{-\Delta E/RT}, \quad (10)$$

where k_{ISC} is that computed from Eq. 9, ΔE is the energy of the barrier from the initial electronic singlet to the triplet state, R is the ideal gas constant, and T the temperature (298 K). In this particular context, ΔE will be estimated as the energy difference between the singlet $S_\pi (\pi\pi^*)$ state, populated at the Franck–Condon geometry, and the triplet $T_n (n\pi^*)$ state in the computed crossing point with the singlet state $(S_\pi/T_n)_X$, considering that the energy obtained initially to populate S_π will be available, at least, to surmount the barrier and populate T_n .

In a previous section, we considered as a barrier the energy difference between the minimum of the S_π state and the crossing point $(S_\pi/T_n)_X$, which is 0.36 eV, but the present approach accounts for the excess vibrational energy available in the

system from the initially populated S_π state (at the Franck–Condon geometry) to the crossing point (0.03 eV), which seems to be more relevant in this context, where the interest focuses on rate constants. The results were $1.11 \times 10^9 \text{ s}^{-1}$ and 0.90 ns for k'_{ISC} and τ'_{ISC} , respectively.
