Because Si clusters undergo such a drastic change in cross section, an excellent experimental technique exists for studying the structure as a function of size. This technique (Jarrold and Constant 1991) is based upon the difference in the mobility of cluster ions that have different shapes. The ion mobility of a cluster depends on its rotationally averaged collision cross section, which depends on its size. Prolate and oblate geometries have a larger cross section and therefore smaller mobilities (Sieck

et al. 2003). Mobility studies indicate that Si_n clusters undergo a phase transition at about $n = 24\text{--}34$ from elongated to spherical, whereas for the Ge clusters, this transition size is between $n = 64$ and $n = 74$ (Jarrold and Constant 1991; Shvartsburg and Jarrold 1999).

The growth sequence of Si is realized by adding on small building blocks to smaller structures. In particular, Si_9 (Shvartsburg and Jarrold 1999) and Si_{10} (Baletto and Ferrando 2005) have enhanced stability and, therefore, act as the fundamental building blocks. On the other hand, medium-sized Si clusters are quasispherical but not crystalline. Crystallinity does not become apparent until N gets as large as a few hundred atoms (Baletto and Ferrando 2005).

In the simulated annealing and DFT-based tight-binding work by Sieck and coworkers (2003), a *prolateness parameter* is defined as follows

$$p = \sum_{j=1}^3 (I_j - \hat{I}) = -\frac{I_1}{2} + I_2 - \frac{I_3}{2}, \quad (3)$$

where $0 < I_1 \leq I_3$ and $\hat{I} = (I_1 + I_3)/2$. For an oblate structure, $p < 0$; for a prolate structure, $p > 0$; and for a spherical structure, $p = 0$. Sieck and coworkers (2003) studied various different isomers corresponding to three fixed sizes, namely, $N = 25$, 29, and 35. In Fig. 3, the cohesive energy versus the prolateness parameter for the low-lying isomers is displayed. An investigation into the most stable structures clearly indicates the tendency to go from elongated to spherical structures as the clusters grow in size.

Fig. 3 Cohesive energy versus prolateness parameter defined in Eq. 3 for 30 lowest lying isomers of Si_{25} , Si_{29} , and Si_{35a} (Reprinted with permission from Sieck et al. (2003). © (2003) by Wiley-VCH)

An important point is noted by Sieck and coworkers (2003), that different methods, even different flavors of the same method (LDA/GGA in DFT), may disagree about the exact energetic ordering of clusters; however, usually the lowest energy structures are local minima in all of them.

As an example to the multiscale methods mentioned above, Bulusu and coworkers (2005) used a basin-hopping algorithm combined with DFT to explore low-lying minima for Ge_{12} – Ge_{20} . Global minima for the Ge clusters in this size range are compared to minima of Si clusters. Various checks were performed to make sure different starting points yield the same global minima, such as different seeding patterns. Unlike most studies in the literature, zero-point motion is taken into account while calculating the binding energies.

In the same work (Bulusu et al. 2005) of Si and Ge, clusters in the size range 12–20 were compared and clusters of both Si and Ge were shown to have prolate geometries. However, their growth patterns were found to diverge at $N = 13$. The global minima for Ge clusters of size 12–16 are obtained by adding atoms to the Ge_9 tetracapped trigonal prism (TTP) structure familiar from Si clusters (Bulusu et al. 2005). For low energy-Si clusters, TTP-to-sixfold puckered ring (six/six) transition occurs at $N = 16$ and clusters with higher number of atoms all contain the six/six pattern. In contrast, TTP-to-six/six pattern may occur at $N = 19$ for Ge clusters, and at $N = 20$, the magic number cluster Ge_{10} appears to be the preferred structural motif.

According to Shvartsburg and Jarrold (1999), clusters of Sn up to $n \approx 35$ follow the trend of germanium and prolate silicon clusters (Shvartsburg and Jarrold 1999). For $N > 20$, the mobility of Sn clusters shows larger fluctuations than either Si or Ge. This might indicate the presence of multiple isomers of Sn clusters in this size range (Shvartsburg and Jarrold 1999). Even though the $\alpha \Rightarrow \beta$ transition occurs between 286 and ≈ 310 K in the bulk, Sn clusters do not undergo such a transition even at higher temperatures. In fact, mobility measurements show that Sn clusters do not show significant changes in structure for a very broad temperature range. Transition from prolate to spherical growth in Sn clusters is not abrupt like the transition in Si and Ge clusters but occurs in steps. Clusters of $N \leq 35$ adopt a stacked prolate morphology much like Si and Ge clusters. This is unexpected because these highly noncompact structures are suitable for covalent materials, whereas bulk Sn under ambient conditions is a metal. In a sense, the covalent-to-metal transition that occurs between the fourth and fifth row of the periodic table for the carbon series in the bulk fails to occur in their clusters. Shvartsburg and Jarrold (2000) also find that Pb_n^- and Pb_n^+ clusters display different magic numbers.

Going down the group IV in the periodic table, a comprehensive set of data is given by Shvartsburg and Jarrold (2000). Their findings reveal that Pb clusters are structurally different from Si, Ge, and Sn cluster for $N < 25$. While the latter clusters have low mobilities in this size range indicating a prolate structure, Pb clusters exhibit much higher mobilities meaning they are quasispherical in shape. For $N > 25$, Si clusters also display mobilities in accord with a spherical shape. However, their mobilities are considerably smaller than the Pb clusters in the same

size range. This is attributed to the densely packed nature of the Pb clusters in contrast with the open, cage-like arrangement of the Si clusters.

Transition metals form the largest group of elements considered in this section. Even as bulk materials, they exhibit very interesting and diverse properties, in particular magnetism. Interesting questions therefore arise concerning whether such properties as magnetism are maintained or altered in clusters (Briere et al. 2002; Kabir et al. 2006). Appearance of magnetism in the clusters of $4d$ elements (such as Ru, Rh, and Pd) is a very interesting phenomenon as these elements are nonmagnetic in the bulk. Clusters of $3d$ elements (such as Fe, Co, and Ni), which are already magnetic in the bulk, exhibit enhanced magnetic moments in the cluster form due to narrower band widths and the increased localization of the electrons (Kumar and Kawazoe 2002; Pawluk et al. 2005). Indeed, a recent Stern–Gerlach experiment revealed that Mn clusters in the range $N = 11$ –99 display ferromagnetic ordering even though no such ordering is observed in the bulk phase (Knickelbein 2001). These results reveal PES minima at $N = 13$ and $N = 19$ and PES maxima at $N = 15$ and $N = 23$ –25.

We should mention here that most of the magnetism studies mentioned in this section take into account only the electronic spin contribution to the magnetic moment. This can be done only in the cases where the spin-orbit coupling can be neglected (Bansmanna et al. 2005).

In the work by Rodríguez-López and coworkers (2003), Co clusters in the range $N = 4$ –60 were studied by means of an evolutive algorithm based on the Gupta potential and tight binding. Experiments reveal that much like the Cr clusters (Payne et al. 2006), different isomers of Co clusters coexist with distinct magnetic moments. In this work two sets of isomers are identified for each size – the lowest and the second-lowest lying. For the lowest lying isomers, an icosahedral growth is observed with structures derived by adding atoms to the main icosahedral sizes at $N = 7, 13, 19, 23, 26, 34, 43,$ and 55 . For the second isomers, no particular growth pattern was identified. The stability of these sizes was also confirmed by the second energy difference ΔE_2 in addition to other intermediate icosahedral structures.

Relative thermodynamic populations of the lowest energy isomers were used to simulate possible experimental conditions. Isomers coexist particularly evenly between sizes of enhanced stability. This is due to the influence of the entropic contribution of the low-frequency normal modes of the isomers to the free energy. For both the global minimum and the second isomer, a nonmonotonic decrease is observed with increasing size. The greatest difference between the two sets of clusters arises in the range $N = 20$ –40, which corresponds to the range where the average interatomic distance and average coordination of the two sets show significant difference. In this size range, two effects seem to compete for determining the magnetization of the two sets of configurations. On the one hand, the average coordination is higher for the global minima, which should result in lower magnetic moments for the global minima. On the other hand, the average nearest-neighbor distance is higher for the global minima, which should yield higher magnetic moments. The results indicate that the average coordination number effect dominates.

For noble and transition metals, the interactions between atoms are not pairwise and simple empirical potentials are inappropriate (Barreateau et al. 2000). Therefore incorporating many body effects into the potentials is essential. Moreover, for magnetism studies, *ab initio* methods need to be employed, which render global optimization efforts extremely computation intensive. Therefore, most results we shall quote here will be based on restricted searches of the potential energy surface.

In the work by Barreateau and coworkers (2000), for instance, the relative stability of cuboctahedra and Mackay icosahedra is determined for Rh and Pd clusters for $N = 13, 55, 147, 309,$ and 561 using a tight-binding method. Since both structures have an identical sequence of magic numbers, it is interesting to determine the transition size. A continuous transition is possible from the Mackay icosahedron to the cuboctahedron, and for the Rh and Pd clusters, this pathway is explored. An analysis of the Mackay transition from the cuboctahedron to the icosahedron reveals that for $N = 13$, the cuboctahedron is unstable for both Rh and Pd, becoming metastable for larger sizes with an increasing activation barrier with size. The magnetic moment of rhodium was found to disappear for sizes more than 100 atoms, and palladium clusters were found to be hardly magnetic.

In Mn clusters, on the other hand, magnetism plays an important role in determining the ground state structures. As mentioned in the work by Briere and coworkers (2002), many spin isomers can lie close in energy. In this work, a few local geometric configurations of $N = 13, 15, 19,$ and 23 were studied using spin-polarized calculations. At all sizes except $N = 15$, the structure with the lowest energy was found to be icosahedral. For $N = 15$, a bcc configuration was found to be favorable. In terms of spin, all the structures were found to be ferrimagnetic with alternating domains of different spin configurations (see Fig. 4). Except for $N = 15$, the mean value of the integrated spin density was found to decrease with increasing size.

In the DFT work by Kabir et al. (2006), the ground state structure for Mn_{13} was found to be the icosahedron with the two pentagonal rings that are coupled antiferromagnetically. Therefore, the resulting magnetization is small, namely, $0.23\mu_B/\text{atom}$. This magnetization is considerably smaller than the neighboring sizes 12 and 14. The $N = 14$ structure differs from the $N = 13$ structure by a single capping atom. However, the presence of this atom changes the magnetization arrangement considerably. In this case the pentagonal rings are ferromagnetically coupled and the magnetization is $1.29\mu_B/\text{atom}$. The case of Mn_{15} is worth mentioning because of the discrepancy between two DFT studies by Briere and coworkers (2002) and Kabir et al. (2006). In the latter, the ground state structure was found to be icosahedral with a magnetic moment of $0.87\mu_B/\text{atom}$, whereas Briere et al. (2002) found a bcc structure with $0.20\mu_B/\text{atom}$. For $N = 19$, a double icosahedron was observed, which again has a smaller magnetic moment, $1.10\mu_B/\text{atom}$, than its neighboring clusters. The central pentagonal ring is AFM coupled to the neighboring pentagonal rings. This behavior is persistent in the $N = 20$ cluster, which has a magnetic moment of $1.50\mu_B/\text{atom}$. In the range $N = 11 - 20$, spin segregation is observed, where like spins tend to cluster. The binding energy is observed to increase monotonically with

Fig. 4 Lowest energy structures of some Mn clusters. Relative spin alignments are marked with dark for spin up and light for spin down (Reprinted with permission from Briere et al. (2002). © (2002) by the American Physical Society)

increasing size. This is due to the increased sp. bonding. However, when compared with other transition metals, Mn clusters remain weakly bound.

An interesting property of Ta clusters was demonstrated in a recent study (Fa et al. 2006), where ferroelectricity and ferromagnetism were proven to coexist. Initial structures were obtained by simulated annealing using an empirical potential. These structures were later reoptimized with DFT calculations. The magic numbers for Ta clusters were found to be 4, 7, 10, 15, and 22. It was therefore deduced that Ta clusters do not prefer icosahedral growth. For $N = 13$, for instance, the lowest energy structure among those studied was found to be a distorted five-capped hexagonal bipyramid. For $N = 19$, the most stable structure is decahedral in contrast with the double icosahedron, which was found to be stable for many other clusters. No perfectly symmetric structures were found indicating that Jahn–Teller distortions play an important role in determining the ground state structures of Ta clusters. In the size range studied in this work (Fa et al. 2006), the atomic packing shows differences such that each size behaves like an individual system rather than steps of a continuous growth sequence. In addition, electronic dipole moment and magnetic moment were also calculated. The electronic dipole moment was found to have the same trend as the *inverse coordination number*, which is a parameter that reflects the asymmetry of the cluster. This agreement is attributed to the strong correlation between the structure and the electronic dipole moment of the clusters. Odd- N Ta clusters also display a magnetic moment of about $1\mu_B$, which suggests the possibility of the coexistence of ferroelectricity and ferromagnetism. The growth pattern of Ta was found to be very similar to that of Nb. However, when compared with vanadium clusters, this similarity is absent (Fa et al. 2006).

In a similar work by Fa and coworkers (2005), Nb clusters were also found to display ferroelectricity supported by a recent experimental study. This is an important discovery because ferroelectricity was never observed in single-element bulk materials. For $N \geq 38$, the electric dipole moment exhibits even-odd oscillations. This suggests that there is a strong correlation between the structure and the ferroelectricity.

In the work by Pawluk and coworkers (2005), the structure and stability of several Ir clusters were studied using DFT. Rather than using a global optimization algorithm, possible configurations both truncated from bulk and built independently were relaxed locally. The results indicate that Ir clusters mostly prefer cube-like structures up to $N = 13$, except for $N = 11$, which assumes an elongated structure. At $N = 13$, the lowest structure among the ones studied is the icosahedron. This is in contrast with Ru and Pt, which prefer simple cubic structures. When compared to clusters cut from the fcc bulk, simple cubic structures turn out to be more stable up to a size of $N = 48$. This transition occurs near $N = 40$ in Ru and $N = 13$ for Pt. Another interesting property studied in this work is the fluidity of clusters. The results indicate that while the Pt clusters exhibit a more fluidlike character and will thus easily coalesce with other clusters, Ir clusters are more rigid and have less tendency toward coalescence.

An interesting experimental result concerning Pt clusters was reported by Liu and coworkers (2006), who found that Pt_{13} clusters exhibit substantial magnetism (about $0.65\mu_B/\text{atom}$) even though bulk Pt is not magnetic.

Although for such clusters as Ni and Au, the icosahedral structure is calculated to be metastable with stability decreasing with size, experiment reveals that icosahedral structures are found in clusters containing several thousands of atoms. This means that kinetic effects are also very important in determining the structure of a cluster (Gafner et al. 2004). In order to simulate these kinetic effects, a 555 Ni cluster was studied using tight binding by Gafner and coworkers in (2004). The cluster was heated to 1,800 K ($T_{\text{melt}} = 1,145$ K) and subsequently cooled to 300 K. The melting and crystallization curves are determined from a sudden change in the potential energy as a function of temperature. They found that slow cooling results in an fcc structure, whereas fast cooling results in the formation of a metastable icosahedral structure.

In the study by Köhler and coworkers (2006), the potential surface of a few sizes ($N = 13, 53\text{--}57$) of Fe clusters was mapped out with respect to magnetization and volume change using a DFT-based tight-binding scheme. Icosahedra were found to be the most stable structures for the magic numbers $N = 13$ and $N = 55$. Two local minima were observed for the $N = 13$ icosahedron, one ferromagnetic and one antiferromagnetic. The PESs for clusters with $N = 53\text{--}57$ were mapped out using a genetic algorithm-based procedure. Derivatives of the $N = 55$ structure were considered for $N = 53, 54, 56$, and 57 . Generally icosahedra and icosahedron-derived structures have relatively small magnetic moments. The structures without apparent symmetry show higher magnetic moment than icosahedra. No ferromagnetic ordering was found for the Fe_{55} cluster.

Tiago and coworkers provide a very comprehensive explanation of the origin of magnetism in small Fe clusters in their article (Tiago et al. 2006). In the Fe atom, the magnetic moment is a result of exchange splitting. The $3d_{\uparrow}$ states are occupied by five electrons, while the $3d_{\downarrow}$ states are occupied by a single electron, which results in a rather high magnetic moment of $4\mu_B$. When the atoms come together to form a crystal, hybridization of the large $4s$ bands and the $3d$ bands reduces the magnetism down to $2.2\mu_B$. In clusters, hybridization is not so strong because of the reduced coordination numbers of the surface atoms. Because this hybridization depends on orientation, clusters with faceted surfaces are expected to have different magnetic properties than those with irregular faces. According to Tiago and coworkers (2006), this effect is the likely cause of the nonmonotonic suppression of magnetic moment as a function of size. Two classes of Fe clusters were considered in this work: faceted and nonfaceted. Nonfaceted structures are nearly spherical in shape and faceted structures are built using the conventional layer-by-layer growth model. The magnetic moment was calculated as the expectation value of the total angular momentum,

$$M = \frac{\mu_B}{\hbar} [g_s \langle S_z \rangle + \langle L_z \rangle], \quad (4)$$

where $g_s = 2$ is the gyromagnetic ratio of the electron. The magnetic moments of the clusters as a function of size are displayed in Fig. 5 for all classes of clusters considered. Suppression of the magnetic moment with increasing size is observed, in good agreement with experiment. Clusters with faceted surfaces indeed have a lower magnetic moment due to more efficient hybridization although the correlation of shape and magnetic moment is not always well defined. Icosahedral structures are predicted to have magnetic moments lower than bcc clusters.

Another good example of disagreement between different methods is given in Krüger and coworkers where Pd clusters having several high-symmetry structures including icosahedra, octahedra, and cuboctahedra were optimized using both the LDA and GGA in the DFT framework. GGA yields larger bond lengths in accord with the general expectation. But the difference is almost independent of size. Icosahedral structures tend to yield larger bond lengths than octahedral and cuboctahedral structures, also displaying a flatter variation with increasing coordination number. The accuracy of this *breathing mode* relaxation was confirmed by comparing to a full relaxation of the Pd₅₅ cluster.

The Pd₁₃ cluster was found in the work of Kumar and Kawazoe (2002) to have an icosahedral structure with a $0.62\mu_B/\text{atom}$ magnetic moment. This result agrees with some of the earlier studies and disagrees with some others. The central atom in the cluster is found to have a smaller magnetic moment than the surface atom only by a very small amount unlike the large difference in the Mn₁₃ study of Kabir and coworkers (2006). For $N = 14$ and 15, icosahedron-derived structures are favored over other high-symmetry structures. The magnetic moments for both sizes remain around $0.5\mu_B/\text{atom}$. Going from $N = 16$ to the double icosahedron at

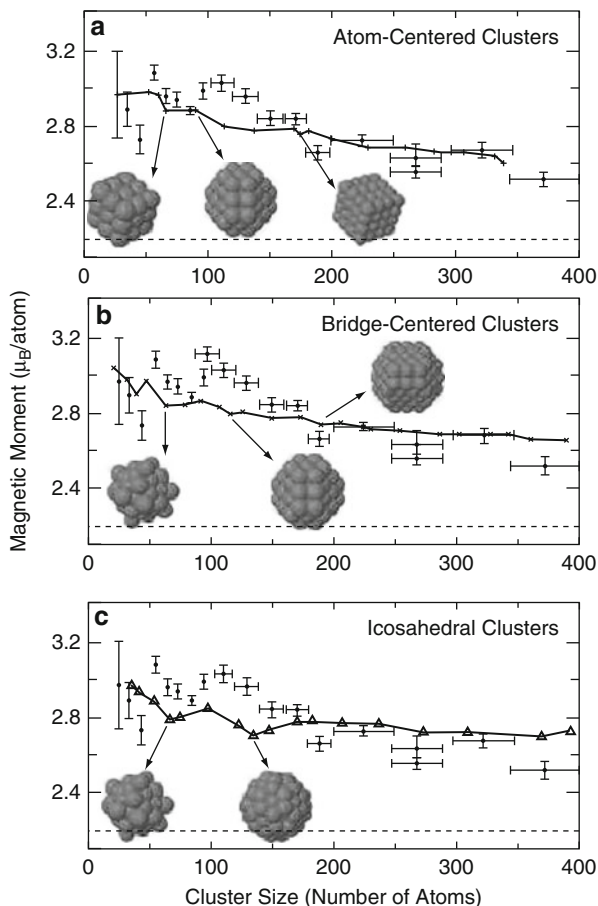

Fig. 5 Magnetic moments of faceted and nonfaceted Fe clusters in the icosahedral and bcc configurations: (a) atom-centered bcc, (b) bridge-centered bcc, and (c) icosahedral. Experimental data is displayed as *black diamonds* for comparison (Reprinted with permission from Tiago et al. (2006). © (2002) by the American Physical Society)

$N = 19$, the magnetic moment decreases from $0.38\mu_B/\text{atom}$ to $0.32\mu_B/\text{atom}$. As the cluster sizes increase, there is a decrease in local (atomic) magnetic moments. For $N = 55$ and $N = 147$, the lowest lying state was found to be the Mackay icosahedra. Cubic and decahedral structures were found to have the next highest energies, with $0.29\mu_B/\text{atom}$ and $0.41\mu_B/\text{atom}$, respectively. For the Pd_{55} cluster, structures with smaller magnetization lie very close to the ground state and would therefore be accessible at room temperature. So magnetic order can be easily lost under experimental conditions. In contrast to the results for Mn (Kabir et al. 2006), the icosahedral structures have a higher magnetic moment than other high-symmetry structures.

In work of Nava and coworkers (2003), Pd clusters were studied using the spin-polarized DFT method in the range $N = 2$ –309. The $N = 13$ cluster was found to have an icosahedral structure with a high spin state. It is seen to undergo a very slight Jahn–Teller distortion, which increases the cohesive energy only by 0.01 eV. The truncated decahedron and the cuboctahedron are found to be less stable.

Yao and coworkers (2007) utilized results from simulated annealing of Ni clusters using an empirical potential as starting configurations to further optimize them using a DFT code. This is another technique often used in cluster literature. In this work, Ni clusters with $N = 10$ –27 atoms were found to attain icosahedron-like structures with the $N = 13$ cluster being a perfect icosahedron and $N = 19$ the double icosahedron. Clusters in the range $N = 28$ –40 have very complicated structures because they are in the transition region between the $N = 13$ icosahedron and the $N = 55$ icosahedron. Around $N = 19$ and $N = 55$, clusters are mostly formed by adding or removing a few atoms from the corresponding perfect icosahedra. Dips are observed in the magnetic moment for $N = 13$ and 55 as expected from the compact structure of these clusters.

While all of the studies mentioned above deal with collinear spin, which singles out one direction along which the magnetic moment may be oriented, a very important class of clusters with high magnetic moments displays noncollinear spin. In these clusters, the magnetic moment is allowed point in an arbitrary direction and thus presents a new degree of freedom. A good example for the investigation of this effect is presented in the work by Du et al. (2010) where six-atom clusters of Co and Mn atoms with several different compositions but always in the octahedral geometry were investigated within the DFT theory including the noncollinear spin formalism. Low-lying isomers with up to more than 40° of average degree of noncollinearity were identified. For certain compositions and geometries, different tendencies for magnetic coupling (AFM vs. FM) are also found to cause a certain degree of spin frustration.

In the work by Zhang and coworkers (2004), Mo clusters were studied within the DFT framework. An interesting result was that the initial icosahedral structure for the $N = 13$ cluster was found to undergo a very large distortion. This distortion was explained by the tendency of Mo clusters to form Mo dimers. The strength of the bonds in Mo_{13} is covalent; therefore, at this size, the cluster shows nonmetallicity. At $N = 55$, the icosahedral structure is found to again undergo a large distortion. However in contrast to $N = 13$, the alternate O_h structure was not found to be much more stable than the distorted icosahedron. This was explained by the decrease of nonmetallicity with size.

1D Structures: Nanotubes, Nanowires, and Nanorods

In nanoscience literature, the name *one-dimensional* was coined to describe systems where one of the dimensions is several orders of magnitude larger than the other two dimensions. Much like the zero-dimensional case, the border between one- and two-dimensional systems is ill defined and system dependent. For this reason,

two-dimensional systems exhibit the same richness in structural and electronic properties as in the zero-dimensional case unlike their bulk counterparts.

One-dimensional structures may, in the broadest classification, be divided into nanotubes, nanowires, and nanoribbons. Graphene nanoribbons (GNRs) (Law et al. 2004; Hyun et al. 2013). *Nanotubes* are simply described as two-dimensional materials (such as graphene, BN sheets, TiO₂ sheets, and many others) seamlessly rolled into a hollow cylinder although the actual fabrication usually follows a much more involved procedure. Nanotubes may be regarded as a unique subset of one-dimensional structures that do not have a surface and are thus devoid of surface effects. In this respect they are analogous to the fullerenes in the zero-dimensional case. *Nanowires* on the other hand are extremely thin wires that are grown or extracted along well-defined crystal directions and may have widely different surfaces. The surfaces, however, rarely remain in their bulk configuration and often reconstruct to reduce strain or saturate broken bonds. This procedure is highly size and material specific, and nanowires therefore display a large variety of strongly surface-dependent properties (Dasgupta et al. 2014; Kempa et al. 2013). Finally, *nanoribbons* are thin strips of two-dimensional materials such as graphene. The edges may reconstruct or be saturated with different species to modify their properties (Ozdamar and Erkoc 2012; Ince and Erkoc 2011; Kilic and Erkoc 2013b).

In addition to structural and electronic properties that are explored in zero-dimensional materials, one-dimensional materials also exhibit rather interesting elastic properties. We shall begin this section with a brief review of elastic considerations regarding one-dimensional nanomaterials and afterward move onto structural and electronic properties.

Elastic and Structural Properties

In nanowire applications such as AFM tips, NEMS, and MEMS, which make use of mechanical properties, it is crucial to have a good understanding of the evolution of elastic properties all the way down to the nanoscale. Elastic properties that are ordinarily under investigation include elastic moduli, plasticity, crack propagation, buckling, and breaking points.

There are numerous examples of experimental determination of elastic properties of nanowires in the literature. A recent study by Barth and coworkers (2009) determines the Young's modulus of SnO₂ nanowires by anchoring and bending them with the help of an AFM tip. By mapping the bending amplitude to the Young's modulus through classical elasticity formulae, the Young's modulus is estimated at around 110 GPa for the samples studied.

Contrary to the macroscopic scale, the elastic properties of nanoscale one-dimensional systems are often seen to depend on their physical dimensions. This intriguing fact brings forth the necessity of studying, among others, the elastic properties of such systems as a function of their size. In fact, the theoretical literature is very rich in examples of such studies. Empirical potentials are particularly suitable for studies of size dependence since systems with large numbers of atoms may be

handled with relative ease, allowing the determination of convergence of elastic properties of nanomaterials to those of their bulk counterparts. A related question to this fact is to what extent the laws of continuum elasticity can be applied to nanoscale systems, which has received much attention both theoretically and experimentally. A recent study by Rudd and Lee (2008) opens with this very same question, where the Young's modulus of Ta (001) and Si (001) nanowires has been determined using a Finnis and Sinclair (1984) and Stillinger and Weber (1985) potential, respectively, in a molecular dynamics simulation. Nanowire radii were explored up to approximately 10 nm and both materials were found to display a strong dependence on the wire width eventually converging to the bulk value. Interestingly, the convergence trends are opposite where the Young's modulus of the Si nanowires increases while that of Ta nanowires decreases with radius. In the same study, DFT calculations were also performed on Si nanowires, partially confirming the outcome of the Stillinger–Weber calculations. However, the match with continuum theory was found to be much better for the DFT results.

Size dependence is also demonstrated in a study by Hu and coworkers (2008) on ZnO nanowires and nanotubes where they use an exp-6-type empirical potential including Coulomb interaction for Young's modulus calculations. The Young's moduli of nanowires and nanotubes show a very strong dependence on the radius and wall thickness, respectively.

Due to the extremely high surface-to-volume ratio in nanowires, the particular surfaces that are exposed at the outer edges of the nanowires play a crucial effect in the determination of their elastic properties (Ozdamar and Erkoç 2013; Kilic and Erkoç 2013a; Yagli and Erkoç 2014). Recent evidence for this fact was demonstrated by Wang and Li (2008) in their DFT-parameterized model study of Ag, Au, and ZnO nanowires with different surface terminations. Their results show discernible albeit small differences in the size dependence of the Young's modulus for different surface terminations of the nanowires in question.

Nanotubes have also received a great deal of attention from researchers due to their extraordinary elastic properties. They have been shown to possess an unusually high axial stiffness in addition to very high reversibility under large distortions. In addition to the large body of literature on experiments probing the elastic properties of nanotubes, many theoretical studies have also been conducted. Due to their varying radii and chirality, nanotubes present endless possibilities for the investigation of their elastic properties. Liang and Upmanyu (2006), for instance, have studied the radius (or equivalently curvature) and chirality dependence of the torsion induced by applied axial strength of the nanotubes. Their studies, which utilize the widely used second-generation reactive empirical bond-order potential (Brenner 1989), revealed a torsional response of up to 0.75 nm, which varied remarkably for different radii and chiral angles. Conversely, as reported in several early studies on nanotubes employing DFT calculations, Young's modulus is known to be largely independent of the chirality.

Elastic properties of nanotubes of many materials other than C have also been theoretically explored. In an exhaustive work, Baumeier and coworkers (2007) used DFT calculations to survey such properties as strain energy and Young's

modulus of SiC, BN, and BeO nanotubes. Baumeier and coworkers observe that being composed of two atomic species instead of one as in carbon nanotubes, the nanotubes made out of these materials exhibit a different relaxation pattern for the relevant anions and cations, suggesting possible different behavior than carbon nanotubes. Nevertheless, the results show that at least for (n, n) and $(n, 0)$ nanotubes of similar radii, the behavior is similar. All three materials display a decreasing Young's modulus as a function of radius converging to the sheet value for large radii. Among the three materials, BN nanotubes display a significantly high Young's modulus, followed by SiC and finally by BeO nanotubes.

The interwall attraction in multi-walled nanotubes opens up another possible avenue for the study of elastic properties. Zhang and coworkers (2008b) have studied the Young's modulus, Poisson ratio, and the buckling point of multi-walled nanotubes using a combination of second-generation reactive bond-order potential to model intralayer bonding and a Lennard-Jones potential for the interlayer interaction. The multi-walled nanotubes studied were divided into two sets, the first formed by embedding increasingly smaller (n, n) tubes into a large $(20, 20)$ nanotube (up to four walls) and the second by placing a $(5, 5)$ tube into increasingly larger (n, n) tubes (again up to four walls). A molecular dynamics algorithm was used during their calculation and the dependence of the moduli in addition to the buckled morphologies was presented. Young's modulus and Poisson's ratio turn out to follow a different trend for the two sets considered. While the set that grows inward displays increasing (decreasing) Young's modulus (Poisson ratio) for increasing number of walls, the set that grows outward follows the opposite trend.

As mentioned in the introduction to this section, one way to saturate the surface bonds of nanowires is through passivation by different species. The elastic behavior of passivated versus unpassivated nanowires raises an interesting question. Lee and Rudd (2007) studied several elastic properties of H-passivated nanowires of a large range of radii varying between 0.61 and 3.92 nm (see Fig. 6) using DFT. As expected, the Young moduli of H-passivated Si nanowires mostly follow predictions from continuum models regardless of the varying proportions of $\langle 100 \rangle$ and $\langle 001 \rangle$ surfaces exposed. This is attributed to the fact that the bulk-like covalent bonding character at the surfaces is preserved when H is used to passivate the dangling bonds at the surface.

Although microscopic modeling is of utmost importance in the understanding of nanoscale materials, there are a number of experimental situations of interest that cannot be handled by these time-intensive methods due to their large size. For large enough systems (such as large portions of nanotubes suspended over a trench), continuum methods may be employed (Ustunel et al. 2005). However, complete coarse graining is also not always a viable choice since one then loses detailed information on locally nonhomogeneous regions of the system such as defects and local deformations. In such cases, *multiscale methods* which apply different methods at different scales of the system are the methods of choice. An illustrative example was studied by Maiti (2008) where a micromechanical sensor made out of a nanotube was deformed by a Li needle. The bent but undeformed portions of the nanotube were modeled by a coarse-grained *molecular mechanics* simulation, while

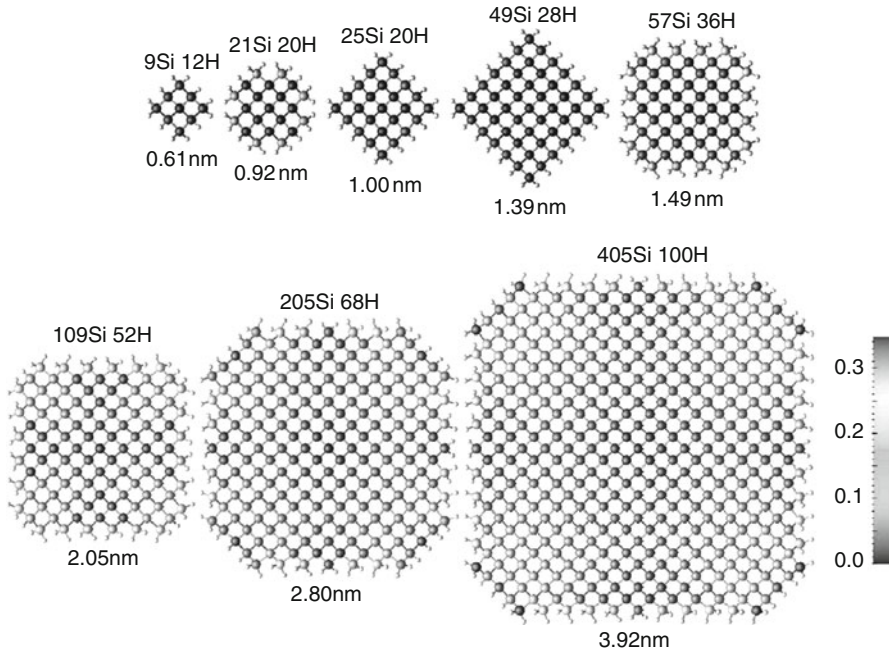

Fig. 6 H-passivated Si nanowires of different sizes studied by Lee et al. (Reprinted with permission from Lee and Rudd (2007). © (2007) by the American Physical Society)

the highly deformed midsection (enclosed in a box) was modeled using a quantum mechanical method. The two methods were then matched at the interface of the two regions.

Structural Properties

The novel electronic properties of nanotubes, nanowires, and nanobelts are inextricably linked to their structural properties. This is largely due to their high surface-to-volume ratio, where the bonding on the surface structure determines the electronic states which in turn determines such properties of the system as conductivity and magnetism.

As mentioned in the introductory section, nanowires nowadays may be manufactured from a great variety of materials. As fabricated, it is experimentally difficult, if not impossible, to intuitively infer their surface structure. Simulations on the other hand provide an inexpensive yet accurate way of studying this relation between structure and electronic properties.

The methods of preference in nanowire modeling are generally tight binding and to a larger extent DFT, since electronic properties depend sensitively on the structure requiring accurate calculations. Once a material (or combination of materials) is

chosen, the important parameters of nanowire modeling are the particular surfaces surrounding the nanowire and passivation, that is, the saturation of the bonds at the surfaces. Two of the most commonly studied surface terminations are surface reconstruction and H passivation.

Due to the axial periodicity of one-dimensional nanomaterials, plane wave-based methods which are traditionally used for crystals are very often employed. In the work of Arantes and Fazio (2007), where they study free and passivated Ge nanowires, the band gap of passivated and unpassivated nanowires was determined using a plane wave-based GGA-DFT method. The nanowires were grown in the $\langle 110 \rangle$ and $\langle 111 \rangle$ directions, and their band gaps were calculated as a function of nanowire diameter. In spite of the well-known underestimation of the band gap by LDA and GGA methods, a trend can be obtained rather reliably. The band gaps are seen to vary with respect to direction and size.

Though not often encountered, global search algorithms are also used for determining the structure of nanowires. Especially in the case of nanowires with smaller radii, the structure may be so different from bulk as to prevent any a priori prediction. Chan and coworkers (2006) conducted a genetic algorithm search based on the formation energy of H-terminated Si NWs where the formation energy is defined as

$$f = (E - \mu_H n_H) / n - \mu, \quad (5)$$

where E is the total energy of the NW in question, μ_H and μ are the chemical potentials of H and Si, respectively, and n is the number of Si atoms. The genetic algorithm was conducted in two stages. In the first stage, a long evolution through several generations was conducted using an empirical potential (of the Hansel-Vogel type). In the second stage, the outcome structures of the evolution for each size were relaxed using a DFT algorithm. The result, reminiscent of cluster structures, is that certain sizes of Si NWs are preferred over other sizes. These structures are once again termed *magic sizes*. In general, structures with even number of Si atoms are preferred over those with an odd number. The most stable structures are observed either in a *platelike* form where chains of Si hexagons join together to form flat structures, or a *hexagon-shaped* cross section.

One of the most important parameters in determining the geometric and therefore the electronic structure of nanowires is surface termination. The high-energy dangling bonds at the surface may either be saturated by a rearrangement and rebonding of the surface atoms or by attaching electropositive species (such as H). In general, while the reconstruction may significantly alter the structural and electronic properties of the material, passivation by other species leaves these properties relatively unaltered. In the recent work of Migas and Borisenko (2008), $\langle 001 \rangle$ -oriented Si nanowires were passivated by O, F, and H, and the structural and a large number of different sizes and geometries were studied using DFT. Under different combinations and coverages by these elements, the band gap of the Si nanowires considered (only nanowires with rhombic cross sections were considered) was

found to vary between 1.20 and 1.96 eV, which shows that termination can be used as a means to control the electronic properties.

Countless other studies in understanding the structure of experimentally relevant one-dimensional structures have been done. Bi nanowires (Qi et al. 2008), CdSe nanorods with hexagonal and triangular cross sections (Sadowski and Ramprasad 2007), and Te nanowires (Ghosh et al. 2007) are some studies that may be mentioned. In addition to materials that have already been manufactured, researchers have also been interested in the possible existence and properties of nanoscale systems that have not yet been experimentally realized. Rathi and Ray (2008), for instance, have examined the possibility of Si–Ge nanotubes, while Qi and coworkers (2008) investigated Bi nanotubes and hollow Bi rods. Recently it was demonstrated by model calculations that the stable carbon nanotube structure might be possible with non-graphene-like form (Erkoc 2004a). Furthermore, nanorod structures constructed from benzene rings only (called as *benzorods*) may also be possible. Their structural and electronic properties were investigated by performing model calculations (Erkoc 2003; Malcioglu and Erkoc 2004).

Electronic, Magnetic, and Optical Properties

As a result of the immense variation in structural properties of one-dimensional structures, one observes an equally diverse spectra of electronic properties. Perhaps the most intriguing property of one- and two-dimensional nanoscale systems is that after the required geometrical deformations in order to reach their equilibrium, one might observe a stark difference between the newly formed system and its bulk counterpart. A material which is an insulator in bulk may become a conductor when taken to the nanoscale. Similarly one- or two-dimensional nanostructures of a nonmagnetic material may have a nonzero magnetic moment. These differences usually stem from the new states introduced into the electronic structure of the material by terminating structures such as surfaces, steps, edges, and corners. The interest in these emergent properties is due to the possibilities of integrating these small-scale materials into technological applications and controlling their properties by controlling the structure.

Due to the ease of interfacing with current technology, *Si* nanowires have perhaps been the most intensely studied system. Rurali and Lorente (2005), for instance, explored a large range of surface reconstructions for $\langle 100 \rangle$ *Si* nanowires with a small radius of about 1.5 nm. They discovered that for certain reconstructions, the nanowires develop conducting states in their band gap, while for others the semiconducting behavior is retained. This is a prime example of effects of confinement on the electronic structure of a system.

Another parameter that has a strong effect on the electronic properties of nanowires is surface termination. As demonstrated by Rurali (2005) that both *Si* and C-terminated H-passivated SiC nanowires have a larger band gap than that of bulk SiC. As discussed by Rurali, this is purely a confinement effect since passivation prevents reconstruction and the related introduction of gap states. However, when

the nanowires are allowed to reconstruct, both species of SiC nanowires are seen to become conducting due to the surface states introduced into the band gap.

In addition to the conventional carbon nanotubes, several other materials were investigated as viable candidates for nanotube structures. BN (Chopra et al. 1995) and more recently (Sun et al. 2002) SiC nanotubes are two such materials which have been successfully synthesized in the nanotube form. Following their synthesis Gao and Kang (2008) conducted a DFT-PAW study of undoped and N-doped SiC nanotubes of varying sizes. For each size the nanotubes were doped initially with 2 and 4 N atoms and their structural and electronic properties were studied. For each doping level, several possibilities were investigated and the most stable structure was identified. As an extreme case, the case in which all the C atoms were replaced with N atoms, in other words SiN nanotubes, was considered. These nanotubes, instead of being circular, were found to have a staggered or starlike cross section. In all the cases considered, the nanotubes were found to be semiconducting with an indirect band gap. Recent model calculations on binary compounds BN (Erkoc 2001b), GaN (Erkoc et al. 2004), InP (Erkoc 2004b), and ZnO (Erkoc and Kokten 2005) nanotubes give reasonable results comparable with experimental findings.

Although by nature rather free of defects, the few existing defects in graphene and nanotubes change the electronic structure of their host material drastically (Pekoz and Erkoc 2008). In spite of the several experimental methods that have been developed to locate and study the properties of such defects, theoretical methods are an indispensable tool for creating isolated defects of the desired nature and studying their effects on electronic properties. A particularly interesting question is the stability of well-characterized graphene defects in nanotubes of varying radius and chirality. Since a graphene sheet can be viewed as a nanotube with an infinitely large radius, the formation energy of any nanotube defect should tend to the equivalent defect on a graphene sheet. Amorim et al. (2007) demonstrated an example of this behavior by studying the so-called 555777 defect, which is a combination of three pentagons and three heptagons. This defect is formed in two steps. In the first step, two divacancies coalesce to form a new defect (585) composed of two pentagons and an octagon. This step is followed by a further structural change, which yields the 555777 defect, see Fig. 7.

In graphene the 555777 defect is found to be more stable than the 585 defect by 0.8 eV. The same defects were then created in zigzag and armchair nanotubes of radius in the range of 7–15 Å. As in the graphene case, the 555777 defect is found to be more stable in all the nanotubes studied. The formation energy is, however, lower than in the graphene case. The expected tendency toward the corresponding graphene values is seen in both cases and convergence is estimated to occur around a radius of 40 Å.

The effect of defects on the electronic properties of their host substance is illustrated in this work by the conductance graph calculated using the Green's function density functional theory. The results indicate that the presence of both the 585 and 555777 reduces the conductance considerably while at the same time displaying different voltage dependence.

Fig. 7 585 (a) and 555777 (b) defects in graphene and 585 (c, e) and 555777 (d, f) defects in a nanotube in different orientations (Reprinted with permission from Amorim et al. (2007). © (2007) by the American Chemical Society)

Another investigation of defects in nanotubes for the purpose of application as a gas sensor was conducted by Andzelm and coworkers (2006). The particular question at hand is the binding of NH_3 molecule to nanotubes and whether or not binding is enhanced by defects. Three defects are considered: a Stone–Wales defect (a defect formed by rotating a given bond by 90° resulting in the formation of two pentagons and two heptagons), a monovacancy, and an interstitial C atom placed on top of a bridge. In addition, the case of an O_2 molecule dissociated on a SW defect was also considered to mimic the environmental effects. Two different orientations, straight and chiral, for the SW defect were considered. All-electron DFT calculations reveal that the monovacancy is the most stable. Calculation of reaction barriers also reveals that defects with preabsorbed O dissociate NH_3 into NH_2 and H.

The heterostructure problem, which has been widely studied in the bulk form, is becoming an increasingly popular topic also in the one-dimensional systems. The band alignment problem has been addressed recently in a DFT study conducted by Kagimura and coworkers (2007) where a Si–Ge interface was studied. The model for such a system is shown in Fig. 8. The band states contributed by the surface dangling bonds were investigated as possible candidates for the induction of a potential well.

The search for nanoscale materials that exhibit spontaneous magnetization has become an increasingly rich field in the past decade. Several materials such as doped nanotubes and nanowires, defective graphene, and nanoribbons of two-dimensional materials can be itemized as candidates considered in these studies. In order to identify the suitability of a material for spontaneous magnetization and electron density in the two spin channels, $n^\uparrow(\vec{r})$ and $n^\downarrow(\vec{r})$ are compared. If there is a significant difference in this distribution, the material is nominated for use in magnetic applications. If in addition the density of states in the two spin channels shows different characteristics at the Fermi level such that in one channel there is

Fig. 8 A Si–Ge interface shaped into a nanotube. (a) Side view, (b) cross view (Adapted from Kagimura et al. 2007)

a significantly larger number of states than the other, then the material provides promise also in *spintronic* applications.

One such candidate material for magnetic applications is BN sheets and nanotubes doped with several different elements. In a recent example, Li and coworkers (2008a), in their DFT study on BN nanotubes with one, two, and three H atoms adsorbed at different locations, observed that some of the configurations considered may give rise to a magnetic moment of up to 2.0. The origin of this magnetic moment is evident from the band structures where the contribution of band gap states is due to only one of the spin channels. The states that are seen in the gap are also shown visually and their origin is unambiguously identified as due to the adsorbed hydrogen.

A rather novel and intriguing application of nanomaterials and its investigation using theoretical modeling is the subject of a recent work by de Oliveira and Miwa (2009). Their study discusses a phenomenon called *self-purification* of nanomaterials, namely, the expulsion of foreign species from the surface. Self-purification is attributed to the fact that nanoscale materials have a lower incorporation rate of impurities compared to their bulk counterpart. In this work SiC nanowires are studied as another potential example of self-purifying materials. B and N impurities were planted at different positions inside and on the surface of three SiC nanowire configurations $\langle 100 \rangle$ Si-coated, $\langle 100 \rangle$ C coated, and $\langle 111 \rangle$ Si and C coated at locations ranging from the center to the surface. The formation energies of the configurations thus formed were then calculated and compared. As a result, the self-purification process was found to be favorable for B-doped SiC nanowires irrespective of their orientation. The B atom was found to segregate favorably to the surface and thus expelled. The N impurities, however, were found to prefer the sites in the core of the nanowires, and therefore, N-doped SiC nanowires were found to fail as self-purifying materials.

One-dimensional systems are actively sought after also for their optical properties. Using the GW method, which is an accurate method for studying excited states, Bruno and coworkers (2007) demonstrated that optical properties of *Si* and *Ge* nanowires depend not only on the nanowire diameter but also on the orientation.

2D Structures: Graphene and Derivatives

Due to the remarkable ability of carbon to exist in different hybridization states, carbon-based materials display an unusually rich variety. Diamond, graphene, cage-like molecules and perhaps most notably carbon nanotubes are examples of the large selection of possibilities.

Graphene, which is a single layer of graphite, may be thought of as the building block of most of the allotropes listed above (Fig. 9). Nanotubes are geometrically rolled up versions of graphene, and fullerenes can be formed by introducing

Fig. 9 Graphene is a 2D building material for carbon materials of all other dimensionalities. It can be wrapped up into 0D buckyballs, rolled into 1D nanotubes, or stacked into 3D graphite (Reprinted with permission from Geim and Novoselov (2007). © (2007) by Nature Publishing Group)

topological defects (heptagons and pentagons) into the perfect honeycomb lattice structure of graphene in order to introduce positive and negative curvature (Freitag 2008; Peres et al. 2006b; Kim and Rogers 2008; Tang and Zhou 2013).

Regardless of the immense attention that graphene received in the theoretical literature, it wasn't until 2004 (Novoselov et al. 2004) that a single layer of graphene was isolated experimentally. Since two-dimensional crystals were proven to be unstable theoretically (Landau and Lifshitz 1980; Mermin 1968), the discovery of free-standing graphene came as a surprise (Meyer et al. 2007). This apparent discrepancy, however, was lifted when upon closer inspection, the isolated graphene sheets were not perfectly flat but had corrugations reaching up to 1 nm in size (Rusanov 2014).

Since the discovery and isolation of graphene was achieved, many other materials were found to form two-dimensional structures. In this chapter, we give an overview of carbon-based two-dimensional materials including graphene, graphene nanoribbons, nanobelts, and strips in addition to two-dimensional structures of several other materials (Singh et al. 2011; Bonaccorso et al. 2015; Niu and Li 2015).

Graphene, Nanosheets, Nanoribbons, Nanobelts, and Nanostrips

With the advent of several sophisticated experimental techniques, the two-dimensional confinement of graphene layers was further extended to one dimensional in the form of *nanoribbons*. Nanoribbons are narrow strips of graphene that may exhibit quasi-metallic or semiconducting behavior depending on the geometry of their edges. Much like nanotubes, graphene nanoribbons (GNRs) are also termed *zigzag* or *armchair* based on the directionality of the bonds with respect to the long axis (see Fig. 10). Due to the dependence of their electronic properties on their geometry, it is important to control the morphology and crystallinity of these edges for practical purposes. It has been experimentally shown that (Jia et al. 2009) controlled formation of sharp zigzag and armchair edges in graphitic nanoribbons is possible by Joule heating. During Joule heating and electron beam irradiation, carbon atoms are vaporized, and subsequently sharp edges and step-edge arrays are stabilized, mostly with either zigzag- or armchair-edged configurations.

In addition to the edge geometry, the electronic properties, in particular the band gap, of nanoribbons also depend on their width (Han et al. 2007; Wu and Zeng 2008). The magnetic properties may also be severely altered upon reduction of size to a graphene fragment (Wang et al. 2008) which results in the emergence of giant spin moments.

Another path for controlling the electronic properties of nanoribbons is by an application of an external electric field or by chemical doping of the pristine samples. Half-metallicity, for instance, which has several applications in spintronics (Wu and Zeng 2008) may be introduced through functionalization with such species as H, COOH, OH, NO₂, NH₃, and CH₃ (Son et al. 2006).

Straight GNRs with zigzag, armchair, or mixed edges are proven to be semiconducting by the experiment. In addition, GNRs can be sculpted by attaching two

Fig. 10 (a) Armchair graphene ribbon model. (b) Zigzag graphene ribbon model

Fig. 11 The model structure of a sawtooth-like GNR (Adapted from Wu and Zeng 2008)

segments together that are manufactured to make a 120° angle with each other thereby forming a *sawtooth-like* nanoribbon (Fig. 11). The structure of a sawtooth-like GNR can be characterized by two integers (w , l). The first integer denotes the width of the nanoribbon, while the second integer describes its periodic length (Wu and Zeng 2008).

Stability is an important issue for a material which is intended to be used as a building block of device applications. Even though perfect two-dimensional crystals are proven to be unstable, graphene is found to be stabilized by corrugations in the third dimension. Understanding the effect of GNR width on the stability is therefore also a central issue for possible applications. Molecular dynamics computer simulations using empirical interatomic potentials predict that structural stability of graphene nanoribbons show dependence on size (width) and edge orientation (Dugan and Erkoç 2008; Ozdamar and Erkoç 2012). Figures 12 and 13 show, respectively, the relaxed structures of armchair- and zigzag-edged GNRs with various widths.

In the recent nanoscale literature, a wealth of materials other than C has been identified, both theoretically and experimentally, as viable candidates for future use as two-dimensional devices.

Boron nitride, for instance, having electronic properties that resemble carbon can exist in a hexagonal structure *h*-BN similar to the graphite-layered geometry.

Fig. 12 Armchair-edged GNRs. *Left* column shows *top* view and *right* column shows tilted view. GNRs of width five hexagonal rings are shown. 1 K, 300 K, and final temperature images are given (Adapted from Dugan and Erkoc 2008)

Much like graphene sheets, BN sheets can be grown on more or less lattice-matched transition metal surfaces (Corso et al. 2004; Huda and Kleinman 2006). A model BN sheet is shown in Fig. 14.

BN, being a member of the III-V semiconductor family, indicates the possibility of nanoribbons or nanobelts made of other semiconductor families. Indeed, several oxide and other II-VI family nanobelts have been discovered and reported (Pan et al. 2001) (ZnO, SnO₂, CdO, Ga₂O₃, PbO₂, ZnS, CdSe, and ZnSe). Some of the oxides in this family such as ZnO and SnO₂, owing to their polarity and crystal structure, deform in novel morphologies such as rings, springs, and spirals in order to bring together the positive and negative charges, counteracting the charge imbalance (Yang and Wang 2006). These structures comprise a versatile set of nanomaterials that are promising candidates for various applications such as sensors, resonators, and transducers.

Fig. 14 The geometric structure of BN sheet (Adapted from Venkataramanan et al. 2009)

Nanobelts, a term coined by researchers working on these structures (Wang 2004), are described as nanowires with not only a well-defined growth direction but also well-defined top, bottom, and side edges and cross section. The nanobelt structures are usually obtained from functional oxides, which are semiconductor materials, such as ZnO, Ga_2O_3 , $t\text{-SnO}_2$, $o\text{-SnO}_2$, In_2O_3 , CdO, and PbO_2 . Pure metal nanobelt structures are also possible; Zn is one of the metals that form fine nanobelt structures (Wang 2004). ZnO, being one of the most versatile materials in nanoscale research alongside with carbon and BN, has once again been investigated at great depth in the context of nanobelts (Kulkarni et al. 2005; Wang 2004). Molecular dynamics computer simulations using empirical interatomic potentials (Kulkarni et al. 2005) reveal that ZnO nanobelts display properties that depend on their size and orientation. Depending on the growth direction, ZnO nanobelts may exhibit an interesting shell structure or a simple surface reconstruction (Wang 2009; Ozgur et al. 2005).

Nanostrips are similar to nanobelts; they are used with the same meaning with nanobelts. All these nanostructures (ribbons, belts, strips) are ideal materials for building nano-sized devices and sensors (Lin et al. 2009).

In addition to the materials mentioned above, recent theoretical studies have proposed a wealth of two-dimensional structures that are composed of less common materials. One such example is the recently proposed B_2C graphene (Wu et al. 2009). The optimized B_2C graphene structure is displayed in Fig. 15. Two neigh-

Fig. 15 (a) A $C_{2V} - CB_4$ motif structure. Each carbon atom is bonded with four boron atoms. Optimized structures of two types B_2C nanoribbons with two different edge configurations, referred as type I (b) and type II (c) (Adapted from Wu et al. 2009)

boring CB_4 motifs share two common boron atoms, giving rise to a hexagon and a rhombus. The mean B–C and B–B bond length is 1.557 and 1.685 Å, respectively. The sheet is slightly corrugated with a distance of only ~ 0.085 Å. The corrugation is a result of an excess of 2p electrons normal to the sheet relative to the gas-phase CB_4 molecule.

The quasi-one-dimensional B_2C nanoribbons are finite-size graphene with parallel edges. The width of the B_2C nanoribbon is defined by the number of C atoms normal to the long axis of the ribbon. As shown in Fig. 15, type I and II B_2C nanoribbons are displayed. The dangling bonds at the edges of B_2C nanoribbons can be passivated by either H atoms or CH groups.

TiO_2 with its uses in solar cell applications and surface catalysis has received much attention both theoretically and experimentally. Its nanostructures are of equal interest to technology due to their chemical inertness, endurance, strong oxidizing power, large surface area, high photocatalytic activity, non-toxicity, and low production cost. The titania nanostructures are constructed by “cutting” of TiO_2 monolayers into nanostrips and by rolling them into cylindrical nanotubes or nanorolls (Enyashin and Seifert 2005). There are two different topological nanostrip models constructed from titania. One model is obtained from (101) surface of titania, called as anatase layer, and the second model is obtained from (010) surface of titania, called as lepidocrocite layer. A view of the structures of (101) and (010) TiO_2 layers is shown in Fig. 16. By rolling of these strips, various nanostructures can

Fig. 17 Idealized 1212 (a) and reconstructed 1221. (b) Boron sheets

be generated, such as nanotubes and nanospirals (nanorolls) (Enyashin and Seifert 2005).

Non-carbon elemental sheet structures have also been investigated. Lau et al. (2006) proposed four possible configuration models for the boron sheet. According to this study, the flat form, denoted $\{1212\}$, seen in Fig. 17 is a triangular network, while the buckled $\{1212\}^b$ and pair-buckled $\{1212\}^{pb}$ configurations include chain-wise and pairwise out-of-plane displacements. Finally, a reconstructed $\{1212\}$ configuration is investigated with inversion symmetry in the unit cell. It can be considered as a triangular–square–triangular unit network.

The DFT calculations reveal (Lau et al. 2006) that the reconstructed $\{1221\}$ configuration is the most stable configuration by 0.23 eV/atom relative to the idealized $\{1212\}$ configuration. Both the $\{1212\}^b$ and $\{1212\}^{pb}$ configurations tend to converge to the idealized $\{1212\}$ configuration when relaxed during the geometry optimization.

Fig. 18 The band structure of a representative three-dimensional solid (*left*) is parabolic, with a band gap between the lower-energy valence band and the higher-energy conduction band. The energy bands of 2D graphene (*right*) are smooth-sided cones, which meet at the Dirac point

Electronic and Mechanical Properties

Graphene has a unique and curious band structure which can be approximated by a double cone close to the six Fermi points at the corners of the Brillouin zone (see Fig. 18). Commonly referred to as Dirac electrons, the conduction electrons follow a linear energy-momentum dispersion and have a rather large velocity.

The conduction in graphene is enabled by the delocalized π -electrons above and below the plane. Due to their relative detachment from the tightly knit planar network, these electrons are free to move along the graphene sheet with rather high mobility. This is of course a rather desirable property for devices used in electronics (Li et al. 2008b).

A good yet simple method for understanding the band structure of graphene is the tight-binding formalism (Neto et al. 2009). Graphene is made out of carbon atoms arranged in hexagonal structure, as shown in Fig. 19. The structure can be seen as a triangular lattice with a basis of two atoms per unit cell. The lattice vectors can be written as

$$\mathbf{a}_1 = \frac{a}{2} (3, \sqrt{3}) \quad \mathbf{a}_2 = \frac{a}{2} (3, -\sqrt{3}),$$

where $a \sim 1.42 \text{ \AA}$ is the carbon-carbon distance. The reciprocal-lattice vectors are given by

$$\mathbf{b}_1 = \frac{2\pi}{3a} (1, \sqrt{3}) \quad \mathbf{b}_2 = \frac{2\pi}{3a} (1, -\sqrt{3}).$$

Fig. 19 Graphene lattice and its Brillouin zone. *Left*: lattice structure of graphene, made out of two interpenetrating triangular lattices (\mathbf{a}_1 and \mathbf{a}_2 are the lattice unit vectors). *Right*: corresponding Brillouin zone. The Dirac cones are located at the K and K' points

The two points K and K' at the corners of the graphene Brillouin zone (BZ) are named Dirac points. Their positions in momentum space are given by

$$\mathbf{K} = \left(\frac{2\pi}{3a}, \frac{2\pi}{3\sqrt{3}a} \right), \quad \mathbf{K}' = \left(\frac{2\pi}{3a}, -\frac{2\pi}{3\sqrt{3}a} \right).$$

The tight-binding Hamiltonian for electrons in graphene, considering that electrons can hop to both nearest- and next nearest-neighbor atoms, has the form (in units $\hbar = 1$)

$$H = -t \sum_{\langle i, j \rangle, \sigma} \left(a_{\sigma, i}^\dagger b_{\sigma, j} + H.c. \right) - t' \sum_{\langle\langle i, j \rangle\rangle, \sigma} \left(a_{\sigma, i}^\dagger a_{\sigma, j} + b_{\sigma, i}^\dagger b_{\sigma, j} + H.c. \right), \quad (6)$$

where $a_{i, \sigma}$ ($a_{i, \sigma}^\dagger$) annihilates (creates) an electron with spin σ ($\sigma = \uparrow, \downarrow$) on-site \mathbf{R}_i on sublattice A (an equivalent definition is used for sublattice B), t (~ 2.8 eV) is the nearest-neighbor hopping energy (hopping between different sublattices), and t' (~ 0.1 eV) is the next nearest-neighbor hopping energy (hopping in the same sublattice). The Hamiltonian in Eq. 7 is solved at various momenta and the energy bands are obtained as follows:

$$E_{\pm}(\mathbf{k}) = \pm t \sqrt{3 + f(\mathbf{k})} - t' f(\mathbf{k}) \quad (7)$$

with

$$f(\mathbf{k}) = 2 \cos(\sqrt{3}k_y a) + 4 \cos\left(\frac{\sqrt{3}}{2}k_y a\right) \cos\left(\frac{3}{2}k_x a\right), \quad (8)$$

where the plus sign applies to the upper (π^*) and the minus sign the lower (π) band.

As illustrated by this simple model, graphene is a semimetal or a zero-gap semiconductor. At low temperatures it does not possess superconducting properties; however, as demonstrated by Pathak et al. (2008) using variational Monte Carlo, there is a possibility that doped graphene may superconduct.

The graphene nanoribbons (GNRs) discussed in the previous sections may also be modeled rather easily using the tight-binding formalism taking as the basis the usual Schrödinger's equation (Ezawa 2006) or the massless particle Dirac equation (Sasaki et al. 2006). These models predict that armchair GNRs can be either metallic or semiconducting depending on their widths and that zigzag GNRs with zigzag-shaped edges are metallic regardless of the width.

The edges of GNRs are also suitable sites for chemical functionalization (Wang et al. 2007). Due to the existence of dangling bonds at the edges, the electronic properties of GNRs may be controlled by modifying these bonds by addition of other species.

The results of first-principles calculations using linear combination of atomic orbital density functional theory (DFT) method predict that the electronic band structures and band gaps of the GNRs show a dependence on the edge structure of the nanoribbons (Wu and Zeng 2008). Clearly, the electronic band structures are sensitive to the edge structure of the nanoribbons. All straight GNRs are semiconducting. Two distinct features can be seen concerning the band gap. The band gap of GNR with zigzag edges slightly decreases with increasing the width w , while that of GNR with armchair edges varies periodically as a function of w .

Like the straight GNRs, the calculated electronic band structures of the sawtooth-like GNRs (see Fig. 20) also show semiconducting characteristics with direct band gap. More interestingly, even though the sawtooth-like GNRs have zigzag edges, their band gaps show similar oscillatory behavior as those of straight GNRs with armchair edges, which depend on the width w . However, for most nanoribbons, their band gap reduces monotonically with increasing periodic length l . The band gaps of nanoribbons with $w = 1, 2$, or 4 reduce much rapidly, whereas those of nanoribbons with $w = 3$ or 5 reduce gradually.

For $(2, l)$ sawtooth-like nanoribbons, the band gap approaches zero rapidly as the l increases (Wu and Zeng 2008). These results show that the band gaps of the sawtooth-like GNRs are much more sensitive to their geometric structures, which is an opportunity for tuning the band gap.

Quantization of electric conductance under the action of an external magnetic field displays a rather interesting trend for GNRs. In the exhaustive tight-binding study conducted by Peres et al. (2006a), the number of plateaus in the quantized conductance was found to be even in armchair GNTs, while the same number is odd for the zigzag edge.

Rosales et al. (2008) investigated theoretically the effects of side-attached one-dimensional chains of hexagons pinned at the edges of the GNRs. These one-dimensional chains could be useful to simulate, qualitatively, the effects on the electronic transport of GNRs when benzene-based organic molecules are attached to the edges of the ribbons. They propose a simple scheme to reveal the main electronic properties and the changes in the conductance of such decorated planar structures.

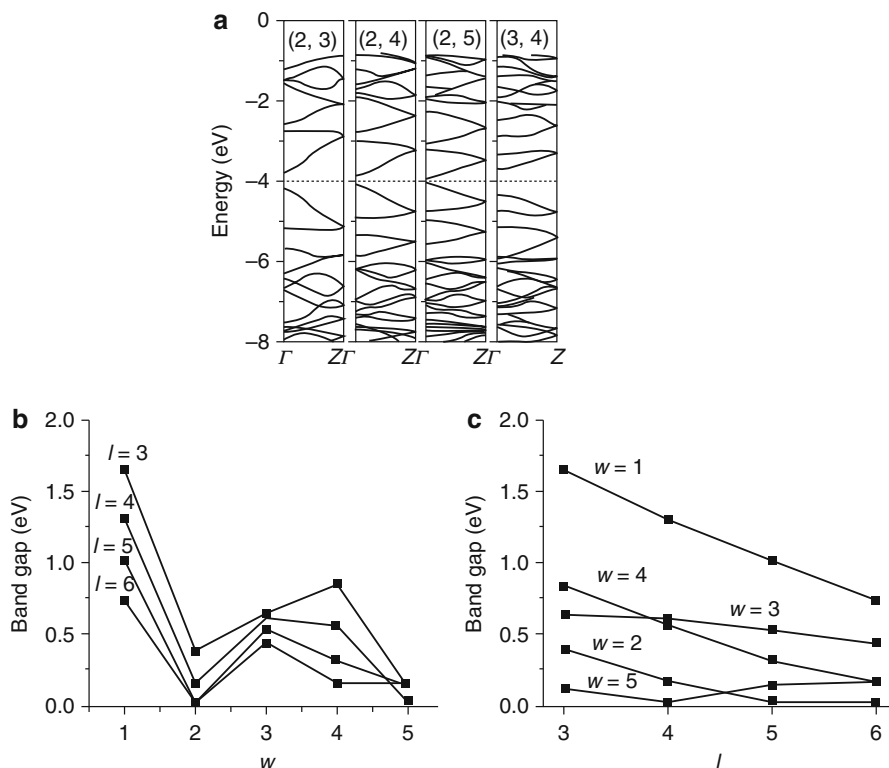

Fig. 20 (a) The electronic band structures of several sawtooth-like GNRs with various w and l . The band gaps versus (b) the width w and (c) the periodic length l (Reprinted with permission from Wu and Zeng (2008). © (2008) by Springer)

For simplicity, they consider armchair and zigzag nanoribbons and linear polyaromatic hydrocarbons (LPHC) and poly(paraphenylene), as the organic molecules. The attached molecules are simulated by simple one-dimensional carbon hexagonal structures connected to the GNRs.

These nanostructures are described using a single-band tight-binding Hamiltonian, and their electronic conductance and density of states are calculated within the Green's function formalism based on real-space renormalization techniques (Rosales et al. 2008).

As revealed by the theoretical analysis conducted by Nakabayashi et al., GNRs are a solution to the difficulty of producing an effective graphene switch for turning off the current. Zigzag nanotubes due to their peculiar band structures may be utilized for better current control rather than graphene. A single layer of graphene has no band gap, which makes it difficult to control current. However, Nakabayashi et al. (2009) found that when a sheet of graphene was in the form of nanoribbons just a few nanometers wide, its electronic structure changed so that currents could be

controlled in radically different ways in comparison to conventional semiconductor devices. Nakabayashi et al. (2009) showed that when a nanoribbon was cut so that its edges formed a zigzag structure with an even number of zigzag chains across its width, and an electrostatic barrier potential applied along part of its length, then it behaved as a so-called band-selective filter, preferentially scattering charges into either even- or odd-numbered bands of its electronic structure depending on the potential. And when two such filters with different potentials were connected in series, they showed it should be possible to completely shut off the flow of current through the nanoribbons.

Tight-binding studies have revealed countless interesting electronic properties regarding GNRs. GNRs, much like single-walled carbon nanotubes, can display metallic or semiconducting properties depending on their orientation and width. Similar to armchair nanotubes, zigzag ribbons are all metallic and may have magnetic properties. Bare and H-terminated ribbons, as studied by Barone et al., may show such effects as gap oscillations which make them a viable choice for possible band structure engineering applications. The results of this study, which is a careful investigation of GNRs of several orientations, widths, and terminations, are displayed in Fig. 21 along with the details of the models used and the band gap profiles of the corresponding models.

GNRs have localized edge states located near the Fermi level. By terminating the edges with different species, one can change the character of these states and consequently the properties of GNRs. In fact, a first-principles calculation within spin-unrestricted local-density functional formalism on zigzag-edged graphene nanostrips terminated with hydrogen and oxygen atoms as well as hydroxyl and imine groups shows that these different species have a significant impact on the electronic structure of these strips near the Fermi level (Gunlycke et al. 2007). Zigzag-edged nanostrips terminated with hydrogen atoms or hydroxyl groups exhibit spin polarization, while the nanostrips terminated with oxygen or imine groups are unpolarized. These differences of course result in very different conductance characteristics for these systems.

In further support of the aforementioned evidence, Zhang and Yang (2009) confirmed in their linear combination of atomic orbitals (LCAO) tight-binding study that H-terminated armchair GNTs exhibit size dependence in their conductance properties.

On the other hand, ZnO nanoribbons show different characteristics from that of carbon nanoribbons. ZnO nanoribbons grown along the [0001] direction can form two different planar monolayer, zigzag and armchair ribbons. First-principles calculations of zinc oxide nanoribbons show that the stability of armchair-edged structures is greater than the zigzag-edged configurations. Furthermore, single-layered armchair ribbons are semiconductors, whereas the zigzag counterparts are metallic (Botello-Mendez et al. 2007). An effect that is not present in purely carbon-based systems is the presence of two differently charged species offering different edge configurations. For the zigzag ZnO ribbons, for instance, the exposed atoms are oxygen atoms while the hidden are zinc. The opposite edge has the inverse

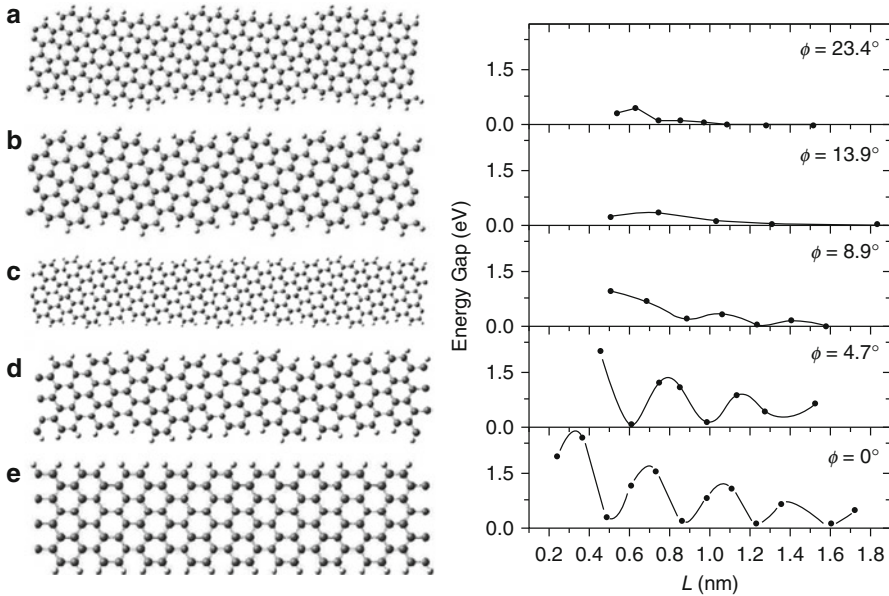

Fig. 21 *Left*: A representative set of semiconducting hydrogen-terminated GNRs, created by “unfolding” and “cutting” different types of CNTs. (a) A GNR with a chiral angle of $\phi = 23.4^\circ$ created by unfolding and cutting a C(6,4). (b) A GNR with a chiral angle of $\phi = 13.9^\circ$ created by unfolding and cutting a C(6,2). (c) A GNR with a chiral angle of $\phi = 8.9^\circ$ created by unfolding and cutting a C(20,4). (d) A GNR with a chiral angle of $\phi = 4.7^\circ$ created by unfolding and cutting a C(10,1). (e) An armchair GNR ($\phi = 0^\circ$) created by unfolding and cutting a zigzag CNT. *Right*: Dependence of the band gap on the width of hydrogen passivated chiral GNRs. structure. The armchair ribbons are characterized by a ZnO pair at the outer edge and another pair at the inner edge. After relaxation, the far edge oxygen ions tend to shift outward on both sides of the ribbon. As in the case of graphene materials, understanding the effects of edge-dimensional variation on band gap energies will provide the new insights into the fundamental principle of architecture design of nanodevices fabricated with ZnO-nanostructured materials. A simple tight-binding model can be used to investigate the electronic properties of nonpolar ZnO nanobelts following the procedure described below.

Consider a simplified unit cell model (see Fig. 22) along the nanobelt growth z direction with Zn and O in the xy plane. This is the actual case for the ultrathin ZnO film oriented along the [001] direction.

In this case, the tight-binding Hamiltonian is given by (Yang and Wang 2006)

$$H = \sum_{r \in A} \varepsilon_r a_r^\dagger a_r + \sum_{r \in B} \varepsilon_r b_r^\dagger b_r + \sum_{r \in A, B} \sum_{i=1,2,\dots} (\tau_{r,i} a_r^+ b_{r+S_i} + \tau_{i,r}^* b_r^+ a_{r+S_i})$$

Fig. 22 Schematic illustration showing a tight-binding unit cell for a ZnO nanobelt (Adapted from Yang and Wang 2006)

where operators $a_r^\dagger(a_r)$ and $b_r^\dagger(b_r)$ create (annihilate) a state at sites A (for Zn) and B (for O) at their coordinates r , respectively. ε denotes the on-site self-interaction energy, whereas τ is the interatomic coupling term. Similarly, the wave functions for Zn and O at their respective lattice sites can be written as a linear combination of Bloch waves along the z direction and standing waves along x and y as the following (Yang and Wang 2006),

$$\left| \text{Zn}, k_x, k_y \right\rangle = \sum_{m_x=1}^{M_x} \sum_{m_y=1}^{M_y} \sum_{z_m} c_p e^{ik_z z_m} \sin(k_x m_x a) \sin(k_y m_y b) a_{m_x m_y}^+ \left| 0 \right\rangle$$

$$\left| \text{O}, k_x, k_y \right\rangle = \sum_{n_x=1}^{N_x} \sum_{n_y=1}^{N_y} \sum_{z_n} c_q e^{ik_z z_n} \sin(k_x n_x a) \sin(k_y n_y b) a_{n_x n_y}^+ \left| 0 \right\rangle$$

in which lattice vectors a and b are as defined in Fig. 19 and c_p and c_q are coefficients.

To simplify the model, one may consider only the coupling term between the nearest neighboring sites. In this case, on the same xy plane, the O-sites take the following coordinates around a Zn center: $n_x = m_x - 1$, m_x and $m_x + 1$; with $n_y = m_y - 1$, m_y and $m_y + 1$ in correspondence. Along the yz plane, there exist two O atoms that directly interact with the center Zn with $z_n = z_m \pm c$, respectively (Yang and Wang 2006).

In addition to the conventional strip-like geometry, other configurations based on GNRs have also been proposed as a part of a search for favorable transport properties. Various graphene nanojunctions based on the GNRs have been studied, such as L-shaped, Z-shaped, and T-shaped GRN junctions (Areshkin et al. 2007; Chen et al. 2008; Jayasekera and Mintmire 2007). Of particular interest is the hybrid junctions which are mixtures of armchair and zigzag GNRs. Some studies have shown that the transport properties of these hybrid GNR junctions are very sensitive to the details of the junction region (Xie et al. 2009). A model calculation based on tight binding and Green's function methods for L-shaped GNRs shows that the corner geometry of the L-shaped junction has great influence on the electron

Fig. 23 (a) A deformed LGNR (called LGNR1) where a triangle graphene flake (in the *dashed-line triangle*) is connected to the inside corner of a standard right-angle LGNR. (b) A deformed LGNR (called LGNR2) in which a triangle graphene flake is cut from the outside corner of LGNR1 in (a). N_A and N_Z represent the widths of the semi-infinite AGNR and ZGNR, respectively; N_1 represents the side length of added triangle flake, while N_2 represents the side length of cut triangle flake (Adapted from Xie et al. 2009)

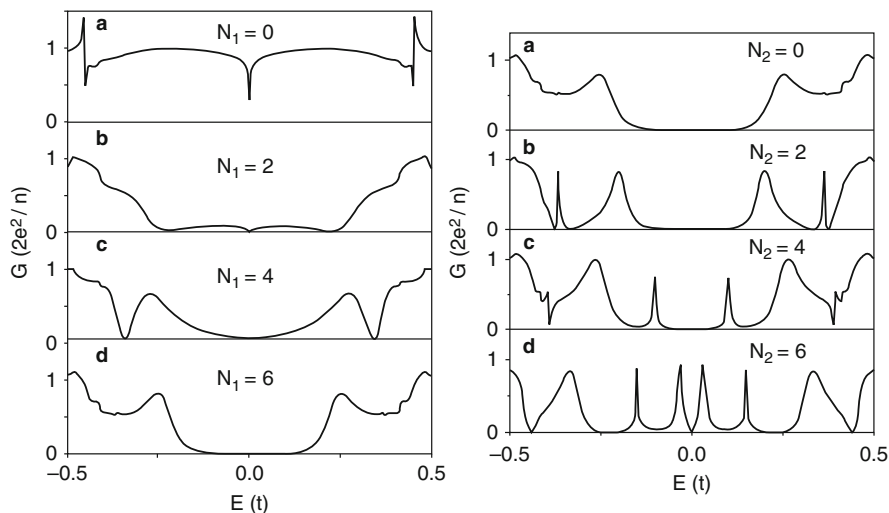

Fig. 24 *Left*: The conductance as a function of electron energy for the LGNR1 in Fig. 23a with different N_1 . Other parameters are $N_A = 11$ and $N_Z = 7$. *Right*: The conductance as a function of electron energy for the LGNR2 in Fig. 23b with $N_1 = 6$ and different N_2 . Other parameters are $N_A = 11$ and $N_Z = 7$ (Reprinted with permission from Xie et al. (2009). © (2009) by Elsevier)

transport around the Fermi energy (Xie et al. 2009). The L-shaped GNR models considered are shown in Fig. 23. The calculated conductance plots as a function of electron energy are shown in Fig. 24. Interestingly the results reveal that the corner is the decisive factor for the electronic properties of these junctions. As more carbon atoms are added to the inner side of the corner, the junction moves from being metal to a semiconductor, developing a band gap.

Carbon nanoribbons have also interesting mechanical properties. For instance, Raman spectra show a remarkable dependence on ribbon width (W) (Zhou and Dong 2008). For the GNRs whose widths are larger than 25 Å, the radial breathing-like mode (RBLM) frequencies follow the $1/W$ rule:

$$\omega = 3086.97 \times \frac{1}{W} + 1.08 \text{ in } 1/\text{cm}.$$

But for the narrow GNRs whose widths are less than 25 Å, their RBLM frequencies follow the $1/\sqrt{W}$ rule:

$$\omega = 1407.81 \times \frac{1}{\sqrt{W}} + 164.38 \text{ in } 1/\text{cm}.$$

A unified fitting function has been proposed (Zhou and Dong 2008), which can be suitable for all the GNRs:

$$\omega = 1584.24 \times \frac{1}{W} + 351.98 \times \frac{1}{\sqrt{W}} - 10.0 \text{ in } 1/\text{cm}.$$

Another interesting application of graphene is the antidot lattices. Antidot lattices are triangular arrangements of holes in an otherwise perfect graphene sheet. In each hexagonal unit cell of the lattice, a circular hole is introduced whose radius R can be adjusted along with the length of the hexagonal unit cell, L . Previously known applications of antidot lattices involve semiconductor lattices, while in a recent publication, the possibility of creating antidot structures on graphene using e-beam lithography has been reported (Pedersen et al. 2008b). The antidot lattice causes graphene to become a semiconductor, introducing a tuning parameter which is the dot size and shape. In addition spin qubit states can be formed in the antidot lattice by manipulating the antidot arrangement. Pedersen et al. (2008a) demonstrated that the hole shape plays a crucial role in determining the electronic structure. A triangular hole instead of a circular hole results in the appearance of a metallic state at the Fermi level. The different band structures are illustrated in Fig. 25.

Magnetic and Optical Properties

Lower-dimensional systems are expected to show electronic, magnetic, and optical properties that are not observed in their bulk counterparts. In two-dimensional structures, the inherent or emergent magnetic properties depend on many factors including shape, size, and the interaction between subregions (Jensen and Pastor 2003; Zhao et al. 2014).

GNRs are a typical example of emergent and controllable magnetic systems. Spin-polarized first-principles calculations by Gorjizadeh et al. (2008) have shown that doping GNRs with 3d transition metals result in the appearance of FM or AFM

Fig. 25 Band structures of a $\{10, 3\}$ antidot lattice and similar structure having a triangular hole with zigzag edges. Note the dispersionless band at 0 eV in the triangular case (Reprinted with permission from Pedersen et al. (2008a). © (2008) by the American Physical Society)

states. In particular Cr and Co provide a large magnetic moment and doping with Fe or Mn at low densities yields half-metallic ribbons.

As discussed in the work by Enoki and Takai, as the dimension of the system decreases, the contribution coming from the edge states increases in proportion (Enoki and Takai 2009). The localized edge states in GNR, which are dispersionless states that appear at the Fermi level, give rise to interesting magnetic properties.

From the application's point of view, the magnetic properties of graphene nanoribbons are more interesting and studied both experimentally and theoretically. Particularly quasi-1D GNRs have magnetic properties depending on their size and symmetry. These are edge states of nanoribbons with opposite spin polarization and band gaps varying with the width of the ribbon (Topsakal et al. 2008).

Using first-principles plane wave calculations within the DFT method, Topsakal et al. (2008) predict that in addition to edge states, electronic and magnetic properties of graphene nanoribbons can also be affected by defect-induced states. In particular, when H-saturated holes are introduced into the GNT, the band structure is modified dramatically altering in return the electronic and magnetic properties. Similarly, vacancies and divacancies induce metallization and magnetization in nonmagnetic semiconducting nanoribbons due to the spin polarization of local defect states. Antiferromagnetic ground state of semiconducting zigzag ribbons can change to ferrimagnetic state upon creation of vacancy defects. In this study, the changes in electronic properties are studied as a function of the location and the

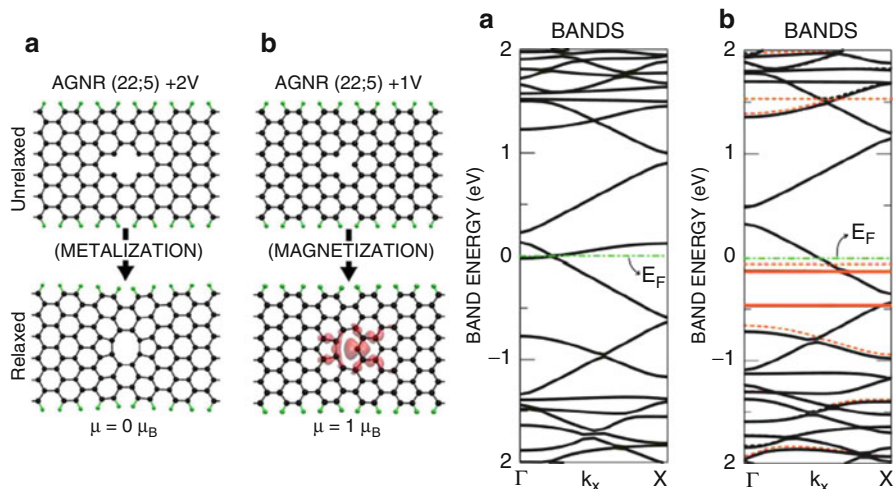

Fig. 26 (a) Metallization of the semiconducting AGNR(22) by the formation of divacancies with repeat period of $l = 5$. (b) Magnetization of the nonmagnetic AGNR(22) by a defect due to the single carbon atom vacancy with the same repeat periodicity. Isosurfaces around the vacancy correspond to the difference of the total charge density of different spin directions. (2008). © (2008) by the American Physical Society)

geometry of the vacancies in different types of armchair GNRs. Due to the spin polarization of localized states and their interaction with edge states, magnetization may be introduced into the GNRs. Some of the representative results of this work are displayed in Fig. 26.

Not only armchair but also zigzag nanoribbons are strongly affected by defects due to single and multiple vacancies (Topsakal et al. 2008). When coupled with the magnetic edge states of the zigzag nanoribbons, the vacancy defect brings about additional changes. The magnetic state and energy band structure of these ribbons depend on the type and geometry of the defects. In a ZGNR(14;8), a single vacancy formation energy is lowered by 0.53 eV when the defect is situated at the edge rather than at the center of the ribbon. Furthermore, two defects associated with two separated vacancy and a defect associated with a relaxed divacancy exhibit similar behavior (Topsakal et al. 2008).

On the other hand, Pisani et al. (2007) investigated theoretically the electronic and magnetic properties of zigzag graphene nanoribbons by performing first-principles calculations within DFT formalism. They predict that the electronic structure of graphene ribbons with zigzag edges is unstable with respect to magnetic polarization of the edge states.

As can be seen from the model calculations of Topsakal et al. (2008, 2007), the energy band gaps and magnetic states of graphene nanoribbons can be modified

by defects due to single or multiple vacancies. Electronic and magnetic properties of finite length graphene nanoribbons also show similar behavior as infinite length nanoribbons. Finite length ribbons are usually referred to as *graphene quantum dots* (GQD). Tang et al. (2008) investigated theoretically the electronic and magnetic properties of a square graphene quantum dot. Electronic eigen-states of a GQD terminated by both zigzag and armchair edges are derived in the theoretical framework of the Dirac equation. They find that the Dirac equation can determine the eigen-energy spectrum of a GQD with good accuracy. By using the Hartree–Fock mean-field approach, they studied the size dependence of the magnetic properties of GQDs. They find that there exists a critical width between the two zigzag edges for the onset of the stable magnetic ordering. On the other hand, when such a width increases further, the magnetic ground state energy of a charge neutral GQD tends to a saturated value (Tang et al. 2008).

Magnetic properties of graphene show a sensitive dependence on single-atom defects; defect concentration and packing play an important role in magnetism. Singh and Kroll (2009) investigated the magnetism in graphene due to single-atom defects by using spin-polarized density functional theory calculations. Interestingly, they find that while the magnetic moment per defect due to substitutional atoms and vacancies depends on the defect density, it is independent of defect density for adatoms. The graphene sheet with B adatoms is found to be nonmagnetic, but with C and N adatoms, it is magnetic. The adatom defects cause a distortion of the graphene sheet in their vicinity. The distortion in graphene due to C and N adatoms is significant, while the distortion due to B adatoms is very small. The vacancy and substitutional atom (B, N) defects in graphene are planar in the sense that there is in-plane displacement of C atoms near the vacancy and substitutional defects. Upon relaxation the displacement of C atoms and the formation of pentagons near the vacancy site due to Jahn–Teller distortion depend upon the density and packing geometry of vacancies (Singh and Kroll 2009). The defect models considered by Singh and Kroll are shown in Fig. 27.

The optical absorption coefficient is one of the most important quantities in solids and is closely related to the electronic band structure. The Kubo formula-based calculations of Zhang et al. indicate that at high frequencies, the optical spectrum of graphene is highly anisotropic (Zhang et al. 2008a). It has also been shown that the

Fig. 27 The model samples of (a) ideal graphene, (b) graphene with one atom vacancy, (c) graphene with one substitutional atom, and (d) graphene with one adatom defect (Adapted from Singh and Kroll 2009)

weak optical response in graphene nanoribbons can be significantly enhanced in an applied magnetic field (Liu et al. 2008).

Another effect important for determining the optical properties of graphene-related materials is spin-orbit coupling. Although spin-orbit coupling is negligible at high frequencies, it is found to have a significant enhancing effect on the optical absorption at lower frequencies as shown in a direct solution of the spin-orbit Hamiltonian in the effective mass approximation by Wright et al. (2009).

Adsorption Phenomena

Adsorption of adatoms on graphene and/or graphene nanoribbons plays an important role in functionalizing graphene materials for various device applications, such as gas sensors and spin valves. Transition metal (TM) atom-decorated graphene shows different magnetic properties depending on the concentration and the species of TM atoms. There are several coverage models, such as one TM atom adsorbed on either (2×2) or (4×4) unit cells on only one side as well as on both sides, namely, above and below the graphene. Sevincli et al. (2008) investigated the possible adsorption sites of TM atoms on graphene and GNR. The geometrical configurations of the structures they considered include bridge (over a C–C bond), atop (on top of a C atom), and on center (over the center of a hexagon) adsorption sites for both perfect graphene and for AGNR of various width N_a .

In relation to another very important application, doping of transition elements was found to increase the hydrogen storage properties of materials (Shevlin and Guo 2006). Especially nickel and rhodium are widely used in the hydrogenation reaction and also in the synthesis of BN sheets. Considering the potential application of Ni and Rh nanoparticles in hydrogen storage and in catalysis, Venkataramanan et al. (2009) investigated the interaction of Ni and Rh atom on the BN sheets through first-principles calculations. They also analyzed the interaction between hydrogen molecules and the metal atoms adsorbed on the BN sheets, which might be useful to maximize the hydrogen storage capacity.

Hydrogen adsorption studies over the metal-doped BN sheets shows that both Ni and Rh atoms can hold three hydrogen molecules. In the case of Ni-doped BN sheet, all three hydrogen molecules are chemically bound and are intact. In the case of Rh-doped BN sheets, the first hydrogen molecule dissociates and the remaining hydrogen molecules are bound to the metal atom. The absorption energy for the first hydrogen was found to have a larger value for the Rh-doped BN sheet, whereas for the second and third hydrogen molecules, the absorption energies were higher for the Ni-doped BN sheets. Upon addition of a fourth hydrogen molecule to the Ni-doped BN sheets, the fourth hydrogen molecule moved to a distance of 3.855 Å. In the case of Rh-doped BN sheet, the Rh atom detached and acted in a similar way to a cluster. Thus Ni atoms are more stable on BN sheets and have higher absorption energy compared to the Rh-doped BN sheets (Venkataramanan et al. 2009).

Metallized graphene can be a potential high-capacity hydrogen storage medium. Graphene is metallized through charge donation by adsorbed Li atoms to its π^* bands. Each positively charged Li ion can bind up to four H_2 by polarizing these molecules. The storage capacity up to the gravimetric density of 12.8 wt% is possible with a favorable average H_2 binding energy of 0.21 eV (Ataca et al. 2008).

Water and gas molecules adsorbed on nanoscale graphene play the role of defects which facilitate the tunability of the band gap and allow one to control the magnetic ordering of localized states at the edges (Berashevich and Chakraborty 2009). The adsorbed molecules push the α -spin (up) and β -spin (down) states of graphene to the opposite (zigzag) edges such that the α - and β -spin states are localized at different zigzag edges. This breaks the symmetry that results in the opening of a large gap. The efficiency of the wavefunction displacement depends strongly on the type of molecules adsorbed on graphene (Berashevich and Chakraborty 2009). The influence of adsorption of water on the electronic and magnetic properties of graphene is based on calculation of the spin-polarized density functional theory, and the results of the calculations are depicted in Fig. 28.

Fig. 28 Plots of the spin density and electron density for the α -spin (*up*) and β -spin (*down*) states in nanoscale graphene. For the spin density, different colors indicate the α - and β -states, while for the electron density distribution (α - and β -states), the different colors correspond to different signs of the molecular orbital lobes. Abstract

Recent extensions of the coupled-cluster (CC) theory for molecular solute described within the polarizable continuum model (PCM) were summarized. The advances covered in this review regard (i) the analytical gradients for the PCM-CC theory at the single and double excitation level, (ii) the analytical gradients for the PCM-EOM-CC theory at the single and double excitation level for the descriptions of the excited-state properties of molecular solute, and (iii) the coupled-cluster theory for the linear and quadratic molecular response functions of molecular solutes. These computational advances can be profitably used to study molecular processes in condensed phase, where both the accuracy of the QM descriptions and the influence of the environment play a critical role.

Introduction: Quantum Cluster Theory and Solvation

In this paper, we present some aspects of our recent work on the extension of computing methods connected to the polarizable continuum model (PCM). Our persevering attention to PCM can be in some sense immediately justified, having us proposed this method years ago and having continued to develop it in the years. In another sense, a justification is required and may be expressed under the form of an answer to a question: why to pass to implement PCM with sophisticated procedures as those given by the coupled-cluster (CC) theory

Coupled-cluster is the top level at which quantum mechanical (QM) calculations on molecules can be nowadays performed (Bartlett and Musiał 2007); PCM is characterized by a drastic simplification of the material system by replacing the degrees of freedom of the solvent molecules with a two body integral operator. Apparently the two methods are operating at very different scales of accuracy, but actually they can be profitably coupled. To show it, we pass to examine some features of PCM. This rapid examination of some technical aspects of the methods used in PCM will be also useful as an introductory section to our exposition.

The methodology on which PCM is based is that of an effective Hamiltonian expressed in terms of interaction integral operators depending on the solution of a nonlinear Schrödinger equation. The method is powerful and versatile, allowing applications of very different nature. A good number of such applications have been elaborated in the years by us and by other groups, and an undetermined, but large, number of new applications looks promising. Many among them are going beyond the field of dilute solutions; others address the description of solvent effects under special conditions, a few regard higher levels of the QM theory.

We are here considering an application of this last type. The features of PCM we have to examine are so limited to the developments of the QM *ab initio* version of the procedures (other versions regard semiempirical and semiclassical descriptions).

PCM was born as a method to describe electrostatic solvation effects on the electronic distribution of a molecule (Miertuš et al. 1981). The method was conceived for *ab initio* QM calculations, using a technique to solve the electrostatic problem never used before in molecular sciences, a technique based on the use of

the concept of apparent charges. The integral interaction operator is thus reduced to the Coulomb interaction with a charge distribution spread on the surface of the solute and represented by a set of point charges.

Solute-solvent interactions are not limited to the electrostatic one. The non-electrostatic terms have been introduced in PCM with the aid of a phenomenological (and effective) Hamiltonian (Bonaccorsi et al. 1982). Each term of the interaction has a different physical meaning but a similar formal expression, given by an integral operator with kernel $Q_X(r, r')$, where X stays for one of the contribution to the interaction energy: electrostatic, repulsion, dispersion, cavity formation. The effective Hamiltonian mixes quantum and classical components. In particular, the medium which appears in the kernel of the $Q_X(r, r')$ operators has to be precisely defined, in agreement with the physical conditions established for the experiments the computational model has to describe.

The formal elaboration of the physical components of the model has to be followed by the elaboration of the corresponding mathematical procedures. In this step, several “concepts” of quantum and classical origin have to be introduced: examples are the molecular surface and the notion of charging process.

We shall use here the concept of charging process as a guide in our exposition. Charging processes are of general use in physics, but rarely mentioned in molecular quantum mechanics; more explicit is its use in statistical thermodynamics to which our model is connected.

The basic task in molecular QM, that of computing energy and charge distribution of an isolated molecule at a clamped nuclear geometry, corresponds to a charging process. The analogous process in solution with an effective continuum Hamiltonian presents however important differences. The medium defining the liquid portion of the material systems is changed (polarized) by charging processes. A portion of the energy gained in a reversible charging process is so lost. The remaining portion of the energy is the free energy of the system, measured from a reference state composed by the unperturbed medium and by the appropriate assembly of noninteracting nuclei and electrons giving origin to the solute molecule. This process has a classical counterpart and can be derived on QM grounds without invoking physical arguments (a derivation is based on the variational theorem with an effective Hamiltonian linearly dependent on the solution) (Tomasi and Persico 1994).

The picture of the charging process can be used for the phenomenological partition we have introduced a few sentences above. This is a practiced used in statistical thermodynamics.

The contributions can be described in an ordered sequence of charging processes; at the end of each process, the medium is modified (polarized), and the so polarized medium is the starting point for the following charging process. The selected order of charging influences the result, because couplings in this procedure are neglected and they change according the ordering, but with an appropriate selection of the sequence, the results of the solvation energy are well reproduced with a computational cost decidedly lower than that of the full calculation (Tomasi et al. 2003).

The option of decoupling the non-electrostatic part from the main calculation has also another practical advantage that we shall exploit in the following of this paper, namely, of provisionally discard the non-electrostatic terms during the elaboration of a new electrostatic procedure. The non-electrostatic contributions to the energy are numerically large, but feebly coupled with the electrostatic one. We stress, however, that decoupling and simplified descriptions of single components are not strictly necessary: *ab initio* procedures computing everything in a unique calculation exists (Curutchet et al. 2006).

We have so far examined some points of the original PCM procedure. Other elements of interest for the present paper, drawn from the numerous procedures implemented and tested later (Tomasi et al. 2005), will be here considered. These points regard the improvements in the description of the solute's electronic wave function and the description of excited states, including nonequilibrium solvent effects.

Improvements in the quantum description of a solute mostly regard the electron correlation effects. There are, in principle, no restrictions to introduce in the formal framework of our effective Hamiltonian any version of QM methods describing electron correlation. Calculations including a description of correlation at a low level are nowadays routinely performed, but for calculations at high levels, the convenience of keeping low computational cost becomes a necessity. There are features in the effective Hamiltonians for continuum solvation promising substantial reductions in some specific versions of post Hartree-Fock calculations. In the present paper, we shall make use of a decoupling of the QM charging process elaborated years ago to better study the behavior of the many-body perturbation scheme in continuum solution and later adopted to simplify calculations in the series of MPn calculations (Olivares del Valle and Tomasi 1991). The perturbation series may be expanded on the electronic configurations of the molecular solute's electron distribution computed in *vacuo* and then used for the calculation of solvent reaction potential and solvation-free energy; this approximation is called PTD, being a version of the perturbation theory based on the electronic density. Another scheme is based on the expansion of the molecular solute's electron distribution computed with PCM at the Hartree-Fock level and used to compute solvent reaction potential and energy; this approximation is called PTE. The comparison of the results obtained with the two schemes gave insights on the relative importance of the decoupled electron correlation and solvation potential effects on the solute. A more complete procedure couples the two effects into a single iterative computational scheme, with the correlated electronic density used to make the solvent field self-consistent; the procedure is called PTED. We shall examine in a following section the PTE and PTDE version for the coupled-cluster method.

In this paper, we shall also consider the first basic aspects of the dynamical, i.e., nonequilibrium, behavior of liquid media. The subject embraces a very large variety of phenomena, requiring different formulations of the continuum models. We cite here an aspect, relatively simple, related to a phenomenon occurring in a span of time relatively short with respect to the characteristic relaxation times (CRT)

of the solvent: the vertical electronic transitions in solutes (Kim and Hynes 1990; Basilevsky and Chudinov 1990; Marcus 1992).

Electronic transitions are very fast, and the solvent molecules have no time to rearrange themselves during this phenomenon, saving for the electronic component of the solvent polarization which has a CRT of the same order of magnitude of the vertical electronic transition. This effect means that the energy of the vertical transition (a free energy, we remark) has a component due to the solvent interaction limited to changes in the fast electronic polarization. The effects of the electronic transition continue in the time, but these do not regard the vertical process and have to be described with a different formulation of the continuum method.

There is to remark, for the sake of completeness, that there are two theoretical models, respectively, named Marcus and Pekar partitions, which describe this simple process, differing in the intermediate stages of the elaboration of the problem, but arriving at the same result when the correct expression for the nonequilibrium free-energy functional is used. The PCM versions of the two models have been presented in papers Aguilar et al. (1993) and Cammi and Tomasi (1995b). For a comment, see also Aguilar (2001). A detailed comparison of the formulas of two models has been reported in Sect. 5.1 of Tomasi et al. (2005). The Pekar partition will be used in the following sections of this paper; the Marcus partition is in this case less convenient.

Quantum models in condensed systems often present alternative computational routes merging into a unique form when the effect of the medium is neglected. In coding the formulas for problems, a great attention must be paid to the correct inclusion of the corrections to satisfy the free-energy requirements.

This last remark also holds for the topic we shall consider now: the calculation of the electronic excitation energies. Two approaches are generally used to get the excitation energies: a version based on the CI approach or a version based on the response theory. Both approaches have in condensed media problems not present in the corresponding calculations in vacuo.

The roots of a CI calculation give in vacuo the energies of the various states; in solution these values have to be corrected for the effect of the solvent electronic polarization. Also the corresponding description of the so defined electronic states has to be modified (with an iterative procedure), because mutual polarization effects occur at the same time. This operation of polarization has to be separately performed for each electronic state, being the effective Hamiltonian of each excited state different from the others. The method is said “state specific” (SS), and it constitutes the main way for the study of excited-state potential surfaces.

The second approach is based on a Hamiltonian with explicit time dependence, provided with an opportune form of the of the time-dependent variation principle (the Frenkel principle is generally used Cammi et al. 1996). From this starting point, linear and nonlinear response functions are derived.

The linear response functions (LR) nowadays are amply used both in gas phase and in solution for the characterization of excited states and of molecular properties. The complete equivalence between SS and LR results for the excitation energies was

universally accepted, but recently it was shown (Kongsted et al. 2002; Cammi et al. 2005; Corni et al. 2005) that this equivalence is valid only in vacuo and that LR results can be seriously in error in solution. A computational strategy to reduce this error was proposed (Caricato et al. 2006; Improta et al. 2006), efficient enough to allow the exploitation of the less expensive LR scheme.

It is convenient to mention here another aspect of the continuum solvation theory that will be used in the following pages: the calculation of analytical derivatives.

It is essential for computational methods addressing chemical problems the availability of analytic expressions for derivatives. The variety of derivatives appearing in molecular calculations is quite large, but we limit ourselves to consider derivatives of the energy with respect to nuclear coordinates.

The derivatives in solution have important additional features with respect to the derivatives in vacuo. In solution it is compelling to compute derivatives taking into account partial derivation with respect to cavity parameters. An accurate description of the cavity shape is compulsory: examples of bad results due to inaccurate descriptions of the cavity are present in every field of application – from the determination of the molecular structure to the equilibrium among conformers to spectroscopic properties. Spherical cavities have to be used only as a first-order approximation; more subtle are the errors with cavities badly defined or treated in a simplified way during the calculations. The problems of accurate handling of the derivatives of the cavity parameters become more complex and computing expensive with the increase of the order of the derivative and of the computational level. The problem of the numerical stability of the second derivatives obliged us in the past to change the definition of the cavity elements. The analytical expressions of the first and second derivatives with respect to nuclear coordinates have been elaborated for the present version, but we shall use in the second part of this paper the first derivatives only.

The methodological and computational bases of PCM have been elaborated more extensively than shown in this exposition, but what said would be sufficient to show the care necessary to develop a reliable version of CC for PCM. Nothing has been said about the numerical accuracy of PCM results. The definition of the accuracy for a method allowing numerous different applications is a problem; it is almost compulsory to separately consider different classes of phenomena. The largest number of applications of solvent methods regards the solvation energy. Actually there is no need for this property of an accurate description of the electronic distribution, and in fact many methods are based on semiclassical approximations. There are however difficult cases in which there is the need of an accurate description of geometry and electronic charge distribution: in these cases, *ab initio* methods of sufficient accuracy are necessary. There are several methods satisfying this criterion, and all perform well. A recent comparison (Cramer and Truhlar 2008; Klamt et al. 2009) gives some indications, even if the really difficult cases were not much abundant in these comparisons. Another point to remark is that the best fitting with experimental data was obtained using “calibrated parameters.” We have not talked in the preceding pages of empirical calibration of parameters over experimental data, because we have not used this procedure in the elaboration of

PCM methods (and we are not using it in this paper). Calibration of parameters is necessary for explicitly declared semiempirical methods, but it is risky for methods aspiring to generality because ad hoc parameterizations are limited to one (or few) property and performed over a single specific definition of the computational parameters (QM method, basis set, etc.). Anyway, versions of PCM parameterized for solvation energies exist, and they behave very well.

More interesting is the consideration of accuracy for more complex problems of spectroscopic type, which actually constitute the direct motivation of this work. PCM is among the best methods in this field, with features not present on other methods, but the need of having description of the electronic structure of the chromophore more accurate than those currently used in these studies is in our opinion quite manifest. There has been a preceding attempt, several years ago, of using a CC wave function modified by continuum solvent effects, just for the calculation of molecular properties. The proposal was made by Mikkelsen and coworkers (Christiansen and Mikkelsen 1999) using a spherical cavity with a multipolar expansion of the solvent reaction potential. This attempt was bold and interesting, but the continuum model was forcibly simple, with the perspective of giving results, when applied to more complex chromophores, in which a gain in the description of the solute is accompanied by a poorer description of the solvent effect. Time was not yet ripe for efficient applications of the approach to systems of real spectroscopic interest. This is the answer to the question put at the beginning of this introduction. There is the need for some specific scopes of molecular calculations more accurate than those currently available, and the more convenient way to arrive at this level of accuracy apparently is given by an accurate (in the formulation and in the execution) *ab initio* continuum code coupled to an efficient procedure of the coupled-cluster family. The first principles of molecular dynamics at a high level of quantum description are not feasible. The use of computer simulations at a lower level accompanied by a final calculation at the CC level is a risky procedure, requiring extensive validation.

In this introduction, we have not examined the details of the coupled-cluster procedures because we have used in the implementation standard aspects of it, on which particularly comments were not necessary (Bartlett and Musiał 2007). Details and comments will be necessary when an extension of the present study shall be published.

The Coupled-Cluster Theory for the Polarizable Continuum Model

The coupled-cluster (CC) theory for the PCM model exploits the formalism of the coupled-cluster energy functional. As for the case of isolated molecules, this formalism allows to recast the coupled-cluster method for PCM into a pseudo-variational problem. However, the physical status of this energy functional has an important difference with respect to isolated molecules as it corresponds to the

free energy of the whole solute-solvent system (Christiansen and Mikkelsen 1999; Cammi 2009), as we have already said in the Introduction.

In this section, we review both the formal derivation of the PCM-CC equations and corresponding explicit equations at the single and double excitation level (PCM-CCSD).

The PCM-CC Reference State and the PCM-CC Energy Functional

The coupled-cluster wave function of the molecular solute is written as the exponential ansatz:

$$|CC \rangle = e^T |HF \rangle \quad (1)$$

where $|HF \rangle$ is the reference state given by the Hartree-Fock ground state of the solvated molecule and the cluster operator T is given as a sum of all possible excitation operators over the N electrons:

$$T = T_1 + T_2 + \dots + T_N$$

$$T_n = \frac{1}{(n!)^2} \sum_{aij\dots} t_{ij\dots}^{ab\dots} a_a^\dagger a_i a_b^\dagger a_j \dots \quad (2)$$

weighted by the amplitude t_i^a, t_{ij}^{ab} , etc. The excitation operators are here represented as products of second-quantization electron creation (a_i^\dagger, a_b^\dagger) and annihilation operators (a_i, a_b). As usual, indexes (i, j, k, \dots) and (a, b, c, \dots) denote, respectively, occupied and vacant spin orbitals MO, while (p, q, r, \dots) denote general spin orbitals.

The PCM Hartree-Fock Reference State

The Hartree-Fock reference state $|HF \rangle$ is obtained by the stationarity condition of PCM Hartree-Fock free-energy functional \mathcal{G}_{HF} (Cammi and Tomasi 1995a):

$$\mathcal{G}_{HF} = \langle HF | H^o + 1/2 \langle HF | \hat{Q} | HF \rangle \cdot \mathbf{V} | HF \rangle \quad (3)$$

where H^o is the Hamiltonian of the isolated solute and $\langle HF | \hat{Q} | HF \rangle \cdot \hat{\mathbf{V}}$ is the solute-solvent interaction term, being $\langle HF | \hat{Q} | HF \rangle$ the solvent polarization charges computed with the Hartree-Fock state reference state $|HF \rangle$ and $\hat{\mathbf{V}}$ the molecular electrostatic potential operator of the solute (see Appendix A); the one-half factor in front of the solute-solvent potential term is due the energy loss during the process of polarization of the dielectric representing the solvent, as already said in the introduction.

In an N -electron system with spin orbitals expanded over a set of atomic orbitals (AO), $\{\chi_\mu, \chi_\nu, \dots\}$, \mathcal{G}^{HF} may be written as

$$\mathcal{G}^{HF} = \sum_{\mu\nu} P_{\mu\nu}^{HF} (h_{\mu\nu} + j_{\mu\nu}) + \frac{1}{2} \sum_{\mu\nu\lambda\sigma} P_{\mu\nu}^{HF} P_{\lambda\sigma}^{HF} [(\mu\lambda||\nu\sigma) + \mathcal{B}_{\mu\nu,\lambda\sigma}] + \tilde{V}_{NN} \quad (4)$$

where $h_{\mu\nu}$ are the matrix elements, in the AO basis, of the one-electron core operator, $(\mu\lambda||\nu\sigma)$ are the antisymmetrized combination of regular two-electron repulsion integrals (ERIs), and $P_{\mu\nu}^{HF}$ indicates the elements of the Hartree-Fock density matrix. The one-electron matrix elements $j_{\mu\nu}$ and the pseudo two-electron integrals $\mathcal{B}_{\mu\nu,\lambda\sigma}$ describe the solute-solvent interactions within the PCM-Fock operator. The one-particle AO integrals $j_{\mu\nu}$ and the pseudo two-electrons integrals $\mathcal{B}_{\mu\nu,\lambda\sigma}$ represent, respectively, the interactions with the nuclear and with the electronic components of the ASC charges. The solvent integrals $j_{\mu\nu}$, $\mathcal{B}_{\mu\nu,\lambda\sigma}$ may be expressed in the following form

$$j_{\mu\nu} = \mathbf{v}_{\mu\nu} \cdot \mathbf{q}_{Nuc} \quad (5)$$

$$\mathcal{B}_{\mu\nu,\lambda\sigma} = \mathbf{v}_{\mu\nu} \cdot \mathbf{q}_{\lambda\sigma} \quad (6)$$

where $\mathbf{v}_{\mu\nu}$ is a vector collecting the AO integrals of the electrostatic potential operator evaluated at the positions \mathbf{s}_k of the ASC charges, \mathbf{q}_{Nuc} is a vector collecting the ASC charges produced by the nuclear charge distribution, and $\mathbf{q}_{\lambda\sigma}$ is a vector collecting the apparent charges produced by the elementary charge distribution $\chi_\lambda^*(\mathbf{r})\chi_\sigma(\mathbf{r})$. The apparent surface charges may be obtained in terms of the electrostatic potential of the solute charge distributions by using the integral equation formalism of the PCM (Cancès et al. 1997).

The last term of Eq. (4), \tilde{V}_{NN} represents the interaction between the nuclei and the nuclear component of the apparent surface charges, $\tilde{V}_{NN} = 1/2 \mathbf{v}_{Nuc} \cdot \mathbf{q}_{Nuc}$.

Requiring that \mathcal{G}_{HF} be stationary with respect to the variation of MO expansion coefficients, we obtain the PCM-HF equations:

$$\sum_{\nu} (f_{\mu\nu}^{PCM} - \epsilon_p S_{\mu\nu}) c_{\nu p} = 0 \quad (7)$$

where $S_{\mu\nu}$ and $f_{\mu\nu}^{PCM}$ are, respectively, the matrix elements of the overlap matrix and of the PCM-Fock matrix, in the AO basis, and ϵ_p and $c_{\nu p}$ are, respectively, the orbital energy and the expansion coefficients of the p MO. The PCM-Fock matrix elements are given by:

$$f_{\mu\nu}^{PCM} = (h_{\mu\nu} + j_{\mu\nu}) + G_{\mu\nu}(\mathbf{P}^{HF}) + X_{\mu\nu}(\mathbf{P}^{HF}) \quad (8)$$

where $G_{\mu\nu}(\mathbf{P}^{HF})$ are the matrix elements of the effective Coulomb-exchange two-electron operator, while $X_{\mu\nu}(\mathbf{P}^{HF})$ are the matrix elements of the solvent operator

representing an effective Coulomb two-electron mediated by the polarization of the solvent.

The Coupled-Cluster PCM Free-Energy Functional

To define the PCM-CC free-energy functional, we introduce the bra coupled-cluster wave function:

$$\langle \tilde{C}C | = \langle HF | (1 + \Lambda) e^{-T} \quad (9)$$

where Λ is a de-excitation operator,

$$\Lambda = \Lambda_1 + \Lambda_2 + \dots \Lambda_n = \frac{1}{(n!)^2} \sum_{ijkabc\dots} \lambda_{abc\dots}^{ijk\dots} a_i^\dagger a_a^\dagger a_j^\dagger a_b^\dagger a_k^\dagger a_c \dots \quad (10)$$

$\lambda_a^i, \lambda_{ab}^{ij}, \dots$ are the de-excitation amplitudes.

In terms of the bra and ket wave functions, the coupled-cluster free-energy functional (Christiansen and Mikkelsen 1999; Cammi 2009) may be written as

$$G_{CC}(\Lambda, T) = \langle HF | (1 + \Lambda) e^{-T} H_0 e^T | HF \rangle + \frac{1}{2} \bar{\mathbf{Q}}(T, \Lambda) \cdot \bar{\mathbf{V}}(T, \Lambda) \quad (11)$$

where $\langle HF | (1 + \Lambda) e^{-T} H_0 e^T | HF \rangle$ is the energy functional for the isolated molecules and $\bar{\mathbf{V}}$ and $\bar{\mathbf{Q}}$ are, respectively, the coupled-cluster expectation value of the PCM operators $\hat{\mathbf{Q}}$ and $\hat{\mathbf{V}}$ (Bartlett and Musiał 2007):

$$\bar{\mathbf{Q}}(T, \Lambda) = \langle HF | (1 + \Lambda) e^{-T} \mathbf{Q} e^T | HF \rangle \quad (12)$$

$$\bar{\mathbf{V}}(T, \Lambda) = \langle HF | (1 + \Lambda) e^{-T} \mathbf{V} e^T | HF \rangle \quad (13)$$

We note that arguments of the expectation values (12) and (13) denote an explicit functional dependence on the T and Λ amplitudes. These amplitudes, which define completely the coupled-cluster wave function of the molecular solute, can be determined imposing the stationary conditions on the energy functional $G_{CC}(\Lambda, T)$.

The PTDE and the PTE Coupled-Cluster Schemes

To develop a coupled-cluster theory within the PTE and PTDE schemes described in the Introduction, the free-energy functional $G_{CC}(\Lambda, T)$ of Eq. (11) is partitioned into a Hartree-Fock component $\mathcal{G}_{\mathcal{HF}}$ and into a coupled-cluster component $\Delta G_{CC}(\Lambda, T)$:

$$G_{CC}(\Lambda, T) = \Delta G_{CC}(\Lambda, T) + \mathcal{G}_{\mathcal{HF}} \quad (14)$$

where $\mathcal{G}_{\mathcal{HF}}$ is the HF contribution, defined in Eq. (3), and $\Delta G_{CC}(\Lambda T)$ denotes the correlative CC contribution:

$$\Delta G_{CC}(\Lambda, T) = \langle HF | (1 + \Lambda) e^{-T} \left[H(0)_N + \frac{1}{2} \bar{\mathbf{Q}}_N(\Lambda, T) \cdot \mathbf{V}_N \right] e^T | HF \rangle \quad (15)$$

The partition of Eq. (14) is based on the so-called normal ordered operators $H(0)_N$, \mathbf{V}_N and \mathbf{Q}_N (Cammi 2009). Specifically, $\bar{\mathbf{Q}}_N(\Lambda, T) \cdot \mathbf{V}_N$ is the component of the solvent reaction potential due to the correlation CC electronic density, and $H(0)_N$ is the normal ordered form of Hamiltonian of the solute in presence of the frozen Hartree-Fock reaction field $\bar{\mathbf{Q}}_{HF}$.

The Coupled-Cluster PTDE Scheme

Within the PTDE scheme, the coupled-cluster electronic density is used to make the solvent reaction field self-consistent. This corresponds to make the free-energy functional $\Delta G_{CC}(\Lambda, T)$ stationary with respect to the Λ and the T amplitudes.

The stationarity with respect to the Λ amplitudes gives the equation for the self-consistent T amplitudes:

$$\frac{\partial \Delta G_{CC}}{\partial \lambda_{ab\dots}^{ij\dots}} = \langle HF | \{i^\dagger a j^\dagger b \dots\} e^{-T} H(\Lambda, T)_N e^T | HF \rangle = 0 \quad (16)$$

In turn, the stationarity with respect to the T amplitudes gives the equation for the self-consistent Λ parameters:

$$\frac{\partial \Delta G_{CC}}{\partial t_{ij\dots}^{ab\dots}} = \langle HF | (1 + \Lambda) e^{-T} [H(\Lambda, T)_N, \{a^\dagger i a^\dagger j \dots\}] e^T | HF \rangle = 0 \quad (17)$$

In Eqs. (16) and (17), $H(\Lambda, T)_N$ is the Hamiltonian of the molecular solute in the PTDE scheme:

$$H(\Lambda, T)_N = H(0)_N + \bar{\mathbf{Q}}_N(\Lambda, T) \cdot \mathbf{V}_N \quad (18)$$

where $H(0)_N$ is the normal ordered form of Hamiltonian of the solute in presence of the frozen HF reaction field and $\bar{\mathbf{Q}}_N(\Lambda, T) \cdot \hat{\mathbf{V}}_N$ is the coupled-cluster component of the solvent reaction potential, as described above.

The equation for the T amplitudes has a clear physical meaning: it corresponds to projection in the manifold spanned by all the orthonormal excitations to $|HF\rangle$ of the coupled-cluster Schrodinger equation for the molecular solute:

$$[H(0)_N + \bar{\mathbf{Q}}_N(\Lambda, T) \cdot \mathbf{V}_N] e^T | HF \rangle = \Delta E_{CC} e^T | HF \rangle \quad (19)$$

where ΔE_{CC} is given by

$$\Delta E_{CC} = \langle HF | (1 + \Lambda) e^{-T} H(\Lambda, T)_N e^T | HF \rangle \quad (20)$$

The coupled-cluster eigenvalue ΔE_{CC} differs from the free-energy functional $\Delta G_{CC}(\Lambda, T)$ by the work spent during the charging process of the coupled-cluster reaction field, i.e.,

$$\Delta G_{CC} = \Delta E_{CC} - \frac{1}{2} \bar{\mathbf{Q}}_N(\Lambda, T) \cdot \bar{\mathbf{V}}_N(\Lambda, T) \quad (21)$$

where $\bar{\mathbf{V}}_N(\Lambda, T)$ is the coupled-cluster expectation value of the electrostatic potential.

Being the Hamiltonian $H(\Lambda, T)_N$ dependent on both T and Λ parameters, the corresponding PTDE equations (16) and (17) are coupled, and they must be solved in an iterative and self-consistent way.

The Coupled-Cluster PTE Scheme

In the PTE coupled-cluster approximation, the electronic distribution is computed with PCM at the Hartree-Fock level. This approximation is easily obtained from the above PTDE equations by neglecting all the contributions related to the coupled-cluster solvent operator $\bar{\mathbf{Q}}_N(\Lambda, T) \cdot \mathbf{V}_N$. Specifically, the PTE Hamiltonian is the Hamiltonian $H(0)_N$, which contains the fixed reaction potential of the solute at the HF level, and the free-energy functional is given by

$$\Delta G_{CC}^{PTE} = \Delta E_{CC}^{PTE} = \langle HF | (1 + \Lambda) e^{-T} H(0)_N e^T | HF \rangle \quad (22)$$

The stationary condition of ΔG_{CC}^{PTE} leads to the following T equations:

$$\frac{\partial \Delta G_{CC}^{PTE}}{\partial \lambda_{ab\dots}^{ij\dots}} = \langle HF | \{i^\dagger a j^\dagger b \dots\} e^{-T} H(0)_N e^T | HF \rangle = 0 \quad (23)$$

and of the Λ equations

$$\frac{\Delta \partial G_{CC}}{\partial t_{ij\dots}^{ab\dots}} = \langle HF | (1 + \Lambda) e^{-T} H(0)_N, \{a^\dagger i a^\dagger j \dots\} e^T | HF \rangle = 0 \quad (24)$$

Within the PTE approximation, the PCM coupled-cluster equations (16) and (17) have the same structure of the coupled-cluster equations of the isolated molecules and the T , and Λ amplitudes equations are not more coupled. As a consequence, we don't need to solve the Λ equations to compute the energy functional ΔG_{CC}^{PTE} .

In the next section, we describe how the basic PTDE and PTE equations lead to explicit expressions suitable for the implementation in quantum chemistry computational codes.

The Explicit PCM-CCSD Equations

The explicit form of the PCM-CC equations (16), (17), (18), (19), (20), (21), (22), (23) and (24) has been recently presented (Cammi 2009) for the coupled-cluster single and double (CCSD) level, which restricts the T and Λ operators to excitation operators T_1, T_2 and to the de-excitation operators Λ_1, Λ_2 , respectively.

The key entities are the similarity-transformed PTE Hamiltonian $\mathcal{H}(0) = e^{-T} H(0)_N e^T$ and the similarity-transformed molecular electrostatic potential operators $\mathcal{V} = e^{-T} \widehat{\mathbf{V}}_N e^T$. Both operators can be expressed as a terminated Baker-Campbell-Hausdorff expansions. Specifically, $\mathcal{H}(0)$ terminates at the fourfold commutator, because it has at most two-particle interactions:

$$\begin{aligned} \mathcal{H}(0) &= \widehat{H(0)}_N + [\widehat{H(0)}_N, T] + \frac{1}{2} [[\widehat{H(0)}_N, T]T] \\ &+ \frac{1}{3!} [[[\widehat{H(0)}_N, T]T]T] + \frac{1}{4!} [[[[\widehat{H(0)}_N, T], T]T]T] = (H(0)_N \exp(T))_C \end{aligned} \quad (25)$$

while \mathcal{V} terminates at the twofold commutator as it has at most one-particle interactions:

$$\mathcal{V} = \widehat{\mathbf{V}}_N + [\widehat{\mathbf{V}}_N, T] + \frac{1}{2} [[\widehat{\mathbf{V}}_N, T]T] = (\mathbf{V}_N \exp(T))_C \quad (26)$$

In Eqs. (25) and (26), the subscript c indicates that only the so-called ‘‘connected’’ terms are considered, when the operators are expressed in terms of normal ordered product of second-quantization creation and annihilation operators (Bartlett and Musiał 2007).

The similarly transformed coupled-cluster PTDE-PCM Hamiltonian can then be written in the connected form

$$\mathcal{H}(\Lambda, T) = (H(0)_N \exp(T))_C + (\mathbf{V}_N \exp(T))_C \quad (27)$$

and the explicit PCM-CC equations may be obtained by substitution into Eqs. (16), (17), (18), (19), and (20). The corresponding integrals may be obtained by an algebraic approach, which exploits the Wick theorem (Bartlett and Musiał 2007) for normal product operators with $H(T, \Lambda)_N$ written in the second quantized form

$$H(T, \Lambda)_N = \sum_{p,q} \left(f_{p,q}^{PCM} + \bar{\mathbf{Q}}_N(\Lambda, T) \mathbf{v}_{pq} \right) \{p^\dagger q\} + \frac{1}{4} \sum_{p,q,r,s} \langle pq || rs \rangle \{p^\dagger q^\dagger sr\} \quad (28)$$

The explicit equation for the correlation energy ΔE_{CC} is obtained as

$$\Delta E_{CC} = \langle HF | \hat{H}(T, \Lambda)_N \left(T_2 + T_1 + \frac{1}{2} \right) T_1^2 | HF \rangle \quad (29)$$

with the corresponding algebraic form given by

$$\Delta E_{CC} = \bar{\mathbf{Q}}_N(\Lambda, T) \cdot \mathbf{v}_{ia} t_i^a + \frac{1}{4} \langle ij || ab \rangle \tau_{ij}^{ab} \quad (30)$$

where $\tau_{ij}^{ab} = t_{ij}^{ab} + t_i^a t_j^b - t_i^b t_j^a$.

The explicit expression for the T_1, T_2 equations are given by

$$\begin{aligned} 0 = & \langle_i^a | \hat{H}(T, \Lambda)_N \left(1 + T_2 + T_1 + T_1 T_2 + \frac{1}{2} T_1^2 + \frac{1}{3!} T_1^3 \right) | HF \rangle_c \\ = & \langle_i^a | f_N^{PCM} \left(1 + T_1 + T_2 + \frac{1}{2!} T_1^2 \right) \\ & + \bar{\mathbf{Q}}_N(\Lambda, T) \cdot \mathbf{V}_N \left(1 + T_1 + T_2 + \frac{1}{2!} T_1^2 \right) \\ & W_N \left(T_1 + T_2 + \frac{1}{2!} T_1^2 + T_1 T_2 + \frac{1}{3!} T_1^3 \right) | HF \rangle \end{aligned} \quad (31)$$

$$\begin{aligned} 0 = & \langle_{ij}^{ab} | \hat{H}(T, \Lambda)_N \left(1 + T_2 + T_1 + T_1 T_2 + \frac{1}{2} T_1^2 + \frac{1}{2!} T_2^2 \right. \\ & \left. + \frac{1}{2} T_1^2 T_2 + \frac{1}{3!} T_1^3 + \frac{1}{4!} T_1^4 \right) | HF \rangle_c \\ = & \langle_{ij}^{ab} | f_N^{PCM} (T_2 + T_1 T_2) + \bar{\mathbf{Q}}_N(\Lambda, T) \cdot \mathbf{V}_N (T_2 + T_1 T_2) \\ & + W_N \left(T_2 + \frac{1}{2!} T_1^2 + T_1 T_2 + \frac{1}{3!} T_1^3 + \frac{1}{2!} T_2^2 + \frac{1}{2!} T_1^2 T_2 + \frac{1}{4!} T_1^4 \right) | HF \rangle_c \end{aligned} \quad (32)$$

where $\langle_{ij}^{ab\dots} | = \langle HF | \{i^\dagger a j^\dagger b \dots\}$.

The explicit Λ_1, Λ_2 equations are obtained as:

$$0 = \langle HF | \hat{H}(T, \Lambda)_N e^T |_i^a \rangle_c + \langle HF | (\Lambda_1 + \Lambda_2) (\hat{H}(T, \Lambda)_N e^T)_c |_i^a \rangle_c \quad (33)$$

and

$$\begin{aligned} 0 = & \langle HF | \hat{H}(T, \Lambda)_N e^T |_{ij}^{ab} \rangle_c + \langle HF | (\Lambda_1 + \Lambda_2) (\hat{H}(T, \Lambda)_N e^T)_c |_{ij}^{ab} \rangle_c \\ & + \sum_{c=a,b;k=i,j} \langle HF | \hat{H}(T, \Lambda)_N e^T |_k^c \rangle_c \langle_k^c | \Lambda_1 + \Lambda_2 |_{ij}^{ab} \rangle \end{aligned} \quad (34)$$

The algebraic form for the T_1, T_2 and Λ_1, Λ_2 equations is reported elsewhere (Cammi 2009).

The above PTDE PCM-CC explicit equations can be easily implemented in any computational quantum code. However, the PTDE coupled-cluster procedure is different with respect to a calculation on isolate molecules, as anticipate above. The electron correlation component of the reaction field $\bar{\mathbf{Q}}_N(\Lambda, T) \cdot \mathbf{v}_{me}$ enters, as an

effective one-body contribution, both in the T and in the Λ equations, which must be solved simultaneously by using a recursive procedure. The coupling between the T, Λ equations has obvious computational consequences, with an increase of computational cost with respect to a coupled-cluster calculation for isolated molecules. In fact, in this case, it is not necessary to solve the Λ equation to obtain the CC energy and wave function.

The explicit equations for the PCM-CC-PTE approximation can be easily obtained from the PTDE equations by neglecting all terms involving the coupled-cluster components of the solvent reaction potential. This makes the computational cost of the PTE approximation similar to a coupled-cluster calculation for isolated molecules.

PCM-CCSD Analytical Gradients

The variational properties of the PCM-CC energy functional can be exploited to obtain analytical expressions of the energy derivative. For reasons of length, in this section, the exposition will be limited to the analytical first derivatives only. The interested reader may find the analytical second derivative expressions in Cammi (2009).

The differentiation with respect to a perturbational parameter α , of the stationary PCM-CC functional ΔG_{CC} , leads to an expression which avoids the first derivative of the T, Λ amplitudes. The first derivative $\partial \Delta G_{CC} / \partial \alpha = \Delta G_{CC}^\alpha$ can be expressed in the following form:

$$\begin{aligned} \Delta G_{CC}^\alpha = & \langle HF | (1 + \Lambda) | e^{-T} [H(0)_N^\alpha e^T | HF \rangle \\ & + \frac{1}{2} \langle HF | (1 + \Lambda) | e^{-T} \mathbf{Q}_N^\alpha e^T | HF \rangle \cdot \bar{\mathbf{V}}_N(\Lambda, T) \\ & + \frac{1}{2} \bar{\mathbf{Q}}_N(\Lambda, T) \cdot \langle HF | (1 + \Lambda) | e^{-T} \mathbf{V}_N^\alpha e^T | HF \rangle \end{aligned} \quad (35)$$

where the upperscript α of the various normal ordered operators denotes the total derivative of their second-quantization form.

The differentiated Hamiltonian $H(0)_N^\alpha$ in the second quantized form is given by

$$H(0)_N^\alpha = \sum_{pq} f_{pq}^{PCM,\alpha} \{p^\dagger q\} + \frac{1}{4} \sum_{pqrs} \langle pq || rs \rangle^\alpha \{p^\dagger q^\dagger sr\} \quad (36)$$

where $f_{p,q}^{PCM,\alpha}$ and $\langle pq || rs \rangle^\alpha$ denote, respectively, the total first derivatives of the PCM-Fock matrix elements and of the usual two-electron integrals, both in the MO basis.

The derivate matrix elements $f_{p,q}^{PCM,\alpha}$ may be written in terms of the derivatives of the constituting MO integrals

$$f_{pq}^{PCM,\alpha} = h_{pq}^\alpha + j_{pq}^\alpha + \sum_j^{occ} (\langle pj || qj \rangle^\alpha + \mathcal{B}_{jj,pq}^\alpha) \quad (37)$$

where the derivatives of the solvent integrals j_{pq}^α and $\mathcal{B}_{jj,pq}^\alpha$ are given by

$$j_{pq}^\alpha = \mathbf{v}_{pq}^\alpha \cdot \mathbf{q}_{Nuc} + \mathbf{v}_{pq} \cdot \mathbf{q}_{Nuc}^\alpha \quad (38)$$

$$\mathcal{B}_{pq,rs}^\alpha = \mathbf{v}_{\mu\nu}^\alpha \cdot \mathbf{q}_{rs} + \mathbf{v}_{\mu\nu} \cdot \mathbf{q}_{rs}^\alpha \quad (39)$$

where $\mathbf{q}_{p,q}^\alpha$, $\mathbf{v}_{p,q}^\alpha$ are, respectively, the differentiated apparent charge integrals and the differentiated electrostatic potential integrals (Cammi and Tomasi 1994).

The differentiated operators \mathbf{Q}_N^α and \mathbf{V}_N^α of Eq. (35) are given by:

$$\mathbf{Q}_N^\alpha = \sum_{pq} \mathbf{q}_{pq}^\alpha \{p^\dagger q\} \quad (40)$$

$$\mathbf{V}_N^\alpha = \sum_{pq} \mathbf{v}_{pq}^\alpha \{p^\dagger q\}. \quad (41)$$

Introducing Eqs. (36), (37), (38), (39), (40), and (41), the analytical gradients ΔG_{CC}^α can be written in the following explicit form:

$$\begin{aligned} \Delta G_{CC}^\alpha = & \sum_{ab} f_{ab}^{PCM,\alpha} \gamma_{ab}^{CC-\text{resp}} + \sum_{ij} f_{ij}^{PCM,\alpha} \gamma_{ij}^{CC-\text{resp}} \quad (42) \\ & + \sum_{ai} f_{ai}^{PCM,\alpha} \gamma_{ai}^{CC-\text{resp}} + \sum_{ia} f_{ia}^{PCM,\alpha} \gamma_{ia}^{CC-\text{resp}} \\ & + \frac{1}{2} \sum_{pqrs} \mathcal{B}_{pq,rs}^\alpha \gamma_{pq}^{CC-\text{resp}} \gamma_{rs}^{CC-\text{resp}} \\ & + \frac{1}{4} \sum_{pqrs} \langle pq || rs \rangle^\alpha \Gamma_{rspq} \end{aligned}$$

where Γ_{rspq} are elements of the effective two-particle density matrix Γ (Bartlett and Musiał 2007).

Equation (42) is the most general form of ΔG_{CC}^α from which we can obtain explicit computational expressions. To proceed further, as in the case of isolated molecules, we have to consider two alternative forms of the PCM-CCSD analytical derivatives: the so-called nonrelaxed MO form, which neglects the orbital relaxation effects, and the so-called relaxed MO form, which includes these effects (Gauss 1999). Which of the two forms must be used is a controversial issue in the CC property calculations of isolated molecules. The use of unrelaxed derivatives has been advocated by Koch and Jørgensen (1990) for the calculation of electrical properties. On the other, the use of the orbital relaxation effect is mandatory in all cases where perturbation-dependent basis functions are employed. For geometrical derivatives, only the MO-relaxed derivatives provide a correct description of the

potential energy surface. In the following subsection, we present the orbital relaxed form, the gradients ΔG_{CC}^α . The interested reader may find the corresponding formulation for the unrelaxed MO gradients in Cammi (2009).

PCM-CCSD Analytical Gradients with Relaxed MO

When the MO are allowed to relax under the perturbation, the occupied-virtual block of the derivative of the PCM-Fock matrix, $f_{a,i}^{PCM,\alpha}$, vanishes by virtue of the Brillouin's theorem. Therefore, the contribution to the gradients ΔG_{CC}^α of Eq. (42) due to the derivative PCM-Fock matrix consists only of an occupied-occupied and virtual-virtual blocks:

$$\begin{aligned} \Delta G_{CC}^\alpha &= \sum_{ab} f_{ab}^{PCM,\alpha} \gamma_{ab}^{CC-\text{resp}} + \sum_{ij} f_{ij}^{PCM,\alpha} \gamma_{ij}^{CC-\text{resp}} \\ &+ \frac{1}{2} \sum_{pqrs} (\mathbf{q}_{pq}^\alpha \cdot \mathbf{v}_{rs} + \mathbf{q}_{pq} \cdot \mathbf{v}_{rs}^\alpha) \gamma_{pq}^{CC-\text{resp}} \gamma_{rs}^{CC-\text{resp}} \\ &+ \frac{1}{4} \sum_{pqrs} \langle pq || rs \rangle^\alpha \Gamma_{rspq} \end{aligned} \quad (43)$$

For the evaluation of the PCM-CC gradient, the first derivatives of the PCM-Fock matrix and of the other one- and two-electron MO integrals are needed. These derivatives lead to terms involving the skeleton derivatives of the MO integrals, i.e., integrals which involve the derivative of the corresponding AO integrals and also lead to terms involving the derivative of the MO coefficients. Then, the gradients ΔG_{CC}^α may be written as:

$$\begin{aligned} \Delta G_{CC}^\alpha &= \sum_{ab} \gamma_{ab}^{CC-\text{resp}} f_{ab}^{PCM,[\alpha]} + \sum_{ij} \gamma_{ij}^{CC-\text{resp}} f_{ij}^{PCM,[\alpha]} \\ &+ \frac{1}{2} \sum_{rs} \gamma_{rs}^{CC-\text{resp}} \left[\mathbf{q}_{rs}^{[\alpha]} \cdot \bar{\mathbf{v}}_N + \bar{\mathbf{Q}}_N \cdot \mathbf{v}_{rs}^{[\alpha]} \right] \\ &+ \sum_{pqrs} \Gamma_{pq,rs} \langle pq || rs \rangle^{[\alpha]} + \sum_{pq} I'_{pq} U_{pq}^\alpha \end{aligned} \quad (44)$$

where the upperscript $[\alpha]$ denotes skeleton derivatives of the MO integrals; U_{mi}^a are the derivatives of the MO coefficients $c_{\mu p}$, in the MO basis; and I'_{pq} are auxiliary matrix elements whose expressions are given in Cammi (2009).

The explicit evaluation of the U_{mi}^a derivatives may be avoided by using the orthonormality constraints of the MO and by using the interchange (Z -vector) method of Handy and Schaefer properly extended to the PCM framework (Cammi et al. 1999).

The resulting PCM-CCSD gradients may be written as

$$\begin{aligned} \Delta G_{CC}^{\alpha} = & \sum_{ab} \gamma_{ab}^{CC-\text{resp}} f_{ab}^{PCM,[\alpha]} + \sum_{ij} \gamma_{ij}^{CC-\text{resp}} f_{ij}^{PCM,[\alpha]} + \sum_{ij} \gamma_{ai}^{MO-\text{resp}} f_{ai}^{PCM,[\alpha]} \\ & + \frac{1}{2} \sum_{rs} \gamma_{rs}^{CC-\text{resp}} \left[\mathbf{q}_{rs}^{[\alpha]} \cdot \bar{\mathbf{v}}_N + \bar{\mathbf{Q}}_N \cdot \mathbf{v}_{rs}^{[\alpha]} \right] + \sum_{pqrs} \Gamma_{pq,rs} < pq || rs >^{[\alpha]} \\ & + \sum_{ij} I'_{ij} S_{ij}^{[\alpha]} + \sum_{ab} I_{ab} S_{ab}^{[\alpha]} - 2 \sum_{ai} I'_{ia} S_{ai}^{[\alpha]} \end{aligned} \quad (45)$$

where the matrix elements $\gamma_{ai}^{MO-\text{resp}}$ are obtained as solution of the PCM-Z vector equation and $I'_{ia} = I_{ia} - \gamma_{ai}^{MO-\text{resp}} f_{ii}^{PCM}$ and I'_{ij} are given by

$$I'_{ij} = I_{ij} - \sum_{em} \gamma_{em}^{MO-\text{resp}} (< ei || mj > + < im || je > + 2B_{em,ij})$$

Finally, the expression of the PCM-CCSD gradients can be reverted from the MO to the AO representation, for an efficient computational implementation. The corresponding AO form is

$$\begin{aligned} \Delta G_{CC}^{\alpha} = & \sum_{\mu\nu} \gamma_{\mu\nu}^{CC-MO} (h_{\mu\nu}^{\alpha} + j_{\mu\nu}^{\alpha}) + \sum_{\mu\nu} I'_{\mu\nu} S_{\mu\nu}^{\alpha} \\ & + \sum_{\mu\nu\rho\sigma} \left(\gamma_{\mu\nu}^{CC-MO} P_{\sigma\rho}^{HF} + \frac{1}{2} \gamma_{\mu\nu}^{CC-\text{resp}} \gamma_{\sigma\rho}^{CC-\text{resp}} \right) B_{\mu\nu\sigma\rho}^{\alpha} \\ & + \sum_{\mu\nu\sigma\rho} \Gamma'_{\mu\nu,\sigma\rho} < \mu\sigma || \rho\sigma >^{\alpha} \end{aligned} \quad (46)$$

where $\Gamma'_{\mu\nu,\sigma\rho} = \Gamma_{\mu\nu,\sigma\rho} + \gamma_{\mu\nu}^{CC-MO} P_{\sigma\rho}^{HF}$.

Equation (46) refers to the PCM-CCSD analytical gradients within the PTDE scheme, as it contains terms involving coupled-cluster contribution to the solvent reaction field. By neglecting these contributions, we obtain the corresponding analytical gradients within the PTE-approximated scheme.

The Equation-of-Motion Coupled-Cluster Theory for the Polarizable Continuum Model

In the previous sections, we have shown the coupled-cluster theory to the description of the ground state properties of molecular solutes. In this section, we present the coupled-cluster theory for the description of the excited states of solvated molecules.

We have already anticipated that the polarizable continuum model supports two approaches for the description of the excited states of molecular solutes, a version

based on the CI approach (state-specific SS) and a version based on the response theory, and that these approaches have in condensed media problems not present in the corresponding calculations in vacuo.

Each approach has advantages and disadvantages. The LR approach is computationally more convenient, as it gives the whole spectrum of the excited states of interest in a single calculation, but is physically biased. In fact, in the LR approach, the solute-solvent interaction contains a term related to the one-particle transition densities of the solute connecting the reference state adopted in the LR calculation, which usually corresponds to the electronic ground state, to the excited electronic state. The SS approach is computationally more expensive, as it requires a separate calculation for each of excited states of interest, but is physically unbiased. In fact, in the SS approach, the solute-solvent interaction is determined by the effective one-particle electron density of the excited states.

An excited-state CC method for continuum solvation models has been developed by Mikkelsen and co-worker (1999), based on the LR approach. In this section, we present an excited-state CC state-specific (SS) method for the PCM. As already discussed in the Introduction, we will limit ourselves to a formulation of the excited-state PCM-CC to describe vertical absorption processes (the emission processes require a slightly different formulation) and in particular of absorption processes from the electronic ground state to a generic excited state. For this processes, we can give two versions: a first version in which the solvent is in equilibrium polarization with both states (state 0 and state K) and a second version in which the polarization of the K -th state is in nonequilibrium for the reasons discussed in the introduction. The formulation that we here report refers to the equilibrium formulation. For the nonequilibrium formulation, there are two versions: the formulation corresponding to the version II (Pekar) can be directly obtained from the equilibrium case by substituting the polarization charges of the solvent that appear in Eq. (52) for the equilibrium case, with those corresponding to the nonequilibrium case (Tomasi et al. 2005) and the version I of the nonequilibrium case requiring a slightly more elaborated formulation.

The Excited-State PCM-CC Wave Functions

In the excited-state PCM-CC approximation, the excited electronic states are represented by a linear (CI-like) expansion buildup on the coupled-cluster wave function for the ground state. The corresponding expansion coefficients are then determined by solving a nonlinear eigenvalue problem. The eigenvalue equations are determined by a variational procedure involving the PCM-CC free-energy functional.

The EOM-CC ket wave function (Nakatsuji and Hirao 1978; Stanton and Bartlett 1993) for the K -th state is defined as

$$|\Psi_K\rangle = \mathcal{R}_K e^T |HF\rangle \quad (47)$$

where $e^T|HF\rangle$ is the coupled-cluster state obtained by solving the PCM-PTE equation (see Eq. (23) in section “The PTDE and the PTE Coupled-Cluster Schemes”) and \mathcal{R}_K is a quasi-particle excitation operator

$$\begin{aligned}\mathcal{R}_K &= \mathcal{R}_{K,0} + \mathcal{R}_{K,1} + \mathcal{R}_{K,2} + \dots \\ \mathcal{R}_{K,n} &= \frac{1}{n!^2} \sum_{ijkl\dots abc\dots} r_{ijk\dots}^{abc\dots}(K) a_a^\dagger a_i a_b^\dagger a_j a_c^\dagger a_k \dots\end{aligned}\quad (48)$$

The corresponding EOM-CC bra wave function is given by

$$\langle \tilde{\Psi}_K | = \langle HF | \mathcal{L}_K e^{-T} \quad (49)$$

where \mathcal{L}_K is a de-excitation operator

$$\begin{aligned}\mathcal{L}_K &= \mathcal{L}_{K,0} + \mathcal{L}_{K,1} + \mathcal{L}_{K,2} + \dots \\ \mathcal{L}_{K,n} &= \frac{1}{n!^2} \sum_{ijkl\dots abc\dots} l_{ijk\dots}^{abc\dots}(K) a_i^\dagger a_a a_j^\dagger a_b a_k^\dagger a_c \dots\end{aligned}\quad (50)$$

The set ket and bra wave functions \mathcal{L}_K and \mathcal{R}_K satisfy the property of bi-orthogonality many-body systems

$$\langle \tilde{\Psi}_K | \Psi_L \rangle = \langle \mathcal{L}_K | \mathcal{R}_L \rangle = \delta_{KL} \quad (51)$$

The variational PCM-EOM-CC free-energy functional for the state of interest, ΔG_K^{EOM} , may be written as

$$\begin{aligned}\Delta G_K^{EOM} &= \langle HF | \mathcal{L}_K e^{-T} H_N(0) e^T \mathcal{R}_K | HF \rangle / \langle \mathcal{L}_K | \mathcal{R}_K \rangle \\ &+ \frac{1}{2} \bar{\mathbf{Q}}_K^{EOM} \cdot \bar{\mathbf{V}}_K^{EOM} \\ &+ \langle HF | \mathcal{Z} e^{-T} H_N(0) \exp(T) | HF \rangle\end{aligned}\quad (52)$$

Here the first term on the right side represents the EOM-CC energy of the state on interest in presence of the fixed HF reaction potential, while the second term $\bar{\mathbf{Q}}_K^{EOM} \cdot \bar{\mathbf{V}}_K^{EOM}$ is the EOM-CC solute-solvent interaction contribution. Specifically, $\bar{\mathbf{Q}}_K^{EOM}$ and $\bar{\mathbf{V}}_K^{EOM}$ are the EOM-CC expectation value, respectively, of the polarization charges and of the electrostatic potential for the K -th state:

$$\begin{aligned}\bar{\mathbf{Q}}_K^{EOM} &= \langle HF | \mathcal{L}_K e^{-T} \hat{\mathbf{V}}_N e^T \mathcal{R}_K | HF \rangle / \langle \mathcal{L}_K | \mathcal{R}_K \rangle \\ \bar{\mathbf{V}}_K^{EOM} &= \langle HF | \mathcal{L}_K e^{-T} \hat{\mathbf{Q}}_N e^T \mathcal{R}_K | HF \rangle / \langle \mathcal{L}_K | \mathcal{R}_K \rangle\end{aligned}$$

The last term of ΔG_K^{EOM} in Eq. (52) introduces the constraint for the ground state coupled-cluster wave function and contains the de-excitation operator \mathcal{Z} given by

$$\mathcal{Z} = \mathcal{Z}_1 + \mathcal{Z}_2 + \dots \quad (53)$$

$$\mathcal{Z}_n = \frac{1}{n!^2} \sum_{ijkl\dots abc\dots} \xi_{ijk\dots}^{abc\dots} a_i^\dagger a_a a_j^\dagger a_b a_k^\dagger a_c \dots$$

The presence of the coupled-cluster constraint term is only relevant for the evaluation of analytical gradient of the PCM-EOM-CC energy functional.

The PCM-EOM-CC Eigenvalue Equations

Imposing that ΔG_{PCM}^{EOM} be stationary with respect to the \mathcal{R}_K and \mathcal{L}_K amplitudes, we obtain a right-hand and a left-hand eigenvalue equation:

$$\mathcal{H}_K^{EOM} \mathcal{R}_K |HF\rangle = \Delta E_K^{EOM} \mathcal{R}_K |HF\rangle \quad (54)$$

$$\langle HF | \mathcal{L}_K \Delta E_K^{EOM} = \langle HF | \mathcal{L}_K \mathcal{H}_K^{EOM} \quad (55)$$

where \mathcal{H}_K^{EOM} is the similarity-transformed state-specific PCM-EOM-CC Hamiltonian:

$$\mathcal{H}_K^{EOM} = e^{-T} H_N^{EOM}(K) e^T = H_N^{EOM}(K) \quad (56)$$

with

$$H_N^{EOM}(K) = H_N(0) + \bar{\mathbf{Q}}_K^{EOM} \cdot \mathbf{V}_N \quad (57)$$

where the first term of state-specific Hamiltonian describes the solute in presence of the fixed HF polarization charges, while the second term, $\bar{\mathbf{Q}}_K^{EOM} \cdot \mathbf{V}_N$, represents the interaction of the solute with the polarization charges produced by the solute in the excited-state K -th.

The left and right eigenvalues and the EOM-CC energy can be obtained from the matrix representing the non-Hermitian Hamiltonian \mathcal{H}_K^{EOM} in a suitable functional space. We limit ourselves to consider the case of the functional space associated to the coupled-cluster reference function at the CCSD level.

The EOM-CCSD and the electronic states are associated with the diagonal representation of \mathcal{H}_K^{EOM} in the subspace $|\mathbf{p}\rangle$, spanned by the $|HF\rangle$ determinant and by its single $|i^a\rangle$ and double $|ij^{ab}\rangle$ excited determinants (i.e., $|\mathbf{p}\rangle = |HF\rangle \oplus |i^a\rangle \oplus |ij^{ab}\rangle$). Equations (54) and (55) can be converted to a non-Hermitian CI-like eigenvalue problem

$$\mathbf{H}_K^{\bar{EOM}} \mathbf{R}_K = \Delta E_K^{EOM} \mathbf{R}_K \quad (58)$$

$$\mathbf{L}_L \mathbf{H}_K^{\bar{EOM}} = \mathbf{L}_K \Delta E_K^{EOM} \quad (59)$$

where \mathbf{R}_k and \mathbf{L}_k represent the vectors of coefficients for the chosen excited state and \mathbf{H}_K^{EOM} is the PCM-EOM matrix Hamiltonian. The elements of matrix \mathbf{H}_K^{EOM} can be evaluated by standard methods. Details are given elsewhere (Cammi et al. 2010; Cammi 2010).

The manifold of the eigenvectors of matrix \mathbf{H}_K^{EOM} can be determined using a non-Hermitian modification of Davidson's method (Hirao and Nakatsuji 1982). From this manifold, we can extract the \mathbf{R}_K and \mathbf{L}_K eigenvectors and the corresponding eigenvalue ΔE_K^{EOM} . The remaining eigenvectors of the manifold are not of interest for the topics treated in this chapter.

Finally, the free-energy functional value for the state of interest may be obtained in terms of the EOM-CC eigenvalue ΔE_K^{EOM} as

$$\Delta G_K^{EOM} = \Delta E_K^{EOM} - \frac{1}{2} \mathbf{v}_K^{EOM} \cdot \mathbf{Q}_K^{EOM} \quad (60)$$

We have so completed the first step of the PCM-EOM-CC procedure, leading to the complete determination of the EOM-CC eigenfunctions and free energy for the target state K . We note that in this first step we have only exploited the stationarity condition of ΔG_K^{EOM} with respect to the left and right eigenvectors. As already said, the stationary conditions on the \mathcal{Z} and T amplitude are not necessary at this stage, but they are instead necessary to obtain analytical derivatives of the ΔG_K^{EOM} functional.

PCM-EOM-CCSD Analytical Gradients

Analytical first derivative of the free-energy PCM-EOM functional ΔG^{EOM} may be easily obtained by introducing the stationarity with respect to the \mathcal{Z} and the T amplitudes. This avoids the evaluation of the first derivative of these parameters with respect to the external perturbations.

The PCM-EOM-CCSD Equations for the \mathcal{Z} Amplitudes

The stationary condition for the \mathcal{Z} amplitudes leads to the PTE coupled-cluster equations for the reference ground state, which are assumed to be satisfied (see Eq. (23)); the stationary condition for the T amplitudes gives in turn the equations for the \mathcal{Z} amplitudes.

The derivative of ΔG^{EOM} with respect to the T amplitudes may be written as

$$\begin{aligned} \frac{\partial \Delta G_K^{EOM}}{\partial t_\tau} = & \langle HF | \mathcal{L} [\mathcal{H}_K^{EOM}, \hat{t}] \mathcal{R} | HF \rangle \\ & + \langle HF | \mathcal{Z} [\mathcal{H}(0), \hat{t}] | HF \rangle = 0 \end{aligned} \quad (61)$$

where $\hat{\tau}$ is the excitation operator associated to the amplitude coefficient t_τ , \mathcal{H}_K^{EOM} is the similarity-transformed EOM Hamiltonian, and $\mathcal{H}(0)$ is the PTE similarity-transformed Hamiltonian of Eq. (25); the square brackets denote a commutator operator.

Equation (61) can be rewritten as an explicit linear system of equation for the \mathcal{Z} amplitudes:

$$\frac{\partial \Delta G_{PCM}^{EOM}}{\partial t_\tau} = \langle HF | \mathcal{Z} | \mathbf{g} \rangle \langle \mathbf{g} | \bar{\mathcal{H}}(0) | \mathbf{g} \rangle - \langle HF | \Xi | \mathbf{g} \rangle = 0 \quad (62)$$

or

$$\langle HF | \mathcal{Z} | \mathbf{g} \rangle = - \langle HF | \Xi | \mathbf{g} \rangle \langle \mathbf{g} | \bar{\bar{H}}(0) | \mathbf{g} \rangle^{-1} \quad (63)$$

where $|\mathbf{g}\rangle$ denotes the subspace of the single and double excited Slater determinants, $|\mathbf{g}\rangle = |i^a\rangle \oplus |ij^{ab}\rangle$, $\bar{\bar{H}}(0)$ is defined as $\bar{\bar{H}}(0) = \mathcal{H}(0) - \langle 0 | \bar{H}(0) | 0 \rangle$, and Ξ denotes the de-excitation operator

$$\Xi = \Xi_{11} + \Xi_2 + \dots \quad (64)$$

$$\Xi_n = \frac{1}{n!2} \sum_{ijkl\dots abc\dots} \xi_{ijk\dots}^{abc\dots} a_i^\dagger a_a a_j^\dagger a_b a_k^\dagger a_c \dots \quad (65)$$

whose amplitudes Ξ_n are given as matrix elements of the operator $\mathcal{R}\mathcal{H}_K^{EOM} | \mathbf{q} \rangle \langle \mathbf{q} | \mathcal{R}$ between $\langle HF |$ and $|\mathbf{g}\rangle = |i^a\rangle \oplus |ij^{ab}\rangle$

$$\langle HF | \Xi | \mathbf{g} \rangle = \langle HF | \mathcal{R}\mathcal{H}_K^{EOM} | \mathbf{q} \rangle \langle \mathbf{q} | \mathcal{R} | \mathbf{g} \rangle \quad (66)$$

The explicit equation of the amplitudes ξ_n contains explicit PCM contributions which are given elsewhere (Cammi et al. 2010; Cammi 2010).

The Analytical Gradients of the PCM-EOM-CCSD Free-Energy Functional ΔG_K^{EOM}

The derivatives of free-energy functional ΔG_K^{EOM} may then written as

$$\begin{aligned} \frac{\partial \Delta G_K^{EOM}}{\partial \alpha} &= \langle HF | (\mathcal{L}_K + \mathcal{Z}) e^{-T} H_N(0) e^T \mathcal{R}_K | HF \rangle \\ &+ \frac{1}{2} \langle HF | \mathcal{L}_K e^{-T} \mathbf{V}_N^\alpha e^T \mathcal{R}_K | HF \rangle \cdot \mathbf{Q}_K^{EOM} \\ &+ \frac{1}{2} \langle HF | \mathcal{L}_K e^{-T} \mathbf{Q}_N^\alpha e^T \mathcal{R}_K | HF \rangle \cdot \mathbf{V}_K^{EOM} \end{aligned} \quad (67)$$

This expression can be recasted in a form that involves contractions between effective one- and two-particle EOM-CCSD density matrices and differentiated one- and two-electron MO integrals as

$$\begin{aligned} \frac{\partial \Delta G_K^{EOM}}{\partial \alpha} &= \sum_{pq} f_{pq}^{PCM,\alpha} \gamma_{pq}^{EOM}(K) \\ &+ \frac{1}{2} \sum_{pqrs} \mathcal{B}_{pq,rs}^\alpha \gamma_{pq}^{EOM-NR} \gamma_{rs}^{EOM-NR}(K) \\ &+ \frac{1}{4} \sum_{pqrs} \langle pq || rs \rangle^\alpha \Gamma_{EOM}(K) \end{aligned} \quad (68)$$

where the Einstein summation convention is followed. The density matrices, γ^{EOM-NR} , γ^{EOM} , and Γ^{EOM} , are defined by Stanton (1993):

$$\begin{aligned} \gamma_{pq}^{EOM-NR}(K) &= \langle HF | \mathcal{L}[p^\dagger q \exp(T)]_c \mathcal{R} | HF \rangle \\ \gamma_{pq}^{EOM}(K) &= \gamma^{EOM-NR} + \langle HF | \mathcal{Z}[p^\dagger q \exp(T)]_c | HF \rangle \\ \Gamma_{pqrs}^{EOM}(K) &= \langle HF | \mathcal{L}[p^\dagger q^\dagger s r e^T]_c \mathcal{R} | HF \rangle + \langle HF | \mathcal{Z}[p^\dagger q^\dagger s r e^T]_c | HF \rangle \end{aligned}$$

where the subscript c denotes a limitation to connected diagrams. The effective density γ^{EOM-NR} is the usual reduced one-particle density (expectation value of $p^\dagger q$), while the effective density matrices γ^{EOM} and Γ^{EOM} contain also correction terms that involve the ξ amplitude to account for the response of T to the perturbation.

The PCM-EOM-CCSD analytical gradients (52) have the same form of PCM-CCSD analytical gradients (42). Then, following the same procedure described for the PCM-CCSD gradients, it is easy to show that the differentiation of the MO integrals in Eq. (52) leads to terms involving the derivatives of the MO coefficients. In turn, the perturbative MO coefficients can be avoided using exploiting the PCM Z-vector technique (Cammi et al. 1999) to obtain a perturbation-independent one-particle $\gamma_{\mu\nu}^{MO-resp}$. The corresponding expression of the PCM-EOM analytical gradients in the AO basis is given by

$$\begin{aligned} \frac{\partial \Delta G_K^{EOM}}{\partial \alpha} &= \sum_{\mu\nu} \gamma_{\mu\nu}^{EOM-MO}(K) \left(h_{\mu\nu}^\alpha + j_{\mu\nu}^\alpha \right) + \sum_{\mu\nu} I'_{\mu\nu} S_{\mu\nu}^\alpha \\ &+ \sum_{\mu\nu\rho\sigma} \left(\gamma_{\mu\nu}^{EOM-MO} P_{\sigma\rho}^{HF} + \frac{1}{2} \gamma_{\mu\nu}^{EOM-NR} \gamma_{\sigma\rho}^{EOM-NR} \right) \mathcal{B}_{\mu\nu,\sigma\rho}^\alpha \\ &+ \sum_{\mu\nu\sigma\rho} \Gamma'_{\mu\nu,\sigma\rho} \langle \mu\sigma || \rho\sigma \rangle^\alpha \end{aligned} \quad (69)$$

where the additional one-particle density matrix $\gamma_{\mu\nu}^{EOM-MO}$ is defined as $\gamma_{\mu\nu}^{EOM-MO} = \gamma_{\mu\nu}^{EOM} + \gamma_{\mu\nu}^{MO-resp}$.

The equation of the PCM-EOM-CC analytical gradients contains additional one-electron MO derivative integrals with respect to the corresponding gradients for isolated molecules (Stanton 1993). As these solvation terms can be evaluated with a small effort, the PCM-EOM-CC analytical gradients can be performed for all the molecular systems for which are feasible the EOM-CCSD gradient calculations in gas phase.

The Response Functions Theory for Molecular Solutes

The response functions theory for molecules in the PCM solvation method (Cammi 2013) is an extension of the response theory for isolated molecules (Olsen and Jørgensen 1995; Helgaker et al. 2012), including this latter as a limit case. The extension from isolated to solvated molecules involves new aspects not present in the first case. These aspects are mainly related to the coupling between the interactions of the molecular solute both with the medium (i.e., the solvent) and with an external field which is in general time-dependent. A first aspect concerns the nonlinearity in the time-dependent QM problem. More specifically, the time-dependent QM problem requires a proper extension of the time-dependent QM variation principle. A second aspect regards the time dependence in the solute-solvent responsive interaction, which must be described in a nonequilibrium solvation scheme (Marcus 1956). Finally, a third aspect regards the problem of the connection of the response functions of the molecular solutes with the corresponding macroscopic counterparts (i.e., the macroscopic susceptibilities) measured in the experiments.¹ For reasons of available space, in the following, we will focus on the first two of these aspects (nonlinearity and nonequilibrium), while for the third aspect (macroscopic susceptibilities), we refer the interested reader to Cammi et al. (2000a) and Cammi and Mennucci (2007).

The Variational Time-Dependent Theory for the Polarizable Continuum Model

Let us consider the time-dependent Schrödinger equation for a molecular solute

$$i \frac{\partial}{\partial t} |\bar{\Psi}(t)\rangle = H |\bar{\Psi}(t)\rangle \quad (70)$$

¹The problem, historically known as *local field problem*, is due to the fact that the molecular solutes are locally subjected to perturbing fields which are different to that measured by the experimenter.

where H is the effective time-dependent Hamiltonian

$$H = H^0 + \bar{\mathbf{Q}}(\Psi; t) \cdot \mathbf{V} + V'(t) \quad (71)$$

where H^0 is the Hamiltonian of the isolated molecule, $\bar{\mathbf{Q}}(\Psi; t) \cdot \mathbf{V}$ is the potential energy term representing the solute-solvent electrostatic interaction, and $V'(t)$ is a general time-dependent external perturbation (We assume that $V'(t)$ is applied adiabatically so that it vanishes at $t = -\infty$).

In Eq. (71), $\mathbf{Q}(\Psi; t)$ represents the polarization charges induced by the solute on the boundary of the cavity hosting the solute itself within the dielectric medium representing the solvent, the dot represents a vectorial inner product, and \hat{V} is a vectorial operator representing the electrostatic potential of the solute at the boundary cavity. The solvent polarization charges collected in $\mathbf{Q}(\Psi; t)$ depend parametrically on time, as they are determined by the first-order density matrix $\Psi^*(t)\Psi(t)$ of the molecular solute; the most general form of $\bar{\mathbf{Q}}(\Psi; t)$ must take into account the nonequilibrium solvation effects related to the intrinsic dynamics of solvent polarization.

In the presence of a general time-dependent perturbation $V'(t)$, the time-dependent polarization charges $\mathbf{Q}(\Psi; t)$ may be formally defined as:

$$\bar{\mathbf{Q}}(\Psi; t) = \int_{-\infty}^t \langle \Psi(t') | \mathbf{Q}(t - t') | \Psi(t') \rangle dt' \quad (72)$$

where $\mathbf{Q}(t - t')$ is an apparent charge operator nonlocal in time, describing a general nonequilibrium solvation regime. In a nonequilibrium solvation regime, the description of polarization of the medium cannot be given in terms of a single value of the dielectric permittivity of the medium (as in the case of the equilibrium solvation), but it requires in principle knowledge of the whole spectrum of the frequency-dependent dielectric permittivity $\epsilon(\omega)$ (Marcus 1956).²

A convenient approach to face both the nonlinear QM problem (70) and the nonequilibrium solvation problem (72) is given by the time-dependent quasi-free-energy formalism.

The Time-Dependent Quasi-Free-Energy and Its Variational Principle

It has been shown (Cammi and Tomasi 1996) that the time-dependent nonlinear Schrödinger (70) can be obtained from the Hamilton principle when a suitable QM Lagrangian density is defined and that this Lagrangian density implies an extension of the time-dependent Frenkel's variational principle (Frenkel 1934) to time-dependent nonlinear Hamiltonians (70).

²When the external perturbation $V(t')$ is limited to static components ($\omega = 0$) and to components in the field of the optical frequencies, the description of the nonequilibrium polarization of the medium can be given in terms of a two-valued dielectric permittivity, ϵ_0 and ϵ_∞ corresponding, respectively, to the static dielectric permittivity and to the dielectric permittivity at optical frequencies.

Let us consider the time-dependent wave function $\bar{\Psi}(t) >$ expressed in the phase-isolated form

$$|\bar{\Psi}(t) > = e^{-iF(t)}|\Psi(t) > \quad (73)$$

where $F(t)$ is a function of time and $\Psi(t)$ is the so-called regular wave function, which depends only parametrically on time and which reduces in the unperturbed limit (i.e., $t = -\infty$) to the time-independent wave function describing a stationary state of the molecular solute.

The phase $F(t)$ of Eq. (73) is determined by substitution into Eq. (70):

$$\dot{F}(t) = \langle \Psi(t) | H - i \frac{\partial}{\partial t} | \Psi(t) \rangle$$

while the regular wave function $\Psi(t)$ satisfies a generalized time-dependent Frenkel variational principles (Frenkel 1934):

$$\delta \mathcal{G}(t) + i \frac{\partial}{\partial t} \langle \Psi | \delta \Psi \rangle = 0 \quad (74)$$

where $\mathcal{G}(t)$ is the time-dependent quasi-free-energy functional

$$\mathcal{G}(t) = \langle \Psi(t) | H^o + \frac{1}{2} \bar{\mathbf{Q}}(\Psi; t) \cdot \mathbf{V} - i \frac{\partial}{\partial t} | \Psi(t) \rangle \quad (75)$$

Let us now consider the case of a periodic time-dependent perturbation:

$$V(t + T; \epsilon) = V(t; \epsilon) \quad (76)$$

with period T , frequency $\omega = \frac{2\pi}{T}$, and perturbation strength ϵ . In this case, the phase-isolated form of the wave function acquires the same periodicity T :

$$|\Psi(t + T) > = |\Psi(t) > . \quad (77)$$

and by a time integration over the characteristic period T ³, the variational condition (74) for the regular wave function (77) reduces to:

$$\delta \{ \mathcal{G}(t) \}_T = \delta \{ \langle \Psi(t) | H^o + \frac{1}{2} \bar{\mathbf{Q}}(\Psi; t) \cdot \mathbf{V} - i \frac{\partial}{\partial t} | \Psi(t) \rangle \}_T = 0 \quad (78)$$

being $\{ \mathcal{G}(t) \}_T$ time-averaged quasi-free-energy functional:

$$\{ \mathcal{G}(t) \}_T = \frac{1}{T} \int_{-T/2}^{T/2} \langle \Psi(t) | H^o + \frac{1}{2} \bar{\mathbf{Q}}(\Psi; t) \cdot \mathbf{V} - i \frac{\partial}{\partial t} | \Psi(t) \rangle dt \quad (79)$$

³The time-average over a period T for a general time-dependent function $g(t)$ is defined as $\{g(t)\}_T = \frac{1}{T} \int_{-T/2}^{T/2} g(t) dt$.

The time-averaged quasi-free-energy $\{\mathcal{G}(t)\}_T$ (79) satisfies a generalization of the time-dependent Hellmann-Feynman theorem. Specifically, if the Hamiltonian (71) contains an external perturbation $\epsilon V(\omega)$ with amplitude ϵ and periodicity $T = 2\pi/\omega$, we have:

$$\begin{aligned} \frac{d\{\mathcal{G}(t)\}_T}{d\epsilon} &= \left\{ \langle \Psi(t) | \frac{\partial H}{\partial \epsilon} | \Psi(t) \rangle \right\}_T \\ &= \left\{ \langle \Psi(t) | V(\omega) | \Psi(t) \rangle \right\}_T \end{aligned} \quad (80)$$

where $\langle \Psi(t) | V(\omega) | \Psi(t) \rangle$ corresponds to the time-dependent expectation value of observable associated with the perturbing operator $V(\omega)$ and the time-average $\{\dots\}_T$ is related to its Fourier components having frequency ω_X .

The time-dependent stationary conditions (78) and the corresponding Hellmann-Feynman theorem (80) are the basic equations for the determination of the response functions of the molecular solutes in the presence of periodic external perturbations.

The Response Functions of Molecular Solutes

The molecular response functions of molecular solutes are defined in relation to a general time-dependent perturbation $V'(t)$ with several components (L) each having multiple harmonic frequencies (K_i):

$$V'(t) = \sum_{i=1}^L \sum_{j=-K_i}^{K_i} e^{-i\omega_j t} \epsilon_{X_i}(\omega_j) X_i \quad (81)$$

where X_i is the i -th perturbation operator, having amplitude $\epsilon_{X_i}(\omega_i)$ in correspondence to the frequency ω_i .

The response functions are defined as the coefficients of a Fourier-perturbation expansion of the time-dependent expectation values of a generic observable Y of the molecular system with respect to the perturbation $V(t)$ (Olsen and Jørgensen 1995):

$$\begin{aligned} \langle \Psi(t) | Y | \Psi(t) \rangle &= \langle Y \rangle_0 + \sum_{i,j}^{L,K_i} e^{-i\omega_j t} \langle \langle Y; X_i \rangle \rangle_{\omega_j} \epsilon_{X_i}(\omega_j) + \\ &+ \frac{1}{2} \sum_{i,j,k,l}^{L,M,K_i,K_j} e^{-i(\omega_k + \omega_l)t} \langle \langle Y; X_i, X_j \rangle \rangle_{\omega_k + \omega_l} \epsilon_{X_i}(\omega_k) \epsilon_{X_j}(\omega_l) + \dots \end{aligned} \quad (82)$$

where $\langle \langle Y; X_i \rangle \rangle_{\omega_{X_i}}$ represents the linear response function describing the contribution of $Y(t)$ of first order in the perturbation X_i having frequency ω_{X_i} and $\langle \langle Y; X_i, X_j \rangle \rangle_{\omega_{X_i} + \omega_{X_j}}$ denotes the quadratic response function describing the contribution of $Y(t)$ quadratic in the perturbations X_i, X_j with frequencies $\omega_{X_i}, \omega_{X_j}$ and in a similar way are defined the higher-order response functions $\langle \langle Y; X_i, X_j, X_k, \dots \rangle \rangle_{\omega_{X_i} + \omega_{X_j} + \omega_{X_k} \dots}$ (see Table 1).

Table 1 Selected response functions $\langle\langle X; Y, Z, \dots \rangle\rangle_{\omega_Y, \omega_Z, \dots}$ of molecular solutes. The operators are μ_α , Cartesian components of the electric dipole operator, $\Theta_{\alpha, \beta}$, element of the electric quadrupolar tensor, m_α Cartesian component of the magnetic dipole operator

Response function	Property
$\langle\langle \mu_\alpha; \mu_\beta \rangle\rangle_\omega$ (Cammi et al. 1996)	Dipole polarizability $\alpha_{\alpha, \beta}(-\omega; \omega)$
$i \langle\langle m_\alpha; \mu_\beta \rangle\rangle_\omega$ (Mennucci et al. 2002; Caricato 2013b)	Optical rotation tensor $G_{\alpha, \beta}^i(\omega)$
$\langle\langle \mu_\alpha; \Theta_\beta \rangle\rangle_\omega$ (Rizzo et al. 2007)	Quadrupolar polarizability tensor $\alpha_{\alpha, \beta}(-\omega; \omega)$
$\langle\langle \mu_\alpha; \mu_\beta, \mu_\gamma \rangle\rangle_\omega$ (Cammi et al. 1996)	First polarizability $\beta_{\alpha, \beta, \gamma}(-\omega_\alpha; \omega_\beta, \omega_\gamma)$
$\langle\langle \mu_\alpha; \mu_\beta, \mu_\gamma, \mu_\delta \rangle\rangle_{\omega_\alpha, \omega_\beta, \omega_\delta}$ (Cammi et al. 1996)	Second polarizability $\beta_{\alpha, \beta, \gamma}(-\omega_\alpha; \omega_\beta, \omega_\gamma)$
$-\langle\langle \mu_\alpha; \mu_\beta, m_\gamma, m_\delta \rangle\rangle_{\omega, 0, 0}$	
$+\langle\langle \mu_\alpha; \mu_\beta, m_\gamma, m_\delta \rangle\rangle_{\omega, 0, 0}$ (Cappelli et al. 2003)	Frequency dependent mixed electric magnetic hyper-magnetizability $\eta_{\alpha, \beta, \gamma, \delta}(-\omega; \omega, 0, 0)$

The molecular response functions (82) may be determined by means of the Hellmann-Feynman theorem (80) when the time-averaged free-energy functional (79) is expanded in orders of the perturbation $V'(t)$ and the variational condition (78) is satisfied at the various order.

The response function theory for molecular solutes within PCM has been developed for linear and nonlinear response functions and at several QM levels, including the variational wave function methods (SCF, MCSCF) and the density functional theory (Cammi et al. 1996; Cammi and Mennucci 1999; Tomasi et al. 1999; Cammi et al. 2000b; Cossi and Barone 2001; Mennucci et al. 2002; Cammi et al. 2003; Cappelli et al. 2003, 2005; Frediani et al. 2005; Jansik et al. 2006; Rizzo et al. 2007; Zhao et al. 2007; Ferrighi et al. 2007; Lin et al. 2008) and more recently at the coupled-cluster level (Cammi 2012a, b; Caricato 2013b). In the following, we will present the general aspects of the theory and its specific formulation at the coupled-cluster level.

The Coupled-Cluster Response Functions

The time-dependent coupled-cluster wave function may be expressed as (Christiansen et al. 1998)

$$|CC(t)\rangle = e^{-iF(t)} e^{T(t)} |HF\rangle \quad (83)$$

where the reference state $|HF\rangle$ is the fixed, time-independent Hartree-Fock ground state of the solvated molecules⁴, the phase factor $F(t)$ is a function of time, and $T(t)$ is the time-dependent cluster excitation operator.

⁴(here, we consider the molecular orbital (MO) *unrelaxed* approach in which the reference state does not depend on the perturbation $V'(t)$ (Christiansen et al. 1998))

The coupled-cluster phase factor $F(t)$ is determined as:

$$\dot{F}(t) = \langle HF | (1 + \Lambda) e^{-T} \left(H(0)_N + \bar{\mathbf{Q}}_N(t) \cdot \mathbf{V}_N + V(t) - i \frac{\partial}{\partial t} \right) e^T | HF \rangle$$

Here $\Lambda(t)$ is the time-dependent coupled-cluster de-excitation operator, and $\bar{\mathbf{Q}}_N(t)$ is the vector collecting the time-dependent apparent charges:

$$\bar{\mathbf{Q}}_N(t) = \int_{-\infty}^t \langle HF | (1 + \Lambda(t')) e^{-T(t')} \mathbf{Q}_N(t, t') e^{T(t')} | HF \rangle dt' \quad (84)$$

where $\mathbf{Q}_N(t, t')$ is an apparent charge operator nonlocal with respect to the time (see Eq. (72) and Λ is a time-dependent de-excitation operator.

The time-dependent coupled-cluster $T(t)$ and $\Lambda(t)$ amplitudes are determined using the quasi-free-energy functional

$$\begin{aligned} \{\Delta G_{CC}(t)\}_T = & \frac{1}{T} \int_{-T/2}^{T/2} \langle HF | (1 + \Lambda(t)) e^{-T(t)} [H(0)_N \\ & + \frac{1}{2} \bar{\mathbf{Q}}_N(t) \cdot \mathbf{V}_N + V(t) - i \frac{\partial}{\partial t}] e^T(t) | HF \rangle dt \quad (85) \end{aligned}$$

(where the time integration is over a common multiple of periods, T , such that $V(t + T) = V(t)$ Christiansen et al. 1998), with the variational condition

$$\delta\{\Delta G_{CC}(t)\}_T = 0 \quad (86)$$

The variational Eq. (86) is solved using an additional perturbative approximation in which the coupled-cluster T and Λ amplitudes are expanded with respect to the components of the perturbation $V'(t)$:

$$T(t) = T^{(0)} + T^{(1)} + T^{(2)} \dots \quad (87a)$$

$$\Lambda(t) = \Lambda^{(0)} + \Lambda^{(1)} + \Lambda^{(2)} \dots \quad (87b)$$

with:

$$T^{(1)} = \sum_i \exp(-i\omega_i t) \sum_x \epsilon_X(\omega_i) T^X(\omega_i) \quad (88a)$$

$$T^{(1)} = \frac{1}{2} \sum_{i,j} \exp(-i(\omega_i + \omega_j)t) \sum_{X,Y} \epsilon_X(\omega_i) \epsilon_Y(\omega_j) T^{XY}(\omega_i, \omega_j) \dots$$

$$\Lambda^{(1)} = \Lambda^{(0)} + \sum_i \exp(-i\omega_i t) \sum_x \epsilon_X(\omega_i) \Lambda^X(\omega_i) \quad (88b)$$

$$\Lambda^{(2)} = \frac{1}{2} \sum_{i,j} \exp(-i(\omega_i + \omega_j)t) \sum_{X,Y} \epsilon_X(\omega_i) \epsilon_Y(\omega_j) \Lambda^{XY}(\omega_i, \omega_j) \dots$$

The expansions (88a), (88b) lead to an expansion of the time-averaged of the quasi-free-energy functional (85):

$$\{\Delta G(t)_{CC}\}_T = \{\Delta G_{CC}^{(0)}\}_T + \{\Delta G_{CC}^{(1)}\}_T + \{\Delta G_{CC}^{(2)}\}_T + \dots \quad (89)$$

where the n -th order term $\{\Delta G_{CC}^{(n)}\}_T$ is defined as

$$\{\Delta G_{CC}^{(n)}\}_T = \frac{1}{n!} \sum_{i,j,\dots} \sum_{x,y,z} \epsilon_X(\omega_i) \epsilon_Y(\omega_j) \dots \times G^{XY\dots}(\omega_i, \omega_j, \dots) \quad (90)$$

where the Fourier components $G^{XY\dots}(\omega_i, \omega_j, \dots)$ are defined as

$$G^{XY\dots}(\omega_i, \omega_j, \dots) = \frac{d^n \{\Delta G^{(n)}\}_T}{d\epsilon_i d\epsilon_j \dots} \quad (91)$$

with $\omega_i + \omega_j + \dots = 0$.

The perturbation expansion of Eq. (89) is then introduced into the time-average variational criterion (86), and separating by orders, we arrive to a set of variational criteria on the Fourier components $G^{XY\dots}(\omega_i, \omega_j, \dots)$

$$\delta G^{XY\dots}(\omega_i, \omega_j, \dots) = 0 \quad (92)$$

that determine the Fourier coefficients $T^{XY\dots}(\omega_i, \omega_j, \dots)$ and $\Lambda^{XY\dots}(\omega_i, \omega_j, \dots)$ for the T and Λ amplitudes (88a) and (88b).

When the variational conditions (92) are satisfied, to the Fourier components $\tilde{G}^{XY\dots}(\omega_i, \omega_j, \dots)$ correspond to the response functions of the molecular solutes:

$$\begin{aligned} \langle\langle X; Y \rangle\rangle_{\omega_i} &= \tilde{G}^{XY}(\omega_i, \omega_j) \\ \langle\langle X; Y, Z \rangle\rangle_{\omega_i} &= \tilde{G}^{XYZ}(\omega_i, \omega_j, \omega_k) \\ \vdots &= \vdots \\ \langle\langle X; Y, Z, \dots \rangle\rangle_{\omega_i} &= \tilde{G}^{XYZ\dots}(\omega_i, \omega_j, \dots) \end{aligned} \quad (93)$$

where the tilde denotes stationarity. The response functions (93) satisfy a generalized $(2n + 1)$ rule with respect to the perturbed T and Λ amplitudes.

In the following subsection, we give a detailed account of the explicit form of the coupled-cluster response equations from which the linear and quadratic response functions can be obtained.

Coupled-Cluster Response Equations

The first-order equations for the coupled-cluster Fourier amplitudes $\Lambda^X(\pm\omega)$ $T^X(\pm\omega)$ are determined from the stationarity of the second-order time-averaged quasi-free-energy $G^{XY}(-\omega, \omega)$:

$$\begin{aligned}
G^{XY}(-\omega, \omega) = & P(XY) \langle HF | (1 + \Lambda) e^{-T} | [X, T^Y(\omega)] e^T | HF \rangle \\
& + \langle HF | (1 + \Lambda) e^{-T} [[H_N, T^X(-\omega)], T^Y(\omega)] e^T | HF \rangle \\
& - \omega P(XY) \langle HF | \Lambda^X(-\omega) T^Y(\omega) | HF \rangle \\
& + P(XY) \langle HF | \Lambda^X(-\omega) e^{-T} [Y + [H_N, T^Y(\omega)] e^T | HF \rangle \\
& \frac{1}{2} P(XY) \bar{\mathbf{Q}}_N^X(-\omega) \cdot \bar{\mathbf{V}}_N^Y(\omega)
\end{aligned} \quad (94)$$

Here, $H_N = H_N(0) + \bar{\mathbf{Q}}_N^{(0)} \cdot \mathbf{V}$ is the unperturbed Hamiltonian of the molecular solute; $\bar{\mathbf{Q}}_N^X(-\omega)$ and $\bar{\mathbf{V}}_N^Y(\omega)$ are given by

$$\begin{aligned}
\bar{\mathbf{Q}}_N^X(-\omega) = & \langle HF | (1 + \Lambda) e^{-T} [\mathbf{Q}_N^{|\omega|}, T^X(-\omega)] e^T | HF \rangle \\
& + \langle HF | \Lambda^X(-\omega) e^{-T} \mathbf{Q}_N^{|\omega|} e^T | HF \rangle
\end{aligned} \quad (95a)$$

$$\begin{aligned}
\bar{\mathbf{V}}_N^Y(\omega) = & \langle HF | (1 + \Lambda) e^{-T} [\mathbf{V}_N, T^Y(\omega)] e^T | HF \rangle \\
& + \langle HF | \Lambda^Y(\omega) e^{-T} \mathbf{V}_N e^T | HF \rangle
\end{aligned} \quad (95b)$$

In Eq. (95a) the polarization charges operator $\mathbf{Q}_N^{|\omega|}$ is defined as

$$\mathbf{Q}_N^{|\omega|} = \mathbf{T}(\omega) \cdot \mathbf{V}_N \quad (96)$$

where $\mathbf{T}(\omega)$ is the frequency-dependent PCM response matrix evaluated with the dielectric permittivity $\epsilon(\omega)$ of the solvent at the frequency ω .

- The equations for the first-order $T^X(\pm\omega)$ amplitudes are obtained from the stationary condition $\delta G^{XY}(-\omega, \omega) = 0$ with respect to the first-order $\Lambda^X(\pm\omega)$ amplitudes:

$$\begin{aligned}
0 = & \langle HF | \tau_p^\dagger e^{-T} \tilde{Y}(\omega) e^T | HF \rangle \\
& + \langle HF | \tau_p^\dagger [e^{-T} H_N e^T, T^Y(\omega)] - \omega T^Y(\omega) | HF \rangle
\end{aligned} \quad (97)$$

where $\tilde{Y}(\omega)$ is an effective perturbing operator:

$$\tilde{Y}(\omega) = Y + \bar{\mathbf{Q}}_N^Y(\omega) \cdot \mathbf{V}_N \quad (98)$$

Note that this operator indicates that to the direct perturbation with the external field, represented by the operator Y , it is added an indirect source of perturbation due to the effect of the direct perturbation itself on the solute-solvent interaction $\bar{\mathbf{Q}}_N^Y(\omega) \cdot \mathbf{V}_N$.

- The equations for the first-order $\Lambda^X(\pm\omega)$ amplitudes are obtained from the stationary condition $\delta G^{XY}(-\omega, \omega) = 0$ with respect to the first-order $T^X(\pm\omega)$ amplitudes:

$$\begin{aligned}
0 = & \langle HF | (1 + \Lambda) e^{-T} [\tilde{Y}(\omega), \tau_p] e^T | HF \rangle \\
& + \langle HF | (1 + \Lambda) e^{-T} [[H_N, \tau_p], T^Y(\omega)] e^T | HF \rangle \\
& - \omega \langle HF | \Lambda^Y(\omega) \tau_p | HF \rangle + \langle HF | \Lambda^Y(\omega) e^{-T} [H_N, \tau_p] e^T | HF \rangle
\end{aligned} \quad (99)$$

Coupled-Cluster Linear and Quadratic Response Functions

- The linear response functions $\langle\langle X; Y \rangle\rangle_\omega$ can then be obtained from Eq. (93) by introducing the stationary condition (97) in to the second-order quasi-free-energy (94)

$$\begin{aligned}
\langle\langle X; Y \rangle\rangle_\omega &= \tilde{G}^{XY} \\
&= \frac{1}{2}C^{\pm\omega} \{ P(XY) \langle HF | (1 + \Lambda) e^{-T} [[X, T^Y(\omega)] e^T | HF \rangle \\
&\quad + \langle HF | (1 + \Lambda) e^{-T} [[H_N, T^X(-\omega)], T^Y(\omega)] e^T | HF \rangle \\
&\quad + \frac{1}{2} P(XY) \langle HF | (1 + \Lambda) e^{-T} [\mathbf{Q}_N^{|\omega|}, T^X(-\omega)] e^T | HF \rangle \\
&\quad \cdot \langle HF | (1 + \Lambda) e^{-T} [\mathbf{V}_N, T^Y(\omega)] e^T | HF \rangle \\
&\quad + \frac{1}{2} P(XY) \langle HF | \Lambda^X(-\omega) \mathbf{Q}_N^{|\omega|} e^T | HF \rangle \cdot \langle HF | \Lambda^Y(\omega) \mathbf{V}_N e^T | HF \rangle \}
\end{aligned} \tag{100}$$

where $C^{\pm\omega}$ is a symmetrization operator with respect to sign change of the frequencies to ensure that only the real part of the response function is retained and $P(x, y)$ is a permutation operator between x and y .

Alternatively, introducing the stationary condition (99) into the second-order quasi-free-energy (94), we can write the linear response functions as

$$\begin{aligned}
\langle\langle X; Y \rangle\rangle_\omega &= \frac{1}{2}C^{\pm\omega} \{ \langle HF | (1 + \Lambda) e^{-T} [X, T^Y(\omega)] e^T | HF \rangle \\
&\quad + \langle HF | \Lambda^Y(\omega) e^{-T} X e^T | HF \rangle \}
\end{aligned} \tag{101}$$

- The quadratic response functions $\langle\langle X; Y, Z \rangle\rangle_{\omega_Y, \omega_Z}$ can be obtained in agreement with the $(2n + 1)$ rule as

$$\begin{aligned}
\langle\langle X; Y, Z \rangle\rangle_{\omega_Y, \omega_Z} &= \tilde{G}^{XYZ} \\
&= \frac{1}{2}C^{\pm\omega} \{ P^3(XYZ) \langle HF | (1 + \Lambda) e^{-T} [[X, T^Y(\omega_Y), T^Z(\omega_Z)] e^T | HF \rangle \\
&\quad + P^6(XYZ) \langle HF | \Lambda^X(\omega_X) e^{-T} [Y, T^Z(\omega_Z)] e^T | HF \rangle \\
&\quad + \langle HF | (1 + \Lambda) e^{-T} [[H_N, T^X(\omega_X)], T^Y(\omega_Y), T^Z(\omega_Z)] e^T | HF \rangle \\
&\quad + P^3(XYZ) \langle HF | \Lambda^X(\omega_X) e^{-T} [[H_N, T^Y(\omega_Y)], T^Z(\omega_Z)] e^T | HF \rangle \\
&\quad + \frac{1}{2} P^3(XYZ) \left(\tilde{\mathbf{Q}}_N^{XY}(\omega_X + \omega_Y) \cdot \tilde{\mathbf{V}}_N^Z(\omega_Z) + \tilde{\mathbf{Q}}_N^X(\omega_X) \cdot \tilde{\mathbf{V}}_N^{YZ}(\omega_Y + \omega_Z) \right) \}
\end{aligned} \tag{102}$$

where $P^3(xyz)$ and $P^6(xyz)$ denote, respectively, the cyclic permutation operator and the full permutation operator of their arguments, while $\tilde{\mathbf{Q}}_N^{XY}(\omega_X + \omega_Y)$ ⁵ and $\tilde{\mathbf{V}}_N^{YZ}(\omega_Y + \omega_Z)$ are defined as

$$\begin{aligned} \mathbf{Q}_N^{\tilde{X}Y}(\omega_X + \omega_Y) &= \langle HF | (1 + \Lambda) e^{-T} [[\mathbf{Q}_N^{|\omega_X + \omega_Y|}, T^X(\omega_X), T^Y(\omega_Y)] e^T | HF \rangle \\ &\quad + P(XY) \langle HF | \Lambda^X(\omega_X) e^{-T} [\mathbf{Q}_N^{|\omega_Z|}, T^Y(\omega_Y)] e^T | HF \rangle \\ \mathbf{V}_N^{\tilde{Y}Z}(\omega_Y + \omega_Z) &= \langle HF | (1 + \Lambda) e^{-T} [[\mathbf{V}_N, T^X(\omega_X), T^Y(\omega_Y)] e^T | HF \rangle \\ &\quad + P(XY) \langle HF | \Lambda^X(\omega_X) e^{-T} [\mathbf{V}_N, T^Y(\omega_Y)] e^T | HF \rangle \end{aligned} \quad (103)$$

Conclusions

We have presented a short review on recent progresses toward the extension of the QM coupled-cluster level for the study of the electronic structure and properties of molecular solutes with the Polarizable Continuum Model framework (Cammi 2009). Specifically, we have presented (i) the detailed expression for the evaluation of the analytical gradients for the PCM-CC theory at the single and double excitation level, for the ground states; (ii) the expressions of the analytical gradients for the PCM-EOM-CC theory at the single and double excitation level for the descriptions of the excited-state properties of molecular solute; and (iii) the expressions of the linear and quadratic PCM-CC response functions.

Several implementations of these PCM-CC theories have been presented in the last years within the Gaussian suite of programs (Frisch et al. 2009b; Frisch et al. 2009a). Caricato et al. have presented implementations of the PCM-CC analytical gradients, of the PCM-EOM-CC gradients, and of the linear response functions PCM-CC (Caricato et al. 2010, 2011; Caricato 2011; Caricato and Scalmani 2011; Caricato 2012a, b, 2013b, a, 2014). Fukuda et al. have presented various implementations of the PCM-CC and PCM-EOM-CC methods and of the corresponding analytical derivatives within the framework of SAC/SACCI methods (Cammi et al. 2010; Fukuda et al. 2011, 2012; Fukuda and Ehara 2013; Fukuda et al. 2014; Fukuda and Ehara 2014; Fukuda et al. 2015).

We hope that these computational progresses can be profitably used to study molecular processes in condensed phase, where both the accuracy of the QM descriptions and the influence of the environment play a critical role, as in photoionization processes, electronic transitions, and charge transfer reactions.

⁵The polarization charges operator $\mathbf{Q}_N^{|\omega_X + \omega_Y|}$ is evaluated from Eq. (96) using the dielectric permittivity $\epsilon(|\omega_X + \omega_Y|)$ of the solvent at the frequency $|\omega_X + \omega_Y|$. Therefore, Eq. (103) is able to describe the nonequilibrium solvation effects in the quadratic response function describing general second-order molecular processes (Cammi et al. 1996).

Appendix A: The Solute-Solvent PCM Operator

In the Polarizable Continuum Model for salvation, the molecular solute is hosted into a cavity of a polarizable dielectric medium representing the solvent. The cavity is accurately modeled on the shape of the molecular solute (Miertuš et al. 1981), and the dielectric medium is characterized by the dielectric permittivity ϵ of the bulk solvent. The physics of the model is very simple. The solute charge distribution polarizes the dielectric medium which in turn acts back on the solute, in a process mutual polarization that continues until self-consistence is reached. The polarization of the solvent is represented by an apparent charge distribution (ASC) spread on the cavity surface. In computational practice, the ASC is discretized to a set of point charges, and the solute-solvent interaction is expressed as in terms of the interaction between these and the charge distribution of the molecular solute.

In this framework, the PCM solute-solvent interaction operator (see Eq. (3)) can be defined in terms of a molecular electrostatic operators \mathbf{V} and of a charge operator \mathbf{Q} describing the PCM solute-solvent interaction operator (Cammi et al. 2002, 2005). \mathbf{V} is a vector collecting the molecular electrostatic potential operator, evaluated at the positions of the ASC charges:

$$(\mathbf{V})_j = v_{el}(\mathbf{s}_j) + v_{nuc}(\mathbf{s}_j) \quad (104)$$

where $v_{el}(\mathbf{s}_j)$ and $v_{nuc}(\mathbf{s}_j)$ are the electrostatic potential of the electrons and of the nuclei, respectively, evaluated at the position \mathbf{s}_j of the j -th ASC point charge. In particular,

$$v_{el}(\mathbf{s}_j) = \sum_i^N \frac{-1}{|\mathbf{r}_i - \mathbf{s}_j|} \quad (105)$$

where N is the number of electrons of the molecular solute and \mathbf{r}_i is the vector position of the i -th electron. A similar expression holds for the nuclei contribution $\hat{v}_{nuc}(\mathbf{s}_j)$.

The apparent charges vector operator \mathbf{Q} can be formally defined in a different way, depending on the different version of the BEM. In the integral equation formalism (IEF) version of the PCM (Cancès et al. 1997), which is here adopted, \mathbf{Q} may be expressed as a linear transformation of the vector operator \mathbf{V} :

$$(\mathbf{Q})_j = \sum_l^{NTS} T_{jl}(\hat{\mathbf{V}})_l \quad (106)$$

where T_{jl} are elements of the BEM square matrix. The matrix is dimensioned as the ASC charges, and it depends on the geometry of surface cavity and on the dielectric permittivity of the medium. The expectation value of the $\hat{\mathbf{Q}}$ operator ($\langle \Psi | \hat{\mathbf{Q}} | \Psi \rangle$) is a vector collecting the actual ASC charges induced by the molecular solute described by the wave function Ψ .

The solute-solvent interaction operator ($\langle \Psi | \hat{\mathbf{Q}} | \Psi \rangle \cdot \hat{\mathbf{V}}$ of Eq. (2) of the text is then the inner product between the expectation values of the ASC, ($\langle \Psi | \hat{\mathbf{Q}} | \Psi \rangle$), and the molecular electrostatic operator \mathbf{V} :

$$\langle \Psi | \mathbf{Q} | \Psi \rangle \cdot \mathbf{V} = \sum_j^{NTS} \langle \Psi | (\hat{\mathbf{Q}})_j | \Psi \rangle (\hat{\mathbf{V}})_j \quad (107)$$

where $\langle \Psi | (\mathbf{Q})_j | \Psi \rangle$ denotes the expectation value of the j -th apparent surface charge.

Abstract

We review the general concept of nonadiabatic quantum spin transitions in biochemistry. A few important examples are highlighted to illustrate the concept: the role of spin effects in oxidases, cytochromes, in dioxygen binding to heme, in photosynthesis, and in tentative models of consciousness. The most thoroughly studied of these effects are connected with dioxygen activation by enzymes. Discussion on the mechanisms of overcoming spin prohibitions in dioxygen reactions with flavin-dependent oxygenases and with hemoglobin and myoglobin is presented in some detail. We consider spin-orbit coupling (SOC) between the starting triplet state from the entrance channel of the O₂ binding to glucose oxidase, to ferrous heme, and the final singlet open-shell state in these intermediates. Both triplet (T) and singlet (S) states in these examples are dominated by the radical-pair structures $D^+ - O_2^-$ induced by charge transfer; the peculiarities of their orbital configurations are essential for the SOC analysis. An account of specific SOC in the open π_g -shell of dioxygen helps to explain the probability of T-S transitions in the active site near the transition state. Simulated potential energy surface cross-sections along the reaction coordinates for these multiplets, calculated by density functional theory, agree with the notion of a relatively strong SOC induced inside the oxygen moiety by an orbital angular momentum change in the π_g -shell during the T-S transition. The SOC model explains well the efficient spin inversion during the O₂ binding with heme and glucose oxidase, which constitutes a key mechanism for understanding metabolism. Other examples of nontrivial roles of spin effects in biochemistry are briefly discussed.

Introduction

Many enzymes, for example, those that contain copper or iron-heme active sites (cytochromes, peroxidases), are paramagnetic and undergo spin transitions depending on the change of the metal site oxidation (Franzen 2002; Jensen and Ryde 2004; Prabhakar et al. 2003; Shaik et al. 2002; Shikama 2006; Sigfridsson and Ryde 2002; Stryer 1995). Oxygen molecules contain two unpaired valence electrons (Sawyer 1991) and are therefore also paramagnetic because of the nonzero total electron spin. The complete oxidation of organic materials by dioxygen in order to transfer them into CO₂ and water is highly exothermic (Sawyer 1991), but the kinetic barriers preclude, fortunately, this spontaneous combustion of living matter at normal conditions in the open air because of the spin selection rules (Prabhakar et al. 2003). Like mass and charge, spin is an integral property of the electron, however, spin reveals itself through the relativistic quantum equation as a pure quantum process associated with the structure of space-time, thus it is more fundamental. The role of this fundamental quantum feature of the electron in biochemistry could be extremely important, especially with respect to the mystery of the brain, the nature of consciousness (Penrose 1994), and oxygen activation by enzymes (Franzen 2002; Jensen and Ryde 2004; Prabhakar et al. 2003; Sawyer 1991; Shaik et al. 2002; Shikama 2006; Sigfridsson and Ryde 2002; Stryer 1995).

When O₂ reaches a red blood cell in the alveoli of the lung, where the gas exchange of carbon dioxide and oxygen takes place, the hemoglobin binds O₂ in such a strange way that the total electron spin of the whole heme-O₂ system is not conserved (Sigfridsson and Ryde 2002). In ordinary chemistry the spin conservation rule is usually fulfilled (Sawyer 1991; Shikama 2006; Stryer 1995), which is in agreement with the general conservation law of physics (Sawyer 1991). But the change of the electron spin is a rather common case in biochemistry of enzymes, in the respiration cycle and in other processes connected with dioxygen consumption (Blomberg et al. 2005; Friedman and Campbell 1987; Lane 2002; Minaev 2007; Minaev et al. 2007; Silva and Ramos 2008; Strickland and Harwey 2007). The spin change has to be compensated by an orbital angular momentum change in order to follow the general conservation law of the total angular momentum. The present review will show that this requirement is fulfilled in a number of enzymatic processes that play key roles in biochemistry; this is accomplished by an analysis of spin-orbit coupling perturbations.

With the appearance of photosynthesis on the primitive earth, a dramatic change in life occurred when living cells adapted themselves from anaerobic life to the aerobic form (Shikama 2006). Anaerobic glycolysis represented a successful attempt to extract some of the chemical energy from glucose. In contrast, the complete oxidation of glucose to CO₂ and H₂O by utilizing oxygen molecules was the most significant and crucial advancement in cellular metabolism. It thus allowed organisms to enhance their ability to utilize the chemical energy of sugar for a most effective consumption. In light of the high efficiency of energy conservation, this dramatic change from anaerobic to aerobic systems was designated as an “oxygen revolution” (Lane 2002; Penrose 1994; Shikama 2006; Stryer 1995). The most essential feature of this revolution was the involvement of spin-catalysis and quantum spin effects in ordinary chemistry (Minaev 2007). In fact, both processes, photosynthesis and respiration, are spin-forbidden; from one side we have diamagnetic reactants and the paramagnetic species from the other side $6\text{CO}_2 + 6\text{H}_2\text{O} + \Delta E \xrightleftharpoons{\text{chlorophyll}} \text{C}_6\text{H}_{12}\text{O}_6 + 6\text{O}_2$. In order to synthesize O₂ with chlorophyll from green plants beneath the sun and to use oxygen for glucose oxidation, nature has designed very smart chemical manipulations that allow spin prohibition in dioxygen activation to be overcome (Minaev 2007). With this revolution a large number of important enzymes that are based on spin-catalysis principles (Blomberg et al. 2000a; Jensen et al. 2005; Lane 2002; Minaev 2002, 2004, 2007, 2010; Minaev et al. 2007; Petrich et al. 1988; Prabhakar et al. 2002, 2004; Silva and Ramos 2008) have been developed and spread (Blomberg et al. 2000b; Klinman 2001; Minaev and Lunell 1993; Sheldon 1993).

O₂ Interaction with Heme, FAD, and Oxidases

Some oxidases include flavin adenine dinucleotide (FAD), which can activate O₂ to produce diamagnetic products without radical chain reaction steps (Minaev 2002; Stryer 1995). For example, glucose oxidase (GO) is a well-known enzyme that can bind dioxygen directly from air and produce hydrogen peroxide in the metabolic

cycle (Prabhakar et al. 2003). An X-ray structure of GO from *Aspergillus niger* is available (Klinman 2001) and used for simulation of the active site in theoretical modeling (Prabhakar et al. 2002). The histidine residue has been assigned an important role in the substrate oxidation by the GO active site.

In the heme biosynthesis pathway a deficient activity of the enzymes often leads to excessive excretion of porphyrins (Silva and Ramos 2008). These toxic products can induce porphyria diseases due to decreased activity of coproporphyrinogen III oxidase (CPO), which catalyzes the oxidative decarboxylation of propionic acid chains. This oxidase is similar to GO in that they both activate dioxygen without using metals and reducing agents. However, mechanisms by which these two oxidases produce diamagnetic peroxides from paramagnetic dioxygen are not properly understood on experimental grounds (Klinman 2001; Prabhakar et al. 2002; Silva and Ramos 2008), while some theoretical predictions seem to shed light on the specific quantum nature of such chemical transformations (Minaev 2007; Minaev et al. 2007; Prabhakar et al. 2003; Silva and Ramos 2008). Density functional theory (DFT) calculations (Prabhakar et al. 2002, 2003; Silva and Ramos 2008) indicate the common feature of spin transitions in these oxidases' mechanisms.

Hemoglobin and myoglobin are important globular proteins that reversibly bind the O₂ molecule. Both proteins contain ferrous iron of a heme group, which is usually simulated by Fe(II) porphyrin, where the iron ion is tetra-coordinated to the nitrogen atoms of the tetra-pyrrole rings (Franzen 2002; Jensen and Ryde 2004; Shikama 2006; Sigfridsson and Ryde 2002). The proximal histidine residue from the protein side chain is also bound to the Fe(II) ion leaving one empty position in the octahedral coordination sphere around the ferrous iron. Hemoglobin and myoglobin bind several small gaseous molecules (CO and NO) besides dioxygen (Sigfridsson and Ryde 2002). The binding of these diatomic ligands to heme has been studied in biochemistry for over a 100 years (Shikama 2006). Dissociation of CO, NO, and O₂ from the iron of heme occurs by both photolysis and thermolysis. In the former case, the fate of the diatomic ligands depends on the competition between geminate recombination and protein relaxation. Binding to heme occurs by the reverse of the thermal process (Franzen 2002).

It is well established that the structure of surrounding protein affects the ligand binding ability of the heme group; carbon monoxide binds to free heme in solution 10⁵ times more effectively than dioxygen, but in myoglobin this ratio is strongly reduced (Franzen 2002). Thus, myoglobin seems to favor O₂ binding compared to CO (Franzen 2002; Jensen and Ryde 2004; Shikama 2006; Sigfridsson and Ryde 2002). Such discrimination is of vital importance: otherwise we would suffocate from CO produced in our body during metabolism. The reason for the discrimination has been connected with different geometric parameters of O₂ and CO binding to the heme iron: the Fe–C–O bond is linear, whereas the Fe–O–O bond is bent (Franzen 2002). Both hemoglobin and myoglobin have another, distal, histidine ligand (His-64) positioned above the Fe(II) ion, but too far away to coordinate directly to the iron. His-64 is in the right position to affect the Fe–CO group and to produce a tension. This idea was supported by early crystal structures,

showing an Fe–C–O angle of 120–130° (Shikama 2006), an idea that has penetrated into the textbooks (Shikama 2006; Stryer 1995). Some newer X-ray measurements, IR spectra, and DFT calculations indicate that the Fe–C–O angle is nearly linear in the heme models; thus one finds the idea of a strongly bent Fe–C–O unit as the reason for the discrimination but which nowadays is agreed to be incorrect (Sigfridsson and Ryde 2002). Recent DFT calculations show that the FeO₂ group is much more polar than the FeCO group in heme models (Franzen 2002; Jensen and Ryde 2004; Shikama 2006; Sigfridsson and Ryde 2002). The electronic structure of the FeP complex with dioxygen is close to that of a superoxide anion bound to a ferric ion, and this charge-transfer complex is in the singlet spin state (Franzen 2002; Jensen and Ryde 2004; Shikama 2006; Sigfridsson and Ryde 2002). Thus, electrostatic interaction between the distal histidine and the Fe(III)–O–O[−] group is stronger than that for the Fe–CO group; therefore, the protein discriminates between O₂ and CO by hydrogen bonding and electrostatic interaction in myoglobin (Franzen 2002; Jensen and Ryde 2004; Sigfridsson and Ryde 2002).

Another important factor in such discrimination is determined by electron spin (Franzen 2002; Jensen and Ryde 2004; Minaev 2010; Shikama 2006; Sigfridsson and Ryde 2002; Stryer 1995). The O₂ binding to heme is highly non-exponential at ambient temperature with a rapid phase of 3 ps, a longer phase of similar geminate recombination (20–200 ps), and a slow bimolecular process of 1 ms; all phases are spin-dependent processes (Franzen 2002; Jensen and Ryde 2004; Petrich et al. 1988; Shikama 2006). At this point we need to consider it in more detail.

Definition of Spin and the Angular Momentum Conservation

Spin is derived from the Dirac equation and is a general intrinsic quantum property of electrons (Esposito 1999; Hagan et al. 2002; Hameroff and Penrose 1996; Hu and Wu 2004; Penrose 1960). Spin is an angular momentum with a length of the momentum vector $\sqrt{S^2} = \sqrt{S(S+1)}\hbar = (\sqrt{3}/2)\hbar$, where the spin quantum number for one electron is equal to $S = 1/2$ and two projection $M_S = \pm(1/2)\hbar$ described by α and β wave functions exist (the doublet state) (Esposito 1999). The role of electron spin in chemistry is rationalized in terms of spin-valence concept: a covalent chemical bond is formed when atomic orbitals of two electrons with opposite spins overlap each other (Stryer 1995). This spin wave function ($\alpha\beta - \beta\alpha$) is antisymmetric with respect to permutation of two electrons. The total spin of such pair is zero ($S = 0$) and the state is singlet (only one state; no spin, no intrinsic magnetic moment, the molecule is diamagnetic). When spins are parallel the total spin has a quantum number $S = 1$ in the equation for the length of the total spin angular momentum $\sqrt{S^2} = \sqrt{S(S+1)}\hbar = \sqrt{2}\hbar$ and there are three spin states ($\alpha\alpha$, $\beta\beta$, and $\alpha\beta + \beta\alpha$) with different projections on z-axis $M_S = \pm\hbar, 0$ (triplet state) (Penrose 1960). For a simple covalent σ -bond the triplet state is unstable and such simple molecule can exist only in the singlet state with two opposite spins. That is why almost all stable organic molecules contain an even number of electrons,

which can be divided into α and β pairs. They are diamagnetic, have paired spins and are in the singlet ground state.

Such diamagnetic substances usually do not change zero spin during chemical reactions (Blomberg et al. 2000a, 2005; Friedman and Campbell 1987; Jensen et al. 2005; Klinman 2001; Lane 2002; Minaev 2002, 2007, 2010; Minaev et al. 2007; Petrich et al. 1988; Prabhakar et al. 2002, 2004; Sawyer 1991; Silva and Ramos 2008; Strickland and Harwey 2007). The absence of the total electronic spin in stable molecules leads to the illusion that spin is not important in organic chemistry and biochemistry. In fact, the total electronic spin is the main regulating factor in many metabolic processes catalyzed by metal-organic enzymes, such as cytochromes (Blomberg et al. 2005; Minaev 2007; Minaev et al. 2007; Shaik et al. 2002; Stryer 1995), copper-aminoxidase (Prabhakar et al. 2003; 2004), and even in metal-free glucose oxidase (Minaev 2002; Prabhakar et al. 2002, 2003). Spin inversion is especially important in many dioxygen reactions, binding to heme (Jensen and Ryde 2004), combustion, and respiration (Minaev 2007). One can propose that the importance of spin inversion is also reflected in the Perutz model of the hemoglobin cooperativity (Franzen 2002; Minaev et al. 2007).

Dioxygen molecule is a well-known exception to the general rule: unlike many chemically stable organic compounds, the O_2 molecule has the triplet ground state (Sawyer 1991). According to Hund's rule, two unpaired electrons in two degenerate $\pi_{g,x}$ - and $\pi_{g,y}$ -orbitals have a lower repulsive energy in the triplet state compared to the singlet one. Because of this, oxygen is paramagnetic, it has intrinsic magnetic moment due to spins of two unpaired electrons and its addition to organic compounds is spin forbidden: starting reactants have the total spin $S = 1$ (from the O_2), whereas the oxidation products are diamagnetic ($S = 0$). This is the reason why organic matter may exist in the oxygen-rich atmosphere (Sawyer 1991). Because of the spin prohibition, combustion of organic fuels requires activation in the form of high-temperature ignition stage (Prabhakar et al. 2002; Sawyer 1991), i.e., generation of primary radicals. Reaction of radical R (the triplet, $S = 1/2$, doublet state) with O_2 molecule is spin-allowed, since the starting reactants ($O_2 + R^\bullet$) and product (RO_2^\bullet) both have the doublet states (reactants also possess quartet state, $S = 3/2$, being non-reactive),

which provide the radical chain character of the combustion reactions (Minaev 2007).

The quantum cell $[\uparrow]$ denotes (Eq. 1) a molecular orbital (MO) with α spin; double brackets embrace one molecule. The radical RO_2^\bullet can decompose into radical RO^\bullet and biradical $\bullet O$ thus providing a branching chain reaction. In radical chain combustion the energy is released in the form of heat and light without any specific control (until fuel exhaustion). Clearly, such mechanism of oxidation by molecular oxygen cannot be realized in living cells. Cells meet their energy needs in the course

of metabolic processes using strictly controlled energy of oxidation of organic compounds in their reactions with dioxygen, overcoming spin prohibition without high-temperature ignition step of a radical chain (Minaev 2007). An aerobic life evolved due to quantum kinetic prohibitions to reactions of paramagnetic oxygen with diamagnetic organic substances. The main reason for sluggish O₂ reactivity at the ambient conditions is the spin prohibition, namely, the starting reagents have two unpaired spins (from O₂ molecule), while in diamagnetic oxidation products (CO₂, H₂O, N₂) all spins are always paired. Overcoming this prohibition by generating radicals to interact with dioxygen (like in combustion) is not possible in living matter. Since the cells cannot resist large temperature gradients, they have to transform the energy released through oxidation to some kind of chemical energy prior to dissipation in the form of heat. This occurs by combining oxidation with ATP synthesis. All versatile energy-supplying metabolic processes and reactions occur under subtle enzymatic regulation, which is often spin-dependent (Blomberg et al. 2000a; Jensen et al. 2005; Minaev 2002, 2007, 2010; Petrich et al. 1988; Prabhakar et al. 2002, 2004).

Molecular Oxygen Structure and Spectra

The O₂ molecule in the triplet ground state has the following electronic configuration (Sawyer 1991) (1σ_g)²(1σ_u)²(2σ_g)²(2σ_u)²(3σ_g)²(1π_u)⁴(1π_g)² (Fig. 1). The two outer electrons in two degenerate 1π_g-MO's provide the lowest triplet state of the type [↑][↑], where the quantum cells [↑] denote the degenerate π_g-orbitals. These two unpaired electrons in antibonding π_g-MOs (Fig. 1) are responsible for the specific character of the dioxygen interaction with radicals (combustion) and chemically stable diamagnetic compounds (slow oxidation), as outlined above. Two antibonding π_g-vacancies make it possible to transform dioxygen into O₂⁻ and O₂²⁻ anions, the formation of the latter being strongly dependent on the presence of electron donors (enzymes) and magnetic perturbations that affect the spin prohibition.

There are four possible quantum states (Eq. 2) for the electronic configuration mentioned above. For the imaginary form of two degenerate 1π_g-MO's: 1π_g[±] = ψ(r, θ) e^{±iφ}, where θ is an angle between the radius vector (r) and the molecular axis (z), φ is the rotation angle of the radius vector about the z axis, the quantum states are represented by the scheme (Minaev 2007):

$$\begin{array}{cccc} [\uparrow][\uparrow] & [\uparrow\downarrow] & \square[\uparrow\downarrow] & [\uparrow][\downarrow] \\ \left| {}^3\Sigma_g^- \right\rangle & \left| {}^1\Delta_g \right\rangle & \left| {}^1\Delta_g \right\rangle & \left| {}^1\Sigma_g^+ \right\rangle \end{array} \quad (2)$$

Exchange interaction stabilizes the triplet state $\left| {}^3\Sigma_g^- \right\rangle$, while the degenerate singlet state $\left| {}^1\Delta_g \right\rangle$ is higher in energy by 22 kcal/mol, and the $\left| {}^1\Sigma_g^+ \right\rangle$ state is the

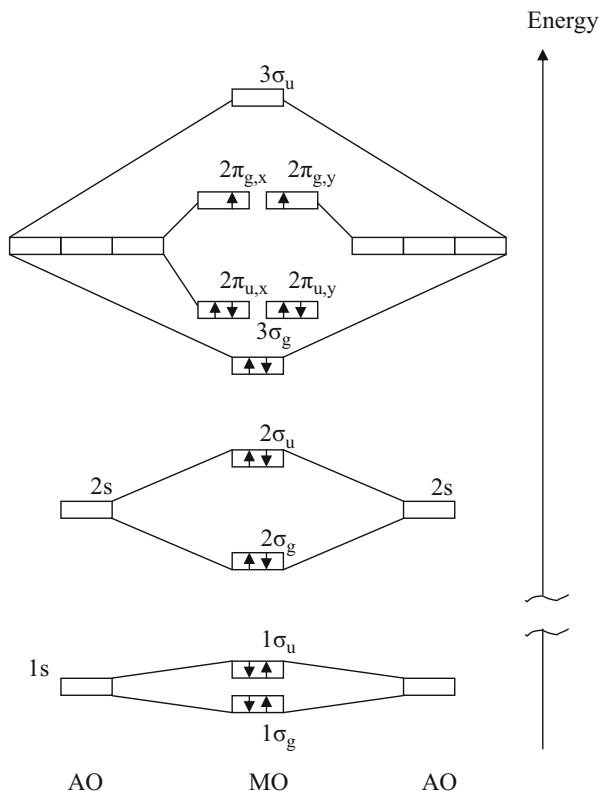

Fig. 1 Molecular orbital configuration of dioxygen

uppermost one (37 kcal/mol above the ground triplet $|^3\Sigma_g^- \rangle$ state). Interelectronic repulsion between the two electrons in the two closely space-distributed $1\pi_g$ -MO's, expressed through exchange integrals, is relatively high. This is an additional reason for a barrier in the $O_2(^3\Sigma_g^-)$ reactions with the closed shell molecules.

The $|^3\Sigma_g^- \rangle$ and $|^1\Sigma_g^+ \rangle$ states are mixed by weak internal magnetic perturbation, the so-called spin-orbit coupling (SOC) (Minaev 2007; Minaev and Lunell 1993). Some small admixture of one state (about 1.3%) is present in the other state, when SOC is additionally accounted for in the nonrelativistic Schrödinger equation. Such a small correction is very important because it makes the forbidden S-T transitions become allowed and can explain large difference in intensities of the atmospheric oxygen bands $^3\Sigma_g^- - ^1\Delta_g$ (1270 nm) and $^3\Sigma_g^- - ^1\Sigma_g^+$ (754 nm) (Minaev 1980, 1989, 2007; Minaev and Ågren 1995, 1996; Minaev and Ågren 1997; Minaev and Minaeva 2001; Minaev et al. 1993; 1996; 1997; 2008; Ogilby 1999; Paterson et al. 2006; Schweitzer and Schmidt 2003). In the following analysis

we want to understand the spin-dependent mechanism of the O₂ binding step once dioxygen has moved from the solvent through the protein chains and reached either the myoglobin distal cavity near the ferrous-heme cofactor or the flavin moiety in the active site of the GO enzyme. In both cases a similar SOC effect of the S-T states mixing is responsible for the biochemically important oxygen activation (Minaev 2002, 2007; Minaev and Ågren 1995; Prabhakar et al. 2002).

The heme-O₂ binding step has been extensively studied after flash-photolysis (Franzen 2002; Jensen and Ryde 2004; Shikama 2006; Sigfridsson and Ryde 2002), which shows interesting kinetic features, like non-homogeneous decay, recombination barriers, etc., and indicates complicated spin-dependence (especially in comparison with NO and CO binding to myoglobin). Kinetics of dioxygen reaction with GO has been investigated by studies of deuterium isotope effect during oxidation half reaction (Klinman 2001; Prabhakar et al. 2002). Explanation of such spin-dependence is the main purpose of the present review. In the beginning we want to consider some general features of spin-effect manifestation in chemistry and in dioxygen activation.

Spin-Prohibition of Dioxygen Reactions

Spins can undergo “depairing” when exposed to light; in (Eq. 3) an electron goes from a doubly occupied orbital [$\uparrow\downarrow$] of the ground singlet state to a vacant MO [] with the simultaneous spin flip to produce the triplet excited state (Minaev 2007):

According to the Pauli principle, both spins can be parallel (total spin $S = 1$) in such an excited state when two electrons occupy two different MOs. This triplet state has three possible orientations of the total spin vector, thus the singlet \rightarrow triplet excitation includes three possible transitions to three spin sublevels. All of them are spin-forbidden. This is a very strict prohibition, since it can be removed only by influence of magnetic interactions that are much weaker in general than the electric interactions. The latter determine the energetics of chemical bonding, electronic “depairing” excitation and the pathways of chemical reactions. The spin influences the energy through exchange interaction (Minaev 2007). A weak SOC slightly mixes the singlet and triplet states of molecules, which provides a non-zero rate for the $T \rightarrow S$ transitions. The late are observed in the form of phosphorescence and are well known as important quenching processes in photochemistry (Minaev 2004, 2007; Minaev and Minaev 2005). The nonradiative T-S transitions also play an important role in dark reactions, in particular, in catalysis (Metz and Solomon 2001; Minaev 2002). Weak SOC acts as a “key” needed to open a “heavy door”: that is, the system chooses a pathway of chemical reaction with low activation barrier in the triplet state instead of overcoming a high activation barrier in the singlet state. We remind that the exchange integral appears with different signs in the energy expression for the S and T states, namely, two radicals form a chemical bond in

the S state and repel each other in the T-state (Friedman and Campbell 1987). The different behavior of the S and T states is important not only for radical reactions, but also for many chemical transformations that include spin “depairing” during bond scission or proceed through biradical intermediates. This often occurs in catalysis by transition metal compounds (Minaev et al. 2007; Prabhakar et al. 2004; Sheldon 1993), especially in hemoproteins (Franzen 2002; Jensen and Ryde 2004; Shikama 2006; Sigfridsson and Ryde 2002; Stryer 1995).

The complete occupation of the degenerate-shell, Eq. 2, requires adding two additional electrons in order to become diamagnetic species, like usual chemical substance. Therefore, the oxygen molecule has a very strong tendency to take electrons from other substances and to make the complete electron-pairing in its unoccupied orbitals. This leads to the sequential formation of highly reactive or toxic oxygen species such as the superoxide anion O_2^- , peroxide anion O_2^{2-} , as by-products of many normal cellular metabolisms. Consequently, the development of enzymes to protect cells against such “oxidant stress” was of great urgency to aerobic organisms. This resulted in the ubiquitous occurrence of superoxide dismutase, catalase, peroxidase, and so on (Shikama 2006).

Cytochrome Oxidases and Related Heme-Containing Enzymes

Many heme-containing enzymes share the same active-species of the iron-ion types, but at the same time they exhibit significant differences in biochemical properties and reactivity with complicated spin-dependent kinetics (Burnold and Solomon 1999; de Winter and Boxer 2003; Kumar et al. 2005; Metz and Solomon 2001; Orlova et al. 2003; Shaik et al. 1998, 2002, 2005). Some of these heme-containing enzymes, cytochrome P450, cytochrome c oxidase, and horseradish peroxidase (HRP), are utilized as the active site of a high-valent oxo-iron heme species, called compound I (Shaik et al. 2002). Shaik et al. (Kumar et al. 2005; Shaik et al. 2002, 2005) proposed that the diverse reactions catalyzed by cytochrome P450 could be explained in terms of the difference in reactivity between the high-spin and low-spin states of the compound I. Their proposed two-state reactivity concept (Kumar et al. 2005; Shaik et al. 2002, 2005) has been widely used for the cytochrome P450 family and based on spin conversion transition between these states during reactions.

HRP, being similar to cytochrome P450 by crystal structure of the active site, differs in axial (proximal) ligand bound to the iron; P450 has a thiolate ligand of a cysteinate side chain, whereas HRP binds an imidazole group of a histidine residue side chain (Kumar et al. 2005). Although HRP functions predominantly as an electron sink (Kumar et al. 2005), it is also known to perform oxygen-transfer reactions (Afanasyeva et al. 2006; Chalkias et al. 2008; Shaik et al. 2002). Generally, however, the reactivity of HRP enzymes is sluggish compared with the P450 enzymes family; sulfoxidation is the most efficient while C-H hydroxylation is rather sluggish. This originates mainly in the much smaller substrate-binding pocket in HRP (Afanasyeva et al. 2006; Shaik et al. 2002). The recent DFT study of sulfoxidation by HRP and by cytochrome P450 reveals a spin-state selection

dependency on the proximal ligand: for thiolate ligand the reaction prefers the high-spin quartet state path while for the imidazole ligand the reaction mechanism involves a two-state reactivity (Kumar et al. 2005). This spin pattern also obeys orbital-selection rules, which are derived from the MO involvement of the ligands into the key oxo-iron porphyrin orbitals (Kumar et al. 2005; Shaik et al. 2005). In the case of the two-state reactivity the SOC-induced spin-transitions between the high-spin and low-spin reaction pathways could be magnetic-field dependent, if the viscosity of the media is sufficiently high (Afanasyeva et al. 2006; Buchachenko and Kouznetsov 2008; Buchachenko et al. 2005; Chalkias et al. 2008; Grissom 1995; Minaev 1983; Minaev and Lunell 1993; Serebrennikov and Minaev 1987). This is because SOC in the active sites is highly anisotropic and provides different rate constants for different spin-sublevels in zero field (Minaev 2002; Minaev and Lunell 1993), which become modified in the external field making the reaction to be magnetic-field dependent (Buchachenko and Kouznetsov 2008; Serebrennikov and Minaev 1987).

Such a dependence is found for the HRP-catalyzed oxidation of NADH, which can be presented by the schemes (Afanasyeva et al. 2006):

where compound II represents the Fe(IV) = O group connected with the porphyrin ring, compound I represents Fe(IV) = O connected with the radical cation of porphyrin, and compound III represents the porphyrin-containing Fe(IV)–OOH group. Here porphyrin denotes the protoporphyrin IX linked with protein chain by the histidine residue. The scheme (Eq. 4) is compatible with the magnetic-field dependence of the rate constants measured by stop-flow spectroscopy (Afanasyeva et al. 2006). The catalytic cycle starts with electron transfer from NADH to native HRP (Per³⁺) to produce NADH⁺• radical and the ferropoxidase intermediate (Per²⁺); (Per³⁺) actually means here the ferric porphyrin-Fe(III).

Interconversion of NADH to form NAD⁺ occurs by hydride transfer, in which the H⁺ ion and two electrons are transferred between the C(4) carbon atom of nicotinamide ring and substrate (Minaev et al. 1999). Catalytic cycle of NADH oxidation in the presence of hydrogen peroxide begins with a two-electron oxidation of the HRP enzyme to form Fe^{IV} and the porphyrin cation radical; this compound I is a highly reactive species that can accept one electron from NADH to form a NADH⁺• radical cation, which can undergo deprotonation to yield NAD[•] and compound II (Afanasyeva et al. 2006; Grissom 1995). The process is competitive with reverse electron transfer to regenerate NADH and Comp I, as shown by chemically induced dynamic nuclear polarization (CIDNP) of one of the C(4) protons in the NMR spectrum of NADH in presence of HRP (Afanasyeva et al. 2006). An alternative explanation of CIDNP is also possible (Minaev 2002; Serebrennikov and Minaev 1987), based on account of anisotropic SOC in compound I (Minaev 2010; Minaev and Lunell 1993; Minaev et al. 2007). The magnetic-field dependence of

the enzymatic reaction helps to reveal electron spin correlation among the catalytic states. Paramagnetic intermediates in the HRP catalytic cycle are difficult to detect, since direct observation by the EPR method depends on trapping unstable kinetically relevant radicals that may be transient or present at insignificant concentrations. Compound I is illusive in the sense that it does not accumulate in the cycle. This transient radical was inferred by cryogenic EPR/ENDOR technique (Davydov et al. 2008). The cryoreduction of the EPR-silent compound II produces Fe(III) species retaining the structure of precursor $[\text{Fe(IV)}=\text{O}]^{2+}$ or $[\text{Fe(IV)}=\text{OH}]^{3+}$; thus the EPR spectra of cryoreduced HRP II provide evidence of the low-spin hydroxy-Fe(III) heme species (Davydov et al. 2008; Kumar et al. 2005).

The first stage (Eq. 4) is thought to be magnitosensitive (Afanasyeva et al. 2006). Electron transfer from NADH to native HRP produces the quartet (Q) radical pair of Per^{2+} and $\text{NADH}^{+\bullet}$, which is unreactive toward recombination. The quartet – doublet (D) transition produces a radical pair that can recombine and quench the enzymatic process. It is claimed (Afanasyeva et al. 2006) that the Q-D transition is governed by isotropic hyperfine interaction and radical g-factors in terms of radical pair theory (Kumar et al. 2005). This Q-D transition is presented in the left part of the following scheme:

Here the set of three orbitals represents the triplet state of the Per^{2+} active site and one unpaired spin in the $\text{NADH}^{+\bullet}$ radical. The ferro-porphyrin intermediate (Per^{2+}) is known now to have a quintet ground state (Davydov et al. 2008) as follows from DFT calculations (Shaik et al. 2005). Thus, the main idea of the magnetic field mechanism (Afanasyeva et al. 2006) gives rise to some doubt. The most important objection is connected with the possible account of SOC, illustrated on the right side of the scheme (Eq. 5). It is possible to construct a number of configurations that could be definitely admixed to the open shell ground states of the Per^{2+} active site, which provides a strong SOC between Q-D states of the radical pair (Eq. 4). Such an SOC-induced mechanism could be applied to a number of magnetic field effects in metal-containing enzymes (Davydov et al. 2008; Engstrom et al. 1998, 2000; Gegear et al. 2008; Hoff 1986; Johnsen and Lohmann 2005; Maeda et al. 2008).

In the context of dioxygen activation we have to mention enzymes with binuclear metal centers, like cytochrome oxidase (Blomberg et al. 2000a, 2005), hemerythrin, and hemocyanin (Burnold and Solomon 1999; Metz and Solomon 2001). Generally speaking, the enzymes containing iron and copper active sites (Metz and Solomon 2001; Prabhakar et al. 2004) play key roles in dioxygen activation by generation of a peroxo intermediate; either O_2 is reduced by two electrons, provided by a binuclear metal site, or one electron is provided by metal and a second electron by a cofactor (Prabhakar et al. 2004). Cytochrome oxidase catalyzes the four-electron reduction of oxygen molecule to water (Stryer 1995). No intermediates were detected in the

reaction $O_2 + 4e^- + 4H^+ = 2H_2O$. However, many experimental measurements (Stryer 1995) have proved the formation of O_2^{2-} . The reaction center of cytochrome oxidase includes one heme ferrous ion and one copper ion (Blomberg et al. 2000a). The oxygen molecule binds to the heme Fe^{2+} cation and to the Cu^+ ion that donates one electron each to form an O_2^{2-} anion. This provides a way to overcome the major obstacle to oxygen activation, that is, spin inversion (T-S transition). The O_2^- and O_2^{2-} species have the following ground state configurations (in addition to Fig. 1):

$$\begin{array}{l} [\uparrow\downarrow][\uparrow] \quad [\uparrow][\uparrow\downarrow] \quad [\uparrow\downarrow][\downarrow\uparrow] \\ O_2^- |^2\Pi_g > \quad O_2^- |^2\Pi_g > \quad O_2^{2-} |^1\Sigma_g^+ > . \end{array} \quad (6)$$

Since the O_2^{2-} dianion has a filled electron shell, the ground state of this species is totally symmetric and characterized by the term $^1\Sigma_g^+$. Transfer of two electrons causes the ground-state term, $^3\Sigma_g^-$ of the O_2 molecule (Fig. 1), to transform smoothly to the term $^1\Sigma_g^+$ of the dianion. The spin-orbit coupling between the states $^3\Sigma_g^-$ and $^1\Sigma_g^+$ is symmetry-allowed (Minaev 1980, 2007); therefore, the reduction $O_2 \rightarrow O_2^{2-}$ is also symmetry allowed with inclusion of SOC. Transition of the active site of cytochrome oxidase to the singlet state removes spin prohibition for subsequent fast chemical reactions up to formation of stable diamagnetic products (Minaev 2010). The orbital doubly degenerate $|^2\Pi_g >$ ground state of the O_2^- ion is split by strong SOC (Minaev 2007), since it has a nonzero orbital angular momentum. This is an important key aspect of many enzymatic O_2 -activation reactions, considered in the following sections.

Dioxygen Reaction with Glucose Oxidase

It is often assumed (Sawyer 1991; Shikama 2006; Stryer 1995) that one can overcome the spin prohibition to oxidation of organic substrates with atmospheric oxygen by successive addition of single electrons and protons in the successive reduction of O_2 . Further reactions of diamagnetic hydrogen peroxide, produced in such reduction, are spin allowed. It is assumed (Sawyer 1991; Sheldon 1993; Stryer 1995) that removal of spin prohibition in such reactions proceeds as in the case of radical-chain oxidation, where the spin prohibition can be removed upon formation of primary radicals. It is important to stress a fundamental difference between the enzymatic reactions involving radicals and the radical reactions in chain oxidation processes. In the latter case radicals go to the bulk of the gaseous plasma flame (or in the solution bulk) and no longer retain the “spin memory” about precursors. All participants of biochemical oxidation reactions, i.e., dioxygen and electron transfer agents, are confined within the same active site of enzyme. If an electron is transferred to the oxygen molecule from a diamagnetic enzyme M , i.e., $O_2 + M \rightarrow O_2^- + M^+$, it produces a triplet radical ion-pair (triplet precursor), all spins remain correlated, the “spin memory” is retained, and the spin prohibition

to subsequent reactions of the radical ion-pair thus generated is not removed and cannot lead to a singlet product.

For example, reaction of O_2 with glucose oxidase (Klinman 2001; Minaev 2002; Prabhakar et al. 2002, 2003) involves flavin adenine dinucleotide (FAD) and includes two stages; namely, glucose oxidation to glucosolactone with reduction of FAD to $FADH_2$ and the reverse cycle $FADH_2 \rightarrow FAD$, with reduction of O_2 to H_2O_2 . From the standpoint of dioxygen activation it is interesting to consider only the second stage (Fig. 2). In this model the protonated histidine residue (His516) is included, which is in close proximity to FAD as follows from X-ray analysis (Klinman 2001). O_2 can occupy the cavity between $FADH_2$ and His516 (Fig. 2a). DFT calculations indicate that an electron is transferred immediately from the reduced cofactor to dioxygen (Fig. 2b); the electron transfer process is determined by low ionization potential of $FADH_2$, relatively high electron affinity of O_2 (0.45 eV), and attraction of the O_2^- to the protonated histidine. After formation of a triplet radical pair, $FADH_2 + O_2 \rightarrow FADH_2^{\bullet} + O_2^{\bullet-}$, the $T \rightarrow S$ transition has to occur in order to provide the final diamagnetic products $FAD + H_2O_2$, to which the singlet-spin stage (Fig. 2c) precedes.

After the $T \rightarrow S$ transition in the ion-radical pair (Fig. 2b), an ordinary chemical transformation on the singlet state PES occurs (Fig. 2c). It involves abstraction of hydrogen atom from the N1 atom of $FADH_2^{\bullet}$ and a proton abstraction from the nearest histidine residue in order to create H_2O_2 by reduction of the superoxide anion. This process, accompanied by the formation of hydrogen peroxide, can occur

Fig. 2 An active center of the glucosidase model. The first phase of the catalytic cycle (not shown) includes the FAD to $FADH_2$ reduction. (a) starting model of the dioxygen entrance to the active site; (b) electron transfer stage and spin transition in the radical pair; (c) hydrogen peroxide production. The final stage (not shown) includes the proton transfer from the N5 atom to the histidine residue along the hydrogen-bond network in peptide chain of the enzyme

only in the singlet state. The final phase of the catalytic cycle (not shown in Fig. 2) consists of a subsequent proton transfer from FADH^+ ion back to histidine across the system of H-bonds in water-protein chain (Prabhakar et al. 2003). This proton transfer does not change the number of active electrons and the closed-shell spin state. The $T \rightarrow S$ transition has been explained (Prabhakar et al. 2003, 2004) by a relatively large SOC between the S and T states of the radical pairs (Fig. 2b), which have different orbital structures inside the superoxide ion. As one can see in the orbital-configuration scheme (Fig. 2), the $T \rightarrow S$ transition includes an electron jump from one $\pi_{g,x}$ molecular orbital of the dioxygen to another $\pi_{g,y}$ orbital (Spin on the FADH_2^{\bullet} moiety is non-active during the transition). Such transformation is equivalent to orbital rotation, or to a torque, which creates a transient magnetic field; finally this magnetic field induces a spin flip (Prabhakar et al. 2003, 2004). Thus, the reductive activation of dioxygen by GO is favored by an increased electron affinity of O_2 due to the proximity of protonated His516-residue and a fast electron transfer followed by the $T \rightarrow S$ transition induced by strong SOC in superoxide ion. This simple consideration is supported by direct quantum-mechanical calculations of the SOC integrals (Minaev 2010; Silva and Ramos 2008). Exactly the same mechanism of the $T \rightarrow S$ transition is applied for explanation of activity of coproporphyrinogen III oxidase (CPO) in catalysis of the oxidative decarboxylation during the heme biosynthesis (Silva and Ramos 2008). Silva and Ramos have supported the so-called Lash's model of CPO oxidation by dioxygen (Silva and Ramos 2008) and obtained the T-S crossing point that lies only 8 kcal/mol above the reactant state. They have calculated the SOC integral between T and S potential energy surfaces crossing to be equal to 77.45 cm^{-1} in an excellent agreement with the earlier prediction for GO reaction (Minaev 2002; Prabhakar et al. 2002).

A similar mechanism of the SOC during the $T \rightarrow S$ transition has been used to explain bioluminescence induced by the luciferase enzyme (Orlova et al. 2003). Attachment of triplet dioxygen to the closed shell luciferin to yield a singlet state intermediate (which finally provides bioluminescence) is a spin-forbidden process (Orlova et al. 2003). It is important to the use of previous GO model (Minaev 2002; Prabhakar et al. 2002) that a critically significant protonated histidine residue resides in the proximity of the acidic group of luciferin (Orlova et al. 2003), quite similar to the GO active site (Fig. 2). Photodestruction of this histidine inactivates luciferase completely, thus it is found plausible that the SOC-induced spin-flip in superoxide ion (Prabhakar et al. 2002) operates in the case of oxygenation by luciferase (Orlova et al. 2003). In the following we want to show that a similar mechanism of SOC enhancement by charge transfer can be applied for spin-dependent reaction of dioxygen binding to heme.

Dioxygen Binding to Heme

The O_2 binding with myoglobin model was studied recently by DFT methods (Blomberg et al. 2005; Franzen 2002; Jensen and Ryde 2004; Jensen et al. 2005; Minaev 2007; Minaev et al. 1993, 2007; Sigfridsson and Ryde 2002; Strickland and

Fig. 3 A simple model of Fe(II)-porphine-NH₃-O₂ model of oxyhemoglobin (heme-cofactor coordinated with O₂. Simulates the heme (with NH₃ as a model of a proximal histidine residue)

Harvey 2007). Fully relaxed potential energy curves (PEC) were calculated for the seven lowest electronic states in Ref. Sigfridsson and Ryde (2002), Strickland and Harvey (2007), and Blomberg et al. (2005), while the PEC for spin states $S = 0, 1, 2, 3$ at fixed geometry as a functions of the Fe–O₂ distances were presented in Ref. Franzen (2002). In this work we have recalculated some points of the fixed Fe–O distance (1.8, 2.0 and 2.5 Å) with full geometry optimization of all other parameters for all possible multiplets and accounting for different symmetries (A' and A'') for the singlet and triplet states. The model of oxyheme is shown in Fig. 3, which includes Fe(II)-porphyrin coordinated with NH₃ as a model of proximal histidine residue. Its calculation gives the similar singlet ground state as for the simplified Fe(II)-Porphin-Imidazole-O₂-model, which poses C_s symmetry (Sigfridsson and Ryde 2002). The simpler Fe(II)-Porphine-NH₃-O₂ model (Fig. 3) has been used in this work for DFT calculations in the vicinity of the equilibrium. The B3LYP/6-31G* method (Frisch et al. 2003) has been employed and the results quite close to those presented in Ref. Sigfridsson and Ryde (2002) have been obtained. For the Fe(II)-Porphyrin-NH₃-O₂ model, shown in Fig. 3, all vibrational frequencies and their intensity in the infrared and Raman spectra have been calculated. Many normal modes are similar to those calculated in Refs. Minaev et al. (2007) and Minaev (2002). An additional Fe–O₂ stretching vibrational frequency is calculated at 539 cm⁻¹, which agrees qualitatively well with the resonance Raman band, observed at 567 cm⁻¹ for oxyhemoglobin by Soret excitation (Potter et al. 1987). This indicates reliability of the chosen model and of the DFT method used in this work.

In the entrance channel of the O₂ binding reaction to heme we have a number of different multiplets. At the infinite separation the deoxyheme has a quintet ground state with the triplet state being very close in energy. This is in agreement with the experimental data (Shikama 2006), showing that the isolated deoxyheme is a high-spin quintet (Friedman and Campbell 1987). The optimized structure of this Fe(II)P complex with NH₃ at the fifth coordination position agrees with the X-ray

analysis of the crystal structure of deoxymyoglobin. In this case the porphyrin Fe–N distances (2.08 Å) are larger than in the low-spin states of deoxymyoglobin (2.0 Å) and the iron ion is above the porphyrin ring plane by 0.3 Å in agreement with the X-ray data (0.36 Å) (Friedman and Campbell 1987; Sigfridsson and Ryde 2002). This illustrates the well-known fact that the high-spin iron ion Fe(II)(⁵D) is too large to fit into the porphyrin ring cavity (Jensen and Ryde 2004).

When this deoxyheme interacts with the triplet ground state dioxygen O₂ ($X^3\Sigma_g^-$), there are six unpaired electrons (two from O₂ plus 4 from heme). Their interaction can provide a variety of possible total spin states. The maximum spin corresponds to the septet ($^7A''$, $S = 5$) state, when both subsystems have parallel spins. If they are anti-parallel, the triplet state $^3A''$ occurs. At long Fe–O distances ($R > 2.5$ Å) these states are degenerate because of the absence of exchange interactions between O₂ and heme. The intermediate quintet $^5A''$ state is also degenerate together with the triplet and septet. The A'' symmetry is determined by the oxygen degenerate π_g orbitals, which have the a' and a'' symmetry, respectively, with respect to the plane, which contains the O₂ and Fe–N bond in ammonia molecule.

In general, all spin states that occur at each random collision of heme and O₂ should lead to oxygen binding. But the rate constants would be spin-dependent and different for the triplet, quintet, and septet states (even for different spin sublevels of one multiplet). More detailed information about O₂ binding has been obtained in flash-photolysis studies of O₂ dissociation from heme, when the fate of dioxygen depends on the competition between intrinsic recombination rate constant and protein relaxation, as well as the O₂ escape from the protein (Shikama 2006). The greatly different recombination dynamics of O₂, CO, and NO molecules with heme have been attributed to spin states of each ligand and to their possible combinations with the iron spin (Franzen 2002; Jensen and Ryde 2004; Shikama 2006; Sigfridsson and Ryde 2002). The observed recombination kinetics can be influenced by protein dynamics, if the intrinsic recombination rate constant is slower than this dynamics. By studies of viscosity and temperature dependence, the general averaged time scale for the recombination rate constant can be estimated (Friedman and Campbell 1987; Jensen and Ryde 2004; Shikama 2006).

It is interesting to compare O₂, CO, and NO molecules in this respect (Blomberg et al. 2005; Friedman and Campbell 1987; Strickland and Harwey 2007). The CO recombination with heme is a single exponential process characterized by a slow rate constant ($k \approx 10^6$ s⁻¹) at the ambient temperature and a low solvent viscosity (below viscosity of globin). This intrinsic (geminate) recombination rate is slower than both protein relaxation and CO escape, thus the recombination yield is very small (0.04) (Shikama 2006). The rebinding of the NO stable radical (doublet ground state, $S = 1/2$) is characterized by two-exponential kinetics with the rapid ($k_1 \approx 10^8$ s⁻¹) and slow ($k_2 \approx 5 \cdot 10^6$ s⁻¹) rate constants under ambient conditions (Friedman and Campbell 1987; Shikama 2006). Since the ground state heme has the quintet spin state ($S = 2$), there are two starting states: ($S = 2\frac{1}{2}$ and $S = 1\frac{1}{2}$) depending on mutual spin orientation of two species, while the recombination NO-heme product has the doublet state ($S = 1/2$) (Friedman and Campbell

1987; Strickland and Harwey 2007). Both types of geminate recombination require spin change. The slow process includes two-step spin-flip transformations ($S = 2\frac{1}{2} \rightarrow (S = 1\frac{1}{2}) \rightarrow (S = \frac{1}{2})$), since spin-orbit coupling can mix states and induces spin transition with the selection rule $\Delta S = 1$ (Minaev 2010). The rapid recombination occurs in one step ($S = 1\frac{1}{2} \rightarrow (S = \frac{1}{2})$).

The CO molecule is diamagnetic; all spins are paired, the total spin is zero. The heme-CO adduct is also diamagnetic ($S = 0$). Since the ground state heme has the quintet spin state ($S = 2$), the geminate recombination reaction is doubly spin forbidden. First it should be a quintet-triplet transition, which needs to overcome an additional activation barrier (besides the spin flip, induced by SOC) and then a final triplet-singlet transition. This is the reason why the CO recombination with heme is so slow, in spite of the high binding energy (Franzen 2002; Jensen and Ryde 2004; Shikama 2006; Sigfridsson and Ryde 2002; Strickland and Harwey 2007).

It is interesting to make the comparison: inorganic ferric ion (Fe^{3+}) has some catalytic activity for the decomposition of H_2O_2 into water and oxygen. When the ion is incorporated into the porphyrin molecule to form heme, the molecule is about a thousand times more effective than Fe^{3+} alone. If the protein component of the enzyme catalase then adds to the heme, the catalytic efficiency increases by a further factor of 10^9 times (Shikama 2006). This means that paramagnetic spin catalysis in combination with the SOC-induced spin-catalysis provide some kind of synergetic effect.

Spin-Orbit Coupling in O_2 -Heme Interaction

In this review we shall consider dioxygen binding in more detail, since the O_2 molecule is the main subject of spin-dependent biochemical phenomena in a general context. The ground state of the oxyheme product is an open-shell singlet in agreement with EPR experiment and Mossbauer spectra (Friedman and Campbell 1987; Sigfridsson and Ryde 2002) (the closed-shell singlet has been obtained in a number of calculations (Jensen et al. 2005; Shikama 2006), however, this result has since been revised (Blomberg et al. 2005; Strickland and Harwey 2007)). Thus, the reaction of O_2 binding to heme is spin forbidden. At least the T-S transition has to occur (Franzen 2002). Such spin flip can be induced by spin-orbit coupling (SOC) between the T and S states. One has to calculate the matrix element of the SOC operator, which can be presented in the effective single-electron approximation as

$$H_{\text{SO}} = \sum_A \zeta_A \sum_i \vec{l}_{i,A} \cdot \vec{s}_i = \sum_i \vec{B}_i \cdot \vec{s}_i = \sum_i (B_{i,x} s_{i,x} + B_{i,y} s_{i,y} + B_{i,z} s_{i,z}). \quad (7)$$

In (Eq. 7) ζ_A is a SOC constant for atom A ($\zeta_0 = 153 \text{ cm}^{-1}$), $\vec{l}_{i,A}$, \vec{s}_i – are the orbital and spin angular momentum operators for the i -th electron, respectively. This is the effective single-electron SOC approximation, which proved to be useful

in many spectroscopic and chemical applications including oxygen spin-forbidden atmospheric bands (Minaev 1989; Minaev and Ågren 1997; Minaev et al. 1996, 1997, 2008; Ogilby 1999; Paterson et al. 2006; Schweitzer and Schmidt 2003) and spin-forbidden enzyme reactions (Minaev 2002, 2007, 2010; Minaev et al. 2007; Prabhakar et al. 2003, 2004).

Deoxyheme has a quintet ground state (four spins are unpaired, $S = 2$) (Minaev et al. 2007; Sigfridsson and Ryde 2002) and the adduct with the triplet dioxygen (two unpaired spins) would be expected to have either six ($4 + 2 = 6$) unpaired spins or two ($4 - 2 = 2$) unpaired spins depending on ferromagnetic or antiferromagnetic relative orientation of the two magnetic moments of the deoxyheme and O_2 . An intermediate quintet spin state is also possible for the ground state species coupling. The triplet state of deoxyheme, being very close in energy, produces adducts with the triplet O_2 , which could be either quintet ($S = 2$), triplet ($S = 1$), or singlet ($S = 0$) depending on if it is ferromagnetic or antiferromagnetic coupling of two species. Thus, only triplet deoxyheme could provide the ground singlet state product in the process of the antiferromagnetic coupling with the triplet O_2 in a spin-allowed oxyheme formation without spin flip. Spin transition from the ground quintet to the close-lying triplet deoxyheme can be induced by SOC in the third shell of the iron ion. In this case the primary electronic reorganization takes place in the ferrous ion at the equilibrium between the quintet and triplet states already before dioxygen approaches the deoxyheme (Franzen 2002; Jensen and Ryde 2004). All other recombination processes include spin flip induced during heme- O_2 interaction; they seem to be more important for dioxygen binding (Blomberg et al. 2005; Franzen 2002; Jensen and Ryde 2004; Minaev 2007; Minaev et al. 2007; Shikama 2006; Strickland and Harwey 2007). Such natural heme - O_2 reactions could start with the $^3A''$ (2) state, which is repulsive at shorter distance ($R < 2.5$ Å) or with the septet $^7A''$ (1) state (Jensen and Ryde 2004) (both are the ground state of the entrance channel heme + O_2 and go in parallel with some other multiplets until the short distances limit (2.5–3 Å)). The energy gap is about 0.1 eV at these limits in agreement with Ref. Jensen and Ryde (2004). The optimized singlet ground state $^1A'$ (1) in the reaction product is lower in energy than other multiplets at least by 0.4 eV; this oxyheme is an open-shell singlet of a complicated orbital and spin structure (Franzen 2002; Jensen and Ryde 2004; Sigfridsson and Ryde 2002). It has a short Fe–O distance (1.81 Å) (Jensen and Ryde 2004) (reproduced in our DFT calculations, 1.84 Å) in contrast to the high-spin states (2–2.7 Å). Our result is close to the $Fe^{3+} - O_2^-$ radical-pair structure in agreement with other DFT calculations and with Weiss' model (Franzen 2002; Jensen and Ryde 2004; Shikama 2006; Sigfridsson and Ryde 2002). The spin densities in oxyheme are equal to 0.94, –0.31, and –0.72 for the Fe–O–O chain, respectively, at the optimized bond angle of 118° . The O–O bond distance (1.36 Å) and vibration frequency (1110 cm^{-1}) correspond better to superoxide ion (Jensen and Ryde 2004; Minaev 2007).

Potential energy surfaces for O_2 binding with the heme model (deoxy-Fe-porphyrin bound with imidazole) have been calculated by Jensen et al. (Jensen and Ryde 2004), who optimized by DFT method the C_s symmetry restricted reaction with fixed Fe–O bond length, which was systematically increased point by point.

Jensen et al. (Jensen and Ryde 2004) found that the spin-change occurs easily due to a broad crossing region of five electronic states. Similar PES crossing are obtained in other studies (Franzen 2002; Minaev et al. 1993; Strickland and Harwey 2007). Accounts of our data and the results of Refs. Sigfridsson and Ryde (2002), Franzen (2002), Jensen and Ryde (2004), and Strickland and Harwey (2007) allow us to consider the following scenario of the O₂ binding to myoglobin. At the intermediate distances 2.5–3 Å the starting ³A'' (2) state from the entrance channel transfers to the triplet Fe³⁺ – O₂⁻ radical-pair. In this region there are few crossing points between S and T states, including the ³A'' (2) – ¹A' (1) states crossing, where spin change could occur (Franzen 2002; Jensen and Ryde 2004; Sigfridsson and Ryde 2002). A simplified electronic structure of the ³A'' (2) and ¹A' (1) states near the crossing of the potential energy surfaces is presented in scheme (7). Outer electrons of the ground triplet state dioxygen in two degenerate π_g-MO's provide a scheme [↑][↑]; electron transfer from Fe²⁺ to O₂ in order to produce the radical pair Fe³⁺ – O₂⁻ (Eq. 8) can be accomplished by the occupation of either π_{g,x}- or π_{g,y}-orbitals. Both radical pairs could be in T and S states; all four states are almost degenerate at the intermediate distances. The most interesting spin states are those presented in scheme (Eq. 8), since they correspond to the desired T → S transition and to the final product of the O₂ binding by heme. The scheme (Eq. 8) is equivalent to the scheme (Eq. 5) and the same explanation for the high SOC matrix element (Minaev 2002; Prabhakar et al. 2002) is relevant.

In this model SOC perturbation occurs entirely in the oxygen moiety and the Fe(III) ion is magnetically silent. The starting triplet radical pair corresponds to a charge-transfer (CT) state described by ³A'' (2) wave function ${}^3\Psi_{CT_x} = \Re \left| (3d\alpha) (\pi_{g,x}\beta) (\pi_{g,x}\alpha) (\pi_{g,y}\alpha) \right|$, that is, transfer of an electron to the π_{g,x}-orbital of O₂ molecule, whereas the singlet radical pair corresponds to a CT state described by ¹A' (1) wave function ${}^1\Psi_{CT_y} = \Re \left| (3d\alpha) (\pi_{g,x}\beta) (\pi_{g,y}\alpha) (\pi_{g,y}\beta) \right|$ and a transfer of an electron to another degenerate orbital of oxygen, π_{g,y}. Here \Re means a proper anti-symmetrization of the wave function. Spin-orbit coupling between these CT states is the maximum possible for a system comprised of such light atoms like oxygen (Minaev 2002, 2004, 2007). The considered matrix element of the SOC operator (Eq. 7) is easily estimated to be equal:

$$\begin{aligned}
 \langle {}^3A''(2) | H_{SO}^Z | {}^1A'(1) \rangle &= \langle {}^3\Psi_{CT_x} | H_{SO}^Z | {}^1\Psi_{CT_y} \rangle = \frac{1}{2} \langle \pi_{g,x} | B_z | \pi_{g,y} \rangle \\
 &= \frac{i}{2} \xi_o = 76.5 \text{ icm}^{-1}
 \end{aligned} \quad (9)$$

The value is identical to those calculated for similar charge-transfer states including the GO (Minaev 2002; Prabhakar et al. 2002) and coproporphyrinogen III oxidase

(Silva and Ramos 2008). This SOC matrix element (Eq. 9) is very close to a value of about 80 cm^{-1} , postulated in estimation of the Landau-Zener rate constant for T-S transitions in spin-dependent O_2 and NO binding to heme (Franzen 2002; Friedman and Campbell 1987; Petrich et al. 1988). With such a proposal for the generally unknown SOC integral (Shaik et al. 2002) a quite reasonable estimation for the spin-dependent rate constants of the CO, O_2 , and NO recombination in heme proteins are obtained (Franzen 2002; Petrich et al. 1988). For CO binding to heme a quintet-triplet-singlet step-wise transition is necessary, which explains the million times slower recombination rate in this case in comparison with the O_2 and NO recombination in heme proteins (Franzen 2002; Shaik et al. 2002; Sigfridsson and Ryde 2002). The gradient difference at the location of crossing points that enters the denominator of the Landau-Zener expression of the rate constant for spin transition is quite small ($0.1\text{--}0.2 \text{ eV/\AA}$) for O_2 and NO binding to heme (Franzen 2002; Jensen and Ryde 2004), thus the topology of the binding curves supports a rapid recombination of both ligands to hemoglobin and myoglobin. The rapid NO rebinding to heme ($k_1 \approx 10^8 \text{ s}^{-1}$) includes one-step quartet-doublet transition; since the NO radical has one outer electron at the degenerate π_x and π_y orbitals, a quite similar theory of SOC in quasi-degenerate charge transfer states, like that, presented in Eqs. 8 and 9, can be applied. The only difference is that the SOC integral (9) now includes π_x and π_y orbitals of the NO molecule and thus is slightly smaller (about 60 cm^{-1}). The rate constant of spin transition in the Landau-Zener model is determined by the square of the SOC integral. This explains that the rapid NO rebinding rate constant is about three times slower than the rapid rate constant of the O_2 recombination in heme proteins (Franzen 2002; Jensen and Ryde 2004; Shikama 2006).

All previous analyses of SOC effects in hemoproteins were based on the assumption that the SOC integral in dioxygen binding to heme is determined by the iron ion and no attempt at direct calculation has been done (Blomberg et al. 2005; Franzen 2002; Jensen and Ryde 2004; Sigfridsson and Ryde 2002; Strickland and Harwey 2007). As follows from our simple analysis, the SOC integral (Eq. 9) is determined entirely by SOC in oxygen molecule and is connected with the degeneracy of the two π_{g,x^-} and π_{g,y^-} -orbitals in the open-shell of dioxygen. This enhancement of SOC effect by inclusion of charge-transfer to O_2 and involvement of superoxide-ion structure seems to be quite general in biochemistry (Minaev 2007, 2010); it is applied also to those enzymes that have no transition atoms, like glucose oxidase, or coproporphyrinogen III oxidase (Minaev 2007; Prabhakar et al. 2002; Silva and Ramos 2008). It is important to stress that the rapid T-S transition in O_2 binding to heme is not only forbidden by spin, but also by orbital symmetry (it includes the $A'' - A'$ symmetry change). Such double prohibition is necessary in order to make the spin change in chemical reaction to be effectively allowed (Minaev and Lunell 1993).

The iron ion can also contribute to the SOC integral in the O_2 binding to heme. In general, contributions from different atoms can cancel each other in SOC calculations; it happens when orbital rotation for different atoms occurs in opposite directions along the same axis during the T-S transition (Minaev 2007; Minaev and

Lunell 1993). This type of SOC suppression is known in the form of the destructive external heavy atom effect (Minaev 2010). However, such an effect cannot be applied for SOC analysis in heme-O₂ interaction. The main axis of the third-orbitals rotation in ferrous ion during the T-S transition is perpendicular to the porphyrin tetrapyrrole plane, while the SOC contribution from dioxygen is determined by the $\pi_{g,x}$ - and $\pi_{g,y}$ -orbitals' rotation around the O–O axis and the two axes do not coincide. The angle of 118° between these axes excludes possibility of cancellation: only the sum of the squares of the x,y,z projections, of the type given by Eq. 9, contributes to the final SOC value, which determines the rate constant of the T-S transition in terms of the Landau-Zener approximation (Harvey 2004; Kondo and Yoshizawa 2003; Minaev 2002; Minaev and Ågren 1995; Poli and Harvey 2003).

The Role of Spin in Biochemistry

We can see that spin-dependent quantum effects and transformations are important in a number of biochemical processes (Afanasyeva et al. 2006; Blomberg et al. 2000a, 2005; Buchachenko 1977; Buchachenko and Kouznetsov 2008; Buchachenko et al. 2005; Burnold and Solomon 1999; Chalkias et al. 2008; Davydov et al. 2008; de Winter and Boxer 2003; Franzen 2002; Grissom 1995; Jensen and Ryde 2004; Jensen et al. 2005; Kumar et al. 2005; Lane 2002; Metz and Solomon 2001; Minaev 1983, 2002, 2007, 2010; Minaev et al. 1999, 2007; Orlova et al. 2003; Petrich et al. 1988; Prabhakar et al. 2002, 2003, 2004; Serebrennikov and Minaev 1987; Shaik et al. 1998, 2002, 2005; Sigfridsson and Ryde 2002; Silva and Ramos 2008; Strickland and Harwey 2007). Spin is a very fundamental quantum phenomenon associated with the structure of space-time (Esposito 1999; Hameroff and Penrose 1996; Hu and Wu 2004; Penrose 1960). Various models of elementary particles in modern physics and even space-time itself are built with spinors (Esposito 1999; Penrose 1960). Spin of the Dirac electron is qualitatively shown to be responsible for all known quantum effects and the quantum potential is a pure consequence of “internal motion” evidencing that the quantum behavior is a direct consequence of the fundamental existence of spin (Penrose 1960). These results have been expanded recently by deriving a spin-dependent gauge transformation between the Hamilton-Jacobi equation of classical mechanics and the time-dependent Schrödinger equation of quantum mechanics that is a function of the quantum potential in Bohm mechanics (Esposito 1999). It is quite natural that the most mysterious peculiarities of living matter, the neuron network machinery of brain, hemoglobin, cytochromes, and oxydases, cannot avoid utilizing such a fundamental property of electrons like spin and quantum behavior. The occurrence of non-zero electron spin in any bio-system indicates that we are at a level of the life science where classical concepts are insufficient for its proper description and understanding. Electron spin is much more important than nuclear spin since it determines the exchange interaction, the most significant part of chemical forces, which are finally responsible for the functions of cells and for metabolism processes.

External Magnetic Field Effects in Biochemistry

Regardless of the comments above, we need to speak about nuclear spins, since they are everywhere (at least in the form of protons) and because they also can be connected with quantum effects in bio-systems. Recent experiments (Buchachenko and Kouznetsov 2008; Buchachenko et al. 2005) demonstrate that intramitochondrial nucleotide phosphorylation is a nuclear spin controlled process because the magnetic magnesium isotope $^{25}\text{Mg}(\text{II})$ increases the rate of mitochondrial ATP synthesis in comparison with the spinless nonmagnetic $^{24}\text{Mg}(\text{II})$, $^{26}\text{Mg}(\text{II})$ ions. Such nuclear spin isotope effect is usually interpreted in terms of radical pair theory for separated spins in solvent cage (Buchachenko 1977), but an alternative explanation based on electronic spin-transition in the active center (Minaev 1983; Minaev and Ågren 1995; Serebrennikov and Minaev 1987) is also possible. New developments in magnetic resonance imaging of the brain demonstrate that induced quantum coherences of proton spins separated by long distances ranging from thousands to millions of nanometers (from 1 μm to 1 mm) are sustained for milliseconds and longer (Hu and Wu 2004). While these quantum couplings are not the type of quantum processes that are likely to prove useful in brain function (Hagan et al. 2002), they nonetheless show that biology can take advantage of mesoscopic quantum coherence in clever ways. These quantum modes are not the stable entangled superpositions required for quantum computations in brain, but the proton spins' coherence can indeed survive in DNA, peptides, and in the brain's milieu (Hameroff and Penrose 1996; Hu and Wu 2004). Some new theory of consciousness is based on an idea that spin is the "mind-pixel" (Hagan et al. 2002; Hameroff and Penrose 1996; Hu and Wu 2004); it postulates that consciousness is intrinsically connected to quantum spin, since the latter is the origin of quantum effects in Bohm formalism and a fundamental quantum process associated with the structure of space-time (Esposito 1999; Hagan et al. 2002; Hameroff and Penrose 1996; Hu and Wu 2004; Penrose 1960). Spin involvement in the theory of consciousness can be connected also with memory storage and magnetic perturbations.

External magnetic field effects (MFE) in biochemistry are well known (Afanasyeva et al. 2006; Buchachenko and Kouznetsov 2008; Buchachenko et al. 2005; Chalkias et al. 2008; Davydov et al. 2008; Engstrom et al. 1998, 2000; Grissom 1995; Hoff 1986; Minaev et al. 1999; Serebrennikov and Minaev 1987) and could be analyzed in terms of competition with the internal magnetic interactions including SOC as the most important one (Minaev 1983; Minaev and Ågren 1995; Minaev and Lunell 1993) and hyperfine coupling (Burnold and Solomon 1999; Metz and Solomon 2001; Minaev 2004); the spin-dependent exchange interactions are also involved in the MFE theories as well as the whole spin-catalysis concept (Minaev and Ågren 1996; Orlova et al. 2003). MFE on enzymatic reactions have been first interpreted (Grissom 1995) entirely in the context of RPT (Buchachenko 1977). It was clear since the 1980a that RPT cannot explain all variety of MFE in chemistry and biology and SOC effects could be taken into account (Minaev 1980, 1983). But only recently, a number of publications (Afanasyeva et al. 2006;

Chalkias et al. 2008; Minaev 2002; Minaev and Ågren 1995) examined the external MFE in terms of SOC effects on the kinetics of enzymatic reactions. Activity increase of horseradish peroxidase (HRP) in the presence of magnetic particles (Fe_3O_4) (Chalkias et al. 2008) and external MFE in enzymatic oxidation of NADH by HRP (Afanasyeva et al. 2006) are the most interesting examples. Interconversion of NADH to form $\text{NADH}^{+\bullet}$ and NAD^+ occurs by hydride transfer, in which H^+ ion and two electrons are transferred between the C(4) carbon atom of nicotineamide ring and substrate (Afanasyeva et al. 2006). Catalytic cycle of NADH oxidation in the presence of hydrogen peroxide begins with a two-electron oxidation of the HRP enzyme to form Fe^{IV} and the porphyrin cation radical; this compound I is a highly reactive species that can accept one electron from NADH to form $\text{NADH}^{+\bullet}$ radical cation, which can undergo deprotonation to yield NAD^\bullet and compound II (Afanasyeva et al. 2006; Grissom 1995).

MFE on the photosynthetic light-harvesting reaction center in bacterium *Rhodospseudomonas sphaeroides* was the first successful observation and interpretation of spin-dependent intermediates in biology (Grissom 1995; Hoff 1986). The quantum yield of the triplet chromophore decreases by 50 % at 0.05 T. As the applied magnetic field increases, the Zeeman interaction between $M_S = \pm 1$ spin sublevels grows and causes a decrease of hyperfine coupling between triplet $T(\pm 1)$ and singlet S states, thus only T(0)-S states can interconvert. At high magnetic fields greater than 0.5 T the quantum yield of the triplet chromophore begins to increase slowly and attains parity with the zero-field ($B = 0$) value at $B = 3$ Tesla. At higher fields a net increase is detected, which is explained by T-S transitions via Δg mechanism (Afanasyeva et al. 2006; Buchachenko 1977; Engstrom et al. 2000). Such biphasic MFE dependence on B is typical for many photochemical (Hoff 1986; Serebrennikov and Minaev 1987) and enzymatic (Afanasyeva et al. 2006; Grissom 1995) reactions that occur through the radical pair mechanism. No total MFE on the photosynthetic reaction center would be expected since the total quantum yield is composed of a series of coupled vectorial processes that create an irreversible free energy cascade and drive proton pumping (Grissom 1995; Hoff 1986). For similar reasons it is impossible to expect other MFE with biological relevance. For example, MFE is possible, in principle, for the spin inversion step in GO, if the rotation of reactants in the step shown on Fig. 2b would be frozen. The T-S transitions for different $M_S = \pm 1, 0$ spin sublevels are characterized by different rate constants even in zero field in the fixed molecular frame. But rotation at room temperature quenches all anisotropy of zero-field splitting and SOC-induced rate constants (Serebrennikov and Minaev 1987). That is why no MFE has been observed for glucose oxidase in vivo (Chalkias et al. 2008).

Many mammals, reptiles, birds, insects, and fish are known to use the Earth's magnetic field for orientation and navigation (Gegear et al. 2008; Johnsen and Lohmann 2005; Maeda et al. 2008). Birds have been studied very intensively, but biophysics and neurobiology of their avian magnetoreception are still poorly understood (Grissom 1995; Johnsen and Lohmann 2005). Maeda et al. (2008) have recently proposed a carotenoid-porphyrin model system to demonstrate that the lifetime of a photochemically induced radical pair is changed by MFE with a low

magnetic field of about 50 μT , which is comparable with the Earth's magnetic field. Radiofrequency MFE can disrupt the ability of birds to orient and also has profound influence on radical pair reactions *in vitro*, which supports the RPT concept (Maeda et al. 2008). The recent DFT study of the electronic mechanisms of oxidative cleavage of the O–O bond by apocarotenoid oxygenase (ACO), which occurs in dark condition and includes a number of biradical and radical stages, is important additional support to the carotenoid-porphyrin model of Maeda et al. (2008).

In this context it is interesting to pay attention to molecular oxygen. Each O_2 molecule contains two unpaired electron spins and is a paramagnetic species capable of producing a fluctuating magnetic field along its diffusing pathway. Thus, O_2 serves as a natural contrast agent in magnetic resonance imaging (Hu and Wu 2004). The existence of unpaired electrons in stable molecules is very rare indeed. Dioxygen is the only paramagnetic species found in large quantities in the brain (besides the nitric oxide) and in other aerobic tissues. The singlet excited $^1\Delta_g$ oxygen (Minaev 2007) is a metastable species with a relatively short lifetime (few microseconds in water) (Schweitzer and Schmidt 2003) and long diffusion path (Ogilby 1999); it could serve as a light signal transmitter or transfer other types of information along definite distance in tissue. Generation and quenching of the singlet $^1\Delta_g$ oxygen are governed by SOC and other quantum perturbations (Minaev 1980, 1989, 2007; Minaev and Ågren 1995, 1996; Minaev and Ågren 1997; Minaev and Minaev 2005; Minaev and Minaeva 2001; Minaev et al. 1993, 1996, 1997, 2008; Ogilby 1999; Paterson et al. 2006; Schweitzer and Schmidt 2003). But the ground state triplet $^3\Sigma_g$ oxygen bound and transported by hemoglobin is a source of many other quantum effects besides those described above.

Spin Neuroscience

Conventional neuroscience has been unable to provide a complete understanding of cognitive processes (Esposito 1999; Hagan et al. 2002; Hameroff and Penrose 1996; Hu and Wu 2004; Penrose 1960). It has been accepted that the brain can be simulated as a neural network organized by the principles of classical physics (Hameroff and Penrose 1996; Shaik et al. 2002). Such an approach has delivered successful implementation of learning and memory and promoted optimism that a sufficiently complex artificial neural network would (in principle, at least) reproduce the full extent of brain processes involved in cognition and consciousness (Hagan et al. 2002). But the functioning of the nervous system lie outside the realm of classical mechanics; one finds ample support for this in analysis of sensory organs of vision, the operation of which is quantized at levels varying from the reception of individual photons by the retina to thousands of quanta in the auditory system (Hagan et al. 2002; Hameroff and Penrose 1996). It is also proposed that synaptic signal transmission has a quantum character (Hagan et al. 2002). The Penrose-Hameroff orchestrated objective reduction (OOR) model (Hameroff and Penrose 1996) of quantum computation in microtubules within neurons of the brain is compatible with modern physiology and can generate testable predictions. Coherent

superpositions of tubulin proteins are unstable in the OOR model and subject to self-collapse under quantum criterion. The phase of quantum superposition/computation is a preconscious process and each self-collapse event corresponds to “moment of conscious experience.” An apparent shortcoming of the Penrose-Hameroff OOR model and other models of quantum processes relevant to consciousness is the question of environmental decoherence (Hagan et al. 2002).

The dioxygen utilization in living matter provides many interesting manifestations of spin-dependent quantum effects that are under a control by very weak relativistic perturbations (Minaev 2007). This illustrates a long-lived quantum coherence in O₂ binding to hemoglobin (Franzen 2002; Friedman and Campbell 1987; Shikama 2006). Spin coherence can occur in photosynthetic systems, in oxidases, and in cytochromes. It depends on hyperfine interactions and spin–spin coupling in the ensembles of paramagnetic complexes. The decoherence can be induced by spin-flip and this review illustrates how to calculate and interpret such phenomena. It seems promising that the SOC-induced spin effects connected with dioxygen activation in bio-systems could be useful in other areas of life science.

Conclusions

In this review we consider spin effects in a number of biochemical processes with special attention to O₂ activation by heme, oxidases, and cytochromes. The universal role of the spin-orbit coupling (SOC) effect in such activations is stressed. Oxidation of organic materials by dioxygen, to give CO₂ and water, is very favorable (exothermic); fortunately, the unfavorable kinetics preclude this spontaneous combustion of living matter into “a puff of smoke” (Sheldon 1993). The reason for the sluggish O₂ reactivity is a spin barrier: the direct reaction of triplet dioxygen with singlet organic molecules to give stable diamagnetic products is a spin-forbidden process with a very low rate. The common way of circumventing this kinetic barrier via a free radical pathway (combustion) is impossible for living cells. The reaction of singlet (diamagnetic) molecules with ³O₂ forming two radicals is a spin-allowed process. Usually it is highly endothermic; Sheldon provides as an example of such a reaction observed at moderate temperature the activation of ³O₂ by flavin-dependent oxygenases (Sheldon 1993). He argues that it is possible only for very reactive substrates (flavins) that form resonance-stabilized free radicals, e.g., reduced flavins, like FADH^{•+}, and HO₂[•] as a counterpart. We have stressed that, even in this case, the complete oxidation in the enzyme (e.g., glucose oxidase) is spin-forbidden if the HO₂[•] radical is not the final product that leaves the active center of enzyme and goes into the bulk of the cell, but still participates in further oxidative transformations (Minaev 2002). We have shown that flavin-dependent oxygenases provide a very efficient way to overcome the spin-prohibition by spin-orbit coupling perturbation at the stage of electron transfer (Eq. 4).

A second way to overcome the obstacle of spin conservation is for ³O₂ to combine with a paramagnetic transition metal ion (Burnold and Solomon 1999; Metz and Solomon 2001; Prabhakar et al. 2003, 2004). Such reactions are spin-

allowed and governed by exchange interactions (exchange-induced spin-catalysis) (Minaev 2007; Prabhakar et al. 2004). Peroxo-, dioxo-, and superoxo-complexes with metals in different oxidation degree are considered during the search of “dream reactions” for selective industrial catalysts (Sheldon 1993). The expectation that the resulting metal-dioxygen complexes may react selectively with organic substrates at moderate temperature forms a background for the extensive studies of metal-catalyzed oxidation during the last four decades (Prabhakar et al. 2002, 2004). In this respect the reactions of $^3\text{O}_2$ with hemoglobin and myoglobin at moderate temperature are very peculiar, since they are still spin-forbidden and quite efficient (Franzen 2002; Jensen and Ryde 2004; Sigfridsson and Ryde 2002).

We have recalculated some potential energy surface cross-sections for different multiplets along the heme- O_2 binding reaction coordinate and obtained results in agreement with Refs. Sigfridsson and Ryde (2002), Franzen (2002), and Jensen and Ryde (2004). The Fe(II)porphine molecule coordinated with ammonia molecules (Fig. 3, NH_3 as a model of the proximal histidine) are used as in other similar studies (Blomberg et al. 2005; Franzen 2002; Jensen et al. 2005; Sigfridsson and Ryde 2002; Strickland and Harwey 2007). The more realistic protoporphyrin IX model provides similar result for the ground state of the heme active site. Results of previous works (Blomberg et al. 2005; Franzen 2002; Jensen and Ryde 2004; Minaev 2007; Minaev et al. 2007; Sigfridsson and Ryde 2002; Strickland and Harwey 2007) indicate that the main reason for the facilitated binding of O_2 to heme is a broad crossing region of the relevant spin states, which provides significant spin transition probabilities. They have shown that porphyrin is an ideal Fe(II) ligand for the spin-flip problem, because it tunes the spin states to be close in energy, giving parallel binding potential energy surfaces, small activation energies and large transition probabilities in terms of the Landau-Zener approach (Prabhakar et al. 2003). But none of these studies (Blomberg et al. 2005; Franzen 2002; Jensen and Ryde 2004; Jensen et al. 2005; Sigfridsson and Ryde 2002; Strickland and Harwey 2007) have considered the reason for relatively large spin-orbit coupling, which induces the necessary spin flip in the heme- O_2 binding reaction; a general assumption that the SOC integral at Fe(II) ion of about 80 cm^{-1} , postulated in Ref. Petrich et al. (1988), has been put forward instead. We have shown that such SOC integral (Eq. 9) is determined entirely by SOC in the oxygen moiety and is connected with the two $\pi_{g,x}$ - and $\pi_{g,y}$ -orbitals in the open-shell of dioxygen. This is also connected with charge transfer (CT) and with the $\text{Fe}^{3+} - \text{O}_2^-$ radical-pair structure of the ground state $^1\text{A}'$ (1) and the close-lying $^3\text{A}''$ (2) state near the crossing of the potential energy surfaces, see scheme (Eq. 8). This scheme indicates that the triplet and singlet states, $^3\text{A}''$ (2) and $^1\text{A}'$ (1), differ by a single electron jump inside O_2 from the $\pi_{g,x}$ MO to the $\pi_{g,y}$ orbital. Such transformation is equivalent to the electronic orbital rotation, i.e., a torque, which creates transient magnetic field during the T-S transition and this magnetic field is responsible for the spin flip. In this model the magnetic perturbation occurs entirely in the oxygen moiety and the iron ion is silent. Account of SOC in the third-shell of the metal has to increase the total SOC integral.

From a broader perspective, the non-zero electron spin and the concepts of quantum mechanics play a fundamental role in our understanding of the mystery of

life. Spin of dioxygen is a property of the ground state of the molecule and protects O₂ from its involvement in the realm of ordinary chemistry, where the brute force of activation energy just governs all spin-allowed biochemical transformations of diamagnetic species. Dioxygen is protected from brute force via the $X^3\Sigma_g^- - a^1\Delta_g$ energy gap (22 kcal/mol) (Hagan et al. 2002) and via spin-prohibition; at the same time O₂ is extremely fragile and easily activated by the presence of small amount of radicals or by magnetic perturbations (Minaev 2007). Such quantum spin protection is very important for biological systems, which operate at room temperature and are extraordinary complex, diverse, noisy, and “wet.” The quantum spin protection of dioxygen reactivity and its dependence on weak internal and external magnetic perturbations is important in connection with a fundamental fact, namely that biological systems are open driven systems. Self-organization in such biosystems should involve additional and very common mechanisms of self control, like S-T transitions in the O₂ activating enzymes, cytochromes, heme, photosynthetic centers, and probably in neural networks.

A fundamental conclusion of this review is an assertion of the fact that the functioning of various enzymes is controlled by spin conversion determined by internal and external magnetic forces. The most important magnetic interaction is spin-orbit coupling and we indicate a simple physical origin of this perturbation as responsible for the functionality of enzymes like glucose oxidase, coproporphyrinogen oxidase, luciferase, and myoglobin, hemoglobin, and other hemoproteins.

dmenyhard@chem.elte.hu

structure determination methods, X-ray diffraction and NMR spectroscopy. In subsequent sections, computer modeling techniques as well as their application to the construction of explicit models are discussed. An overview on molecular mechanics and structure prediction is followed by an overview of molecular graphics methods of structure representation. Protein electrostatics and the concept of the solvent-accessible surface are treated in detail. We devote a special section to dynamics, where time scales of molecular motions, structures, and interactions are discussed. Protein in relation to its surroundings is especially important, so protein hydration, ligand binding, and protein-protein interactions receive special attention. The case study of podocin provides an example for the successful application of molecular dynamics to a complex issue. At last, computer modeling of enzyme mechanisms is discussed. It is demonstrated that protein representation by computers arrived to a very high degree of sophistication and reliability; therefore, even lots of experimental studies make use of such models. A list with a large number of up-to-date bibliographic references helps the reader to get informed on further details.

Introduction

In order to obtain versatile models, we attribute a definite spatial structure and shape to molecules, which may, however, change in time. In case of proteins, the structure is too complicated and complex; thus, the use of computer graphics is unavoidable. In this chapter, we give an overview on the experimental and computational methods, which provide information on protein structure and allow deriving its relation to function. Neither of the techniques currently available is able to yield full information. X-ray diffraction works only for crystalline samples, NMR techniques refer to restraints, which determine a manifold of related but nonidentical structures, while modeling still lacks full reliability. Accordingly, in order to obtain thorough information on protein structure, various techniques should be combined, although in several cases even a single technique provides a model, which is adequate for some considerations. The present chapter may contribute to an overview on up-to-date techniques with reference to more detailed reviews on specific subjects, like the book published recently (Náray-Szabó [2014](#)).

Structure Determination

Both experimental and modeling techniques are available for the determination of the three-dimensional structure of proteins. They vary in performance and neither of them offers a unique tool to be applied for any type of proteins and their complexes. In most cases, publications refer to a single method only, structures are determined either by X-ray diffraction, nuclear magnetic resonance (NMR) spectroscopy or, eventually, by computer modeling. In order to get a more realistic, broad and rather complete information on structural and dynamic properties of proteins, a comparison of data obtained by a variety of methods is required.

Experiment

The first protein structures were determined by X-ray diffraction techniques in the late 1950s, and due to intensive work 95,375 structures are available now in the Protein Data Bank (as of 2015). Structure determination by NMR spectroscopy is also rapidly expanding; the number of deposited structures is 10,789 (Protein Data Bank 2015).

Protein Crystallography

Protein structures can be visualized at the atomic level by X-ray crystallography. An appropriate crystal has to be irradiated and the obtained diffraction pattern is recorded and analysed by mathematical tools. The result is an electron density map with relative maxima at the position of atomic nuclei. Using classical chemical information, the density map can be evaluated and the three-dimensional molecular model of the protein can be constructed. In order to determine the structure of a protein, the following steps have to be performed (Brandén and Tooze 1999; Drenth 2007).

Sample preparation and crystallization. Its goal is to produce a well-ordered crystal that is large enough to provide an appropriate diffraction pattern when irradiated with X-rays. It is inherently difficult because of the fragile nature of protein crystals. Proteins have irregularly shaped surfaces, which form large channels within the crystal. The noncovalent bonds that hold together the lattice must often be formed by flexible amino-acid residues of the protein surface. The success of protein crystallization depends on several factors, like purity, pH, concentration, temperature, precipitants, or additives. In order to ensure sufficient homogeneity, the protein should be pure to at least 97 %. It is necessary to screen a reasonable number of conditions, for that at least 200 μ l of material in a concentration of about 10 mg/ml is needed. The most commonly used techniques for crystallization are the hanging- and sitting-drop methods (Horsefield and Neutze 2006), although alternative approaches also have emerged, e.g., the microbatch method (Luft et al. 2003; Merlino et al. 2011). Efficient high-throughput methods have been developed to speed up the process and to determine optimal crystallization conditions (Chayen 2007).

Data collection. Having an appropriate crystal, its symmetry, the unit cell parameters and the resolution limit have to be determined. Then, it will be irradiated by an X-ray beam and continuously rotated by a small angle. Thus, the X-ray diffraction pattern containing relevant information on the position of scattering centers can be recorded. For crystals of lower quality, application of synchrotron radiation is recommended, where the beam intensity is greater; therefore, data collection times are shorter, sometimes less than 10 min. Synchrotron radiation is also the basis of time-resolved crystallography (Bourgeois and Royant 2005; Petsko and Ringe 2015). The relatively slow reaction rates allow following changes in atomic positions during the enzymatic process.

Structure determination. The relationship between the scattering angle and the distance between planes passing through the atoms in the crystal is given by

the Bragg's law. The electron density is related to the diffraction pattern by a mathematical function termed inverse Fourier transform. In order to compute this, both the amplitude and the phase of the diffracted waves should be known. Since experimental measurement of the relative phase angles is impossible, we face the so-called phase problem, often the most serious bottleneck in determining a new structure. A possible technique to solve this issue is the isomorphous replacement, i.e., to provide a crystal, which is nearly identical to the one studied, except that a few atoms have been replaced or added (e.g., using selenomethionine instead of methionine). If these atoms have a large atomic number, they will strongly perturb the diffraction pattern and allow deducing possible values for the phase angles. A similar technique applies the multiple-wavelength anomalous dispersion (MAD). By changing the wavelength of the X-rays, the degree to which the anomalously scattering atoms perturb the diffraction pattern also changes. This gives the same kind of information as isomorphous replacement.

Model building. If the studied crystals were perfectly ordered, all the atoms would scatter in phase and the electron density map would have peaks at each of the atomic positions. However, in electron density maps of most proteins, atoms are not resolved from each another; we need a model to be fitted to the electron density. Fitting models to density requires the use of computer graphics programs such as COOT (Emsley and Cowtan 2004) and as a result the electron density map is interpreted in terms of a set of atoms. In most cases, the protein backbone is fitted first then the side-chain atoms are positioned if the resolution permits. The result is dependent on the resolution and the quality of the phases (Fig. 1). Often regions of high flexibility (e.g., surface lysine side chains) are not visible since the corresponding electron density is smeared.

Refinement and validation. An atomic model can be improved by refinement, in which it is adjusted to the measured diffraction data. Refinement improves the

Fig. 1 Atomic (1.2 Å) resolution electron density map of a section of the complex between crayfish trypsin and an inhibitor from the desert locust *Schistocerca gregaria* (SGTI) (V. Harmat, unpublished)

phases leading to clearer maps and better models. The quality of an atomic model can be judged by the so-called *R*-factor, which is the average fractional error in the calculated amplitude compared to the observed one. Since, in general, there are insufficient diffraction data, these may be completed by restraints on geometry, which keep the bond lengths, angles, and close contacts within a reasonable range. Main-chain torsion angles are difficult to restrain but the distribution of these angles is strongly restricted as shown by the Ramachandran plot (Hovmöller et al. 2002), which is thus an additional indicator of the quality of a structure.

Neutron diffraction provides special information on proteins, a special method requiring high thermal-neutron fluxes, which can be obtained only from nuclear reactors (Fitter et al. 2006; Dambrot 2012). Hydrogen atoms can be precisely located, which is almost impossible by X-ray diffraction. A diffraction experiment can be performed on a crystal; the results can be evaluated similarly as done for the X-ray technique.

Nuclear Magnetic Resonance Spectroscopy

Nuclear magnetic resonance (NMR) spectroscopy is a versatile tool of modern structural biology, which allows determining protein structures even in some cases, where X-ray diffraction fails. It has become an independent method of routine structure determination for proteins with up to about 300 residues. Structure determination by NMR consists of multiple consecutive steps.

Sample preparation and stability testing. For successful NMR experiments, a protein solution of high purity (>95 %), stability (over a week), and appropriate concentration (0.1–1 mM) is needed; the total sample volume and mass should be 350–550 μ l and 3–30 mg, respectively. 2,2-dimethyl-2-silapentane-5-sulfonic acid (DSS) rather than tetramethylsilane (TMS) is used as a reference compound. Although both natural and synthetic polypeptides and proteins can be used, most samples are expressed via a suitable prokaryotic or eukaryotic cellular or cell-free recombinant technique. The latter method eliminates most toxic effects attributed to the overproduction of recombinant proteins. Biotechnological approaches have the common advantage of large-scale protein production, specific or nonspecific stable isotope labeling, and easy sequence variation.

Data acquisition (Schorn and Taylor 2004). Some magnetically active nuclei (e.g., ^1H , ^{13}C , or ^{15}N) experiencing a large magnetic field (10–20 T) possess two energy states. The energy difference between these states is large enough to be detectable if the resonance criterion is met during a radiofrequency irradiation (at or very near to the Larmor-frequency of the nucleus in question) as long as relaxation mechanisms are long enough. For example, the resonance frequencies, mostly between 500 and 950 MHz for ^1H nuclei, referring to the energy of the absorption are proportional to the strength of the static magnetic field. Depending on the local chemical environment, nuclei of the same type in a molecule resonate at slightly different frequencies. The relative shift from a reference (DSS for proteins in aqueous solution) resonance frequency is called the chemical shift. Peptides and proteins from natural sources are typically restricted to utilizing resonances based solely on protons; however, to get more information and/or to decrease spectral

crowding/overlap and hence to decrease assignment ambiguity, further NMR active nuclei have to be introduced or enriched in the molecule (mostly ^{13}C and ^{15}N).

In ideal signal dispersion, each magnetically active atom has its unique chemical shift by which it can be recognized and assigned. Assignment of each measured chemical shift to a single atom (or a group of atoms, e.g., a methyl group) is a mandatory step toward structure determination. Resonance frequency assignment is a very complicated and laborious procedure and often needs to introduce further “dimensions” into measurements but provides useful information on protein structure, dynamics, interaction, and ligand binding. Beside the most common direct dimension, typically associated with ^1H , experiments exploiting other nuclei (vide supra) are run to generate additional dimensions to minimize spectral overlap. For structure determination, two major types of NMR experiments are in everyday use: (i) the one based on coherence transfer between chemically connected atoms via indirect (through bond or J) coupling (e.g., COSY, TOCSY, HSQC, HNCQ, HNCA, ...) and (ii) those relying on magnetization transfer between spatially close atoms (through space or direct coupling); see below. The first set is for the identification of connected chemical shifts, while the second one is to localize spatial proximity. In both cases, it is the electron that mediates these interactions.

Resonance frequency assignment. The basis of the analysis of NMR-spectra is the distinction of real and artificial (background) signals; in other words, a large signal-to-noise ratio is needed, which is met if using concentrated samples. Then, one has to find out which chemical shift corresponds to which nuclei within the macromolecule. Several different protocols were invented to achieve this tedious goal, primarily depending on the type of isotope labeling introduced for proteins. Homonuclear techniques are used for unlabeled typically smaller molecules by taking advantage of a series of specific experiments. Resonance assignment for proteins of medium size ($5 < \text{MW} < 15$ kDa) relies on ^{15}N -labeled samples by using suitable parameterized methods. Larger proteins require double (^{15}N -, ^{13}C) or triple (^2H -, ^{15}N -, ^{13}C) labeling to achieve resonance assignment for both backbone and side-chain atoms. In principle, by filtering peaks, grouping of resonances, identifying spin-systems, and by grouping stretches of sequences into segments, the full assignment procedure can be automated. A sophisticated software, like DYNASSIGN (Schmucki et al. 2009), ensures high completeness of the assignment procedure.

Restraint collection. Structure determination by NMR-spectroscopy depends on various structural restraints. Distance restraints are typically obtained from NOESY experiments, where cross peaks appear due to successful magnetization transfer events between spatially close nuclei. Once assigned, each of the NOESY cross peaks can be converted into the approximate internuclear distance. The success of a structure determination depends on several factors, such as the total number of Nuclear Overhauser Effect (NOE) defined hydrogen-hydrogen distance restraints, on their distribution within the molecule, accurate assignment, and on their proper calibration. Because of various limitations, these distances cannot be determined precisely; rather they are sorted as short (1.8–2.7 Å), medium (1.8–3.5 Å), or long (1.8–6.0 Å) ones. Restraints on the backbone (φ and ψ) and side-chain (χ_1 , χ_2 , etc.) dihedral torsion angles can be obtained by measuring conformation sensitive

indirect coupling constants. Various 2D and 3D methods have been developed for the accurate measurement of coupling constants by NMR both in solution and in solid state. By suitable measurements followed by careful calibrations, these data can be converted into dihedral angle restraints. Orientation NMR restraints are commonly obtained for macromolecules. Dipolar couplings are averaged in solution because of fast molecular tumbling. However, due to slight overpopulation of one state, residual dipolar coupling (RDC) can be measured even in solution by using suitable oriented media to restrict overall molecular tumbling. Dipolar coupling is routinely used in solid state NMR and provides useful information about the relative orientation of bond vectors. Hydrogen bonds as structural restraints are typically determined by hydrogen/deuterium exchange experiment. H/D exchange can be quantitatively monitored by the isotope effect of deuterium on the chemical bond strength. The slower the NH exchanges to ND, the more the amide group is buried within the protein. Temperature dependence of NH chemical shifts (termed as temperature coefficients) can also be detected and used to estimate the involvement of the NH bond in an intramolecular H-bond, especially for peptides and shorter proteins. Various paramagnetic restraints can also be used for solution structure determination. Finally, order parameters introduced as restraints reflect an advanced view on the dynamic structure of proteins. Raw data typically involving longitudinal R_1 , transversal R_2 relaxation rate constants, and $^{15}\text{N}\{-^1\text{H}\}$ -NOE are required to determine general order parameters (S^2) for each and every backbone NH beside the overall- (τ_c) and local-correlation times (τ_l) and chemical exchange rates (R_{ex}). Recently, chemical shifts have been used to obtain preliminary models of protein structures (Cavalli et al. 2007).

Structure calculation and refinement. Experimentally determined structural restraints are used as input for these structure elucidations. Computer programs, like XPLOR (Schwieters et al. 2006; Güntert 2011) combine as many restraints as possible in conjunction with general properties of proteins. These approaches convert the different structural restraints into target functions with general protein properties describing energy terms, all to be minimized at once. A bundle of structures will be obtained reflecting a selected molecular fold. Structure determination by NMR is yet a time-consuming iterative process requiring well-trained and devoted specialists. The most time-consuming processes are the chemical shift and the NOE assignments. Automating and black-boxing the assignment to increase the throughput and to eliminate subjective decisions during structure elucidation is an important goal, yet partially achieved. Efforts are made to fully automate resonance assignment in conjunction with structure calculations in an integrated manner (Volk et al. 2008).

Structure validation is strongly recommended by using special software (e.g., CheckShift (Ginzinger et al. 2007)) to check both the quality of the NMR experimental data and structural information before publication. In general, these programs provide a means of validating both the geometry and restraint violations of an NMR-driven protein structure bundle. The output provides both statistical summaries and visualizations on restraint violations, agreement with already deposited model parameters, quality of geometrical properties, etc.

Although NMR is a versatile tool for protein structure determination, it may have severe limitations such as spectral crowdedness, too fast relaxation, poor automation, etc. Traditionally, NMR has been used for small- or medium-size proteins. Drawbacks and technical problems originate from the limited spectral resolution and signal overlap. Introducing multidimensional NMR spectroscopy, in conjunction with the different isotope labeling schemes, as well as the increase of the applied static magnetic field equipped with cryoprobe helped a lot in enhancing the power of NMR spectroscopy. An additional limitation is connected to spin relaxation; coherence (T_2) and magnetization (T_1) vanishes fast in time for larger macromolecules. This means that there is less and less time to acquire NMR signals (uncertainty of chemical shifts), causing signal-broadening (half-width at half-height of Lorentzian) and weakening. Two techniques have been introduced lately to overcome this problem, a chemical one by the introduction of sample deuteration and a spectroscopic one, namely the transverse relaxation optimized spectroscopy (TROSY). Today, these technical novelties allow determining even structures of larger water soluble and membrane proteins (Wüthrich 2002).

Computer Modeling

Modern computer hardware and software technology allows to model proteins at the atomic level quite precisely. Several computer methods are available for experiment-based structure determination, interpretation of structure-function relationships, as well as construction of explicit models of proteins from atomic or molecular fragments.

Molecular Mechanics

Since proteins are very large, containing several thousand atoms, quantum mechanical calculations are not tractable for doing calculations on the whole system. Instead, the much simpler molecular mechanics (MM) or force-field methods are applied, where a molecular system is treated as an ensemble of atoms connected by strings (bonds). A price for simplicity is that electrons are not treated explicitly and correctly. Forces acting between atoms are described by simple mathematical expressions, adapted from classical physics. A certain force field is composed by interaction terms describing different types of strain present in a molecule. The total energy of the system is typically calculated as the sum of the following terms:

$$E_{\text{MM}} = V_{\text{stretch}} + V_{\text{bend}} + V_{\text{torsion}} + V_{\text{outofplane}} + V_{\text{nonbonded}} \quad (1)$$

where stretching, bending, torsion, out-of-plane bending, van der Waals, and electrostatic terms, respectively, are defined as follows

$$V_{\text{stretch}} = \sum_{\text{bonds}} K_{\text{stretch}} (r_{ij} - r_{ij}^0)^2 \quad (2)$$

$$V_{\text{bend}} = \sum_{\text{angles}} K_{\text{bend}} \left(\theta_{\text{ijk}} - \theta_{\text{ijk}}^0 \right)^2 \quad (3)$$

$$V_{\text{torsion}} = \sum_{\text{dihedrals}} K_{\text{torsion}} [1 + \cos(n\varphi - \delta)] \quad (4)$$

$$V_{\text{outofplane}} = \sum_{\text{impropers}} K_{\text{outofplane}} c_{\text{ijk;l}}^2 \quad (5)$$

$$V_{\text{nonbonded}} = \sum_{\text{non-bonded pairs}} [A_{\text{nonbonded}} (C_{12} r_{\text{ij}}^{-12} - C_6 r_{\text{ij}}^{-6}) + q_i q_j / D r_{\text{ij}}] \quad (6)$$

where r_{ij} , r_{ij}^0 , θ_{ijk} , and θ_{ijk}^0 are the actual and equilibrium bond lengths (interatomic distances) and bond angles, respectively, φ is the dihedral angle and δ is its phase shift, $\chi_{\text{ijk;l}}$ is the angle between the bond jl and the plane ijk , where j is the central atom. K_{stretch} , K_{bend} , K_{torsion} , and $K_{\text{outofplane}}$ refer to respective force constants; n is the multiplicity of the torsional function. $A_{\text{nonbonded}}$, C_6 and C_{12} are adjustable parameters. q_i is the net charge on atom i , D is the dielectric parameter. For review and comparison of various force fields see (Wang et al. 2001; MacKerell 2004; Hu and Jiang 2009; Khoruzhii et al. 2014).

Van der Waals and electrostatic parameters in Eq. 6 are usually not calculated for atoms that are relatively close (at a distance of one or two bonds). In order to reduce computational efforts (e.g., methyl) groups of atoms may be considered as a single interacting unit. On this basis a variety of so-called coarse-grained models has been developed (Giorgetti and Carloni 2014). Force constants and other parameters in the energy expression are fitted to experimental or calculated data. Different parameters are used, e.g., for sp^3 -, sp^2 -, and sp -type atoms and additional ones for atoms in carbonyl or peptide groups or in aromatic systems. Accordingly, the total number of adjustable parameters may be quite large. As the number of atom pairs in $V_{\text{nonbonded}}$ increases quadratically, in order to reduce computation time most programs use a cut-off value, beyond which the interactions are set to zero over an additional short distance. It has to be noticed that a certain set of parameters works only for a given force field, and a single parameter has no meaning in itself, it cannot be transferred to another force field.

Basically two ways of parameterization can be followed. Class I force fields like AMBER (Case et al. 2005) or GROMOS (2011) work with a simpler energy expression and their parameterization is based on experimental data. They find a wide application to proteins, nucleic acids, and carbohydrates, as well as their complexes. Class II force fields, e.g., the Merck Molecular Force Field (Halgren 1996), include higher order and cross terms as well; they are calibrated to quantum mechanically calculated energies and gradients, which increases their transferability and reliability.

Various, freely or commercially available protein modeling software packages make use of different force fields. AMBER (Case et al. 2005) is a package of molecular simulation programs including both source code and demos. GROMACS (Van der Spoel et al. 2005) is a highly optimized and fast program, which supports

several force fields and has an open source code. INSIGHT II from ACCELRYNS (<http://accelrys.com/>), SYBYL from TRIPOS (<http://www.tripos.com/>), CHARMM (<http://www.charmm.org>) and SCHRODINGER (<http://www.schrodinger.com/>) are licensed packages with many components, including force fields and programs for energy calculations.

A basic limitation to classical force fields is that they are valid only near local minima of the potential energy surface (PES) of a molecular system. Thus, they cannot be applied to, e.g., enzyme reactions, which pass through other regions of the PES, where the electronic distribution is strongly perturbed. In order to overcome this limitation, quantum mechanics and molecular mechanics may be combined by partitioning large covalent systems in a quantum region, which is embedded in a classical one. The total energy in this approach (hybrid quantum mechanical/molecular mechanical, QM/MM, method) (Gao and Truhlar 2002; Hu and Yang 2008) is as follows:

$$E = E_{QM} + E_{MM} + E_{QM/MM} \quad (7)$$

where E_{QM} , E_{MM} , and $E_{QM/MM}$ refer to the energies of the quantum and classical regions and their interaction, respectively. $E_{QM} = \langle \Psi | H_{QM} | \Psi \rangle$ is the expectation value of the Hamiltonian for the atoms in the quantum region, which is composed of kinetic, electron-electron, and electron-nucleus interaction energy terms.

$$H_{QM} = \sum \Delta_i + \sum 1/r_{ij} + \sum Z_a/r_{ia} \quad (8)$$

Here, subscripts “i,” “j,” and “a” refer to electrons and nuclei of the quantum region. E_{MM} is calculated for atoms of the classical region as in Eq. 1; the third term in Eq. 7 refers to the interaction between atoms of the quantum and the classical region, respectively. $E_{QM/MM} = \langle \Psi | H_{QM/MM} | \Psi \rangle$ with

$$H_{QM/MM} = \sum q_M/r_{iM} + \sum [Z_a q_M/r_{aM} + A_{\text{nonbonded}} (C_{12} r_{aM}^{-12} - C_6 r_{aM}^{-6})] \quad (9)$$

where M denotes an atom in the classical region.

For most QM/MM studies on proteins definition of the quantum region, (mostly the active site) needs cutting covalent bonds, which requires special care in treating the boundary. This is very important to avoid artifacts and to ensure a relatively smooth variation of the energy and its gradient when passing from the quantum to the classical region, prerequisite for a successful molecular dynamics calculation. Two main approaches are available for the appropriate treatment of atoms at the boundary: the link atom and the localized orbital methods. In the first method an artificial link (dummy or hydrogen) atom is used to saturate the dangling bonds, the quantum calculation should be done for the saturated system. In the second method, the bonds connecting the quantum and classical regions are cut and represented by

a set of strictly localized molecular orbitals, which are assumed to be transferable (Ferenczy and Náray-Szabó 2014).

Structure Prediction and Homology Modeling

Protein structures are very complicated; therefore, their determination by energy minimization, like in case of small molecules, would need astronomical computational work. However, several methods are available for the prediction of such structures (Bujnicki 2009; Krieger et al. 2003). Below we discuss some of them.

Homology modeling. Proteins, derived from a common ancestor, are called homologous and their primary sequence overlaps to a certain extent. It has been observed that overlap in the sequences results in the partial conservation of three-dimensional structures. This allows constructing a model of an unknown protein on the basis of other, homologous ones, possessing some sequence similarity. Conservation of folds among homologues guides modeling, which follows four steps: fold recognition and template selection, target-template alignment, model building, and model assessment.

The first two steps are often performed together, as the most common methods of identifying templates rely on the production of sequence alignments. Selection of the correct template is of basic importance to the quality of the final model. Subsequent steps can be performed iteratively to improve the quality of the result. After the template was chosen on the basis of percentage of identities and similarities with the target protein it has to be corrected with respect to missing residues and improper bond lengths and mutated to the corresponding residues of the target protein. The gaps in the target sequence have to be excised; loops should be built and inserted by selecting anchoring residues (cf. Fig. 2).

Loops satisfying the distance condition for connecting secondary structures can be located by a search in the Protein Data Bank. At last, using an appropriate force field the generated complete model has to be optimized.

Assessment of homology models can be performed with two main methods: statistical potentials or energy calculations. Both methods produce an estimate of the energy (or an analogous quantity) for the model being assessed. Unfortunately, neither of the two methods correlates very well with structural accuracy. Statistical potentials are computationally quite efficient and can be constructed empirically on the basis of observed residue-residue contact frequencies among proteins of known structure. Energy calculations are performed using a molecular mechanics force field (cf. section “[Molecular Mechanics](#)”). The use of these methods is based on the hypothesis stating that a native structure of a protein refers to a minimum on the energy hypersurface; thus, the lower the energy the better the structure. Some methods employ implicit solvation, representing the solvent around a single protein

ARIFYDKG---RCYKSECPNLQP
```

Fig. 2 Sequence alignment of template (*top*) and target (*bottom*) in homology modeling

molecule as a continuous dielectric medium. Quality of homology models decreases with decreasing sequence identity. At 70 % and 25 % identity, the RMS deviation between the matched C^α atoms ranges between 1–2 and 2–4 Å, respectively. Several computer programs, like WHAT IF (Krieger et al. 2003), MODELLER (Fiser and Sali 2003), and SWISS-MODEL (2011), are available for homology modeling.

Protein threading (fold recognition) is based on the observation that the number of different folds in nature is limited to approximately 1000. Furthermore, 90 % of the new structures submitted to the Protein Data Bank in the past few years have similar folds to the ones already stored. The method uses sequences which have the same fold as some known structures but are not homologous with any of these. Prediction uses statistical relationships between structure and sequence. The prediction is made by aligning each amino acid in the target sequence to a given position in the template structure, and evaluating how well the target fits the template. After that the best-fit template is selected, the structural model of the sequence is built on the basis of the alignment with the chosen template.

Ab initio methods. When structural analogues are not available, prediction has to be based on other information. Various types of potentials as well as evolutionary information may be used in generating spatial restraints or identifying local structural building blocks. A popular ab initio method is Rosetta@home (2011), where the conformations, specified by the nonhydrogen backbone and C^β atoms, observed for each short sequence segment in known protein structures are used as an approximation of the set of local conformers, which the same sequence segment would occupy in the modeled protein. The combination of local conformers, which has the lowest overall energy, is considered as the best model. Before its structure has been determined experimentally, ROSETTA provided a model for the protein T0283 having 112 residues. Comparison of this model to the experimental structure indicates an RMS deviation of 1.8 Å over 92 residues. Despite significant success, the enormous computer cost of the procedure is still prohibitive for routine use.

Structure Representation

Protein structures contain typically thousands of atoms; therefore, their graphical representation, replacing old mechanical models, is essential for understanding structure, function, and their relationship. Modern computer technology provides an irreplaceable tool and allows insight into structural and functional details.

Molecular Graphics

Three-dimensional structure of a molecule may be displayed on the computer screen in various representations (Lesk et al. 2008). The simplest is where the molecule is displayed as a chemical graph, in which vertices stand for atoms and edges for bonds. Usually this representation is not very useful for molecules as large as proteins, as the figure gets too crowded. However, for structures derived

from X-ray data it is often used when mobility of various atoms is represented by spheres or ellipsoids centered at edges. In most cases, evaluation of data from NMR spectroscopy provides a bundle of structures, a superposition of those 10 or 20 ones, which fit best to restraints extracted from the spectrum. In order to simplify the model often a single structure, adopting the “average” conformation of the bundle, is shown.

More sophisticated is the ball-and-stick model, displaying atoms as balls and bonds as sticks connecting them. In space-filling, or CPK, representation atoms, represented by spheres with van der Waals radii, within which most of the electron density can be located, are drawn to suggest the amount of space they occupy. For proteins, ribbon diagrams offer a simple yet powerful means to visualize special features of protein structure. They indicate whether the polypeptide chain is twisted, folded, or unfolded. They are generated by interpolating a smooth curve through the polypeptide backbone. α -helices are shown as coiled ribbons, β -strands as arrows, random coils as lines or thin tubes. As an example for the performance of ribbon diagrams, we display a β -barrel, a bunch of large β -sheets that twist and coil to form a closed structure, on Fig. 3. The ribbon representation allows easy recognition of backbone structural motifs, while the space-filling model refers to other steric aspects of the macromolecule, e.g., location and shape of crevices.

A special feature of molecular graphics is that it can generate various surfaces around the molecule, on which a variety of its properties can be displayed. For proteins, the electrostatic potential (see section “[Electrostatics](#)”), water accessibility, and hydrophobicity (see section “[Solvent-Accessible Surface](#)”) patterns are most important. Commercial (see section “[Molecular Mechanics](#)”) and open source code software, like PyMOL (<http://www.pymol.org/>) and Jmol (<http://jmol.sourceforge.net/>), are available for molecular graphics.

Electrostatics

Since proteins have several polar or charged side chains, especially on their surface, electrostatics is a simple, yet quite reliable tool to study various processes involving proteins (Baker and McCammon 2009; Rocchia and Spagnuolo 2015). Electrostatic interactions may play a role in protonation, ligand binding, enzymatic catalysis, redox processes, and electron-proton coupling (e.g., in photosynthesis).

The electrostatic potential generated by the electrons and the nuclei of a protein molecule in a given spatial point, r_i , is calculated as follows

$$V(r_i) = \int \rho(r) |r - r_i| dr + \sum Z_a |r_i - R_{ia}| \quad (10)$$

where ρ is the electron density of the protein and Z_a is the nuclear charge of an atom located at the point R_{ia} . Exact calculation of the electron density involves the quantum mechanically determined total wave function; for proteins, this would need astronomical computer time. In order to reduce computational work, the density can be approximated by a sum of quantum mechanically defined molecular fragments, classical atomic monopoles, or multipoles.

Equation 10 refers to a protein molecule in vacuo; however, a realistic model should include explicit treatment of the surrounding biophase. This is done in the Poisson-Boltzmann approach, where the mobile ions around the protein are represented by a mean field approximation. A linearized equation can be derived, which combines the electron density of the protein and the charge represented by the mobile ions.

$$\nabla [\varepsilon(r)\nabla V(r)] + 4\pi [-2IV(r)/kT + \rho(r)] = 0 \quad (11)$$

Here $V(r)$, $\varepsilon(r)$, and $\rho(r)$ are the electrostatic potential, the dielectric constant and the protein electron density in point r , while I stands for the ionic strength. DelPhi, a versatile software package providing numerical solutions to the Poisson-Boltzmann equation, is widely used for the calculation and visualization of the protein electrostatic potential (DelPhi 2014).

An application of the Poisson-Boltzmann equation is the estimation of the effective pK_a of a given side-chain, which is related to the electrostatic potential generated by the whole protein near the protonated atom. pK shifts caused by, e.g., site-directed mutagenesis can be precisely calculated using electrostatics (Gilson and Honig 1987). In subtilisin mutants the calculated, ionic strength-dependent pK shifts lie very close to the experimental values. The trend is correctly reflected for all but the lowest ionic strengths (cf. Table 1).

The electrostatic approach is quite useful in describing the binding of small ligands to proteins. Figure 4 shows a representation of the protein electrostatic potential on the surface, providing a simple means to roughly estimate position and binding strength of charged ligands. This point will be discussed in more detail in section “Protein Hydration.” Molecular recognition by proteins, as well as enzyme

Table 1 Comparison of calculated and experimental (in parentheses) pK_a shifts in subtilisin mutants as a function of the ionic strength

I	D99S mutant	E156S mutant
0.500	0.10 (0.09)	0.19 (—)
0.100	0.18 (0.23–0.29)	0.27 (0.25)
0.025	0.25 (0.36)	0.34 (0.41)
0.010	0.29 (0.42)	0.37 (0.42)
0.005	0.31 (0.38)	0.39 (—)
0.001	0.34 (—)	0.42 (0.39)

catalysis is also partly determined by electrostatics (cf. sections “[Ligand Binding](#)” and “[Enzyme Mechanisms](#),” respectively).

Redox processes involve a change in the charge distribution of the participating protein fragments; therefore, electrostatics may play here again a significant role. If a negative charge is located near the redox center, addition of an electron becomes more difficult, which lowers the redox potential. This effect is formally similar to the pK shift upon point mutation of a neutral side chain to a negative one. A specific advantage of the calculations is that contributions of various protein groups, the biophase, and ionized side chains can be treated separately. This information is very useful in the design of experiments, because probable effect of point mutations, ionic strength, and pH variation, respectively, can be predicted with a fair accuracy.

As an example, values of the one- and two-electron reduction potential of pheophytin-*a* were calculated in *N-N*-dimethylformamide by a combination of quantum mechanical, statistical mechanical, and polarizable continuum methods (Mehta and Datta 2008). Two different computational methods gave -0.92 and -1.03 V for the one-electron, while -1.34 and -1.30 V for the two-electron reduction potential values, respectively. The observed one- and two-electron potentials are -0.90 V and -1.25 V, respectively. Solution of the Poisson-Boltzmann equation

gave for the reduction potential of pheophytin-*a* within the thylakoid membrane -0.58 V, which is in good agreement with the reported value of -0.61 V.

Protonation-mediated modulation of electron transfer has been supposed to explain the location of the radical site in Compound I, an intermediate of the enzymatic reaction, of two related heme peroxidases (Menyhárd and Náray-Szabó 1999). Both molecular orbital and electrostatic potential calculations suggest that the spin distribution depends on the protonation state of the proximal His-Asp-Trp triad. If the transferable proton is shifted from the Trp side chain to Asp, the radical localizes on the indole group, while if it remains on the Trp the unpaired electron transfers to the heme group. Therefore, in cytochrome C peroxidase, Trp is deprotonated in Compound I, while it is protonated and neutral in cytosolic ascorbate peroxidase. Protonation state of the proximal residues is influenced by the electrostatic effect of the protein environment that differs in these enzymes, especially in the immediate vicinity of the Asp side chain.

Solvent-Accessible Surface

Protein surfaces are quite irregular; their analysis has application in structure-based drug design, since drugs bind in protein crevices. Since the hydrogen atom positions are generally not known, heavy atoms binding hydrogens are represented by a single sphere, whose van der Waals radius is increased by 0.1 – 0.3 Å. Several surfaces can be defined around proteins, maybe most important is the solvent- (typically water-) accessible surface (Connolly 1996). This is constructed using a probe sphere, representing the solvent molecule, which is rolled around the protein surface. A typical value of its radius is 1.4 Å, which corresponds to a water molecule. The contact surface is that part of the van der Waals surface which can be touched by the probe sphere; the solvent-accessible surface is derived as the location of the center of the probe as it rolls over the van der Waals surface (see Fig. 5). The solvent-excluded

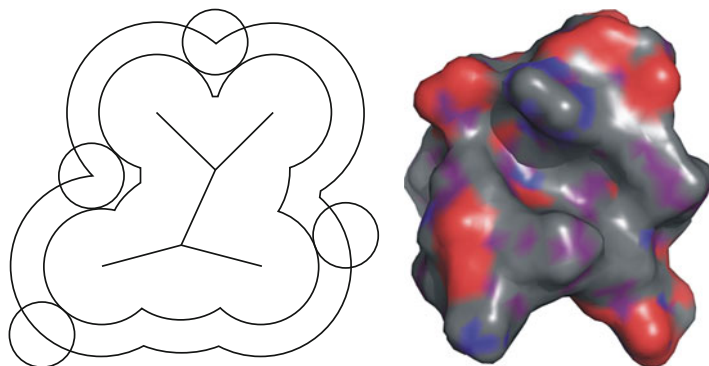

Fig. 5 *Left*: construction scheme of the solvent-accessible surface from the van der Waals surface (*inside*, obtained as a union of van der Waals spheres representing protein atoms). *Right*: solvent-accessible surface of the miniprotein Tc5b_D9E

volume of a protein is that volume of space where the probe sphere is in contact but does not collide with the atoms of the molecule.

The solvent-accessible surface area (SASA) is often used as a descriptor in quantitative structure-activity relationships (Connolly 1996). For a wide variety of molecules there is an approximate linear relation between solvation free energies and SASA. However, theoretical considerations indicate that the SASA model is incapable of accurately describing nonpolar solvation phenomena at length-scales comparable to the size of a water molecule. It is more useful at large length-scales when more extended hydrophobic surfaces are in contact with the solvent.

Dynamics

Finding the optimum structure representation of a protein is often not easy, as for larger molecules even the simplest ball-and-stick models can be too cumbersome. Thus, any simplification (neglecting H-atoms, fold representation by ribbons, etc.) of the graphics (see above) especially on a paper plot is important. It can also be misleading to use rigid representations of a flexible macromolecule. Graphical representations are based on set(s) of congruent experimental or computational restraints typically not shown in a figure. Clearly, it is inconvenient to display the electron density alone when reporting an X-ray structure or plotting all collected NOE restraints of structural models determined by NMR spectroscopy. However, the necessity to provide simple and easy-to-understand 3D structures of proteins drives scientists to neglect inherent dynamical properties of these molecules. For the very same reason, NMR spectroscopists tend to overrefine protein structures. Striving to obtain low RMSD values and to display an “X-ray-like” static structure, the reported model can be biased. The static picture often provided fails to satisfactorily explain the results of associated biological assays and is not fully compatible with ligand docking data. With the recent appearance of intrinsically unstructured proteins (IUPs) on stage, the importance of inherent dynamics is unquestionable. In other words, the absurdity of reporting only a single mean conformer is becoming evident. The present chapter gives an account of the dynamics occurring on different time scales and their interpretations and includes them in protein representation; it also gives some hints on the relevance of dynamics to biology.

Time Scales

Motions and events – especially when occurring periodically – are commonly characterized by their repetition rate, frequency, or by their time requirement. For example, our heart beats about once every second, so the heartbeat cycle, incorporating several steps such as the relaxation of the heart, opening of valves, etc., is occurring on the time scale of seconds. There are many slower events requiring more time than a second, and thus introduction of minutes, hours, days, seasons, years, etc., is easily justified. In our everyday life, people are experiencing

motions happening simultaneously but often on very different time scales. While going to work, which could take about an hour, our heartbeats about 4000 times and this daily routine is repeated nearly 300 times in a year. Proteins also have their “life,” which starts with folding after its translation, which event typically occurs on the millisecond time scale. As proteins are continually synthesized and degraded in all cells, the half-life of a protein is about an hour, varying from a few minutes to several weeks. However, protein dynamics typically comprises much faster events such as secondary structure formation (e.g., winding and unwinding of an α -helix) on the 10 ns–1 ms, or opening and closing of loops and hairpins on the 10 μ s–1 ms time scale.

The rotational diffusion correlation time, τ_c , is characteristic of any molecule as τ_c^{-1} is the average frequency of molecular tumbling in solution. The *correlation time* for short of a protein stands for the time that it takes for the molecule to reorient by 1 rad via tumbling in solution. Among others, being dependent on molecular size, τ_c is in the range of 1–10 ns for proteins in aqueous solution at normal conditions. However, there are additional interesting types of motions on an even faster time scale, such as protein backbone (1 ps–10 ns) and protein side-chain (0.1–10 ps) dynamics. Although even faster events may take place in proteins (e.g., bond vibrations studied by Fourier transform infrared or vibrational circular dichroism spectroscopy), these are less characteristic to the whole and more complicated to interpret.

NMR has long been used to decipher dynamics of biopolymers as the relaxation times and the line shapes of selected resonances are rather sensitive to chain motions. For proteins in solution, relaxation of the magnetically excited states occurs because of the above described very rapid and slower segmental motions. The somewhat localized motions are effective in causing relaxation in solution. As more than a single relaxation process often spanning a large time scale of motions (ps \leftrightarrow ms) characterizes the correlation function $G(\tau)$, it is advised to measure a number of different relaxation parameters at various magnetic fields and temperatures. During typical relaxation measurements, nuclear spins are excited by suitable radio frequency (RF) pulses, and then relaxation to equilibrium is monitored by heteronuclear single quantum coherence (HSQC) type 2D experiments. Commonly measured relaxation parameters are longitudinal (R_1), and transverse (R_2) relaxation rate constants, constraints obtained on the basis of the heteronuclear Overhauser effect ($^{15}\text{N}\{-^1\text{H}\}$ NOE) and additional cross-correlated relaxation parameters (Jarymowycz and Stome 2006).

Today, when routinely working with ^{15}N - and ^{13}C -labeled proteins, it is common to estimate the degree of main-chain mobility by using ^{15}N NMR relaxation. The associated experiments are straightforward to complete and the interpretation is relatively easy as it probes the reorientation of N–H bond vectors of protein amide bonds. Coupled primarily to fast (1 ps–10 ns) motion of the protein, heteronuclear NMR relaxation of backbone ^{15}N atoms is usually interpreted in the “model-free” framework, where it is supposed that global (τ_c) and local (τ_l) motions are uncorrelated. R_1 , R_2 , and $^{15}\text{N}\{-^1\text{H}\}$ NOE relaxation data of each ^{15}N atom are measured and subsequently fitted to the model to reconstruct spectral density

Fig. 6 Residue-specific square of the generalized order parameters, S^2 , mapped on the Tc5b miniprotein represented by its ribbon structure. Mobility is color-coded: *brown* ($S^2 < 0.4$) stands for high while *yellow* ($S^2 > 0.5$) for lower backbone NH mobility occurring on the 1 ps \leftrightarrow 10 ns time scale of motion. *Orange* represents 0.4–0.5 S^2 values (Pohl et al. unpublished)

components, $J(\omega_j)$. Results are analyzed in terms of the lowest number of sufficient secondary parameters. Local N–H motions are quantified by the square of the generalized order parameter, $0 \leq S^2 \leq 1$, reflecting the amplitude of N–H fluctuations with characteristic time constants (e.g., effective internal correlation time) (Cavanagh et al. 2007). A possible interpretation and graphical representation of the backbone dynamics is to map S^2 values on the graphical representation of the structure (cf. Fig. 6). In case of the present example, conformation of the central Trp residue, forming the hydrophobic cluster of the protein, is most restricted.

Molecular dynamics techniques allow consideration of S^2 values and NOE restraints as an ensemble property (Lindorff-Larsen et al. 2005; Richter et al. 2007). The obtained ensembles represent a more realistic view of these flexible molecules in solution than those calculated with conventional NMR structure refinement methods. The dynamically restrained ensembles occupy a considerably larger conformational space than the conventionally calculated ones and reproduce independent NMR parameters (e.g., chemical shifts) much better. The reconstruction of spectral density components, $J(\omega_j)$, from R_1 , R_2 , and $^{15}\text{N}\{-^1\text{H}\}$ NOE measurements is possible but more experiments are required (e.g., relaxation measurements at several B_0 values). Nevertheless, IUPs can also be analysed in terms of raw data as done recently, e.g., for the unstructured protease inhibitor calpastatin (Kiss et al. 2008).

Until now, we have discussed molecular motions 10 or 100 times faster than the rotational diffusion correlation time, τ_c , of the protein. As mentioned above, slower motions occurring on the microsecond-millisecond time scale are also of

significance (loop fluctuations, secondary structure reorientations, etc.). Motions of this regime are accessible to spin relaxation arising from modulation of the isotropic chemical shift of ^1H , ^{13}C , and ^{15}N spins coupled to chemical exchange. NMR can also provide information on this much slower motional regime by recording ^{13}C and ^{15}N heteronuclear ZZ-exchange, NOESY-spectroscopy, or various relaxation data (Cavanagh et al. 2007). More recently, residual dipolar couplings (RDCs) are also used for assessing dynamics of supra- τ_c time scales (Lange et al. 2008). These techniques are sensitive to protein motions or chemical kinetic processes happening on microsecond time scales (Palmer et al. 2001). Beside conformational events such as protein folding, other biochemical processes, e.g., enzyme catalysis, also occur on this time scale. It seems that information on the slower dynamics could be of great use in the future when interconversion rates and populations of states, cooperative conformational transition(s), functional aspects of enzymes, enzyme dynamics, etc., are modeled.

Dynamical Structures

Partially folded and molten globule states are of considerable interest and can be characterized by NMR and additional spectroscopic techniques. The molten globule state of a protein is folded to a given extent; it has native-like secondary structural elements and comprises a native-like 3D structure. The main difference from the native state is the absence of important side-chain/side-chain interactions. This intermediate structure can be stabilized under selected conditions making possible to obtain structural information. Proteins studied in their molten globule form are characterized as ensembles of a diverse set of interchanging conformers (Gspöner et al. 2006). The study of molten globule states by X-ray diffraction is often impossible and can be difficult using NMR techniques. However, from simple line shape and H/D exchange analysis obtained by NMR spectroscopy, measurement of the hydrodynamic radius, and deciphering stable (or residual) secondary structural subunits (by, e.g., circular dichroism or fluorescence spectroscopy), molten globule states can be appropriately characterized (Redfield 2004). Thus, protein modeling can be possible even in the molten globule state.

Dynamics of Interactions

Protein-protein and protein-ligand interactions have two apparently contradicting aspects. As these molecules are interacting 3D objects getting in contact with each other, partners should have complementary shapes of considerable stiffness over time (cf. section “[Ligand Binding](#)”). However, several phenomena cannot be understood without considering the inherent flexibility and plasticity of proteins. Thus, the shape of a protein should be kept rigid to enhance selectivity, but it is also dynamically changing upon binding of a partner molecule. Thus, proteins should both have a well-defined shape and the ability to change it.

Although the rigid lock-and-key model has been revisited in the past decades, one of the last standing cases is that of the so-called canonical protease inhibitors. Proteases have the task to cut other proteins into pieces for various reasons such as: digestion, activation, degradation, etc. Thus, they should be under severe control both in space, time, and concentration, often manifested by fine-tuned canonical inhibitors. Upon binding, they are not expected to influence any conformational changes around the binding site of the protease, as they have to bind in a substrate-like manner to inhibit activity. Recently, fast (ps-ns) backbone dynamics of some canonical inhibitors was measured and found that in contrast to the expectations they are quite mobile. In fact, these 35–40-residues-long inhibitor proteins stabilized by three disulfide bonds are as mobile as their protease binding region. Thus, even for canonical inhibitors, the classical lock-and-key model cannot remain valid. It was shown that the interaction cannot be properly described without taking into account the internal mobility of the partner proteins. Interestingly enough, the presence of flexible rather than rigid keys removes the necessity of an entirely complementary shape of the interacting partners. In fact, “keys” can gently adapt to the locks, which are slightly different from case to case (Fodor et al. 2005). Moreover, conformational changes or flexibility of partners was found to be synchronized and also encoded (Szenthe et al. 2004). This might even mean that the lock-and-key concept, proven utterly useful in the early days of biochemistry, should be interpreted dynamically and replaced by the more general hand-and-a-glove analogy (cf. section “[Ligand Binding](#)”) (Goh et al. 2004).

Interactions

Interaction of proteins with water, drugs, and other biological macromolecules plays an essential role in physiological processes. Owing to the very high number of atoms in a protein, in general, such interactions cannot be handled at the atomic level explicitly; simplified, still reliable models are needed.

Protein Hydration

Hydration of proteins is especially important in determining their properties (Makarov et al. 2002; Chaplin 2015). For example, protein activity is practically zero in the absence of hydrating water. The first hydration shell around proteins is ordered; surface water forms hydrogen-bonded patterns and positively charged surface side chains also take part in stabilization. The first hydration shell is denser by about 10–20 % than bulk water and this is probably responsible for keeping the molecules sufficiently separated so that they remain in solution.

Proteins are flexible in solution, which involves a variety of hydration states, absent in the crystal or in nonaqueous environments. Hydration also affects redox potentials. The biological activity of proteins appears to depend on the formation of a hydrogen-bonded network connecting the protein surface and water clusters.

Water molecules can form a bridge between the carbonyl oxygen atoms and amide protons of different peptide residues to stabilize protein-ligand and protein-protein complexes. Enzyme-substrate contact may be controlled by water molecules located in the protein environment, and one or more water molecules may be part of the catalytic machinery of enzymes. These water molecules act as proton donors or acceptors (or both) during reaction.

Computer modeling of protein hydration follows essentially two ways. One is to treat all water molecules in the hydration sphere explicitly and apply an appropriate force field (cf. section “[Molecular Mechanics](#)”) in molecular mechanics or molecular dynamics calculations. As an example, we present results of molecular dynamics calculations on aquaporin, a membrane protein facilitating the transport of water and other small solutes across biological membranes (Hub et al. 2009). Simulation was carried out with full electrostatics in a periodic simulation box containing the aquaglyceroporin tetramer, embedded within a lipid bilayer surrounded by water. The whole model consists of about 100,000 explicit atoms. The mechanism of water permeation through aquaporin was described, and it was found that protons are strictly excluded from the channel by a large electrostatic barrier. Both protein electrostatic field and desolvation contributes to this effect. Permeation of apolar molecules like carbon dioxide is hindered by a high energy barrier; therefore, this process can only be expected to take place in membranes with low intrinsic gas permeability. Analysis of MD simulations indicated that a narrowing region, containing aromatic and arginine side chains, filters uncharged solutes. Here, selectivity is controlled by the hydrophobic effect and steric restraints. As we see, simulation provides a specific tool to understand membrane permeation in atomic detail and to recognize its basic factors. No experimental means is available at present to provide such a detailed picture of the process.

Another way to consider protein hydration is to extend the concept of the solvent-accessible surface (cf. section “[Solvent-Accessible Surface](#)”) applying continuum dielectrics models. For example, combination of the electrostatic and an appropriate hydrophobic potential, accounting for hydrophilic and hydrophobic interactions, respectively, may be used as a solvation function, which considerably increases the reliability of protein structure predictions (Lin et al. 2007).

Ligand Binding

Binding of small-molecule ligands, such as drugs, vitamins, flavors, or pheromones, takes place in crevices of the protein surface. In a broader sense, ligand binding means the formation of a stable complex between a host and a guest (molecular recognition (Harmat and Náray-Szabó 2009)), and it can be best understood in terms of the *lock-and-key* analogy. Under lock we mean here the protein crevice, while the key stands for a small molecule or a fragment of a larger one, fully or partly embedded in the crevice. In general, we suppose that both lock and key are rigid; however, in many cases they are flexible and adopt their final shapes only upon binding. This process is best illustrated by the *hand-and-a-glove* analogy. If the macromolecular

crevice undergoes conformational changes in order to provide the optimal shape for embedding the relatively rigid guest molecule, we speak about induced fit. Alternatively, the guest molecules may adopt different conformations, some of which are appropriate for binding. This alternative is called conformational selection.

Steric fit means that interacting atoms may not interpenetrate beyond their van der Waals spheres and, simultaneously, the host crevice should be filled as perfectly as possible reducing the empty space between host and guest atoms to a minimum. Electrostatic fit refers to the maximization of ionic, hydrogen bonding and other types of polar interaction and is well accounted for by the molecular electrostatic potential provided by the host acting on a charge distribution representing the guest. The term hydrophobic fit refers to the association trend between apolar groups in the biophase. This may be explained either in terms of density differences between water and the host, or macromolecular crowding, an entropy effect reducing water-accessible surfaces of dissolved molecules upon association, in order to avoid unfavorable perturbation of water structure around the separated solutes.

The accurate prediction of the binding mode and affinity of a small molecule to its putative receptor is crucial for successful drug design and optimization; therefore, a variety of computer methods have been developed for that. *Docking* is an optimization method which predicts the preferred orientation of the ligand bound to the protein and forming a stable complex. It may be also used to predict the binding affinity using energy terms or an appropriately defined scoring function. Essentially three types of docking procedures are available (Mohan et al. 2005; Brás et al. 2014).

Rigid body docking assumes both the receptor and the small molecule to be rigid. *Flexible ligand docking* means that the receptor crevice is held fixed, but the ligand is treated as flexible (conformational selection, see above); this is the most commonly used method. In *flexible docking* both partners are considered to be able to change conformation easily. Following another classification, either a matching technique is used, which describes the protein crevice and the ligand as complementary surfaces, or the actual docking process is simulated and the ligand-protein interaction energies are calculated (Guvencs and MacKerrell 2009). Furthermore, modeling the role of the aqueous solvent in ligand-protein interactions is one of the key components. Three main computational techniques have been developed to model hydration: free energy methods, ligand-protein docking and scoring, and the explicit inclusion of tightly bound water molecules in modeling (Mancera 2007).

Shape complementarity methods describe the protein and ligand in terms of complementary molecular surfaces. The host and guest protein surfaces are defined in terms of the SASA (cf. section “[Solvent-Accessible Surface](#)”) and the matching surface description, respectively. The complementarity between these two surfaces is defined as the shape matching, which may help finding the appropriate orientation of the ligand in the crevice. These methods are typically fast and robust; however, in general, they cannot model the dynamic changes in the conformation of the protein-ligand complex. They can scan through several thousand guest molecules in some seconds and figure out which of them can bind at the crevice.

Fig. 7 The thermodynamic cycle used to compute solvation (*left*) and protein binding (*right*) free energies. *L*: ligand with substituents A or B, *P*: protein

Differences in binding energies of similar ligands, A and B, differing only by a few atoms, can be precisely calculated by the free-energy perturbation method (see Fig. 7). A thermodynamic cycle is constructed, where the horizontal free energies are determined experimentally, since they are difficult to calculate. The vertical free energies are calculated by simulation based on a force field or a continuum electrostatic model. ΔG_{solv} corresponds to the hydration energy change mutating A into B in water, while ΔG_{prot} is the binding energy change upon replacing A by B in the binding pocket. Since the thermodynamic cycle is closed and the free energy is a state function, we may write: $\Delta\Delta G_{\text{bind}}(A - B) = \Delta G_2 - \Delta G_1 = \Delta G_{\text{prot}} - \Delta G_{\text{solv}}$, the difference can be obtained from calculated quantities. Instead of simulating the horizontal physical binding processes, which is quite uncertain, the nonphysical transformations represented by the vertical reactions can be calculated relatively easily and precisely. An example for the successful application of the free-energy perturbation method is the calculation of the absolute binding free energy of benzamidine to trypsin, which is found to be $-6.78 \text{ kcal} \cdot \text{mol}^{-1}$ (Jiao et al. 2008), while the experimental binding free energy ranges from 6.3 to 7.3 $\text{kcal} \cdot \text{mol}^{-1}$. The calculated binding energy of a close analogue, diazamidine is weaker than that of benzamidine by $1.21 \text{ kcal} \cdot \text{mol}^{-1}$, agreeing well with the experimental value of $1.59 \text{ kcal} \cdot \text{mol}^{-1}$.

Docking by simulation is a much more complicated process. In this approach, the protein and the ligand are separated by a physical distance, and the guest finds its position in the crevice after a certain readjustment in the conformational space. This refers to translations, rotations, and conformational changes. Each of these induces an energy change of the system, which is calculated on the basis of a force field or a scoring function. Clearly, this method is much more sophisticated; it incorporates ligand flexibility, which is, in general, absent from complementarity techniques (see Zsoldos et al. 2007; Bras et al. 2014 and references therein). A disadvantage is that it takes much longer time to evaluate the optimal binding arrangement, since a rather large energy landscape has to be explored.

Docking is most commonly used in the field of drug design to quickly screen large databases of potential drugs *in silico* and to identify molecules that are likely to bind to a certain protein target (virtual screening). In lead optimization, docking may predict how a ligand binds to a protein crevice, which information may be used to design more potent and selective analogues. Several computer platforms are available for efficient and relatively fast docking, e.g., AUTODOCK (<http://autodock.scripps.edu/>).

Protein-Protein Interactions

Proteins often exert their function through interaction with other ones, forming complexes, e.g., in the ribosome or in cell membranes, during immune response or enzyme catalysis. Complex structures are essential in understanding action; therefore, beyond experimental techniques, like X-ray diffraction, electron microscopy, or mass spectrometry, *in silico* methods also are of great interest. However, due to a number of practical difficulties, it seems unlikely that solving the structures of protein complexes will become routine in the near future. Hence, computational docking techniques play an important role (Ritchie 2008).

The simplest protein-protein docking methods are based on the complementarity principle and focus on the properties of the contact surface. To do this, interaction patterns, observed in protein-protein complexes of known structure, have to be analysed. An example is based on shape and electrostatic complementarity (Fig. 8), where spatial matching of surfaces with complementary electrostatic potential patterns can be observed (Harmat and Náray-Szabó 2009). It can be supposed that much less improper orientations of the interacting partners would be obtained if one could first identify the interaction surfaces on them. For many (e.g., antibody-antigen or most enzyme-inhibitor) interactions, the binding site is known on one or more of the proteins to be docked. In other cases, a binding site may be strongly suggested by mutagenic or phylogenetic evidence.

Although the properties of protein-protein interfaces have been analysed in considerable detail, it remains a significant challenge to reliably predict the loca-

Fig. 8 Steric and electrostatic complementarity between C1 inhibitor (*left*, the docked heparin disaccharides are shown in *green*) and target proteases, factor XIa (*top right*) and C1s (*bottom right*). *Blue*, positive, *red*, negative electrostatic potential. *Yellow* arrows indicate the presumed position of the reactive center loop of C1 inhibitor in the complex. *Gray* arrows indicate that one of the interacting molecules must be rotated by 180° in order to get in the right position for overlap with the other at the contact surface (Figure by V. Harmat, Budapest)

tions of protein-protein interaction surfaces using computational techniques alone (Porollo and Meller 2007). Machine learning techniques are being used to develop automated protein-protein interface prediction software. These systems are typically trained using various combinations of, e.g., buried surface areas, desolvation and electrostatic interaction energies, hydrophobicity scores, and residue conservation scores.

Like in case of protein-ligand docking (cf. section “[Ligand Binding](#)”), for protein-protein docking we have essentially two alternatives (Ehrlich and Wade 2001; Vakser 2014). In the rigid-body approach interacting partners do not relax, their structures remain unchanged during complex formation. Quite often substantial conformational change occurs within the components as a result of their interaction. In this case a soft docking technique has to be applied, where conformational relaxation is allowed.

Docking involves two main steps: (i) generating a set of reliable configurations and (ii) distinguishing correct configurations from those not appropriate for complex formation. Docking algorithms may start with a rigid body representation of the protein, obtained by projecting interacting partners onto a three-dimensional grid and by distinguishing grid cells according to whether they are near or intersect the protein surface or are deeply buried within the core of the protein. A docking search is then performed by scoring the degree of overlap between pairs of grids in different relative orientations. After making exclusions based on experimental evidence or steric conflict, the remaining structures must be sampled by appropriately scoring each configuration. In the geometric hashing approach, each protein surface is first preprocessed to give a list of a few hundred critical points, which are then compared in a special algorithm to generate a relatively small number of trial docking orientations for grid scoring (Fischer et al. 1995).

An automated algorithm was developed to identify molecular surface complementarity (Katchalski-Katzir et al. 1992). It involves a digital representation of the molecules distinguishing between surface and interior, calculates a correlation function assessing the degree of surface overlap and penetration upon displacement using Fourier transform, and scans relative orientations in three dimensions. The algorithm estimates the degree of geometric match between the surfaces of the interacting molecules. The procedure is equivalent to a six-dimensional search, but it is much faster. The computation time depends only moderately on molecular size. Such methods can be used to evaluate very large numbers of configurations; however, this advantage is lost if conformational changes are also considered. Furthermore, it is possible to construct reasonable convolution-like scoring functions combining both steric and electrostatic fit.

Conformational changes can be considered in Monte Carlo methods, where an initial configuration is refined by taking random steps which are accepted or rejected based on their induced improvement in score, until a certain number of steps have been tried (Gray et al. 2003). It is assumed that convergence to the best structure should occur from a large class of initial configurations, only one of which needs to be accepted. Because of the difficulty of finding a scoring function which is highly discriminating and also converges to the correct configuration, various

refinements have been proposed. Monte Carlo methods are not guaranteed to search exhaustively, so that the best configuration may be missed even using a scoring function which would in theory identify it.

To find a scoring function, which forms an appropriate basis for selecting the best configuration, studies should be carried out on a standard benchmark of protein-protein interaction cases. For example, a benchmark of several dozens of known protein-protein complexes has been developed for testing docking methods (Mintseris et al. 2005). The set is chosen to cover a wide range of interaction (e.g., enzyme-inhibitor, antigen-antibody) types and to avoid repetition. Scoring functions are assessed on the rank they assign to the best structure and on the proportion of the benchmark cases for which they provide an acceptable result. Scores may be based on residue contacts, shape complementarity, interaction energies estimated by a force field, or on phylogenetic considerations. Often hybrid scores are created by combining one or more categories above.

Although solvation and desolvation effects are crucial in complex formation, most docking algorithms do not take into account the presence of water molecules near the protein-protein interface. An exception is the work by Van Dijk and Bonvin (2006).

In the following, we give an example for the successful application of molecular dynamics to a special problem, where impairing the flexibility of a small protein leads to severe consequences. A rare kidney disease, nephrotic syndrome type 2, is due to the pathogenicity of an allele encoding the R229Q polymorph variant of podocin, a small protein, which exists in the podocytes of the kidney, key members of its filtration system (Tory et al. 2014). Malfunction of the polymorph variant claiming the life of young patients is caused by the mutation it carries, but only under special circumstances. If both parents carry the polymorph – R229Q – variant, they will not necessarily have an unhealthy child. Only the polymorphism in association with a certain set of missense mutations will be detrimental. It was proposed that the R229Q mutation must impair the ability of podocin to dimerize: paired combination of missense mutations on one monomer of podocin and the polymorph mutation on the other must lead to nonfunctional dimers.

In a computational study, homology models of monomers of the wild-type and the polymorph variant of podocin were subjected to a 40 ns MD simulation. Podocin monomers contain a globular head domain and a long, helical tail. The mutated R229 residue is located in the head-domain. It turns inside and is stabilized by at least two H-bonds formed with negatively charged amino acids of the head-domain (E233, E237, and D244). In the R229Q polymorph monomer, where Q229 is too short to allow these contacts, E233 and E237 flip toward the tail domain and form H-bonds with positively charged amino acids of it (Fig. 9).

While the domains themselves are unchanged by the R229Q mutation, interactions between the head and tail domains restrict their hinge-like movement, and strongly affect the dynamics of the monomer (Fig. 10).

All the associated mutations that lead to unhealthy dimer formation when paired with the R229Q mutant are found in the helical tail region of the protein; thus, it was

Fig. 9 (a). Structure of the native podocin monomer. (b). Interactions of the R229 residue of the wild-type protein with negatively charged groups of the head domain. (c). Interactions of the Q229 residue of the polymorph variant. Note that a new link is formed between the head and tail domains

Fig. 10 Difference in the flexibility of the wild-type protein (*green*) and the polymorph (*cyan*) monomers. All clusters of more than 0.1 % population of the last 10 ns of our simulations are shown, with their head domains superimposed

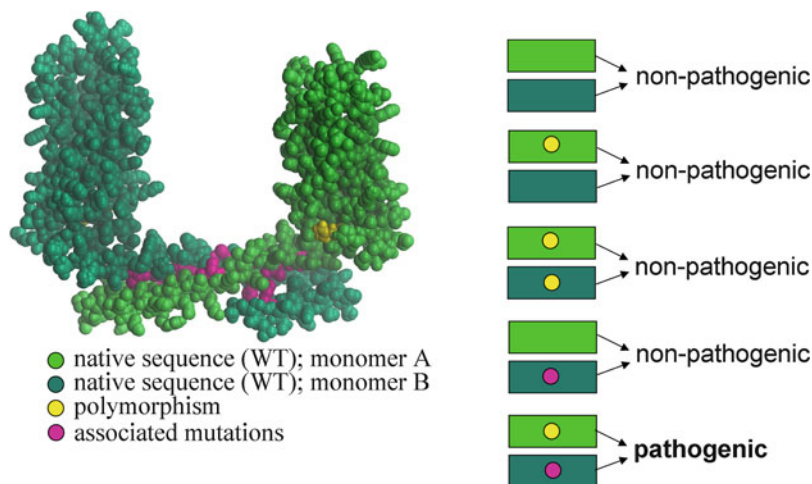

Fig. 11 Wild-type podocin dimer formation. Residue 229 is shown in *yellow*, mutation sites that lead to pathogenic dimer formation when faced with the polymorph monomer are shown in *magenta*. *WT* wild type

suggested that this must be the primary site of dimerization. A next set of 100 ns MD simulations involved dimer pairs, both nonpathogenic and pathogenic combinations (Fig. 11).

Interestingly, it was found that the loss of flexibility as a result of the R229Q mutation leads to formation of distorted dimers when pairing up with monomers carrying missense mutations on the helical tail region of podocin. On the other hand, it seems that the flexibility of the wild-type monomer allows for correction of small misfits in the dimerization process; thus, paired up with the same tail-mutated variants, the resulting dimers will not differ greatly from the wild-type dimer structure (Fig. 12). It was therefore shown that an inheritance pattern that defies the laws of Mendel could be explained by the impaired dimer-forming capacity of the R229Q polymorph, which is the result of the change of its overall flexibility, caused by a single mutation. Molecular dynamics simulations proved to be an ideal method to follow such changes.

Enzyme Mechanisms

Catalysis is a molecular transformation where the rate of the chemical reaction increases through the interaction of the reacting partners with the catalyst without changing the equilibrium constant. Accordingly, the catalyst modifies the potential surface of the noncatalyzed reaction and reduces the activation barrier. In case of

Fig. 12 Structure of nonpathogenic and pathogenic dimers of podocin. (*Left*) nonpathogenic dimers (colored by indifferent shades of *blue*: WT/R229Q, R229Q/R229Q, A284V/WT) superimposed on the WT/WT dimer (shown in *green*). (*Right*) pathogenic dimers (colored indifferent shades of *red*: A284V/A284V, A284V/R229Q, A297V/R229Q) superimposed on the WT/WT dimer (shown in *green*). *WT* wild type

enzyme catalysis, the reference is the activation energy in aqueous solution, where the reaction mechanism may considerably differ from that in the enzyme. The enzymatic process is especially effective, since rate increase may be as large as 10^{10} -fold in some cases. Protein modeling plays a crucial role in the understanding of the basis of enzymatic rate acceleration since experiments do not provide direct information on details, e.g., potential transition-state stabilization by the protein environment (Náray-Szabó et al. 1997, 2013).

Entropy effects may play an important role, though the actual advantage of their contribution to rate acceleration is still unresolved. This is partially due to the difficulties in obtaining estimates of entropic effects by modeling. Quite often, it is argued that the binding of reacting partners to an enzyme active site freezes their motion reducing the entropy contributing to the activation energy. However, it has been shown that this effect is much smaller than thought, because many of the movements that are free in the initial state of the reference solution reaction are also free in the transition state of the enzymatic process. The binding to the enzyme does not completely freeze the motion of the reacting fragments so that the entropy change during reaction is not zero. Furthermore, the binding entropy in the enzyme active site is not necessarily equal to the entropy change in the reference solution reaction (Warshel 2003).

Many enzymes make use of general acid or base catalysis, when a reaction step is modified and proton transfer is mediated by an acidic or basic side chain. This reduces the free energy of the proton transfer step and accelerates the reaction. For proton transfer, it may be supposed that rate acceleration is a consequence of the reduced distance between proton donor and proton acceptor, which is known to

determine the activation energy. However, it has been shown that both in enzymes and the reference reaction in water H-bond distances are similar. General acid/base catalysis plays a role in enzymes by reducing the free energy of the proton transfer step using a different reaction path with different reactants, which is, however, not a true catalytic effect. Simulation studies have indicated that special effects such as desolvation, low-barrier hydrogen bonds, steric strain, or entropy traps do not account for the major part of the catalytic power of enzymes (Warshel 2003).

Molecular modeling and experiments provide more and more evidence for the crucial role of protein electrostatics in enzymatic rate acceleration. Enzymes, acting as a “supersolvent,” can strongly stabilize polar structures, like ion pairs or the $(- + -)$ charge distribution located in their active sites. Stabilization in enzymes is stronger than in water, since preorganized and fixed protein dipoles are almost optimally oriented at the active site. The enzyme, therefore, provides a preoriented environment that stabilizes the transition state of the reaction. In contrary, water dipoles are distributed randomly and have to reorient in order to stabilize transition states. Reduction of the reorganization free energy in the enzyme is due to its folding into its final configuration, which precedes the catalytic process and takes place independently, during protein synthesis.

This contribution of the protein reorganization rather than the enzyme-substrate interaction is the most important factor in enzyme catalysis (Warshel 2003). In other words, enzymes have evolved to bind reacting groups in the correct position for reaction with a very high accuracy.

Because of the extreme importance of the protein environment in determining enzymatic reaction rates, the use of extended models and QM/MM computations methods is a must (cf. section “[Molecular Mechanics](#)”). Until now, a wide variety of QM/MM methods are available, which can be applied to the calculations on various enzyme reactions; it is therefore not easy to make a ranking. It seems, however, that basic features of most processes can be described by practically all types of methods, if a large enough number of protein atoms and surrounding water molecules is considered explicitly or if using a continuum approach combined with a relatively large model of the active site.

In the following we discuss a specific example, the catalytic mechanism of enzymatic phosphoryl transfer (Lasilla et al. 2011). This reaction plays a crucial role in most cellular functions, as DNA replication, signal transduction, metabolism, and transcription; it is involved in several enzymatic processes. Kinases catalyze the transfer of γ -phosphate from ATP to other molecules; mutases transfer phosphoryl groups between two atoms of the same molecule. Phosphatases accelerate the removal of phosphoryl groups, while polymerases catalyze the synthesis of nucleic acid polymers. Endonucleases are able to cleave the phosphodiester bond by transferring a phosphoryl group from a bridging oxygen atom to an activated water molecule.

It is generally claimed that phosphoryl transfer may follow basically two pathways (see Fig. 13). In the dissociative mechanism a trigonal metaphosphate intermediate is formed (Xu and Guo 2008), while the associative mechanism involves a relatively stable, trigonal bipyramidal intermediate (Lahiri et al. 2003).

Fig. 13 Two pathways of the phosphoryl transfer reaction. *Top*: dissociative, *bottom*: associative. X and Y denote an enzyme or some functional group

Note that an intermediate refers to a local energy minimum on the reaction path. However, a third option has to be mentioned as well. This is the classical S_N2 mechanism with a trigonal bipyramidal transition state, referring to a maximum on the reaction path (Bernardi et al. 2002). The preferred pathway is determined by the nature of the phosphorus electrophile, the nucleophile, and the reaction medium (solvent or enzyme active site). Earlier computer simulations indicate that associative and dissociative mechanisms are similarly favored in the aqueous phase (Florian and Warshel 1998), and also calculations for different enzymes support either dissociative or associative pathways depending on a variety of factors (Klahn et al. 2006).

It is not easy to propose a mechanism on the basis of experimental evidence alone, since measured data provide in most cases indirect information on the energy and structure of the transition-state complex. Mildvan (1997) evaluated possible mechanisms by using the distances between the attacking and leaving axial oxygen atoms and phosphorus in the trigonal bipyramidal state to decide between associative or dissociative character. These distances may be considered as a measure of the strength of the P–O bond. The Mildvan criterion may be presented as an example for the unclear information often inherent in experiment. Based on X-ray diffraction experiments, Lahiri et al. (2003) reported on a pentacovalent phosphorane intermediate in the phosphoryl transfer reaction catalyzed by β -phosphoglucomutase, which refers to an associative mechanism. However, the associative character, as calculated from experimental bond distances in the intermediate, is quite weak (0.2), while for a truly associative reaction it should be near 1.0 (Berente et al. 2007). Another example of a trigonal bipyramidal intermediate, as observed by X-ray diffraction experiments, has been published by Barabas et al. (2004).

In general, the character of the transition state (TS) changes from associative to dissociative upon decrease in the pK_a of the leaving group, but the potential surface is very flat; therefore, careful calculations have to be performed in each special case in order to get reliable information on the associative character of the reaction

(Florián and Warshel 1998). Recently calculations have been performed on a variety of enzyme reactions where the associative mechanism seems to be supported; see, e.g., Elsasser et al. (2009).

Enzymatic phosphoryl transfer reaction provides an example where quantum mechanical calculations are irreplaceable in the precise description of the mechanism. The process is very complicated; however, up-to-date methods are available for sophisticated studies, and it can be anticipated that in the not too far future, mechanistic studies will be considered even by experimentalists as very useful in understanding subtle details.

Conclusion and Outlook

Molecules are not “seen” like macroscopic or microscopic objects, which provide a picture in our eyes by using visible light and human or artificial lens(es). As molecules are submicroscopic, they are too small to be visible even under the most powerful optical microscope. Although special optical microscopy allows seeing even cell cycles, the entire universe of atoms and molecules remains hidden for such a direct observation scheme. We may obtain “pictures” even on viruses having the size of 10–50 nm by transmission electron microscopy via electrons passing through an extensively prepared sample. Scanning tunneling microscopy and atomic force microscopy can improve resolution; however, neither of these techniques enable us to investigate molecules at an atomic level, especially not in solution. Accordingly, we must use indirect methods for visualization, by which we collect information on various physical properties related to the spatial position of atoms within a molecule. An ideal scenario is when a representation, or in other words a model, of a molecule on the screen is extracted and subsequently reconstructed from a suitable set of experimental data typically processed and evaluated by the computer.

Acknowledgments We are indebted to our colleagues Dr. Z. Gáspári, Dr. V. Harmat, and Ms. P. Rovó for important remarks on the manuscript and for providing most of the figures.

Abstract

The present advanced state of the computer hardware offers superb opportunities for further explorations of protein structure and dynamics. Sound and well-established theoretical models are successfully used for searching new biochemical phenomena, correlations, and protein properties. In this chapter, the fast-growing field of computer simulations of protein dynamics is panoramically presented. The principles of currently used computational methods are briefly outlined, and representative examples of their recent advanced applications are given. In particular protein folding studies, intrinsically disordered proteins, protein-drug interactions, ligand transport phenomena, ion channel activity, molecular machine mechanics, origins of molecular diseases, and simulations of single-molecule AFM experiments are addressed. Special attention is devoted to emerging methods of enhanced molecular dynamics.

Introduction

Proteins perform their functions through selective intermolecular interactions. These forces are exerted on external objects such as other proteins, inhibitors, nucleic acids, membranes, signal molecules, etc. The strength and temporal evolution of interactions do depend on proteins' amino acid composition and a particular spatial arrangement of these basic building blocks. Non-native conformations usually prevent proteins from performing their "natural" tasks. The definition of what is "a protein conformation" is somewhat blurry, since proteins are flexible molecules. The energy landscapes of such large systems are very rich, complex, and highly multidimensional. In other words, one may expect that in its native, functional form, a protein adopts not only one particular conformation, but rather numerous, closely lying related structures may participate in a given chemical or biological process. Quite often large-scale molecular motions are required for performing a given protein function (Bahar et al. 2010; van Oijen 2007). For example, hemoglobin increases its oxygen-binding capability via famous allosteric effects (Tekpinar and Zheng 2013), the enzyme polymerase augmented by PCNA DNA clamp (Rydzewski et al. 2015b) processes 1,000 base pairs per second during DNA replication, and G protein-coupled opioid receptor is activated by subtle conformational changes (Huang et al. 2015).

Capturing protein dynamical structures at work is not an easy task (Russel et al. 2009). Numerous experimental techniques have been developed: spectroscopy of all sorts, NMR, EPR, and even time-dependent X-ray crystallography. The computer era brought an excellent additional tool for studies of protein structures and dynamics. Since the pioneering ideas of A. Warshel et al. (1970) and the first application work by J.A. McCammon et al. (1977), empirical force fields have been used thousands of times to describe computationally proteins' dynamics and their interactions. At this point, one has to note that currently, quantum mechanics is the only physical theory having appropriate rigor for the description of molecular

systems and their interactions. Unfortunately, *ab initio* (or force field free) molecular dynamics (MD) simulations of proteins are still in their childhood and far from being available for every research group (Dal Peraro et al. 2007) (Rydzewski and Nowak, chapter “► [Molecular Dynamics in Excited State](#)”). On the other hand, a classical approximation, where individual atoms (or even groups of atoms in the so-called coarse-grained MD) are replaced by model material points interacting through analytically predetermined potentials, offers a very promising alternative for tedious, expensive, and difficult experimental studies of proteins. Computer modeling of protein structure and dynamics is a currently mature field of science (Karplus and McCammon 2002). Its role has been recognized by the 2013 Nobel Prize in chemistry awarded to Michael Levitt (2014), Martin Karplus (2014), and Arieh Warshel (2014) for “taking the chemical experiment into cyberspace” (Staffan Normark, Permanent Secretary of the Royal Swedish Academy of Sciences).

Why do we use computational molecular mechanics and/or molecular dynamics methods for studies of structure and protein dynamics? Here is a partial list of good reasons for their popularity and widespread applications:

1. Give models for mechanistic interpretation of protein functions.
2. Help to connect a protein structure and dynamics with its functions.
3. Provide time-resolved data on protein structures.
4. Generate visual models easy to manipulate (great pictures in papers).
5. Promise to determine intra- and intermolecular interactions quantitatively.
6. Help to discover subtle functional differences in protein architectures.
7. Are useful in drug design.
8. Provide an easy tool to study protein mutants.
9. Allow for checking catalytic properties.
10. Are easy to verify, extend, or modify.
11. Bring information on thermodynamics.
12. Provide data on mechanical strength.
13. Direct comparisons with experimental data such as NMR or X-ray structures, single-molecule AFM spectroscopy, etc. are possible.
14. Have a strong impact on biochemistry, biology, biophysics, and bioinformatics.
15. Cheap computers are available everywhere.
16. Good quality, free software is accessible via WWW.
17. A relatively short “learning curve.”
18. Allow for computer experiments in fully controlled conditions.
19. Provide “molecular big data” suitable for data mining.
20. The field of computer modeling is well established and has many experts, conferences, specialized journals, and university courses around.
21. Supercomputer power doubling every 18 months.
22. Strong support from the industry and governments, biopharma sector, medical agencies, computer makers, etc.

And, of course, the last but not the least reason for the great popularity of computational modeling of proteins is just human curiosity and interest in solving

scientific problems. For example, solving the protein folding problem is still the great challenge to scientific community. We know over 100 million protein sequences, but only some 100,000 3-D structures are available in the Protein Data Bank (as of year 2015). It is commonly believed that finding a realistic and sturdy method of converting 1-D protein sequence into 3-D structure should bring another Nobel Prize to the authors of such a discovery.

The purpose of this chapter is twofold: (a) we want to draw attention to major review papers and resources regarding studies of molecular dynamics of proteins and (b) we want to point out the most representative, current applications of MD methods which have been published in recent years.

Formalism of Molecular Mechanics and Molecular Dynamics Methods: A Short Presentation

In order to describe atomistic level chemical phenomena, one has to use quantum mechanics (Dahl 2001; Greenberger et al. 2009). This theory applied to molecules brought “an explosion” of quantum chemistry and together with the computer revolution has changed the way the chemistry is done in the twenty-first century. Despite great successes of quantum chemistry, this approach is still limited to small- or medium-size systems, having 20–300 atoms (Piela 2014). Proteins usually are composed of thousands of atoms; moreover, their realistic models should take into account a substantial number of water molecules. Thus, classical models of proteins are necessary. In such a simplified approach, electrons are neglected, quantum bonds are replaced by effective analytical potentials, and instead of atoms, we have carefully designed model balls. The motion of model atoms is treated in a classical way: validity of Newton equations of motion is assumed in the proteins’ nanoworld. Structures of molecules may be optimized using classical force fields and methods of molecular modeling; the time evolution of a position of each individual atom may be followed for a reasonably long period of time using the molecular dynamics formalism, but a possibility of forming/breaking chemical bonds is in classical simulations basically lost. Thus, the real chemistry, based on chemical reactions, needs the quantum theory. Nevertheless, the classical modeling provides so many useful hints into the nature of biomolecules that computational modeling of protein structure and dynamics is a fundamental part of the research in all major laboratories. Current technology allows for performing at least 35-ns classical MD simulations for 10,000,000 atoms in one computer day (Andoh et al. 2013).

Some History

The Electronic Numerical Integrator And Computer (ENIAC) was built at the University of Pennsylvania in Philadelphia in 1945. It weighed more than 27,000 kg (60,000 lb) and contained more than 18,000 vacuum tubes. It is regarded as the

first successful digital computer. Already in 1955, E. Fermi, J. Pasta, and S. Ulam calculated numerically the motions of a chain of coupled anharmonic oscillators. This is probably the first example that molecular dynamics simulation suggested analytical solution for the problem studied. In 1957, Alder and Wainwright studied dynamics of a system of hard, two-dimensional discs (Alder and Wainwright 1957). In 1971, Rahman and Stillinger used a more realistic Lennard-Jones interaction potential to study motions in water (Rahman and Stillinger 1971). The duration of those simulations was about 10 ps.

The concept of interaction force field has been applied to proteins by S. Lifson in 1969. This model was aimed at facilitating refinement process of protein structure determination based on X-ray diffraction experiments (Levitt and Lifson 1969). The role of quantum electronic effects in enzymatic reactions has been recognized later as well in the form of QM/MM approach (Warshel and Levitt 1976). Current force fields – sets of analytical formulas together with carefully chosen parameters – are based on infrared spectra, geometrical information from amide crystals, and quantum mechanical calculations. The famous paper by McCammon et al. (1977) on BPTI dynamics may be regarded as the first atomistic MD modeling of a protein. Interesting stories on the history and development of molecular dynamics simulation science may be found in the review published by M. Karplus (2003) and the article by W. Jorgensen (2013). At the end of 2015 in the PubMed Bibliographics database, nearly 20,000 papers were listed under the query “molecular dynamics simulation protein.” This number has doubled since 2011. The area of computational chemistry and biology is very strong and is fast growing.

On the Origin of Potential Energy Surface (PES) Concept

As we know, on the grounds of quantum mechanics, the complete information of the molecular system may be obtained from the wave function $|\Phi\rangle$, which is a solution of the Schrodinger equation:

$$\hat{H} |\Phi\rangle = \varepsilon |\Phi\rangle$$

where Hamiltonian \hat{H} contains both electron (i,j) and nuclear (A,B) degrees of freedom (in atomic units):

$$\begin{aligned} \hat{H} = & -\sum_{i=1}^N \frac{1}{2} \nabla_i^2 - \sum_{A=1}^M \frac{1}{2M_A} \nabla_A^2 & \text{atomic units (a.u.):} \\ & - \sum_{i=1}^N \sum_{j=1}^M \frac{Z_A}{r_{iA}} + \sum_{i=1}^N \sum_{i>j}^N \frac{1}{r_{ij}} + & \hbar = 1 \\ & + \sum_A^M \sum_{B>A}^M \frac{Z_A Z_B}{R_{AB}} & "c = 1" \quad (137.) \\ & & m = 1 \\ & & e = 1 \end{aligned}$$

If we adopt Born-Oppenheimer approximation, a separation of electronic and nuclear degrees of freedom is possible:

$$\widehat{H}_{el} \Phi_{el} = \varepsilon_{el} \Phi_{el}$$

where electronic Hamiltonian is

$$\widehat{H}_{el} = -\sum_{i=1}^N \frac{1}{2} \nabla_i^2 - \sum_{i=1}^N \sum_{A=1}^M \frac{Z_A}{r_{iA}} + \sum_{i=1}^N \sum_{i>j}^N \frac{1}{r_{ij}}$$

and electronic wave function Φ_{el} depends in a parametric way on positions of all nuclei $\{\vec{R}_A\}$:

$$\begin{aligned} \Phi_{el} &= \Phi_{el} \left(\{\vec{r}_i\}; \{\vec{R}_A\} \right) \\ \varepsilon_{el} &= \varepsilon_{el} \left(\{\vec{R}_A\} \right) \end{aligned}$$

As one can see, the electronic energy ε_{el} depends on positions of nuclei as well. Thus, for each different arrangement of atoms, Φ_{el} is a different function of electron coordinates \vec{r}_i . For a fixed position of atoms (nuclei), the total energy reads

$$\varepsilon_{tot}^{fix N} = \varepsilon_{el} + \sum_A^M \sum_{B>A}^M \frac{Z_A Z_B}{R_{AB}}$$

Such an approximation leads to the following nuclear Hamiltonian \widehat{H}_{nucl} :

$$\begin{aligned} \widehat{H}_{nucl} &= -\sum_{A=1}^M \frac{1}{2M_A} \nabla_A^2 + \langle \widehat{H}_{nucl} \rangle_{\Phi_{el}} + \sum_A^M \sum_{B>A}^M \frac{Z_A Z_B}{R_{AB}} = \\ &= -\sum_{A=1}^M \frac{1}{2M_A} \nabla_A^2 + \underbrace{\varepsilon_{el} \{R_A\} + \sum_A^M \sum_B^M \frac{Z_A Z_B}{R_{AB}}}_{\varepsilon_{tot}^{fix N} \{R_A\}} = \\ &= -\sum_{A=1}^M \frac{1}{2M_A} \nabla_A^2 + \varepsilon_{tot}^{fix N} \{R_A\} \end{aligned}$$

This total energy $\varepsilon_{tot}^{fix N}$ (with the fixed positions of atoms) provides a potential for nuclear motion. Such quantity is called potential energy function (called sometimes potential energy surface PES) and in molecular dynamics simulations is approximated by a force field. In terms of quantum mechanics solutions to the nuclear Schrödinger equation,

$$\widehat{H}_{nucl} \Phi_{nucl} = \varepsilon_{nucl} \Phi_{nucl}$$

provides information on vibrations, rotations, and translations of the molecule. But the dynamics of a molecule (protein) may be studied also classically, provided that the realistic molecular PES is known.

Force Fields

Classical force fields (FFs) have common assumption that the analytic potentials are good approximation to the “real” PES. It is also assumed that parameters pertaining to particular atom types (or groups of atoms) are transferable from one model biomolecular system to similar ones.

The general expression for potential energy V is the following:

$$V = \sum_{\text{bonds } i} V_i^B + \sum_{\text{bond angles } j} V_j^A + \sum_{\text{torsional angles } k} V_k^D + \sum_{\text{improper angles } l} V_l^E \\ + \sum_{\text{atom pairs } (r,s)} (V_{r,s}^C + V_{r,s}^P + V_{r,s}^{VdW})$$

The physical meaning of each term is described in the legend in Fig. 1. In general, an intuitive decomposition of energy is used in the above equation. Additive components correspond to energies of chemical bonds (V_i^B), energies related to angular deformation of the optimal molecular structure (V_j^A , V_k^D , V_l^E), and pairwise interactions of all atoms present in the system related to Coulomb energy of a system of partially charged model atoms (V^C) and so-called Lennard-Jones (or van der Waals) term ($V^P + V^{VdW}$).

One should distinguish between all-atom and united-atom force fields. In this second type, the groups of real atoms are used as basic model “atoms,” for example, the methyl group CH_3 may be treated as a special type of a united atom having molecular weight of 15. Such simplification saves some computer time and in certain cases does not affect the results of modeling. The drawback of the majority of force fields currently used is the lack of atomic polarization effects. Partial changes on atoms to some extent include polarization, but usually, parameters remain fixed through the whole simulation. But the reality is different. Induced dipole moments may change the dynamics of the molecule and may affect results of modeling. Charges are modified “on the fly.” Thus, the next generation of force fields shall include atomic polarizability (Warshel et al. 2007; Huang et al. 2014).

There are numerous classical force fields designed for the description of protein structure and dynamics. Among the most popular ones are CHARMM (MacKerell et al. 1998), AMBER (Weiner et al. 1984), GROMOS05 (Christen et al. 2005), and OPLS (Jorgensen and Tirado-Rives 1988). Perhaps, the best up-to-date account of various force fields and computer codes available for protein simulation is the Wikipedia on the Internet. The problem of the design of a potential energy function for proteins is discussed in Boas and Harbury (2007). Some papers concerning

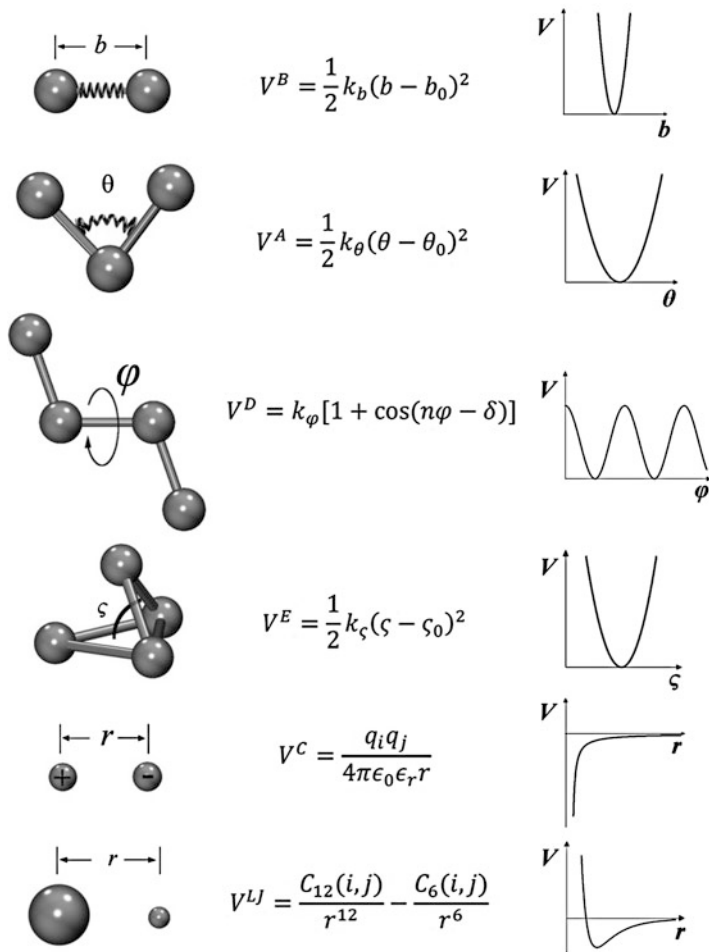

Fig. 1 Based on H. Grubmueller, “Proteins as Molecular Machines: Force Probe Simulations,” published in Computational Soft Matter: From Synthetic Polymers to Proteins, Lecture Notes, Norbert Attig, Kurt Binder, Helmut Grubmueller, Kurt Kremer (Eds.), John von Neumann Institute for Computing, Julich, Germany, NIC Series, Vol. 23, ISBN 3-00-012641-4, pp. 401–422, 2004. © 2004 by John von Neumann Institute for Computing. Interaction contributions to a typical force field. Bond stretch vibrations are described by a harmonic potential V^B , the minimum of which is at the equilibrium distance b_0 between the two atoms connected by chemical bond i (the indices i, j , etc. are not shown in the figure). Bond angles and out-of-plane (improper) angles are also described by harmonic potential terms, V^A and V^E , where Θ_0 and ζ_0 denote the respective equilibrium angles. Dihedral twists (torsional angles) are subjected to a periodic potential V^D ; the respective force constants are denoted by k 's with appropriate indices. Nonbonded forces are described by Coulomb interactions, V^C , and Lennard-Jones potentials, $V^{LJ} = V^P + V^{vdW}$, where the latter includes the Pauli repulsion, $V^P \sim r^{-12}$, and the van der Waals interaction, $V^{vdW} \sim -r^{-6}$, respectively

comparison of the quality of various force fields have appeared (Hornak et al. 2006; Guvench and MacKerell 2008; Lindorff-Larsen et al. 2012a). It is obvious that each force field was optimized for a different set of systems and they were tuned to reproduce different properties, so it is not clear how a fair comparison should be performed. On the other hand, in the protein modeling community, there is continuous tension and pressure that more effort should be devoted for careful scrutinizing of the force fields and for setting clear recommendations regarding “justified” error bars for results of computations (Aliev and Courtier-Murias 2010; Pantelopulos et al. 2015).

Structure Optimization or Energy Minimization

The most standard problem of molecular mechanics applied to proteins is the following: what is the best (optimum) structure of the studied protein? The common assumption is that the minimization of the energy (or sometimes other thermodynamic functions such as free energy) will give the answer. It is believed that such a structure is a good approximation to the native structure of the protein of interest.

There are many computational methods of finding local minima (Klepeis et al. 2003; Chou 2004; Kmiecik et al. 2007). Unfortunately, there is no general method known which might lead to the global minimum of PES of a given protein. Such techniques as simulated annealing (Kannan and Zacharias 2009) or replica exchange (Sugita and Okamoto 1999; Sugita 2009), supported by genetic algorithms, may help to sample the conformational space efficiently and may generate plausible “candidates” for the global minimum, but these approaches are rather heuristic recipes than rigorous procedures. Quite often, the energetics of transition from a conformation A to a conformation B is of interest and should be calculated (Schlegel 2003). There are numerous methods of finding classical reaction paths appropriate for proteins, for example, the self-penalty walk (Nowak et al. 1991). It is worth noting a tricky technique of milestoning (Kuczera et al. 2009). The interested reader may find details of reaction path calculations for large molecular systems in Elber et al. (2002) or Tao et al. (2012).

General Molecular Dynamics Scheme

The basic physics behind a simple molecular dynamics scheme seems to be trivial. We want to solve simultaneously M Newton’s equation of motion for each individual atom i (or a grain of atoms):

$$\mathbf{a}_i = \frac{1}{m_i} \mathbf{F}_i, \quad i = 1, \dots, M$$

The force \mathbf{F}_i acting on each atom may be calculated (locally) as gradient of the potential (PES):

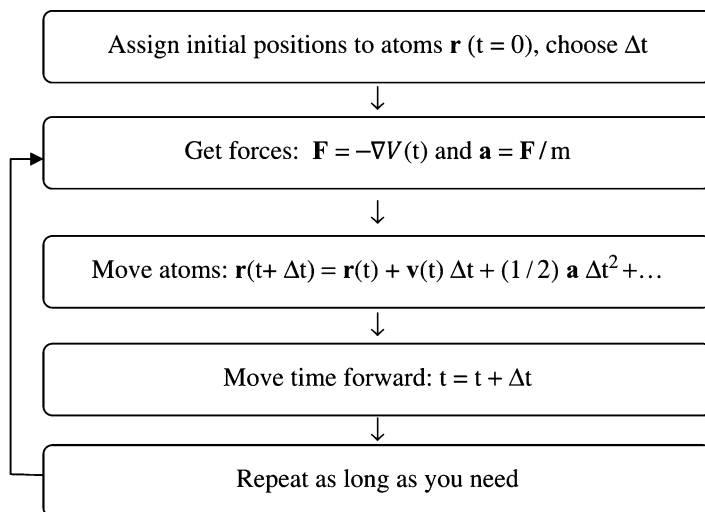

Fig. 2 A general scheme of generating MD trajectory

$$\mathbf{F}_i = -\nabla V$$

Having forces, one can easily have accelerations acting on each atom. We assume that the molecular system is deterministic (not always the case), and we may predict the position of all atoms by integrating the acceleration (twice) with respect to time. There are many numerical algorithms suitable for solving these problems, but due to its simplicity and numerical stability, Verlet algorithm is perhaps the most frequently used in real simulations (Frenkel and Smit 2002). Of course, one must assume the initial structure of the protein and has to plug in time into numerical algorithm. Time variable is discretized; the size of the time step depends on the timescale of the fastest motions we want to study. For real proteins in ambient temperatures, it is usually 1 fs (10^{-15} s). Figure 2 shows major steps in MD routines.

Here, we present typical steps in doing molecular dynamics simulations of proteins:

1. What is the scientific problem we want to solve?
2. Is classical MM/MD modeling an appropriate methodology for this type of problem? Would these calculations help to understand nature, indeed? How our results might be verified experimentally?
3. Do we have enough knowledge/experience/expertise or we prefer “black box” approach (“let’s calculate something, and we will see . . .”)?
4. What is the expected time of calculations required to obtain reasonable, publishable results? (Note: one trajectory usually is not enough.)
5. Do we have sufficient resources (licensed codes, computer time, storage space, manpower, etc.)?

6. Having answered points (1–5), we need to set up an initial model of the protein. Usually, an experimental structure (X-ray or NMR) downloaded from the PDB www.pdb.org (Berman et al. 2000) is a good starting point.
7. We should check whether the structure is complete. Is the resolution of the structure adequate for our purposes? Does it contain all amino acids? Are there any missing atoms? Do we have force field parameters for prosthetic groups, ligands, metal ions, and exotic stuff present in our favorite protein? One should always check the “biological unit” entry in PDB to avoid misunderstanding of the real structure of a protein of interest.
8. We need to decide in what particular environment simulation will proceed. Vacuum? Water? Continuum dielectric? Exotic solvent? pH? Should ions be added for charge neutralization?
9. In what conditions of temperature and pressure we plan simulations? How the temperature will be maintained? Shall we switch to the Langevin dynamics?
10. Do we need quasi-infinite model (periodic boundary conditions – PBC)? What is an appropriate shape and size of the solvation box? Should we use the Ewald summation technique to properly calculate electrostatic interactions?
11. Let us assume we perform a standard 50-ns MD simulation of a protein having a reasonable initial structure. We will add a box of model water molecules at least 6 (or 9) angstrom thick at each protein border region.
12. After this initial preparation, the first step will be an optimization of the protein structure. We may initially freeze the protein and allow for some steps of minimization of solvated water molecules (e.g., 500 steps of the steepest descent (SD) method).
13. Next, we may allow for some MD simulations of the solvent (water). We may gradually increase the temperature of waters from 0 K (minimized structure in principle is not related to any temperature) to 300 K, for 500–1,000 ps period of time. The time step in MD is usually 1 fs; thus, we will ask the MD code to perform up to 1,000,000 steps.
14. We may relax constraints and “unfreeze” the protein. Some 200–500 SD steps should be sufficient to transfer the protein (+water) from the “experimental” minimum to a “local force field-related” minimum. Too many steps result in overminimization (Rydzewski et al. 2015a)!
15. We may increase the temperature in a stepwise manner from 0 to 300 K for the whole system. 1–5 ns of such heating phase is often more than enough.
16. If we perform $T = \text{const}$ simulation, we need to equilibrate the system well before useful data may be collected. The equilibration time t_{eq} depends on the system studied. In the current papers, one can find t_{eq} from 1 to 10 ns. We should observe at least a few geometrical parameters of our protein. The RMS distance calculated for C_{α} atoms from the minimized (or PDB) structure to the current one may help to estimate whether the model is fully equilibrated. The RMS plot versus time should be flat.
17. Now, we may use the equilibrated system (protein + water) and launch a long production run (50 or more up to 1,000 ns).

18. The structures at selected time point (frames) should be stored. These structures are further analyzed using computer graphics and specialized software analysis tools. One may store structures every 100 steps (fs) or even every 1,000 steps or more; it depends on what data are needed.
19. In the theory, we should set up modeling for infinite time in order to sample all configuration space of the protein studied. This is obviously not possible; thus, we cross our fingers and believe in ergodicity of the trajectory obtained. Once calculated quantities do not depend on time of simulation, it is a reasonable signal that the longer calculation will not bring new information. Usually, several shorter trajectories, with different initial conditions, will provide better understanding of the protein than one but very long trajectory.

During MD simulations, temperature and pressure have to be controlled using special algorithms, and infinite systems may be mimicked by using periodic boundary conditions. Long-range electrostatic interactions are often accounted for by using the Ewald summation technique (Sagui and Darden 1999). Inclusion of stochastic character of atomic motion results in using Langevin dynamics instead of Newton dynamics (Schlick 2010).

One should note that solvation effects may be accounted for not only by including into the studied system explicit water molecules but also via implicit solvent models (Chen and Brooks 2008; Chen et al. 2008). Changes in free energy upon solvation are often estimated using the generalized Born model (Hou et al. 2011; Cumberworth et al. 2015).

Practical Aspects

Even the most sophisticated and advanced methods (Schwede and Peitsch 2008) need tools to perform computations. Both computer codes and hardware are required. The majority of papers published in this field utilized public domain codes to obtain data on protein dynamics. There are of course numerous commercial packages, such as Discovery Studio (Biovia), Sybyl-X (Certara), Yasara (YASARA Biosciences), and Desmond/Maestro (Schrödinger Inc.), popular in industry and certain research environments, but it seems that routine academic work is based on basically freely available software.

MD Codes

One of the first codes was CHARMM (commercial version is called CHARMM) developed originally at Harvard University. This suite of programs is very versatile and contains all major computational methods. It is parallelized and allows also for QM/MM simulations (Brooks et al. 2009). AMBER force field is popularly used for modeling of nucleic acids, but thousands of simulations of proteins have been published as well (Case et al. 2005; Salomon-Ferrer et al. 2013). The most recent,

14th, version of AMBER is heavily optimized with respect to performance (GPUs) and contains such advanced techniques as locally enhanced sampling and SCC-DFTB QM/MM methods.

In Europe, the GROMACS code has growing popularity due to its speed and good scaling on parallel clusters (Pronk et al. 2013; Van Der Spoel et al. 2005). The methods of essential dynamics, principal component analysis, and flooding (Lange et al. 2006) are available here. The most recent version – GROMACS 5.1 – takes advantage of multicore processors present in modern PCs and workstations and runs not only under many Unix distributions but Windows as well (Pronk et al. 2013). Both CUDA and OpenCL graphics card environments are supported (Abraham et al. 2015).

In our lab, we are quite happy with the NAMD code having 40,000 registered users (Phillips et al. 2005). It is well documented, relatively fast, well maintained, and often updated and scales nicely. It has certain flexibility in selection of the force field (CHARMM, AMBER). The authors have implemented locally enhanced sampling (LES), implicit ligand sampling (ILS), replica exchange, and steered molecular dynamics (SMD) schemes. New versions of NAMD (2.11 as of 2015) will run effectively on GPUs; there are also attempts to port this code to a computational grid environment.

This short presentation of major packages devoted to protein dynamics simulations is very far from being complete. Some WWW services, including Wikipedia, try to maintain the updated lists of available MD codes.

Developments in Force Fields and Parametrization

MD data may give insights into chemical or biological phenomena only if calculations are based on good-quality force fields and adequate parameters. Thus, much effort is devoted to testing and development of advanced force fields (Lindorff-Larsen et al. 2012a; Pantelopulos et al. 2015). Some researchers argue that NMR measurements provide objective measures of quality of FFs (Robustelli et al. 2010; Beauchamp et al. 2012; Huang and MacKerell 2013), while others warn that such an approach is not necessarily correct (Martin-Garcia et al. 2015).

Subtle intermolecular interactions often depend on deformations of atomic electronic densities. To account for such effects in a classical FF, atomic polarizability has to be added. Calculations with such polarizable FF are more time-consuming, but new phenomena may be studied using such more advanced protein models. The additive and polarizable variant of CHARMM FF has been very recently published (Vanommeslaeghe and MacKerell 2015). Other advances in polarizable force fields, with special attention devoted to longtime simulations, are discussed in Huang et al. (2014). Notably, a great deal of efforts is devoted to construction of new force fields suitable for modeling of medically important protein-surface interactions (Martin et al. 2015). Also efforts to optimize implicit solvent FF (Bottaro et al. 2013) are promising since longer and longer simulations are required, for example, in protein

folding studies. Comprehensive discussion of current status of FF developments may be found in the review by Lopes et al. (2015).

Programming user-friendly procedures of generating new parameters enhances area of MD applications. For example, a practical way to generate parameters (CHARMM, GROMACS) required for protein simulations with small organic ligands is to use the SwissParam server (Zoete et al. 2011). Another option of extending CHARMM MD simulations to new ligands offers the tool kit fTK implemented into newer versions of VMD (Mayne et al. 2013). For GROMACS users, an automated topology builder (Malde et al. 2011) may facilitate a lot of routine MD research on new proteins. Some hints of building new parameters may be found here (Wang et al. 2014).

Visualization

In the era of the Internet and efficient graphics cards, we have tens of programs designed to visualize a protein structure. Each year brings new players in this competition. Many researchers prefer to pay license fee and to use professional graphics for visualization of their structure and MD data: Chimera, PyMOL, Discovery Studio, Maestro, HyperChem, Yasara, etc. Open software is also available, for example, OVITO (Alexander 2010) or Avogadro (Hanwell et al. 2012). A comprehensive list of currently used molecular visualization codes may be found in the book by Gu and Bourne (2009).

User-friendly and robust code evolved from the early Visual Molecular Dynamics (VMD) software, created by K. Schulten group at UIUC in the USA (Humphrey et al. 1996). There are thousands of users of this package. An example of VMD visualization of the extracellular matrix synaptic protein reelin is presented in Fig. 3. Preparation of a similar picture is not difficult if one uses critically (Knapp and Schreiner 2009) the VMD guide (Hsin et al. 2008).

Review of Reviews

Since the very first proceedings of CECAM workshop in France devoted to models for protein dynamics (Berendsen 1976), details of computer simulations of physical and biological systems have been described in many comprehensive books. For example, a good starting point may be the book by Allen and Tildesley published already in 1987 (Allen and Tildesley 1987). It is devoted mainly to simulations of liquids, but many methodological aspects of computational modeling of physical systems are well covered. Details of molecular simulations are presented by Haile (1992). In a classical text by Rapaport (1995), explanations of basic software and algorithms may be found. The introductory but very informative book by Frenkel and Smit focuses on Monte Carlo and molecular dynamics methodologies. The authors analyze algorithms and present useful FORTRAN-based pseudocodes for basic steps of simulations (Frankel and Smit 2001). Broader aspects of molecular

Fig. 3 A fragment of extracellular matrix protein reelin (2ee2 PDB code, two out of eight BNR-EGF-BNR repeats are shown) that plays a role in a synaptic plasticity and maintenance of synaptic function, visualized using the VMD code (Humphrey et al. 1996). NAG cofactors are shown in ball-and-stick representation, green spheres represent Ca^{+2} ions, the surface denotes EGR parts, and a disulfide bridge critical for mechanical resistance is shown in red mesh. Abnormal reelin expression is observed in autism spectrum disorders, schizophrenia, or Alzheimer's (author: K. Mikulska, UMK, Poland)

modeling are covered by A. Leach (2001). In this book, besides main algorithms and methods of computational chemistry and modeling methods of protein structure prediction, free energy calculations, solvation, and drug design applications are presented. The book coauthored by M. Karplus, one of the founding fathers of MD simulations of proteins, is a valuable source of information for everyone interested in protein dynamics (Becker and Karplus 2006).

Excellent reviews on various aspects of biomolecular modeling are published quite often. Here only a very concise, subjective, and limited review of the recent (i.e., published in the twenty-first century) reviews is presented, just to provide a handy reference to further search for relevant information.

A large body of proteins perform catalytic functions. MD calculations of enzymatic mechanisms are a great challenge to theory, and the best strategy for simulations is a matter of continuous debate. In reviews by A. Warshel et al. (Warshel 2002, 2003), main aspects of proper understanding of catalysis are described. Modeling of chemical reactions requires a special approach – some possibilities are outlined in van Speybroeck and Meier (2003), and a comprehensive review of computational enzymology, largely based on QM/MM methods, may be found in Lonsdale et al. (2010). Yet another class of problems arise when protein-protein interactions are modeled (Ritchie 2008).

Basic methods and main applications of computer modeling of biosystems are presented in a comprehensive work by Schlick (2010), a review by Goodfellow et al. (Moraitakis et al. 2003), a paper by van Gunsteren et al. (2002) (Hansson et al. 2002), or the review by K. Kremer (2003). Historical development of MD techniques is presented by Field (2015). Protein modeling field is outlined by

Naray-Szabo et al. in the previous 2012 edition of the *Handbook of Computational Chemistry* (Leszczynski 2012) and in more recent comprehensive and general review by Orozco (2014). Useful accounts on are presented in a recent review by Lorenz and Doltsinis (2012). Particularly interesting are studies of membrane proteins (Gumbart et al. 2005; Stansfeld and Sansom 2011a, b) since receptor proteins are common and attractive drug targets (Borhani and Shaw 2012). One can also find reviews dedicated to application of simulations in narrow subdisciplines, such as biotechnology (Aksimentiev et al. 2008). It is worth noting that more integrative approach, combining MD simulations, experimental data, and network analysis, is advocated as a tool to get an understanding of biological process in the cell (Papaleo 2015).

An account on classical methods, problems, and goals of biomolecular simulations is given in a comprehensive article by van Gunsteren et al. (2006). Focused mainly on proteins, a very informative paper by Adcock and McCammon provides an excellent description of methods and key results from MD (Adcock and McCammon 2006). Methodological advances were also reviewed at the same time: Chu et al. popularized multiscale simulations (Chu et al. 2007), Elber et al. critically commented the literature on longtime simulation methods (Dal Peraro et al. 2005), and Liwo et al. enumerated efficient methods of sampling of proteins' conformational space (Liwo et al. 2008). Newer review of enhanced sampling techniques has been published by Fujisaki et al. (2015). Coarse-grained MD simulations have a growing importance in computational biochemistry and biology. Numerous excellent reviews have been published recently (Marrink and Tieleman 2013; Saunders and Voth 2013; Kmiecik et al. 2014; May et al. 2014; Vicatos et al. 2014; Ingolfsson et al. 2014; Barnoud and Monticelli 2015).

Enhanced sampling of conformational space has been always promising keyword for progress in MD simulation methods (Spiwok et al. 2015; Fujisaki et al. 2015). Collective variables may reduce the space (Vashisth et al. 2014), but typically metadynamics, replica exchange, or Gaussian accelerated MD and their variants are extensively explored (Granata et al. 2013; Abrams and Bussi 2013; Comer et al. 2014; Andersen et al. 2015; Miao et al. 2015).

A lot of effort has been put in elaborating reliable and practical methods of calculating changes in free energies (Kholmurodov et al. 2003; Meirovitch 2007; Christ et al. 2010; Pohorille et al. 2010). Even "computational alchemy" term has been coined for some counterintuitive but physically valid methods (Straatsma and McCammon 1992; Aleksandrov et al. 2010). Such data are required, for instance, in drug design (Galeazzi 2009; Morra et al. 2008). Increasing role of taking into account entropic effects is now widely accepted (Noel and Whitford 2014; Rydzewski et al. 2015a). Enhanced MD helps now to access better ligand-protein docking (Andersen et al. 2015). Time-consuming free energy calculations may profit a lot from using enhanced sampling techniques (Bernardi et al. 2015; Miao et al. 2015) as well.

Advantages of using the computational approach to chemistry and biology are outlined in a comprehensive review of Mulholland et al. (van der Kamp et al. 2008). Supercomputers contribute a lot to the current blooming state of MD simulations

of large biosystems (Chipot 2015). One can find also more focused, specialized reviews of MD approach to biological problems (Dodson et al. 2008; Avila et al. 2011) or to future nanotechnology applications of self-assembling systems (Klein and Shinoda 2008), biotechnology (Aksimentiev et al. 2008), and drug design (Borhani and Shaw 2012). Quite often modern simulation techniques are called “computational microscope,” just to stress its role in molecular biology (Dror et al. 2012). Interestingly enough, with the petaflop computer system currently available, multimillion atom simulations are possible (Sanbonmatsu and Tung 2007). Promising efforts are made to construct computers dedicated to MD simulations on hardware level (Scarpazza et al. 2013). The success of ANTONs from D.E. Shaw Research is notable (Shaw et al. 2014).

Milliseconds in simulations of protein folding problems are currently sought (Bowman et al. 2011; Piana et al. 2014); thus, all means helping to reach this target are welcome (Lane et al. 2013), including optimization of MD codes (Krieger and Vriend 2015). Protein folding phenomena still pose more questions than answers (Dill and MacCallum 2012).

For sure, this field profits from the use of the Internet. Some groups have developed user-friendly and even charming portals to the simulation software (Miller et al. 2008). Folding@Home project has reached 20-Tflop computer power (Lane et al. 2013), and this software is available for other distributed computing environments now (Eastman and Pande 2015). Other researches, for example, the group of V. Daggett, invest in large-scale depositories of scientific data stemming from MD simulations (Van der Kamp et al. 2010). Sharing data, especially obtained using advanced computer resources and easy to expose in clouds, is always a good idea. Such an “ocean” of numbers deserves careful scrutiny. Hopefully, some scientific treasures will be fished out in the near future.

Selected Examples of Applications of MD to Study Proteins

In this short chapter, we point out selected, representative, widely discussed problems where the MD methods have been applied.

Protein Folding Studies

Proteins are synthesized as linear polymers, but for their function, precise 3-D structure is usually necessary. The process of folding to such a native structure may be conveniently studied using molecular dynamics simulations (Fersht and Daggett 2002; Zhang et al. 2009; Freddolino et al. 2010; Towse and Daggett 2013). The main obstacle in this research is still relatively limited (100–1,000 ns) timescale accessible for standard modeling (Scheraga et al. 2007). However, more and more benchmark calculations achieve microseconds (Piana et al. 2011), including classical studies for very small systems such as villin headpiece fragment, one of

the most stable and fastest-folding naturally occurring proteins (Duan and Kollman 1998; Ensign et al. 2007; Freddolino and Schulten 2009) or ubiquitin (Piana et al. 2013). Simulations help to propose universal folding mechanisms and to determine intermediates (Freddolino et al. 2008; Rizzuti and Daggett 2013; Piana et al. 2014). Better algorithms and huge computer power make performing meaningful folding simulations possible within a few days (Nguyen et al. 2014). Quite promising are new methodological developments adding core physical insights into a standard Replica Exchange MD (REMD) (Perez et al. 2015) or even mixing MD with experimental data (Sborgi et al. 2015). A lot of effort is devoted to finding an intelligent method of “ab initio” protein folding (Shakhnovich 2006; Blaszczyk et al. 2013). The progress may be checked by following the worldwide folding competition CASP (Kryshtafovych et al. 2016).

Intrinsically Disordered Proteins

Not all proteins are nicely folded, and numerous proteins remain disordered through the whole (or majority) of their life-span in a cell. The paradigm that only well-structured biomolecules may play significant physiological role has been abandoned at the beginning of the twenty-first century (Wright and Dyson 1999). The role of intrinsically disordered protein (IDP) is intensively studied (Wright and Dyson 2015) and opens very attractive field for MD simulations (Lindorff-Larsen et al. 2012b; Baker and Best 2014; Fu and Vendruscolo 2015). Notably, there is an ongoing discussion of what MD force field (Baker and Best 2013; Rauscher et al. 2015; Piana et al. 2015) and methodology (Do et al. 2014; Granata et al. 2015; Zerze et al. 2015) are the best for IDP modeling.

Protein-Drug Interactions and Docking

The pharmaceutical industry badly needs reliable theoretical methods for calculating ligand binding affinities (Aqvist et al. 2002; Gallicchio and Levy 2011; Zhao and Caflisch 2015; Yuriev et al. 2015). The problem is not easy, since many factors, for example, multiple binding sites, protein flexibility, and solvent model, affect a small value of the free energy of binding (Simonson et al. 2002; Deng and Roux 2009; Spyraakis et al. 2011). The chance of getting wrong results is high. However, in the literature, there are hundreds of papers devoted to protein-drug interactions. One of the main topics is HVI-related enzyme inhibitors (Monroe et al. 2014). The threat of a bird or swine flu pandemic triggered studies of interactions of neuraminidases or influenza A peptides with antiviral drugs (Le et al. 2011; Khurana et al. 2011). The role of induced fit effects during ligand docking to steroid hormone-binding receptors was analyzed by Cornell and Lam (2009). MD may be used in an anticancer drug development (Rosales-Hernandez et al. 2009; Lauria et al. 2010), GPCR inhibitors/activators (Dror et al. 2013; Tautermann et al. 2015), or studies of inhalational anesthetics' interactions with proteins (Vemparala et al. 2010). Studies

on microsecond timescale MD explained mechanisms of chemokine receptor CCR5 inactivation (Salmas et al. 2015), macrolide binding to the ribosome (Sothiselvam et al. 2014), or opioid receptor activation (Huang et al. 2015). The review of MD applications in drug design, especially in stability of drug-macromolecule complexes, has been recently published (Mortier et al. 2015).

Spectroscopy Experiments

Spectroscopy is an extremely useful analytical and diagnostic technique with wide applications in chemistry, physics, life sciences, industry, medicine, etc. Molecular dynamics helps to interpret experimental data; some examples are given below. Sen et al. used simulations to explain time-resolved Stokes-shift experiments with biopolymers (Sen et al. 2009). Fluorescent proteins, especially based on GFP, are often studied computationally. Sun et al. applied QM/MM and MD to explain dependence of red fluorescent protein on pH of the environment (Sun et al. 2010). Computational studies of energy transduction in photoactive yellow protein may give useful hints for spectroscopic studies (Gamiz-Hernandez and Kaila 2016) as well as do the modeling of visual pigments (Brunk and Rothlisberger 2015; Wanko et al. 2006). Quite often, the interpretation of NMR experiments profits from simulations, such as studies of lipid-binding sites to neurotoxin (Weber et al. 2015) or evaluation of rotational diffusion constants from MD (Wong and Case 2008). On the other hand, the NMR spin relaxation data help to improve force fields (Beauchamp et al. 2012).

Functionally Important Motions (FIMs)

Some motions of proteins are critical for their proper functioning (Henzler-Wildman and Kern 2007). MD simulations may identify such modes. Relation of protein's mechanics and function was reviewed in 2003 by Schulten (Tajkhorshid et al. 2003), but since that time, this group studied new problems, for example, plant phototropism (Freddolino et al. 2006b) and complete satellite *Tobacco mosaic virus* vibrations (Freddolino et al. 2006a). Other groups investigated large-scale motions in biosensors (Tatke et al. 2008), linker motions crucial for ligase (Liu and Nussinov 2010), or retinal release from opsin (Wang and Duan 2011). Extraction of information on FIM needs special methodology (Schuyler et al. 2009), such as essential dynamics (Amadei et al. 1993) or metadynamics (Biarnes et al. 2011); thus, new ways of MD data analysis are suggested (Hub and de Groot 2009; Vuillon and Lesieur 2015). Critical assessment of FIM analysis methods may be found in Moradi and Tajkhorshid (2014). The main global motions are encoded in protein structures, and these features may be explored in protein ligand studies using normal mode analysis (Bahar et al. 2015). A very interesting step toward systematic classification of dynamical properties of proteins called dynasome has

been proposed in paper (Hensen et al. 2012). Studies of over 100 distinct proteins show that internal mobility patterns exhibit rather continuous distribution. The strong correlation between structure and dynamics has been, however, noted.

Molecular Machines

Having such powerful computers at hand, we are ready to study molecular machines – proteins or bio-complexes that perform some mechanical work during their activity cycle (Scheres 2010; Elber and Kirmizialtin 2013). Rotations of parts of ATPase were studied by Ma et al. already in 2002 (Ma et al. 2002) and molecular rotation in ATP synthase by Aksimentiev et al. in 2004 (Aksimentiev et al. 2004). Solvent-induced lid opening in lipases was also analyzed computationally (Rehm et al. 2010). Even the whole cellular mechanics simulations were reviewed by Gao et al. (2006). In recent years, a flux on papers in this fascinating phenomenon of molecular machines has been observed (Kutzner et al. 2011; Sanbonmatsu 2012; Bock et al. 2013; Czub and Grubmuller 2014; Ito and Ikeguchi 2014; Mukherjee and Warshel 2012, 2015a, b; Ma and Schulten 2015).

Mechanoselective ion channels may be considered as molecular machines, too, and an ion gating is better understood now due to MD (Vasquez et al. 2008). Simulations were applied to the helicase motor (Dittrich and Schulten 2006; Yu et al. 2007; Flechsig and Mikhailov 2010) and perhaps to the most advanced (not counting more static virus capsids) object: the ribosome (Becker et al. 2009; Romanowska et al. 2008; Trylska 2010). Recent progress in ribosome simulations has been summarized by Sanbonmatsu (2012). The MD application in this field obviously profits from using 3-D animation; such tools bring new dimensions to protein science (Iwasa 2015). More information on large macromolecular complexes may be found in Perilla et al. (2015).

The Mechanism of Enzymatic Activity

Progress in computational enzymology is described in Lonsdale et al. (2010) and Carvalho et al. (2014). Reactions have to be treated using quantum mechanics, but some features of enzyme dynamics may be revealed by MD. For example, Peplowski et al. used the steered MD method to enforce a ligand transport within the biotechnological enzyme nitrile hydratase (Peplowski et al. 2008). In that way, residues that may change catalytic properties of this metalloprotein have been indicated. Carloni et al. used the MD approach to explain the mode of action of G proteins (Khafizov et al. 2009). Lid opening in proteasome has been studied in detail (Ishida 2014). Worth checking are papers devoted to computational studies of the model enzyme dihydrofolate reductase, since this enzyme is a target in cancer therapy and anti-malaria drug development (Kohen 2015). MD may serve also as a useful tool in designing new enzymatic functions (Damborsky and Brezovsky

2014). Free energy calculations in the context of enzymatic activity are easy to perform due to empirical valence bond (EVB) + MD software developments (Isaksen et al. 2015). Useful guidelines on how to perform effectively free energy simulations may be found in Klimovich et al. (2015).

Transport Phenomena in Proteins

Heme proteins are popular objects of MD simulations (Bikiel et al. 2006) since transport processes of small gaseous ligands (O_2 , NO, CO) are important for physiology, and therefore they serve as a “test ground” for new methods. Myoglobin is even sometimes called a “hydrogen atom” of MD simulations (Elber 2010). Other members of the heme globin family have been recently discovered, and studies of diffusion paths and free energy landscapes for neuroglobin (Orlowski and Nowak 2008), cytoglobin (Orlowski and Nowak 2007), or protoglobin (Forti et al. 2011a, b) were published. It seems that such systematic study allows for construction of uniform picture of ligand migration pathways and the evolution of transport protein structure (Cohen et al. 2008; Forti et al. 2011b). MD simulations are helpful in the explanation of complex enzymatic mechanisms, for example, of dehydrogenase/acetyl-CoA synthase (Wang et al. 2013) or cytochrome C oxidases (Oliveira et al. 2014), and interpretation of X-ray experiments (Tsuduki et al. 2012). However, determination of larger ligand diffusion paths is not trivial (Kingsley and Lill 2015). The standard MD protocol is not practical since simulation times required to collect reasonable statistics are long. Special variants of steered molecular dynamics are useful in such problems; see Fig. 4. The review of recent methodological progress and new ideas based on memetic algorithms are presented in a recent paper by Rydzewski and Nowak (2015).

Structure and Dynamics of Ion Channels and Porins

Dynamics and transport through ion channels and other pores in biological membranes is a subject of vigorous research (Khalili-Araghi et al. 2009; Sigg 2014). Among many papers, the work on channel gating by M. Sansom group (Fowler and Sansom 2013; Aryal et al. 2015) is worth mentioning as well as B. Roux et al. computational studies of ion channels (Horn et al. 2014; Li et al. 2014) and numerous papers on the ion conductance in a potassium channel (Boiteux et al. 2007; Kim and Warshel 2014; Delemotte et al. 2015; Linder et al. 2015) and sodium channels as well (Li and Gong 2015). The main research groups have tried to formulate a uniform picture on the voltage-dependent ion channel conductance mechanism (Vargas et al. 2012). One should note that external electric field has critical impact on ion channel activity and this effect may be effectively modeled (English and Waldron 2015).

Fig. 4 A schematic view of complex access/exit paths PW1–PW3 of camphor ligand (licorice) in cytochrome P450cam enzyme calculated by our fast SMD memetic algorithm (Rydzewski and Nowak 2015). The figure was prepared using the PyMOL code (DeLano 2002) by J. Rydzewski

References to interesting computational studies of aquaporins may be found in a review by Hub et al. (2009). The water transport in eye lenses was investigated using large-scale simulations by D.E. Shaw group (Ikeguchi 2009). At the same time, K. Schulten's team has modeled nanomechanics of RNA in nanopores (Miao and Schulten 2009; Khalili-Araghi et al. 2009). More recently, a huge simulation of nanopore formation provided new data on nuclear pore gating (Gamini et al. 2014).

Sodium symporter modeling has been recently reviewed by Bisha and Magistrato (2016); other symporters are described in Kardos and Héja (2015) or Espinoza-Fonseca and Ramírez-Salinas (2015). Increasing computational resources open possibility of all-atom simulations of a protein translocation through a nanopore (Di Marino et al. 2015).

Protein-DNA Interactions

Transfer of information from DNA to proteins and its impact on the whole cell activity is determined by protein-DNA interactions. Such complexes are difficult to model due to their size and heterogeneity, but good understanding of these systems is a key to genetics (Mac Kerell and Nilsson 2008; Rohs et al. 2009). Good examples of successful MD applications are studies of p53 protein binding modes to DNA quadruplexes (Ma and Levine 2007), investigations of zinc-finger proteins binding to DNA (Lee et al. 2010), or modeling of DNA bending (van der Vaart 2015). Details of the mechanism of Lac repressor interactions (Villa et al. 2005) and sliding along DNA (Furini et al. 2010) have been discovered by the MD methods. There is a growing interest in studies of proteins related to clustered regularly interspaced

short palindromic repeats (CRISPRs) present in prokaryotic cells. A recent example of insightful study of CRISPR-related endoribonuclease may be found in Estarellas et al. (2015).

Origins of Molecular Diseases

Applications of computer simulations in the areas related to medical problems are numerous: funds come both from the public budgets and private charities. Many diseases have well-defined etiology, related to abnormalities in a protein structure, point mutations, etc. Such “molecular diseases” are popular objects of the theoretical modeling (Papaleo and Invernizzi 2011).

The epidemic of BSE spawned the great interest in the prion protein research. Simulations of folding (Sakudo et al. 2010; Kupfer et al. 2009) evolved into studies of membrane-bound complexes (DeMarco and Daggett 2009). The Alzheimer disease is related to amyloid fiber formation in the brain, and this process is successfully modeled (Urbanc et al. 2010; Kassler et al. 2010; Straub and Thirumalai 2010; Nasica-Labouze et al. 2015), too. Less known are studies of transthyretin (TTR) fibril formation (Ortore and Martinelli 2012; Rodrigues et al. 2010). However, the problem is serious since the aggregation of TTR leads to a lethal illness. It is necessary to notice some impressive studies of HIV virus (Carnevale et al. 2009; Zhao et al. 2013). There are examples of computational research on proteins involved in primary congenital glaucoma (Achary and Nagarajaram 2009), osteoporosis (Lee et al. 2011), epidermolysis bullosa simplex (Jankowski et al. 2014), autism spectrum disorders (Mikulska et al. 2011), or cancer (Kumar and Purohit 2014). An excellent example of MD exploratory study of point mutations in CFTR chloride channel involved in cystic fibrosis is the recent paper by Morion et al. (2015).

Simulations of Single-Molecule AFM Experiments

In the opinion of this author (and many others as well), non-equilibrium protein dynamics has an excellent overlap with single-molecule experiments performed by atomic force microscope (AFM) (Nowak and Marszalek 2005; Kumar and Li 2010; Galera-Prat et al. 2010). One of the first computational studies of ligand-antibody enforced dissociation has been published in 2001 by Karplus et al. (Paci et al. 2001). Stretching of individual molecules by the AFM cantilever gives force spectra, i.e., dependence of a force (in the range 0–3,000 pN) on protein extension (0–100 nm or even more) (Rief and Grubmuller 2002) that may be confronted with special type of MD simulations, for example, steered molecular dynamics (Nowak and Marszalek 2005) or even quantum-type SMD (Lu et al. 2004). An example of SMD stretching of reelin (see Fig. 2) – a protein important in neural system development and proper functioning of synapses – is presented in Fig. 5.

One can see that despite rather low stretching velocity, the computed SMD forces are much higher (1–2 nN) than that (100–300 pN) typically observed in AFM

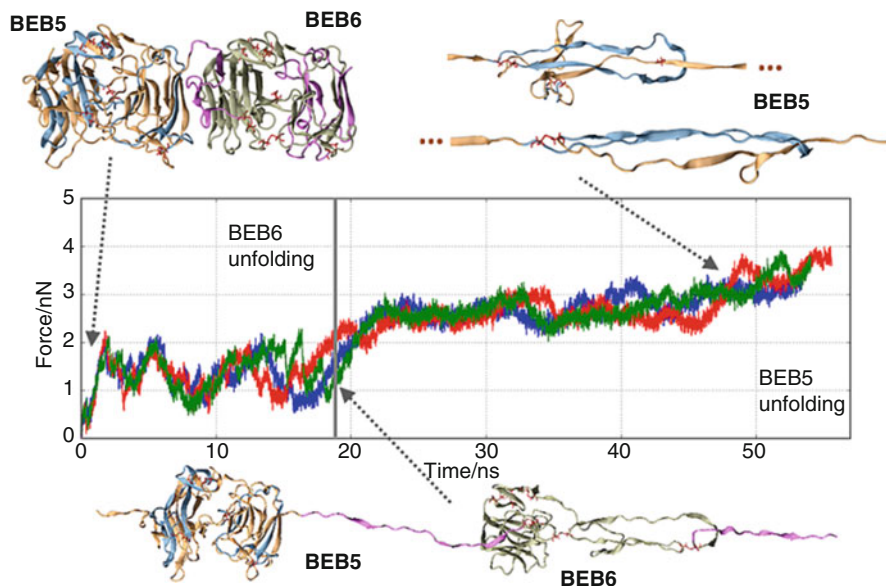

Fig. 5 An example of mechanical unfolding scenario of modular protein reelin recovered by SMD (CHARMM27 force field, NAMD code (Phillips et al. 2005)). K. Mikulska, W. Nowak (unpublished results). The figure was prepared using the VMD code (Humphrey et al. 1996)

experiments (Mikulska et al. 2012); this is related to high loading rates imposed by limited SMD time (G. Lee et al. 2004). Good progress toward SMD and high-speed AFM result consistency is observed (Sotomayor and Schulten 2007; Rico et al. 2013) especially if coarse-grained models of proteins are employed (Kumar and Li 2010; Galera-Prat et al. 2010; Mikulska et al. 2014; Chwastyk et al. 2014; Chen et al. 2016). Free energy profiles along a stretching coordinate may be calculated using Jarzynski theorem (Hummer and Szabo 2010; Rydzewski et al. 2015). Therefore, more and more laboratories use SMD modeling as a tool to interpret results of SMFS (He et al. 2012) and optical tweezers (Sieben et al. 2012) experiments. A computational microscope postulated long time ago (Lee et al. 2009) is at hand.

Conclusions and Future Directions

Computational chemistry is currently a well-established, fully functional branch of science (Akimov and Prezhdo 2015). Easy access to computers and high-quality, specialized computer codes results in myriad of applications. There is a large, well-trained, and active community of computational chemists. Results of calculations are useful and hard to obtain without the theoretical and computational approaches. Virtually all chemical and a large body of biological systems may be modeled using current facilities.

It looks that computer simulations of proteins have still very good prospects ahead. There are new, promising directions of the investigations. Better computational power offers possibility of real-time calculations of protein dynamics, including aggregates and membrane-embedded systems. MD simulations of proteins may help in rational drug design (Harvey and De Fabritiis 2012). Electronic excited states of proteins are unexplored area. The methodology of MD simulations of photoexcited states is still not well established (Kubiak and Nowak 2008) (Rydzewski and Nowak, chapter “► [Molecular Dynamics in Excited State](#)”), but future MD applications should include interactions of biological systems with light (Dittrich et al. 2005; Hayashi et al. 2009; Rossle and Frank 2009). For example, nice progress of understanding protonic gating in the popular green fluorescent protein chromophore has been achieved through dynamical simulations (Olsen et al. 2010). Similar studies related to optogenetics will appear soon. Every month brings new better software for extensive analysis of MD trajectories (Zwier et al. 2015) or new ways of doing MD (Kukic et al. 2015).

An interpretation of special experiments, such as high-pressure studies (Paci 2002) and especially cryo-electron microscopy (McGreevy et al. 2016) or X-ray data fitting (McGreevy et al. 2014), may be fruitfully augmented by an application of computational modeling. Computer scientists and physicists work hard to enlarge the maximum size of the simulated system. The whole virus all-atom simulation is not a record study anymore (Zink and Grubmuller 2009; Sanbonmatsu and Tung 2007; Zhao et al. 2013; Goh et al. 2015), computational virology field has been established (Reddy and Sansom 2016), and there are plans to use computational methods in the design of useful viruses {Zhang et al. 2015, p. 8316}. However, one should note that recent record of 64-million-atom NAMD simulations required 8,000 Cray XK7 nodes for a period of 2 months (Perilla et al. 2015).

Long time ago, it has been shown in Los Alamos National Laboratory that even 320-million-atom protein simulations are technically possible (2009). Large systems, such as big protein complexes in the living cell, will require coarse-grained approaches (Clementi 2008). A lot of insight comes from such modeling of membrane proteins (Sansom et al. 2008; Ayton et al. 2010; Stansfeld et al. 2015). Multiscale modeling is yet another line of methodological progress (Tozzini 2010; Nielsen et al. 2010; Goga et al. 2015). Such techniques expand timescale accessible for MD studies beyond 1 μ s limit (Chu et al. 2007; Ayton et al. 2007; Sherwood et al. 2008). Impressive simulations on microsecond timescale coarse-grained Martini FF molecular dynamics simulations of enveloped virions in explicit solvent (5,000,000 particles) were performed by Sansom group at Oxford (Reddy et al. 2015). The calculated properties of the influenza A virion were consistent with experimental measurements.

What is the best technological strategy for the optimum performance of MD simulations is a matter of debate (Borell 2008; Goga et al. 2015). For example, D.E. Shaw has invested a lot of resources in order to develop dedicated chips with record performance for specialized tasks (Klepeis et al. 2009). Other groups, such as K. Schulten's team, prefer improving algorithms and developing software for

running calculations on very powerful, relatively inexpensive, graphical processing units, mass produced for computer game fans (Hardy et al. 2009; Stone et al. 2007; Zhmurov et al. 2010).

Both approaches have difficulty with surpassing grid computing idea: “Folding@Home” project created perhaps the most powerful computational device ever and attracted a lot of young people to science (Pande et al. 2003; Belden et al. 2015). Hopefully, all this computational chemistry modeling effort will bring us a better understanding of nature and a better life for everybody.

Acknowledgment This work was supported in part by Polish funds for science NCN (N N202 262038 and 2012/05/N/ST3/03178). Infrastructure of ICNT UMK is also acknowledged.

Abstract

Molecular dynamics (MD) simulations based on a classical force field are increasingly being used to study the structure and dynamics of nucleic acids. Simulation studies are limited by the accuracy of the force field description and by the time scale accessible by current MD approaches. In case of specific conformational transitions, it is often possible to improve the sampling of possible states by adding a biasing or umbrella potential along some coordinate describing the conformational transition. It is also possible to extract the associated free energy

change along the reaction coordinate. The development of advanced sampling methods such as the replica-exchange MD (REMD) approach allows significant enhancement of conformational sampling of nucleic acids. Recent applications of umbrella sampling and REMD simulation as well as combinations of both methodologies on nucleic acids will be presented. These approaches have the potential to tackle many open questions in structural biology such as the role of nucleic acid structure during recognition and packing and the function of nucleic acid fine structure and dynamics.

Introduction

Nucleic acids have essential functions in a variety of biological processes including storage of genetic information, replication of DNA, regulation of transcription, mRNA splicing, RNA interference, and protein synthesis. Most cellular DNA adopts primarily a double-stranded (B-form) helical structure and the interaction with proteins is mediated through major groove or minor groove recognition. The accessibility of DNA is also controlled by the condensation with nuclear proteins (histones) to compact structures (nucleosomes and chromatin in eukaryotes). Many cellular RNA molecules form more complex three-dimensional structures compared to DNA that consist only partially of double-stranded base-paired regions frequently interrupted by extra-unmatched nucleotides, mismatched base pairs, bulge structures, or hairpin loop structures that cap the end of helices (Zacharias 2000; Leontis and Westhof 2003; Al-Hashimi and Walter 2008; Huang and Lilley 2015).

In recent years, structural knowledge of RNA and RNA in complex with proteins, small organic ligands, and ions has increased dramatically since many new structures have been solved by X-ray crystallography or nuclear magnetic resonance (NMR) spectroscopy (Hall 2008; Steitz 2008; Furtig et al. 2003). The rapid increase of structural information has also helped to collect and better understand the types of interactions in folded nucleic acid structures and at nucleic acid–ligand interfaces (Hall 2008; Al-Hashimi and Walter 2008). Since RNA and DNA are of functional importance in many cellular structures, nucleic acids have also been increasingly recognized as possible drug targets. In addition, nucleic acids themselves may serve as drugs (DeJong et al. 2002; Zacharias 2003; Wong et al. 2009). In addition to X-ray crystallography and NMR spectroscopy, the structure determination using electron microscopy under low-temperature cryo conditions (CryoEM) has made dramatic progresses in recent years due to the development of new detectors and computational methods for evaluating EM images (Nogales and Scheres 2015). By averaging over many images in different orientations, it is possible for large nucleic acid molecules in complex with proteins (e.g., ribosome) to determine structures with near-atomic resolution without the requirement of a crystal (Knoops et al. 2012). Furthermore, it is also possible to classify images and define different structural states of a biomolecular assembly. However, this type of classification still results in the determination of static or partially averaged structures of a nucleic acid containing assembly. Possible intermediates or pathways of structural changes

cannot be covered by experimental methods alone at high spatial resolution. In addition, the static experimental structures of nucleic acids alone do not provide the energetic and entropic contributions for structure formation or association with respect to unfolded or unbound reference states. Despite the increased structural knowledge on nucleic acids and complexes with proteins, the structure formation process and the associated driving forces are still poorly understood. Since DNA is mostly in a regular B-form duplex geometry in a cell, the most urgent questions are how specific association with proteins is mediated and how the dynamics and the fine structure (meaning backbone conformations compatible with a B-helix) influence specific binding and packing of DNA. In contrast to DNA, RNA can form a variety of complex three-dimensional (3D) structures (Leontis and Westhof 2003). One can distinguish between secondary structure and tertiary structure, since relatively short duplex structures (minimum length of 4–6 base pairs) are thermodynamically stable and once formed typically do not refold into another structure upon tertiary structure formation of the RNA. Hence, in contrast to the small secondary structure elements in proteins, the secondary structure of RNA can be stable without stabilization by tertiary interactions. On the level of empirical rules and experimentally derived free energy contributions, the energetics and thermodynamics of RNA duplex formation are quite well understood (at least for duplex formation) (Liang and Schlick 2011). Tertiary structure formation corresponds then to the arrangement of secondary structure elements including the sterical constraints imposed by the structural motifs that connect stable secondary structure elements. The forces that drive the packaging of secondary structure elements into complicated and stable 3D structures (e.g., ribosome) are much less well understood (even on an empirical level). The packing of RNA into a compact structure leads to an accumulation of many negative phosphate groups with strong electrostatic repulsion balanced by a corresponding accumulation of counterions (Draper et al. 2005). Hence, 3D structure formation of RNA depends heavily on the surrounding ions and often also on the presence of proteins or other molecules that stabilize the structure. The term “metal core” in relation to the typical hydrophobic core in case of proteins has been introduced to characterize the interior of a large folded RNA molecule (Draper et al. 2005). Comparison with proteins also indicates that folded RNA structures are much less well packed than folded proteins, and numerous waters and ions are still present in the interior of the RNA tertiary structure (Draper 2008). To complement experimental structure determination, the application of computer simulation methods in particular of molecular dynamics (MD) approaches is increasingly being used to study the equilibrium dynamics and the structure formation process.

Molecular Dynamics Simulations of Nucleic Acids

For the theoretical investigation of nucleic acid structure and function, the application of quantum mechanical approaches is currently limited by the large size and complexity of nucleic acids. However, computer simulation studies based on

classical molecular mechanics force fields that use the position of whole atoms as variables (instead of electrons and nuclei in case of quantum mechanics) are used frequently to study the dynamics of nucleic acids (Cheatham 2004; McDowell et al. 2007; MacKerell and Nilsson 2008; Orozco et al. 2008; Kara and Zacharias 2013a). Simulations can complement experimental studies if the time scales or the molecular properties of interest are difficult to access experimentally. Detailed atomistic computational studies of nucleic acid dynamics and even folding of small structural motifs have become possible in recent years (Kara and Zacharias 2013a). In the current chapter, we will focus on the application of advanced sampling molecular dynamics (MD) methods to follow the dynamics of biomolecules at high spatial and time resolution. These methods could be useful to study the driving forces of structure formation, provided that the force field to describe the molecular interactions is sufficiently accurate.

Typically, MD simulation studies include the nucleic acid molecule at atomic resolution. During the simulation Newton's equations of motion are solved numerical in small time steps of $\sim 1-2$ fs ($1-2 \times 10^{-15}$ s). The interatomic interactions are described using a classical molecular mechanics force field of the following form:

$$V_{\text{tot}} = \sum_{i=1}^{\text{Nbonds}} \frac{1}{2} k_{b_i} (b_i - b_{oi})^2 + \sum_{i=1}^{\text{Nangles}} \frac{1}{2} k_{\theta_i} (\theta_i - \theta_{oi})^2 + \sum_{i=1}^{\text{Ndihedral}} \sum_{n=1}^{N\tau} k_n (1 + \cos(n\tau_i + \delta_{ni})) + \sum_{i \neq j}^{\text{Npairs}} \left(\frac{A_{ij}}{r_{ij}^{12}} - \frac{B_{ij}}{r_{ij}^6} + \frac{q_i q_j}{r_{ij}} \right) \quad (1)$$

The bonded terms (first three summations in the above equation) contain a sum over all chemical bonds, all bond angles, and dihedral angles of the nucleic acid structures. Usually, simple quadratic penalty terms with appropriate force constants (k_b and k_θ , respectively) are used to control the bond length (b) and bond angles (θ) variations of the molecules. A linear combination of periodic functions is typically employed to control dihedral torsion angles (τ). Additional nonbonded terms describe van der Waals and Coulomb interactions (as a double sum over all nonbonded pairs of atoms, last two terms in the above equation). The form of the energy function allows a rapid evaluation of the potential energy of a molecule and calculation of gradients necessary for energy optimization and molecular dynamics simulations based on a numerical solution of the classical equations of motion.

Simulation studies on biomolecules require the inclusion of surrounding aqueous solvent and ions. However, the inclusion of a sufficiently large number of explicit water molecules significantly increases the computational demand. The possibility to implicitly account for solvent effects in molecular mechanics calculations is of great interest because it would allow longer simulation times and a better convergence of calculated thermodynamic averages. However, in the present review,

we will focus on simulation studies on nucleic acids with an explicit consideration of surrounding ions and water molecules. In order to account for long-range electrostatic interactions, most simulations employ particle mesh Ewald (PME) methods where the long-range part of the electrostatic interaction is considered by an Ewald summation technique for periodic systems (Darden et al. 1993).

Several molecular mechanics force fields are available for simulation studies on nucleic acids. Among the most extensively tested force fields are the Charmm36 (Vanommeslaeghe and MacKerell 2015) and the Amber parmBsc0 (Perez et al. 2007a). In particular the parmBsc0 force field has been tested during very long simulations starting from B-DNA (Perez et al. 2007b). The simulations gave good agreement with the B-DNA starting structure for simulations that were extended to more than 1 μ s total simulation time. In addition, the combined effort of several groups (ABC consortium) has resulted in the characterization of the dynamics of all possible tetra base pair (bp) steps (136) embedded at the center of a longer (18 bp) DNA duplex, each extended for the time range of 1 μ s (Pasi et al. 2014). This gives a detailed picture of the available conformational space of duplex DNA and how it is influenced by all possible sequential arrangements of four consecutive base pairs (Pasi et al. 2014). Starting from standard B-DNA, these structures are equilibrated and simulated under identical conditions to allow direct comparison and extraction of sequence-dependent structural and dynamic features. This effort could eventually lead to a comprehensive description of the sequence-dependent flexibility of DNA.

An extension of the parmBsc0 force field also improves the performance for simulations of RNA molecules (Perez et al. 2007a, b). However, RNA molecules often contain noncanonical and non-regular structural motifs (such as bulges and loop structures) that require further optimization of force field parameters. An important aspect is here the realistic parameterization of conformational dihedral states around the *N*-glycosidic bond that connects nucleobases with the ribose unit (syn- vs. anti-conformations). Considerable improvement has been achieved in the force field description even for noncanonical motifs in recent efforts which requires, however, further evaluation. A further improved force field (extension of parmBsc0), the parmBsc1 force field shows even better agreement with experiment concerning the description of DNA but also allows an improved representation of folded non-helical RNA and DNA motifs (such as hairpin structures) (Ivani et al. 2015).

Also recently, force fields that account approximately for electronic polarization due to the strong electrostatic fields around nucleic acid molecules have become available (Babin et al. 2006). Additional terms often in form of field-induced dipoles on atoms are used to approximately describe the deformation of the electron cloud due to an electrostatic field. It has been shown that such force field models can improve MD simulations of DNA resulting in overall better agreement with available experimental data than the standard force field form with fixed partial charges on atoms and no additional polarization term (Babin et al. 2006).

Nucleic acids are highly solvated systems and are surrounded by nonspecifically and specifically bound ions that stabilize the polyelectrolyte character of the nucleic acid molecule. A number of biophysical techniques allow the investigation of the

effective charge of nucleic acids, and high-resolution X-ray crystallography can provide detailed spatial information on specifically bound solvent molecules and ions. However, the dynamics of nucleic acid hydration and ion binding is difficult to study experimentally at high spatial and time resolution. MD simulation studies have been extensively used to characterize the distribution and lifetimes of bound water molecules and ions in both DNA and RNA (reviewed in Hashem and Auffinger 2007).

In contrast to DNA, most RNA molecules are single stranded in a cell which results in the possible formation of a variety of secondary and tertiary structures. Many larger functional biological assemblies contain not only proteins but also structured RNA components (e.g., ribosomes, spliceosomes, and editosomes). The flexibility of several RNA structural motifs which form building blocks for larger RNA-containing biomolecules has been studied by MD simulations on the nanosecond time scale. Simulations on such motifs start typically from experimentally determined structures and can give important insights into the dynamics and how it is coupled to the function of RNA structural motifs.

An ultimate goal of simulation studies on nucleic acids is to follow the complete structure formation process starting from an unfolded RNA or DNA conformation. As described below this is indeed possible for small structural motifs such as short hairpin structures using atomistic MD simulation methods but still impossible for any larger structure of biological relevance. Since it involves large structures with dozens or even hundreds of nucleotides and involves time scales that are beyond current atomistic simulation approaches, often simplified (coarse-grained) models are used. In such simulations each nucleotide is represented by a reduced number of beads (interaction centers) and the solvent is not modeled explicitly (reviewed in Kara and Zacharias 2013a). However, even more extensive coarse-graining is possible. Coarse-grained representations have, for example, been successfully applied to model the fiber structure of chromatin (reviewed in Sim et al. 2012) with whole nucleosomes (or parts of nucleosomes) as coarse-grained centers. In the current chapter, we will focus on atomistic simulation studies on nucleic acids and methods to improve sampling such that structural transitions occurring on long time scales can still be sampled during advanced sampling MD simulations.

Unfortunately, the conformational sampling during conventional (c)MD simulations is strongly limited by the maximum simulation time that can currently be achieved. Even simulations of hundreds of nanoseconds or few microseconds that are currently possible are often too short to observe significant conformational transitions or the refolding of RNA or DNA structures. The poor sampling is due to kinetic trapping events in low-energy regions of the conformational free energy surface. The rugged nature of the energy hypersurface is in particular due to frequent atomic surface proximity inducing hard-core van der Waals repulsion and due to a restricted allowable set of rotamers in the nucleic acid backbone dihedral angles. Thus, many interesting questions about non-equilibrium dynamics of biomolecules cannot be resolved by current equilibrium cMD simulations.

Induced Conformational Changes During Molecular Dynamics Simulations

In cases where one is interested in specific conformational transitions, it is possible to overcome the sampling problem by inducing a desired conformational change during a simulation. This is possible if one can associate a specific parameter (reaction coordinate) with the conformational change of interest. The choice of such reaction coordinate is in general nontrivial and very task dependent. It is then possible to enforce structural transitions in MD simulations by adding a penalty potential (called umbrella potential) that biases the sampled conformations toward a desired state. The reaction coordinate can, for example, be the bending or stretching of a DNA molecule. Variants of this approach like targeted MD simulations where one enforces movement of atoms toward a desired target structure have also been developed (Sanbonmatsu and Tung 2007).

Typically, in umbrella sampling simulations, one adds a quadratic penalty term to the force field for keeping sampled states close to a desired interval along the reaction coordinate.

The consecutive sampling windows ensure a good probability of sampling along the generalized reaction coordinate. From the distributions of conformations within all the intervals along the reaction coordinate, it is possible to extract the associated free energy change for the transition (Fig. 1). Then an optimal unbiased probability density along the generalized coordinate can be recovered by statistical methods based on the analysis of weighted histograms (WHAM, see reference Kumar et al. 1992). The corrected probability density in turn equates the free energy along the generalized coordinate. The umbrella sampling methodology has been applied frequently to study structural transitions in nucleic acid molecules in recent years. Among these simulations are studies on the energetics of stacking and unstacking of nucleotides (Norberg and Nilsson 1995) and studies of the groove deformation of DNA (Zacharias 2006) which can play a major role for the binding and recognition by proteins. The specific looping out of single bases (base flipping) within a duplex DNA is another process that has been studied using umbrella sampling methods (Giudice et al. 2003; Giudice and Lavery 2003; Huang et al. 2003). Nucleo-base looping out events are of significant biological importance because it forms the mechanistic basis for repairing mispaired or damaged bases by a number of DNA repair enzymes (Dalhus et al. 2009). In addition, many DNA methylases induce looping out of nucleo-bases to perform sequence-specific methylation (Cheng and Blumenthal 2008).

Several umbrella sampling studies have been performed in order to calculate the free energy change associated with looping out a stacked and paired base in duplex DNA and RNA (Giudice et al. 2003; Giudice and Lavery 2003; Huang et al. 2003; Hart et al. 2005; Barthel and Zacharias 2006) and using either a pseudo angular or dihedral angle reaction coordinate. The calculated free energy in the range of 10–18 kcal mol⁻¹ indicates that looping out a paired base in DNA is unfavorable and corresponds to a rare event in case of free duplex DNA. In case of

Fig. 1 Illustration of umbrella sampling simulations on induced minor groove opening in two DNA sequences (according to Zacharias 2006). The reaction coordinate for this simulation was the distance between two groups of backbone atoms on opposite DNA strands (*double arrow*). The distance was harmonically restrained to various values close to the reference distance d_{ref} (*upper panel*). Conformational snapshots observed during different stages of the umbrella sampling simulation are shown as van der Waals representations (*upper panel*, atom color code), and the d_{ref} distance and the helical axis directions (*bold arrows*) are indicated. In the *lower panel*, the calculated free energy changes versus distance extracted from the umbrella sampling simulations for a self-complementary 5'-CGCGAAATTCGCG sequence (upper set of curves) and for the 5'-CGCGTATATACGCG sequence (smaller free energy changes) are indicated. The different *line* colors correspond to different simulation lengths (1 and 2 ns per simulation window and combined data) in the forward direction (increasing d_{ref}), and the *dashed line* represents the result for a backward simulation starting from the DNA with the opened minor groove (Further details in Zacharias 2006)

looping out extra-unmatched bases stacked between neighboring base-paired duplex RNA, a significantly smaller barrier for looping out was found and it was possible to characterize stable conformational substates such as base triples that formed during the looping out process (Barthel and Zacharias 2006; Hart et al. 2005). The lower associated free energy of looping out extra-unmatched bases indicates that such conformations can be significantly populated and are in equilibrium with stacked intra-helical states. In addition to localized structural transitions such as looping out bases, the umbrella sampling method has also been used to study global deformations of DNA and RNA molecules. This includes induced minor groove

opening and closing (Zacharias 2006) as well as over- and under-twisting of duplex DNA (Kannan et al. 2006). The opening of the minor groove is essential for the binding of several DNA-binding proteins, among them the prominent example of the TATA box-binding transcription factors (Kim and Burley 1994; Nikolov et al. 1996). Simulation studies on duplexes with a central TATATA or AAATTT sequence motif showed significant differences in the calculated free energies associated with minor groove opening and a much smaller associated free energy change for the TATATA versus AAATTT case (see Fig. 1). The calculations indicated that the free energy change associated with the deformation of DNA toward a form with an open minor groove (as seen in several protein–DNA complexes) can be significant and depends on the sequence. It also allows one to estimate the free energy contribution to the indirect readout of DNA due to differences in deformability.

Replica-Exchange Molecular Dynamics Simulations

The application of classical molecular dynamics (cMD) simulations for studying the dynamics of biomolecules is limited by the accuracy of current force fields and the simulation time scale. Biomolecules like peptides and nucleic acids can adopt a variety of locally stable conformations that are separated by large energy barriers. Standard MD simulation at room temperature may be kinetically trapped in one of these local minima, and conformational transitions between stable states can therefore be rare events on currently accessible time scales. The replica-exchange (parallel tempering) technique is a widely used method to enhance conformational sampling in Monte Carlo (MC) (Swendsen and Wang 1986) and MD simulations (Gnanakaran et al. 2003; Sugita and Okamoto 1999; Kaihsu 2004; Ostermeir and Zacharias 2013; Luitz et al. 2015). In replica-exchange simulations, several copies (replicas) of the system are simulated independently and simultaneously using classical MD or MC methods at different simulation temperatures (or force fields: Hamiltonians). In standard REMD, copies or replicas of the system are simulated at different temperature ($T_0, T_1, T_2, \dots, T_N$). Each replica evolves independently, and after preset intervals (in the range of 500–1000 MD steps ~ 1 –2 ps), an exchange of pairs of neighboring replica is attempted according to a Metropolis acceptance criterion:

$$\begin{aligned} w(x_i \rightarrow x_j) &= 1 && \text{for } \Delta \leq 0; \\ w(x_i \rightarrow x_j) &= \exp(-\Delta) && \text{for } \Delta > 0 \end{aligned} \quad (2)$$

where

$$\Delta = (\beta_i - \beta_j) [E(r_j) - E(r_i)]$$

with $\beta = 1/RT$ (R , gas constant, and T , temperature) and $E(r)$ representing the potential energy of system for a given configuration.

The random walk in temperature allows conformations trapped in locally stable states (at a low simulation temperature) to escape by exchanging with replicas at higher simulation temperature. The REMD method has been successfully applied in

folding simulations of several peptides and mini-proteins (Kaihsu 2004; Kannan and Zacharias 2007a; reviewed in Ostermeir and Zacharias 2013; Luitz et al. 2015) and has more recently also being used for studying nucleic acids (Kannan and Zacharias 2007a; Zhuang et al. 2007; Villa et al. 2008; Kannan and Zacharias 2009; Garcia and Paschek 2008; Villa et al. 2008; Chen and García 2013).

Recently, Kannan and Zacharias (2007a) applied the REMD method to study the folding process of a DNA hairpin structure. Hairpin loops with a central GNA trinucleotide motif (G, guanine; A, adenine; N, any nucleotide) have been found to form particularly stable structures (Yoshizawa et al. 1997). For example, the 5'-GCGCAGC sequence in DNA forms a stable trinucleotide hairpin loop (with a sheared G:A closing pair) flanked by a two-base pair stem helix. The thermodynamic stability of the GCA trinucleotide loop, the influence of loop expansion, the influence of closing and flanking sequences, and also the contribution of individual hydrogen bonds and other nonbonded contacts to the folding stability have been studied extensively (Moody and Bevilacqua 2003).

Temperature-based REMD with 16 replicas in explicit solvent was used to study the structure formations of the 5'-GCGCAGC motif in DNA (Kannan and Zacharias 2007a) starting from single-stranded DNA. After an equilibration phase at constant pressure and temperature, the REMD simulations were conducted under constant volume using 16 replicas ranging in temperature from 315 K to 425 K. During REMD simulations (each 36 ns), conformations in very close agreement with the experimental hairpin structure appeared as dominant conformations during the final phase of the REMD simulations (~35 % at the lowest temperature replica). During REMD simulations already at a simulation time of 12 ns, conformations with an Rmsd of ~2 Å from experiment were sampled. After ~15–20 ns simulation time conformations as close as 1.2–1.6 Å (heavy atoms) with respect to the reference hairpin conformation were sampled as the dominant conformational states (Fig. 2). Simultaneous compaction and accumulation of folded structures were observed. Interestingly, at early stages of the simulations, a variety of central loop conformations but also arrangements close to experiment were sampled before the fully folded structure appeared. The analysis of intermediates at or shortly before the occurrence of fully folded hairpin structures indicated the formation of near-native trinucleotide loop conformations (without fully formed stem). Most of these intermediates included a stacking of the C₂ and G₃ bases which was further stabilized by hydrogen bonding to the A₅ base. Folding to the native hairpin structure appeared to occur almost simultaneously or quickly after the formation of the near-native trinucleotide loop. The folding of a similar DNA hairpin motif has also been successfully achieved in very long continuous MD simulations (Portella and Orozco 2010).

The REMD methodology has also been used for simulation studies of an RNA hairpin and for the folding of an RNA tetraloop r(5'-GCUUCGGC) in explicit solvent starting from a fully extended conformation using 52 replicas (Garcia and Paschek 2008). Apart from the folding process, REMD simulations were used to study the effect of changing the loop sequence and the closing base pair on the conformational distribution and on the thermostability of two RNA hairpins that

Fig. 2 (Left panel) Heavy atom root mean square deviation (*Rmsd*) of sampled DNA conformations (5'-GCGCAGC) from folded hairpin structure during a continuous MD simulation (*upper graph*) and a T-REMD simulation (*lower graph*) versus simulation time. (Right panel) Single-stranded start structure (*left*) and fully folded hairpin loop structure from the REMD simulation (*green stick model, right side*) superimposed onto the experimental hairpin structure (*blue color*)

have similar structures (Villa et al. 2008). A variation of REMD, called serial replica-exchange molecular dynamics (SREMD), has been employed to gain insight into the folding intermediates of another common RNA tetraloop hairpin with a central GCAA loop sequence (Bowman et al. 2008). Recently, also more complex motifs have been studied using T-REMD (Haldar et al. 2015).

T-REMD will fail if barriers are mostly entropic, and it has also been shown that sampling can even become worse compared to regular cMD for particular systems (Denschlag et al. 2008). The total number of exchanges within a fixed total simulation time can simply be increased by attempting more exchanges per time interval. This is expected to enhance the diffusion in the temperature ladder and in turn may improve the sampling (per simulation time interval). It has also been argued that a minimum time interval of ~ 1 ps should be respected to allow sufficient relaxation of the system after an exchange. However, recent studies suggest that increasing the exchange attempt rate may indeed improve the sampling of relevant states (Sindhikara et al. 2010). It has also been emphasized that the temperature control algorithm itself (the thermostat) of each replica run can influence the efficiency of T-REMD simulations and can create simulation artifacts (Rosta and Hummer 2010). Use of velocity scaling schemes, in particular, may not guarantee canonical sampling in each replica. Also, the schemes of performing exchanges between neighbors can affect the T-REMD performance (Rosta and Hummer 2010). Although the REMD methodology improves sampling in the above-discussed cases, a drawback of the conventional temperature (T-)REMD is the rapid increase of the number of replicas with increasing system size in order to cover a desired temperature range (Fukunishi et al. 2002). The ratio of the standard deviation of the system potential energy (a measure of the energy fluctuation) versus average energy decreases with the square root of the system size. Hence, to achieve sufficient overlap of the energy distributions between replica runs at different temperatures (required to achieve a reasonable exchange acceptance ratio),

the temperature “spacing” between neighboring replicas is required to decrease with system size. Another drawback of large numbers of replicas is the need to run longer simulations (or more exchanges) to allow sufficient “traveling (diffusion)” or exchanges between high- and low-temperature replicas compared to a small number of replicas. Especially in the case of simulations that include a large number of explicit water molecules, the rapid increase of the number of replicas in T-REMD simulations limits the applicability to small bimolecular systems.

Instead of using the simulation temperature as a replica coordinate, one can also use the force field or Hamiltonian of the system as a replica coordinate (Fukunishi et al. 2002; Jang et al. 2003; Liu et al. 2005; Affentranger et al. 2006; Kannan and Zacharias 2007b; Zacharias 2008). In H-REMD simulations it is possible to modify only a part of the Hamiltonian along the replica simulations. The advantage is that then exchanges between replicas depend only on the part of the Hamiltonian that differs between replicas. Consequently such approaches may require much fewer replicas for efficient sampling compared with T-REMD. Various H-REMD methods have been proposed mainly for peptides and proteins and demonstrated enhanced conformational sampling can be achieved with fewer replicas as compared to standard T-REMD (reviewed in Ostermeir and Zacharias 2013; Lutz et al. 2015).

Combining Replica-Exchange and Umbrella Sampling Simulations

Combining umbrella sampling with the replica exchanges is a variant of the H-REMD method (Sugita et al. 2000; Curuksu et al. 2009a) and consists of periodically swapping conformations between adjacent umbrella sampling windows i and j . The exchange criterion takes the form of an equation of micro-reversibility which takes into account the conformational probability density of the two windows i and j , i.e., Boltzmann factors based on the biased potential energy function of window i and window j . One advantage of coupling umbrella sampling with replica exchanges (REUS) is due to the fact that in general there is no obvious best possible coordinate for a given dynamical conformational transition (Sugita et al. 2000), especially when it involves many degrees of freedom (typically bending and folding of biomolecules). As a consequence it may not be possible to overcome all relevant barriers within the phase space associated to a given value of the generalized coordinate, i.e., within each umbrella window. The restriction of sampling only a narrow range along a reaction coordinate can cause conformational trapping of the sampled structures. Through periodic swaps between the sampling windows, the conformations trapped in a low-energy region of the conformational landscape easily diffuse to neighboring windows with a different associated umbrella energy function. Hence, the neighbor replicas provide an enhanced variety of conformations accessible to every sampling window in the limit of a high number of swaps between the windows. In the area of nucleic acids, this methodology has been applied, for example, in a study of adenine riboswitches (Di Palma et al. 2015)

and in simulation studies on the free energy of bending of the kink-turn motif in RNA (Curuksu et al. 2009a).

Simulation Studies on DNA Bending

Bent (i.e., curved) conformational states of DNA over several base pairs can be seen in many protein–DNA complexes (Zakrzewska 2003), in nucleosomal organizations of eukaryotic genetic material (Ong et al. 2007), in the prokaryotic nucleolus (Travers and Muskhelishvili 2005), and in viral DNA packed in capsids (Garcia et al. 2007). Several experimental studies employing cyclization assays (Cloutier and Widom 2004), molecular force sensors (Shroff et al. 2005), FRET (fluorescence resonance energy transfer) (Yuan et al. 2008), and AFM (atomic force microscopy) (Wiggins et al. 2006) experiments indicate that strong DNA bending may result in base pair kinking and a smaller deformation energy than expected from simple elastic models. The occurrence of sharp kinks in MD simulations of short minicircles was reported in (Lankas et al. 2006) with the same DNA sequences as studied experimentally in (Cloutier and Widom 2004).

DNA bending during MD simulations can be imposed by an appropriate restraint between regions flanking the DNA region of interest (Curuksu et al. 2009b) or, alternatively, circularizing this DNA sequence into minicircles (Lankas et al. 2006; Fig. 3). A full dynamical pathway of nucleic acids, global bending can also be characterized by MD simulations combined with enhanced sampling (Curuksu et al. 2008, 2009b), such as the umbrella sampling and replica-exchange (REUS) method introduced in the previous paragraph.

To gain insight into the full dynamical pathway of DNA global bending, our laboratory has carried out umbrella sampling by defining a generalized coordinate

Fig. 3 Geometrical methods to induce bending of nucleic acids molecules. (*Left panel*): “self bent” DNA minicircle system. (*Right panels*): duplex DNA oligonucleotide bent by the load imposed at its two ends when restraining the angle between two vector handles (Curuksu et al. 2008). The vector handles (local helical axis) are indicated as *lines* and the local axis vectors as *short arrows*

for bending short DNA oligomers (Curuksu et al. 2008, 2009b). The bend angle is defined as an angle between two screw axes of the double helical segments referred to as handles. To calculate each screw axis, internucleotide rotation vectors are calculated for several neighboring dinucleotide steps within a fragment of n base pairs. Each rotation vector is based on a rotation matrix that is the total transformation from one nucleotide-fixed axis system into the coordinate frame of its neighboring nucleotide. The sum of the rotation vectors defines a vector “handle” oriented as a function of $(2n-2)$ specific internucleotide rotation angles (Curuksu et al. 2008).

During the simulations described in Curuksu et al. 2009b, four terminal base pairs at each end of a 15-base pair duplex DNA molecule were included to define two (terminal) handles. The global bend angle is given by the angle between the two handle vectors, and a restraining potential of the form $V(\theta) = k(\theta - \theta_{\text{ref}})^2$ was added to the force field (θ corresponds to the angle between the two handles). Since the bend angle restraining potential depends on the position of many atoms (because each handle is influenced by all the atoms that define the local axis system), the restraining force is optimally distributed over all atoms that affect the bending angle. Simulation of several nanoseconds per umbrella sampling window and periodical swapping of conformations between adjacent windows was carried out at regular intervals (every 2 ps). The global bending angle can be smoothly restrained to values around 0° and up to 150° (the most extreme DNA bending regimes as observed in nucleosomes are on the order of 90° for a 15 bp duplex DNA). Figure 4 illustrates the probability histograms of the rotation variable about the long base pair axis between two adjacent base pairs (helical “roll” variable) that characterizes kink motifs through which DNA fragments may relax the bending stress (Lankas et al.

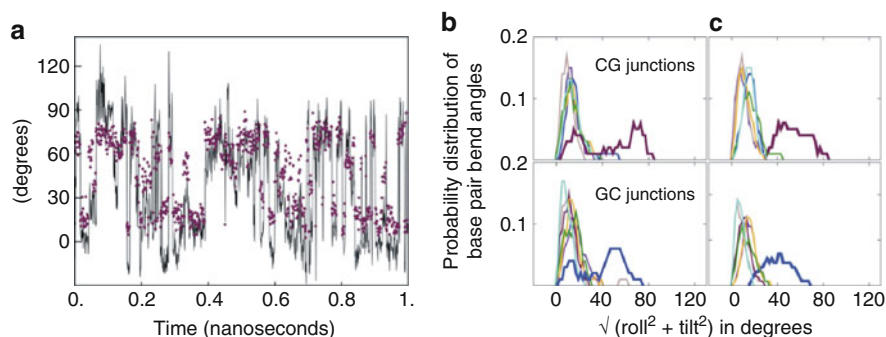

Fig. 4 (a) Time series of roll angle for base pair step C7pG8 (*dots*) and propeller angle at base pair C7:G24 (*line*) in the regime of large induced bending angle (150°) during umbrella sampling *with* replica exchange of the duplex $d(\text{CGCGCGCGCGCGCG})_2$. Roll values were averaged over four adjacent umbrella windows. Base pair kink density histogram observed for simulation windows with large DNA bending strain ($135\text{--}150^\circ$) during umbrella sampling, with (b) and without replica exchanges between neighboring sampling windows (c). Upper set of plots corresponds to roll fluctuations for every pyrimidine–purine base pair steps (CG) and the second set of plots to every purine–pyrimidine base pair steps GC in the oligomer (Unpublished results and Curuksu et al. 2009b)

2006; Curuksu et al. 2009). Reversible partial unstacking events associated with strong local bending kinks at central GC and CG steps were observed in several sampling windows of the REUS application (results for the 150° bending window are shown in Fig. 4a) characterized by a roll angle $>40^\circ$.

The base pair bend density histograms appeared as distributions with two maxima for the two junctions that form a kink (C7G8 in purple and G6C7 in blue) which is not the case in the umbrella sampling without replica exchange (Fig. 4b, c). This means that these two neighboring junctions are both kinked during a significant part of the trajectory as in conventional umbrella sampling [106] but can also adopt stacked conformations (no kink) during another significant part of the same trajectory. This is also indicated in Fig. 4a which illustrates the bend angle of the C7G8 junction and at the propeller twist of the base pair intermediate between G6C7 and C7G8 (C7:G24) as a function of simulation time. Propeller twist is the contrarotation about the long base pair axis within one base pair, and together with the roll deformations above, they were shown to characterize a specific kink motif called type II kink (Lankas et al. 2006). The time series for roll (purple dots) indicates a number of transitions between large bend angles ($\sim 60^\circ$) and small bend angles ($\sim 15^\circ$) corresponding to the two submaxima on the density plot (Fig. 4b) for the C7G8 step. Moreover these transitions occur in concert with propeller transitions (black line) between values typical for B-form DNA and values specific to the type II kink. Thus, the simulations suggested that type II kink is an elastic reversible deformation, which could not have been deduced from a standard umbrella sampling (Curuksu et al. 2009) where no exchange between the sampling windows took place. Clearly, type II kink appears as an important transient DNA motif at the regime of bending probed in the induced bending simulations (up to bend angles of 150°).

Conformational Flexibility of the Kink-Turn Motif in RNA

Recurrent structural motifs can stabilize the tertiary structure of large RNA-containing molecules such as ribosome, spliceosomes, and many other RNA-protein assemblies. Among the most common structures are kink-turn motifs (K-turns) that are characterized by a sharp bend ($\sim 120^\circ$, included angle of $\sim 60^\circ$, also frequently called “V-type” structure) of the phosphodiester backbone between a canonical helix (Watson-Crick base pairs, C-stem) and a helix that contains noncanonical (typically Hoogsteen) base pairs (termed NC stem) (Huang and Lilley 2015). The tip of the “V” structure forms a short asymmetric loop comprising nominally unpaired nucleotides between the two flanking rigid stems. K-turns can also form protein-binding regions and may mediate hinge motion in RNA-containing assemblies. The dynamics of such K-turn motifs have been studied extensively by continuous MD simulations (e.g., Razga et al. 2006) and also by a number of experimental approaches (Goody et al. 2004; Huang and Lilley 2015). However, continuous MD simulations may not cover the full range of possible conformational states for bending and kinking because of the existence of local minima separated by large barriers along a bending coordinate. In order to quantify

the full free energy landscape of K-turn bending, Curuksu et al. (2009) performed umbrella sampling simulations on this system (Fig. 5). A key structural element of the K-turn structure is the A-minor motif (illustrated in Fig. 5b). The A-minor motif stabilizes the characteristic global kinked (V-shaped) conformation of the K-turn. In order to characterize the relation between global structure and stability of the central A-minor motif, a reaction coordinate corresponding to the center-of-mass distance between the central adenine base and the adjacent G:C base pair (Fig. 5b) was employed (Curuksu et al. 2009). A quadratic penalty potential was used to open the A-minor motif, and in order to improve the sampling of relevant conformational states, the authors combined the US approach with H-REMD (H-REUS) allowing for exchanges between neighboring umbrella windows at frequent intervals during the simulations. The application of this H-REUS technique significantly improved the convergence of the calculated free energy landscape along the bending/kinking coordinate for the K-turn structural motif (Fig. 5c, d). It was also possible to identify intermediate states and to investigate the role of water molecules to mediate transitions or stabilize intermediate structures (Curuksu et al. 2009).

Conformational Transitions of Nucleic Acid Backbone States

Various phosphodiester backbone substates can be found in X-ray crystal structures of free nucleic acids and in complexes with proteins (Djuranovic and Hartmann 2004; Varnai et al. 2002). In particular, the coupled ε (rotation around C3'-O3' bond in C4'-C3'-O3'-P) and ζ (rotation around O3'-P bond in C3'-O3'-P-O5') in gauche-/trans and in trans/gauche-regimes, termed B_I and B_{II} substates, respectively, are frequent in crystal structures of free DNA (Varnai et al. 2002).

Since conformational transitions in dsDNA or dsRNA often require transitions of backbone dihedral angles, a generalized coordinate defined as a set of dihedral angles can in principle promote more global transitions. For example, we have designed a replica-exchange method that employs different levels of a specific biasing potential (illustrated in Fig. 6) to induce coupled transitions of the nucleic acid backbone dihedral angles (e.g., ε/ζ dihedral angles or pseudo-dihedral angles; see below) along the replicas (Curuksu and Zacharias 2009). The sampled conformations can exchange with a reference replica that is controlled by the original force field. The choice of biasing potentials in the replicas can be either fixed at the beginning of the simulation or optimized during an equilibration phase. The nucleic acid dihedral angle-dependent biasing potential that destabilizes a given ε/ζ combination takes the following form (penalty term added to the original force field):

$$v_i(\varepsilon, \zeta) = k \times \begin{cases} \left((x-r)^2 - (R-r)^2 \right)^2 & \text{if } r < x < R \\ (R-r)^4 & \text{if } x < r \\ 0 & \text{otherwise} \end{cases} \quad (3)$$

Fig. 5 (a) Sequence and secondary structure of a kink-turn motif (pdb-entry 1jj2) used for umbrella sampling (H-REUS) simulations along a reaction coordinate to separate the central A-minor motif (b) (Curuksu et al. 2009a). The reaction coordinate (distance between central adenine and a contacting guanine:cytosine base pair) was changed in steps of 0.5 Å using a quadratic biasing potential. (c) Illustration of intermediate states sampled during the simulations (A-minor motif in blue sticks) (d) Calculated free energy change along the reaction coordinate (bold line: H-REUS result, hair line and thin lines correspond to US simulations in the forward and backward directions, respectively, along the reaction coordinate)

where $x = \sqrt{(\epsilon - \epsilon_r)^2 + (\zeta - \zeta_r)^2}$ is the coordinate in the two-dimensional ϵ/ζ phase space defined by taking the center of the ceiling (ϵ_r , ζ_r) as origin (see Fig. 6), r is the radius of the ceiling, and R is the radius of the biasing potential. This function has the shape of a quasi-Gaussian with flat ceiling but does not use the computationally expensive exponential function. The width and height of the potential can be independently chosen, and different levels of the potential (with different values of k or E_{\max}) were used along the replicas to destabilize some

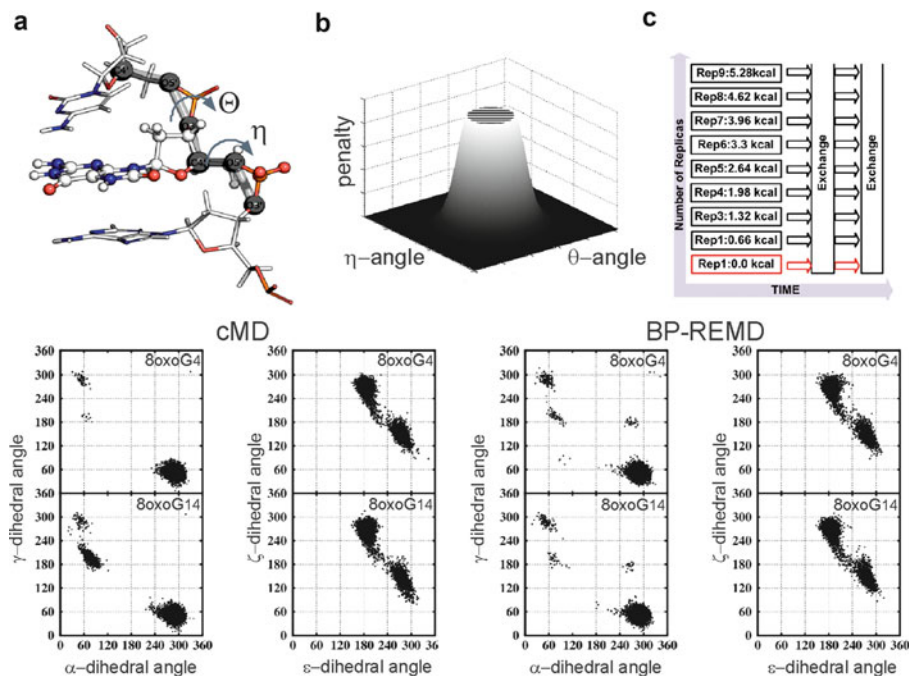

Fig. 6 (a) Illustration of the pseudo-dihedral angles η and θ used to define biasing potentials along replicas in biasing potential H-REMD simulations to promote dihedral transition in the nucleic acid backbone (Kara and Zacharias 2013b). The form of the two-dimensional biasing potentials is illustrated in (b) and the scheme of the BP-REMD simulations in (c). Note that one simulation (out of nine replicas) run without biasing under the control of the original force field. In the *lower panels*, the sampling of α/γ and ε/ζ backbone dihedral angle at the damaged 8oxoG nucleotides (at the two equivalent positions 4 and 14 of the duplex) is illustrated (Kara and Zacharias 2013b) for the cMD simulations (200 ns) and the BP-REMD simulations (10 ns). Each dot in the plots corresponds to sampled dihedral pairs of a conformation sampled every 0.75 ps. Only the sampling in the reference replica (at the original force field in BP-REMD) is recorded. Since the sampling at the two equivalent damaged sites (positions 4 and 14 in the duplex, Kara and Zacharias 2013b) is expected to be the same, the comparison especially of the α/γ states indicates a 10 ns BP-REMD simulation achieves much better convergence than a 200 ns cMD simulation (compare lower plots for the α/γ case)

given ε/ζ substates. Instead of employing a two-dimensional (2D) biasing potential specific for a given pair of ε/ζ dihedral angles, it is also possible to extend the method to employ a biasing potential that acts on pairs of pseudo-dihedral angles (Kara and Zacharias 2013b). The advantage is to cover the coupling of a larger set of dihedral angles embedded in the backbone segment defined by the pseudo-dihedral angles. Kara and Zacharias (2013b) used the nucleic acid backbone atoms $O3'-O5'-C4'-O3'$ in case of the η (here the first $O3'$ belongs to the previous nucleotide) and $C4'-O3'-O5'-C4'$ in case of the θ ($O5'$ and $C4'$ belong to the next nucleotide) pseudo-dihedral angle (illustrated in Fig. 6). Changes in these dihedral angles correlate with the two

most important conformational substates compatible with B-DNA: coupled changes of the α and γ dihedral angles (also called crank shift motions or α/γ -flip) and coupled changes of ϵ and ζ dihedral angles (Perez et al. 2007b).

The method was applied to study the conformational substates of nucleotides damaged by oxidation at the C8 atom of the guanine base (Kara and Zacharias 2013b). Oxidation of nucleobases is one of the most common sources of mutations in DNA and plays a crucial role in mutagenesis of human DNA, carcinogenesis, and aging (Dempfle and Harrison 1994). DNA damage can also alter the fine structure of DNA which may serve as a recognition signal for DNA repair enzymes. The most common and among the most mutagenic oxidative DNA modifications is the formation of 7,8-dihydro-8-oxoguanine, often called 8-oxoguanine. It is a result of the oxidation of the guanine C8, N7 atoms. The damaged guanine has the potential to pair not only with cytosine (C) but also with other bases (most commonly with adenine, A). An 8oxoG can incorrectly pair with A in a Hoogsteen mode (can form during the replication process) which during further replication rounds increases the number of G:C to T:A transversion mutations (Dempfle and Harrison 1994) These transversions are the second most common somatic mutations found in human cancers.

Biasing potential replica-exchange MD (BP-REMD) simulations as described above (see also Fig. 6) were started from regular B-form duplex start structures. The example DNA structures corresponded to palindromic sequences which contain 8oxoG sites in identical sequence context in the two equal strands. Hence, in case of convergence, the same sampling of conformational substates is expected to be identical for both damaged sites (or undamaged sites in case of the reference simulations with G instead of 8oxoG). The same start structures were used for cMD simulations and BP-REMD simulations. The use of nine replicas with biasing potentials on pseudo-dihedral pairs varying between 0 and 5.28 kcal·mol⁻¹ was sufficient to promote transitions between substates and still allowed sufficient exchanges and traveling along the replicas (acceptance rate $\sim 50\%$). The BP-REMD simulations were performed for 10 ns and continuous 200 ns cMD simulations were run for comparison (Kara and Zacharias 2013b). For the sampling of B_I and B_{II} substates, very similar results as for the cMD simulations were observed (Fig. 6) which are consistent with the above conclusion of converged sampling of the B_I/B_{II} ratio of substates during 100–200 ns of cMD simulation. The estimated free energy differences between the B_I and B_{II} substates (1.4 vs. 0.5 kcal·mol⁻¹) in case of damaged 8oxoG obtained from the probability distributions agreed quantitatively with the results from the direct free energy calculations for the dihedral angle transition (Kara and Zacharias 2013b). Also similar to the cMD simulations, the BP-REMD results did not indicate any alternative B_I/B_{II} substates at nucleotides 4 and 14 in case of undamaged DNA (G at positions 4 and 14, Fig. 6).

However, although 10 ns BP-REMD and 200 ns cMD indicated similar distributions for the B_I/B_{II} states at the two damaged nucleotides, the situation is different for the sampling of alternative α/γ -substates (Fig. 6). In case of the 8oxoG-containing duplex, not only substantial sampling of several possible substates at

the 8oxoG was observed but importantly also much closer agreement between the substate distributions at the two equivalent positions 4 and 14 in the duplex (Fig. 6). Due to the rapid exchanges between biased replicas and also frequent exchanges with the reference replica, a much more frequent sampling of alternative states in the reference replica was obtained. It is important to note that the total simulation length of the BP-REMD simulations (10 ns) is substantially shorter than the “lifetime” of alternative α/γ -states observed during the cMD simulations. The result indicates that cMD simulations even of 200 ns length are insufficient to yield converged results on possible nucleic acid α/γ -backbone substates, whereas much shorter BP-REMD simulations are better converged as judged by the close agreement in sampling of two equivalent sites in the self-complementary duplex.

From a stereochemical viewpoint, it is possible to qualitatively explain the observed substate preferences. The transition to a BII state results in an on average larger distance (by 0.6 Å) between the deoxyribose O4 atom of the nucleotide and the H8/O8 atoms of the G/8oxoG nucleo-base. While this is a small average distance change, it can result in a substantial decrease of the electrostatic repulsion in case of an 8oxoG in which case both oxygen atoms are partially negatively charged (in case of a G, the closer distance is electrostatically slightly stabilized because the H8 has partially positive charge). The pseudo-dihedral angle dependent 2D biasing potential specifically accelerates the sampling of ϵ/ζ and α/γ dihedral angle pairs but it was found that it also accelerates indirectly transitions of sugar pucker angles (Kara and Zacharias 2013b).

The BP-REMD method using a biasing potential in the replica runs for adjacent ϵ/ζ and α/γ dihedral angles (Curuksu and Zacharias 2009) was also applied to an experimental structure of an abasic site embedded in double-stranded DNA (seven central base pairs of a DNA abasic site deposited in the Protein Data Bank: PDB-entry: 2HSS; Chen et al. 2007). An abasic site occurs notably when chemical or radiation damage of DNA results in the loss of a base in one strand leaving an unpaired base in the opposite strand (Dempfle and Harrison 1994). From conventional MD simulations, it is known that abasic sites have significantly altered dynamics compared to regular DNA (Fujimoto et al. 2005).

In this study a variety of (ϵ/ζ) dihedral substates at the abasic site were sampled during cMD, T-REMD, and BP-REMD simulations. Both cMD and T-REMD approaches undersampled (or did not sample at all) the (*-gauche/trans*) and (*-gauche/+gauche*) regimes for the abasic site (Curuksu and Zacharias 2009). Alternatively, the application of the BP-REMD methodology to a DNA with a central abasic site significantly improved sampling of the ϵ and ζ dihedral angle substates at overall smaller computational costs. The coupling of the global structure of the DNA with a central abasic site to the (ϵ/ζ) dihedral substate sampling is illustrated in Fig. 7. Each of the sampled substate regions at the abasic site correlated with a different global bending geometry of the DNA molecule. This coupling may have important consequences for the recognition process of damaged DNA by repair enzymes.

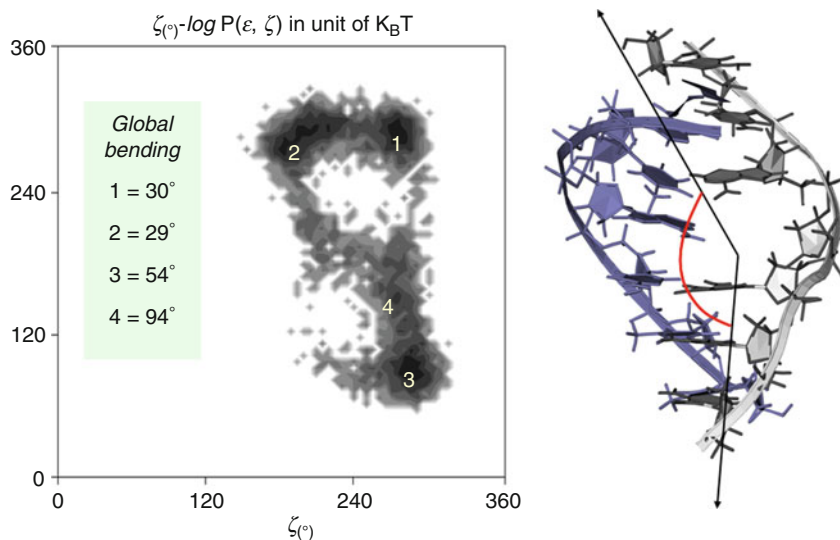

Fig. 7 Coupling of sampled ϵ/ζ dihedral angle substates and global bending of the abasic site [109]. (*Left panel*) Distribution of ϵ/ζ dihedral angles during BP-REMD (replica with the original force field) at the abasic site. The global bend angle of the DNA related to each ϵ/ζ dihedral angle regime is indicated. (*Right panel*) Illustration of the global bend angle in the BP-REMD simulation of a DNA oligonucleotide with central abasic site

Conclusions

The focus of this chapter contribution was the description of Hamiltonian replica-exchange methods to improve umbrella sampling and in combination with a specific biasing potential to promote dihedral transitions in nucleic acid molecules. Umbrella sampling can greatly benefit from frequent exchanges between neighboring sampling intervals to avoid trapping of conformations due to the restraining of the system with respect to a selected regime along a reaction coordinate. This can significantly improve the free energy convergence of such calculations. The technique has a wide range of possible applications to investigate the deformability of DNA and RNA molecules and to better understand its coupling to recognition by proteins and other ligands. The H-REMD technique based on specific biasing potentials to promote dihedral transitions described in the last paragraph can help to better characterize available backbone dihedral angle substates of nucleic acids. In future applications it could help to yield a better understanding of the relation between nucleic acid fine structure and how it is influenced by protein binding or could also be used to improve sampling during nucleic acid folding simulations.

Abstract

Mixed-quantum classical dynamics simulations have recently become an important tool for investigations of time-dependent properties of electronically excited molecules, including non-adiabatic effects occurring during internal conversion

processes. The high computational costs involved in such simulations have often led to simulation of model compounds instead of the full biochemical system. This chapter reviews recent dynamics results obtained for models of three classes of biologically relevant systems: protonated Schiff base chains as models for the chromophore of rhodopsin proteins; nucleobases and heteroaromatic rings as models for UV-excited nucleic acids; and formamide as a model for photoexcited peptide bonds.

List of Abbreviations

BLA	Bond length alternation
BP	Bicycle pedal
bR	Bacteriorhodopsin
CAS	Complete active space
CASSCF	CAS self-consistent field
CASPT2	CAS second-order perturbation theory
DFT	Density functional theory
DFTB	Density functional based tight binding
ESI	Electrospray ionization
FT	Folding table
GVB,PP	Generalized valence bond in the perfect pairing approximation
HT	Hula-twist
LIIC	Linear interpolation of internal coordinates
MALDI	Matrix-assisted laser-desorption ionization
MCSCF	Multiconfigurational self-consistent field
MCTDH	Multiconfigurational time-dependent Hartree
MRCI	Multireference configuration interaction
MR-CIS	MRCI with single excitations
MR-CISD	MRCI with single and double excitations
MXS	Minimum on the crossing seam
NRBP	Non-rigid bicycle pedal
OBF	One bond flip
OM2	Orthogonalization model 2
PSB	Protonated Schiff base
PSB _n	PSB with n double bonds
QM/MM	Quantum-mechanical/molecular-mechanical
Rh	Rhodopsin
ROKS	Restricted open-shell Kohn-Sham
RPSB	Retinal protonated Schiff base
SA	State average
TDSE	Time-dependent Schrodinger equation
UV	Ultraviolet
WC	Watson-Crick
ZPE	Zero point energy

Introduction

Photoelectronic excitation of organic molecules may trigger complex series of chemical and physical events, which are activated not only by the excess of energy provided by the photon but also by the reactive nature of the excited-state potential energy surfaces. While electronic ground states normally present relatively high barriers for interconversion between minima and strong adiabatic character, excited-state potential energy surfaces tend to show much lower energy barriers and numerous crossings between adiabatic states. The low energy barriers allow the molecule to explore geometric conformations that challenges the chemical intuition. The state crossings bring the molecule to the limit of validity of the Born–Oppenheimer approximation.

Between the photoabsorption and the formation of the final products, the electronic energy excess may be converted into mechanical energy of molecular vibration, isomerization, and dissociation, it may be dissipated as heat into the environment, or it may be reemitted with a red-shifted wavenumber. A measure of how diverse and complex these processes are can be seen from the fact that, depending on the molecule and on the excitation wavelength, they span a range of more than ten orders of magnitude between a few tens of femtoseconds of a radiationless decay and the milliseconds of the phosphorescent decay (Zewail 2000). Besides their intrinsic interest in basic sciences, molecular photoactivated processes are relevant for important natural phenomena and technological applications. In terms of the natural phenomena that will be discussed in this chapter, they constitute the first steps for the primary process of vision (Wald 1968) and the remarkable photostability of the five natural nucleic acid bases may have had important impact on life on Earth (Crespo-Hernandez et al. 2005).

In this chapter we will focus on dynamics simulations for photoexcited molecules and the understanding these simulations may provide. Naturally, dynamics simulations are tailored to answer questions related to time-dependent properties such as time constants of specific processes. In addition, dynamics simulations show which regions of the configuration space are explored and whether they are populated or not. For example, one may frequently find multiple reaction pathways departing from the Franck-Condon region that are all energetically accessible (Barbatti and Lischka 2008). While conventional static calculations with optimization of stationary structures can reveal such pathways but only give indirect information on the importance of each one based on relative energies, dynamics simulations can, in principle, tell much more precisely which one will be preferred and when it will be activated.

The applicability of excited-state dynamics simulations is still limited by its extreme computational demands. Different from ground-state dynamics simulations for which good force-fields and semi-empirical methods are available for computationally efficient simulations, the treatment of molecules in excited states depends very much on costly electronic structure calculations and on hybrid methods like QM/MM approaches. Moreover, when the molecule evolves into state-crossing regions of the configuration space, non-adiabatic corrections are required too

(Worth and Cederbaum 2004). Despite several attempts to develop semiempirical and DFT-based methods to treat the molecule in such regions (Fabiano et al. 2008b; Granucci et al. 2001; Levine et al. 2006; Tapavicza et al. 2007), the most reliable approaches to date are based on the multiconfiguration self-consistent field (MCSCF) and multireference configuration interaction (MRCI) *ab initio* levels.

Currently, most of the dynamics simulations for systems of chemical or biological interest are performed with the on-the-fly approach, in which energy gradients and other properties are computed as needed during the dynamics propagation. This avoids the cumbersome work of building a multidimensional potential energy surface or being forced to make educated guesses about a few important degrees of freedom. The price to pay for the on-the-fly approach is the lack of non-local information during the dynamics. Thus, the use of the on-the-fly, excited-state dynamics simulation approach should be done with an awareness of the risk of improper description of the zero-point energy and phase space distribution (Santoro et al. 2007b). Luckily, as soon as medium- and large-sized molecules move out of the Franck-Condon region, hot species are formed and such quantum effects tend to be reduced.

In view of the computational costs of the on-the-fly, excited-state dynamics simulations, these calculations are currently limited to few picoseconds of a 10- to 20-atom molecule. This is usually enough to investigate ultrafast internal conversion processes and will be the main topic of this chapter.

With the double aim of reducing computational costs as well as of understanding the most basic constituents in photodynamics processes, it has been common to investigate model systems, which are supposed to be the minimal unit that can still reproduce the photodynamics observed in the complete molecule. In the following sections, we shall review three classes of molecules and their model systems: (1) protonated Schiff bases, models for rhodopsin chromophores; (2) heteroaromatic rings, models for nucleic acid bases; and (3) formamide, model for peptide bonds.

Mixed Quantum-Classical Dynamics Simulations

Mixed quantum-classical approaches (Tully 1998) are the most popular methods to perform on-the-fly, excited-state dynamics simulations including non-adiabatic effects. In these approaches, which include the multiple spawning (Ben-Nun et al. 2000), the surface hopping (Tully 1990), and the Ehrenfest (Li et al. 2005) methods, the nuclear time evolution is treated classically by means of Newton's equations, while the time evolution of the population of each electronic state is treated separately, within different degrees of approximation. In the surface hopping method, the time evolution of the population is obtained in two steps: first, a non-adiabatic transition probability between each pair of states is computed and a stochastic algorithm is applied to decide in which state the classical trajectory is propagated in the next time step. Second, statistics over a large set of independently computed trajectories allow acquisition of the fraction of trajectories (occupation) in each state as a function of time.

Several procedures have been proposed to compute non-adiabatic transition probabilities in the surface hopping approach, from the most simple one, which just assumes that the probability is the unity if the energy gap between two states is smaller than some threshold (Hayashi et al. 2009), to more sophisticated approaches that take into account the variation of wavefunction coefficients (Fabiano et al. 2008a) or compute the Landau-Zener transition probability (Lasser and Swart 2008). One of the most reliable procedures for computing the non-adiabatic transition probability is Tully's fewest switches algorithm (Tully 1990). In this approach, the time-dependent Schrodinger equation (TDSE) is integrated simultaneously to the classical trajectory (Ferretti et al. 1996). To cope with the lack of non-local information introduced by the on-the-fly approach, non-local terms in the TDSE are neglected and the nuclear wavefunction is supposed to be entirely localized at the classical position determined by Newton's equation. Integration of this semi-classical version of the TDSE gives the adiabatic population of the states, which are then used to compute the probability using the fewest switches formula.

The integration of the TDSE depends on non-adiabatic coupling terms connecting different states. If an adiabatic representation is used to expand the molecular wavefunction, non-adiabatic coupling vectors need to be computed. Alternatively, if a diabatic representation is used, non-diagonal Hamiltonian elements are required. Either way, the computation of the non-adiabatic coupling terms are the bottleneck in non-adiabatic dynamics approaches. These terms are usually not available for most of quantum chemical methods and, when they are, they are computationally expensive with the cost increasing with the square of the number of states (Pittner et al. 2009). These difficulties have motivated, on one hand, the search for approximated hopping algorithms as those mentioned above, and on the other hand the computation of the coupling terms based on wavefunction overlaps (Fabiano et al. 2008a; Granucci et al. 2001; Hammes-Schiffer and Tully 1994; Pittner et al. 2009; Tapavicza et al. 2007; Werner et al. 2008). We should also point out that the availability of analytical gradients and non-adiabatic coupling vectors procedures at MRCI and MCSCF levels has been of great importance for dynamics simulations (Dallos et al. 2004; Lischka et al. 2004, 2006; Shepard 1995; Shepard et al. 1992).

One consequence of the hyperlocalization of the nuclear wavefunction in this approach is that non-diagonal terms in the density matrix do not vanish with time as they should do (Granucci and Persico 2007; Zhu et al. 2004). Decoherence can be imposed by applying an ad hoc correction to the adiabatic population every time step (Granucci and Persico 2007), which forces the non-diagonal terms in the density matrix to be reduced to zero within a certain time constant.

When a hopping event between two states takes place, this usually happens at a finite energy gap. To keep the total energy constant in the subsequent trajectory, it is necessary to correct the kinetic energy, for example, by rescaling the momentum or by adding more momentum to the direction of the non-adiabatic coupling vector (Ferretti et al. 1996; Muller and Stock 1997). It may also happen that the stochastic algorithm attempts to make a hop from a lower to an upper state in a region where there is not enough energy to do so. Such cases have been usually treated by forbidding the hopping occurrence (Ferretti et al. 1996). The momentum can be kept

or reversed afterwards. Another possibility is to take the time uncertainty principle to search for a geometry nearby where the hopping is allowed (Jasper et al. 2002).

Because of the stochastic nature of the fewest switches surface hopping approach, trajectories starting with the same initial conditions will give rise to different time development. Moreover, the initial conditions should reflect the initial phase space distribution. Therefore, the averages that define the state occupation should in principle be performed over this double ensemble of trajectories starting in different points of the phase space, several times in each one. Because of computational limitations, this procedure is usually reduced to a single ensemble of trajectories starting only once in different points of the phase space.

The ensemble of initial conditions can be generated in a diversity of ways. For instance, the simulation of an instantaneously excited wave packet into the Franck-Condon region may be achieved by selecting geometries and velocities obtained from a dynamics in the ground state, with this dynamics performed for a period long enough as to allow an adequate sampling of the phase space. Alternatively, each nuclear degree of freedom can be treated within the harmonic approximation and a Wigner distribution can be built. In most of the applications discussed here, the second alternative is used since it is expected to provide realistic initial conditions for single molecules.

Several applications will be reviewed and discussed in the following sections. Specific information about methods used will be given. Details can be found in the proper references. The simulations carried out by the present authors have been performed with the Newton-X program (Barbatti et al. 2007a, b) for mixed quantum-classical dynamics simulations, interfaced with the Columbus program (Lischka et al. 1981, 2001, 2006) for MRCI and MCSCF electronic structure calculations.

Protonated Schiff Base Chains and Retinal

The Primary Mechanism of Vision

Understanding the initial molecular mechanism of vision has been one of the most challenging subjects in the area of computational science during the last four decades (Andruniow et al. 2004; Ben-Nun et al. 1998; Birge 1981; Frutos et al. 2007; Garavelli et al. 1999b; González-Luque et al. 2000; Hayashi et al. 2009; Logunov and Schulten 1996; Polli et al. 2010; Rohrig et al. 2005; Saam et al. 2002; Send and Sundholm 2007; Szymczak et al. 2008, 2009; Wanko et al. 2005; Warshel 1976; Warshel and Barbov 1982; Warshel and Chu 2001; Weingart et al. 2007). The photoisomerization of the retinal protonated Schiff base (RPSB), the chromophore of the visual pigment rhodopsin (Rh) (Birge 1981, 1990; Palings et al. 1987; Schoenlein et al. 1991; Wang et al. 1994), followed by conformational changes in the protein is the primary event that initiates vision. This reaction, involving *cis-trans* isomerization of 11-*cis* RPSB (Fig. 1) to its all-*trans* form belongs to the fastest photochemical reaction in nature (Birge 1990). Many theoretical studies have been dedicated to the exploration of the nature of this process, however, the

Fig. 1 Retinylidene, the chromophore of the rhodopsin proteins, and the Protonated Schiff Base (PSB) models

question of the detailed mechanism and assignment of experimentally obtained lifetimes remains open, mostly due to the fact that the structures of intermediates are unknown to a large extent. The proper description of the mechanism requires involvement of a high-level theoretical treatment, which is especially challenging due to the large size of RPSB, the multireference character of the electronic wavefunction in regions of interest, and the need of dynamics simulations. Besides vision, photoisomerization in rhodopsin proteins is also important for proton pump processes in archae microorganisms (Birge 1981).

The photochemical properties of RPSB have been studied theoretically, mostly by simulation of model systems. Various mechanisms of the process were proposed in the literature, related strongly to the model used in investigations. In the last two decades, large effort has been dedicated to the theoretical modeling of the Rh photo-behavior in the single-torsion motion called one-bond flip (OBF) as the main isomerization mechanism. These predictions, however, were based mostly on calculations of the minimum energy path or dynamics of the short PSB3 model (Garavelli et al. 1997; Migani et al. 2003; Szymczak et al. 2008; Vreven et al. 1997; Weingart et al. 2004, 2006). On the other hand, investigations on longer PSB chains in earlier works by Warshel (Warshel 1976; Warshel and Barboy 1982) or in more recent investigations (Andruniow et al. 2004; Frutos et al. 2007; Hayashi et al. 2009; Ishida et al. 2009; Polli et al. 2010; Saam et al. 2002; Szymczak et al. 2009) indicate that double-torsion mechanisms like bicycle pedal and nonrigid or asynchronous bicycle pedal should be the main isomerization mechanisms. Also our recent results (Szymczak et al. 2009), based on ab initio dynamics simulations of PSB4 model (discussed below) strongly indicate that RPSB isomerizes in the excited state by performing two concerted twist motions, from which only one tends to be continued during the relaxation into the ground state. Torsional motions of similar character were observed in the recent works by Buss and co-workers (Schapiro et al. 2009; Weingart et al. 2007), whose studies were based on similar four double-bond models augmented by two additional methyl groups in the C₉ and C₁₃ positions. It is also worth mentioning that QM/MM simulations of full RPSB employing the restricted open-shell Kohn-Sham (ROKS) method (Rohrig

et al. 2004) do not support double-torsions mechanism, pointing entirely to OBF as a way of performing photoisomerization in the Rh pocket. At the same time, QM/MM minimum energy path investigations of the same system (Gascon and Batista 2004) report non negligible involvement of four additional torsions to the main torsion in the isomerization process. The uncertainty among the scientific community about the nature of mechanism of RPSB photoisomerization clearly shows the need for further investigations in this field.

Model 1: PSB3

The penta-3,5-dieneiminium cation (PSB3) is the shortest of homologues that are investigated to understand the basic principles of the excited state behavior of retinal. It is the first molecule in the group reaching from methaniminium to retinal that features a double bond with further conjugated double bonds on both sides. At the same time the molecule is small enough to still be treated with high computational methods and medium-sized basis sets, even in dynamics. Therefore it has been subject of extensive theoretical investigations, especially by the groups of Robb, Buss, and Olivucci, which have contributed to the understanding of the excited state behavior and deactivation pathways of PSB3 in gas and solvated phases (Barbatti et al. 2007a, 2008; Garavelli et al. 1999a; Keal et al. 2009; Migani et al. 2003; Szymczak et al. 2008; Weingart et al. 2004, 2005).

Most dynamics investigations of PSB3 have been performed on a CASSCF level including all π orbitals in the active space with 6-31G/6-31G* or similar basis sets. The gas phase dynamics of PSB3 can be explained in a two-state, two-mode model (Garavelli et al. 1997; González-Luque et al. 2000; Migani et al. 2003) involving the ground and the first excited ($\pi\pi^*$) states and two dominating motions, a torsion around the central double bond, and the adjustment of the bond length alternation (BLA).

After vertical excitation into the first excited state the bond pattern adjusts to the changed electronic structure. The double/single bond distinction of the ground state is lifted and the BLA, being expressed as the difference between average single bond length and average double bond length, which is somewhat positive at the beginning, drops quickly to a larger negative value. This is accompanied by a shift of the highest occupied orbitals, π and π^* . They are separated from each other at the respective ends of the PSB3 molecule and, each occupied with one electron, induce a torsional motion around the central double bond of the molecule, in a mechanism known as one-bond-flip (Szymczak et al. 2008). This motion leads exactly to a conical intersection that is reached at a perpendicular orientation of the two halves of the molecule and small BLA. The excited state lifetime is about 100 fs. The high torsional momentum leads to a quantum yield of isomerization of PSB3 after photoexcitation of about 60%, regardless of the conformation the process started in, *cis* or *trans*. When restrictions are applied to the extremes of PSB3, another relaxation mechanism starts to compete with the one-bond-flip (Szymczak et al. 2008). This mechanism, named folding table, involves the torsion around the central bond occurring simultaneously to the semi-torsions around the other two formal double bonds.

Surface hopping dynamics simulations of PSB3 with the semiempirical OM2 method (Keal et al. 2009) show a picture very distinct from the CASSCF simulations. Depending on the choice of active space, the excited state relaxation shows a bi-exponential decay profile of the S_1 population, with a fast sub-picosecond time constant and a picosecond time constant. Overall, the relaxation process is predicted to be larger than 600 fs, much slower than the 100 fs predicted by CASSCF. Similar multi-exponential decay has also been described in wave packet propagation on a two-dimensional surface model for RPSB (Santoro et al. 2007b).

Inclusion of a solvent has the potential to change the dynamics drastically. A wide, space-requiring motion of a molecule would be hindered by collisions with the solvent molecules and different deactivation channels, which are normally not accessed, can become the primary path.

To assess the steric environmental effects on the photochemical deactivation of PSB3 it was embedded in a small sphere of n-hexane molecules at room temperature using a QM/MM scheme (Ruckebauer et al. 2010). The surface hopping dynamics simulations discussed here were computed at the MRCIS(4,5)/SA3CASSCF(6,6)/631G level, where 11 orbitals were frozen during the MR-CIS procedure. For solvation, the same quantum mechanical level was employed and 150 n-hexane molecules were introduced into the calculation using electrostatic embedding with the OPLSAA/TIP3P force field (Jorgensen and McDonald 1998).

The comparison of dynamics simulations in gas phase to simulations in n-hexane shows that the relaxation process is not too much affected by solvation. PSB3 is still too small a molecule to show steric hindering of the isomerization. Figure 2, right, shows a snapshot of one trajectory for the twisted PSB3 in n-hexane. It clearly demonstrates that PSB3 rotates in a quite volume conserving way, which minimizes the interactions with the solvent. As a consequence, the lifetime is roughly the same in gas phase and n-hexane (Fig. 2, left), in n-hexane slightly longer than in gas phase simulations, but the effect is limited to a difference of about 3 fs, which is statistically not significant.

Model 2: PSB4

The recent progress in computer capacity and in computational methods made it possible to address by high-level ab initio dynamics more realistic models than the just-described PSB3. In one of our latest investigations (Szymczak et al. 2009), the photodynamics of the hepta-3,5,7-trieniminium cation (PSB4) is investigated by performing extended on-the-fly surface hopping dynamics calculations in vacuo. This compound exhibits a significantly enhanced torsional variability while keeping the computational effort for the on-the-fly surface hopping calculations manageable so that good statistics within the framework of ab initio approaches can be achieved. Similar to our previous work on PSB3 (Szymczak et al. 2008), mechanical restrictions corresponding to the protein link on one PSB4 end and representing the remaining RPSB molecule on the other were applied by increasing masses of corresponding hydrogens to 1,000 amu. The constrained 5-cis isomer of PSB4 was investigated in order to model RPSB in the rhodopsin; dynamics results for doubly

Fig. 2 Average adiabatic populations of PSB3 in gas phase and n-hexane (*left*) and twisted PSB3 in n-hexane (*right*)

restricted PSB4 were then compared to time-dependent femtosecond-resolved experiments (Kochendoerfer and Mathies 1996; Kukura et al. 2005; Peteanu et al. 1993; Schoenlein et al. 1991).

Dynamic simulations were performed at CASSCF level. Eight electrons were included in the calculations within an active space consisting of eight orbitals (four π and the corresponding four π^* orbitals) and averaged over two states [SA-2-CASSCF(8,8)]. To validate the correctness of the method employed, calculations of the vertical excitation energies and conical intersections (MXS) were performed also at MRCI level. Additionally, calculations of LIIC paths from the S_1 minimum to the MXSs give similar, very satisfactory accord between different methods. Thus, the applied theoretical level has been carefully chosen and verified to balance quality of the approach and the computational cost of few hundred thousands of quantum chemical calculations (energies, gradients, and non-adiabatic coupling vectors).

The photorelaxation of PSBn chains is well described by the two-state, two-mode model discussed in the previous section (Garavelli et al. 1997; González-Luque et al. 2000; Migani et al. 2003). After photoexcitation, in the initial stage of the dynamics the PSBn system relaxes by adjusting the bonds lengths, elongating the double bonds and shortening the single bonds. This phase, common to all currently studied PSBn systems, has been described in the previous section. After adjusting all bonds, PSBn proceeds to the second step of the dynamics. The crossing seam is reached by skeletal torsions around one or more bonds. When the molecular system switches from the excited state to the ground state it can either continue or reverse its motion that led to the crossing seam and further relax to the final product geometry.

The kind of torsional motion taking place in PSB4 was assigned to one of five main groups (see Fig. 3): one-bond flip (OBF), bicycle pedal (BP) (Warshel 1976),

Fig. 3 Torsional motions involved in the main isomerization mechanisms: (a) OBF; (b) HT; (c) BP; (d) NRBP; (e) FT

non-rigid bicycle pedal (NRBP) (Warshel and Barboy 1982), hula-twist (HT) (Liu and Asato 1985), and the recently proposed folding table (FT) (Szymczak et al. 2008) mechanisms. A classification scheme was developed (Szymczak et al. 2008, 2009) facilitating the automatic assignment of these structures. It divides the analysis of the torsional dynamics into two stages: motions driving the system to the conical intersection and motions after decaying to the ground state, with independent possibility of investigation of the product formation. The advantage of the proposed scheme is that this classification algorithm is general enough to be applied for the massive amount of information coming from dynamics simulations. It can also be applied for investigations of longer PSBs and can even be further used to study behavior of complete RPSB.

The analysis of the first stage of the process, the mechanisms leading 5-cis-PSB4 to the seam of conical intersections, shows the coexistence of two groups of mechanisms. The first one includes OBF and FT mechanisms and proceeds as such to produce a complete torsion around only one bond, mostly around the one equivalent to the $C_{11}C_{12}$ bond in RPSB. The other rotation proceeds around the $C_{13}C_{14}$ bond, however, its importance is significantly smaller (less than 20% of cases featuring single torsion mechanism). All together, OBF and FT constitute around one third of motions driving 5-cis-PSB4 to the conical intersection. The second group, double-torsion mechanisms, is dominating and appears about twice as frequent as the single-torsion group. It includes BP and NRBP, which are characterized by performing concerted twists around two bonds. Within this group twice as many trajectories feature the NRBP than the BP mechanism. Not a single case of hula-twist motion was observed during the dynamics simulations of 5-cis-PSB4, no matter what was the degree of restrictions (Szymczak et al. 2009).

When returning to the ground state, the excess electronic energy is converted into mechanical energy. In this vibrationally hot ground state there will be freedom to move into different conformations, which in normal thermal situations are usually confined by high potential energy barriers. Since the transfer of the mechanical energy to the protein will take at least several picoseconds (Birge 1981), the motion in the hot ground state may be decisive for the actual quantum yields. The behavior of PSB4 after decaying to the ground state was analyzed from two points of view: firstly, whether the mechanism bringing PSB4 to the intersection seam is reversed or not after hopping; secondly, whether the initial motion results in the associated products or not. Here we concentrate only on the double-torsion mechanisms. The most abundant way of continuation of concerted double-torsion motions is not a complete continuation or reversion, but partial continuation. Interestingly, the second torsion involved in concerted motion is the one equivalent to the $C_{13}C_{14}$ bond in RPSB. The same pattern was observed by Buss and co-workers (Schapiro et al. 2009; Weingart et al. 2007), whose studies were based on a similar four double-bond model PSB4 augmented by two additional methyl groups in the C_9 and C_{13} positions. On the hand, available studies on complete RPSB (Hayashi et al. 2009; Ishida et al. 2009; Warshel 1976; Warshel and Barboy 1982) point to C_9C_{10} as the other torsion involved in the concerted twist mechanism. This difference may suggest that either the chain lengths of the systems studied is still too short for representing complete RPSB or that the methyl group at the C_{13} plays important role in blocking the given torsion in the protein pocket. The full continuation (rotation around both involved double-bonds) of double-torsion group of mechanisms appears only in 22 % of NRBP cases and 10 % of the BP cases. But even when full continuation is observed, the associated photoproduct is formed in half or less of the cases because of the hot ground state isomerization processes. The overall picture that can be drawn from our simulations is the one in which 5-cis-PSB4 performs concerned twists around two double bonds to reach the region of conical intersection of which only one is continued after decaying to the ground state.

Although we expect that inclusion of at least one more double bond to PSB4 model may affect the relative importance of mechanisms or may even reveal new mechanisms, one can clearly see qualitative advance in comparison to the PSB3 case for revealing the role of multiple-bond torsional mechanisms. The next natural step in this sequence of models of Rh and bR chromophores investigations is to perform a full nonadiabatic dynamics for RPSB.

Current Status of the Field

The large improvement of computational capabilities opened new possibilities in the field of studies of the excited state behavior of retinal and retinal model systems. Recent studies on the subject of dynamics are basically going in two directions. First, they combine more extended and complete models of retinal with use of higher theoretical levels. Second, they focus on studies of environmental influence on the electronic structure and excited state behavior. For the latter, two main features are of highest interest: the influence of charged groups on the spectral sensitivity of

retinal and the change in the mechanism leading to the conical intersection when the molecule is restricted in a confined and restricted space. The problem of including environmental effects on the static and dynamic properties of retinal and its models is mostly addressed by using hybrid QM/MM methods. Other studies, as discussed in the previous section, simulated the mechanical constraints for the molecules by means of explicitly constraining the movement of single atoms or groups.

As was previously mentioned, recent work by Schapiro et al. (2009), who employed the PSB4 model augmented by two methyl groups, reports bicycle pedal mechanism involving the equivalent of $C_{13}C_{14}$ bond as a second torsion. Although, these findings are in line with others based on PSB4 (Szymczak et al. 2009) and modified RPSB models (Ishida et al. 2009), simulations involving complete RPSB suggest that the C_9C_{10} should be the secondary bond performing concerted torsion with $C_{11}C_{12}$. Hayashi et al. (2009), have performed CASSCF QM/MM surface hopping dynamics for the complete retinal mechanically embedded in rhodopsin. Their analysis gave a picture in which isomerization around the $C_{11}C_{12}$ double bond is accompanied by coupled torsions around C_9C_{10} and C_6C_7 . It is concluded (Hayashi et al. 2009) that the excited state dynamics proceeds in such a way as to minimize interaction with the protein. On the other hand, scaled CASSCF QM/MM dynamics simulations of a single trajectory of retinal in bovine rhodopsin by Frutos et al. (2007) suggested the action of steric constraints for the torsion around C_9C_{10} . A quenching influence of protein was also proposed in the recent semiempirical QM/MM multiple spawning dynamics by Martinez and coworkers (Virshup et al. 2009). There, in contrast to RPSB simulations in vacuo, environmental effect was predicted to create highly directed dynamics leading to high yields of specific photoproducts. The same was concluded in simulations employing the ROKS method (Rohrig et al. 2004), which predict OBF as the only mechanism responsible for formation of all-*trans* RPSB.

As one can see in this brief review, despite important advances in the studies of retinal and its models based on dynamics simulation methods achieved in the last years, there is still an ongoing discussion about the mechanism of retinal isomerization in rhodopsin proteins, which calls for further investigations.

Heteroaromatic Rings and Nucleic Acid Bases

Photostability of DNA and RNA

The five natural nucleobases, adenine, guanine, cytosine, thymine, and uracil, absorb UV radiation in the range of 250–280 nm (UVC band) and at higher energies of about 200 nm (Abouaf et al. 2003; Clark and Tinoco 1965; Clark et al. 1965; Duggan et al. 1957; Middleton et al. 2009). This radiation, mainly the UVC, which is not blocked by the ozone in the air, causes DNA damage that, when not repaired by enzymatic mechanisms, may lead to mutagenesis and carcinogenesis (Cadet and Berger 1985).

The five nucleobases are non-fluorescent species (Longworth et al. 1966), which implies that the photo-energy is dissipated by means of ultrafast internal conversion. Time-resolved spectroscopy experiments have shown that either in gas phase or in solution the time constant for deactivation of the nucleobases excited at the 260 nm $\pi\pi^* \leftarrow S_0$ band is in the range of 0.5–6 ps (Canuel et al. 2005; Crespo-Hernández et al. 2004; Kang et al. 2002; Ullrich et al. 2004). This means that pathways to conical intersections where radiationless decay occurs are easily available from the Franck-Condon region.

The fact that nucleobases remain in reactive excited states only for a short time has been taken as an indication of enhanced photostability against UV irradiation (Middleton et al. 2009; Serrano-Andres and Merchan 2009). It may have happened that in the prebiotic era or in the early stages of evolution of the genetic code, nucleobases showing ultrafast decay had a competitive advantage against other chemical species more prone to undergo photochemical reactions. Indeed, one of the problems in understanding how life originated is to understand how chemical reactions not controlled by biogenetic mechanisms could lead to a few key substances instead of a multitude of chemicals, all of them with minor concentrations. It has been recently shown (Powner et al. 2009) that one possible route for prebiotic formation of nucleotides possesses as one of the steps an UV bath that could eliminate all but the nucleotides themselves, which reinforce the hypothesis that the intrinsic photostability of the nucleobases played an important role in the origin of life on Earth.

The mechanisms by which the nucleobases return to the ground state are subtly connected to the molecular structure of these bases. For instance, simple tautomerization of adenine into 2-aminopurine results in an increase of excited-state lifetime from 1.1 to 30 ps (Canuel et al. 2005). Methyl-substitution of cytosine or cytidine at C₅ position increases the lifetime in water solution by a factor of seven (Malone et al. 2003). Fluoro-substitution at the same site or acetyl-substitution at N₄ have even larger effects, increasing the lifetime from 1 ps to, respectively, 88 and 280 ps (Malone et al. 2003). Double methyl substitution in positions N₁ and N₃ of thymine increases its lifetime in gas phase from 5 ps (Canuel et al. 2005) to about 150 ps (He et al. 2003). Similar effects were also reported for single and double methyl substitutions in uracil (He et al. 2003).

Protonation and deprotonation of the bases depending on the environmental conditions has also influence on the excited-state lifetimes, although not so strong to make them fluorescent (Longworth et al. 1966). For cytosine, for example, the lifetime in water solution is raised from 1 to 13 ps when the pH is changed from 6.8 to 13 (Malone et al. 2003). For cytidine, the lifetime in water solution is reduced from 1 to 0.6 ps when the pH is changed from 6.8 to 0.08 (Malone et al. 2003). The excited-state lifetimes of nucleobases are dependent on the excitation wavenumber as well. For adenine, it increases from 1.1 ps to about 1.7 ps when the pump wavelength is changed from 276 to 267 nm (Chin et al. 2007). For 1-3-dimethyl thymine, it increases from about 60 to 200 ps when the pump wavelength is changed from 240 to 280 nm (He et al. 2003).

A great deal of theoretical work has been dedicated to nucleobases and their derivatives to identify conical intersections and reaction paths leading to them. In summary it has been found that these conical intersections can be formed by four different mechanisms:

1. Ring-puckering (Marian 2005; Perun et al. 2005a). In these conical intersections, the pyrimidine ring is deformed into conformations that produce twisted bonds (Barbatti et al. 2008). These conical intersections, which normally connect the $\pi\pi^*$ to the ground state, have the same origin as the twisted conical intersection in the methaniminium cation or the twisted pyramidalized conical intersection in ethylene (Barbatti et al. 2008). They are usually connected to the $\pi\pi^*$ state at the Franck-Condon region by barrierless pathways (Merchan et al. 2006). Out-of-plane amino and methyl deformations observed in conical intersections of adenine, cytosine, and thymine are caused by ring puckering as well.
2. Carbonyl out-of-plane deformation (Matsika 2004). In these conical intersections the ring remains planar, while the CO bond becomes almost perpendicular to the ring plane. The paths connecting the Franck-Condon region to them show an up-hill profile, which should decrease their efficiency for internal conversion (Zechmann and Barbatti 2008). This kind of conical intersection is analogous to formamide (Antol et al. 2007) and formaldehyde (Araujo et al. 2008) and connects the $n_O\pi^*$ state to the ground state.
3. Ring-opening (Perun et al. 2005b). These conical intersections are caused by stretching of CN ring bonds and connect $\pi\sigma_{CN}^*$ states to the ground state. Usually they appear in low-energy regions but are separated from the Franck-Condon by high barriers. They are analogous to the stretched-pyramidalized conical intersection in the methaniminium cation (Barbatti et al. 2008).
4. NH stretching (Perun et al. 2005b). These conical intersections connect the $\pi\sigma_{CH}^*$ and the ground states. They are accompanied by small barriers to the $\pi\pi^*$ state in the Franck-Condon region. Several of such conical intersections are not available in the nucleotides because of the hydrogen substitution by the sugar linkage.

Internal conversion may take place not only at the conical intersections of isolated nucleobases but also at intersections formed along the hydrogen bonds connecting base pairs. It has been shown that a charge-transfer state crosses the ground state along the inter-pair hydrogen transfer (Schultz et al. 2004). When this mechanism is compared between guanine-cytosine Watson-Crick (WC) pair and other non-WC pairs formed by the same bases, it turns out that the WC pair possesses the lowest energy crossings (Sobolewski et al. 2005). This has been taken as an indication that inter-pairs internal-conversion may have constituted an evolutionary advantage for WC conformations. This hypothesis, however, has been disputed based on experiments showing that single and double stranded DNA decay follow a similar kinetics (Crespo-Hernandez et al. 2005). According to these experiments, initially excited state decays to an exciplex state in less than 1 ps.

Fig. 4 The five nucleobases and the heterocycle models aminopyrimidine and pyrrole. The connections to the sugar in the nucleotides are indicated by the detached hydrogen atom

The exciplex state involves stacked nucleobases and lives for 10–100 ps before returning to the ground state via charge recombination. The stacking character of the exciplex state limits the damage to one single strand. The undamaged strand may then be used as a template for the repair mechanisms (Crespo-Hernandez et al. 2005; Middleton et al. 2009).

In the next sections we will focus on recent investigations of internal conversion in nucleobases and nucleobase models using dynamics simulations. First, we will explore aminopyrimidine (Fig. 4), a model system that can help to understand how pyrimidine rings deactivate after UV excitation. Then, we will focus on pyrrole, to see how five-membered rings deactivate. Finally, in section “Current Status of the Field,” we will discuss dynamics simulations of the nucleobases themselves.

Model 1: Aminopyrimidine

Pyrimidine rings are structural subunits of all five nucleobases. In fact, the strong UV absorption in the 260 nm band is due to the $\pi\pi^*$ transition in the pyrimidine ring of both pyrimidine and purine nucleobases. For this reason, it is especially relevant to understand how internal conversion takes place in these systems.

Conical intersections in aminopyrimidine are very similar to those in the pyrimidine ring of adenine. The same is true for reaction paths connecting the Franck-Condon region to these conical intersections (Barbatti and Lischka 2008; Barbatti et al. 2008). As can be expected from simple inspection, main differences arise in the two carbon sites where the imidazole group connects with pyrimidine to form the purine structure (Fig. 4). While in aminopyrimidine a low energy conical intersection is formed by puckering of the C_4 atom, this kind of deformation is hindered in the C_4 site of adenine. (Note that the numbering for aminopyrimidine

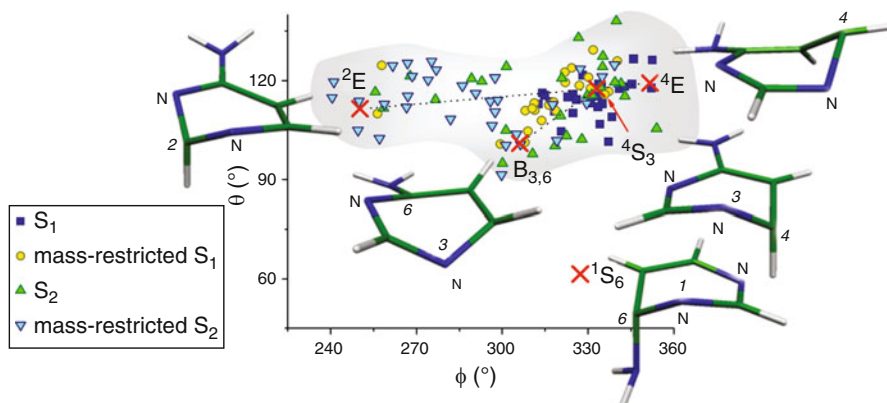

Fig. 5 $S_1 \rightarrow S_0$ hopping position in the $\theta - \phi$ Cremer–Pople space for aminopyrimidine (Data from Barbatti and Lischka 2007; Barbatti et al. 2008)

indicated in Fig. 4 is not the conventional one, but that it is chosen to make the comparison to adenine straightforward.)

A series of investigations have focused on dynamics simulations for aminopyrimidine (Barbatti and Lischka 2007; Barbatti et al. 2008). As we discuss in this section, these results show that in spite of the strong similarities between the electronic excited states of adenine and aminopyrimidine, the restrictions imposed by the imidazole group make the dynamics of the two species essentially distinct.

Surface-hopping dynamics simulations was performed at SA-3-CASSCF(8,7)/6-31G* level (Barbatti and Lischka 2007; Barbatti et al. 2008). First, 30 trajectories were started in the S_1 state. The molecule returned to the ground state in 0.4 ps. A second batch of 30 trajectories was started in the S_2 state. In this case, the $S_2 \rightarrow S_1$ deactivation occurred in only 9 fs. The return to the ground state took place again in about 0.4 ps. These time constants are too fast compared to adenine, which has an excited-state lifetime of 1 ps (Canuel et al. 2005). In order to understand the reason for the difference, we can look at the nuclear conformation at the $S_1 \rightarrow S_0$ hopping time. These conformations are show for all trajectories in Fig. 5 projected on the $\theta - \phi$ Cremer–Pople space (Boeyens 1978; Cremer and Pople 1975). Each point in this space represents a different kind of puckering of a six-membered ring, constituting a very convenient way to describe puckered conformations in heterocycles. As we can see in the figure, both sets of trajectories (starting in S_1 and starting in S_2 states) return to the ground state preferentially at conical intersections showing ring deformation at N_3 and C_4 sites, mainly at the screw-boat conformation 4S_3 . The hopping distribution is more broadly spread when the dynamics starts in S_2 , which can be explained by the energy excess. In this case, we can observe trajectories returning to ground state at the boat conformation $B_{3,6}$ and even a few of them at the envelope 2E conformation.

Since puckering at the C_4 site is hindered in adenine by the imidazole group, the concentration of hopping events involving deformation of this site in

aminopyrimidine explains the difference between the lifetimes of both species. Apparently, aminopyrimidine is decaying at conical intersections not available in adenine. This hypothesis can be tested by restricting puckering deformation at sites C_4 and C_5 of aminopyrimidine in a similar way as they are restricted in adenine (Barbatti and Lischka 2007). To do so, the mass of the hydrogen atoms at these sites is increased to 45 amu. as to emulate the moment of inertia imposed by an imidazole group. Two new sets of 30 trajectories were run. One set starting in the S_1 state and another set starting in the S_2 state. Results of this second set are shown for the first time in this work.

Mass-restricted trajectories starting in S_1 returned to ground state in 0.96 ± 02 ps (Barbatti et al. 2008). In spite of the good agreement with the 1 ps measured for adenine, the hopping conformations are still concentrated in N_3 and C_4 deformations (Fig. 5). This occurs because the mass restrictions at C_4 -H and C_5 -H are decoupled. This is different in adenine, where the ring imposes a strong correlation in the motion of these sites. The long lifetime of mass-restricted aminopyrimidine in comparison to the non-restricted case is due to the longer period that the molecule needs to tune the conical intersection coordinates. Figure 5 also shows that the hopping events of mass-restricted aminopyrimidine starting in the S_1 state are displaced in the direction of $B_{3,6}$ conformations.

Curiously, when mass-restricted dynamics is started in the S_2 state, the lifetime is increased even more, to 1.4 ps (Fig. 6). Hopping events occur along the whole region connecting the envelope 4E conformations to envelope 2E conformations indicating that a branch of crossing seam exists in this region. Different from the other three sets of dynamics simulations, a substantial amount of hopping events occurs at the 2E conformation, which, as we shall review in section “Current Status of the Field,” is the main conformation accessed for adenine deactivation (Barbatti and Lischka 2008). Note that two conditions were necessary to trigger internal conversion in this region of the crossing seam, first the restriction of the C_5 and C_4 sites and second the excess of energy of the S_2 initial state.

Fig. 6 State occupation of mass-restricted aminopyrimidine starting in the S_2 state

Hopping events at 6S_1 conical intersections, which are energetically accessible from the Franck-Condon region, were not observed in any of the four sets of trajectories (Fig. 5). Characteristically, 6S_1 conformations imply a strong out-of-plane deformation of the amino group. A plausible explanation for the lack of internal conversion in this region of the crossing seam is that trajectories are trapped in other regions of the S_1 surface before the molecule has time to undergo this strong deformation. Results for aminopyrimidine starting in S_2 state without mass-restriction, but increasing the active space from (8,7) to (10,8) by addition of one more n orbital to the active space show that a fraction of trajectories (about 15 %) can access this conical intersection (Szymczak et al. 2011).

The effect of stacking interactions in DNA conformation has also been investigated in the dynamics of aminopyrimidine interacting with guanine nucleobases (Nachtigallova et al. 2010). The results show that the ring puckering process observed in gas phase is not restricted by the neighbor molecules.

Model 2: Pyrrole

Pyrrole cannot be directly regarded as a model for nucleobases. However, the understanding of its UV-excited dynamics may bring insights of the role of the imidazole ring in the pyrimidine bases adenine and guanine. Different from the pyrimidine subunit, which is responsible for the UV absorption in the near UV region, both pyrrole and imidazole absorb at much shorter wavelengths of about 200 nm (Daura et al. 1999; Devine et al. 2006). Because of this, it may be expected that purine bases absorbing in the far UV region may present an excited state dynamics similar to that of five-membered rings.

Pyrrole is a simple five-membered heterocyclic compound which undergoes a rapid non-adiabatic deactivation (Lippert et al. 2004) with very low quantum yields (Shin 2004). It has been proposed (Sobolewski and Domcke 2000) that deactivation occurs via a NH-stretching mechanism along a ${}^1\pi\sigma^*$ excited state surface. Although it is certain that fast H fragments are formed through this mechanism, it cannot explain experimental findings of slow H atoms and other fragments such as HCN and C_3H_3 (Blank et al. 1994; van den Brom et al. 2005; Wei et al. 2004). This means that another mechanism should occur in competition with the NH stretching, which was proposed to involve ring-puckering and ring-opening of the heterocyclic ring (Barbatti et al. 2006; Poterya et al. 2007).

Non-adiabatic dynamics simulations for the pyrrole radical cation and other five-membered rings were performed in reduced dimensionality by means of wave packet propagation using the multiconfigurational time-dependent Hartree approach (MCTDH) together with the linear vibronic model, allowing a good reproduction of spectral features (Köppel et al. 2004; Venkatesan et al. 2007). Wave packet dynamics simulations have also been performed focusing on the NH-stretching reaction coordinate (Lan and Domcke 2008; Vallet et al. 2004, 2005) revealing details of the reaction along this coordinate, especially of the dependence of the dissociation branching ratios and time scales on the initially excited modes. These simulations in reduced dimensionality predict a quantum yield for NH dissociation near to unity. Dynamics simulations of pyrrole in its full dimensionality have been performed

Fig. 7 Average adiabatic populations of trajectories for five states as a function of time after photoexcitation of pyrrole into the S_4 state (Data from Vazdar et al. 2009)

using surface hopping approach (Vazdar et al. 2009). And, as we are going to discuss in more detail next, it revealed that other deactivation channels beyond the NH-stretching are activated. These channels involve strong ring deformation. The adiabatic dynamics in the vibrationally excited ground state, also discussed below (Sellner et al. 2009), showed that these ring deformation channels result in photochemical products consistent with the heavy fragments experimentally observed.

Excited-state non-adiabatic dynamics simulations were performed for 90 trajectories in a total simulation time of 200 fs with a time step of 0.5 fs (Vazdar et al. 2009). The dynamics simulations have been calculated at the MR-CISD/SA-5-CASSCF(4,5) level of theory including five electronic states (ground state, two $\pi\pi^*$ states and two Rydberg π -3s (σ^*) states).

After excitation to the S_4 state, pyrrole depopulates via a series of conical intersections between valence and Rydberg states in a very short time. The average adiabatic population of ground and excited states as a function of time is presented in Fig. 7.

The analysis shows that the valence S_4 state depopulates very quickly. After around 10 fs, the average population of S_4 and S_3 states is identical. After 50 fs, the S_4 state is completely depopulated, while S_3 and S_2 state depopulate after ca 75 fs. The S_1 state starts to depopulate after ca 100 fs. After 100 fs, the dynamics is basically a two-state dynamics between ground and first excited state. The complete population transfer to the ground state occurs within 200 fs.

The statistical analysis presented in Fig. 8 reveals that 80 % of trajectories follow the NH stretching mechanism for deactivation into the ground state. The remaining 13 % of trajectories undergo a ring deformation mechanism (10 % is ring puckering and 3 % is ring opening). Finally, 7 % of trajectories do not deactivate during 200 fs

Fig. 8 Statistical analysis of different trajectory types in excited-state dynamics of pyrrole (Data from Vazdar et al. 2009)

of the dynamics simulation. Dynamics performed with TDDFT method showed a very similar distribution of mechanisms (Barbatti et al. 2010b).

The observation of the ring deformation deactivation mechanism for a substantial number of trajectories confirms that it can be the source of experimentally observed heavy fragments. To verify this hypothesis, dynamics in the ground state should be performed. This is a specially challenging task because after deactivating, the photoenergy is converted into vibrational energy. In this very hot vibrational ground state, pyrrole can reach strongly distorted geometries and dissociate through several channels. Most of conventional quantum chemical methods are not tailored to work under such extreme conditions.

This problem has been addressed by starting the hot ground state dynamics at a ring-puckered ring-opened conical intersection (see Fig. 9a) using a wavefunction formed by a combination of the generalized valence bond method in the perfect pairing approximation (GVB-PP) and complete active space (CAS) (Sellner et al. 2009). The GVB-PP-CAS(6,5)/6-31G* level applied to the gradient calculation for the dynamics has proven not only to be more reliable concerning photoproducts but also much more stable during dynamics compared to conventional SA-2-CAS(6,6) calculations. The results reported here have been calculated with this GVB-PP-CAS(6,5) space. A hundred trajectories have been propagated for a maximal time of 1 ps using a step size of 0.5 fs.

As the dynamics is started on a point in the crossing seam, special care has to be taken to generate initial velocities. Two approaches have been employed, sampling initial velocities only in the branching space and sampling random velocities in the complete space using weighted Gaussian random numbers, both showing good correlation. The results discussed here are based on the second approach. Translational and rotational contributions of these velocities were removed, which

Fig. 9 (a) Ring-puckered ring-opened S_0/S_1 conical intersection (initial geometry of adiabatic ground state dynamics for pyrrole); and (b) quantum yield within 1 ps of simulation (Data from Sellner et al. 2009)

Fig. 10 Largest CC distance in C_3H_3 as a function of time showing the dynamics of the formation of $NH=CH$ -cyclopropene out of the biradical chain (Data from Sellner et al. 2009)

have been rescaled to an energy of 3.01 eV. This energy is the sum of half of the ZPE (2.24 eV) and the energy difference between the Frank Condon point and the MXS which is assumed to be converted from potential to kinetic energy.

The results show that besides pyrrole itself, two main photoproducts were obtained within the simulation time (see Fig. 9b). These are $NH=CH-C_3H_3$ and a biradical chain ($NH=CH-CH-CH=CH$). A detailed analysis of the trajectories ending at these photoproducts shows that the biradical chain is mainly a precursor to the substituted cyclopropene fragment. The cyclization starts after 200 fs and the new ring formation occurs in an average time of only 17 fs (see Fig. 10). Regarding the consequences on the experimentally observed (cyclo)propene fragment, this shows that the ring formation can not only happen before the dissociation into the HCN and C_3H_3 fragments takes place, but seems to be the dominating process.

Dissociation into H_xCN ($x = 1, 2$) and C_3H_3 did not take place within the 1 ps simulation time and it should occur on a longer timescale. The systematic investigation of the average bond distances during the dynamics (Sellner et al. 2009), clearly reveals that cleavage of those bonds yielding the experimentally observed fragments are more likely to occur than the cleavage of bonds leading to non-observed fragments.

Summarizing, non-adiabatic excited state dynamics of pyrrole showed two main deactivation mechanisms, the first one being the NH stretching explaining the (fast) hydrogen atoms and the second one the ring deformation (including opening and puckering). Dynamics from the puckered conical intersection showed that the second pathway is responsible for $NH=CH-C_3H_3$ and the biradical chain which can be seen as precursors to the experimentally observed heavier fragments regarding their electronic structure and bonding situation.

Current Status of the Field

A relatively large number of investigations reporting dynamics simulations for nucleobases, nucleobase tautomers, nucleotides, derivatives, WC pairs and quartets in different solvation conditions has been published in the last years. Recent overviews of the field can be found in Alexandrova et al. (2010) and Barbatti et al. (2010a). In this section, we shortly review the dynamics of isolated bases focusing on which relaxation mechanism these works have proposed for each molecular system.

Adenine: In spite of a large number of different conical intersections that has been described for this nucleobase (see Barbatti and Lischka 2008 and references therein), theoretical analyses have converged to two main pathways, one involving puckering of the C_2 atom (envelope E_2) and another one involving puckering of the C_1 and C_6 atoms along with out-of-plane displacement of the amino group (screwboat 1S_6). Surface hopping dynamics simulations based on MR-CIS potential energy surfaces showed that adenine is trapped in envelope E_2 geometries much before it can reach other reaction pathways (Barbatti and Lischka 2008). Nevertheless, a different result has been achieved by surface hopping simulations based on semiempirical methods, with most of trajectories following the 1S_6 pathway (Alexandrova et al. 2010; Fabiano and Thiel 2008). Dynamics simulations based on TD-DFTB surfaces indicated a intermediary situation with selective activation of the 1S_6 and E_2 pathways depending on the excitation energy (Lei et al. 2008) and very long lifetime (Mitric et al. 2009b).

Guanine: A series of investigations on guanine tautomers and derivatives in gas phase and water employing surface hopping based on ROKS potential energy surfaces have shown that out-of-plane distortions increase the non-adiabatic transition probability and induce the transition to the ground state in about 1 ps (see Santoro et al. 2007a and references therein). Surface hopping dynamics based on OM2 surfaces predicted a major role for processes involving C_2 puckering, with a lifetime of about 0.2 fs. Similar process has been observed at the ab initio level (Barbatti et al. 2011b). In the particular case of the enol form of guanine, simulations predicted that OH dissociation channel is a major deactivation pathway (Langer et al. 2005).

Cytosine: Multiple spawning dynamics simulations based on CASSCF(2,2) surfaces predicted that deactivation of this nucleobase should occur in approximately 0.5 ps mainly through conical intersections involving out-of-plane distortions of the amino group (65 %) and with minor contribution of the $n_O\pi^*$ (15 %) and of the ethylene (5 %) pathways (Hudock and Martinez 2008). OM2-based surface hopping dynamics, on the other hand, predicts that the ethylene pathway should dominate the deactivation, which occurs in about 0.4 ps (Lan et al. 2009). Dynamics for this molecule computed with surface hopping at CASSCF surfaces predict dominance of the $n_O\pi^*$ pathway (Barbatti et al. 2011a; González-Vázquez and González 2010).

Thymine: This nucleobase has the longest lifetime among the five naturally occurring bases (Canuel et al. 2005; Kang et al. 2002). Multiple spawning dynamics simulations based on CASSCF surfaces have revealed that the source of this feature may be a trapping of thymine in a minimum of the S_2 state for a few picoseconds (Hudock et al. 2007). Surface hopping dynamics based on the OM2 method, however, predict a very short stay in the S_2 state (0.02 ps) and an overall excited-state lifetime of 0.4 ps (Lan et al. 2009). In this latter case, the decay to S_0 occurred mainly through the out-of-plane O conical intersection (82 %) and pathways involving puckering at the C_5 atom were observed in the other 12 % of trajectories. Surface hopping dynamics based on CASSCF surfaces agree with the multiple spawning results and predicts that the $n\pi^* S_1$ state will be populated after 2.6 ps (Gustavsson et al. 2006). Surface hopping simulations also based on CASSCF surfaces, but starting at the transition state in the S_2 state, predict that both the $\pi\pi^* S_1$ state (65 %) and the $n\pi^* S_1$ state should be populated (Asturiol et al. 2009). While according to Gustavsson et al. (2006) trajectories should remain in the $n\pi^* S_1$ state for additional few picoseconds, results of Asturiol et al. (2009) indicated that, independently of the diabatic character, the S_1 state should be depopulated in about 0.1 ps through conical intersections involving puckering at the C_5 atom.

Uracil: Similarly to thymine, multiple spawning CASSCF dynamics predict a long stay of uracil in the S_2 state (Hudock et al. 2007). Surface hopping OM2 dynamics, in contrast, predict a very fast decay to S_1 and an overall lifetime of about 0.6 ps with trajectories following out-of-plane O pathways in 85 % of the cases and puckering at C_5 atom in the remaining 15 % of the cases (Lan et al. 2009). Wave packet propagation in a 3-D model surface also predicts a very fast $\pi\pi^* \rightarrow n\pi^*$ transition taking place in less than 0.1 ps (Improta et al. 2009). Surface hopping dynamics simulations on ROKS surfaces in gas phase and in water favor deactivation through the C_5 puckering pathway (Nieber and Doltsinis 2008).

As we have seen, dynamics simulations carried out with different methods have often presented conflicting results. This may be mainly attributed to differences between quantum-chemical electronic structure methods used to compute the potential energy surface, rather than to the different non-adiabatic dynamics methods. More about the limitation of the methods will be discussed in the conclusions for this chapter. For now, we may note that even though dynamics simulations have not achieved a degree of agreement that would allow assigning specific relaxation

mechanisms for each nucleobase, they have been able to reduce the possibilities to a few mechanisms in each case.

Formamide and Peptide Bonds

Probing Photoexcitation of Proteins

The peptide linkage plays an important role in many biological processes and the knowledge of how it interacts with ultraviolet light is of fundamental importance for understanding biological activities in living organism. This holds in particular for interaction of peptides with 193 nm excimer ArF laser due to its proximity to the absorption maximum of peptide bonds (Gingell et al. 1997). This is an effect of considerable importance because ArF lasers are widely used clinically for laser surgery (Mulcahy et al. 2000). It is shown, for instance, that the peptide bond is the main target of irradiation in collagen and its scission is claimed to be the most important photochemical reaction taking place during photorefractive keratectomy (Torikai and Shibata 1999). Furthermore, the peptide group appears as the repeat unit in some industrially important polymeric materials (Greenberg et al. 2002) and knowledge about the mechanism of its interaction with ultraviolet light has implications for understanding crucial factors influencing their photostability. The smallest molecule of the peptide prototype is formamide (Fig. 11) and as such it has been frequently used as the simplest model for studying fundamental aspects of photochemical and photophysical processes taking place in peptides and proteins (Antol et al. 2007, 2008a, 2008a, b; Back and Boden 1971; Kang and Kim 2006; Liu et al. 2000; Lundell et al. 1998). An overview of the recent studies related to the second topic will be presented in section “Model I: Formamide” of this chapter.

Photoinduced fragmentation of charged small polypeptides has also been studied extensively in recent years due to their importance in “soft” ionization methods such as MALDI and ESI (Cui et al. 2005; Grégoire et al. 2007; Jeong et al. 2005, 2007; Kang et al. 2004; Nolting et al. 2006; Thompson et al. 2004, 2007). Photo-dissociation dynamics of small protonated peptides containing aromatic amino acids

Fig. 11 Schematic presentation of a polypeptide chain with the peptide bond showed in bold (*left*), of formamide (*center*) and of oxygen-protonated formamide (*right*). R_1 and R_2 stand for the amino acid chains

excited by 266 nm laser beams have been also explored by pump/probe femtosecond measurements (Grégoire et al. 2006, 2007; Nolting et al. 2006). However, the deactivation mechanism of possible pathways could not be derived, neither experimentally nor theoretically due to the size and complexity of the explored systems. Concomitantly, several experimental and computational photoexcitation studies have been undertaken on gas-phase protonated amino acids (Cui et al. 2005; Thompson et al. 2007). This led to the proposition of a deactivation mechanism (Kang et al. 2005, 2004) compatible with experimental results obtained for small polypeptides containing aromatic amino acids (Grégoire et al. 2006, 2007; Nolting et al. 2006). A recent review on this topic is given in Grégoire et al. (2009). With the aim of exploring possible alternative pathways of photodissociation of polypeptides we recently examined impact of protonation on fragmentation of the peptide bond using protonated formamide as the model molecule (Antol et al. 2008b). The most salient results from this work will be described in section “Model 2: Protonated Formamide.”

Model 1: Formamide

Photodissociation of formamide has been studied in the gas phase (Back and Boden 1971), solution (Petersen et al. 2008) and in noble-gas matrices of argon and xenon (Lundell et al. 1998). In gas phase photolysis, CH, H₂, and NH₃ fragments with quantum yields of 0.8, 0.6, and 0.2, respectively, were detected (Boden and Back 1970). Their formation was rationalized by three major primary processes forming the products NH₂ + CO + H, HNCHO + H, and NH₃ + CO. Subsequently, Lundell et al. (1998) reported that photolysis of formamide in the argon matrix by 193 nm laser leads to formation of a weakly bound complex between NH₃ and CO. Its formation was ascribed to the breaking of the C–N bond in formamide followed by hydrogen atom transfer from the formyl radical HCO to the NH₂ radical. On the other hand, when the formamide was trapped into solid Xe matrix major photoproducts were H₂ and HNCO. The change in composition of the products was explained by intersystem crossing to the triplet state induced by a strong external heavy-atom effect in the Xe matrix.

The mechanism of photodissociation in the gas phase has been also studied computationally at various levels of theory (Back and Boden 1971; Liu et al. 2000; Lundell et al. 1998). For instance, Liu and co-workers (2000) considered the mechanism of formamide photodissociation in the S₁ and the T₁ excited states using the CASPT2/CASSCF method. They located transition structures for each of the paths presented by Eqs. 1, 2, 3, 4, and 5 and found that the transition structure for C–N dissociation (Eq. 1) has the lowest energy on the S₁ as well on the T₁ potential energy surfaces, indicating that this reaction path is the most probable one.

However, the full understanding of the photodeactivation process in addition to characterization of the energy minima of the reactants and products and the transition state structures, requires also knowledge about minima on the crossing seams between involved excited states and the ground state, as well as information about nuclear motion of atomic nuclei during the process. Therefore, we recently reexamined the reaction paths considered by Liu and coworkers (2000) for the S_1 state taking into account both of these requirements and at higher level of theory. In addition, photodissociation of formamide in the second excited singlet state was considered also. The details of computational methods are given in Antol et al. (2007). Following location of all critical points on the S_1 and S_2 surfaces, we turned to dynamic simulations, which were carried by the direct trajectory surface hopping method based on the state average SA-3-CASSCF(10,8)/6-31G(d) calculations. For each of the initial states, 100 trajectories were propagated for 1 ps. The average occupations of the S_1 and S_2 states are shown in Fig. 12. It appears that the average occupation of the S_1 state remains practically unchanged for about 43 fs. After this initial stage, its occupation starts to decay exponentially. The lifetime of the state was calculated to be 441 ± 4 fs. On the other hand depopulation of the S_2 state starts after only 12 fs and the overall estimated lifetime is 66 ± 1 fs. After passing through the S_2/S_1 conical intersection, formamide resides on the S_1 surface only shortly and decays to the ground state.

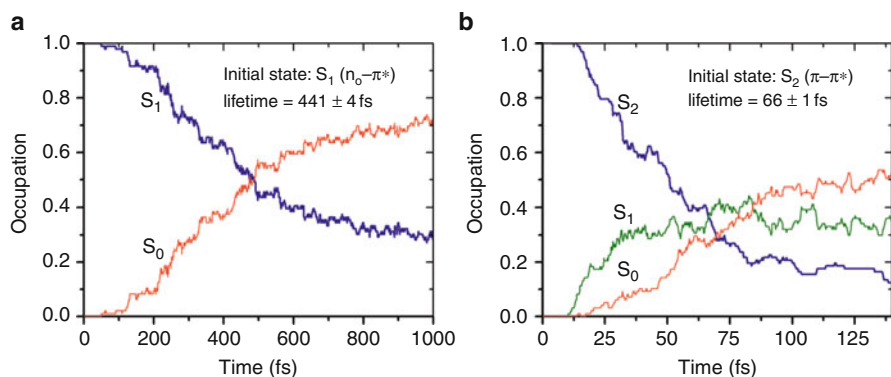

Fig. 12 Fraction of trajectories for each state as a function of time after photoexcitation into (a) S_1 initial state; and (b) S_2 initial state (Data from Antol et al. 2007)

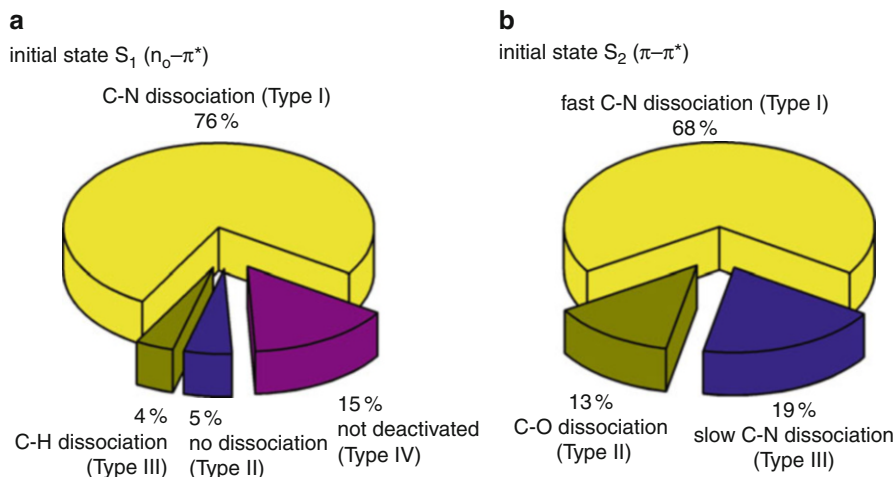

Fig. 13 Photodeactivation paths observed during dynamics simulations of formamide starting at the (a) S_1 ($n_O\pi^*$) and at the; (b) S_2 ($\pi\pi^*$) states (Data from Antol et al. 2007)

Analysis of the trajectories (Fig. 13) revealed that after excitation into the S_1 state about 75 % of the examined trajectories followed the C–N dissociation channel. After reaching the ground state, the energy of the system is transferred to translational motion of the HCO and the NH_2 radicals and to C–H dissociation from vibrationally hot CHO fragment, which finally results in formation of NH_3 and CO.

In addition to this channel, three additional types of trajectories were observed, but their fraction was found to be much lower. In trajectories of type II, the molecules decay to the ground state either via the same C–N conical intersection as in the previous case, followed by back formation of formamide on the S_0 PES or return to the ground state via a nondissociative MXS (Antol et al. 2007). In either case, no dissociation is observed within the simulation time. In trajectories of type III, hoppings to the ground state cause activation of the C–H vibrations and the molecule undergoes C–H bond stretching. Full C–H dissociation, however, was observed in only one trajectory. Finally, in 15 % trajectories, formamide did not decay to the ground state and did not dissociate within the simulation time.

Following excitation to the second excited state, three types of trajectories were observed. The dominant type, corresponding to 68 % of the trajectories, is characterized by a very fast C–N bond cleavage starting immediately after photoexcitation and still taking place on the S_2 surface. The deactivation to the S_1 occurs in an average time of 31 fs. The system remains on the S_1 surface only for a short time and then switches to the S_0 state in an average time of 65 fs. Such fast $S_1 \rightarrow S_0$ decay is opposite to the slow $S_1 \rightarrow S_0$ decay observed when the initial state was S_1 . This is ascribed to the cooperative action of the energy transferred from the S_2 state, and the momentum acquired by the system along the C–N stretching coordinate during its motion from the Franck-Condon region to the S_2/S_1 conical

intersection. A similar process has been observed in the dynamics of protonated formamide (Antol et al. 2008b) and the CH_2NH_2^+ cation (Barbatti et al. 2007a).

In addition to the C–N dissociation channel, two alternative types of trajectories, both of them involving the C=O stretching mode, were observed, but their fraction was found to be much lower. The first among them (trajectories of type II) is characterized by dissociation of the oxygen atom and concomitant merging of all three potential energy surfaces. It corresponds to 13 % of all observed events. Finally, trajectories of type III (19 %) are best described as combination of the trajectories of types I and II. In this case, initial motion involves the C–O stretching mode, but the C–O bond cleavage does not occur due to recombination of the molecule in the S_2 followed by C–N bond dissociation.

Model 2: Protonated Formamide

The most basic site of formamide in the ground, as well as in the excited state is the oxygen atom (Antol et al. 2008a). Therefore, in this section we shall restrict our discussion to the photofragmentation of the O-protonated species (Fig. 11). The calculations were carried out by means of the same computational approach used for the parent molecule, the SA-3-CASSCF(10,8)/6-31G(d) method. A summary of dynamics calculations results are presented in Fig. 14. More detailed discussion, including dynamics simulations of photodissociation of N-protonated formamide, can be found in Antol et al. (2008b).

Examination of the results shows that dissociation of the O-protonated formamide from the S_1 state strongly resembles the mechanism of dissociation observed from the second excited state in the neutral molecule, as expected, due to the fact that both states are of $(\pi\pi^*)$ character. This is also reflected in considerable shortening of the calculated lifetime relative to that calculated for the S_1 state in the neutral molecule (33 ± 1 fs vs. 441 ± 4 fs).

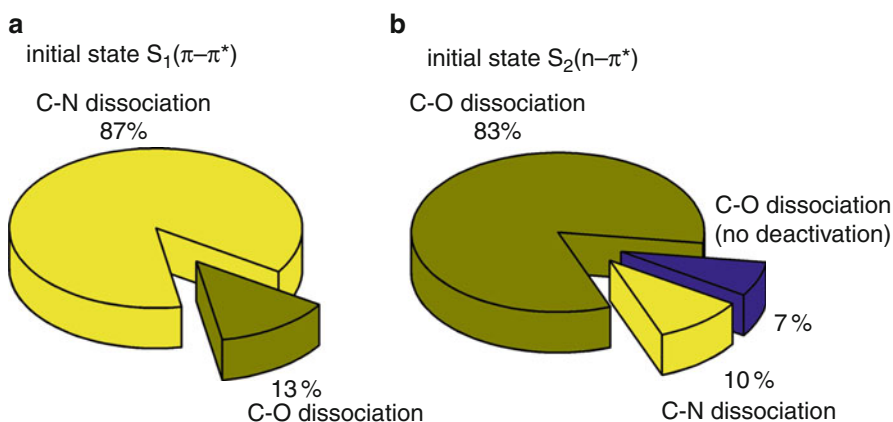

Fig. 14 Photodeactivation paths observed during dynamics simulations of O-protonated formamide starting at the (a) S_1 ($\pi\pi^*$) and at the; (b) S_2 ($n\pi^*$) states (Data from Antol et al. 2008b)

Fig. 15 Schematic presentation of reaction paths in photodissociation of oxygen protonated formamide. MXS_{NH} , MXS_{CO} , and MXS_{CN} denote minima on the crossing seam for dissociation of N-H, C=O, and C-N bond, respectively. Geometries are optimized at the CASSCF(10,8)/6-31G(d) level (Data from Antol et al. 2008b)

In searching for possible deactivation paths, three minima on the crossing seam between S_1 and S_0 were found to be accessible without energy barrier indicating very fast dynamics. The other interesting feature is that, in contrast to the neutral molecule, the MXS for the C-N dissociation has the highest energy (Fig. 15). In spite of that, analysis of the calculated trajectories revealed that this is the major dissociation channel. The reason for that lies in the fact that this reaction path has the steepest “slope” in the Franck-Condon region (Fig. 15). In other words, as the molecule in the Franck-Condon region does not have information about energies of conical intersections, it selects the energetically most favorable reaction path and not one leading to the most stable minimum on the crossing seam. The predominance of non-adiabatic transitions near highest energy MXS has also been observed in photodissociation of aminopyrimidine (Barbatti and Lischka 2007). In protonated formamide this deactivation path is activated in 87 % of trajectories. After reaching the ground state, the energy of the system is transferred to translational motion of the HCOH and NH_2 fragments in 33 % of trajectories, while in 47 % of trajectories HCOH and NH_2 recombine into the vibrationally excited starting structure. Furthermore, in 7 % of trajectories the proton transfer from the HCOH radical cation to the NH_2 radical occurs resulting in formation of the NH_3 radical cation and HCO radical.

In addition to the C-N dissociation path, in 13 % of trajectories the dissociation channel involving stretching of the C-O bond becomes activated. This dissociation path strongly resembles the C-O dissociation channel from the second excited state of the neutral molecule (trajectories of type II).

Dissociation of the O-protonated formamide following excitation to the second excited state is also interesting. It triggers a very fast switch (10 fs) from the S_2 to the S_1 state via a highly pyramidalized non-dissociated MXS (Antol et al. 2008b), followed by activation of two dissociation processes (C-O and C-N) on the S_1

surface, with the C–O dissociation path being observed in 83 % of trajectories. It is interesting to note that the resulting branching ratio between C–O and C–N dissociation pathway differs considerably from that observed upon photodissociation from the $n\pi^*$ state in the neutral molecules in which the C–N dissociation was the major photodissociation channel. The major reason for this behavior could be connected to the direction of the momentum along the C–O stretching coordinate inherited from the S_2/S_1 conical intersection in the O-protonated formamide. Another point worth of noting concerns formation of the OH radical, indicating that protonated formamide might be a precursor in the photogeneration of potentially deleterious OH radical.

Current Status of the Field

One point of particular relevance in the photodynamics studies of formamide and peptides that has not been considered in this section is the effect of the environment. Environmental effects are expected to change the relative position of the electronic states, the position, and the topology of the conical intersections (Burghardt and Hynes 2006). QM/MM dynamics simulations of photodissociation of formamide embedded in argon matrix showed strong impact on the outcome of the process. This was illustrated by formation of the 1:1 complex between ammonia and CO and prevention of full separation of the NH_2^+ and HCO^+ subunits in the $\text{NH}_2^+ + \text{HCO}^+$ radical pair. Also, the argon matrix influenced the lifetime of the S_1 state, which increased by 211 fs relative to the gas phase (Eckert-Maksić et al. 2010b). Another important issue that deserves attention concerns the effect of substituents on the mechanism of photodissociation of formamide. Some experimental, as well as computational studies, on the effect of methyl (Chen et al. 2003; Eckert-Maksić and Antol 2009; Liu 2002) and benzyl (Chen and Fang 2004; Pei et al. 2008) substituents related to this issue have been recently reviewed (Eckert-Maksić et al. 2010a). Finally, the possibility of intersystem crossing to the first triplet state has not been fully explored. This holds, in particular, for photodissociation of formamide in matrices, but also for photodissociation of higher analogues of formamide. This possibility, however, cannot be considered by dynamic simulations because it demands propagation times that are too long.

Conclusions and Outlook

We have reviewed a series of investigations of π -conjugated molecules using mixed quantum-classical dynamics simulations. All these molecules have been chosen as models for biologically relevant systems. Dynamics simulations are able to provide information on time-dependent phenomena, which can only be obtained in a very indirect way by conventional static quantum-chemistry simulations. The main pieces of information brought by dynamics in excited states are the time constants for the relaxation processes following the photoexcitation and the relative importance of each available pathway.

In an effort to reduce computational demands, several levels of approximation are employed, starting with the dynamics methodology itself, which propagates the nuclear motion classically for all degrees of freedom, while partially recovering the quantum information of the non-adiabatic transitions between states. Although methodological progress has been achieved by the development of the multiple spawning (Ben-Nun et al. 2000; Hack et al. 2001; Levine et al. 2008) and MCTDH (Worth et al. 2003) approaches, the everyday method for tackling dynamics simulations in excited state is still the surface hopping approach, mainly due to its easy implementation and intuitive conceptual background.

At another level of approximation, simplified models have often been employed in substitution of the full biochemical system. In this chapter, we have discussed protonated Schiff base chains as models for the chromophore of rhodopsin proteins, heteroaromatic rings as models for UV-excited nucleic acids, and formamide as a model for photoexcited peptide bonds. With development of quantum chemical methods and computational resources, effective progress has been achieved by taking larger models at higher theoretical levels. This process, however, evolves very slowly and there are no perspectives of extending the quantum-mechanical treatment much beyond the chromophore region of the system. Instead, the development of hybrid methods, especially the quantum-mechanics/molecular-mechanics based approach, have been demonstrated to be of great utility in accounting for the effects of the molecular environment into the excited-state region of the molecule (Ciminelli et al. 2008; Hayashi et al. 2009; Levine et al. 2008; Lin and Truhlar 2007). Recently, methods for treating the excited-state evolution under the influence of an external electric field have been proposed (Jones et al. 2008; Mitric et al. 2009a; Yagi and Takatsuka 2005). They open the perspective of achieving a more complete treatment of the photo-excitation phenomena, by, for example, taking into account the effect of laser fields.

In a third level of approximations, the quantum chemical methods employed in dynamics simulations are naturally much lower than those employed at conventional quantum chemical calculations. As an example, dynamics simulations for molecules of biological interest are quite restricted to the use of double- ζ basis sets. Moreover, it is common to have a poor treatment of ionic states and non-adiabatic events, to neglect Rydberg states, and to neglect electron dynamic correlation. Although all these approximations are usually carefully employed by extended comparisons to high-level benchmark data, dynamics results obtained under such approximations should be regarded only as semi-quantitative.

Even in view of all these limitations, excited-state non-adiabatic dynamics simulations based on mixed quantum-classical methods constitute a fascinating and active research field providing essential information on the nature of molecular phenomena.

Abstract

Low-energy electrons (LEE) have been experimentally found to structurally alter DNA by induction of base damage, base release, and strand breaks. This has engendered a considerable number of theoretical studies of the mechanisms involved in this DNA damage. In this chapter, we discuss the various pathways for LEE interaction with DNA and the theoretical treatments most suited to

unravel these pathways. For example, inelastic electron scattering produces excitation, ionization, and transient negative ions (TNI) via shape, core-excited, and vibrational Feshbach resonances, which can all lead to DNA damage. Each of these pathways is distinguished, and their pertinence to the experimental results observed is described. Theoretical approaches used to explain these pathways are also described. Shape resonances can be understood as interactions with the electron with unoccupied molecular orbitals of neutral molecule, while core-excited states involve excitation of inner shell electrons and can be treated with theoretical methods such as time-dependent density functional theory (TD-DFT) or CASSCF. In treating the electron–molecule interaction, special care is needed to distinguish between diffuse and valence states of the TNI. The role of the vertical and adiabatic states of the radical anion is important as the electron adds to the neutral molecular framework, and reactions induced likely occur before equilibration to the adiabatic state. The effect of solvation is critical to both energetics of the interaction and the nature of the TNI formed. For example, gas-phase calculations show diffuse dipole-bound character for adenine, guanine, and cytosine anion radicals, but each of these is found to be in a valence state in aqueous solution by experiment. DNA base anion radicals often show ground states that are diffuse in character and that collapse to valence states on solvation. Such processes are shown to be accounted for inclusion of the polarized continuum model (PCM) for solvation. TD-DFT excited-state calculations including solvation show that the diffuse states rise in energy on solvation as expected. For LEE in the aqueous phase, new energy states become available such as conduction band or presolvated electrons, which may have sufficient energy to cause DNA damage. DNA radiosensitizers such as halogen-substituted uracils are being used to produce highly reactive uracil-5-yl radical, a precursor of DNA strand breaks, through its reaction with LEE.

Introduction

The DNA sequence contains the information necessary for the functioning of all cellular processes. Exposure of DNA to high-energy radiation leads to disruption of this sequence or actual strand cleavage that results in potential mutagenic or lethal damage (Becker and Sevilla 1993, 2008; Swarts et al. 1992; Becker et al. 2007, 2010; Li and Sevilla 2007; Swiderek 2006; Kumar and Sevilla 2008b, 2010a, b; Sevilla and Bernhard 2008; Sanche 2008; Yokoya et al. 2008; Denifl et al. 2007; von Sonntag 1991). In the early stage of the radiation-induced DNA damage, high-energy radiation ionizes and excites each component of DNA (i.e., base, sugar, and phosphate backbone) and the surrounding water molecules randomly and produces “holes,” secondary electrons, and excited states (Kumar and Sevilla 2008b, 2010a, b; Sevilla and Bernhard 2008; Sevilla et al. 1991). The hole (positive charge or radical cation), produced during ionization event in DNA, usually transfers to the site in DNA with the lowest ionization energy. Of the four DNA bases (adenine [A], guanine [G], cytosine [C], and thymine [T]), guanine is found to have the lowest ionization potential (Kumar and Sevilla 2008b; Hush and Cheung 1975;

Orlov et al. 1976; Yang et al. 2004; Steenken and Jovanovic 1997) and acts as the locus for hole transfer in DNA (Becker and Sevilla 1993, 2008; Swarts et al. 1992; Becker et al. 2010; Li and Sevilla 2007; Kumar and Sevilla 2008b, 2010a, b; Sevilla and Bernhard 2008; Sevilla et al. 1991). The guanine radical cation ($G^{\bullet+}$), formed on ionization, reacts further to produce oxidative DNA damage in the form of 8-oxoG (Burrows and Muller 1998; Cadet et al. 2008). A hole created on the sugar phosphate backbone undergoes two competitive reactions: (a) formation of neutral sugar radical after deprotonation ($-H^+$) from the specific sites of the sugar ring (Becker et al. 2003; Shukla et al. 2004, 2005; Adhikary et al. 2005, 2006a, b, 2007, 2008; Khanduri et al. 2008) and (b) hole transfer to the nearby base in DNA followed by *base-to-base* transfer to guanine (Adhikary et al. 2006b). Secondary electrons formed by the ionizing event lose their kinetic energy, thermalize, add to DNA, and transfer to the bases of highest electron affinities, that is, the pyrimidines, T and C. This produces the anion radicals ($T^{\bullet-}$ and $C^{\bullet-}$) (Sevilla et al. 1991). Secondary electrons before thermalization possess substantial kinetic energy, which can lead to DNA damage. Such electrons with kinetic energies below 20 eV are known as *low-energy electrons* (LEE) (Sanche 2008; Pimblott et al. 1996; Pimblott and LaVerne 2007) and are produced in great numbers ($\sim 4 \times 10^4$ electrons per MeV energy deposited) (International Commission on Radiation Units and Measurements 1979) along the tracks of the ionizing radiation. LEEs have been recognized as the potential significant contributor to DNA damage. Collisions of LEEs with the aqueous medium result in most being thermalized within 10^{-12} s to become solvated electrons. Those LEEs produced in or near DNA are able to damage DNA via resonant absorption processes (Kumar and Sevilla 2010a). In their pioneering work, Sanche and coworkers (Boudaïffa et al. 2000; Huels et al. 2003; Sanche 2005; Zheng et al. 2005, 2006, 2008; Ptasinska and Sanche 2007a, b) established that LEEs are able to create single- and double-strand breaks (SSB and DSB) in plasmid DNA through a dissociative electron attachment (DEA) mechanism. This finding initiated several studies by a number of workers on the interaction of LEEs with DNA and its components (Baccarelli et al. 2007; Sulzer et al. 2006; Bald et al. 2006, 2008; König et al. 2006; Ptasinska et al. 2005a, 2006). A number of other recent reviews have focused on this important area of research (Li and Sevilla 2007; Swiderek 2006; Kumar and Sevilla 2008b, 2010a, b; Sanche 2008, 2009, 2010; Rak et al. 2008). The initial events induced in DNA by high-energy radiation discussed above are summarized in Fig. 1. The events shown in Fig. 1 follow the oxidative and reductive processes that are initiated by radiation to the dominant end products formed. When a number of the damage sites, shown in Fig. 1, are formed in proximity, a multiple damage site (MDS) is formed. MDSs are often irreparable owing to the loss of DNA information and the inability of enzymatic repair processes to recognize individual damages. They therefore represent the most lethal type of damage.

Ionization and, to a lesser extent, excitation as outline above were in the past considered the primary causes of DNA radiation damage. However, results have strongly implicated the role of low-energy electrons in this damage, and their study has been of intense interest in recent times. In this chapter, we will be focusing on the interaction of LEE with DNA, which leads to a variety of physical and chemical changes in DNA. A number of efforts to elucidate the mechanisms of

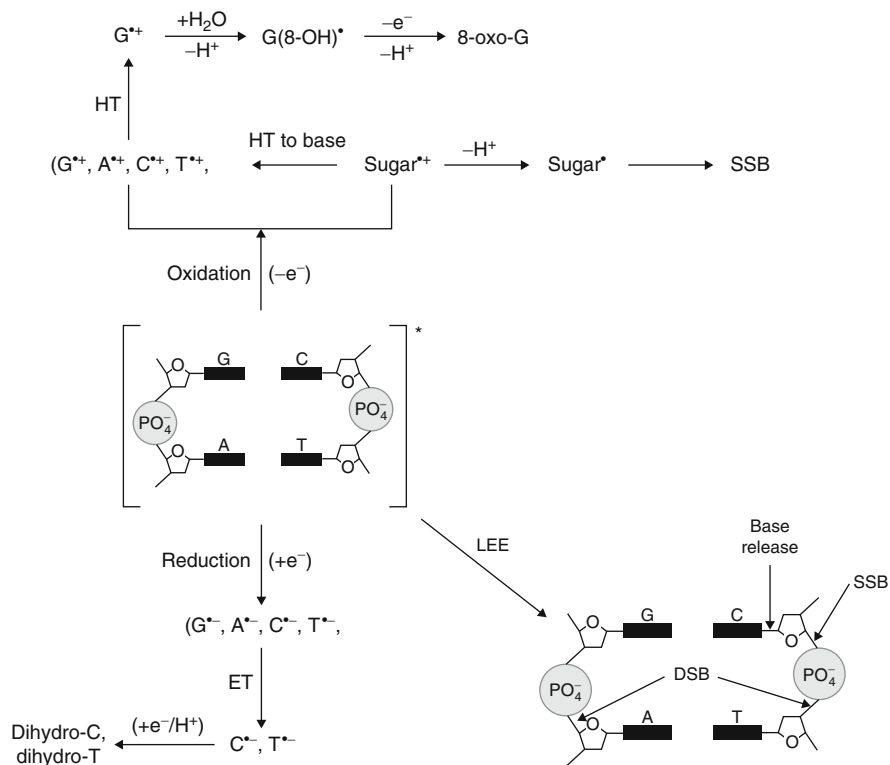

Fig. 1 Schematic diagram showing the overall processes (oxidation, reduction, and LEE-induced DNA damage) that occur during high-energy radiation interaction with DNA. *HT* hole transfer, *ET* electron transfer

LEE-induced DNA damage have been made in recent years employing theory (Li and Sevilla 2007; Kumar and Sevilla 2008b, 2010a; Rak et al. 2008; Simons 2006) and experiments (Sanche 2005, 2008, 2009; Denifl et al. 2007; Boudaïffa et al. 2000; Huels et al. 2003; Zheng et al. 2005, 2006, 2008; Ptasńska and Sanche 2007a, b; Baccarelli et al. 2007; Sulzer et al. 2006; Bald et al. 2006, 2008; König et al. 2006; Ptasńska et al. 2005a, 2006; Rak et al. 2008). Recent efforts have implicated the role of vibrational and electronic excited states in LEE interactions with DNA. The advent of substantial computing power at low cost and the accessibility of computational resources at national centers (Baker et al. 2009) allow the use of rigorous ab initio quantum chemical methods such as density functional theory (DFT), Møller–Plesset perturbation theory (MP2), CCSD(T), and CASPT2 for DNA components. Such theoretical studies shed light on the underlying mechanisms of LEE-induced DNA damage. The applicability of MP2, CCSD(T), and CASPT2 methods are still limited to small-to-modest size molecules such as DNA base pairs. However, DFT can be applied to larger molecular systems having as many as a 1,000 atoms (Neese et al. 2009) and has been found suitable to handle

electron–molecule interaction processes (Schwabe and Grimme 2008; Zhao and Truhlar 2008; Shao et al. 2006). In this chapter, we include a brief summary of the experimental findings and provide a detailed description of the recent applications of theory toward the understanding of the mechanisms of action of LEE-induced DNA damage. The chapter includes discussions of (1) shape and core-excited resonances, (2) valence and dipole-bound states of DNA bases and their associated electron affinities, (3) the best choice of the basis sets to tackle the valence and dipole-bound radical anions, (4) effects of condensed phase on dipole-bound states and thermodynamic properties of the solvated electron, (5) single-strand breaks formation in the ground state of the radical anion, (6) importance of the excited states of radical anions (resonances) for LEE-induced DNA single-strand breaks formation, (7) LEE-induced base release, (8) the effect of solvation on the formation of LEE-induced strand breaks, and (9) LEE interaction with DNA radiosensitizers.

Proposed Mechanism of LEE-Induced DNA Strand Breaks

As briefly described in the introduction, low-energy electrons (LEE) are produced abundantly during high-radiation events and are increasingly being recognized as potent DNA-damaging agents. In fact, LEEs are found to be several times more damaging than photons that have similar energy. The pioneering series of experiments by Sanche and coworkers (Boudaïffa et al. 2000; Huels et al. 2003; Martin et al. 2004; Panajotovic et al. 2006; Brun et al. 2009; Li et al. 2008; Zheng et al. 2004; Abdoul-Carime et al. 2001), showed that LEEs in the 0–10 eV range produce single- and double-strand breaks in DNA. In their first report (Boudaïffa et al. 2000), the plasmid DNA (pGEM 3Zf(–)) was extracted from *E. coli*, hydrated to 2.5 water/base pair, and then irradiated with LEE beam with kinetic energies 3–20 eV. From these experiments, it was concluded that electrons having energy below the ionization limit of DNA (ca. 7.5–10 eV (Hush and Cheung 1975; Orlov et al. 1976; Yang et al. 2004; Colson et al. 1992)) were able to cause SSB and DSB. The corresponding yields of SSB and DSB were found to be 8.2×10^{-4} and 2×10^{-4} strand breaks per incident 10 eV electron. The yields of SSB and DSB in DNA depended on the energy of the interacting electron and have been suggested to be caused by the rapid fragmentation reactions of transient molecular resonances localized on DNA components, that is, base, sugar, and phosphate backbone (Boudaïffa et al. 2000). In later experiments, Sanche and coworkers (Martin et al. 2004; Panajotovic et al. 2006) found that 0–4.7 eV electrons can effectively produce SSB in plasmid DNA with similar yields to those produced at far higher energies. (See Fig. 2, where it is evident that the cross section for SSB formation at 1 eV is actually greater than that found at 10 eV (Panajotovic et al. 2006).) They also found that 0.1–4.5 eV electrons induce only SSB (Martin et al. 2004) (see Fig. 1 in Martin et al. (2004)). Apparent resonances for inducing SSB are found at 0.8 and 2.2 eV, characterizing the formation of transient negative ion (TNI) at these energies (Martin et al. 2004). Due to low energies, these resonances were interpreted as shape resonances (Martin et al. 2004). The SSB yields at 0.8

Fig. 2 Effective cross sections (σ) for the formation of SSB in plasmid DNA by 0.1–4.7 eV electrons. The peaks at 1 eV and around 2.5 eV (see *shaded portion*) correspond to shape resonances (Reprinted with permission from Panajotovic et al. (2006). © (2006) Radiation Research Society)

and 2.2 eV, found in Sanche's work, were compared with electron capture cross sections of the DNA bases which were assigned to π^* -shape resonances. The vertical attachment energies of DNA bases were taken from electron transmission spectroscopy (ETS) (Aflatooni et al. 1998), and their peak magnitudes were scaled to reflect the inverse energy dependence of the electron capture cross sections. The lowest peak present at 0.39 eV in the modeled cross section was shifted by 0.41 eV to match the SSB yield at 0.8 eV (Martin et al. 2004). A good agreement between the experimental and simulated SSB yield between 0 and 4 eV certainly suggests the involvement of shape resonances in creating LEE-induced single-strand breaks. Indeed, from the studies of strand breaks in plasmid DNA induced by 3–100 eV electrons (Huels et al. 2003; Martin et al. 2004; Panajotovic et al. 2006), it was concluded that below 5 eV LEE-induced SSB occurs through dissociative electron attachment (DEA) via shape resonances (Boudaïffa et al. 2000; Huels et al. 2003; Martin et al. 2004; Panajotovic et al. 2006; Brun et al. 2009), while between 5 and 15 eV, the core-excited resonances induce SSB and DSB similar to those produced at far higher energies such as 100 eV. Illenberger and coworkers (Baccarelli et al. 2007; Sulzer et al. 2006; Bald et al. 2006, 2008; König et al. 2006; Ptasińska et al. 2005a, b, 2006; Abdoul-Carime et al. 2004a, b; Hanel et al. 2003) have contributed to the understanding of these processes by showing that electron attachment directly to the phosphate moiety can lead to fragmentation (Bald et al. 2006). The involvement of shape resonances to create molecular fragmentation in DNA model compounds was also proposed in their work (Baccarelli et al. 2007; Sulzer et al. 2006; Bald et al. 2006, 2008; König et al. 2006; Ptasińska et al.

2005a, c, 2006). Several groups used scattering theory to help elucidate the nature of LEE interactions resulting in DNA damage (Caron and Sanche 2003, 2004, 2005, 2006; Caron et al. 2008; Tonzani and Greene 2006b; Dora et al. 2009; Gianturco et al. 2008; Winstead and McKoy 2006) through resonances. The modeling of shape resonances, created during electron–molecule interaction, using theory is discussed in section “[Resonance \(TNI\) Formation: A Molecular Orbital Approach.](#)”

Electron–Molecule Interaction Events

Electron–molecule interactions give rise to energetic species that result in physical and, subsequently, chemical changes in the parent molecule. The initial energy of the interacting electron is critical to the formation of such species. Understanding the physical and chemical changes induced requires an understanding of the underlying fundamental processes that govern the electron–molecule interaction. One of the most important of these interactions is dissociative electron attachment (DEA), which may result in DNA strand breaks discussed in section “[Proposed Mechanism of LEE-Induced DNA Strand Breaks.](#)” A scheme that depicts the various paths available during electron–molecule interaction is shown in Fig. 3. The collision of an electron with molecule involves two types of interactions: (a) direct scattering and (b) resonant interactions. In nonresonance electron–molecule scattering (direct scattering), the electron interacts with the molecule for a very short time (typically less than ca. 10^{-15} s), that is, approximately the transit time for an electron through

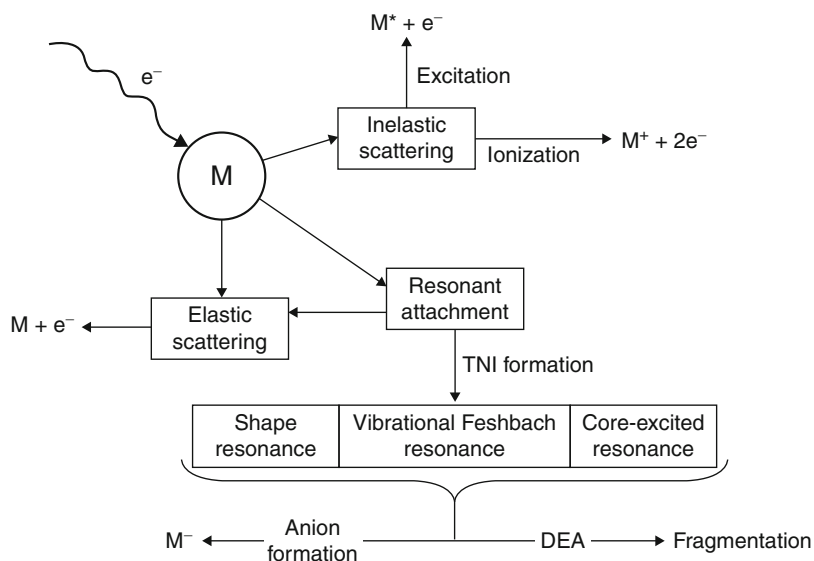

Fig. 3 Schematic diagram showing the scattering and resonant attachment events taking place during electron–molecule interactions

the dimensions of a molecular framework. A state with angular momentum such as a p-state can extend the time of the resonance. Depending on the energy transferred from electron to the molecule during collision, the direct scattering is known as (a) elastic, if no kinetic energy is transferred to the internal degrees of freedom (electronic, rotational, and vibrational) of the parent molecule, and (b) inelastic, if some part of the electron energy is transferred to the molecule and excites these internal degrees of freedom. In an elastic collision, only kinetic energy can be transferred through the conservation of momentum. However, no significant kinetic energy is transferred in an elastic collision owing to the small mass of the electron, which is negligible compared to the mass of the molecule. Inelastic scattering can result in ionization as well as vibrational and/or electronic excitation, as shown in Fig. 3.

In resonant interactions, the electron–molecule interaction lasts for a longer time ($\sim 10^{-12}$ to 10^{-15} s) and results in the formation of transient negative ions (TNI) of several types discussed in section “[Resonance \(TNI\) Formation: A Molecular Orbital Approach](#).” Once these resonances are formed, they may decay via (a) autodetachment, in which the electron is emitted from the negative ion $(M^-)^*$ resulting M^* and e^- ; (b) dissociative electron attachment (DEA), in which the negative ion $(M^-)^*$ stabilizes by dissociating one of its chemical bonds to form anion and neutral fragments; and (c) radiative cooling, which means the negative ion $(M^-)^*$ is stabilized by emission of one or more photons. This last process does not usually occur in the gas phase as the lifetimes are short owing to processes (a) and (b).

For the DEA process (b), the time needed to stretch a specific bond in its neutral potential energy surface (PES) so that it crosses the repulsive anion surface is usually less than the vibrational period of that bond. On the basis of the timescale, DEA and autodetachment are clearly in competition with each other. Such electron resonances are well described in the literature (Schulz 1973a, b; Lane 1980; Sanche 1995; Jordan and Burrow 1987; Simons and Jordan 1987; Simons 2008; Modelli and Martin 2002; Wetzel and Brauman 1987; Chen and Gallup 1990; McConkey et al. 2008; Hotop et al. 2003). Since the TNI formation can occur in the continuum, special care is needed to handle these problems in any theoretical treatment. Quantum chemical methods employing compact basis sets (Chen and Gallup 1990) have been used to study the nature and properties of TNIs/resonances by several groups such as Burrow (Jordan and Burrow 1987), Jordon (Jordan and Burrow 1987; Simons and Jordan 1987), Simons (Simons and Jordan 1987; Simons 2008), and Modelli (Modelli and Martin 2002). This method has been widely used and can give reasonable estimates of the energetics involved. However, the scattering phenomenon can only be approximated by such approaches. The present chapter elucidates the mechanism of DNA damage caused by resonant interaction events only.

Resonance (TNI) Formation: A Molecular Orbital Approach

From the above discussion, we see that electron–molecule interactions can lead to transient negative ion (TNI) formation and subsequently to a variety of chemical changes. On TNI formation, an extra electron

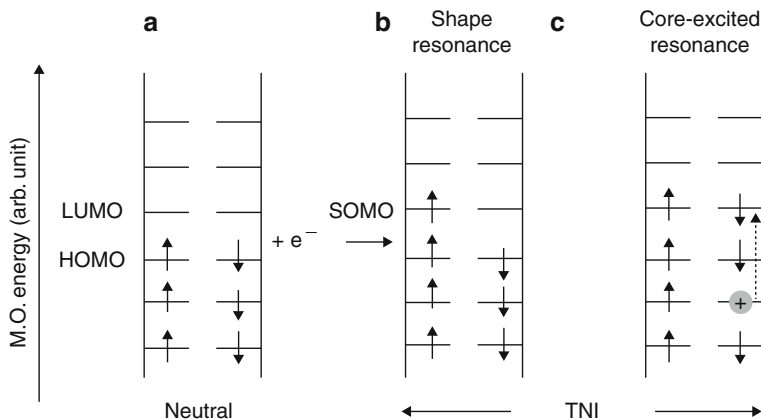

Fig. 4 Schematic diagram showing the electronic configuration of a neutral (a) and transient negative ion (TNI) (b, c). The interacting electron initially captures into the unoccupied MOs of the neutral molecule resulting in TNI formation via (a) shape resonance or (b) core-excited resonance. For a shape resonance, the electron can interact with any unoccupied MO. The SOMO was the empty LUMO before the LEE interaction. In core-excited resonance, on electron interaction an electronic transition takes place from an inner shell to the vacant MOs creating a “hole” (+ charge) in the inner shell, shown by an arrow (c). The up and down arrows show the occupancy of the molecular orbitals (MOs) with electrons of α and β spins. HOMO highest occupied molecular orbital, LUMO lowest unoccupied molecular orbital, SOMO singly occupied molecular orbital

is captured into the unoccupied molecular orbital (UMO) of the neutral molecule, and a shape or core-excited resonance results (see Fig. 4).

Shape resonances: In a shape resonance, an extra electron occupies a normally unoccupied (vacant) MO without perturbing the inner electronic configuration of the parent molecule. This results in the formation of a transient negative ion (TNI) (Schulz 1973a, b; Lane 1980; Sanche 1995) (see Fig. 4b). In a time-dependent picture, such TNIs (Schulz 1973a, b) are formed by an electron transition from the continuum ($e + M$) to a quasi-discrete state of the transient molecular anion (M^-)*. Because electron attachment is rapid with respect to nuclear motion, the negative ion (M^-)* is formed at the geometry of the neutral molecule. Shape resonances are also known as “single-” or “one-particle, no-hole” resonances. Generally, they occur at low energies (0–4 eV) and have lifetimes in the range 10^{-15} to 10^{-10} s. Longer lifetimes may occur if the attachment is followed by vibrational motion into portions of the nuclear potential surface lying below that of the neutral, where the electron cannot autodetach. Shape resonances may result in a dissociative electron attachment (DEA) process forming an anion fragment and a neutral fragment.

Core-excited resonances: A core-excited resonance is formed when an interacting electron excites one of the core electrons of the parent molecule, resulting in a hole in the inner filled MOs and two electrons, an extra electron and one from the core, in unoccupied MOs (see Fig. 4c). Such resonances are also known as “two-particle, one-hole” resonances. Core-excited resonances occur typically above 4 eV;

those lying below the “parent” molecular excited state are known as “Feshbach resonances” and may have lifetimes comparable to vibrational periods. If they lie above the parent, they are called “core-excited shape resonances” (Schulz 1973a) and generally have much shorter lifetimes because of decay into the parent state. Thus, core-excited shape resonances exhibit a negative electron affinity, relative to the excited parent, whereas Feshbach resonances have a small positive electron affinity (Schulz 1973a). Core-excited resonances are highly energetic and have been suggested to play a role in double-strand breaks in DNA (Huels et al. 2003; Martin et al. 2004; Panajotovic et al. 2006; Brun et al. 2009).

Vibrational Feshbach resonances (VFRs): In a vibrational Feshbach resonance, the interaction of a slow electron takes the form of a virtual excitation of a vibrational level of the neutral molecule with capture of the electron (Hotop et al. 2003; Dessent et al. 2000). For the zero point vibration, the maximum probability of interaction of the electron with parent molecule occurs at zero energy. If the dipole moment of the neutral molecule exceeds the critical value of approximately 2 Debye, the impinging electron may be trapped into the diffuse bound state, which provides a much longer timescale for the electron to stay near the molecule (Hotop et al. 2003; Dessent et al. 2000; Illenberger 1992), and VFRs may appear as shown in Fig. 5. Here, the PES of the anion lies close to, but below, the neutral surface, and the lowest vibrational levels of the dipole-bound anion are located just below the corresponding vibrational levels of the neutral. These long-lived VFRs appear as narrow features below the vibrational thresholds in elastic or vibrationally inelastic electron scattering cross sections (Hotop et al. 2003). VFRs may also decay through the dissociative electron attachment mechanism. For an excellent, detailed overview, see reviews by Schulz (1973a, b) and Hotop et al. (2003).

Fig. 5 Diabatic potential energy surfaces of neutral and dipole-bound anion showing the origin of the vibrational Feshbach resonances (VFRs). An extra electron attaching into the diffuse dipole-bound MO of the parent can excite the nearby vibrational levels of the parent molecule resulting in VFRs

An excellent example of the synergy of vibrational Feshbach resonances with dipole-bound anion states of uracil and thymine in DEA of N_1 -H bond has been reported by Burrow et al. (Burrow et al. 2006; Scheer et al. 2004). Sharp peaks (<3 eV) in the dissociative electron attachment cross sections of uracil and thymine were assigned as vibrational Feshbach resonances (Burrow et al. 2006; Scheer et al. 2004). Methylation at N_1 or N_3 site of these bases selectively eliminates the hydrogen atom (H) loss at the site of methyl substitution and thus allows for site assignments of DEA yield with energy of the LEE. At 1 eV, the H loss occurred from the N_1 site, while at 1.8 eV, the H loss occurred from the N_3 site (Ptasińska et al. 2005a), indicating the involvement of two distinct DEA pathways (Ptasińska et al. 2005a; Burrow et al. 2006) for dissociation. Using quantum chemical calculations and very diffuse basis sets 6-311G(d) augmented with four Gaussian sets of (s , p_x , p_y , p_z) orbitals with scale factors of 0.04, 0.004, 0.0004, and 0.00004, Burrow et al. (2006) showed that an excess electron is bound in the electric dipole potential field of the uracil molecule, resulting a dipole-bound anion state (DBS), which lies below the neutral state of the uracil (see Fig. 6). From Fig. 6 (left), we see that the DBS and the σ^* (N_1 -H) anion state can mix by symmetry, and LEE excitation of the N_1 -H bond vibrations can then lead to dissociation.

This results in H loss in uracil ($(U-H)^- + H^*$) (see Fig. 4 of Burrow et al. 2006). LEE resonances at 0.69 and 1.01 eV were identified with the second and third vibrational levels for the N_1 -H bond stretch (see Fig. 6).

(2006). © (2006) American Institute of Physics)

Shape Resonances of DNA Bases

As pointed out above, when LEEs are captured in the virtual (unfilled) orbitals of the parent (neutral) molecule, a transient negative ion formation results, known as a “shape resonance.” These resonances are generally unstable with respect to the autodetachment and therefore possess negative electron affinity, that is, the anion state lies above the neutral state of the molecule. In the gas phase, they are commonly studied by electron transmission spectroscopy (ETS). In ETS, a signal consisting of the derivative with respect to energy of the electron beam current transmitted through a gas cell is plotted as a function of electron kinetic energy. The energies of the resonances are termed as electron vertical attachment energies (VAEs) and are always found positive by ETS experiment (Aflatooni et al. 1998; Schulz 1973a, b; Jordan and Burrow 1987; Simons and Jordan 1987; Allan 1989). In this chapter, we will refer to such states as having negative vertical electron affinities. To our knowledge, there are no experimental available LEE scattering data for a complete DNA fragment (composing base, sugar, and phosphate). However, there are ETS results for the DNA/RNA bases, that is, adenine, cytosine, thymine, uracil, and guanine, reported by Aflatooni et al. (1998).

From ETS experiments (Aflatooni et al. 1998), Aflatooni et al. showed that energies required to attach an electron into the lowest empty valence molecular orbitals of all the bases are positive. This means that all the bases have negative valence vertical electron affinity (<0). The vertically formed anions of pyrimidines bases (C, T, and U) were found to be more stable than the purines (G and A) by ca. 0.2 eV. The ETS spectra of U, T, C, G, and A are shown in Fig. 7. The spectra in Fig. 7 arise due to the occupation of the lowest empty π^* MOs of the parent molecules by the electron. The vertical lines on the spectra (Fig. 7) show the position of the vertical attachment energies. For guanine anion, the ETS (shown in Fig. 7) was observed for its enol tautomer (for details see Aflatooni et al. (1998)). For each of these molecules, three VAEs, associated with the three lowest vacant π_1^* , π_2^* , and π_3^* MOs, were determined. The VAEs 0.22, 1.58, and 3.83 eV for uracil; 0.29, 1.71, and 4.05 eV for thymine; 0.32, 1.53, and 4.50 eV for cytosine; 0.54, 1.36, and 2.17 eV for adenine; and 0.46, 1.37, and 2.36 eV for guanine(enol) tautomer were determined by ETS.

The VAEs of bases were also predicted using theoretical methods such as semiempirical Pariser–Parr–Pople (PPP) (Compton et al. 1980; Younkin et al. 1976) and ab initio methods (Sevilla et al. 1995). Since these anion states are metastable with respect to the autodetachment of the electron, special care was taken in the aforementioned theoretical approaches to handle these anion states by employing confined basis set, Koopmans’ theorem approximation, and empirical determination of parameters to scale the theoretical results to the experimentally measured anion state energies for other compounds. Sevilla et al. (1995) used calculated values for VAEs of benzene, naphthalene, pyridine, pyrimidines, and uracil, which have experimentally known values to scale theoretically calculated VAEs for the DNA bases. A comparison of the experimental VAEs of the bases to those predicted

Fig. 7 ETS spectra of uracil, thymine, cytosine, guanine, and adenine. The experimentally determined π^* anion state energies are indicated by vertical lines (Reprinted with permission from Aflatooni et al. (1998). © (1998) American Chemical Society)

theoretically is presented in Table 1. From Table 1, we see that the calculated VAE values are in excellent agreement with experimental VAEs and the difference between theory and experiment lies in the range 0.03–0.2 eV. The PPP method only shows a qualitative agreement with the experiment. The resonance energies of DNA/RNA bases, including deoxynucleosides and deoxynucleotides, were studied using scattering theory (Winstead and McKoy 2008; Gianturco and Lucchese 2004; Tonzani and Greene 2006a; Yalunin and Leble 2007). The calculated values (Gianturco and Lucchese 2004; Tonzani and Greene 2006a; Yalunin and Leble 2007) were found to be several electronvolts more than the experimental ETS values (Aflatooni et al. 1998); however, the first π^* resonance energies reported by Winstead and McKoy (2008) were in reasonable agreement with experiment (Aflatooni et al. 1998) for uracil, thymine, and cytosine.

Recently, we studied the vertical attachment energies of 5'-thymidine monophosphate (5'-dTMP) using the density function theory (DFT) B3LYP/6-31G* method (Kumar and Sevilla 2007). A nucleotide such as 5'-dTMP represents the smallest fragment of DNA containing all three components: base, sugar, and phosphate. This study was carried out with a view to draw some fruitful insights about the nature and location of the “shape resonances” during transient negative ion (TNI) formation.

Table 1 Experimental (ETS) and theoretical vertical attachment energies (VAEs) in uracil and the DNA bases^{a,b}

Compound	Vertical attachment energies (eV)				
	Assignment	Theory			
		Exp. (ETS)	PPP	Sevilla et al. (1995)	6-31G*/3-21G
Uracil	π_1^*	0.22	0.48	0.19	0.216
Thymine	π_2^*	1.58	1.50	–	1.609
	π_3^*	3.83	3.35	–	5.009
	π_1^*	0.29	–	0.32	0.364
Cytosine	π_2^*	1.71	–	–	1.771
	π_3^*	4.05	–	–	4.057
	π_1^*	0.32	–	0.4	0.524
Adenine	π_2^*	1.53	–	–	1.918
	π_3^*	4.50	–	–	5.235
	π_1^*	0.54	0.82	0.74	0.794
Guanine (keto)	π_2^*	1.36	1.43	–	1.379
	π_3^*	2.17	2.39	–	2.405
	π_1^*	–	0.94	1.23	1.191
Guanine (enol)	π_2^*	–	1.64	–	1.441
	π_3^*	–	2.55	–	2.575
	π_1^*	0.46	–	–	0.908
	π_2^*	1.37	–	–	1.662
	π_3^*	2.36	–	–	2.597

^aSee Aflatooni et al. (1998)^bValues correspond to negative electron affinities

In this study, the five lowest unoccupied molecular orbitals (LUMOs) along with the highest occupied molecular orbital (HOMO) of the neutral 5'-dTMPH were considered. The B3LYP/6-31G* method predicted HOMO and the lowest two UMOs as π -type localizing on the thymine base, while the third, fourth, and fifth UMOs as σ -type localized on the phosphate (PO_4) group, the sugar moiety, and the sugar phosphate group, respectively (see Fig. 8). The B3LYP/6-31G* calculated orbital energies in eV of HOMO, and the five LUMOs are $-6.24(\pi)$, $-0.84(\pi_1^*)$, $0.43(\pi_2^*)$, $0.73(\sigma_1^*)$, $1.27(\sigma_2^*)$, and $1.78(\sigma_3^*)$, respectively (see Fig. 8). From ETS and the theoretical calculations discussed above, it is evident that within Koopmans' theorem approximation, the vertical attachment energies (VAEs) are equivalent to the virtual orbital energies (VOEs). But these VOEs calculated at the Hartree–Fock or DFT (B3LYP) levels are appreciably overestimated by several electronvolts and thus need scaling to appropriately represent the measured VAEs (Aflatooni et al. 1998; Sevilla et al. 1995). Using this procedure, Modelli (2003) proposed an equation for appropriate scaling of B3LYP results for π^* resonances. Using Modelli's equation (Modelli 2003), the scaled VOEs of corresponding B3LYP/6-31G* computed LUMOs of 5'-dTMPH are found to be $0.53(\pi_1^*)$, $1.56(\pi_2^*)$, $1.80(\sigma_1^*)$, $2.23(\sigma_2^*)$, and $2.64(\sigma_3^*)$ eV, respectively (Kumar and Sevilla 2007). The

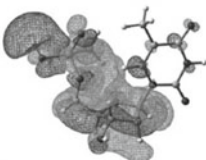

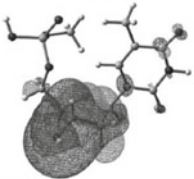

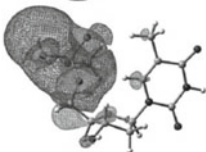

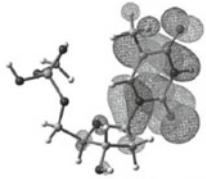

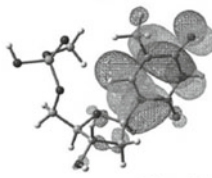

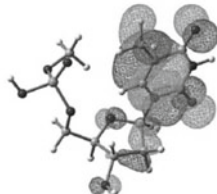

MOs		Orbital Energy (eV)	Scaled VOE (eV)
LUMO + 4 (σ_3^*)		1.78	2.64
LUMO + 3 (σ_2^*)		1.27	2.23
LUMO + 2 (σ_1^*)		0.73	1.80
LUMO + 1 (π_2^*)		0.43	1.56 (1.71)
LUMO (π_1^*)		-0.84	0.53 (0.29)
HOMO (π)		-6.24	

Fig. 8 Molecular orbital plots of neutral 5'-dTMPH, calculated using the B3LYP/6-31G* method. B3LYP/6-31G* calculated orbital energies along with scaled values are given in electronvolts. The experimental VOEs of thymine (Aflatooni et al. 1998) are given in electronvolts (in parentheses) (Reprinted with permission from Kumar and Sevilla (2007). © (2007) American Chemical Society)

calculated lowest two VAEs 0.53(π_1^*) and 1.56(π_2^*) are in reasonable agreement with those reported by Aflatooni et al. (1998) using EsTS of thymine, as shown in Table 1. This theoretical calculation predicts that for energies of less than 2 eV, there are UMOs on base, sugar, and phosphate available to capture the LEE. The theoretical procedure of scaling of orbital energies of neutral LUMOs gives good

estimates of the resonance energies; however, it has several drawbacks, for example, (a) during TNI formation, the UMOs of the neutral molecule can be perturbed and can reorder the UMOs energies so they are not as in the neutral molecule and (b) this procedure gives no information about core-excited resonances. In this context, the excited-state calculations for the TNI provide the only convenient means to rectify these drawbacks. This will be discussed in section “[Excited States of TNI \(Resonance Formation\)](#).”

A summary of the semantics of electron molecular resonances occurring in the gas phase has been described by Schulz (1973a) (see Table 2) with relevance to the condense phase.

Electron Attachment to DNA/RNA Bases in Gas Phase

The energy change on electron attachment to a molecule is described as the electron affinity of that molecule. Upon electron attachment to the neutral molecule (M), the geometry of the neutral molecule undergoes nuclear relaxation with adiabatic anion (M⁻) formation. Electron attachment to the neutral molecule without a nuclear relaxation gives vertical electron affinity (VEA), and on nuclear relaxation the overall energy change gives the adiabatic electron affinity (AEA). The energy needed to detach an electron from the adiabatic anion without relaxation of the resulting neutral molecule is termed as vertical detachment energy (VDE). Depending on the stability of the anion formation with respect to the neutral molecule, a molecule has positive or negative electron affinity (VEA and AEA) values (see Fig. 9). The various processes taking place during electron attachment to a molecule (M) are shown in Fig. 9.

Fig. 9 Potential energy surfaces (PES) of an anion formation (M^-) after electron (e^-) attachment to the neutral molecule (M). When the energy of an anion (M^-) lies below the neutral molecule, positive electron affinity is observed (*left*); otherwise the molecule is said to have negative electron affinity (*right*). Energy changes shown for an electron attachment or detachment event are (1) the vertical electron affinity (VEA), (2) the adiabatic electron affinity (AEA), and (3) the vertical detachment energy (VDE). The VDE and VEA impose the upper and lower bounds to AEA

From theory (Compton et al. 1980; Younkin et al. 1976; Sevilla et al. 1995; Winstead and McKoy 2008; Gianturco and Lucchese 2004; Tonzani and Greene 2006a; Yalunin and Leble 2007; Kumar and Sevilla 2007) and experiment (Aflatooni et al. 1998), it is well established that all the DNA/RNA bases have negative vertical electron affinity (VEA) values in gas phase. The adiabatic electron affinities (AEA) of these bases were also studied using anion photoelectron spectroscopy by Bowen (Hendricks et al. 1996, 1998) and Weinkauff (Schiedt et al. 1998), and Rydberg electron transfer (RET) experiments by Schermann (Desfancois et al. 1996, 1998) and their coworkers. These experiments showed the formation of stable dipole-bound anion of uracil, thymine, and cytosine having AEA in the range of 0.06–0.1 eV (see Table 3). The experimentally estimated dipole-bound AEA of uracil ~ 93 meV and thymine ~ 68 meV were found to be in excellent agreement with the theoretically predicted dipole-bound AEA values 86 and 88 meV of the corresponding bases by Oyler and Adamowicz (1993, 1994) using SCF and MP2 methods in combination with a very diffuse basis set. In recent years, density functional theory (DFT) and CCSD(T) methods were also applied to evaluate the electron affinities (EAs) of the bases (Li et al. 2002a; Vera and Pierini 2004; Puiatti et al. 2009; Wesolowski et al. 2001; Bachorz et al. 2007). The DFT-calculated positive electron affinity values for the pyrimidines are overestimated by about 0.15 eV (see Table 3). From theory and experiment, it is now well established that VEAs of the bases are negative and the AEAs of U, T, and C are near zero and still negative for A and G. The best estimated theoretical electron affinities of bases along with their experimental values are presented in Table 3.

Table 3 Selected theoretical and experimental gas-phase electron affinities of DNA/RNA bases (eV)

More recently, Schaefer and coworkers (Gu et al. 2014b) used the Weizmann Bruecker doubles composite method (W1BD) to benchmark the valence AEA of uracil. The W1BD method predicted a positive electron affinity of uracil and estimated its valence AEA to be 0.024 ± 0.013 eV (see Table 3). From their benchmark study (Gu et al. 2014b), these authors proposed that Hartree-Fock and MP2 methods are not suitable and severely underestimate the AEA of uracil, while the Gaussian-4 (G4) theory (Curtiss et al. 2007), CASPT2 and M06-2X (Zhao and Truhlar 2008) methods were found to be quite accurate, see Table 1 in Gu et al. (2014) and Table 2 in Gu et al. (2012).

Choice of the Basis Set

From the discussions in the preceding sections, it is clear from theory and experiment that vertical electron affinities of all the nucleic acid bases are negative, while the adiabatic electron affinities of pyrimidines are near zero. This means that an electron is unbound with the bases in the vertical state (TNI formation) and very loosely bound into the diffuse orbital of the bases in the adiabatic state, and in both the cases the choice of the basis set is crucial in determining the electron attachment process. The extent of the electron density localization with respect to the molecular frame for “dipole-bound” and “valence-bound” states can only be treated by an appropriate selection of the basis set. Generally, the basis set needed in a calculation consists of valence and extended (double- and triple- ζ) basis, which is further augmented with polarization and diffuse functions. While the polarization functions are important to study molecules with strained chemical bonds (Simons 2008), diffuse functions are necessary for dealing with anions or Rydberg type of species. In calculations for “dipole-bound” anions, the valence basis set must be augmented with very diffuse functions to successfully describe the system. Such basis sets were employed by Burrow et al. (2006) in the study of VFRs of thymine and uracil and by Oyler and Adamowicz (1993, 1994) for estimating the dipole-bound adiabatic binding energy of excess electrons to uracil and thymine. At times, the diffuseness of the basis functions is inadequate and the dipole-bound state mixes with the valence-bound state of the molecule (see Fig. 1 in Oyler and Adamowicz (1993)). If the energy of the dipole-bound and valence-bound states is equal, such a mixture could represent a proper solution for the molecular anion radical.

Diffuse functions are not a good choice for dealing with virtual “valence” states in TNIs or the available energies for shape resonances in the continuum. Any ab initio calculation employing the variational method with diffuse functions for a molecule with a negative electron affinity will fail and result in an unbound electron in the continuum at zero energy as the lowest energy state. Thus, the calculation of the negative electron affinity is not properly treated by a variational method. Nevertheless, virtual TNI states can be estimated with the use of compact basis sets such as 6-31G* as these compact basis sets avoid mixing with dipole-bound states and the continuum. Calculations using compact basis sets, when scaled, can provide good estimates of the virtual “valence” states in reasonable agreement with experiment. Further, these calculations can provide insights into the nature of such intermediate states and mechanisms of action of LEE in the induction of chemical change. The use of the compact basis set in the study of resonances (TNIs) is well documented in the literature (Jordan and Burrow 1987; Simons and Jordan 1987; Simons 2008; Modelli and Martin 2002; Staiey and Strnad 1994). Using compact 6-31G(d) to very diffuse 6-311++G(2d,p) basis sets, Li et al. (2002a) calculated the negative valence electron affinities of the bases. Their calculated SOMO surfaces of the DNA bases demonstrated that while the compact basis set represents the valence type π^* anions (the SOMO surfaces reside on the molecular frame) and gives good estimates of negative electron affinities, the use of extended basis sets results in

a collapse of the electron-binding energy to near zero, which is expected for the continuum and dipole-bound states. SOMO surfaces for extended basis sets show the characteristics of the dipole-bound state with the electron density residing away from the molecular frame. In the extreme of extension of the basis set, the electron would reside in the continuum, or if the molecule has a dipole, a weakly bound electron in a dipole-bound state.

Effect of Solvation (Condensed Media)

The discussion above describes the events of electron–molecule interaction in the gas phase. However, in condensed aqueous media, the nature of these processes is significantly altered. For example, dipole-bound states are not likely to be present as they are suppressed by the surrounding medium, and this is confirmed from the photoelectron spectroscopy of the hydrated uracil, thymine, cytosine, and adenine (Schiedt et al. 1998; Eustis et al. 2007) as the photoelectron spectra are blue-shifted with the increase of the number of hydrated water molecules and show valence-bound anion formation. For a visual inspection of this phenomenon, we plotted the LUMO and SOMO surfaces of guanine in neutral and anion radical states, using the B3LYP/6-311++G(2d,p) method in gas phase and in aqueous media using polarized continuum model (PCM). The LUMO and SOMO surfaces in the gas phase and in the solvated phase of guanine in neutral and in anion radical states are shown in Fig. 10. From Fig. 10, it is inferred that LUMO and SOMO represent a dipole-bound state (Li et al. 2002a) in the gas phase (see Fig. 10a, c), which is destabilized under the influence of the full solvation and becomes the valence-bound state (see Fig. 10b, d).

The solvent has a number of other effects on TNIs. First, relaxation of an excited TNI in the condensed media is rapid owing to the coupling with the high density of states in the matrix such as vibrational and phonon modes. Coupling to matrix energy levels quickly deactivates the excited vibrational states (within 1–10 ps). Further, the dielectric of the medium changes the energetics of the TNI first by the fast dielectric response, and as nuclear relaxation and reorientation takes place in the matrix, the full dielectric response ensues. The fast electronic response accounts for ca. 1 eV of stabilization and the slow dielectric response can account for several electronvolts. This stabilization can move the TNI (resonances) from the continuum into a valence-bound state. As a result, the autodissociation pathway is diminished or stopped altogether. In this context, it is worth considering the effect of secondary electrons generated by radiation damage to liquid water surrounding the DNA. It is found that on thermalization, the spatial extent of radiation-produced electrons in liquid water is in the range of 20–50 Å in what is considered the conduction band (Galduel et al. 1989; Crowell and Bartels 1996). In solution, the electron has several energy states (see Table 4), all lower than in the gas phase. The ground or the lowest energy state for the electron is the fully solvated electron (e_{aq}^-), which is stabilized

Fig. 10 B3LYP/6-311++G(2d,p)-calculated lowest unoccupied molecular orbital (LUMO) of neutral guanine in gas phase (**a**) and in solution (**b**). The singly occupied molecular orbital (SOMO) of guanine anion radical in gas phase (**c**) and in solution (**d**). The dipole-bound anion in (**a**, **c**) becomes a π^* -valence anion in (**b**, **d**). The effect of full solvation was considered through the use of polarized continuum model (PCM) considering the optimized gas-phase geometries

Table 4 Electron energies in gas phase and in liquid water

Electron type	Medium	Energy (eV)
LEE	Gas phase	0–20

(–) VDE of solvated electron		–3.3
Adiabatic energy of conduction band electron		Ca. 0.0
Adiabatic solvation energy (free energy of solvation)		–1.6

^aEnergy at 300 K

by ca. 1.6 electronvolts of solvation energy. The electron can be photoexcited to a p-state ($h\nu = 1.8$ eV) or to the conduction band by a ca. 2.5 eV photon or photoejected from water by a 3.3 eV photon. To properly account for the reaction of the solvated electron (e_{aq}^-) with DNA, knowledge about its thermodynamic properties is of utmost importance. These properties are discussed below.

Physical Observables of Solvated Electron (e_{aq}^-)

In 1962, Hart and Boag (1962) reported the absorption spectrum of e_{aq}^- using pulse radiolysis experiments. Owing to its fundamental importance to radiation chemistry (Young and Neumark 2012; Casey et al. 2013; Abel et al. 2012; Feng and Kevan 1980; Coe et al. 2008; Jordan 2004), the hydrated electron (e_{aq}^-) has been extensively studied using theory (Jordan 2004; Marsalek et al. 2012; Uhlig et al. 2012; Herbert and Head-Gordon 2005; Larsen et al. 2010; Jacobson and Herbert 2011; Turi and Madarász et al. 2011; Hammer et al. 2004; Madarász et al. 2009; Vysotskiy et al. 2012; Shkrob 2007; Bartels 2001; Bartels et al. 2005) and experiment (Coe et al. 1990; Coe 2001; Verlet et al. 2005; Siefermann et al. 2010; Siefermann and Abel 2011; Shreve et al. 2010; Tang et al. 2010; Kevan 1981) to elucidate its structure, dynamics, and binding energy. Considerable controversy exists in the literature regarding the energetics and structural aspects of its binding with bulk water, at water interface and in water clusters (Young and Neumark 2012; Casey et al. 2013; Abel et al. 2012; Feng and Kevan 1980; Coe et al. 2008; Jordan 2004; Marsalek et al. 2012). From electron spin resonance (ESR) data at 77 K in glasses, Kevan proposed a “cavity model” for binding the electron in water (Feng and Kevan 1980; Kevan 1981). In this model, the electron was surrounded by six water molecules arranged in an octahedral fashion and OH bond of each water points towards the electron at the center with *electron-to-hydrogen* ($e^- \rightarrow \text{HO}$) distance ca. 2.1 Å (Kevan 1981). Cavity size representing the radius of gyration (R_g) of the e_{aq}^- in the bulk water was computed as 2.5 Å by Bartels (Bartels 2001; Bartels et al. 2005) using moment analysis of the anionic water cluster spectra.

Coe et al. (1990, 2001, 2008) used photoelectron spectroscopy to measure the vertical detachment energy (VDE) of water anion clusters ranging from 2 to 69 in the gas phase. From the photoelectron spectra, they found that for clusters ranging from 11 to 69, the VDE varies linearly with $n^{-1/3}$ where n is the number of cluster. The extrapolation of this plot for $n = \infty$ (bulk water) had provided VDE = 3.3 eV, which was suggested to be the threshold for the solvated electron in bulk water.

Very recently, Siefermann et al. (2010) used ultrafast liquid micro-jet photoelectron spectroscopy and reported the VDE of e_{aq}^- in the water solution as = 3.3 eV. Using the time-resolved photoelectron spectroscopy, Tang et al. (2010) reported the VDE = 3.17 ± 0.1 eV in H_2O and 3.20 ± 0.1 eV in D_2O of e_{aq}^- . Neumark and coworkers (Shreve et al. 2010) measured the VDE = 3.6 ± 0.1 eV at 280 K using liquid micro-jet photoelectron spectroscopy, while Schultz and coworkers (Lübcke et al. 2010) reported the VDE = 3.4 eV of e_{aq}^- .

The thermodynamic properties of e_{aq}^- , such as the solvation free energy (ΔG_{hyd}^0), the enthalpy of hydration (ΔH_{hyd}^0), and entropy of hydration (ΔS_{hyd}^0), were first estimated by Jortner and Noyes (1966) assuming a cavity model for e_{aq}^- . Their estimated $\Delta G_{\text{hyd}}^0 = -37.5$ kcal/mol is in close agreement with experimental values (Han and Bartels 1990; Schwarz 1991; Hickel and Sehested 1985; Buxton et al. 1988); however, ΔH_{hyd}^0 and ΔS_{hyd}^0 were poorly estimated. Using Arrhenius parameters for the reaction $\text{H}^+ + \text{OH}^- \rightarrow e_{\text{aq}}^- + \text{H}_2\text{O}$, Bartels (Han and

Bartels 1990) reported $\Delta G^{\circ}_{\text{hyd}} = -38.5$ kcal/mol, $\Delta S^{\circ}_{\text{hyd}} = 28.2$ cal/mol deg. From pulse radiolysis, Schwarz (1991) estimated the $\Delta H^{\circ}_{\text{hyd}}$ and $\Delta S^{\circ}_{\text{hyd}}$ of e_{aq}^{-} as -34.0 kcal/mol and 16 cal/mol deg, respectively, giving $\Delta G^{\circ}_{\text{hyd}} = -38.8$ kcal/mol. Using pulse radiolysis, Hickel and Sehested (1985) and Buxton et al. (1988) estimated $\Delta G^{\circ}_{\text{hyd}} = -38.9$ kcal/mol, $\Delta H^{\circ}_{\text{hyd}} = -33.9$ kcal/mol, and $\Delta S^{\circ}_{\text{hyd}} = 11.7$ cal/mol deg. From the standard thermal constants of ions in aqueous solution, Ryabukhin (1977) estimated the $\Delta S^{\circ}_{\text{hyd}}$ of e_{aq}^{-} as 15.6 cal/mol deg. Zhan and Dixon (2003) used first-principles calculations including full solvent through dielectric continuum and calculated $\Delta G^{\circ}_{\text{hyd}} = -35.5$ kcal/mol for e_{aq}^{-} for anionic $(\text{H}_2\text{O})_8$. In addition to the thermodynamical quantities, the experimental redox potential (E° vs NHE) = -2.87 V of e_{aq}^{-} (see Table 5) is a quantity of fundamental interest to the understanding of the reaction of e_{aq}^{-} with DNA components. Very recently Kumar et al. (2015) model the solvated electron residing in a cavity formed

by four water molecules in tetrahedral structure employing density functional theory with PCM. This simple model successfully described many of the properties of the solvated electron including the thermodynamic properties, see Table 5. In Table 5, we summarized the physical observables of the solvated electron.

The values in Table 5 suggest that the $\Delta G^{\circ}_{\text{hyd}}$ of e_{aq}^- lies in the range -35 kcal/mol to -38 kcal/mol, $\Delta H^{\circ}_{\text{hyd}}$ in the range -29 kcal/mol to -34 kcal/mol, and $\Delta S^{\circ}_{\text{hyd}}$ in the range between 12 and 28 cal/mol deg. The positive entropy indicates that solvated electron is a structure breaker. The VDE lies in a small range of 3.3 eV to 3.6 eV. This experimental VDE value is also supported by the recent molecular dynamics simulations of large anionic water clusters ($32\text{H}_2\text{O}$ treated by quantum mechanics (QM) and $992\text{H}_2\text{O}$ treated by molecular mechanics (MM)) from the group of Jungwirth (Uhlig et al. 2012).

Recently, Siefermann and Abel (Siefermann et al. 2010; Siefermann and Abel 2011) misinterpreted the redox properties of e_{aq}^- based on its VDE = 3.3 eV. Arguing from this value of the VDE (3.3 eV), they suggested that the hydrated electron (e_{aq}^-) should not react with DNA, see Fig. 5 in Siefermann et al. 2010 and Fig. 4 in Siefermann and Abel 2011. Their interpretation is incorrect because the VDE is clearly not the energy of the thermally equilibrated system. The redox potential of a aqueous electron depends on the AEA ($-\text{AEA} = \Delta G^{\circ} = -1.52$ eV to -1.65 eV, see Table 5), which is derived from the thermodynamically equilibrated system in question. The known E° vs NHE is -2.87 V for e_{aq}^- (Schwarz 1981; Wardman 1989) when added to the absolute potential for the NHE of 4.44 V gives absolute $E^{\circ} = 1.57$ V or $\Delta G^{\circ} = -36.2$ kcal/mol, which agrees well with the values in Table 5. The redox potential (E° vs NHE) for one electron reduction of DNA/RNA bases (G (<-2.76 V), C (-2.35), A (-2.52), T (-2.18), and U (-2.07 V)) was measured in DMF using pulse polarography and cyclic voltammetry by Seidel et al. (1996). From the known redox potential (E° vs NHE) values of the e_{aq}^- (-2.87 V) and of the of DNA/RNA bases, it is clear that e_{aq}^- can efficiently reduce all the DNA/RNA bases and the reaction will be exergonic in nature as shown in Fig. 11.

The energetics of the electron in the gas phase and in solution is shown in Fig. 11. Figure 11 also shows the TNI of DNA in the gas phase or in solution. Once formed in solution, the TNI will undergo solvent and molecular reorganization, which liberates additional solvation energy. This occurs within 100 ps and results in stabilization by several electronvolts. For a stable (adiabatic) anion radical to be formed, the energy must be below the energy of the solvated electron (e_{aq}^-), as shown in Fig. 11. The adiabatically solvated DNA radical anion ($\text{DNA}^{\bullet-}$) can subsequently undergo protonation reactions on pyrimidines for further stabilization, but will not produce a strand break. The reaction of the TNI to form a DNA strand break must take place before solvation, which forms the stable anion radical. This allows only a short time window for the reaction to take place. In Fig. 12, the energetic cycle for the adiabatic electron solvation (AEA), photo ejection of the solvated electron (e_{aq}^-) into the gas phase (VDE), and the solvent reorganization to equilibrated water (SRE), based on values in Table 5, are shown.

Fig. 11 Schematic diagram showing the addition of LEE to DNA in gas phase (e_{gas}^-) and in liquid water via prehydrated electrons (e_{pre}^-) from the conduction band and by LEE addition. In the gas phase, LEE (e_{gas}^-) can be captured into one of the UMOS of DNA (shown as SOMO after the (e_{gas}^-) capture) creating the TNI ($\text{DNA}_{\text{gas}}^{-.*}$). A TNI formed in the liquid water ($\text{DNA}_{\text{aq}}^{-.*}$) is quickly solvated, resulting in the adiabatic DNA radical anion ($\text{DNA}_{\text{aq}}^{-.*}$). The energy of the adiabatic radical anion must be below the energy of the solvated electron (e_{aq}^-) to be stable to electron loss to water. For clarity, the MOs of DNA below the HDMO (highest doubly occupied MOs) and above the SOMO are not shown in the figure (Figure based in part from Wang et al. (2009))

Because of the importance of solvation to the reactivity of electrons, studies of electrons in water at various energy states are needed (Alizadeh and Sanche 2012; Kheir et al. 2013; Petrovici et al. 2014; Adhikary et al. 2010). A few recent studies (Wang et al. 2009; Orlando et al. 2008) have appeared. The first (Wang et al. 2009) reported the plasmid DNA damage by the prehydrated electron (e_{pre}^-) (energy of the conduction band in Fig. 11). The electrons were generated by water excitation using two UV photon laser pulses. The TNI formation was reported to result in fast DEA processes, resulting in strand breaks. This work is the first to

Fig. 12 Schematic diagram showing the energetic cycle for the adiabatic electron solvation (AEA), the photoejection of the solvated electron (e^-_{aq}) into the gas phase (VDE), and the solvent reorganization to equilibrated water (SRE). The various energy changes are designated as VDE (vertical detachment energy), AEA (adiabatic electron attachment), and SRE (Solvent reorganization energy). The VDE has the same geometry for the upper state as in the ground state. The solvent after photoejection of the electron is unstable by ca. 1.7 eV over a stable water-phase geometry. The difference between the AEA and VDE gives the value of the SRE

suggest conduction band electrons (e^-_{pre}) would be reactive in this manner. The results appear problematic because the concentrations of the solutes may not have been high enough to scavenge sufficient extremely short lived (0.3 ps) prehydrated electrons. Confirmation experiments are needed to verify this very interesting result. LEE-induced damage in hydrated A- and B-DNA has also been studied by Orlando et al. (2008) using elastic scattering of 5–30 eV electrons. In this study, a featureless amplitude buildup of elastic scattered electrons on the sugar and phosphate groups was observed for all energy ranges from 5 to 30 eV.

Proposed Theoretical Models of DNA Damage

After the discovery that low-energy (3–20 eV) electrons induced single- and double-strand breaks in plasmid DNA (Boudaïffa et al. 2000), a number of theoretical studies have attempted to elucidate the mechanism of LEE induction of DNA strand breaks. As the calculation of the entire DNA molecule at the ab initio or DFT levels is currently prohibitive, fragments of DNA structure usually including the base, sugar, and phosphate attached at 3'- and 5'-ends of the sugar ring have been treated.

The first mechanism for LEE-induced SSBs was proposed by Simons and coworkers employing a Hartree–Fock (UHF) level of theory and 6-31+G* basis set

(Barrios et al. 2002). In their study, they considered 3'-cytidine mono phosphate (3'-dCMPH) as a model of DNA and studied the ground-state potential energy surfaces (PESs) of the $C_{3'}-O_{3'}$ bond dissociation in the neutral and in radical anion states, and at each $C_{3'}-O_{3'}$ bond increment, the geometries were fully optimized. The calculations suggest a shape resonance, that is, the initial attachment of the excess electron on the π^* virtual molecular orbital localized on the cytosine base. During the $C_{3'}-O_{3'}$ bond elongation process on the PES of the anion radical, the excess electron, captured on the base, was found to be transferred to the $C_{3'}-O_{3'}$ bond region (joining the sugar and phosphate groups) at the transition state. From the calculated energy profile of $C_{3'}-O_{3'}$ bond dissociation, the energy barrier was estimated to be ca. 13 kcal/mol and the fragmentation process was found to be exothermic in nature. Based on this study, the authors proposed an *indirect mechanism* of SSB in which an electron transfers from base (π^*) to break the remote (σ^*) C–O bond. Here, we note that the statement “indirect mechanism” is not related to the terms direct and indirect effect of radiation-induced DNA damage. This first theoretical calculation clearly predicted that SSBs can occur below 3 eV as later found in LEE experiments (Martin et al. 2004; Panajotovic et al. 2006). While groundbreaking in nature, this study had several drawbacks: (a) it did not consider the higher energy shape resonances; (b) it considered the adiabatic state of the radical anion for the bond fragmentation, not the TNI, which is the initial state of the shape resonance formation as discussed in the section “[Shape Resonances of DNA Bases](#)”; and (c) it was not clear whether the proposed mechanism was pertinent to the actual DNA environment, where the bases are stacked over each other and the electron transfer process between the bases is likely preferred over the electron transfer process to the sugar phosphate region (Wagenknecht 2005).

Just after Simons's work (Barrios et al. 2002), Li, Sevilla, and Sanche (Li et al. 2003a) proposed that the direct attachment of the excess electron to the sugar phosphate backbone of the DNA may create the SSB. To investigate this process, they modeled the sugar–phosphate–sugar (S-P-S) backbone of the DNA without bases attached to the sugar ring (see Fig. 13). Because of the large size of the model, they used the ONIOM approach to optimize the geometry of the S-P-S model shown in Fig. 13. In the ONIOM treatment, B3LYP/6-31+G(d) level of theory was used for the critical bond cleavage atoms (higher layer), and the semiempirical AM1 method was used for the rest of the atoms (lower layer). In their treatment, they calculated the PESs of the $C_{3'}-O_{3'}$ and $C_{5'}-O_{5'}$ bonds dissociation of the S-P-S model in their neutral and anionic radical states. The study showed that in the radical anion state, the 3'- and 5'-C–O bonds cleavage occurred with a low activation barrier (ca. 10 kcal/mol) in comparison with the neutral state. The bond dissociation process for radical anion was found to be highly favorable thermodynamically (see Fig. 14). This work suggested that a vibrational excitation of the C–O bond could capture an electron and lead to a strand break. An important aspect about the nature of an excess electron association into the sugar phosphate region showed the formation of the dipole-bound anion state rather than the valence anion state, which is expected as only electronic excited states are expected to be available for electron capture in the sugar phosphate structure.

Fig. 13 Sugar–phosphate–sugar (S-P-S) model representing a section of DNA backbone. Electron-induced bond dissociations at the 3'- and 5'-ends of the model are investigated. Figure modified according to the spin density distribution shown in Li and Sevilla (2007), which showed no valence state but a dipole-bound precursor (Reprinted with permission from Li et al. (2003a). © (2003) American Chemical Society)

Fig. 14 Adiabatic potential energy surfaces for 3'C-O and 5'C-O bond rupture before and after electron addition to the S-P-S model. All energies are relative to the energies of the anions at equilibrium (Reprinted with permission from Li et al. (2003a). © (2003) American Chemical Society)

In a recent work (Kumar and Sevilla 2007), the interaction of LEE with a model for DNA (5'-dTMPH) was studied at the B3LYP level of theory considering both the vertical (TNI) and the adiabatic states of the radical anion. Since the TNI (shape resonance) formation has only a short life time of 10^{-15} to 10^{-10} s, the study was performed with the hypothesis that SSBs may occur before as well as after molecular relaxation, as shown in Scheme 1.

In this calculation, the potential energy surface (PES) for $C_{5'}-O_{5'}$ bond dissociation of 5'-dTMPH in vertical and adiabatic states was calculated using both compact (6-31G*) and diffuse (6-31++G**) basis sets. At each step on the PES, the singly occupied molecular orbital (SOMO) was plotted to observe the pattern of the excess electron localization on the molecular frame. To elucidate the mechanism of SSB, the PES was scanned by stretching the $C_{5'}-O_{5'}$ bond from the equilibrium bond length of the neutral and anion radical of 5'-dTMPH to 2Å in the increments of 0.1Å. On the vertical radical anion (TNI) PES, the $C_{5'}-O_{5'}$ bond was scanned by maintaining the remainder of the geometry in the neutral state; however, on the adiabatic state, the geometry was optimized at each step of the bond elongation on the PES. The B3LYP/6-31G* and B3LYP/6-31++G** calculated PESs of $C_{5'}-O_{5'}$ bond dissociation are shown in Figs. 15 and 16, respectively. On the adiabatic surface, both methods gave similar barrier heights, that is, 14.8 and 13.5 kcal/mol for the $C_{5'}-O_{5'}$ bond dissociation. The SOMO, which is initially localized on the thymine as expected (Becker et al. 2010; Li and Sevilla 2007; Kumar and Sevilla 2008b), transfers to the $C_{5'}-O_{5'}$ bond region only after the transition state for the $C_{5'}-O_{5'}$ bond rupture. For the vertical PES, B3LYP/6-31G* theory predicted the barrier height for $C_{5'}-O_{5'}$ bond dissociation as 9 kcal/mol, while the corresponding barrier was predicted to be 17 kcal/mol at the B3LYP/6-31++G** level of theory. An important feature of this study is that in the vertical state excess electron begins transferring smoothly into the $C_{5'}-O_{5'}$ bond region before the TS during bond elongation process; however, in the adiabatic state electron transfer takes place from base to $C_{5'}-O_{5'}$ bond region after the TS (see SOMO plots in 15 and 16). The facile electron transfer from base to sugar in the vertical state supports the hypothesis that the transiently bound electron in the TNI (shape resonance) results in SSBs in DNA without the need for significant molecular relaxation. From this work, it was also inferred that TNI formation may excite some specific vibrational mode which has the lower barrier for the bond fragmentation, as already proposed by Burrow et al. (Afatooni et al. 1998; Jordan and Burrow 1987) and Sanche et al. (Levesque et al. 2003). It is also noted that on timescale appropriate for the transition state ($<10^{-12}$ s) (Zewail 2000), specific vibrational motions may dominate. Therefore, on TNI formation a vibrational excitation of the $C_{5'}-O_{5'}$ bond would need only a small or negligible barrier for the bond dissociation. In this model, the incoming LEE must vibrationally excite the $C_{5'}-O_{5'}$ bond during the TNI (shape resonance) at thymine base. Since this mechanism seems improbable, alternatively, the LEE may directly attach into the phosphate group in an UMO and create such a vibrational excitation through resonance formation on phosphate. From the computed vertical attachment energies of 5'-dTMPH, shown in Fig. 8, it is evident that <2 eV UMOs on phosphate group and base are available to capture

LEEs (Kumar and Sevilla 2007). Thus, it is quite possible that on TNI formation these UMOs will excite the vibrational mode and result in SSBs.

Excited States of TNI (Resonance Formation)

The theoretical model (Kumar and Sevilla 2007) of LEE attachment to the LUMO leading to strand break formation provides one pathway that TNI formation can lead to DNA strand breaks, but it ignores the role of shape resonances that are available at 1–2 eV and above (estimated from the vertical attachment energies of the UMOs of 5'-dTMPH, see Fig. 8 and Kumar and Sevilla (2007)). It is well known that during electron–molecule interactions, a variety of excited states can be involved. Therefore, the study of excited states of the TNI, which model resonance states formed on the electron attachment to the parent molecule, can be pursued to better understand LEE interactions in DNA. With this in mind, we studied the excited states of anion radical of 5'-dTMPH (as a model of DNA) using time-dependent (TD) density functional theory (Kumar and Sevilla 2008b). The geometries of 5'-dTMPH in

Fig. 16 B3LYP/6-31++G** calculated adiabatic and vertical potential energy surfaces (PESs) of $C_5'-O_5'$ bond dissociation of 5'-dTMPH radical anion. Energies and distances are given in kcal/mol and angstroms ($^{\circ}A$), respectively. their neutral and anion radical state were fully optimized using the B3LYP/6-31G* method. The lowest excited states of the TNI were calculated using TD-B3LYP and TD-BH and HLYP methods using the 6-31G* basis set. In this study, a compact basis set (6-31G*) was employed to avoid the mixing of the valence states with the dipole-bound states and continuum (Li et al. 2002a). The assumption of this work is that the TNI (resonance) formation is equivalent to an excited state of the electron adduct of the parent molecule. Further, the applicability of both functionals was tested for a number of anion radicals for which experimental and theoretical values were available (for details see the supporting information of Kumar and Sevilla (2008b)). Also, the transition energies, calculated using both the methods, were compared with the available shape resonance energies of adenine, thymine, cytosine, and uracil, as determined from the ETS experiment (Aflatooni et al. 1998), and 5'-dTMPH with their scaled vertical attachment energies (see Table 6). From Table 6, we see that both the methods provide reasonable estimates of shape resonance energies of the bases. However, for 5'-dTMPH radical anion, the B3LYP method was found to largely underestimate the transition energies, while the BH and HLYP method was found to give more realistic values. The problem with the B3LYP

method in underestimating the long-range Coulomb interactions in charge transfer states is well documented in the literature, and this arises from the small contribution of the Hartree–Fock exchange (20 %) in the B3LYP functional (Dreuw and Head-Gordon 2005). However, for this case, the charge transfer state is not created during the excitation because only the excess electron transfers between the nominally neutral portions of the molecule; this is another limitation of the B3LYP functional. In view of this, we employed the BHandHLYP/6-31G* method to compute the excitation energies of 5'-dTMPH radical anion in the vertical and adiabatic states.

In this study, the ground- and excited-state potential energy surfaces were generated by scanning the C_{5'}–O_{5'} bond from their equilibrium bond length in neutral and anion radical state to 2° Å in the step size of 0.1° Å. At each fixed C_{5'}–O_{5'} bond length, the lowest excited states were calculated. The excited states of the TNI of 5'-dTMPH, calculated at the optimized geometry of the neutral 5'-dTMPH, are shown in Fig. 17. The TD-BHandHLYP/6-31G* calculated three lowest transition

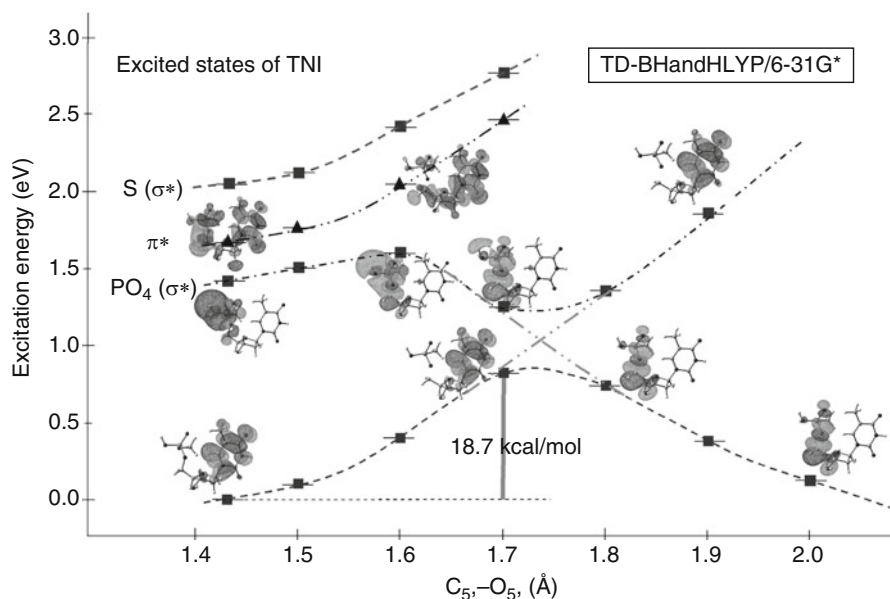

Fig. 17 Lower curve: Potential energy surface (PES) of the 5'-dTMPH transient negative ion (TNI) calculated in the neutral optimized geometry of 5'-dTMPH with $C_{5'}-O_{5'}$ bond elongation. SOMO is shown at selected points. Upper curves: calculated vertical excitation energies of the radical anion at each point along the PES; MOs involved in excitations are also shown. Energies and distances are given in electronvolts and angstroms, respectively. energies of TNI were found to be $\pi(T) \rightarrow \sigma(\text{PO}_4)^*$, $\pi(T) \rightarrow \pi(T)^*$, and $\pi(T) \rightarrow \sigma(S)^*$ in nature, and the corresponding transition energies are 1.42, 1.68, and 2.06 eV, respectively. The calculated $\pi(T) \rightarrow \pi(T)^*$ transition energy 1.68 eV is in good agreement with those calculated using ETS experiment of thymine (see Table 6 and Fig. 17). From the ground-state surface, it is evident that SOMO is localized on the base as found from the ESR (electron spin resonance) experiments (Sevilla et al. 1991). From the nature of the PES in the ground state, we see that the ground-state surface (lowest surface, in Fig. 17) shows the bound character and attains the transition state at 1.7 Å with a barrier height of 18.7 kcal/mol (see Fig. 17). The second and third surfaces corresponding to $\pi(T) \rightarrow \pi(T)^*$ and $\pi(T) \rightarrow \sigma(S)^*$ transitions also exhibit the bound character. However, the first surface, which is a $\pi(T) \rightarrow \sigma(\text{PO}_4)^*$ type, shows a dissociative nature.

Such a dissociative nature of $\pi \rightarrow \sigma^*$ transitions in excited states is well documented in the literature (Domcke and Sobolewski 2003; Sobolewski and Domcke 2002; Ashfold et al. 2006). The presence of $\pi(T) \rightarrow \sigma(\text{PO}_4)^*$ transition < 2 eV clearly indicates that LEEs with this energy can directly attach to the sugar-phosphate group during TNI formation and result in a prompt SSB formation in

DNA. This transition is dark in nature and cannot be populated directly; however, it can be populated through vibronic coupling when the neighboring $\pi(T) \rightarrow \pi(T)^*$ state lies at 1.68 eV. The coupling of π^* and σ^* surfaces leads to a facile strand break formation within picoseconds. Sanche and coworkers (Martin et al. 2004; Panajotovic et al. 2006) studied the yields of SSB and DSB induced by 0–4 eV electrons and found two peaks near 0.8 ± 0.3 and 2.2 eV, respectively. Our calculated transitions at 1.4 and 1.7 eV are in reasonable agreement to the experimental observation. Further, the σ^* nature of shape resonance localized on the phosphate group in 5'-dTMPH radical anion is also supported from the recent experimental study carried out by Burrow et al. (2008) for the temporary anion states of trimethyl phosphate and several P=O groups containing compounds. The electron-scattering study of the A and B forms of DNA concluded that electrons with energies between 2 and 5 eV had the largest probability of electron capture on the phosphate group versus on the other components of the DNA (Caron and Sanche 2005). Experiments reported by Illenberger and coworkers (König et al. 2006) showed that C–O bond rupture is caused by LEE that directly attacks to the phosphate group.

The above study was extended to radical anions of a series of nucleoside diphosphate: 2'-deoxyguanosine-3',5'-diphosphate(3',5'-dGDP), 2'-deoxyadenosine-3',5'-diphosphate (3',5'-dADP), 2'-deoxythymidine-3',5'-diphosphate(3',5'-dTDP), and 2'-deoxycytidine-3',5'-diphosphate (3',5'-dCDP). The excited states of these species in gas phase and in the condensed phase in their TNI and adiabatic states were calculated using the BH and HLYP/6-31G* method (Kumar and Sevilla 2009). The geometries of each species (3',5'-dGDP, 3',5'-dADP, 3',5'-dTDP, and 3',5'-dCDP) in their neutral and radical anionic states, in the gas phase, and in the presence of two and three water molecules were fully optimized at the B3LYP/6-31G* level of theory. In this work, the nature of the resonances under the influence of the bulk solvent was modeled by the use of integral equation formalism-polarized continuum model (IEF-PCM) on the optimized hydrated geometries in the neutral and radical anion states. To the best of our information, this was the first study that showed that while in the gas phase the dissociative (σ^*) state is accessible by LEEs, in solution these states are blue-shifted toward higher energy and are not accessible by LEEs having energy under 4 eV. This phenomenon is well understood from the photoelectron spectroscopy of the solvated anions. It is well known that under solvation, anions become energetically more stable (see discussion in section “Effect of Solvation (Condensed Media)”) and a higher detachment energy (VDE) is needed in solution in comparison with the gas phase. As a result, the photoelectron spectra of solvated anions have their peaks blue-shifted (Simons 2008; Schiedt et al. 1998; Eustis et al. 2007) in comparison with their gas-phase spectra.

In this work, the lowest vertical $\pi \rightarrow \pi^*$, $\pi \rightarrow \sigma^*$ excited states and core excitation of each of the molecules in gas phase and in solution were calculated. As an example, we present the excited states of TNI of 3', 5'-dADP in the gas phase and in solvation in Fig. 18. In the gas phase, the lowest three transitions of 3',5'-dADP are $\pi(A) \rightarrow \pi(A)^*$, $\pi(A) \rightarrow \sigma(3'-PO_4)^*$, and $\pi(A) \rightarrow \sigma(5'-PO_4)^*$ in nature and the corresponding transition energies are 0.99, 1.07, and 1.14 eV, respectively.

Fig. 18 TD-BH and HLYP/6-31G* computed transition energies in TNI state of 3',5'-dADP in gas phase (*left*) and aqueous solution (*right*). The effect of bulk water solvent was considered using IEF-PCM model on the trihydrated 3',5'-dA⁺-DP system. Transition from SOMO to different MOs (*shape resonance*) is shown. Transition energies are given in electronvolts (Reprinted with permission from Kumar and Sevilla (2009). © (2009) Wiley-VCH Verlag GmbH & Co. KGaA Weinheim)

The first transition, S₁, occurs from SOMO(π) \rightarrow (121 α and 124 α) MOs on the adenine base. The other two transitions, S₂ and S₃, occur from SOMO(π) to 3'- and 5'-ends of the PO₄ group. These transitions are singly dominant transitions and each has ca. 90 % contribution. In Fig. 18, we present the excited states of TNI of fully solvated 3',5'-dADP + 3H₂O. In this case, we found the two lowest transitions (S₁ and S₂) are $\pi(A) \rightarrow \pi(A)^*$ in nature, and the corresponding transition energies are 0.76 and 1.54 eV, respectively. Interestingly, the transitions $\pi(A) \rightarrow \sigma(5'-\text{PO}_4)^*$ and $\pi(A) \rightarrow \sigma(3'-\text{PO}_4)^*$ are blue-shifted under solvation toward high energy in comparison with their corresponding gas-phase values (see Fig. 18). This phenomenon is observed for all the cases studied here (for details see Kumar and Sevilla (2009)).

Since $\pi \rightarrow \sigma^*$ states, localized on 5'- and 3'-ends of the PO₄ group, are dissociative in nature, they are of particular interest. Therefore, we also calculated the variation of the transition energies of these states in (1) gas phase, (2) with discrete water molecules, and (3) and (4) in the presence of bulk solvent with two dielectric constant values $\epsilon = 7.0$ and 78.4, respectively, for TNI and their adiabatic states. As an example, the plot of the variation of transition energies of $\pi \rightarrow \sigma(5'-\text{PO}_4)^*$ with increasing solvation is shown in Fig. 19. From Fig. 19, it is evident that transition energies for the $\pi \rightarrow \sigma^*$ states increase with increasing solvation and become less accessible by LEEs < 4 eV. This conclusion is also supported by the earlier conclusion of Sevilla et al. (1994) that diffuse states are destabilized under the influence of the solvation. Therefore, from this work we conclude that σ^* states lie in the range of 1.1–1.7 eV (in the gas phase) and are in close agreement with the experimental threshold value of 0.8 ± 0.3 eV for creating SSBs (Martin et al. 2004;

Fig. 19 Variation of transition energies (eV) of the $\pi \rightarrow \sigma(5'-\text{PO}_4)^*$ excited state of nucleotides in adiabatic state with increasing solvation. Different solvation levels labeled on X-axis are 1 – gas phase, 2 – three discrete water molecules, 3 – three waters and a continuous dielectric ($\epsilon = 7.0$) and 4 – three waters and a continuous dielectric ($\epsilon = 78.4$) (Reprinted with permission from Kumar and Sevilla (2009), © (2009) Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim)

Panajotovic et al. 2006). However, the most important point we can draw from this work is that in solution these dissociative (σ^*) states increase in energy by several electronvolts. This clearly suggests that solvation of DNA would reduce the direct cleavage of DNA by LEEs in the energy range of 0–4 eV.

Leszczynski and coworkers (Bao et al. 2006; Gu et al. 2006) used the B3LYP/DZP++ method to study the $\text{C}_{5'}-\text{O}_{5'}$ and $\text{C}_{3'}-\text{O}_{3'}$ bond cleavage in pyrimidine nucleotides anion radical in their adiabatic states. This work supported the mechanism suggested by Simons and coworkers (Barrios et al. 2002). An alternative mechanism using the concept of electron-induced proton transfer mechanism was proposed by Dabkowska et al. (2005) considering a cytosine nucleotide as a model of DNA for creating SSBs in DNA. In this model, two electrons and a proton add to the cytosine base, which then undergoes proton transfer from the sugar C_2 site to the base subsequently resulting in strand cleavage. Such a mechanism may be active in radiation damage regions where several excess electrons and protons are produced in a small spatial region, that is, a spur. Using first principle molecular dynamics simulations, Kohanoff and coworkers (Gu et al. 2014a) showed that amino acids can protect DNA from damage by LEE. In their model, they used hydrogen-bonded thymine and glycine dimer and attach an excess electron to it. In this study, they found that (i) LEEs initially attached to thymine produce a thymine radical anion and then a barrierless proton transfer takes place from glycine to thymine and (ii) LEEs are also captured by the glycine, which acts as an electron scavenger thus protecting the thymine to form thymine radical anion.

Recently, Kopyra (2012) reported DEA to the gas-phase dCMP ($2'$ -deoxycytidine $5'$ -monophosphate) using a crossed electron molecular beam arrangement experiment. From the yield of the different ions and resonant electron attachment profile to

dCMP, they concluded that both direct electron attachment to backbone and excess electron transfer from cytosine (base) to backbone contribute the SSB. They further estimated the relative contribution of these mechanisms leading to SSB. According to their estimate, (a) 60 % electron localizes at the phosphate unit, (b) 25 % electron localizes at the sugar unit, and (c) 15 % electron initially localizes at the base and transfers to backbone. These estimates clearly suggest that direct localization of LEE to backbone leading to SSB is a major pathway, while *base-to-backbone* excess electron transfer leading to SSB is likely only a minor pathway. This experimental study supports the theoretically proposed mechanism of direct LEE attachment to phosphate group leading to SSB (Li et al. 2003a; Kumar and Sevilla 2008b; Kumar and Sevilla 2009).

We note that most of the theoretical investigations used density functional theory, particularly B3LYP method to estimate the barriers for $C_{3'}-O_{3'}$ and $C_{5'}-O_{5'}$ bonds dissociation due to LEE electron attachment to the DNA units. Generally, the barrier computed by the B3LYP method is underestimated because at transition state electron overly delocalizes from base to sugar phosphate region (Kumar and Sevilla 2008). This excess delocalization in B3LYP method mainly arises due to self-interaction error. This discrepancy in the B3LYP method in underestimating the barrier for C–O bond dissociation was also raised in a very recent study by Chen et al. (2014), which is described below.

In the recent work, Chen et al. (2014) benchmarked the different DFT methods to compute the barrier for $C_{3'}-O_{3'}$, $C_{5'}-O_{5'}$, and $C_{1'}-N$ bonds dissociation on LEE attachment to a nucleobase. The benchmark was carried out relative to the most accurate CCSD(T) method. The study showed that the glycosidic ($C_{1'}-N$) bond cleavage was well described by the DFT methods, but the barriers for $C_{3'}-O_{3'}$, $C_{5'}-O_{5'}$ bonds dissociation were severely underestimated. The error for $C_{3'}-O_{3'}$, $C_{5'}-O_{5'}$, and $C_{1'}-N$ bonds dissociation relative to CCSD(T) is shown in Fig. 20. From Fig. 20, it is evident that M06-2X and ω B97XD density functionals are quite accurate in predicting the $C_{3'}-O_{3'}$, $C_{5'}-O_{5'}$ bonds dissociation and the absolute maximum error relative to CCSD(T) is ca. 2 kcal/mol (Chen et al. 2014). The most used B3LYP method underestimated the C–O bond dissociation barrier by about 7 kcal/mol relative to CCSD(T), see Fig. 20. On the basis of this benchmark study, authors also concluded that *base-to-backbone* electron transfer leading to SSB does not occur as easily as proposed in earlier studies. Alternatively, the direct LEE localization to phosphate group to produce SSB is a possible mechanism.

Recently, using DFT (M06-2X/6-31+G(d,P) quantum mechanics/molecular mechanics (MM/QM) molecular dynamics simulations, Cauët et al. (2013) considered solvated 12-mer fragment of B-DNA ((a) 3'-TTTTTTTTTTTTT-5' (b) 3'-CCCCCCCCCCC-5' (c) 3-GCGCTATGCGA-5') to study LEE-induced strand breaks. In this study, 2-base pairs in the center of the 12-mer fragment were considered by the QM, while rest of the system was considered by the MM. From the analyses of the electronic and the nuclear Fukui functions, they found that after vertical electron attachment to the DNA fragment (12-mer B-DNA) the position and dynamics of the atomic nuclei in DNA are largely modified. The LEE interaction

Fig. 20 Errors in $C_{3'}-O_{3'}$, $C_{5'}-O_{5'}$, and $C_{1'}-N$ bonds dissociation by different DFT methods relative to CCSD(T) calculations (Reprinted with permission from Chen et al. (2014), *J. Phys. Chem.* © (2014). American Chemical Society)

induces nuclear motions that involve the elongation of P–O and C–C (deoxyribose) bonds. If the acquired kinetic energy becomes high enough, the neighboring $C_{3'}-O_{3'}$ or $C_{5'}-O_{5'}$ phosphodiester bonds may break within a 15–30 fs timescale. In other words, DNA strand breaks can take place before electron localization on the base. Such fast reaction to induce strand breaks in DNA needs experimental verification as strand break formation will be in competition with electron localization at the base and subsequent protonation of the anionic base radical from solvent.

In addition to these works, a number of other studies related to the LEE-induced DNA damage have appeared over the last few years (Zhang et al. 2008; Xie et al. 2008; Takayanagi et al. 2009; Solomun et al. 2009; Solomun and Skalicky 2008; Gu et al. 2011; Smyth and Kohanoff 2012; Baccarelli et al. 2011; González-Ramírez et al. 2012).

Profile of DNA Damage Produced by LEE and Ionizing Radiation

Very recently, Sanche and coworkers (Park et al. 2013) experimentally compared the DNA damage produced by LEE (<10 eV) and high-energy photons. In this study, they considered solid TpTpT trinucleotide as a model of DNA. The radiation-produced damage was measured by high-performance liquid chro-

matography (HPLC) with UV detection and HPLC coupled with tandem mass spectrometry. Their analyses found thymine release, strand breaks, and the formation of base modifications, such as 5,6-dihydrothymine, 5-hydroxymethyluracil, and 5-formyluracil. The damage by high-energy X-rays was found to be 20 % (base release), 19 % (strand break), and 61 % (base modifications), respectively, while the corresponding damage produced by LEE (≤ 10 eV) was found to be 35 %, 13 %, and 51 %, respectively. X-rays give lower base release in comparison with LEE. From the analyses, it was found that LEEs overall give a similar profile of products compared to ionizing radiation. The similarity in damage profiles suggests that LEE maybe a significant contributor in X-ray damage.

LEE-Induced Base Release

In addition to LEE-induced SSBs and DSBs in DNA, glycosidic bond cleavage (base release) induced by LEE has also been experimentally observed by Sanche and coworkers (Zheng et al. 2004, 2005, 2008) as well as by Illenberger and coworkers (Ptasińska et al. 2006; Abdoul-Carime et al. 2004b). LEEs with 4–15 eV energy were found to be effective in causing base release in thymidine, as well as in the DNA sequence 5'-TpTpT-3' (Zheng et al. 2004, 2008). The initial quantum yield for thymine release in thymidine was found to be 3.2×10^{-2} preincident electron (Zheng et al. 2004). The conversion of thymidine into thymine and sugar was proposed due to the localization of LEEs into the antibonding MOs of $N_1-C_{1'}$ (glycosidic) bond, which leads either to homolytic or heterolytic cleavage of the $N_1-C_{1'}$ bond joining the thymine and sugar ring (Zheng et al. 2004).

Using the B3LYP/DZP++ method, Schaefer and coworkers (Gu et al. 2005) calculated the ground-state adiabatic PESs for the $N_1-C_{1'}$ bond dissociation considering the radical anions of 2'-deoxyribothymidine (dT) and 2'-deoxyribocytidine (dC). Subsequently, a detailed analysis of the base release process in dC, dT, and deoxyadenosine in two conformations, that is, dA1 (with internal hydrogen bonding) and dA2 (without hydrogen bond), was carried out by Li, Sanche, and Sevilla (Li et al. 2006) using B3LYP/6-31+G(d) level of theory. This work provided some insight into the relative energies of $N_1-C_{1'}$ (glycosidic) bond dissociation of these molecules in their neutral and anion radical states in gas phase as well as in the presence of bulk solvent via the PCM method. This study showed that LEEs in fact greatly weakened the $N_1-C_{1'}$ bond strength of these molecules in comparison with their corresponding bond strength in neutral state. The bond dissociation energy of the $N_1-C_{1'}$ bond in gas phase is found to be exergonic for dA ($\Delta G = -14$ kcal/mol) and dT ($\Delta G = -6$ kcal/mol) and is endergonic for dC ($\Delta G = 1$ kcal/mol). The PESs for the $N_1-C_{1'}$ bond dissociation of these molecules are shown in Fig. 21. From Fig. 21, it is clearly evident that the barrier for the $N_1-C_{1'}$ bond dissociation is located between 19 and 23 kcal/mol for all the molecules. The experimental value for LEE-induced thymine release in dT of about 1 eV (ca. 23 kcal/mol) (Zheng et al. 2004, 2005, 2008; Ptasińska et al. 2006; Abdoul-Carime et al. 2004b) is in good agreement with the calculated value of barrier for thymine release in dT

Fig. 21 Anionic N1-C potential energy surfaces of deoxyadenosine (*dA2*), thymidine (*dT*), and deoxycytidine (*dC*). *dA1* has a similar profile to *dA2* (Reprinted with permission from Li et al. (2006). © (2006) Radiation Research Society)

(19 kcal/mol) (see Fig. 21). From the SOMO, it was found that in adiabatic states all the molecules showed the valence-bound π^* state. Also, on the PES as the $N_1-C_{1'}$ bond extends from its equilibrium value, the π^* (valence state) crosses the antibonding σ^* dissociative state at transition state and excess electron localized on $N_1-C_{1'}$ bond region creating a negative nitrogen site on the base and a free radical at $C_{1'}$ site on the sugar ring.

Effect of Solvation on Strand Break Formation

In comparison with gas-phase investigations, studies concerning electron-induced strand breaks under the influence of solvation are few in number. From pulse radiolysis experiments, it is well known that solvated electrons do not cause strand breaks upon attachment to DNA in an aqueous environment (von Sonntag 1987; Nabben et al. 1982); this is discussed in detail in section “Effect of Solvation (Condensed Media).” Most theoretical studies to date have assumed adiabatic systems and have attempted to explain the effect of solvation on strand breaks using polarized continuum model (Simons 2006; Barrios et al. 2002; Li et al. 2003a, 2006; Bao et al. 2006; Gu et al. 2006). Though the PCM model is adequate for

bulk solvent effects, it neglects the specific local interactions and hydrogen-bonding energetics, which are substantial contributions to solvation energetics and are critical in determining reaction pathways. This level of sophistication is usually avoided owing to the increase in complexity of the treatment.

In order to gain an understanding of the influence of specific hydrogen-bonding effects in an aqueous environment on potential strand breaks, we considered (Kumar and Sevilla 2007) a 5'-dTMP that includes a solvation shell of 11 waters and a sodium counterion to neutralize the phosphate group. Using this hydrated (5'-dTMPNa + 11 H₂O) model, we calculated the adiabatic PES of C_{5'}-O_{5'} bond dissociation in the neutral and radical anion states using the B3LYP/6-31G** level of theory. On the PES of radical anion state, we also plotted the SOMO at each step of the C_{5'}-O_{5'} bond elongation. This calculation showed that the solvent has a pronounced effect, which would essentially eliminate strand break formation. The barrier for the C_{5'}-O_{5'} bond dissociation in the radical state was found to be 29 kcal/mol. This is in accord with the experimental finding that aqueous electrons do not cause strand breaks.

Very interestingly, we found that SOMO initially localized on the π* MO on thymine was still localized on the thymine at the TS. However, in gas phase (see Figs. 15 and 16), the SOMO transferred to the σ* C_{5'}-O_{5'} bond at the TS. The B3LYP/6-31G** calculated AEA and VDE of 5'-dTMPNa + 11 H₂O in full solvent using PCM was found to be 2.17 and 3.20 eV, respectively. This study confirmed that in comparison with the gas phase, the vertical detachment energies (VDEs) of the 5'-dTMP radical anion in the solvated environment are enhanced appreciably (3.20 eV), which shows that the excess electron in the solvated anion radical is highly stable toward electron detachment. Recently, the 3'- and 5'-C-O bond rupture in cytosine monophosphate was studied by Schyman et al. (2008) in the aqueous environment using a molecular dynamics study. The authors also found a higher barrier for the 3'- and 5'-C-O bond rupture. In another study, Schyman and Laaksonen (2008) studied the C_{3'}-O_{3'} bond dissociation in guanine 3'-monophosphate (3'-GMPH) radical anion in gas phase as well as in the presence of 21 water molecules using the B3LYP/DZP++ method. In this calculation, the authors found dipole-bound state for gas phase, which was expected. Surprisingly they also reported dipole-bound state for the hydrated system. As has already been mentioned, solution diffuse states such as dipole-bound states are destabilized relative to valence-bound states, which become lower in energy (see Fig. 10 and Li et al. (2002a)). This is already well established experimentally from the photoelectron spectroscopy of nucleic acid bases (Schiedt et al. 1998) as well as from theoretical calculations (Li et al. 2002a). Thus, the calculation of Schyman and Laaksonen (2008) for hydrated 3'-GMPH radical anion is considered to be problematic.

Loos et al. (2009) calculated the C_{3'}-O_{3'} bond cleavage of the radical anion of 2-deoxycytidine-3'-monophosphate moiety (3'-dCMPH) in single- and double-stranded DNA (5'-CCC-3' sequence) in gas phase using the QM/MM approach. The authors also reported the dipole-bound diffuse state localized near the phosphate group. They did not, however, report the initial attachment of the excess electron

on the cytosine. Thus, the approach which may be applicable to the gas phase is not predictive for the condensed phase. A similar calculation was already done by Simons and coworkers (Anusiewicz et al. 2004) considering a single-strand CCC sequence. Due to the large size of the system, they considered the ONIOM approach. The central nucleotide was treated with the UHF method with a 6-311+G* basis set; however, the two terminal nucleotides were treated at the lower level using a 4-31G* basis set. In this calculation, the initial attachment of an excess electron was found to be localized on the π^* MOs of the middle cytosine, showing valence-bound nature as expected from ESR experiments (Sevilla et al. 1991). Kobyłeczka et al. (2008) also showed a valence-bound anion formation on thymine in the DNA π -stacked system using the MP2/aug-cc-pVDZ method.

Park et al. (2011) investigated the DNA damage caused by LEE for nucleotides and short oligonucleotides in the solid state. The samples of TpTpT were irradiated with monoenergetic electrons of energy 10 eV and subsequently analyzed by high-performance liquid chromatography (HPLC) and mass spectrometry. The study showed that about 67 % of the total damage was identified as 5,6-dihydrothymine and 33 % damage involved the phosphodiester–sugar (C–O) bond and the *N*-glycosidic bond (CN) dissociation. However, in a similar type of study (Li et al. 2010), the total damage (base release and C–O bond cleavage) was found to undergo a twofold decrease for the following trimer sequences in the order: TTT > TCT > TAT > TGT. The nonmodified base release was found to be 17–24 % of the total damage and mainly occurred from the terminal sites of the trimers. The phosphodiester–sugar (C–O) bond cleavage was found to be only 9–20 %. Both the studies certainly conclude that an excess electron initially attached to the base forms a stable radical anion, which protonates to form 5,6-dihydrothymine as observed in a variety of ESR experiments on hydrated DNA samples (Sevilla et al. 1991; Gregoli et al. 1989). Once localized to the base, no transfer to phosphodiester–sugar bond region is likely, as discussed in sections “Effect of Solvation (Condensed Media)” and “Proposed Theoretical Models of DNA Damage.” Thus, SSBs are not produced from the adiabatic base anion radicals by reductive cleavage.

Using B3LYP/DZP++ level of theory, Gu et al. (2010a, b) reported the $C_{3'}-O_{3'}$, $C_{5'}-O_{5'}$ σ bond and *N*-glycosidic bond dissociation energies of anion radicals of 2'-deoxycytidine-3',5'-diphosphate (3',5'-dCMP), 2'-deoxythymidine-3',5'-diphosphate (3',5'-dTMP), and 2'-deoxyguanosine-3',5'-diphosphate (3',5'-dGMP) in gas phase and in aqueous media using the PCM model. For 3',5'-dCMP and 3',5'-dTMP, the order of bond dissociation energy was found to be $C_{3'}-O_{3'} < C_{5'}-O_{5'} < N$ -glycosidic bond, and the calculated energies lie in the range ca. 6–29 kcal/mol for both gas phase and in aqueous solution. For 3',5'-dGMP, the energies for breaking the corresponding bonds in the gas phase were calculated to be 11–24 kcal/mol, while in aqueous solution, the energies decrease appreciably than their gas-phase values and lie in the range ca. 1–10 kcal/mol, which indicates that $C_{5'}-O_{5'}$ bonds are more susceptible for cleavage than $C_{3'}-O_{3'}$ bonds. However, these activated processes are unlikely in aqueous solutions since the faster protonation reactions of the anion radicals will outcompete with such processes as pointed out above.

ESR work by Becker et al. (1996, 2003) has found evidence for both phosphodiester–sugar (C–O) bond cleavage and P–O bond cleavage (see Scheme 1). In these experiments, free radicals formed from 60 MeV/nucleon $^{16}\text{O}^{8+}$ ion beam irradiation of DNA samples at 77 K were analyzed by the ESR, and a new phosphorus-centered radical species was identified by its large ^{31}P parallel hyperfine coupling of about 780 G (Becker et al. 1996). The radical was identified as a phosphoryl radical, which was produced by the direct dissociation of the P–O bond. However, the yield of this radical was found to be very small (0.1 % of the total radicals). In other experiments, DNA samples were irradiated by ^{36}Ar and ^{40}Ar ion beams, and these two types of radicals were again identified by ESR at 77 K (Becker et al. 2003). These radicals were produced from dissociation of the C–O and P–O bonds at the $\text{C}_{3'}$ of the sugar moiety. The yield of the $\text{C}_{3'}$ -dephos radical produced by C–O bond dissociation was estimated as 95 %, while the ROPO_2^- produced by P–O bond dissociation was estimated to be 5 %.

Recently, a mechanism of SSB by P–O bond fragmentation in DNA was proposed by Rak et al. (2011) using B3LYP/6-31++G** level of theory. In their model, the authors proposed that LEE initially attached to the thymine, which is subsequently protonated at the C5 position of the thymine to produce the dihydro-6'-thymyl radical. In the next event, intramolecular hydrogen atom transfer takes place from $\text{C}_{3'}$ or $\text{C}_{5'}$ sites of sugar ring to the C6 site of the thymine, and finally the P–O bond is broken. However, from the calculated kinetic and thermodynamic barriers related to the P–O bond fragmentation, the authors concluded that the proposed mechanism was not favorable over the LEE-induced C–O bond fragmentation. ESR studies in solution suggest protonation at C6 of the thymine anion radical is favored, and the most favored reaction path for the $\text{C}_{5'}$ radical in aqueous media is by phosphate loss, that is, C–O bond cleavage.

LEE Interaction with 5-Bromouracil (5-BrU) and Radiosensitization Activity

Uracil (U) and thymine are very similar in structure and differ only by substitution at the C5-position (H for uracil and CH_3 for thymine). Thus, in DNA, 5-halogenated uracils are easily incorporated in place of thymine (Djordjevic and Szybalski 1960; Bagshaw et al. 1967; Doiron et al. 1999). These halogenated uracils are very sensitive to radiation such as γ - and X-rays and UV light. Because of this property (photosensitivity), 5-halogenated uracils were considered an efficient radiosensitizers in anticancer therapy. Particularly, 5-BrU and 5-Idouracil (5-IU) showed increased sensitivity in DNA to UV and X-ray radiation, and 5-BrU is used as lead drug for radiotherapy (Djordjevic and Szybalski 1960). 5-BrU is most easily incorporated in DNA as the bromine atom is very close in size to a methyl group. It is also observed that irradiated 5-BrU labeled DNA showed more damage to DNA (SSB and DSB) in comparison with native DNA (Webb et al. 1993; Dextraze et al. 2007; Li et al. 2011; Park et al. 2012; Hashiya et al. 2014; Wiczek et al. 2013; Zdrowowicz et al. 2014; Ling and Ward 1990). A number of

Fig. 22 Attachment of an excess electron to 5-BrU leads to transient negative ion (5-BrU)^{*-} formation which produces uracil-5-yl radical and bromide anion via DEA mechanism

theoretical and experimental studies confirmed that its radiosensitization activity is primarily related to the rapid reaction of the 5-BrU with secondary electrons that are generated during radiation (Wieczór et al. 2014; Golon et al. 2014; Sevilla et al. 1974; Li et al. 2002b, 2003b; Riederer et al. 1978; Voit et al. 1986; Razskazovskii et al. 1997; Wang et al. 2006; Wang and Lu 2007, 2010). The attachment of the secondary electrons to 5-BrU leads to the formation of very reactive uracil-5-yl radical (U-5-yl[•]) and bromide anion (Br⁻) via dissociative electron attachment mechanism as shown in Fig. 22. The U-5-yl[•] has been suggested to abstract a H atom from a neighboring 2'-deoxyribose unit in double-stranded (ds) DNA, which then leads to strand break formation, that is, SSB and DSB, and neutral U base release (Dextraze et al. 2007; Li et al. 2011; Park et al. 2012; Hashiya et al. 2014; Wiczek et al. 2013). However, very recently, in an interesting study (Chomicz et al. 2014) regarding the reactivity of U-5-yl[•], the authors point out that to produce a DNA strand break the sugar C3', C4', or C5' hydrogens must be abstracted; however, in dsDNA these hydrogens are too far from the adjacent 5-U-yl[•], to be readily involved in this process. These workers suggest an alternative mechanism that 5-U-yl[•] reacts with a water molecule to produce uracil and OH radical, which is described below.

Hydration of the Uracil-5-yl Radical

A joint experimental (electron spin resonance (ESR)) and theoretical (DFT) approach was used to study the hydration of U-5-yl[•] [244]. In this study, the ESR spectra of γ -irradiated aqueous glasses (7.5 M LiCl in H₂O/D₂O) containing 5-Bromouridine (5-BrdU) at 77 K show the initial formation of 5-BrdU π -anion radical. After 15-min annealing at 145 K, U-5-yl[•] was formed due to loss of Br anion. Further, after 15-min annealing at 160 K, hydrated U-5-yl[•] (5-UHOH[•]) was formed and was confirmed by the four line components in the ESR spectrum. The experimental ESR spectra are shown in Fig. 23. The reaction of U-5-yl[•] with water to form 5-UHOH[•] (hydrate radical) was also reported earlier by Sevilla et al. (1974) using ESR. The formation of 5-UHOH[•] was proposed due to addition of

Fig. 23 ESR spectra of BrdU in 7.5 M LiCl in H₂O with K₄[Fe(CN)₆] as a hole scavenger (a) immediately after γ -irradiation; (b–d) obtained after annealing the sample for 15 min; all recorded at 77 K. Structure of the radical assigned to each spectrum is shown. The simulated (gray) spectrum (d) employed is a combination of ca. 70 % quartet from 5-UHOH[•] (H-axial to the radical site p-orbital) and of ca. 30 % doublet from 5-UHOH[•] (H-equatorial to the radical site p-orbital) as well as from 6-UHOH[•] and is superimposed on the experimental (black) spectrum for comparison. The three triangular field markers are individually separated by 13.09 G with the central marker at $g = 2.0056$ (Reprinted with permission from Chomicz et al. (2014), *Chem. Commun.*, © (2014), The Royal Society of Chemistry)

HOH to the C5 radical site of neutral U-5-yl radical. To support this experiment, DFT calculations using M06-2X/6-31++G(d, p) method was used to calculate the reaction energy between U-5-yl[•] and a water molecule to directly form the hydrate radical 5-UHOH[•] or abstract from water to form uracil and OH[•] (U-5-yl[•] + H₂O → U + OH[•]). In the calculation, the effect of full solvent was considered through the use of polarized continuum model (PCM). Considering two possible reaction modes of a water molecule with U-5-yl[•], see Fig. 24, the energies of the reactants, transition state, and product were calculated. From the calculation, the forward lowest barrier ca. 12 kcal/mol was calculated to form uracil and OH[•] (product), and the product was calculated to be nearly isoenergetic with respect to reactants (U-5-yl[•] + H₂O). Subsequently uracil and OH[•] were suggested to rapidly react

Fig. 24 Possible reaction paths calculated at the M06-2X/6-31++G(d,p) level for 2'-deoxy-5-U-yl^{*} and the water molecule system. ΔG and ΔG^* stand for reaction free energy and activation free energy, respectively. All values are expressed in kcal/mol. For 2D models, R refers to the 2'-deoxyribose ring. P1 and P2 are tautomers with P2 being the most stable (Reprinted with permission from Chomicz et al. (2014), *Chem. Commun.* © (2014), The Royal Society of Chemistry)

to form C5-adduct radical (5-UHOH^{*}), involving a small activation barrier of ca. 2 kcal/mol, see Fig. 24. The C5-adduct radical (5-UHOH^{*}) was found to be more stable than the reactants (U-5-yl^{*} + H₂O) by ca. 17 kcal/mol. This interesting work provides an alternative pathway to the proposed hypothesis that U-5-yl^{*} abstracts hydrogen atom from neighboring 2'-deoxyribose moiety yielding strand breaks (Dextraze et al. 2007; Li et al. 2011; Park et al. 2012; Hashiya et al. 2014; Wiczek et al. 2013). It is also known that in ds-B-DNA, U-5-yl^{*} could abstract hydrogen atom from C_{1'}-H and C_{2'}-H of the adjacent sugar moiety as these two sites are close to the U-5-yl^{*} (Sugiyama et al. 1996; Tashiro and Sugiyama 2010). It is well known that C_{1'} and C_{2'} do not produce strand breaks in ds-B-DNA. Thus, in this situation, the produced U-5-yl^{*} can also react with surrounding water molecule to produce uracil and OH radical. The produced OH radical can abstract H atom from 2'-deoxyribose to yield strand breaks in ds-B-DNA.

Modeling 5-Substituted Uracil as an Efficient DNA Radiosensitizer

Recently, eight 5-substituted 1-methyl-uracil derivatives (5-R-U) with R=SCN, NCS, SH, CN, OCN, NCO, NNN, andNOO (see Fig. 25) were considered by theory and experiment. The reaction of these molecules with an excess electrons was studied using the B3LYP/6-31++G(d,p) method, including full effect of solvent through PCM (Chomicz et al. 2013). The aim of this study is to search a potent DNA radiosensitizer which has similar reaction mechanism as 5-BrU. In devising a potent DNA radiosensitizer, authors considered two criterions: (i) the molecule should have large electron affinity and form stable anion radical after electron attachment, and (ii) the chemical bond that connects a substituent (R) to the C5 atom of uracil ideally should be quite weak to produce U-5-yl[•], after electron attachment (see Fig. 25). Thus, to meet these two requirements, authors (i) studied the electron capturing strength of these derivatives by calculating their AEA and VDE in the gas phase and in aqueous solution, and (ii) estimated the reaction barrier to produce U-5-yl[•] and R⁻ from (R-U)^{•-}. From the calculations in the aqueous phase, it was found that all the considered molecules have positive AEAs in the range 2.26 eV to 3.55 eV and the calculated VDEs lie in the range 2.66 eV to 3.86 eV. The large positive AEAs and VDEs clearly indicate that all the molecules are able to capture hydrated electrons and are quite stable against electron detachment. The reliability of the calculated VDE for these molecular anion radicals was tested by comparison with the results of photo electron spectroscopy experiments, which were in good agreement. The calculated reaction barrier to produce U-5-yl[•] and R⁻ from (R-U)^{•-} for all the considered molecules lies in the range 2.5 kcal/mol to 41.2 kcal/mol (see Fig. 26). From the analyses of the AEAs, VDEs, and the reaction barriers, SCN-U and OCN-U were proposed to be the possible potent radiosensitizers. The calculated AEA, VDE, and barrier height for SCN-U are 2.70 eV, 3.07 eV, and 3.4 kcal/mol, respectively, and the corresponding values for OCN-U are 2.62 eV, 3.07 eV, and 2.5 kcal/mol, respectively. This study demonstrates that solvated electron after attachment to SCN-U and OCN-U is predicted to dissociate the C5-S and C5-O bonds of SCN-U and OCN-U to produce U-5-yl[•] involving a small barrier of ca. 3 kcal/mol (see Fig. 26). For 5-BrU, the AEA, VDE and the barrier for

Fig. 26 B3LYP-PCM/6-31++G(d,p) calculated free energy profiles in kcal/mol for electron-induced degradation of 5-substituted modified uracils (Reprinted with permission from Chomicz et al. (2013), *J. Phys. Chem. Lett.* © (2013), American Chemical Society)

C5–Br bond dissociation are 2.48 eV, 2.74 eV, and 2.5 kcal/mol, respectively (see Fig. 26). Further, the mass spectrum of SCN-U anion radical shows strong signal intensity originating from SCN⁻, which confirms the theoretical prediction. We also note that in this study authors investigated the dissociation of only the C5–R bond (see Fig. 25) and did not check the barrier for other possible bond fragmentation. For example, there are few reports (Hamed et al. 2006; Houmam et al. 2003a, b; Houmam 2008; Ciszek et al. 2004) in the literature that one electron reduction of thiocyanate (SCN)-substituted benzyl and aryl compounds leads to the dissociation of the S–CN bond, that is, R–SCN + e⁻ → RS[•] + CN⁻ (R = benzyl; aryl). The RS[•] further reacted to form R-S-S-R dimer. Thus, an experimental verification was needed to further characterize electron-induced bond cleavage site in SCN-U, and very recently, this process has been tested by Zdrowowicz et al. (2015) employing ESR and product analysis experiments along with theory. These workers found that both S–CN bond cleavage and C–SCN bond cleavage occurred in a 10 to 1 ratio favoring S–CN bond cleavage to form U–S[•] + CN⁻. The major radical produced U–S[•] was found to dimerized to the U-S-S-U product, which was identified by LC-MS.

Conclusion

Our understanding of the interaction of low-energy electrons with DNA has increased substantially over the past few years. From experiment, it is clear that single- and double-strand breaks, base damage, and base release are all direct results of DEA. For strand breaks, addition of an electron to the base and the sugar phosphate backbone can lead to strand breaks from shape and core-excited

resonances. From their higher energies and nature, core-excited resonances are those likely to be involved in double-strand breaks. Simple vibrational excitations have been shown to provide the necessary excitation when combined with an even 0 eV electron to result in strand cleavage. While much work presented in this chapter has focused on the DNA components without surroundings (“gas-phase” calculations), these calculations often give diffuse states (dipole-bound electrons and continuum states) as ground states for the system. Theoretical treatments of DNA systems, relevant to biology, must include the aqueous phase, including specific water hydrogen bonding, as well as the base stacking and counterion placement. In such systems, diffuse states are greatly destabilized and valence-bound states dominate. Theoretical methods such as DFT with various solvation models are now able to treat more complex and more biologically relevant systems. The reaction of excess electrons with DNA depends on its energy, phase, and state of solvation, that is, the LEEs in the gas phase (0 – 20 eV) and prehydrated electron (e^-_{pre}) (–0.5 to –1.0 eV) are expected to be more damaging and dissociate chemical bond, while fully solvated electron (e^-_{aq}) is considerably less damaging and is captured by DNA bases to form base anion radicals which subsequently are protonated from surrounding solvent.

A variety of compounds have been employed as radiosensitizers to treat cancer, and 5-Bromouracil has been of considerable interest in this regard. The radiosensitization activity of 5-bromouracil is due to its reaction with electron which rapidly produces bromide anion and U-5-yl^{*}. The highly reactive U-5-yl^{*} formed is believed to then abstract hydrogen from neighboring sugar moieties in DNA to create strand breaks. While this mechanism is quite likely, other mechanisms have been proposed and discussed in this review. Initiative has been taken to develop more efficient radiosensitizers employing accurate DFT methods. In the future, improved techniques should provide a better understanding of the actions of LEEs with the DNA in a biological environment.

Abstract

A comprehensive analysis of the benefits and pitfalls of quantum chemical methods used to determine the structures, properties, and functions of DNA and RNA fragments is presented. Main emphasis is given to the application of different ab initio quantum chemical methods. An overview of computations reveals that quantum chemical methods provide an important means to investigate structures and interactions in nucleic acids. However, judicious selection of

computational approach is necessary, depending upon the nature of the problem under investigation.

Introduction

Over the past several decades, investigations of the structure and property of nucleic acids have been an important subject of scientific research. Such investigations have been motivated by the fundamental roles played by ribonucleic acid (RNA) and deoxyribonucleic acid (DNA) in biology.

DNA has been considered to be the central biology molecule, being the depository of genetic information, where hereditary information (of higher-level life forms) is encoded in the form of specific sequences of hydrogen bonds formed between the purine (adenine and guanine) and complementary pyrimidine (thymine and cytosine) bases. Obviously, any permanent variation in the hydrogen bonding pattern may change the function and can even be lethal (especially when specific mutations accumulate). On the other hand all kinds of beneficial mutations, ranging from small-scale mutations (such as point mutations, insertions and deletions) to large-scale mutations (such as chromosomal translocations), are the driving force of evolution. This demands that the structural integrity of DNA be maintained for the identity of each and every organism. It is, however, notable that the biology of DNA does not depend only on the “digital” information of the base sequence. In reality, key aspects of DNA storage in the chromatin and all major aspects of DNA-based control of gene expression are regulated by the subtle sequence-dependent variability of conformational and physicochemical properties of DNA double helix, which is definitely everything else than just a regular double helix.

RNA was, until the 1980s, considered a boring and unimportant cousin of DNA. However, since earth-shaking discovery of RNA catalysis in 1982 (Guerrier-Takada et al. 1983; Kruger et al. 1982) (1989 Nobel Prize for chemistry, Cech and Altman), major RNA discoveries keep coming one after another. We now assume that the RNA molecule is likely the primary molecule of life, the first modern replicator, which in later stages of primary evolution created chemically more stable DNA for better coding and proteins for more diverse catalysis. Since the early stages of evolution, RNA has kept control over many key processes in cellular life while also acquiring new functions. Thus, in the last two decades in biology and biochemistry much of the research focus shifted from DNA to RNA (not reflected by adequate efforts in the field of computational chemistry), as exemplified, e.g., by the 2006 Nobel Prize in Physiology and Medicine awarded to Fire and Mello for their 1998 discovery of RNA interference (Fire et al. 1998) and 2009 Chemistry Nobel Prize to Ramakrishnan, Steitz, and Yonath for solving (in 2000) the atomic resolution structures of the most formidable molecular machine, the ribosome (Ban et al. 2000; Wimberly et al. 2000). A ribosome is a large RNA assembly that has been in the course of evolution supplemented by dozens of ribosomal proteins. It is now well established that while less than 2 % of the genomic DNA codes protein sequences, over 80 % of the genome is actually transcribed into RNA during the cellular life,

most of it (obviously besides genes coding, e.g., ribosomal and transfer RNAs) as noncoding RNA molecules of yet unknown function. In other words, what was not a long time ago considered as “junk” DNA with no obvious role has emerged as DNA template coding for critically important regulatory RNAs that probably affect every corner of gene expression and regulation. One example is the discovery of small RNA molecules (microRNA) that regulate gene expression at multiple levels. The structural versatility and complexity of RNA molecules is incomparably larger than the variability of DNA.

Although the research related to nucleic acids has grown manifold, giving rise to various distinct research fields, the age-old question as to the origin of life on earth remains to be answered. We do not know if it was a spontaneous process which, over the period of time, evolved into the current form on earth or it was endowed from outer space. In fact, we still do not know all the species present on our planet. The existence of different simple molecules, which can be precursors of genetic monomers, such as water, carbon mono- and dioxides, formaldehyde, nitrogen, hydrogen cyanide, hydrogen sulfide, and methane, have been shown in cometary comas (Mix 2006). The purine base adenine has been observed in asteroids and comets. The existence of significant amounts of HCN and HNC molecules in the interstellar space is well known (Ishii et al. 2006). Tennekes et al. (2006) have measured the distribution of these isomers (HCN and HNC) in the protostellar dust core. Smith et al. (2001) have discussed the formation of small HCN-oligomers in the interstellar clouds. It has been demonstrated experimentally that under certain conditions adenine can be formed from the pentamerization of HCN in the solid, liquid, and gas phases (Miller and Urey 1959; Ponnampertuma et al. 1963). Based on the appearance of the brown-orange color as the consequence of impacts of comet P/Shoemaker-Levy 9 on the planet in 1994, the presence of HCN polymers has been speculated on Jupiter (Matthews 1997). The coloration of the Saturn has also been speculated to be due to the presence of HCN polymer. To understand prebiotic adenine synthesis, Glaser et al. (2007) recently performed theoretical calculations on the pyrimidine ring formation of monocyclic HCN-pentamers and found that the key steps proceed without any catalysts producing the purine ring under photolytic conditions and no activation barrier was involved. Roy et al. (2007) proposed a step-by-step pathway for formation of adenine from 2,3-diaminomaleonitrile (DAMN) and 4-amino-5-cyanoimidazole (4-aminoimidazole-5-carbonitrile, AICN) under prebiotic conditions. Experiments for abiotic adenine and purine synthesis from formamide were also reported (Hudson et al. 2012), and a related self-catalyzed mechanisms for the reactions were investigated theoretically (Wang et al. 2013a–c). Based on GC-MS, high-resolution FTIR spectroscopic results and theoretical calculations, an interdisciplinary effort by Ferus et al. (2015) simulated the high-energy synthesis of nucleobases from formamide during the extraterrestrial impact body of the Late Heavy Bombardment (LHB) period. This demonstrated that nucleobases may be synthesized in an impact plasma through reactions of the dissociation products of formamide, without any catalyst.

It is a valid assumption to speculate that life on earth probably evolved under acute harsh environments including the presence of different kinds of irradiations.

Therefore, it is expected that several structural transformations/refinements with respect to genetic code preservation must have taken place. Survival of the fittest prevailed over the period of time in evolution, thereby bringing the purine and pyrimidine bases as the genetic molecules. Further, since these molecules absorb ultraviolet (UV) irradiation, some sort of mechanism was needed to avoid the excited state photo reactions. This was probably achieved through the ultrashort excited state lifetimes of nucleic acid bases (de La Harpe and Kohler 2011; Middleton et al. 2009; Serrano-Andres and Merchan 2009; Shukla and Leszczynski 2007, 2008). Recent state-of-the-art investigations have suggested that such ultrafast excitation processes are achieved through internal conversion where excited and ground state potential energy surfaces conically intersect (Barbatti et al. 2010; Bisgaard et al. 2009; de Vries and Hobza 2007; de La Harpe and Kohler 2011; Kohler 2010; Middleton et al. 2009; Serrano-Andres and Merchan 2009; Shukla and Leszczynski 2007, 2008; Yamazaki et al. 2008). And thus the absorbed energy is efficiently dissipated in the form of heat. Therefore, it is not unexpected that accurate structural determination of nucleic acids and their fragments have been one of the fundamental areas of research. Another obvious precondition that has to be fulfilled in the initial selection of a nucleobase is its inability to tautomerize in aqueous solution, as tautomers would bias any nucleobase-based genetic code as well as RNA folding; thus none of the native nucleobases tautomerize under biochemical conditions to any appreciable amount.

Computational quantum chemical techniques are fast becoming an attractive alternative to the expensive and time-consuming experimental methods in determining the structures and activities of molecular systems. Although we would like to state that modeling of the exact experimental environment, in particular the large biological systems *in vivo*, is not yet possible, computational methods can still provide reliable predictions and thus can be useful to experimentalists. Theoretical methods are especially attractive in the area where experimental measurements are still not possible, e.g., the determination of excited state geometries of complex molecular systems. For the smaller molecular species, one can routinely apply a high level of electron correlated methods and large basis sets; however, for larger molecular systems one has to make a compromise between the level of theory and the basis set and thus with computational accuracy. Experimental determination of excited state geometries of complex molecules like nucleic acid bases is still not possible; only some limited information such as possibility of excited state nonplanarity can be deduced. On the other hand, quantitative information about the excited state geometries can be obtained using the reliable theoretical level, although one has to make a compromise between the theoretical method and the size of the system under investigation. Further, while there was some indication about the amino group nonplanarity in nucleic acid bases in the crystal environment (McMullan et al. 1980), quantitative prediction about amino group nonplanarity was obtained through the quantum mechanical calculations about a decade ago (Leszczynski 1992). It should be noted that such nonplanarity in the gas phase of molecules using experiment was obtained by Dong and Miller in 2002 (Dong and Miller 2002). However, we believe that theoretical and experimental methods are

complementary to each other, and a judicious decision is needed for their efficient application. One of the classical examples would be the tautomerism in guanine.

It is well known that due to the lowest ionization energy among nucleic acid bases, guanine is the primary target for nucleic acid damage by ionizing irradiation (Crespo-Hernandez et al. 2004; Lin et al. 1980). Further, low-energy electrons can also cause the strand break (Boudaffa et al. 2000; Gu et al. 2006, 2007a, b, 2010a–d, 2011a, b; Kumar and Sevilla 2007; Cauet et al. 2014). A combination of molecular dynamics and density functional theory approaches was applied to simulate the reactions that can damage DNA by the attachment of a low energy electron to the nucleobase (McAllister et al. 2015). A low-energy electron interaction with the phosphate group in DNA molecule demonstrates a single-strand break pathways (Bhaskaran and Sarma 2015). DNA labeled with electrophilic nucleobases was reported to be damaged by ionizing or UV radiation (Rak et al. 2015). A recent experimental study on single-strand DNA oligonucleotide suggests that there is a linear correlation between the low-energy electron-induced DNA damage and the presence of the guanine molecules in the sequence (Solomon et al. 2009). Further, guanine can potentially form the most diverse set of energetically accessible rare tautomers in nonpolar environments. Initially, based upon the infrared (IR) spectroscopic analysis of guanine in the argon matrix the presence of equal proportions of keto and enol forms was suggested (Sheina et al. 1987). But, the canonical form of guanine dominates in the polar solvent (Leszczynski 2000). Theoretical methods have generally predicted that the keto-N7H tautomer of guanine is the most stable in the gas phase, but the keto-N9H tautomer dominated in the water solution. At the MP2 and CCSD(T) levels along with several large basis sets, the four low-energy tautomers of guanine (keto-N9H, keto-N7H and cis and trans forms of enol-N9H) have been shown to be within 1 kcal/mol of energy (Gorb et al. 2005). The assignments of resonance-enhanced multiphoton ionization spectra of laser-desorbed, jet-cooled guanine have suggested the presence of four tautomers of guanine (Mons et al. 2002; Nir et al. 2001). Based upon the comparison of IR spectra of thermally vaporized guanine trapped in helium droplets with that of computed vibrational frequencies at the MP2 level with the 6-311++G(d,p) and aug-cc-pVDZ basis sets, Choi and Miller (2006) have assigned the presence of keto-N9H, keto-N7H, and cis and trans forms of enol-N9H tautomer of guanine. The results of guanine in helium droplets necessitated the reassignment of earlier R2PI data and accordingly, based upon the comparison of experimental and theoretical results, Mons et al. (2006) found the presence of enol-N9H-trans, enol-N7H, and two rotamers of the keto-N7H-imino tautomers of guanine in the supersonic jet-beam. Thus, in the new assigned R2PI spectra the stable keto-N9H and keto-N7H tautomers of guanine are not present. The high-level of theoretical calculations (Chen and Li 2006; Marian 2007) on guanine tautomers also supported the reassignment of the R2PI spectra of guanine tautomers in the supersonic jet-cooled beam and suggested the presence of efficient nonradiative deactivation channels as the reason for the missing of spectral origins of the stable tautomers in the R2PI experiments. Recently, Zhou et al. (2009) have performed a comprehensive investigation of guanine tautomers using the VUV photoionization technique, where

the gas phase of guanine was obtained at both the thermal vaporization and laser desorption methods. It was revealed that the method used to generate the gas phase sample of guanine has significant influence on the population of tautomers in the experiment. Consequently, it was found that in the thermal vaporization, a maximum of five most stable tautomers are populated and these results are in agreement with that obtained in the helium droplet experiment. On the other hand, when the laser desorption technique was used to make a gas phase sample of guanine, up to seven tautomers are populated. As noted above, however, guanine for obvious reasons does not tautomerize in biochemically relevant environments, as convincingly shown more than a decade ago also by advanced computational methods (Colominas et al. 1996). Eventual computations suggesting formation of tautomers of natural bases in water are to be dismissed and are at odds with all other experimental data.

Another unique feature of QM methods is their capability to reveal relation between molecular structures and molecular energies at the level of direct (contact, gas phase, electronic structures) interactions. This concerns mainly the two fundamental interactions, base stacking and base pairing. Stacking interactions play an important role in the biological structure, providing both thermodynamics stability and structuring of nucleic acids. For example, base stacking is assumed to be the primary determinant of sequence dependence of B-DNA structure and flexibility, which is the single most important feature of DNA that enters all of DNAs molecular interactions, genetic material storage, replication, and gene expression. The sequence dependence of DNA (and the role of base stacking) has been intensely studied. Despite this, all the experimental and theoretical research failed to provide clear rules allowing to predict the fine B-DNA structural variability from sequence (Calladine 1982; Dickerson and Drew 1981; Šponer and Kypr 1991; Suzuki et al. 1997; Wing et al. 1980; Yanagi et al. 1991). The research in this area has been stalled for some time and perhaps improved description of stacking with the help of modern QM methods could bring some new ideas.

Base pairing (extended beyond the base-base interactions) is especially interesting in large functional RNAs, where it determines their architectures and gives very strict constraints on RNA evolutionary patterns (Leontis et al. 2002; Šponer et al. 2010; Stombaugh et al. 2009; Zirbel et al. 2009). Large RNA molecules are organized as complex (and often very dynamical) jigsaw puzzles, where the exact shapes of the base pairs determine function and thus also allowable mutations (isostericity principle). Nevertheless, recent studies also indicate a nonnegligible role of energy of molecular interactions supplementing the basic isostericity principle (Zirbel et al. 2009).

Although stacking interactions are important and high-level *ab initio* methods are needed to account for such interactions, it is only possible to use these methods to model systems and very small fragments of large biomolecules, even using the large computational resources. Therefore, especially force field methods (and QM/MM method to certain extent) are mainly used to study larger biopolymers and other large biological systems. Nevertheless, QM calculations remain instrumental in reference studies on the nature and magnitude of molecular interactions in nucleic

acids and in verification of the other methods. Quantum chemical calculations provided the ultimate answer about the physicochemical nature of base stacking and characterized many other features of nucleobase interactions (Hobza and Sponer 1999; Morgado et al. 2009; Svozil et al. 2010).

Hydrogen Bonding and Stacking Interactions in Nucleic Acids

The most fundamental roles of nucleic acid bases (nucleobases) in biology and chemistry are their involvement in two qualitatively different mutual interactions: hydrogen bonding (base pairing) and aromatic base stacking.

The base pairing is utilizing the H-bond donor and acceptor capabilities of nucleobase exocyclic groups and ring nitrogen atoms. In RNA molecules, the base pairing also involves the sugar ribose which, in contrast to DNA deoxyribose, possesses hydroxyl group in the 2' position (Leontis et al. 2002; Sponer et al. 2005a, 2007, 2009, 2010; Stombaugh et al. 2009). The 2' -hydroxyl group is a powerful donor and acceptor of hydrogen bonds. In fact, key RNA base pair families utilize the 2' -OH group for base pairing, and these extended base pairs are known as sugar-edge (SE) base pairs or interactions. Many important "SE" base pairs include no direct base to base H-bonds, and yet they are crucially important for folding of complex functional noncoding RNA molecules and ribonucleoprotein particles. By noncoding RNAs we mean RNA molecules that are not translated to proteins via messenger RNA and perform different functions instead. Note that recent research highlighted that while less than 2 % of the human genome directly codes for proteins, at least 80 % of the genomic DNA is actually transcribed into RNA. Thus, majority of the genome encodes noncoding RNAs that play absolutely essential roles in life and evolution (many of the RNA functions have yet to be discovered, but they are assumed to be key players in fine regulation of gene expression), which is a finding that has truly revolutionized biology in recent years. The largest noncoding RNAs are, obviously, ribosomal RNAs. The most important RNA tertiary interactions (A-minor and P-interactions) are base pairs, triads, and quartets mediated by base-sugar and sugar-sugar interactions (Sponer et al. 2007). Recently, the RNA base pairing classification was extended to include base-phosphate (BPh) interactions, after recognizing that $\sim 12\%$ of nucleotides in ribosome are involved with BPh interactions with other proximal or distal nucleotides while these interactions bring important evolutionary constraints (Zirbel et al. 2009).

Base stacking occurs between the aromatic faces of the nucleic acid bases and is at least equally as important as base pairing, for both thermodynamics stabilization and shaping of nucleic acids. Stacking is responsible for the local conformational variations and other sequence-dependent properties of B-DNA. With the help of eight micro-solvation water molecules, the dinucleoside phosphate deoxyguanylyl-3',5'-deoxycytidine dimer octahydrate, [dGpdC]₂ illustrative minimal unit of the DNA double helix has been constructed and its geometry fully optimized (B3LYP/6-31 + G(d,p) level) (Gu et al. 2011a). Similarly, four water molecules microhydrated

dApdT, dTpdA, dGpdC, and dCpdG species have been predicted to have reasonable stacking structure using both B3LYP and M05-2x functionals (Gu et al. 2009, 2010c). The Minnesota density functionals, M05-2X and M06-2X, level calculations were carried out to evaluate the stacking and H-bonding patterns for the structures of the nucleotide oligomers (dGpdC, dGpdG, and dGpdCpdG) for single-strand DNA. This level of calculations shows excellent agreement with the results from the MP2 theory (Gu et al. 2011a, 2012a, b). Unambiguous classification of base stacking is missing. One of the reasons is flexibility of base stacking, as the stacked bases can always slide and twist over a range of mutual stacked geometries, being not fixed by the individual H-bonds (note, however, that many complex RNA base pairs also possesses complex conformational space with multiple competing conformations). While classification of base pairing could have been done purely by considering structural data (i.e., geometries seen in X-ray structures), classification of base stacking will likely require appropriate energy analyses.

The *ab initio* QM technique can be used to determine optimal structures of molecular clusters and to calculate energies for any single geometry of the cluster. QM calculations provide molecular wave functions, which can be used to derive physicochemical properties, such as vibrational spectra, dipole and higher multipole moments, polarizabilities, proton affinities, NMR parameters, and others. Nevertheless, the main achievement of QM calculations was the description of the nature and energetics of nucleobase interactions. This is because the leading experimental approaches of structural biology, that is, mainly X-ray crystallography, provide purely structural data. Information about energetics of molecular interactions can be inferred only indirectly, while the interpretation of structural data ignoring energetics of molecular interactions is often misleading.

QM calculations can help to understand the role of molecular interactions in nucleic acids because of their capability to give a direct link between structures and energies. Nevertheless, QM calculations are always done on small systems and typically in the gas phase that is far from real environments and structural contexts. To make meaningful QM computations with biological relevance, we need to follow several rules (Svozil et al. 2010).

First, we need to make the strategic decision whether our computations aim to be indirectly or directly relevant to biology. By indirect relevance we mean, for example, the use of QM calculations for parameterization or validation of other methods (mainly the molecular mechanical force fields) or for basic understanding of the physical chemistry of interactions. By direct relevance we mean applications that range from calculations of some specific interaction patterns seen in structural studies (Sponer et al. 2003) through combined QM-bioinformatics studies aimed at classifying interactions (Sponer et al. 2003; Zirbel et al. 2009) up to QM/MM calculations of RNA catalysis (Banáš et al. 2009). Then, there are at least three tactical issues that need to be very carefully decided. We need to select the level of calculations, i.e., primarily the method and basis set. Equally important is the appropriate choice or preparation of geometries used in computations. Inappropriate geometries may easily blow up the whole effort and result in computations that are misleading (Svozil et al. 2010). Finally, the results should be properly interpreted. We also need to separately consider applications that deal with nucleic acid bases

but are directed to other areas of science (basic physicochemical experiments, origin of life studies, adsorption on surfaces, supramolecular assemblies, etc.)

Level of Computations

Let us assume that we have a dimer of two nucleic acid bases, A and B , with a given geometry. For that geometry, the interaction energy between A and B , $\Delta E^{A \cdots B}$, is the energy difference between the total electronic energy of the dimer $E^{A \cdots B}$ and the electronic energies E^A and E^B of isolated bases.

$$\Delta E^{AB} = E^{AB} - E^A - E^B \quad (1)$$

The interaction energy reflects a hypothetical dimerization process at 0 K and is not measurable. In order to be related to experimental dissociation energies D_0 and enthalpies of formation, the deformation energy of monomers and the zero-point vibration energy must be included. The zero-point energies and enthalpy and entropy contributions at nonzero temperature are usually calculated in the harmonic approximation. Since base pair complexes are weak, anharmonicity can play an important role, especially for stacked systems and particularly at higher temperatures. Nevertheless, except for direct comparison with gas phase experiment, interaction energy evaluation is the sufficient outcome of QM analysis.

Methods suitable for base stacking and base pairing calculations have been discussed many times (Morgado et al. 2009; Spomer et al. 2008; Gu et al. 2008; Svozil et al. 2010) and will thus be only briefly noted here. With modern computers, we have methods that are satisfactorily accurate.

Base stacking stabilization is dominated by the intermolecular electron correlation effects (i.e., the dispersion energy). Therefore, stacking calculations must be done with inclusion of electron correlation effects and with large basis sets of atomic orbitals. The dispersion energy is created in the space between the interacting monomers that are separated by $\sim 3.3\text{--}3.4$ Å. This space needs to be covered by atomic orbitals, dictating the use of diffuse-polarized basis sets. H-bonded complexes are not dominated by the dispersion energy, albeit it is still a very significant contribution. Thus, HF calculations or computations with “dispersion-neglecting” DFT methods, while not being accurate, are not entirely incorrect. When including electron correlation, higher angular momentum functions are important for base pairing, since the space between the interacting monomers is bridged by H-atoms so the requirement for the diffusivity of atomic orbitals is not as strict as for stacking.

The best accuracy is achieved by complete basis set (CBS) extrapolation methods, when two systematically improved basis sets are applied and the data is then extrapolated. The interaction energy computations, even with large basis sets, need to be corrected for basis set superposition error (BSSE). We oppose suggestions to ignore the BSSE correction or to attempt only its partial inclusion while assuming that the numbers can be correct due to error cancellation. This is a risky game. It is much better to provide BSSE-corrected numbers where a solid

estimate of the underestimation of the interaction is typically possible. Fortunately, the CBS calculations are intrinsically BSSE-free. Similarly, computations with modern parameterized DFT-D methods (see below) do not require BSSE correction, since it is indirectly (effectively) included via parameterization.

H-bonded complexes are rather well described by the MP2 method while for aromatic stacking this method typically significantly overshoots the stabilization. Thus, for stacking higher-order electron correlations are quite important.

Gold Standard

Within the variation (supramolecular) approach, definitely the method of choice for interaction energies would be the coupled cluster CCSD(T) method (in which the single and double excitations are evaluated iteratively while the triple excitations are included in a noniterative way). The CCSD(T) method yields a significant portion of the correlation energy. The MP2 method, including the double electron excitations at the second order of perturbation theory, overestimates the correlation interaction energy for stacking, as noted above.

The determination of a CBS limit of CCSD(T) calculations is still difficult. Until recently, the CCSD(T) calculations for larger complexes were performed only with medium basis sets (e.g., 6-31G*) and even these calculations were at the computer limits. Thus, the gold standard in base stacking and pairing calculations is the method sometimes abbreviated as CBS(T), which utilizes the similar basis set dependence of the CCSD(T) and MP2 energies. Thus, the difference between CCSD(T) and MP2 interaction energies ($\Delta E^{\text{CCSD(T)}} - \Delta E^{\text{MP2}}$) exhibits small basis set dependence, and the CCSD(T)/CBS interaction energy can be approximated as

$$\Delta E_{\text{CBS}}^{\text{CCSD(T)}} = \Delta E_{\text{CBS}}^{\text{MP2}} + \left(\Delta E^{\text{CCSD(T)}} - \Delta E^{\text{MP2}} \right) \Big|_{\text{medium basis set}},$$

which is abbreviated as CBS(T) to distinguish from full CCSD(T)/CBS computation (Sponer et al. 2006, 2008). Various extrapolation schemes have been suggested for the determination of the $\Delta E_{\text{CBS}}^{\text{MP2}}$ term; the one proposed by Halkier et al. (1999) is the most widely used.

For aromatic stacking interactions the Δ CCSD(T) correction term is systematically nonnegligible (repulsive) and should never be omitted. For H-bonding interactions, the Δ CCSD(T) correction term is typically very small (Sponer et al. 2004, 2006, 2008).

Other Approaches

Earlier calculations on base stacking were done with the MP2 method utilizing the modified 6-31G*(0.25) basis set (Hobza and Sponer 1999; Sponer et al. 1996b, 1997). The polarization d-functions of the standard 6-31G* basis with an exponent

of 0.8 were replaced by more diffuse ones with an exponent of 0.25, allowing inclusion of a major part of the dispersion energy. While the MP2/6-31G * (0.25) method is now outdated, the main conclusions reached by the MP2/6-31G * (0.25) studies remain valid.

DFT methods were for years not recommended for stacking calculations, because common DFT methods (based on the local density, its gradient, and the local kinetic-energy density) notoriously fail to capture the (nonlocal) dispersion energy (Hobza et al. 1995; Kristyán and Pulay 1994).

This is a common feature of all LDA and GGA functionals, not excluding even the most advanced meta-GGA functionals. Many recent DFT methods provide much better results for dispersion-controlled complexes (Zhao and Truhlar 2008).

Nevertheless, we still suggest use of caution (and testing) in their application to stacking complexes. An alternative (which can achieve, at least for now, better accuracy and major speed up) is based on augmenting the DFT energy by an empirical London dispersion energy term (Elstner et al. 2001; Grimme 2004; Jurecka et al. 2007).

To correct for the overlap effects, the dispersion energy is damped by distance-dependent damping function. The dispersion energy, represented by the C_6/R^6 formula, is calculated separately from the DFT calculation and is simply added to the DFT energy. The disadvantage of DFT-D methods is obviously the need to combine electronic structure calculations with classical “force field” correction term, which also affects the transferability of these methods. Thus these methods are expected to be surpassed in the future by “true” DFT-based dispersion-including methods; however, for the moment it seems to us that DFT-D is more satisfactory for routine calculations of nucleobase interactions. One present difficulty is that we have so many new methods in the literature that is difficult to choose. This issue is beyond the scope of this chapter and we refer the reader to specialized literature (Banaš et al. 2009; Spöner et al. 2008). We hope that standard (optimal) wide-spectrum dispersion-including DFT methods will soon be identified.

Interaction energies can also be obtained by perturbation methods, as a sum of perturbation contributions. The symmetry adapted perturbation theory (SAPT) provides the interaction energy as a sum of first-, second-, and higher-order perturbation terms (Heßelmann et al. 2005; Jeziorski et al. 1994). The first-order contribution contains the electrostatic and exchange energies, while the second-order term includes induction and dispersion energies. The charge transfer energy is included in the second-order induction energy and higher-order contributions. SAPT (with extended basis sets) yields accurate values of the energy components and also of the total interaction energies. The determination of the interaction energy is straightforward and is not biased by additional theoretical problems, such as the BSSE inherent to variational methods. The broad use of SAPT is, however, hampered by large computer requirements. A significant improvement was reached by the combination of SAPT and DFT theories (Jeziorski et al. 1994). The DFT-SAPT approach has been rather routinely used for base-base calculations. When making SAPT decompositions, it is extremely important to use well-defined geometries, as the SAPT components are exceptionally sensitive to inter-monomer

separation, much more than the total interaction energies. SAPT decompositions can be spoiled by inappropriate choice of geometries (Sponer et al. 2008). Note also that from the biological point of view, what primarily matters are the interaction energies. Thus the usefulness of decompositions should not be overinterpreted (Sponer et al. 2008).

Geometries

Quantum-chemical calculations can provide meaningful data only when the energies are derived at appropriate geometries.

The easiest systems to deal with are well-behaved base pairs where gradient optimization leads to relevant structures. Modern QM programs allow easy gradient optimizations of base pairs, where all coordinates (or parameters) are optimized. Standard optimizations are not corrected for BSSE. Some earlier studies where base pairs were optimized in a step-by-step manner are of historical interest only. Since the optimization itself is more computer-demanding than the subsequent interaction energy evaluation, very often a better level of theory (level X) is used for interaction energy calculation than for optimization (level Y). This is abbreviated as X/Y. For example, the abbreviation MP2/aug-cc-pVTZ/MP2/cc-pVDZ indicates that the optimized structure was obtained at the MP2/cc-pVDZ level, while the energies were derived for this optimized geometry at the MP2/aug-cc-pVTZ level.

The gradient optimization is good for systems with well-defined local minima, while the minima correspond to the biochemically relevant structures. Stacking patterns seen in nucleic acids do not correspond to minima on the potential energy surfaces of isolated stacked dimers and thus conformational scanning is preferred. Further, gradient optimizations of dispersion-controlled clusters are affected by enormous BSSE, unless a very large basis sets are used. With lower quality methods the structures are unstable and convert to H-bonded ones. In addition, gradient optimizations of stacked dimers lead to puckering of the aromatic ring (Hobza and Sponer 1998). This is usually not desirable since in real environments the nucleobases have some interactions at both their sides, probably preventing such puckering. Thus, stacking calculations are mostly carried out as a series of single points with fixed geometries and rigid monomers (Sponer et al. 1996b, 1997).

An attractive option is to take structures from experimental (X-ray) studies (Sponer et al. 1997). However, usual accuracy of these experiments does not guarantee their straightforward utilization in QM energy computations. First, it is not advisable to directly use monomer geometries from PDB files of NA X-ray structures. Due to limited resolution the monomer geometries carry limited experimental information about monomer geometries, while the bases are often deformed after the refinement. Such deformed monomer geometries frustrate the electronic structure. It is necessary to replace (for example via overlay) the monomers from the PDB files via QM-optimized monomers.

In addition, intermolecular X-ray geometries may cause substantial errors in calculations. Especially drastic distortions of the calculated energies can be introduced

by steric clashes in the refined crystal structures (Sponer and Kypr 1993). A real nightmare occurs when the X-ray base stacks are effectively vertically compressed or extended due to inaccurate determination of the interbase angles (propeller twist, base pair roll, etc). This requires a case-by-case judgment and some experience with crystallography. Note that a rather small error in the interbase distances (which may still be tolerable from the geometry point of view) can lead to a considerable energy artifact. This is when the geometry falls into a region of interatomic distances where the short-range repulsion starts to dominate. The calculated energy is a highly nonlinear function of the interatomic distance (Sponer et al. 2008).

Similarly, H-bonded base pairs are sensitive to experimental geometry errors due to the genuine close contact between H-bond partners. Besides data and refinement errors a bad geometry can result from the presence of two or more local substates. Substates cannot be distinguished except as having nominal resolution better than $\sim 1 \text{ \AA}$. The refined geometry reflects an averaged geometry which may have very poor energy. Fiber diffraction models cannot be recommended for direct calculations (Svozil et al. 2010).

We would like to caution against using averaged (3D-bioinformatics) geometries, as they can represent unrealistic single structures from the energy point of view. It is always advisable to generate a range of structures around such geometries and to analyze the properties of the potential energy surfaces. Actually, an open question remains whether the base stacking can be characterized by some single representative geometry. Most likely stacking states correspond to a range of populated geometries, as evidenced, for example, by significant coordinate fluctuations seen for stacked bases in explicit solvent molecular dynamics simulations (Svozil et al. 2010).

We are interested in analyses of specific interactions which are neither stacking nor H-bonding and are substantially affected by the overall topology of the studied systems. The best approach is to fix the intermolecular geometry of interest (typically using a set of three dihedrals and two valence angles plus one intermonomer distance per each dimer) and then relax the monomers intramolecularly (Sponer and Hobza 1994; Sponer et al. 2003; Vlieghe et al. 1999). This approach has been applied in studies of cross-strand close amino group contacts in B-DNA, DNA-drug interactions, bifurcated H-bonds, out-of-plane H-bonds, and some other interactions. If a steric clash is suspected, then the intermonomer distance can again be varied (Sponer and Hobza 1994; Sponer et al. 2003; Vlieghe et al. 1999).

A specific problem is represented by the complex RNA base pairing patterns involving the sugar edges (Sponer et al. 2005a, b, 2007). Many of these base pairs have multiple minima. For many of them, the functional (observed) structures do not correspond to any intrinsic gas phase minimum energy structures, since they are constrained by other interactions and the overall RNA topology. Some base pairs can be intrinsically water-mediated. Huge problems in computations can be created by the sugar hydroxyl group in position 3', which normally is involved in the covalent backbone chain. One option is 3'-methylation. In some cases, the phosphate groups participate in the interactions and need to be included in computations. This creates problems due to a strong ionic nature of the associated interactions which are, in

real systems, obviously attenuated by solvent screening. Close to insurmountable electrostatic problems arise when more than one phosphate directly participates in the interaction. Thus, QM studies of RNA base pairs often require applications of sophisticated geometrical constraints which need to be implemented case by case. For nonneutral systems, even optimizations upon inclusion of continuum solvent could be a viable option. The situation is further complicated by very limited resolution of the experimental structures of folded RNAs (not mentioning ribosome) and their dynamical nature. This can lead to large coordinate errors (including poorly refined *syn* vs. *anti* orientation of the bases or incorrect sugar puckers). Thus, studies of RNA base pairs are far from routine. Studies of geometries that are substantially rearranged compared to the experimental structures are of a little value, similar to studies neglecting the sugar rings for base pairs where the 2'-OH groups are directly involved in base pairing.

When gradient optimization is carried out, the monomer geometries are changed upon complexation. This is due to mutual adaptations of the monomers that improve the intermolecular interaction at the expense of the intramolecular energy terms. Some of the deformations can be directly related to the binding strength. However, for larger systems, some monomer rearrangements reflect rather long-range effects. For example, there could be a substantial reorientation of the flexible sugar-phosphate backbone upon complex formation. Thus, real deformations consist of two contributions. Direct deformations (always present) reflect the strength of the binding and may be complemented by various indirect larger-scale conformational rearrangements. Besides real deformations, the BSSE contributes to the deformation when standard gradient optimization is applied. The BSSE contribution is obviously a computational artifact.

As explained above, the interaction energies of the optimized complexes should be a posteriori corrected for the BSSE using the geometry of the complex and dimer-centered basis set. Then we separately calculate the deformation energy using the monomer basis sets, as difference of monomer energies in the deformed (complex) and optimized (isolated) monomer geometries.

$$E_{\text{Def}}^A = E^{A(\text{dimer geometry})} - E^{A(\text{monomer geometry})}$$

Thus, the interaction energy of a dimer is defined in the following way:

$$\Delta E^{A\dots B} = E^{A\dots B} - (E^A + E^B) + E_{\text{Def}}^A + E_{\text{Def}}^B.$$

The first three energies are calculated in a dimer-centered basis set. The intramolecular deformation energy actually cancels a large part of the intermolecular energy improvement caused by mutual monomer adaptations.

In some of the literature, the authors include deformation energy formally as part of the BSSE correction. We consider this a weird option which may substantially spoil the interpretation of the results. Although it might look more sophisticated mathematically, this approach is misleading, mixing apples and oranges, and is especially unsuitable for larger systems such as base pairs and other fragments

of biopolymers (Sponer et al. 2004). In fact, the integrated expression is, after formal rearrangements, *entirely identical* to the above definition, which in addition is older (Sponer et al. 1996a), i.e., the correction was commonly known before researchers started to include deformations into BSSE correction. Second, while BSSE is a mathematical artifact, monomer deformations are not. They correspond to fundamental properties of the studied clusters including their vibrational spectra and polarization/charge transfer effects. Thus, it is useful to evaluate the magnitude of the monomer deformations explicitly. For flexible systems with large indirect rearrangements (as explained above) any formal inclusion of the deformation term into the BSSE correction is meaningless. Thus, albeit widespread, for base pairs and larger systems of chemical and biological interest, this approach is not appropriate (Szalewicz and Jeziorski 1998).

An alternative approach is to use counterpoise-corrected gradient optimization where the BSSE is removed in each gradient iteration, although with a substantial increase of the computer requirements. It eliminates the BSSE part of the deformation energies while true deformations persist.

In base pairing studies the deformation energy can be calculated either with respect to the planar monomers, thus neglecting the amino group nonplanarity, or with respect to nonplanar bases. These two numbers differ simply by the difference between energies of planar and nonplanar monomers and can be easily compared when needed (Sponer et al. 2004).

Interpreting the Computations

QM calculations (on nucleobase dimers) reveal the binding energy between two bases in the gas phase, i.e., in *complete isolation*. They thus describe the *intrinsic* interactions of the systems with no perturbation by external effects such as solvent. The intrinsic intermolecular stabilities are directly linked to molecular structures and can be derived in any selected geometry. However, the gas phase interaction energies do *not* correspond to the stability of the interactions in nucleic acids, as measured by thermodynamics experiments. It is not possible to easily correlate the QM calculations with measured base pairing and stacking stabilities in nucleic acids. The apparent (measured) strength of the base-base interactions in nucleic acids in various experiments is determined by a complex interplay of many factors and the intrinsic base-base term is only one of them. Many researchers incorrectly believe that the experiments reflect the “true” stabilities of base-base interactions and vice versa.

A textbook example of complexity of molecular interactions is stacking of consecutive protonated cytosines. This is a highly repulsive interaction in the gas phase due to a charge-charge repulsion (Sponer et al. 1996c). Nevertheless, in intercalated i-DNA quadruplex, stacking of a set of consecutive closely spaced protonated cytosines occurs (Gehring et al. 1993). The i-DNA tetraplex is paired via cytosine – protonated (N3) cytosine base pairs, each possessing charge +1. Both cytosines are equivalent in X-ray and NMR experiments suggesting rather fast intra-base pair proton switches (Chen et al. 1994). Two duplexes intercalate to form

the tetraplex. Stability of i-motif is due to this massive accumulation of closely spaced protonated base pairs. In i-DNA, the vertical repulsion between consecutive protonated base pairs is counterbalanced by solvent screening effects and possibly specific interactions with the anionic backbone (Spackova et al. 1998). Thus i-DNA indeed has, in contrast to other DNAs, *repulsive intrinsic stacking energy terms*. This example clearly demonstrates the actual magnitude of mutual compensation of molecular interactions in nucleic acids. The i-DNA stability contradicts the gas phase stacking energy calculations and demonstrates why we cannot use these calculations to directly predict DNA stability. However, the relation can be also reversed. It is not possible to unambiguously evaluate the *intrinsic* stacking energetics based on thermodynamics studies of nucleic acids. There is no unambiguous way to decompose the measured free energies into separate terms that would correspond to stacking, base pairing, etc. In other words, we cannot make straightforward extrapolation from gas phase to nucleic acids, while, conversely, studies of nucleic acids bring no unambiguous information about the intrinsic base-base terms.

To show the full complexity of molecular interactions, let us underline that the screening is specific for i-DNA. Strikingly contrasting i-DNA is the behavior of consecutive protonated cytosines in C + -G.C triples of Pyr-Pur.Pyr triplexes. Consecutive protonated cytosines would be needed to recognize consecutive guanines in the second strand (Soliva et al. 1998). The vertical position of protonated cytosines in triplex would adopt arrangement closely resembling i-DNA, and also planar H-bonding of the third-strand protonated cytosines to N7 of second-strand guanines resembles the i-DNA base pairing. However, this sharply destabilizes the DNA triplex, and even two or three consecutive CH^+ are not tolerated. This indicates that in triplex the screening of the vertical electrostatic repulsion by the backbone and solvent is less efficient than in i-DNA. Thus in this particular case of i-DNA and triplexes we cannot transfer experience concerning nucleobase interactions between two DNA forms. Each case should be studied separately. In other words, a given type of base pairing and base stacking may have entirely opposite roles in different nucleic acid forms. A given interaction may be a crucial stabilizing factor for one type of nucleic acid architecture (protonation of consecutive cytosines in the i-motif), while it may be even not tolerated in another architecture. This illustrates that there is no way to design some ultimate experiments to decide about the *common nature* of base stacking in nucleic acids. This simply is a wrong question. In order to understand the interactions in nucleic acids, we need to consider a wide range of systems, and the gas phase data represent an important part of the overall picture.

It is nevertheless clear that proper inclusion of solvent screening could help in interpretation of the QM data. Unfortunately, accurate inclusion of solvent effects into QM calculations is difficult. One option is to extend the studied system by a finite set of explicit water molecules. Such calculations still deal with a gas phase molecular cluster and do not correspond to bulk hydration. The cluster hydration patterns differ from those in water where the first shell waters interact with the second shell, etc., and the whole system is dynamical, as evidenced by large-scale explicit solvent simulations of nucleic acids. In a small cluster, individual

water molecules will form bridges and zippers between bases in order to maximize the number of H-bonds. The hydration picture in solution (MD data) and X-ray structures is different and reveals simple noncooperative in-plane hydration of the polar nucleobase sites (the nitrogens and oxygens). Water binding sites in common hydration sites around nucleic acids have water binding times ~ 50 – 500 ps. In complex RNA molecules or in molecular complexes, some hydration sites may be occupied by tightly bound water molecules (Rěblová et al. 2003). A substantial problem of cluster calculations is that the potential energy surface contains a large number of minima and, without an efficient sampling technique, it is virtually impossible to verify the true global minimum (Kabelác and Hobza 2001).

The other option is to include the solvent as a polarizable continuum. QM methods consider effects of the continuum on the electronic structure of the solute molecules, in contrast to classical continuum approaches. The outcomes are quite sensitive to the choice of parameters such as the atomic radii used to define the “solute” cavity; no universal accurate set of “true” radii can be established. The continuum calculations may be combined with cluster calculations, where the first hydration shell is treated explicitly. Even if QM continuum solvent calculation is properly performed, such calculations are not sufficient to achieve a direct correspondence with thermodynamics experiments. In practice we are neglecting, for example, the loss of degrees of freedom upon duplex formation, all effects associated with the presence of sugar-phosphate backbone including the only partial exposure of the bases to the solvent, etc. In addition, different base sequences are likely associated with different solute flexibilities (some base pair step sequences are stiff, others flexible) which will contribute to the free energy balance via solute entropy contributions. Reliable evaluation of these contributions is outside the applicability of available computational methods. Thus, the continuum solvent calculations should be considered just as rough estimates of the attenuation of the electrostatic contributions to the free energy upon solvation, which are still far from fully competent free energy computations.

All of the abovementioned considerations explain why the QM calculations on base stacking and base pairing do not (and should not) correlate with the measured thermodynamics properties of nucleic acids. Therefore, QM calculations and intrinsic interaction energies should never be interpreted as straightforward determinants of nucleic acid stabilities. This naive overinterpretation of otherwise very valuable computed data can discredit the computations. There is a plenty of evidence suggesting that the role of molecular interactions in thermodynamics stabilization of even the simplest duplex nucleic acids is more complex than usually assumed, and results from tiny, irregular, and case-specific interplays of all molecular forces, where literally a single specific hydration site or pocket can change the balance. Even simple base modifications and substitutions, as small as deletions of a single exocyclic group, may have complex and, at first sight, mutually contradicting context-dependent impacts on the measured thermodynamics stabilities that cannot be a priori predicted (Chen and Turner 2006; Siegfried et al. 2007).

We nevertheless suggest that this enormous complexity of molecular interactions defines new roles for modern computations, combing well-calibrated simulation

approaches and accurate QM calculations. The calculations can provide key insights into the tricky games of molecular interactions that are shaping up the molecules with their associated free energies and that are not fully understandable based on purely experimental approaches (Kopitz et al. 2008; Yildirim and Turner 2005; Yildirim et al. 2009).

Conclusion

QM calculations represent the leading tool to study intrinsic molecular interactions in nucleic acids, such as base stacking and base pairing. However, the QM data should not be overinterpreted, and any extrapolation to nucleic acids requires proper consideration of the gas phase nature of QM calculations. In addition, in order to obtain meaningful QM data, basic methodological requirements must be fulfilled. These include, in addition to the obvious selection of appropriate level of calculations, very careful selection or determination of geometries, which is discussed in detail in this chapter.

Abstract

This chapter concerns some of the computational studies devoted to interactions of metal cations with nucleobases, nucleotides, and short oligonucleotides considered as DNA/RNA models. Our topic is fairly complex, therefore the results obtained using mainly *ab initio* and DFT methods are discussed. The first part focuses on the interactions of isolated bases with metal cations either in bare, hydrated, or ligated forms. We begin with interactions of naked cations with nucleobases in gas phase. Subsequently, solvation effects using polarizable continuum models are analyzed together with a comparison to explicitly hydrated

ions. In the second part, adducts of various metals with base pairs and oligomeric models of DNA/RNA are discussed. Separate sections are devoted to complexes of promising anticancer drugs. Stacked bases and larger systems (quadruplexes) studied by semiempirical and QM/MM methods are mentioned in the last part.

Introduction

This chapter provides a brief overview of recent model calculations and simulations of metal-cation interactions with nucleic acid (NA) bases, base pairs, and short oligomeric models. From historical reasons, alkali metals and metals of alkaline earth are discussed first. All possible forms of metal cations are considered, starting with bare ions, which were mostly studied in older papers. Later, complexes with their first solvation shell or in ligated form are reviewed. Despite the simplicity and the fact that bare cations overestimate the bonding energies because of exaggerated contribution of Coulomb interaction, these models enable a clear insight into the basic bonding characteristics and other electronic properties. Many studies are focused on transition metal complexes, motivated by anticancer activity of cisplatin and other possible metallodrugs. While the electrostatic contribution dominates in the interaction of alkali metals, the coordination covalent term is important in the complexes of transition metals.

In general, the structure and function of DNA are modified by metal ions. These ions can interact with many sites in DNA (Saenger 1983; Sigel 1993), including the phosphate groups, the sugar moiety, and the NA bases. Although the metal cations usually interact with the phosphate group and, to a lesser extent, with bases, cation-base interactions are involved in many important biophysical processes, such as different stabilization of DNA triple helices (Potaman and Soyfer 1994), stabilization of quadruple helices (Hud et al. 1996), and stabilization of the ribose-base stacking in Z-DNA (Egli and Gessner 1995). It is assumed that the interaction of a divalent cation with the base can cause a significant polarization of the bases associated with stabilization of certain H-bonded base pairs and other interactions (Hud et al. 1996; Egli and Gessner 1995; Anwander et al. 1990; Santangelo et al. 2010). However, some ions do not interact with nucleic acids in a direct manner but rather contribute to unspecific loose ion atmosphere around the nucleic acids (Chu et al. 2008). While theoretical studies usually deal with binding of cations to DNA, the RNA-cation binding is much more biochemically important and diverse. Many folded RNAs contain indispensable specific structural ions, which may also be directly involved in RNA catalysis (Draper et al. 2005; Banas et al. 2009; Lilley and Eckstein 2008).

In the DNA double helix, the known sites for the cation coordination are mainly the N7 atoms of purines sometimes supported by forming the chelate structure involving also O6 atom of guanine. Some other sites, such as N3 of cytosine or thymine and N1 of adenine, are usually blocked by the hydrogen bonding. Nevertheless, several experimental as well as theoretical examples of coordination into this position exists especially in the metal bridges like cytosine-silver-cytosine (Šponer et al. 1999a) or thymine-mercury-thymine (Yamaguchi et al. 2014; Šebera

et al. 2013a) as mentioned below. It should be noted that the metal cation interactions are not restricted only to the NA bases and the cation can simultaneously interact with the phosphate group. The coordinated metal cations can interact with the NA base directly (inner-sphere coordination) or mediated by a water molecule, which links the NA base with the metal cation (outer-sphere coordination) (Sigel 1993; Egli et al. 1991). Experimental studies on 5'-monophosphates revealed the following order of macrochelate coordination involving the N7 position of purines: GMP > IMP (I – inosine) > AMP (Sigel 1993). This order was explained as a result of different basicity of the N7 sites of guanosine, inosine, and adenine. It also correlates with the dipole moments of NA bases.

Properties of Metal Adducts with Nucleobases

Interactions of Bare Cations with Bases

The first models investigated in connection with metal-nucleobases interactions employed bare cations. One of the pioneering studies, which considered the influence of water and divalent ions on the base pairing, was published in 1970 by Rozsnyai and Ladik (1970). Later Del Bene (1984) explored interactions of naked Li⁺ cation with all DNA bases. In this work, all basic features of modern quantum chemical calculations are already present – the structures were optimized at the HF/STO-3G level with single point calculations (SP) using double-zeta basis set (6-31G). As the most stable adduct, the [Li-(Gua-O6,N7)]⁺ chelate was found (with association energy of 78.4 kcal/mol – which can be compared with more recent value of 78.3 at MP2/6-31G(d,p) (Burda et al. 1996)) followed by cytosine complex [Li-(Cyt-O2,N3)]⁺ (77.1 kcal/mol). The association energy of the most stable adenine conformer [Li-(Ade-N3)]⁺ was estimated to be substantially lower – 48.4 kcal/mol (40.4 at MP2 (Burda et al. 1996)). These energies clearly demonstrate the dominant role of the monopole (cation)-dipole moment (nucleobase) electrostatic interaction. When the multipolar formula for energy evaluation between monopole and dipole is considered, $E = q_{Li} \cdot \mu_{gua} / R^2_{Li-gua}$, then ca 92 kcal/mol can be obtained for Li charge of 0.84 e, guanine dipole moment of 7.28 D, and mutual distance of 2.09 Å (supposing a collinear orientation of cation and vector of dipole moment (cf. for instance Burda and Gu 2008; Futera et al. 2009a)). In the study, both O2 and O4 thymine complexes were predicted to be more stable than the adenine adducts by about 10 kcal/mol. Closely after this keystone study, another work dealing with interactions of the A-T and G-C base pairs with Li⁺ cation appeared (Del Bene 1985). In the most stable Li⁺-A-T conformer, the Li cation was coordinated to O2 site of thymine. In the G-C pair, the N3 position of guanine was preferred by 4 kcal/mol over O6, N7 chelate structure. This A-T and G-C base pair was later explored with extended set of metal cations (Burda et al. 1997) roughly confirming all these results. We would like to address here one important point. The numbers above, as well as many other numerical values in this study, refer to gas phase interactions of metal cations with nucleic acids

Table 1 Preferred sites for metalation and protonation

Base	Metalation	Protonation
Adenine	N7 > N1	N1 > N7
Cytosine	N3	N3
Guanine	N7 > N1	N7 > N1
Thymine, uracil	O2 > O4	O4 > O2

components. Such interactions are dominated by the electrostatic effects, which are substantially (sometimes almost completely) extinct in nucleic acids as well as in typical bioinorganic experiments. This needs to be kept in mind while the results are interpreted. For more discussion of various aspects of the interplay between the gas phase interactions and real systems, see, e.g. refs. (Šponer et al. 2001; Schmidt et al. 2002; Burda et al. 2003; Petrov et al. 2005).

Metal coordination sites in natural nucleotides are: (a) oxygen atoms of phosphate groups where cations neutralize the negative charge (these sites can be considered quite unspecific for any cation), (b) hydroxyl groups of sugar moiety usually chosen by alkali metals or metals of alkaline earth, (c) nitrogen atoms of heterocyclic bases – especially N1, N3, and N7 atoms of purine and N3 of pyrimidine bases, which exhibit large affinity to cations or generally electrophiles (In DNA/RNA oligomeric sequences, only sites in minor or major groove are accessible for interactions. It means that solely the N3 and N7 sites of purine bases are available for the interactions.), and (d) oxygens of keto-groups (O2 of cytosine, O6 of guanine, and O2, O4 of thymine and uracil) as positions for binding of “hard” cations, e.g., alkali metals (and less frequently for transition metal). Preference for individual hetero atoms in all five NA bases was explored for Ru(II) cation also in study of Futera (Futera et al. 2009a) demonstrating the preference for N7 site of purine bases and (after deprotonation) N3 of pyrimidine.

Comparing cation coordination and protonation of these active sites, large similarities can be noticed in the case of guanine, cf. Table 1. On the contrary, more remarkable differences are observed for adenine, uracil, or thymine. Unfortunately, deprotonation of N3 in thymine/uracil is not considered.

Coordination of the Mg²⁺ cation to purine DNA bases was recently explored in many experimental as well as computational studies (e.g., ref. (Elmahdaoui and Tajmirriahi 1995; Sychrovsky et al. 2004)), where bonding properties of selected mono- and divalent metal cations with the N7 position of guanine and adenine were examined.

The interaction of bare monovalent (alkali metals and coinage metals) and divalent (alkaline earth and zinc group metals) cations with the N7 site of purine NA bases was investigated in gas phase using the MP2/6-31G(d,p)//HF/6-31G(d,p) level of theory (Burda et al. 1996). The stabilization energies of base...M complexes were determined according to the formula:

$$\Delta E^{\text{Stab}} = - [E^{\text{Complex}} - (E_{BSE}^{\text{base}} - E_{BSE}^{\text{metal}})] + \Delta E_{\text{deform}}^{\text{base}} \quad (1)$$

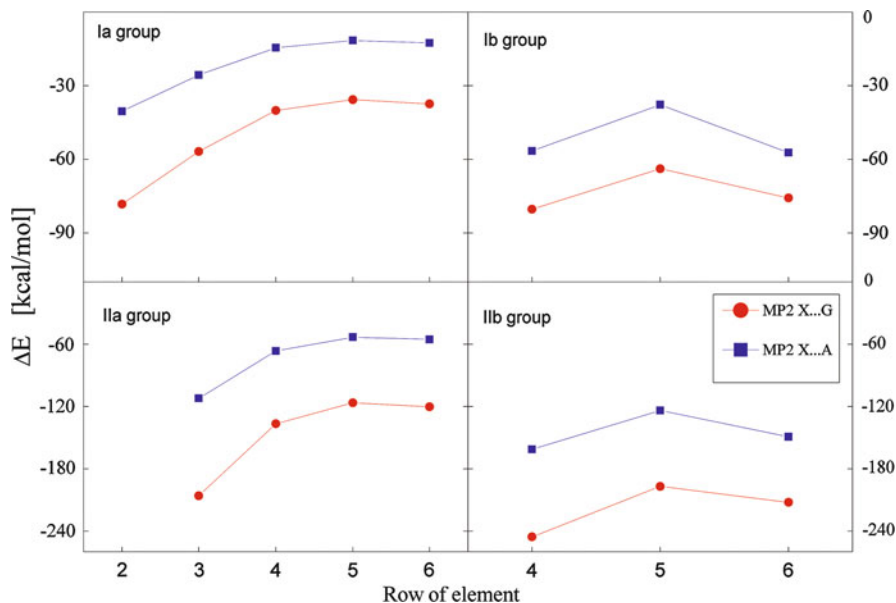

Fig. 1 Stabilization energies of metal-base complexes for Ia, Ib, IIa, and IIb metal cations interacting in N7(O6) position of the base

Here the $E_{B SSE}^{\text{base}}$ represents total energy of the base (adenine or guanine) within the basis set superposition error (BSSE) scheme of Boys Bernardi (Boys and Bernardi 1970). The results are displayed in Fig. 1 and it is evident that the values for guanine complexes are systematically nearly twice as large as those of adenine. This is due to the larger dipole moment of guanine and also its more favorable orientation close to the direction forming M-N7 bond, as it can be seen in Fig. 2a, c. The stabilization energies of the complexes with divalent ions are larger than those with monovalent ions and, as could be expected, the stabilization energies decrease with increasing atomic number of the metal ions. The only exception is revealed for the Au^+ and Hg^{2+} complexes where, due to the more pronounced relativistic effects, the respective stabilization energies are larger than the energies of the preceding cations (Ag^+ and Cd^{2+}).

In the coinage and zinc-group metal complexes, the bonding interaction is markedly stronger in comparison with coordination of the Ia and IIa metals. This is due to the presence of lower-energy vacant s-orbitals (compared with the same orbitals of the alkali metals), enabling to some extent the dative bonding into these orbitals from the occupied MO's of the bases. This leads to the increase of covalent character of the interaction that explains the basic difference between coordination of, e.g., K^+ and Cu^+ cations.

Complexes with Li^+ bare cation were computationally explored in gas phase by Russo et al. (Russo and Toscano 2001) at the DFT(B3LYP) level within several

Fig. 2 Orientation and size of dipole moments in the isolated NA bases: (a) guanine – 6.98 D, (b) N7 protonated guanine tautomer – 9.16 D, (c) adenine – 2.43 D, (d) cytosine – 6.64 D, (e) thymine – 4.47 D, (f) uracil – 4.54 D determined at B3LYP/6-311++G(2df,2pd)//B3PW91/6-31G(d,p) in gas phase. Standard atom numbering is used (e.g., textbook of Saenger (1983))

Fig. 3 Structure of the $[\text{Li}-(\text{Ura-O2,N3})]^+$ cation (enol form of O2,N3-chelate)

basis sets. They found that the most stable complex of adenine with lithium is imino-tautomer with N6,N7 coordination. In this way, a five-membered chelate is formed where Li^+ -N6 bond is 1.971 Å, and Li^+ -N7 distance is 2.022 Å. The remaining explored (amino) structures, $[\text{Li}-(\text{Ade-N3,N9})]^+$, $[\text{Li}-(\text{Ade-N6,N7})]^+$, and $[\text{Li}-(\text{Ade-N3})]^+$, lie by about 2, 10, and 15 kcal/mol higher on the potential energy surface. In the guanine adducts, the most stable structure is $[\text{Li}-(\text{Gua-O6,N7})]^+$ followed by chelate $[\text{Li}-(\text{Gua-N3,N9})]^+$, its enol form, and the enol form of the (O6,N7)-chelate, which are by 11, 12, and 15 kcal/mol less stable. The most stable complex with uracil is $[\text{Li}-(\text{Ura-O4})]^+$ adduct. The chelate structures $[\text{Li}-(\text{Ura-O2,N3})]^+$ (cf. Fig. 3) and $[\text{Li}-(\text{Ura-O4,N3})]^+$ lie about 3 and 7 kcal/mol above the global minimum and the $[\text{Li}-(\text{Ura-O2})]^+$ adduct is about 5 kcal/mol above

the O4-conformer. This fact indicates the electrostatic origin of the interaction when one considers the direction of the uracil dipole moment. In the cytosine complexes, the $[\text{Li}-(\text{Cyt-O2,N3})]^+$ structure is the most stable minimum followed by enol-tautomer of $[\text{Li}-(\text{Cyt-N1,O2})]^+$ (where N1 proton is transferred to O4 site) and the enol form of $[\text{Li}-(\text{Cyt-O2,N3})]^+$. These two complexes lie about 12 and 17 kcal/mol higher on the potential energy surface. The same strategy was also applied for evaluation of Mg^{2+} and Ca^{2+} in their next paper (Russo et al. 2003). Later Marino et al. (2007, 2010) and Bagchi et al. (2012) performed DFT calculations on the interaction of naked zinc group metals with NA bases in gas phase obtaining qualitative agreement with our energies (Burda et al. 1996). Moreover pyrimidine bases are explored, too. Altogether, the preference for binding to various NA bases is $G > C > A > T > U$. We performed another study on the $\text{Ru(II)Cl(en)(arene)}$ piano-stool complex where various sites of all NA were also investigated (Futera et al. 2009a). In this study ligated Ru(II) cation, similar preferences followed for gas phase calculations: $G > A > C > T > U$. When solvated (CPCM) model was considered, the order of binding preferences changed: $G > C > T > U > A$. Nevertheless, it should be stated that the difference between binding to G and A is only about 9 kcal/mol and all three last bases (T, U, and A) are in 1 kcal/mol energy span.

The coordination of divalent metal cations with the phosphate group of various nucleotides (GMP, AMP, UMP, and CMP) was studied (probably) for the first time by Varnali (Varnali and Tozumcalgan 1995). In her study semiempirical PM3 method was used. From the results it follows that the most stable metal adducts are formed with the phosphate group of AMP closely followed by CMP for all explored metals.

The calculations of the NMR spin-spin coupling constants and the NMR shifts of the direct and water-mediated binding of divalent metal cations to guanine were performed by Sychrovský (Sychrovsky et al. 2004). The intermolecular coupling constants $^1J(X, \text{O6})$ and $^1J(X, \text{N7})$ ($X = \text{Mg}^{2+}, \text{Zn}^{2+}$) were unambiguously assigned to the specific binding motif of the hydrated cation with O6 and N7 sites of guanine. The calculated coupling constants $^1J(\text{Mg}, \text{O6})$ and $^1J(\text{Zn}, \text{O6})$ are 6.2 and -17.5 Hz for the inner-shell complex where the cation directly interacts with the guanine O6 position. For the inner-shell coordination of the cation at nitrogen N7, the calculated coupling constants $^1J(\text{Mg}, \text{N7})$ and $^1J(\text{Zn}, \text{N7})$ are 5.6 and -36.5 Hz, respectively. When the cation binding is water-mediated, the corresponding coupling constants are zero. The calculated NMR shifts $\delta(\text{N7}) = -15.3$ and -12.2 ppm upon the coordination of Mg^{2+} and Zn^{2+} ion are similar to the NMR shift of 19.6 ppm toward the high field measured by Tanaka (Tanaka et al. 2002) for the coordination of Cd^{2+} to the N7-guanine site.

The B3LYP/6-311 + G(2df,2p) level was used to explore geometry of all possible adducts originating from the interaction of Cu^{2+} cation with the most stable tautomers of NA free bases (Marino et al. 2004). Several attachment sites for both purine and pyrimidine bases have been taken into account for possible formation of both monoadducts and chelates. It was concluded that the copper ion Cu(II) has the highest affinity for the most stable tautomer of guanine base. Further, a comparison of various divalent metal cation complexes (Zn, Cu, Ni) with hypoxanthine and

uracil was performed by Matsubara (Matsubara and Hirao 2002). The B3LYP level stabilization energies of both M(II)-hypoxanthine and M(II)-uracil complexes reflect the strength of the M-N(base) interaction giving the same stability sequence $Zn > Cu > Ni$ for both bases.

Metal Interactions in Implicit Solvent Model

The calculated interaction energies of the bare cations with nucleobases have revealed a great overestimation of the electrostatic interaction in comparison with experimental samples. This overestimation is clearly due to the uncompensated charge of the bare cation in the gas-phase calculation compared to water solution where the charge of the cation is screened by solvent molecules. In this way, the electrostatic part of the metal-base interaction is substantially reduced. A role of the electrostatic contribution in the case of the Pt-base coordination will be enlightened later. The approach of implicit solvent models is very popular in many variants (COSMO (Frank Eckert 2006; Klamt and Schuurmann 1993), PCM (Mennucci et al. 1998; Miertus et al. 1981), SMD (Marenich et al. 2009), GBM (Roux et al. 1990; Mukhopadhyay et al. 2014) etc.), and there is a large number of such studies. Here only a few recent works will be mentioned for illustration.

In 2008, Ai et al. (2008) published a study on the tautomer equilibrium of adenine in presence of Zn^{2+} cation at the DFT level (B3LYP/6-311 + G**). It was found that the $[Zn-(Ade-N6,N7)]^{2+}$ imino complex is the most stable structure in accord with the gas-phase calculations of Kabeláč (Kabeláč and Hobza 2006). The latter calculations explored tautomers of all DNA bases in presence of bare Na^+ , Mg^{2+} , and Zn^{2+} cations evaluated at the RI-MP2/TZVPP level of theory.

The binding of first-row transition metal monocations (Sc^+-Cu^+) to N7 of guanine and N7 or N3 of adenine nucleobases was studied using the DFT approach with B3LYP functional. The electrostatic character of these interactions is mainly represented by metal-ligand repulsion. The M^+ -guanine binding energies are about 18–27 kcal/mol larger than those of M^+ -adenine, when the differences decrease along the row (Noguera et al. 2008).

Another study on an interaction of bare cations with metabolite of purine bases-uric acid should be mentioned (Allen et al. 2006). Geometries of the complexes of Li^+ , Na^+ , K^+ , Be^{2+} , Mg^{2+} , and Ca^{2+} metal cations with various nucleophilic sites of uric acid were optimized at the B3LYP/6-311++G(d,p) level. Single point energy calculations were performed at the MP2/6-311++G(d,p) level. It was found that cations mainly form chelate structures with a bidentate coordination. In the gas phase, the most preferred position for the interaction of Li^+ , Na^+ , and K^+ monovalent cations is between the N3 and O2 sites, while all divalent cations prefer coordination between the N7 and O6 sites of the urate. However, it was simultaneously shown that the incorporation of aqueous solution in the model has a significant impact on the relative stability of various complexes. The global minimum of urate with Mg^{2+} and Ca^{2+} cations is represented by the O2,N3-chelates

Fig. 4 The optimized structures of the metal complexes with urate: (a) O2,N3-chelate, (b) O6,N7-chelate

in analogy with monovalent cations. Moreover, the relative energy differences are very small. Especially for the Ca^{2+} structures, energies of all conformers are practically in the 2 kcal/mol range. The most stable structures are depicted in Fig. 4.

Metal cation binding to deoxyguanosine monophosphate was examined by Bouř (Andrushchenko and Bour 2009). Infrared spectra of complexes with Na^+ , Mg^{2+} , Ca^{2+} , Ni^{2+} , Cu^{2+} , Zn^{2+} , and Cd^{2+} cations were recorded and interpreted on the basis of the density functional theory. The solvation effects were simulated by PCM and cluster models (combined explicit solvent and PCM). The coordination to the guanine N7 position was considered and the obtained calculated spectra predict a blueshift of the characteristic 1578 cm^{-1} frequency, in accord with experimental data. Metal binding to the phosphate group causes significant spectral changes in the sugar-phosphate vibration region but also notable frequency shifts of the carbonyl vibrations. The Cu^{2+} and Zn^{2+} cations induce the largest changes in measured vibrational absorption, which corresponds to the computationally determined strong interaction energies in the N7-complexes. The Cu^{2+} binding to guanine was revealed to be a two-step process, which was also confirmed by the microcalorimetry titration curve.

Interactions of Explicitly Hydrated Cations

The most realistic approach to the description of metal cation interactions with nucleobases is represented by a model of the explicitly hydrated cations – usually up to hexacoordinated cations. Recently, explicit hydration has been used in connection with implicit solvation shell (combined model), e.g., in the study for hydration of Ag^+ by Martínez et al. (1997), for acid-base properties of goethite surface model (Aquino et al. 2008) or for modeling of electrified interfaces (Benedikt et al. 2013) or already mentioned study of Bouř (Andrushchenko and Bour 2009).

Table 2 Interaction energies in the complexes of solvated cation (Mw)-(N7)purine (G/tG/A)

	ΔE_{Mw-G}	ΔE_{Mw-tG}	$\Delta E_{MG\text{bare}}$	ΔE_{Mw-A}	$\Delta E_{MA\text{bare}}$
Mg^{2+}	-89.3	-84.8	-198.7	-46.0	-107.9
Ca^{2+}	-82.6	-80.1	-133.9	-33.5	-61.6
Sr^{2+}	-76.0	-	-	-28.9	-48.9
Ba^{2+}	-71.2	-71.4	-118.3	-28.1	-54.4
Zn^{2+}	-93.8	-90.1	-237.2	-53.7	-152.9
Cd^{2+}	-87.9	-107.6	-192.6	-45.9	-116.6
Hg^{2+}	-94.3	-149.2	-208.0	-55.3	-141.1

Hydrated Alkaline Earth and Zinc-Group Metal Cations

One of the first studies on this topic was published by Šponer et al. (1998a). In the study, pentaqua cation adducts (of Mg^{2+} , Ca^{2+} , Sr^{2+} , Ba^{2+} , Zn^{2+} , Cd^{2+} , and Hg^{2+}) to the N7 position of guanine were explored at the MP2/6-31G*//HF/6-31G* level. Quasi-relativistic energy-averaged Stuttgart pseudopotentials were used for the description of the third and higher-row cations. The interaction between hydrated cation and guanine is significantly reduced compared to the guanine-unsolvated cation model, cf. Table 2. The cations of IIb group together with Mg^{2+} are tightly bound to the N7 atom of guanine, whereas the O6 site is involved in H-bonding with the aqua ligands from the metal hydration shell. The metals with greater radius (Ca^{2+} , Sr^{2+} , and Ba^{2+}) prefer simultaneous coordination to the N7 and O6 atoms of the base. Also, the cation-guanine distance increases with the atomic number. The energy difference between the N7 and N7-O6 types of coordination is rather small. Relativistic effects are apparent in the case of Hg^{2+} , similarly to the complexes with the bare cation reported above (Burda et al. 1996). The Zn^{2+} and Mg^{2+} cations show a different balance between the cation-base and cation-water interactions. While the Zn^{2+} cation is bound more tightly to the base (93 kcal/mol) and its water shell is more flexible (203 kcal/mol), a different situation (with stronger metal-water binding) was found in the Mg^{2+} complex. The binding energy of the $Mg(H_2O)_5^{2+}$ cation with N7 position of guanine in GC pair is approximately 89 and binding energy of five water molecules with $Mg(GC)$ complex is about 220 kcal/mol. The different binding picture for Zn and Mg cations can be partly explained as a shift from the interaction between nucleobase and hydrated cation (Mg) toward the hydration of a metalated base (Zn).

It follows from Table 2 that despite the substantial reduction of the M-N7 interaction energy, the ratio of the energies for guanine and adenine remains approximately equal to two, similarly to the results obtained in the study of the bare cations (Burda et al. 1996). This confirms the dominant role of electrostatic term in these complexes. In platinum complexes, substantially higher coordination-covalent contribution is demonstrated in the limit of total charge going to zero (cf. in Figs. 9 and 15, below).

The tautomeric equilibrium and hydrogen bonding in nucleotide 2'-deoxyguanosine monophosphate in interaction with hydrated $[Mg(H_2O)_4]^{2+}$

cation were studied at the MP2/cc-pVDZ//B3LYP/cc-pVDZ and B3LYP/aug-cc-pVTZ//B3LYP/cc-pVDZ levels of theory by Gorb (Kosenkov et al. 2008). The Mg^{2+} ion forms two inner-shell contacts with the nucleotide, similar to small phosphorylated molecules under physiological conditions. The hydrated magnesium cation in the presence of the phosphate group can change the guanine tautomeric equilibrium in comparison to free guanine. The canonical O6-oxo form of guanine is more stable (by 6–8 kcal/mol) than the O6-hydroxo form in anticonformation. The interaction with Mg^{2+} ion is capable to suppress a spontaneous transient formation of the rare tautomer. The question, which coordination mode of hydrated Mg^{2+} cation with DNA is dominant (direct metal-N7 coordination or indirect interaction by water molecule through the polarized H-bonding), was addressed by Bandyopadhyay (Bandyopadhyay and Bhattacharyya 2003). Based on HF and DFT calculations, the authors show that both binding modes are of a similar importance.

An interesting situation was revealed when interactions of thioguanine (tG) base was explored (Šponer et al. 1999b). In accord with the Pearson HSAB principle (Parr and Pearson 1983), a stronger interaction with S6 site of thioguanine is observed for the heavier transition metal cations, as can be seen by corresponding columns ΔE_{Mw-G} and ΔE_{Mw-tG} in Table 2. While a mild weakening of the binding energy is even visible in the case of alkaline earth cations (Mg^{2+} , Ca^{2+}), a very robust adduct is formed with the Hg^{2+} cation. This strong coordination is also partially the consequence of a smaller number of water molecules in the first hydration shell. Due to this strong Hg-S coordination, two water molecules are pushed out from the first hydration shell. Optimized N7,S6-chelate structure resembles the arrangement with the bare cation, cf. Fig. 5b. However, a shorter Hg-S distance (2.50 Å) was obtained comparing the Hg-N bond (2.57 Å). A similar chelate structure was also found in the Cd^{2+} complex, despite the coordination with four water molecules, cf. Fig. 5c. A slightly longer Cd-S distance (2.67 Å)

Fig. 5 Different cases of hydrated-metal coordination to thioguanine: (a) Zn, (b) Hg, and (c) Cd

than Cd-N (2.40 Å) was obtained in that structure. In the remaining complexes no direct metal-sulphur interaction was found at the HF/6-31G* optimization level. Nevertheless, using the DFT level, slightly different coordination pattern is revealed for Mg and Zn cations. The preferred structure contains six coordinated cation sphere but only with four water molecules similar to the chelate arrangement of the Cd²⁺ complex (Šponer et al. 1999b) as shown in the Fig. 5c.

Possible binding of hydrated cations to nucleobases in a cation- π manner led to the conclusion that such interactions are very unlikely in the case of nucleic acids as they are outcompeted by conventional cation binding patterns. The suggestion of existence of cation- π interactions in DNA was shown to be a case of misinterpretation of structural data (Šponer et al. 2000a).

Later extended study by Rulisek (Rulisek and Šponer 2003) explored adducts of hydrated divalent metal cations (Mg²⁺, Cu²⁺, Zn²⁺, and Cd²⁺) to the guanine N7 position interacting in outer- and inner-shell manner with an anionic phosphate group. The results obtained by the B3LYP and MP2 computational level are compared. Their calculations illustrate that the cations have a different balance of water-cation and N7-cation binding, leading to selectivity toward the N7 binding in the following order: Cu²⁺ >> Zn²⁺ = Cd²⁺ > Mg²⁺. It is consistently reflected by changes of interatomic distances upon cation substitution, changes of both absolute electronic and interaction energies. The energetics of the cation selectivity is typically on a scale of 3–10 kcal/mol. The calculations demonstrate that the inner-shell binding to the phosphate is more stable than the outer-shell binding. Nevertheless, this does not mean that such a conclusion can be generalized for real samples where the phosphate group is included in the form of sugar-phosphate backbone.

Complexes of Hydrated Copper Cations with Guanine

Interaction of hydrated Cu(I)/Cu(II) cations with guanine represents another interesting explored system. In this case also redox properties under hydration can be compared to copper complexes with water and ammonium ligands (Pavelka et al. 2008; Burda et al. 2005). One of the examined features of the copper complexes involves the number of coordinated ligands. While the Cu(I) complexes prefer two-coordinated structures, the geometry of Cu(II) complexes has usually the coordination number four or five, in accord with the small inorganic copper complexes studied previously (Pavelka and Burda 2005; Pavelka et al. 2006). Also, the affinity of various active sites of the metalated guanine for water molecules in comparison with nonmetalated (isolated) base was explored. The resulting preference for individual conformers determined at the B3LYP/6-311++G(2df,2pd) level can be seen in Table 3 and the most stable structures are displayed in Fig. 6. The affinity of individual sites of the isolated bases was explored by Poltev et al. (1996) using empirical potentials. They found that in the case of guanine hydration by a single water molecule, the global minimum structure has one water molecule between O6 and N1 sites, followed by the N1-N2 water adduct. The N9 position was not considered since this position is not accessible in nucleosides. In another study (Colominas et al. 1996), various tautomeric forms of guanine and cytosine

Table 3 The relative differences of Gibbs' free energies ΔG and stabilization energies ΔE^{Stab} and Cu-N7 and Cu-O binding energies for the selected conformers in kcal/mol

Conformer	ΔG	ΔE^{Stab}	$E(\text{Cu-N})$	$E(\text{Cu-O})$
1	0.0	-168.4	83.4	60.4

and their influence on Watson-Crick H-bonding were explored. From these results, it is clear that there is no substantial change due to the polarization effects of Cu(I) cation revealed by semiempirical methods, in comparison with the MP2 approach. Also, metal-N7 binding energies can be compared with results of our earlier studies (Burda et al. 1996, 1997) on metal coordination to the purine DNA bases. Despite the fact that in the earlier investigations only bare cations were considered at the MP2/6-31G(d)//HF/6-31G(d) level, the interaction energy is fairly similar to the analogous energies of these hydrated structures.

The adducts of the hydrated copper(II) cation with guanine were explored in the study of Pavelka (Pavelka et al. 2006). Various numbers of water molecules were considered in combination with the different coordination pattern of the Cu^{2+} cation. The most stable structures are summarized in Table 4 and displayed in Fig. 7. The full set of investigated structures can be viewed in the original paper (Pavelka et al. 2006).

From this study it follows that the penta-coordination of Cu(II) in these complexes is visibly less convenient than that in the case of the small inorganic complexes (for both aqua ligands (Burda et al. 2004) or mixed aqua-ammine ligands

Fig. 7 The most stable structures of Cu-guanine complexes with four and five water molecules

(Pavelka and Burda 2005)). The Cu(I) complexes do not create chelate structures since linear monoaqua form with the remaining water molecules in the solvation shell is substantially more stable. In the monoaqua Cu(I) and Cu(II) complexes, the strength of Cu-N7 bond ($-81/-230$ kcal/mol for Cu(I)/Cu(II)) and Cu-O(aq) bond ($-35/-46$ kcal/mol) roughly follows formal electrostatic relationship. The higher preference for N7 coordination in Cu(II) complex is related to the possibility of the higher electron transfer from more polarizable nitrogen atom.

Interactions with Platinum Metal Complexes

One of the most frequently studied metals in connection with nucleobases is platinum. Since late sixties when B. Rosenberg published his study on anticancer activity of cisplatin (Rosenberg et al. 1965, 1969), a lot of effort is devoted to this compound and its derivatives, as well as to some other transition metal complexes where similar activities can be expected. One of the early calculations was performed by Basch et al. (1986) and by Lipinski (1989). Since then a vast number of both experimental and theoretical studies can be found in literature on this topic, especially on platinum interactions with nucleobases, nucleotides, and other DNA models. One of the most important questions, which need to be solved, concerned tautomeric equilibria due to the possible point mutations. This topic was addressed in several studies considering various nucleobases. Metallodrugs are generally expected to coordinate predominately in the major groove of genomic DNA. Therefore our discussion starts with the interaction in N7 position of purine bases.

An interesting study on the difference between protonation and metalation of the N7 position of deoxyguanosine was published by Baik et al. (2002). While under

Fig. 8 Reaction free energy profile for dissociation of N9-C1' glycoside bond of dGuo, dGuo(H)⁺, and dGuo(Pt)⁺ in solvent

protonation the glycoside N9-C1' bond breaks, the Pt(II) adduct does not change the strength of the glycosidic bond substantially, as can be noticed from the Fig. 8.

The Tautomeric Equilibrium of the Metalated Nucleobases

Several platinum complexes with varying total charge were explored at B3LYP/6-31G(d) level (Burda et al. 2000): neutral trans-dichloro-ammine-platinum, +1 charged trans-diammine-chloro-platinum, and +2 charged triammine-platinum. Two tautomers of guanine were considered – keto and enol forms as well as N6-amino and syn- and anti-imino forms of adenine. In this way the role of electrostatic contribution could be elucidated. Despite the gas-phase calculations, the bonding energy and tautomeric relations in solvent can be easily estimated. In Fig. 9, the relative tautomeric stabilization energies are displayed for adenine and guanine.

From this figure it follows that the trans-imino-tautomer of adenine is better stabilized under platination, which could lead to mispairing. In the case of guanine, the regular keto form is more stable for charged complexes. Moreover, the enol preference in the electroneutral complex is caused by the additional H-bonding stabilization between platinum ligand (aqua or chloro) with hydrogen from the enol group (cf. Fig. 10a). Such stabilization may not be present in solvent due to competitive H-bonding interactions with other water molecules. This study in

Fig. 9 Stabilization energies of the platinum-base complexes in dependence on total charge of the (a) Pt-adenine and (b) Pt-guanine complex

Fig. 10 Structure of platinum(II) complexes with (a) enol-tautomer of guanine and (b) trans-imino-tautomer of adenine

general suggests that the largest part of the tautomeric effects of the N7 platination is due to gas phase effects, which are assumed to be annihilated in real assays.

Metalation of the exocyclic amino group of cytosine and adenine nucleobases was explored in the case Pt(II) and Hg(II) complexes (Šponer et al. 1999c). It induces protonation of the N3 site of cytosine and N1 site of adenine. Hence, it causes a proton shift from an exocyclic to an endocyclic N atom (similar to situation in Fig. 10b). In this way the metal-assisted process can lead to the generation of rare nucleobase tautomers. The calculations demonstrate that metalation of the exocyclic amino group of nucleobases significantly increases the protonation energy of the aromatic rings of nucleobases by about 30–34 kcal/mol for the Pt(II) adduct and by about 10–14 kcal/mol for the Hg(II) adduct. This study demonstrates a

tautomeric shift that is caused by changes of the electronic structure of nucleobases and is unrelated to electrostatic effects. Thus, authors suggested a separation of purely electrostatic effects from nonelectrostatic (molecular orbital) contributions. The former ones are expected to be rather unimportant in aqueous solution or x-ray crystallography experiments, where the systems are overall strictly neutral. The nonelectrostatic contributions are assumed to remain insensitive to the environment and fully expressed under usual experimental conditions.

Rare tautomers of 1-methyluracil (MeUH) and 1-methylthymine (MeTH) in coordination with Pt(II) complexes were explored by van der Wijst et al. (2009). Comparing the calculations in gas phase and water, the influence of the solvation effects was estimated. They also showed that relative stabilization energies of the Pt(II) complexes with various tautomers of MeUH and MeTH differ from the isolated tautomers. This leads to the conclusion that some rare tautomers may become favored under metalation.

Recently, a reduction mechanism of $\text{Pt}^{\text{IV}}(\text{DACH})\text{Cl}_4$ in the presence of dGMP was explored (Šebesta and Burda 2016). The first step represents a substitution reaction of a chloro-ligand by dGMP followed by a nucleophilic attack of phosphate or sugar oxygen to the C8 position of guanine. Subsequently, the reduction reaction occurs forming the $\text{Pt}^{\text{II}}(\text{DACH})\text{Cl}_2$ complex. The whole process is completed by hydrolysis. Two different pathways for the substitution reaction were examined: direct associative and Basolo-Pearson autocatalytic mechanism. While activation barriers for direct association were too high, the barriers based on Basolo-Pearson mechanism are used for estimation of the rate constants (according to Eyring's TST) and are compared with experimental values. It was found that the rate determining step is the nucleophilic attack with a slightly faster performance in 3'-dGMP branch than in 5'-dGMP with the activation barrier of 21.1 and 20.4 kcal · mol⁻¹ comparing with experimental values of 23.8 and 23.2 kcal · mol⁻¹, respectively. The reduction reaction is connected with the electron flow from guanine to Pt complex (cf. Fig. 11).

The product of reduction reaction is a chelate structure, which dissociates within the last reaction – hydrolysis. The whole redox process (substitution, reduction, and hydrolysis reactions) is exoergic by 34 and 28 kcal · mol⁻¹ for 5'-dGMP and 3'-dGMP, respectively.

Interaction of Nucleobases with Half-Sandwich Ru(II) Complexes

Recently, computations on ruthenium complexes with nucleobases were published by Futera (Futera et al. 2009b). In his comprehensive study, interactions of piano-stool ruthenium metallodrug with nucleobases were investigated. In the same study, the reaction profile of the chloro-ligand replacement by water molecule and the role of the arene-ring size were also explored. From the point of this review, an important part of Futera's study deals with interactions of Ru(II) with various sites of all the nucleobases in vacuum and in the implicit solvent model. For the optimized structures, the bonding and stabilization energies were determined. Characteristics of the most stable conformers are summarized in Table 5. From the Table 5 it follows that in the case of purine bases, the most stable adenine structure (Ru-(Ade-N1) conformer) differs from the most stable guanine complex (Ru-(Gua-N7) conformer)

Fig. 11 Electronic flux from HOMO to LUMO of the supermolecular Tetraplatin/dGMP system

as revealed in the gas-phase calculations. Nevertheless, in the PCM model, the N7-conformer represents the most stable form of the both purine nucleobases. This change of the Ru-adenine global minimum follows from the general reduction of the electrostatic forces, which are substantially screened in PCM approaches. In gas phase, the Ru-(Ade-N1) coordination is enhanced by favorable orientation of the adenine dipole moment of about 2.70 D (determined at the MP2/6-31++G(d,p), gas-phase level) aiming in N1-C8 direction while the guanine dipole of 6.36 D points in N7-N3 direction, as can be seen in Fig. 2. Even larger dipole moment was predicted for N1-guanine tautomer with proton transferred to N7 atom ($\mu = 9.55$ D). This dipole moment correlates with the fact that the Ru-(Gua-N1) adduct exhibits the highest $\Delta E^{\text{BE}}(\text{Ru}-(\text{base}-\text{N}))$ binding energy among all the explored complexes (interestingly, in both gas phase and PCM approach). The analogous effect of decreased electrostatic enhancement is also responsible for the change in energy preference in the case of cytosine adducts. The Ru-(Cyt-O2) structure becomes

Table 5 Binding and stabilization energies (in kcal/mol)

the least stable in implicit water model (by more than 7 kcal/mol) and the most stable adduct is Ru-(Cyt-N1) closely followed by the Ru-(Cyt-N3) complex with practically the same stabilization and total electronic energies. The thymine and uracil bases favor the N3 coordination regardless the environment. This preference is in accord with different orientation of the dipole moment of uracil and thymine in comparison with cytosine (cf. Fig. 2). Another computational study dealing with interaction of different forms of ruthenium complexes with DNA bases was published recently (Besker et al. 2007). Here similar binding energies (in comparison to Futera's work) were obtained for relevant structures in both gas phase and PCM.

Molecular mechanism for the replacement of chloro-ligand by water and subsequently of aqua-ligand by nucleobase was also explored by Futera (Futera et al. 2009c). Similarly to the platination process, the hydration reaction is mildly endoergic ($\Delta G = 2$ kcal/mol). Formation of the guanine adduct is exoergic by ca 7 kcal/mol. Nevertheless, all these reactions are faster in the case of the ruthenium complex (in equimolar concentrations) since the activation barriers are lower, e.g., the values for replacement of both adenine and guanine are about 18 kcal/mol while in the cisplatin case analogous barriers are ca 20 kcal/mol (cf. Table 8). Moreover, while "simple" mechanism was found in adenine reaction (as displayed in Fig. 12a), a two-step reaction mechanism was suggested for the guanine replacement (Fig. 12b).

In these mechanisms, a lower activation barrier for the substitution by adenine corresponds to higher rate constant ($1.7 \text{ M}\cdot\text{s}^{-1}$ vs. $0.5 \text{ M}\cdot\text{s}^{-1}$). Nevertheless, since the minimum associated with the reaction coordination ("direct reactant") of adenine is about 4 kcal/mol higher than the global minimum it means the

Fig. 12 (a) Reaction coordinate for replacement of water by adenine and (b) guanine

concentration of the conformer corresponding to this local minimum will be by three orders of magnitude lower (according to the Boltzmann equilibrium law). A different situation occurs for the analogous local minimum of guanine. Here the instant concentration (under assumption of equilibrium) of the local reaction minimum is comparable to the global minimum and therefore, the real reaction rate will be actually substantially higher in the reaction with guanine.

Osmium complexes were also considered as possible metallodrugs. The hydrogenation energies of various nitrogen heterocycles in the presence of osmium tetroxide were investigated and published by Deubel (2003). While hydrogenation of pyrimidine bases is exothermic, the purine C4-C5 bond does not have a tendency to hydrogenate.

Another study on tautomeric equilibria and connected proton transfer (PT) from the N3 site to O2 site of thymine was explored by Burda et al. (2016). It is shown that PT in the presence of additional water molecule reduces activation barrier from 51 kcal/mol to ca 22 kcal/mol. Nevertheless, when solvated cations ($[\text{Mg}(\text{H}_2\text{O})_6]^{2+}$, $[\text{Zn}(\text{H}_2\text{O})_6]^{2+}$, and $[\text{Hg}(\text{H}_2\text{O})_6]^{2+}$) are coordinated to the O2 and O4 site of thymine by two of their aqua ligands, then further reduction of the activation barrier to ca 6–8 kcal/mol was observed due to polarization of these ligands.

The Metal Coordination to Multiple Nucleobase Systems

Interaction with Base Pairs

Metal Cations from Ia, Ib, IIa, and IIb Groups

An influence of metal coordination in major groove on the enhancement of base pairing was explored by Burda et al. (1997). The energy decomposition for these systems requires, besides total stabilization and pair energies, also the nonadditive three-body contribution.

The studied complexes were partitioned into three subsystems: the two bases (B_1 , B_2) and a metal cation (M). The total stabilization energy (ΔE^{Stab}) is, within the BSSE counterpoise error, defined as:

$$\Delta E^{\text{Stab}} = -\{E(B_1, B_2, M) - [E(B_1, gB_2, gM) + E(gB_1, B_2, gM) + E(gB_1, gB_2, M)]\} \quad (2)$$

where $E(B_1, B_2, M)$ represents the total energy of the whole complex, and, e.g., $E(B_1, gB_2, gM)$ is a total energy of the base B_1 in the presence of the basis functions on the ghost systems B_2 and M . Alternatively, the total stabilization energy ΔE can be expressed in terms of pair stabilization energies and the three-body contribution:

$$\Delta E^{\text{Stab}} = E(B_1 - B_2) + E(B_1 - M) + E(B_2 - M) + E(3) \quad (3)$$

where each pair-stabilization energy is calculated within the BSSE scheme. For example, the $E(B_1 - B_2)$ energy can be determined from formula:

$$E(B_1 - B_2) = -\{E(B_1, B_2, gM) - [E(B_1, gB_2, gM) + E(gB_1, B_2, gM)]\} \quad (4)$$

Besides these pairwise energies, interactions of one subsystem of the complex (metal or pyrimidine) with the remaining part were also evaluated. The interaction of thymine with (metal + adenine) subsystem can be determined as:

$$E(MA - T) = -\{E(A, T, M) - [E(A, gT, M) + E(gA, T, gM)]\} \quad (5)$$

The whole systems can be regarded as a composition of a strongly bonded metal cation-purine base part plus two weak interactions: metal cation-remote pyrimidine base and Watson-Crick H-bonded base pair. The latter two terms represent only a small perturbation of the first one, and their mutual influence is basically very small. Therefore, it is not surprising that similar geometry and energy parameters for metal coordination were obtained, comparing with the analogous characteristics in ref. (Burda et al. 1996). Also, the obtained geometries match well with the results reported by Anwander et al. (1990) for complexes with Ca^{2+} , Mg^{2+} , and Zn^{2+} . Some small differences originate from a smaller basis set, which they have used: too short distances between the purine base and the metal cation, especially for the Zn^{2+} complexes (our calculations predict 1.95 Å for the Zn^{2+} GC complex, while Anwander reported 1.72 Å).

The metal cation significantly influences the geometry of the base pair. The (C)O2...H-N2(G) H-bond lengths in the GC complexes are systematically reduced, in comparison with the isolated pair. This reduction is the largest for bivalent ions (up to 0.3 Å). The central H-bond N3-H...N1 remains practically unchanged, and the third N4-H...O6 H-bond, which is the closest one to the metal cation, is significantly lengthened in comparison with the isolated GC pair. The elongation is again the largest for bivalent ions (0.65 Å in Zn^{2+} GC and Mg^{2+} GC). In the AT pair, the metal cations affect the H-bonds in a different way. The (T)O4...H-N6 H-bond, which is closer to the metal-ion coordination site, shows a substantial shortening (0.35 Å in complexes with Zn^{2+} and Mg^{2+}), while the other H-bond (N3-H...N1) is lengthened (by 0.18 Å in Zn^{2+} AT complex). The geometric rearrangements of the pair structures can be regarded as rotation around the center of the pyrimidine ring towards the metal cation in the case of the AT pair and away from it in the case of the GC pair.

Basically, the same dependencies of the stabilization energies on increasing atomic numbers of metal cations are observed in metal-purine-pyrimidine complexes like in previously published metal-purine species (Burda et al. 1996). Stabilization energies of complexes with divalent ions are larger than those of monovalent ions, and M-GC stabilization energies are larger than those for M-AT complexes. Both conclusions reflect the dominant role of the ion-dipole electrostatic contribution to the stabilization energy of these complexes.

Compared with the study of Anwander (Anwander et al. 1990), a very close agreement was obtained for complexes of Ca^{2+} with base pairs (within 5 kcal/mol). However, larger differences were found in Mg^{2+} -containing systems (≈ 20 kcal Mg^{2+} -AT and ≈ 40 kcal Mg^{2+} -GC; the values in our work describe larger stabilization – for both base pairs). Nevertheless, the use of a

minimal basis set (MBS) for zinc (all-electron calculations) nearly doubles the stability ($\Delta E^{\text{HF}}(\text{MBS}:\text{Zn}^{2+}\text{-GC}) = 448$ kcal/mol vs. our value $\Delta E^{\text{HF}}(\text{AREP}:\text{Zn}^{2+}\text{-GC}) = 254$ kcal/mol and $\Delta E^{\text{HF}}(\text{MBS}:\text{Zn}^{2+}\text{-AT}) = 328$ kcal/mol vs. $\Delta E^{\text{HF}}(\text{AREP}:\text{Zn}^{2+}\text{-AT}) = 158$ kcal/mol).

The H-bond WC interactions in the AT pair within the geometries of M-AT complexes are systematically weakened in comparison with the isolated optimized AT pair ($\Delta E^{\text{MP2}} = 12.3$ kcal/mol). This weakening, which is larger for divalent ions amounts to about 4 kcal/mol, leading to AT pairing energy of ca 8 kcal/mol. A similar weakening of H-bonds was expected to occur in the M-GC complexes (cf. Table 6). However, it was found that ΔE^{MP2} of H-bonds in the GC pair within the M-GC complexes are a little stronger (with Ca^{2+} - Ba^{2+} exceptions) than those of the H-bonds in the isolated GC pair ($\Delta E^{\text{MP2}} = -26.3$ kcal/mol). It can be shown that these changes correspond to the geometry deformation under the metal coordination. From the energy decomposition it can be concluded that the H-bond strength of GC or AT pair, calculated as a pairwise interaction energy within the optimized M-GC or M-AT complexes, is influenced by cations only marginally. However, metal cations bound to the WC base pairs dramatically (directly or indirectly) change many characteristics of the base pairing. Actually, one should not consider pairwise energies of the G-C and A-T pairs but the MG-C and MA-T H-bonding energies and these values are systematically higher – up to 24 kcal/mol for A-T and 48 kcal/mol for G-C H-bonding in the presence of Zn^{2+} cation. It amounts to nearly two times enhancement of the original base pairing energy.

Similar conclusions are also reported in other studies on the metal-nucleobases interactions. A trimer base arrangement was explored using a similar computational model. The enhancement of G.GC(rH), G.GC(H), A.AT(rH), T.AT(H) and some other base interactions including reverse Hoogsteen pairs GG(rH) and AA(rH) was proved in the presence of Li^+ and Ca^{2+} cations (Šponer et al. 1997). A study on the strength of H-bonding of WC base pairing under metalation at various active sites of bases concluded that the N3(Adenine) site available in the minor groove has higher chances for platination, in comparison with the N7-site of the base (Zhang and Huang 2007).

The results of investigation on $\text{Cu}^+/\text{Cu}^{2+}$ interaction with AT and GC pairs were published by Sodupe's group (Noguera et al. 2004, 2007). The influence of metal cations coordinated to N7 of guanine on the intermolecular proton-transfer reaction in guanine-cytosine base pair was studied with the B3LYP density functional. Gas phase metal cation interaction stabilizes the ion pair structure derived from the N1-N3 single-proton-transfer reaction, the effects being more pronounced for the divalent cation than for the monovalent one. For Cu^{2+} -GC, the reaction is largely favored due to both electrostatic and oxidative effects. Hydration of the metal cation reverts this trend due to the screening of electrostatic effects.

In the section on the interaction of hydrated metal complexes, Šponer's study (Šponer et al. 1998a) was mentioned where in addition to purine nucleobases, the GC, AT, and AA base pairs were also considered. Since the metal-purine base interaction is not substantially influenced by the remote pyrimidine base we will

focus on the base pair enhancement and some changes observed in comparison with the study on bare metal cations complexes (Burda et al. 1997). The strength of the guanine-cytosine Watson-Crick base pair is enhanced by ca. 20–30 % due to the coordination of the hydrated cation, while in the case of bare cations this enhancement was about 60–90 %.

In the study of Oliva et al. (Oliva and Cavallo 2009), an impact of binding of hydrated Mg^{2+} , Mn^{2+} , Co^{2+} to the N7 position of guanine on Watson-Crick and reverse Watson-Crick base-pairs was investigated at the MP2 level. The combined model, where implicit solvent (COSMO) is considered together with an explicit first hydration shell of the cation shows that the stabilization effect of metalation on Watson-Crick geometry is rather weak – from 0.1 kcal/mol for Mg^{2+} to 0.8 kcal/mol for Co^{2+} cation. In the case of reverse Watson-Crick base pair, the stronger stabilization was determined in the range from 1.7 kcal/mol for Mg^{2+} and Mn^{2+} to 2.2 kcal/mol for Co^{2+} , which is in accord with our previous study (Šponer et al. 1998a). It was also shown that for the hexahydrated cations, the binding energies increase in the order $Mg^{2+} < Mn^{2+} < Co^{2+}$. The lowest stability of Mg^{2+} cation can be explained by missing back-donation from the aromatic ring of the guanine to empty d orbitals of metal. An impact of metalation of GC base-pair by hydrated Mg^{2+} , Ca^{2+} , Zn^{2+} , Cu^{2+} on vibrational spectra was studied using SIESTA code by Morari et al. (2012, 2014) clearly showing the effect of adduct formation.

An interesting comparison of Zn^{2+} and Mg^{2+} hydrated cations in Pu-Pu-Py triplexes was carried out (Šponer et al. 1998b) where a hydrated metal is coordinated to the N7 position of purine base attached to the Watson-Crick base pair. Using this model, metal assisted triplex stabilization was studied. It was shown that in both A.A and GG, the Hoogsteen pairing is strengthened under metalation. A substantially stronger enhancement of (MG).G pairing was revealed (19.8 and 20.4 kcal/mol for Mg^{2+} and Zn^{2+} cations, respectively), in comparison with similar adenine structures where no additional stabilization was practically detected (only about 2.7 kcal/mol for both metal cations). In another study (Šponer et al. 1999d), a more extended set of divalent metal cations (Mg^{2+} , Ca^{2+} , Sr^{2+} , Ba^{2+} , Zn^{2+} , Cd^{2+} , and Hg^{2+}) hydrated by five water molecules was explored with rAA and AT base pairs interacting with N7 site of adenine confirming the previously obtained results.

Rare tautomers of NA bases are important from the point of view of the global mutagenicity of DNA. Their formation by proton transfer between N1(G) and N3(C) in canonical Watson-Crick base pair was studied by Céron-Carrasco et al. (Ceron-Carrasco and Jacquemin 2011), extended later using ONIOM (QM/QM) method (Ceron-Carrasco et al. 2012b) for metalated B-form d(G-C,Mg-G-C,G-C) trimer. These authors explored also cisplatin cross-linked ds-DNA 5'-d(AG*G*C)-3' (Ceron-Carrasco et al. 2012a) tetramer. In the latter case, the calculations of PT energy profile were performed using ONIOM approach at M06-2X/6-311++G(d,p):AMBER(UFF) level with both crosslinked G*C base pairs and cisplatin in the QM part. LANL2DZ basis set was used for a description of Pt atom. The formation of the rare tautomer in crosslinked G*C pairs through the PT is characterized by an increase of the electronic energy by 9–12 kcal/mol if the considered DNA arrangement is close to the experimental NMR structure

Fig. 13

Cytosine- M^+ -Adenine complexes, $M = (\text{Cu}, \text{Ag}, \text{Au})$

(Wu et al. 2007). The corresponding activation barriers are only by 0.2–0.5 kcal/mol higher than reaction energy in the given case. In the former case, the hydrated Mg^{2+} cation is coordinated to nitrogen N7 of guanine. The reaction energy of 3.2 kcal/mol and the activation barrier of 8.0 kcal/mol for the considered N1(G) to N3(C) proton transfer were determined at M06-2X/6-311++G(d,p):B97-D/6-31+G(d)/PCM level. The inner part was consisted of GC base pair and hydrated Mg^{2+} cation.

An interesting idea is related to a replacement of proton in H-bonding by metal. Nowadays, these metal mediated NA base structures are highly investigated for the purpose of obtaining novel materials which might be employed as, for example, electric, fluorescent, or luminescent sensors. In this way, the noncanonical A-C base pair was examined with the coinage metal cations (Cu^+ , Ag^+ , and Au^+) used as a bridge between both bases (Šponer et al. 1999e), cf. Fig. 13. A possibility of additional water coordination to the metal was also considered. In the original paper, it is concluded that these metal bridged complexes are substantially more stable than original (protonated) base pair. The water coordination does not influence the strength of the metal bridge substantially; nevertheless, its presence has some impact on the geometry of the complexes. Comparing bonding properties of all three metal cations, it was found that Ag cation coordinates relatively weakly, which is in good accord with the previous results (Burda et al. 1996, 1997). Slightly shorter bond length $d(\text{M-N7-Adenine})$ than $d(\text{M-N3-Cytosine})$ contradicts the estimated bonding energies since ΔE^{M-A} is smaller than ΔE^{M-C} . This can be explained by two facts: (a) the electrostatic contribution to the metal coordination is much smaller in adenine case (see the size and orientation of the dipole moments of both bases in Fig. 2) and (b) the metal-cytosine interaction cannot be considered purely of the M-N3 character since the M-O2 contribution plays a nonnegligible role too.

Schreiber et al. (Schreiber and Gonzalez 2007a) explored the Ag(I) adducts with DNA base and the influence of Ag(I) coordination for adenine-cytosine mispairing. Their calculations show that in gas phase the canonical form of cytosine is stabilized upon metalation, whereas the lowest energy structure of Ag-adenine corresponds to the imino tautomer. The most stable metalated adenine-cytosine mispair is formed from the canonical cytosine and adenine tautomers. Other types of A-C pairs (e.g., reverse Wobble) were found much less stable. The same authors also performed

an interesting study dealing with the role of Ag(I) cation on electronic spectra of the A-C pairs using very accurate MS-CASPT2 approach (Schreiber and Gonzalez 2007b).

Stability of silver-mediated cytosine:cytosine or cytosine:adenine mismatches was also studied in implicit solvent in more recent studies (Megger et al. 2011a; Fortino et al. 2015). In the case of C:C mismatch, the Ag⁺ cation is coordinated to both N3 nitrogen atoms and the trans arrangement of cytosines is favorable since it enables formation of the weak hydrogen bond O2...H-N4 (2.13 Å). The presence of this hydrogen bond simultaneously causes that N3-Ag-N3 angle is about 160°. Counterpoise corrected binding energy (BE) for described base pair is 34 kcal/mol at B3LYP-D3/6-311++G(2df,2pd)/SDD/COSMO level while the gas phase BE is 43 kcal/mol according to ref. (Fortino et al. 2015).

In contrast to rather planar geometry of C-Ag-C structure, one of the pairs in DNA dimer d(C-Ag-C)₂ is characterized by rather large propeller twist of 78°. The Ag...Ag distance (3.9 Å) in the optimized dimer structure is comparable with Hg...Hg distance of 3.8–3.9 Å in (T-Hg-T)₂ dimer (Benda et al. 2011). BE of dimer (73 kcal/mol) shows that this energy is practically additive.

Considering C-Ag-A base pair, the Hoogsteen arrangement, where Ag⁺ ion is coordinated to N7(A) and N3(C) nitrogen atoms, is more favorable than the Watson-Crick type. The corresponding energy difference is 5.9 and 2.3 kcal/mol for C-Ag-A monomer and (C-Ag-A)₂ dimer, respectively.

It was found that if concentration of Ag⁺ ions is sufficient, stabilization through two Ag⁺ ions becomes preferable in the case of thymine:1,3-dideazaadenine (D) base pair (Megger et al. 2011b). In addition to usual N7(D)-Ag-N3(T) linkage, the second Ag⁺ ion is coordinated to N6(D) nitrogen and O4(T) oxygen. The optimized mutual distance between Ag atoms is 2.88 Å. The energy difference of 24 kcal/mol between the base pair with two Ag linkage atoms and the base pair with one linkage N7(D)-Ag-N3(T) plus monohydrated Ag⁺ ion was determined at the ZORA-BLYP-D/TZ2P/COSMO level.

Interestingly, possibility of the so-called M-DNA crosslink stabilization of GC base pairs by divalent zinc has been investigated by Fuentes-Cabrera et al. (2007). Further, stabilizations of the base pair of Watson-Crick (AT, AU, GC), Hoogsteen (AT, AU), and Wobble (GU) type by Ib transition metals – Cu⁺, Ag⁺, and Au⁺ cations – were explored (Marino et al. 2012). Additionally, 1-deazaadenine instead adenine was considered in the case of the Hoogsteen type base pairs. The metal cation is coordinated to N7 nitrogen of purine bases and N3 nitrogen of pyrimidine bases in these structures except for N1(G)-M-O2(U) linkage in Wobble base pair. In order to maintain one strong hydrogen bond in Watson-Crick base pairs after incorporation of the metal ion, angle N3-M-N7 is not exactly 180°, but it is in the range from 150° to 180°. The coordination of the metal cation causes an increase of binding energies (determined at the B3LYP-D3 level in gas phase) about 20–35 kcal/mol in comparison with hydrogen-bonded base pairs. Independently on the base pairs and type of binding, stabilization by Cu⁺ and Au⁺ cations is comparable, while in the case of Ag⁺ ion, the binding energy is about 10–20 kcal/mol lower in agreement with (Šponer et al. 1999e).

A detailed study of formation of (T)N3-Hg-N3(T) linkage was performed by Šebera et al. (2013b) The ds-DNA was modeled as trimer G-C, T-T, T-Hg^{II}-T, and the ONIOM (B3LYP/6-31G(d)/SDD:BP86/LANL2DZ with implicit water solvent IEF-PCM/UFF) was used. The initial step represents proton transfer from N3 to hydroxo ligand of hydrated Hg²⁺ ion and subsequent formation of the first Hg-N3(T1) bond. This step is slightly endergonic ($\Delta G_r = 1.4$ kcal/mol) and is related to the very low barrier of 2.9 kcal/mol. The reaction proceeds with the second proton transfer from N3(T2) to O2(T2) (tautomerization) or to another hydroxo ligand of Hg²⁺ ion if it is present. The activation barrier corresponding to tautomerization is 16.5 kcal/mol high, while for proton transfer to the hydroxo ligand the barrier is about 3 kcal/mol lower. The total reaction Gibb's energy is -9.5 kcal/mol and the bond length of both Hg-N3 bonds is 2.15 Å, when the deprotonated product at O2 position was considered.

In order to show changes in electronic properties after formation of Hg^{II} linkage between thymine: thymine mismatch, a charge transfer from donor Ap to acceptor G in ds-DNA tetramer sequence Ap-T-A-G was studied in the low temperature region (Kratochvílová et al. 2014). Electronic coupling $|J_{Ap,G}|$ between Ap and G bases determined using relativistic ZORA at the B3LYP/TZ2P/COSMO level shows that the value of $|J_{Ap,G}|$ increases about 4–5 meV after formation of the Hg^{II} linkage compared to T-T mismatch structure. When the structure of the metal-mediated mismatch is preserved and just Hg atom is removed, the value of $|J_{Ap,G}|$ decreases only by 1 meV. Hence, it was concluded that the structure of the thymine-thymine mismatch is more important for the charge transfer than the presence of Hg²⁺ cation.

Also differences in Raman spectra related to formation of T-Hg^{II}-T linkage were investigated both experimentally and theoretically (B3LYP-D2/6-31+G**/COSMO) (Benda et al. 2012). Spectral shifts are fairly small for both experimental and calculated spectra. However, calculated spectra provide usually slightly overestimated values compared to the experiment. An exception represents the vibrational mode corresponding to C = O stretching (1664 cm^{-1} in TpT), where the red shift of -77 cm^{-1} was observed.

The stability of dimer Tp-Hg-T · T-Hg-Tp with two Hg²⁺ ions was verified for RNA analogue U-Hg-U · U-Hg-U dimer at the spin-component-scaled MP2 level (Benda et al. 2011). The equilibrated distance $d(\text{Hg}\cdots\text{Hg})$ was determined to 3.8–3.9 Å. Simultaneously, a metallophilic attraction (dominance of a dispersion interaction over repulsive electrostatic one) between Hg atoms was estimated in the range from -1.1 to -0.7 kcal/mol according to a mutual arrangement of the metal-mediated base pairs. The trimeric systems (T-Hg-T)₃ and (U-Hg-U)₃ were studied by Marino et al. (Marino 2014) at B3LYP-D3(M06-L)/TVP level in the gas phase. The vertical binding energies between layers were 29.8 and 30.8 kcal/mol for (T-Hg-T)₃ and (U-Hg-U)₃, respectively. The binding energies of Hg²⁺ ion in T-Hg-T and U-Hg-U monomers was also determined and their values are 200 and 186 kcal/mol.

Study focused on Ag-mediated Hoogsteen-type base pairs containing cytosine and modified 1,3-dideazapurine and 1-deazapurine at exocyclic O6 position with hydroxo, methoxo, fluoro, chloro, and bromo group was published (Megger et al.

2011a). It was concluded that BE were always lower in comparison with the mediated C-Ag-G base pair except the base pair containing 1,3-dideaza-6-hydroxypurine, which is characterized by the same energy.

Interactions of Hydrated Cations with Nucleotides

Šponer et al. (2000b) studied the coordination of hydrated zinc and magnesium group divalent cations to the N7 position of purine nucleotides. They showed that the sugar-phosphate backbone provides a significant screening of the metal charge, while the backbone geometry is affected by the cation. Polarized water molecules of the cation hydration shell form very strong hydrogen bond bridges between the cation and the anionic oxygen atoms of the phosphate group. Weaker hydrogen bonds are formed between the cation hydration shell and the exocyclic purine X6 atoms. The cation binding to N7 of adenosine monophosphate forces the adenine amino group to adopt nonplanar conformation. Its nitrogen atom serves as an H-acceptor for a water molecule from the cation hydration shell. Cation binding to N7 does not lead to any major changes in the geometry of the base pairing. However, the stability of the base pairing can be increased by polarization of the purine base by the cation and by long-range electrostatic attraction between the hydrated cation and the other nucleobase. The stability of guanine-cytosine Watson-Crick base pairing is enhanced by the polarization mechanism while the stability of the adenine-thymine Watson-Crick base pair is amplified by the electrostatic effects as shown in the case of base pairs model discussed previously (Burda et al. 1997). Also, the guanine-guanine reverse-Hoogsteen base pairing is stabilized by both contributions while the adenine-adenine reverse-Hoogsteen system is not influenced by the cation. Binding of a cation to the N7 of guanine promotes transfer of its H1 proton to the N3 acceptor site of cytosine. However, the negatively charged backbone exerts a significant screening effect on this potentially mutagenic process, and the probability of such a proton transfer in DNA should be only moderately enhanced by a cation binding.

A comprehensive study dealing with a coordination of hydrated cations Zn(II) and Mg(II) to guanosine 5' monophosphate was performed by Gresh (Gresh et al. 2003) in order to obtain parameters for polarizable molecular mechanics for metal-DNA and metal-RNA simulations.

An important role of the position of Mg^{2+} ion in the active site of hepatitis delta virus (HDV) ribozyme during its self-cleaving process was described by Mlynsky et al. (2015) using the ONIOM method implemented in Gaussian 09. The reaction starts with deprotonation of O2'-H(U-1) group in the active site of HDV, which is followed by the nucleophilic attack of O2'-(U-1) on phosphorus of the scissile phosphodiester. As a consequence, the P-O5'(G1) bond is broken and O5' position is saturated by the proton from C75 (cf. Fig. 14). The protonated state at the N3 position of C75H⁺, which occurs with only low probability, was considered as a reactant (estimated pKa for this protonation is 8.8–11.2) together with $[Mg(H_2O)_nOH]^+$ used as Brønsted base. The experimentally determined pKa constant for hydrated Mg^{2+} ion is 11.4. On the basis of estimated pKa constants, the Gibbs energy correction for considered protonation state of reactant was 8.3 kcal/mol. In ONIOM calculations (BLYP/6-31 + G(d,p):AMBER(ff99bsc0χOL3), reoptimized with hybrid

Fig. 14 Active site of HDV ribozyme with coordinated Mg^{2+} cation. Electron transfers during the self-cleavage process are depicted by *arrows*

MPW1K functional), the authors considered eight pathways with the different position of Mg^{2+} ion coordination in reactants based on previous MD simulations. The QM part contained hydrated Mg^{2+} cation, uracil U-1, G1 guanosine, cytosine C75, and guanine G25. The resulting Gibbs energy barriers are in the range from 14.2 to 28.8 kcal/mol and the lowest barrier (14.2 kcal/mol) corresponds to the initial coordination of Mg^{2+} cation to O2(U-1) and O2'(U-1).

Enhancement of Base Pairing by Pt Complexes

Several studies related to platinum metal interactions with base pairs and the influence of metal complexes on the strength of pairing should be mentioned.

Molecular structures of several Pt complexes with the Watson-Crick AT and GC base pairs were optimized using the B3LYP method. The interaction energies were analyzed using B3LYP and MP2 approaches (Burda et al. 2001). Platination causes some distortion in the H-bond arrangement of the base pairs. The pyrimidine bases rotate around their centre of mass under the influence of the charged Pt entities. This effect is quite general and was already discussed above (Burda et al. 1997; Šponer et al. 1998a, 1999b). The metal-binding affects the strength of individual H-bonds involved in the base pairing. It was concluded that ligands attached to the Pt(II) cation form rather strong intramolecular H-bonds with the X6 exocyclic site

of purine bases. The adenine amino group adopts a pyramidal-rotated geometry and its nitrogen serves as H-bond acceptor for the ammine ligands of cisplatin.

The Pt-binding has a comparable effect on the base pairing stability as binding of hydrated metals of IIa and IIb groups. In the electroneutral form, the Pt-adducts does not practically influence the base pair stability. Charged Pt adducts substantially strengthen the stability of GC base pair via polarization effects. The influence of the +2 charged Pt-adduct is even larger compared with hydrated metals of IIa and IIb groups. No such polarization effects have been revealed for the AT base pair. However, gas-phase stability of this pair is effectively enhanced by long-range electrostatic interaction between the charged metal group and thymine.

The dependence of the stabilization and Pt-N7 binding energies on the total charge of the complex is displayed in Fig. 15a. Here, the role of electrostatic contributions is clearly demonstrated for the both kinds of energies. Interestingly, in electroneutral complexes, the Pt-N7 binding energies are similar in guanine and adenine structures (≈ 50 kcal/mol corresponding to “pure” coordination covalent contribution). In the Fig. 15b, the base pairing energies are drawn showing that the geometry deformations do not basically influence these values. Nevertheless, the interaction of metalated purine base with pyrimidine base is substantially strengthened, especially in the case of charged complexes (e.g., in complexes of hydrated cisplatin). It is important to point out that the effect of base pair stabilization enhancement due to cation binding has been confirmed experimentally by Sigel and Lippert (1999).

Fig. 15 (a) Stabilization and metalation Pt-N7 energies. (b) Enhancement of the Watson-Crick pairing energies for AT and GC base pairs

Table 7 Gas phase stabilization energies of the Pt-cross-linked structures (in kcal/mol)

Pt-a ₂ AG	514.6
Pt-a ₂ G ₂	528.3

Zilberberg et al. reported an influence of chelated cisplatin complex with guanine(O6,N7) on Watson-Crick base pairing (Zilberberg et al. 1997). In such chelate structures, more distinct perturbation of base pairing was revealed. However, such chelate binding pattern is unlikely to be relevant to experimental conditions.

Metal Cross-Linked DNA Structures

Platinum(II) Complexes

Cisplatin bridges between two consequent bases (1,2-GpG) are believed to be the key structure for triggering the apoptotic process. Recently, several studies on these cross-linked structures have been published. The properties of Pt-bridges were explored (Burda and Leszczynski 2003; Zeizinger et al. 2004) showing that relatively strong Pt-N7 coordination is formed. The process of the aqua ligand replacement by a nucleobase is mildly exoergic in both steps forming: (a) a monofunctional adduct and, consequently, (b) the cross-linked structure. Stabilization energies of the Pt-GG, Pt-GA, and Pt-AA bridges are collected in Table 7. The relative amount of these values correlates well with the abundance of individual structures in real samples, assuming the gas-phase calculations require some additional rescaling in correspondence to the reduced electrostatic interactions in solvent.

An influence of the sugar phosphate backbone on the strength of Pt-bridge was also examined (Zeizinger et al. 2004). An additional stabilization of the Pt cross-linked structures appeared as a result of the interaction between negatively charged phosphate group and the Pt cation.

One of the first papers studying transition states of the replacement aqua ligand by nucleobase was published by Chval (Chval and Sip 2003). His model was based on the gas-phase calculations and the estimated activation barrier is too low in comparison with the experimental value. This situation was improved in studies of Raber (Raber et al. 2005) and Baik (Baik et al. 2003). They have taken into account the hydration effects employing implicit solvent model. Especially, Raber's results are in fairly good accord with experimental data. Activation barriers of mono aqua and diaqua Pt(II) complexes are summarized in Table 8 for both guanine and adenine replacement of the first and second leaving (aqua) ligand. In Table 9, the activation barriers for second and third generation Pt(II) drugs – oxaliplatin, nedaplatin, and carboplatin – are displayed (Alberto et al. 2011), where higher barriers also occur in the case of adenine. According to the calculation of oxaliplatin, the second reaction step should be visibly more energy demanding.

A comprehensive study on formation of Pt-N7 cross-links between fully hydrated oxaliplatin – cis-[Pt(DACH)(H₂O)₂]²⁺ (DACH = cyclohexane-1R,2R-diamine) – and double-stranded pGpG·CpC dinucleotide was performed by Chval et al. (2013). Structures were optimized in the implicit solvent model at the RI-TPSS-D/MWB-60(f)/def2-SV(P)/COSMO level and the energy profile and interaction energies were subsequently obtained at the ω-B97XD/MWB-60(2f)/6-311 + G-(2d,2p)/IEFPCM/UFF and B3LYP-D/MWB-60(2f)/def2-TPZVPP/COSMO levels. The whole reaction mechanism is depicted in Fig. 16. In the study, both 5' → 3' and 3' → 5' binding directions to the DNA dimer were investigated. The reaction energies for the monoadduct formation are –3.3 kcal/mol and –1.8 kcal/mol, respectively. The subsequent cross-link formation from the monoadduct is connected with releasing of –1.0 and –8.5 kcal/mol, respectively. Formation of the first Pt-N7 bond represents the rate-limiting step and the binding to N7 (5'G) is slightly kinetically preferred over N7(3'G). The corresponding activation barrier is 21.2 kcal/mol. The following chelation reaction is more favorable in the 3' → 5' direction (activation barrier of 17.1 kcal/mol) in agreement with the experimental measurements. Formation of each Pt-N7 bond leads to an increase

Fig. 16 Scheme of the reaction mechanism for formation of the cross-linked structure by fully hydrated oxaliplatin

of the stabilization between the ds(pGpG) and the Pt(DACH) fragments by about 15 kcal/mol in aqueous solution. Further, the solvent-phase pairing energies are enlarged by about 10 % with respect to the pGpG · CpC dinucleotide itself and do not visibly depend on the number of Pt-N7 bonds for most of the platinated structures. Simultaneously, hydrogen bond O6(G) ··· H4(C) is weakened as a consequence of interaction between amino group of Pt(DACH) and O6 (G). Nevertheless, the described weakening is compensated by strengthening of H1(G) ··· N3(C) and H2(G) ··· O2(C) H-bonds.

An arrangement of two adjacent guanosines (G), which are cross-linked by kiteplatin (cis-Pt(1,4-DACH)Cl₂), were studied by Margiotta et al. (2015) in the case of cis-Pt(1,4-DACH)d(GpG), cis-Pt(1,4-DACH)d(GGTTT), and cis-Pt(1,4-DACH)d(TGGT). An initial systematic conformation search at the LFMM (Ligand Field Molecular Mechanics) (Deeth 2001; Deeth et al. 2009) level for cis-Pt(1,4-DACH)d(GpG) was followed-up by reoptimization in gas and also aqueous phase using the semiempirical PM6-DH2 method (Korth et al. 2010; Řezáč et al. 2009). It was determined that the head to head arrangement of anticonformers of Gs is preferred over the head to tail arrangement by 6 kcal/mol (in solvent), which is in accord with experimental measurements.

Binding energies of cisplatin, oxaliplatin [(cyclohexane-1R,2R-diammine)-oxalato platinum(II)], and kiteplatin (Fig. 17) are mutually compared by Mutter et al. (2015). The strongest binding energy was determined for cisplatin if the interaction of Pt complexes with GpG · CpC dimer was considered at the DFT level (B97-D/TZVP). Binding energies of kiteplatin and oxaliplatin are comparable. This trend is independent on the fact whether the system is in the gas phase or in the water solution represented by COSMO solvent model. Nevertheless, when the GpG · CpC dimer is replaced by octamer (ds-CCTGGTCC) and QM/MM approach was used, the binding energies of cisplatin are the weakest, then follows kiteplatin and the strongest interaction shows oxaliplatin (cf. Table 10). In another study (Gkionis et al. 2013), the interactions of heptaplatin ([2-(1-Methylethyl)-1,3-dioxolane-4,5-dimethanamine-*N,N'*]-[propanedioato(2-)-*O,O'*]-platinum(II)) and lobaplatin

(1,2-diammino-methyl-cyclobutane-platinum(II)-lactate) (besides oxaliplatin and cisplatin) with the same octamer were investigated and it was determined that the binding energies are about 38 kcal/mol and 28 kcal/mol, resp., higher than for oxaliplatin. In the former paper, (Mutter et al. 2015) was also mentioned an interesting trend that when the DNA dimer, tetramer, octamer, and dodecamer is considered, the ONIOM binding energy of kiteplatin increases towards octamer, however it is (slightly) smaller for dodecamer. Basically it is a question why binding energy should increase so dramatically with increasing size of the system and it is pity that some deeper analysis (or energy decomposition) is not present.

Ruthenium(II) Complexes

An interesting continuation of the investigations of the “piano-stool” Ru(II) complexes with DNA base mentioned from section “Properties of Metal Adducts with Nucleobases” represents formation of Ru(II) cross-linked structures studied using hybrid ONIOM and QM/MM Umbrella sampling-MD by Futera et al. (Futera and Burda 2014; Futera et al. 2012). An interaction of piano stool complexes with DNA is to some extent similar to cisplatin. The considered representative of piano stool complexes, $[\text{Ru}^{\text{II}}(\eta^6\text{-benzene})(\text{en})\text{Cl}]^+$, must be initially activated by hydration reaction. Subsequently, the Ru(II) complex/DNA monoadduct is formed with the

Fig. 18 Formation of Ru(II) cross-link in the presence of hydrated $[\text{Ru}^{\text{II}}(\eta^6\text{-benzene})(\text{en})\text{Cl}]^+$ complex

bond between Ru and N7 nitrogen of one of the adjacent guanines G^* . Formation of the Ru(II) cross-link is completed by binding of the complex to N7 position of the second guanine G^* (cf. Fig. 18).

The free energy profile in QM/MM MD approach was built using the umbrella sampling approach together with weighted histogram analysis (WHAM) and umbrella integration (UI) methods at the B97D/LANL2DZ:AMBER(parm03) level. Additionally, the FEP (free energy perturbation) corrections determined at B3LYP/SDD/6-31++G(d,p) level were added to increase the accuracy of the model. The ds-DNA was modeled by decamer structure with 5'-AATGG1*G2*ACCT-3' sequence. The QM core consists of the piano-stool complex and one explicit water molecule in hydration reaction and of hydrated Ru(II) complex and both adjacent guanines G^* in the remaining reactions.

For hydration reaction with smaller quantum core, the B3LYP/SDD/6-31G level was used. The Gibb's free reaction energy corresponding to this activation process is 2 kcal/mol and the activation barrier of 19.5 kcal/mol is in good agreement with experimental value (21.1 kcal/mol) (Wang et al. 2005). Formation of the monoadduct and subsequent cross-linked structure leads to decrease of total ΔG energy of the system by 3.4 kcal/mol and 9.5 kcal/mol, respectively. The most stable form of the monoadduct, i.e., with Ru-N7(G1^*) coordination, is not formed directly; the substitution goes through a structure where Ru-O6(G1^*) is formed first as an reaction intermediate. Similarly to the study (Chval et al. 2013) mentioned above, coordination of the Ru complex to guanine G represents the rate-determining step characterized with the activation barrier of 21.1 kcal/mol in the two step mechanism. Formation of the (G1^*)N7-Ru-N7(G2^*) cross-linked chelate complex is connected with release of the arene ligand, which is initially η^6 -coordinated. In the products, Ru-N7(G2^*) bond to the 3'-end guanine is substantially weaker

which is documented by bonding energies of -47 kcal/mol and -35 kcal/mol for Ru-N7(G1*) and Ru-N7(G2*), respectively. The previous ONIOM calculations at the B3LYP/6-31++G(d,p):AMBER(ff96) level (Futera et al. 2012), where the ds-DNA hexamer 5'-GCG*G*GC-3' model was used, predict higher activation barriers by about 4 kcal/mol for monoadduct formation in the two-step mechanism and by about 2 kcal/mol for direct monoadduct formation.

Ions in DNA Quadruplexes

The infrared (IR) and vibrational circular dichroism (VCD) spectra of guanosine-5'-hydrazide have been measured and analyzed on the basis of ab initio modeling (Setnicka et al. 2008). The B3LYP/6-31G(d,p) calculations predict that guanine, forming a clear solution in deuterated DMSO, is present in monomeric form in this solvent, whereas strong gelation in a phosphate buffer is due to the formation of a guanine-quartet structure. Here, the four bases are linked by hydrogen-bonded guanine moieties and stabilized by an alkali metal cation. The DFT prediction of the IR and VCD spectra are based on the nearly planar quartet structure, which is slightly distorted from the C_{4h} symmetry. The guanine bases interact via four Hoogsteen-type hydrogen bonds and a sodium cation is positioned in the middle of the guanine quartet. The obtained results are in very good agreement with the experimental spectra, indicating that calculated structure is highly probable in the gel state.

The guanine quartets were examined also by Gu and Leszczynski (2000). The normal four-stranded Hoogsteen-bonded G-quartet structures were optimized in the gas-phase with a monovalent cations obtaining the stability order $\text{Li}^+ > \text{Na}^+ > \text{K}^+$. However, after the correction on solvent effects, the stability sequence of the monovalent cation-guanine-tetrad complexes follows the opposite trend $\text{K}^+ > \text{Na}^+ > \text{Li}^+$. The preferential binding of potassium over sodium and lithium in water solutions reproduces the experimental ion selectivity of the guanine quadruplex. Moreover, the weak stabilization energy of the K^+ -G-quartet in the coplanar form corresponds with the fact that the potassium cation tends to locate between two successive quartets. These results are in accord with the study of Hud et al. (1998) on the ion selectivity of the guanine quartets in water solutions, which are governed by the relative free energies of hydration. The experimental data on the cation-oxygen distances in the sodium ion complex are 2.34 ± 0.02 Å. This value matches the HF value of 2.33 Å. The slightly shorter Na^+ -O6 distance were predicted by the DFT approach together with a significant shortening of the hydrogen bonds suggesting an overestimation of the H-bonding in the guanine quartets at the DFT level. A very comprehensive study on metal-quartet interactions has been published also by Meyer et al. (Meyer et al. 2001). It is to be noted, however, that, in principle, accurate studies of quadruplex-ion interactions would require inclusion of the whole solvated quadruplex fragment, due to the unique balance of molecular interactions in such a noncanonical structure (Šponer and Špacková 2007).

Fig. 19 An initial localization of ion(s) in 15-TBA in five studied systems

Apart from papers concerning guanine stems, duplexes consisting of all NA and isoguanine (iG) tetrads and iG pentads were investigated by Meyer et al. (Meyer et al. 2005, 2007; Meyer and Sühnel 2008) where K^+ or Na^+ ion was used for stabilization of these structures.

Seven distinct folds of two-quartet G-DNA stem which is stabilized by monovalent K^+ ion were studied using the large-scale QM calculation (Šponer et al. 2013). In contrast to the previous studies by Meyer (Meyer and Sühnel 2008), dispersion is included in the model. Optimization of the structures was performed at the RI-TPSS-D3/TZVP/COSMO level and results were compared to few MD approaches. It was shown that the relative stability of 5'-anti-anti-3' GpG steps (AA) in G-stems is underestimated in comparison with 5'-syn-anti-3' steps (SA) at the MM level. The final reevaluated stability order (due to the MM approach) gives that the AA arrangement is the most stable followed by SA step lying by 1.2 kcal/mol higher. An exception represents the terminal SA step at the 5'-end, which is by 3.2 kcal/mol more stable than the AA arrangement.

A localization of an ion in the quadruplex stem was investigated at the QM/MM MD level by Reshetnikov et al. (2011). As the model structure, the thrombin-binding aptamer (structure 15-TBA in PDB database) was chosen. The QM part was consisted of all nucleic acid bases (except T7) and K^+ or Ba^{2+} ions and was considered at the DFT level using the PW91 functional. The initial position (upper, central, lower) of ion(s) in five studied systems is depicted in Fig. 19. In systems 1–4, K^+ ion was present, while Ba^{2+} ion was considered in system 5. It was concluded that only the central binding site is stable, since the ion in the systems 1 and 3 moved to the center of the stem. Further in system 4, the lower ion was released and the upper one moved to the center.

The study of Gkionis et al. (2014) explored an ion binding in guanine stems at the DFT-D3 and the MM level (Cornell force field (Cornell et al. 1995)). Series of PES scans of binding of one ion (Li^+ , Na^+ , and K^+) to two- and three-quartet stems (without the sugar-phosphate backbone) and subsequent PES scans for binding of the second cation were performed for this purpose. In the single-ion case, the difference between the DFT-D3 and MM approach becomes acceptable, when the implicit solvent (COSMO in QM calculations and MM-PBSA (Poisson-Boltzmann surface area)) is concerned as the model. However, in the gas phase, a more attractive potential inside the channel for single-ion case was obtained at the MM level. A different situation occurs in a multi-ion case. The problem dwells in the missing polarization in the MM calculations. Symmetry adapted perturbation

theory (SAPT0) energy decomposition showed substantially weaker electrostatic repulsion between ions at QM level, where the ions can be polarized. Same results followed from the QTAIM analysis. Authors concluded that system with more than one cation cannot be even described correctly with fixed charged model, where the reduced charge on ions in MM simulation is considered.

Noncovalent interactions in two or three stacked guanine or xanthine quartets containing one or two univalent cations (Na^+ , K^+) were also investigated at DFT-D3 level by Yurenko et al. (2014). The study shows a structural and energetic compatibility between guanine and xanthine quadruplexes. The hydrogen bonding, ion coordination, and base stacking contributions to the total internal stabilization are compared. The determined contribution of hydrogen bonding is practically independent on the size of the system, and it approximately corresponds to 50% of the total noncovalent interaction. On the contrary, electrostatic repulsion between cations in trimer systems causes a slight decrease of a share of ion coordination on the total stability, which represents 34–41% of interaction energy for the duplex. A higher influence of K^+ ion on weakening of hydrogen bonds in the duplex compared to Na^+ cation is caused by stronger interaction with O6 atom given by its larger ionic radius is also mentioned. In general, the absolute values of the energy of ion binding to the considered quadruplex structures are higher for Na^+ than for K^+ . An Energy decomposition analysis further shows that the orbital contribution to ion binding is not negligible in comparison with the electrostatic term. Hence, it was concluded that ions interaction in the stem channel cannot be described purely by an electrostatic model.

A similar topic was examined also by Ida (Ida and Wu 2008). In this study, molecular dynamics was employed exploring G-quadruplex stabilized by Na and Rb cations, which were found to be tightly bound to the quadruplex structure. Moreover, in d(G(4)T(4)G(4)) sequences, the Na^+ ions are found to be located in the diagonal T-4 loop region of the G-quadruplex, which is formed by two strands of d(G4T4G4) sequence. The authors proposed that the loop Na^+ ion is located above the terminal G-quartet, coordinating to four guanine O6 atoms from the terminal G-quartet, one O2 atom from a loop thymine base, and one water molecule. The Na^+ coordination was also supported by quantum chemical calculations on ^{23}Na chemical shifts.

Conclusions

In this review, the results of some of the recent investigations on metal interactions with nucleobases, base pairs, and larger models (including base stacking or oligomer sequences) are summarized.

The studies dealing with metal cations (in naked, hydrated, and ligated forms) provide various details on their interactions with nucleobases, however such models are in many cases oversimplified. Despite the fact that some sites on the isolated nucleobase (especially in adenine) exhibits higher affinity to metal cations, in DNA helix not all of them are available for interactions since they are involved in H-bonding (purine N1 site) or in the glycosidic bond (N9 site).

All forms of metal cations enhance the Watson-Crick base pairing interaction if their positive charge is not fully compensated. The different mechanism for the AT and GC adducts was revealed. While in AT the direct electrostatic link between remote thymine (negatively charged O4) and metal cation exists, in the GC pair the nonadditive three-body term is important since the positively charged $\text{NH}_2(\text{C})$ exogroup is in the proximity of the metal cation.

Clearly, metalation at the N7 position leads into many new, exceptional properties of the studied systems that are dependent on characteristics of involved metals. Some of them are discussed in details in various parts of this text.

Acknowledgments The study was supported by projects Grant Agency of the Czech Republic (GAČR) No. 16-06240S. The authors thank the Meta-Centers in Prague (Charles University and Czech Technical University), Brno (Masaryk University), Pilsen (University of West Bohemia) for the generous support of the computational resources.

Abstract

Two-photon absorption (TPA) leads to higher-energy excited electronic states via the simultaneous absorption of two photons. In TPA, the absorption is directly proportional to the square of incident light intensity, and thus lasers are required for excitation. The advantages of TPA microscopy include better focus and less out-of-focus bleaching, together with absorption at longer wavelengths than in one-photon absorption, which leads to deeper penetration in scattering media, such as tissues. However, TPA probes are usually associated with less sensitivity, and thus designing TPA fluorophores with large absorption probability is an important area of research. TPA of biological molecules like fluorescent proteins and nucleic acids is of particular interest. These molecules are experimentally produced through utilization of the naturally present transcription mechanism in the cell and thus pose less cell toxicity. In this chapter, we review the theory of TPA highlighting the computational approaches used to study biological

molecules. We discuss the computational methods available for exploring TPA and recent computational studies on the TPA of fluorescent proteins and nucleic acid base analogues. The chapter concludes by highlighting possible research avenues and unanswered questions.

Introduction

Two-photon absorption (TPA) is defined as the simultaneous absorption of two photons, of the same or different energies, leading to excitation to a higher electronic state. Although this phenomenon was predicted theoretically in 1931 by Goppert-Mayer, experimental evidence was not available until 1961 (Kaiser and Garrett 1961) after the development of lasers. Since TPA is a third-order nonlinear process, where the absorption is directly proportional to the square of incident light intensity, intense light sources, i.e., lasers, are required to observe significant TPA. The quadratic dependence on light intensity provides better focus and less out-of-focus bleaching and thus deeper penetration in scattering media, such as tissues, as compared to one-photon absorption (OPA) (Denk et al. 1990; Drobizhev et al. 2011). However, there is a drawback as TPA probes are usually associated with less sensitivity. This drove the desire to design TPA fluorophores with large TPA probabilities; see, for example, the reviews by Pawlicki et al. (2009), Ciuciu et al. (2014), and Morales et al. (2013) for more recent work. In TPA, the transition to the excited electronic state is achieved by two photons, and thus the energy of incident photons is approximately half of those used for OPA in the same system. Therefore, the excited state leading to fluorescence can be accessed at longer wavelengths, desirable in biological media where the absorption in the IR or near-IR region is required to overcome the competitive absorption of other naturally present pigments. Moreover, TPA follows different quantum mechanical selection rules from OPA, and therefore both spectra can be used in a complementary fashion (Drobizhev et al. 2011).

The focus of this chapter is the TPA of biological molecules which is gaining more interest as exemplified by the increasing number of recent studies cited here. Optimizing the photophysical TPA properties of proteins and other molecules that could be naturally present in biological systems is of paramount advantage. These molecules are produced through hijacking the transcription mechanism naturally present in the cell, and thus they are usually more benign to the complex cell environment than synthetically introduced dyes or quantum dots that may have other interactions and/or cell toxicity. Moreover, no membrane penetration is needed in the case of endogenously produced biological molecules. For more information on the advantages of using biological molecules, see, for instance, Campbell and Davidson (2010) about fluorescent proteins and the references therein.

In this chapter, we review the theory of TPA highlighting the computational approaches used to study biological molecules. We then discuss the computational studies on the TPA of fluorescent proteins which are of central importance in modern biological imaging and the TPA of nucleic acid base analogues which provide a

newer imaging tool that appears to be very promising. We conclude each section with open questions that should drive more computational (and experimental) work.

Theory

The theory of multiphoton absorption has been reviewed by Cronstrand et al. (2005). Here, we present a brief description of the theory of TPA. The theoretical description of TPA can be understood by considering the interaction of an external electric field, E , with a dielectric material. The induced polarization, P , within the dielectric material is given by

$$P = \varepsilon_0 \chi^{(1)} E + \varepsilon_0 \chi^{(2)} E^2 + \varepsilon_0 \chi^{(3)} E^3 + \dots, \quad (1)$$

where ε_0 is the permittivity of free space, and $\chi^{(n)}$ is n^{th} -order electric susceptibility: $\chi^{(1)}$ represents the linear susceptibility and the quantities $\chi^{(2)}, \chi^{(3)}, \dots$ denote the nonlinear susceptibilities. The two-photon absorption probability (or the cross section, σ^{TPA}) is related to the imaginary part of the third-order susceptibility, as

$$\sigma^{TPA} = \frac{24\pi^2 \hbar \omega^2}{c^2} \text{Im}(\chi^{(3)}), \quad (2)$$

where ω is the photon energy, c is the speed of light, and \hbar is the (reduced) Planck constant.

Susceptibilities are closely related to (hyper)polarizabilities which can be, in principle, computed by quantum mechanical methods (Cronstrand et al. 2005). However, a great simplification can be achieved when the photon energy is such that near-resonant conditions are achieved (Cronstrand et al. 2005). The two-photon transition matrix can then be defined as

$$S_{\alpha\beta} = \sum_n \left[\frac{\langle 0 | \mu_\alpha | n \rangle \langle n | \mu_\beta | f \rangle}{\omega_n - \omega} + \frac{\langle 0 | \mu_\beta | n \rangle \langle n | \mu_\alpha | f \rangle}{\omega_n - \omega} \right] \quad (3)$$

where μ_α (or μ_β) refers to the dipole moment operator in one Cartesian direction ($\alpha, \beta = x, y$, and z), ω_n is the energy spacing from the ground state, $|0\rangle$, to the intermediate state $|n\rangle$, and $|f\rangle$ is the final excited state.

Although this sum-over-states expression (SOS) has been used to compute TPA (see, e.g., Yang et al. 2005), it is generally not computationally efficient due to its slow convergence. On the other hand, response theory offers a more computationally efficient framework through the residue analysis of (hyper)polarizabilities. The two-photon transition matrix elements, $S_{\alpha\beta}$, and the transition dipole moments between excited states can be deduced from the single and double residues of the quadratic response function, respectively (Olsen and Jørgensen 1985).

For linearly polarized light, the transition moment for TPA is

$$\delta^{TPA} = \frac{1}{15} \sum_{\alpha\beta} [S_{\alpha\alpha} S_{\beta\beta}^* + 2S_{\alpha\beta} S_{\alpha\beta}^*]. \quad (4)$$

It can then be shown that the transition moment is related to the previous definition in Eq. 2 by

$$\sigma^{TPA} = \frac{24\pi^2 \hbar \omega^2}{c^2} \text{Im}(\chi^{(3)}) = \frac{4\pi^3 a_0^5 \alpha \omega^2}{c} \delta^{TPA} \quad (5)$$

where α is the fine structure constant and a_0 is the Bohr radius. The two-photon absorption cross section can be related to experimental measurements by including a term for lifetime broadening, $\frac{1}{\pi\Gamma}$, derived from a Lorentzian function:

$$\sigma^{TPA} = \frac{4\pi^2 a_0^5 \alpha \omega^2}{c} \frac{\delta^{TPA}}{\Gamma}, \quad (6)$$

where $\omega = \frac{\omega_f}{2}$ is the photon energy and Γ is the broadening factor. In previous computations, Γ has been chosen as 0.1 eV (Cronstrand et al. 2005; Nifosi and Luo 2007a; Salem and Brown 2014) or 0.5 eV (Friese et al. 2012; Silva et al. 2009) for comparison with experiment. The TPA cross section, σ^{TPA} , is conveniently reported in units of $10^{-50} \text{ cm}^4 \text{ s molecule}^{-1} \text{ photon}^{-1}$ that is referred to as one GM (which stands for ‘‘Goepfert-Mayer’’). Care should be taken when values of computed cross sections are compared in microscopic units due to variations caused by different forms of Eq. 6. In a recent comprehensive study, Beerepoot et al. (2015) discuss the reasons behind these variations and give recommendations for the details that should be provided when TPA cross sections are reported: (i) excitation energies and TPA strengths in atomic units, (ii) the formulae for the conversion to macroscopic units (Eq. 6) and that of the transition moment (Eq. 4), (iii) the proper choice of the conversion to match the experiments (here, we use the full definition for δ^{TPA} and scale Eq. 6 for comparison with single-beam experiments), and (iv) the type of lineshape function (Lorentzian or Gaussian) and the broadening factor. The interested reader is invited to examine the details of the discussion provided by Beerepoot et al. (2015).

The Two-Level Model

The SOS expression (Eq. 3) can be truncated to include only the initial and final (two) states, the so-called two-level model. More generally, the most significant transitions in an excitation scheme can be considered in an N -level model. Such

truncations can be used to relate TPA cross sections to transition dipole moments and permanent dipole moments of the ground state and excited states (Meath and Jagatap 2011, 2013; Meath et al. 2006).

For the first excited state ($f = 1$), and setting $\omega_0 = 0$, the SOS expression can be written within the two-level model as

$$S_{\alpha\beta} = \frac{2}{\omega_1} [\mu_{\beta 01} (\mu_{\alpha 11} - \mu_{\alpha 00}) + \mu_{\alpha 01} (\mu_{\beta 11} - \mu_{\beta 00})]. \quad (7)$$

For the same Cartesian direction ($\alpha = \beta$), it can be expressed as

$$S_{\alpha\alpha} = \frac{4}{\omega_1} \mu_{\alpha 01} (\mu_{\alpha 11} - \mu_{\alpha 00}). \quad (8)$$

From this expression and Eqs. (3) and (4), it is clear that (within the two-level model) the TPA cross section is proportional to the squares of the transition dipole moment and the difference between the permanent dipole moments of the excited and ground states. Hence, structural or environmental effects that increase the extent of charge delocalization upon excitation (while having a large transition dipole moment) would increase the TPA of a system (see section “Fluorescent Proteins”).

Computational Implementation

In this section, key computational implementations of TPA theory within electronic structure programs that can be used for studying biological molecules are highlighted. The interested reader is directed to see the original references for a more in-depth presentation of the computational details. In principle, any method that can provide excited-state properties, i.e., transition dipole moments between and permanent dipole moments for excited states, can be used to compute TPA cross sections within the SOS formalism (with the concomitant slow convergence mentioned previously). In practice, however, TDDFT (Runge and Gross 1984) with quadratic response (Safek et al. 2003; Frediani et al. 2005; Tretiak and Chernyak 2003) has been used extensively to compute TPA cross sections for large molecules because of its relatively low computational cost and, within known limitations, good accuracy (Nifosì and Luo 2007a; Yuan et al. 2013; Terenziani et al. 2008; Beerepoot et al. 2014; Nifosì and Luo 2007b; Vivas et al. 2010; Kamarchik and Krylov 2011; Steindal et al. 2012; Nayyar and Tretiak 2013). In standard response theory, each excited state within the frequency range of interest has to be addressed separately to obtain an absorption spectrum. This complicates the problem in large molecules, as they have high excited-state densities. Damped response theory has been formulated to compute TPA spectra in such cases (Kristensen et al. 2011).

Until recently, higher-level *ab initio* methods were limited to small molecules. A benchmark in 2006 evaluated the effect of electron correlation in TPA computation (for small molecules) using a hierarchy of coupled cluster (CC) models ranging from CC2 to CC3 (Koch et al. 1997; Christiansen et al. 1995a), and the results were compared to those from TDDFT (Paterson et al. 2006). Both Pople- and Dunning-style basis sets were tested. The results highlight the importance of diffuse basis functions especially in larger molecules with the Dunning series performing significantly better than Pople basis sets. These early results showed that TPA cross sections computed via TDDFT with the CAM-B3LYP functional (Yanai et al. 2004) and a modest basis set were in good agreement with the CC3 results (to within 15%). Another study (Friese et al. 2012) on the yellow fluorescent protein (YFP) (Wachter et al. 1998) showed that TPA results of CAM-B3LYP are in qualitative agreement with those from resolution-of-identity (RI) CC2 (Christiansen et al. 1995b; Hättig et al. 1998). A recent benchmark compared the TPA cross sections of fluorescent protein (FP) chromophores as computed by TDDFT for four functionals (B3LYP (Becke 1988), PBE0 (Adamo 1999), CAM-B3LYP, and LC-BLYP (Iikura et al. 2001; Tawada et al. 2004)) and full CC2 to averaged experimental values (see section “Fluorescent Proteins”) (Salem and Brown 2014). Results showed that the B3LYP (Becke 1993) functional with the modest 6-31+G(d,p) basis set can be used to semiquantitatively compare the TPA for the lowest energy excitation of fluorescent protein chromophores. Generally in the response theory formulation, time-dependent perturbation theory is applied to an approximate state, and properties are derived from the residues of the relevant response functions (*vide supra*). An alternative formulation employing the expectation value approach has been developed (Nanda and Krylov 2015) for computing TPA with the equation-of-motion coupled cluster model with single and double substitutions (EOM-CCSD) (Stanton and Bartlett 1993; Bartlett 2010). The method utilizes the RI and Cholesky decomposition (CD) techniques (for further information regarding these approximations, please see Nanda and Krylov (2015) and the references therein). In this approach, expressions for exact states are first derived, and then approximate wave functions are used for evaluation of matrix elements. Other methods that have been applied to large biological molecules, e.g., proteins, are reviewed in section “Understanding TPA of FPs via Computational Studies.”

A number of the computational approaches developed for TPA evaluation are now available in distributed *ab initio* electronic structure software. The DALTON (Aidas et al. 2014) program has flexibility in TPA computation by having both TDDFT and the CC hierarchy of methods with quadratic response available. The GAMESS-US (Schmidt et al. 1993) program can also be utilized for TPA calculations based on TDDFT. Other software includes Q-Chem with recent TPA implementation for the algebraic diagrammatic construction (ADC) method (Shao et al. 2015; Krylov and Gill 2013) and EOM-CCSD (Nanda and Krylov 2015). The implementation of RI-CC2 in Turbomole (2015) (not yet in the latest publicly distributed version, i.e., Version 7.0) also opens the field for the computation of TPA for relatively large biological systems (Wachter et al. 1998).

Applications

Fluorescent Proteins

Fluorescent proteins (FPs) are a family of homologues of the *Aequorea victoria* green fluorescent protein (*avGFP*) that was discovered in the 1960s (Shimomura et al. 1962). Later, the cloning of the GFP gene (Prasher et al. 1992) and its expression in other organisms while maintaining its fluorescent properties (Chalfie et al. 1994; Inouye and Tsuji 1994) paved the avenue to a new era of microscopy and cell biology. FPs are capable of forming a fluorescent chromophore by a posttranslational modification of three amino acids (Ormo et al. 1996; Yang et al. 1996). Changing these precursory amino acids yields different chromophores (see Fig. 1). The chromophore structure provides a coarse tuning of the color of the fluorescence associated with a given FP. Fine tuning is provided by the rest of the protein residues which form a barrel shape encapsulating the chromophore, while changes in the close-by residues of the chromophore can also strongly influence its spectral properties, as further discussed below. Among the full palette of FPs that is now available spanning red to blue FPs (Nifosì and Tozzini 2012; Shaner et al. 2005), red-shifted FPs have been of great interest due to their lower cell toxicity and better tissue penetration for light absorption and emission at these wavelengths (Weissleder 2001). For more information about FPs, the interested reader is directed to any of the available reviews (see, for instance, the book chapter by Campbell and Davidson (2010) and the references therein). The majority of photophysical studies on FPs focused on their OPA with a recent growing interest in TPA properties. Both OPA and TPA properties of FPs have been reviewed by Nifosì and Tozzini (2012).

Experimentally, there is a known general difficulty in measuring absolute TPA cross sections (Oulianov et al. 2001). Measurements in biological systems like FPs are more challenging, and, therefore, the reported measurements of TPA cross sections for a single FP may differ by up to two orders of magnitude, e.g., the reported measurements of the low-energy peak of EGFP (Zhang et al. 1996) vary from 1.5 GM (Hosoi et al. 2008) to 180 GM (Kawano et al. 2008). In 2011, Drobizhev et al. comprehensively cited the available experimental measurements

Fig. 1 GFP chromophore highlighting the head and tail positions that vary between FP chromophores

of TPA cross sections of FPs and discussed the sources of experimental error that could lead to such discrepancies (Drobizhev et al. 2011). Nevertheless, while there are discrepancies in the quantitative determination of the TPA cross sections, the experimentally determined TPA spectra of FPs exhibit common qualitative features: (i) The TPA spectrum generally shows two regions of absorption, one at (nearly) double the wavelength of the OPA peak and an additional (usually stronger) absorption band at a shorter wavelength. (ii) The long-wavelength (low-energy) TPA peak is blueshifted with respect to the corresponding OPA peak in the FPs with anionic chromophores (Drobizhev et al. 2011). In the rest of this section, we discuss the levels of complexity and the various computational approaches and benchmarks associated with TPA studies of FPs highlighting how computations improved our understanding of TPA in FPs and some of the unanswered questions.

Levels of Complexity and Computational Approaches

In general, three levels of complexity influence the TPA of a given FP: (i) The intrinsic nature of the chromophore which is directly related to the extent of π -conjugation and the involved transition and permanent dipole moments (see below) (Nifosi and Luo 2007a; Salem and Brown 2014). (ii) The effect of the protein shell on the geometry of the chromophore (Salem and Brown 2014, 2015; List et al. 2012). This includes consideration of both the change of chromophore conformation due to nearby residues and the conformational flexibility permitted by the hydrogen-bond network of interactions (including with water in the protein cavity) and the steric hindrance inside the protein pocket. (iii) The electric field of the protein surrounding the chromophore, which can greatly influence the TPA cross section (Drobizhev et al. 2011; List et al. 2012).

The first level of complexity is addressed by studying the isolated chromophore. The GFP chromophore is shown in Fig. 1, where we highlight the two sites that vary across FP chromophores. The “head” arises from the R-group of the amino acid Tyr66 which is the second amino acid in the tripeptide that matures into the chromophore. Point mutation of Tyr66 changes the head of the resulting chromophore. The “tail” of the chromophore arises from the amino acid Ser65. An additional step occurs in the maturation of the red FP family resulting in an acylimine moiety which is thought to increase the π -conjugation in these systems (Gross et al. 2000). Further cyclization in the tail region can also take place in some chromophores, such as in mKO (Kikuchi et al. 2008) and mOrange (Shaner et al. 2004; Shu et al. 2006). When studying the bare chromophore, the connections to the protein are broken and capped with hydrogens or methyl groups. In proteins with no additional maturation step (i.e., GFP-like), the tail is usually removed, and the imidazolinone ring is capped. Methyl capping of the GFP chromophore yields the thoroughly studied HBDI model (Nifosi and Tozzini 2012). Salem and Brown showed that methyl capping of FP chromophores with modified tails, e.g., RFP or mBlueberry (Ai et al. 2007), can be necessary to obtain an optimized structure resembling the one found in the protein (Salem and Brown 2014). Even when only the isolated chromophore is considered, its size renders TDDFT as the method of choice for the majority of TPA studies (see section “Computational Implementation”). For TDDFT studies of FP chromophores, it has been shown

that B3LYP and PBE0 functionals yield S_0 to S_1 excitation energies that are very close to the experimental values in the FP, while both energies and TPA cross sections are systematically larger with CAM-B3LYP and LC-BLYP (Salem and Brown 2014). TPA cross sections computed with the four functionals (with the 6-31+G(d,p) basis set) were significantly lower than the corresponding CC2 values using the same basis set (Salem and Brown 2014). The most sophisticated ab initio methods considered at this level of complexity, i.e., for isolated chromophores, were RI-CC2 (Friese et al. 2012), full CC2 (Salem and Brown 2014), and EOM-CCSD (Nanda and Krylov 2015). At this level of complexity, the absolute values of the TPA cross sections for a given protein determined experimentally cannot be reproduced quantitatively by any available computational method. Therefore, computational studies on the isolated chromophores are useful for initial screening of modified chromophores (i.e., to rank their intrinsic TPA cross section) or to study qualitatively the TPA photophysics for a given chromophore.

To address the second level of complexity, the chromophore needs to be studied in its native conformation dictated by the surrounding protein shell. This can be readily accomplished if the experimental three-dimensional structure is available for the studied FP, i.e., a PDB file is available. To go beyond the single-structure static picture, molecular dynamics (MD) simulations can be utilized to sample accessible chromophore conformations in its protein environment. To date, only one study systematically looked at the variations of TPA with chromophore conformations (see section “Understanding TPA of FPs via Computational Studies”) (Salem and Brown 2015). Only a small number of studies have accounted for the third level of complexity by including the electronic (nonmechanical) effect of the protein environment on its TPA. The polarizable embedding (Olsen et al. 2010) (PE)-DFT/MM scheme allows for mutual polarization between the chromophore in its ground state and the protein (ground-state polarizable embedding). More importantly, PE-DFT accounts for the response of the protein electronic degrees of freedom to the excitation of the chromophore through a response formalism (List et al. 2012). The two available studies that utilized PE-DFT are discussed in the following section.

Understanding TPA of FPs via Computational Studies

Although studying a bare chromophore is the simplest approximation, it provides a very good starting point for understanding the TPA properties of a given protein. Through this first level of complexity, Nifosì and Luo explained the origin of the high-energy absorption peak in the TPA spectrum that has no corresponding OPA peak (Nifosì and Luo 2007b). They showed that this peak can be attributed to excitations to higher electronic states (S_0 to S_n). Further, they used TDDFT at the B3LYP/6-31G+(d) level of theory in the gas phase, to compute TPA for a series of FP chromophore models and predicted the presence of such high-energy peaks in other chromophores as well (Nifosì and Luo 2007a). These predicted absorptions were later validated via experiments (Drobizhev et al. 2011). Computations at this first level of complexity also helped to understand the blueshift of the low-energy TPA peak in anionic FP chromophores. It was first suggested that this shift is due to a bright TPA state that is dark under OPA (Hosoi et al. 2008).

No computation, however, found evidence for such a state (Epifanovsky et al. 2009; Polyakov et al. 2010). Kamarchik and Krylov computed the non-Condon effects in the TPA spectrum of an anionic HBDI model (see Fig. 1 and the discussion in section “Levels of Complexity and Computational Approaches”). Their results showed that an increase in the transition moment associated with certain vibrational modes of the S_1 electronic state causes a preferential vibronic transition. Ai et al. reached a similar conclusion via a CASSCF computation (Ai et al. 2013).

Very recently, Salem and Brown screened 22 hypothetical chromophores derived from noncanonical amino acids (ncAAs) for their (S_0 to S_1) TPA cross sections (Salem and Brown 2015). A chromophore with a nitro group (that replaces the hydroxyl group in Fig. 1) exhibited an exceptionally large TPA cross section relative to other ncAA-derived and natural chromophores as computed at the B3LYP/6-31+G(d,p) level of theory in PCM. Using a two-level model (see section “The Two-Level Model”), they attributed this large intrinsic TPA to both a large transition dipole moment (μ_{01}) and a large difference between permanent dipoles of the excited and ground states ($\Delta\mu$). They accounted for the conformational dependence of the TPA (the second level of complexity) through a MD simulation of a modified EGFP. Results showed that the TPA dependence on conformation is directly related to the change in $\Delta\mu$ in the direction of the C–C=C bond in the plane of the chromophore.

Chakarbarti and Ruud showed that systems with supermolecular π -stacking have enhanced TPA cross sections associated with intermolecular charge-transfer (ICT) transitions (Chakarbarti and Ruud 2009a, b). Interestingly, YFP, a mutant of GFP, has π -stacking between the chromophore and a close-by Tyr residue. Beerepoot et al. studied the TPA of the YFP π -stacking systems (chromophore and close-by residue) via RI-CC2/aug-cc-pVDZ and CAM-B3LYP with both aug-cc-pVDZ and a smaller 6-31+G(d) basis set (Beerepoot et al. 2014). Their results show ICT transitions with significantly enhanced TPA. They further determined the dependence of (part of) the TPA spectrum on the separation between the π -aromatic systems (across which ICT occurs). This work partially accounts for the third level of complexity, that is, the local environment of the chromophore. In a very recent study, Drobizhev et al. evaluated local electric fields in a series of 26 GFP homologues that share the same anionic structure. Their study elegantly compared experimental measurements of OPA and TPA spectra and the deduced total and long-range fields to findings from MD simulations to justify their method of measurements (Drobizhev et al. 2015).

To date, only two QM/MM studies fully accounted for the third level of complexity mentioned in section “Levels of Complexity and Computational Approaches.” The first study by Steindal et al. (at the PE-CAM-B3LYP/6-31+G(d) level of theory) showed that embedding the GFP chromophore in the FP matrix significantly enhances its TPA as compared to the isolated chromophore model (Steindal et al. 2012). On the technical side, they mention the importance of including PE to reproduce experimental spectra. Although they theoretically accounted for (nearly) all

the factors that should affect the TPA of GFP, they failed to reproduce quantitatively the experimentally measured intensities of the TPA spectrum. The need to include PE to correctly account for the protein matrix and the TPA enhancement it produces are confirmed in the second study by List et al. that examined DsRED, a red FP, also at the PE-CAM-B3LYP/6-31+G(d) level of theory. Further, List et al. studied the physical mechanisms leading to the enhancement of TPA cross sections by the electrostatic effects of the protein (List et al. 2012). To do so, they determined the TPA cross sections for the isolated chromophore at the geometry optimized in vacuum and at its conformation in the native protein. By comparing the results of the three computations, they distinguished the effect at different levels of complexity. To account for the importance of PE, they computed the TPA and other parameters with the PE turned off (which they refer to as NPE and is the same as electrostatic embedding) and with PE frozen at the ground-state value only (FPE). Through a plane-projected two-level model that accounts for the angle between dipoles, they noticed that the increased TPA cross section is related to an enlarged $\Delta\mu$ (the difference between permanent dipoles of the ground and excited states) and its closer alignment with μ_{01} (the transition dipole moment). According to their results, the ground-state dipole is actually larger than the excited-state one, so increasing the former and decreasing the latter increases $\Delta\mu$. Computation of the ground- and excited-state permanent dipoles using different levels of theory showed that the ground-state polarization (FPE) causes enhancement of both permanent dipoles with the ground state being slightly more enhanced. Further inclusion of full PE cancels the enhancement of the excited-state dipole which increases $\Delta\mu$ and also decreases the angle between $\Delta\mu$ and μ_{01} leading to the TPA enhancement. Evaluation of the individual contribution of each amino acid showed that the largest contribution to TPA enhancement comes from the positively charged Lys163 which is also mainly responsible of the blueshift of the OPA spectrum. They finally suggested a mutation that should improve the TPA intensity and at the same time redshift the OPA spectrum.

Although the absolute TPA cross sections computed by List et al. (2012) match the experiment (perhaps somewhat fortuitously), there are still open questions. Clearly, more PE-DFT/MM studies need to be carried out before there is confidence that we can successfully reproduce experimental TPA cross sections, as Steindal et al. (2012) failed to reproduce them although they used the same method that should account for the full environmental effects. The conclusions of List et al. regarding the direction of $\Delta\mu$ mediation by the protein (List et al. 2012) contradict those by Drobizhev et al. (2009). As pointed out by Beerepoot et al. (2015), there is a need to evaluate the inherent error associated with CAM-B3LYP through a benchmark against a higher-level, more accurate method. More experiments need to be undertaken to test the tuning suggestions presented by some of the computational studies mentioned above. Finally, FPs for the promising chromophores made from noncanonical amino acids (as computed by Salem and Brown 2015) need to be experimentally synthesized and tested.

Nucleic Acid Base Analogues

The basic building blocks of the nucleic acids DNA and RNA are the five nitrogenous bases: adenine, cytosine, guanine, thymine, and uracil. The ultrashort excited-state lifetimes of these bases grant them photostability which is crucial for the protection of the nucleic acid to photo-initiated processes. As a result of their non-emissive nature, the natural nucleobases cannot be utilized as fluorescent probes. Modifications to the structure of the nucleobases can yield molecules with different photophysical characteristics such as enhancement of their fluorescence. In the design of fluorescent base analogues, it is desirable that analogues exhibit sensitivity to their local environment while having minimal impact on the overall nucleic acid structure. The utilization of these “isomorphic” analogues is advantageous as they offer minimal perturbation to the helix, whereas bulky dyes can disrupt interactions necessary for nucleic acid functionality. Experiments utilizing fluorescent DNA/RNA nucleotide analogues have provided an effective way to study conformational dynamics of nucleic acids over a range of timescales (Alemán et al. 2014; Song and Mandal 2014; Ha 2004; Xavier Michalet and Jäger 2006). For example, studies in the millisecond to second timescale provide information about protein-DNA interactions, while fluorescence anisotropy can provide structural characteristics on the picosecond to nanosecond timescale (Katilius and Woodbury 2006). Fluorescence microscopy at the single-molecule level has emerged as a powerful technique to investigate conformational dynamics of DNA (Pitchaiya et al. 2014). Challenges such as photobleaching arise with excitation in the UV range for many fluorescent base analogues. Investigating the photophysical properties and understanding how they are related to their structure are crucial for the design of more effective analogues. We refer the reader to recent, comprehensive discussions of modified nucleobases by Sinkeldam et al. (2010) and Matsika (2015). The most common challenges in the design of fluorescent nucleobase analogues for biological applications are the following (and these echo the general challenges outlined in the introduction): (i) The absorption cross sections of nucleobase analogues are much lower compared to the extrinsic dyes, and hence their brightness is insufficient for accurate imaging. (ii) Most analogues absorbing in the UV region can be prone to photobleaching. (iii) The penetration of light in biological tissues is poor at these wavelengths due to scattering processes. An alternative approach is to use multiphoton excitation in the near-IR range. This change in absorption wavelengths enables the analogues to be utilized as probes for applications requiring deep tissue penetration and can overcome the problems arising from photobleaching.

While several experiments have investigated the two-photon absorption properties of nucleobase analogues, corresponding computational studies are far more limited; to our knowledge there is only one. Nearly a decade ago, the two-photon cross sections of the guanine analogue 6-methylisoxanthopterin (6-MI) and the adenine analogue 4-amino-6-methyl-8-(2'-deoxy- β -D-ribofuranosyl)-7(8H)-pteridone (6-MAP) were measured to be 0.8 GM and 3.4 GM, respectively (Katilius and Woodbury 2006; Stanley et al. 2005). Recently, Lane and Magennis determined the

σ_{TPA} of 2-aminopurine (2-AP), as well as tricyclic cytosine (tC), as 0.2 and 1.5 GM, respectively (Lane and Magennis 2012). Although these analogues demonstrate resistance to photobleaching, their brightness is not sufficient for single-molecule detection. Recently, a set of isomorphous analogues synthesized by Tor et al. have been investigated for two-photon induced fluorescence (Lane et al. 2014). The structures of these modified nucleosides are depicted in Fig. 2.

Computational Investigations of Nucleoside Analogues

As with the study of fluorescent proteins, we can investigate the properties of nucleic acid analogues in varying levels of complexity. The simplest approach (i.e., first level of complexity) is to determine the excitation properties of the isolated nucleobase which is the chromophoric moiety in the molecule. We can build upon that by including the ribose or deoxyribose (nucleoside), and, furthermore, we can investigate the analogues as a nucleotide or sequence of nucleotides (oligonucleotide). Of course in all of these cases, one would ideally want to include the effects of solvent, although often this can be accomplished through the use of polarizable continuum models (PCM). In some cases, the first level of complexity is sufficient for predicting the desired properties, and inclusion of the sugar moiety (and phosphate group) does not alter the findings. An extensive analysis of the one-photon excitation properties of the thiophene analogues (thA, thU, thG, and thC) by Gedik and Brown (2013) demonstrated this effect. For TPA, it is expected (yet remains to be confirmed) that the sugar group should have a more drastic effect on the cross sections since the orientation/geometry of the ribose will alter the permanent dipole moments (ground and excited state) of the molecule thus affecting $\Delta\mu$. Another factor that needs to be considered in the determination of TPA is the possible role of tautomerization. For example, it has been established experimentally that the tC analogue exists as a mixture of amino and imino tautomers (Lane and Magennis 2012). In order to obtain accurate theoretical data, both tautomers would need to be examined.

To our knowledge, the only theoretical investigation of the two-photon excitation properties of nucleic acid analogues was performed by Samanta and Pati (2015). In this study, the TPA cross sections of the set of analogues depicted in Fig. 2 were determined at the B3LYP/6-31++G(d,p) level of theory. The computations were performed both in the gas phase and in solvent (implicit solvation with PCM). The OPA parameters have been determined by Samanta et al. in a previous study (Samanta et al. 2012). A summary of their findings is presented in Table 1.

The results from Table 1 reveal that small alterations in the structure of the nucleosides can greatly impact their photophysical properties. The analogues display a very large variation in their TPA cross sections ranging from approximately 4 to 73 GM (computational determination) or 0.17 to 7.6 GM (experimental measurement) in water. From the computational results, the thiophene and furan analogues display the lowest cross sections, while the quinazoline analogue shows the highest σ_{TPA} in water. This trend is not observed in the experimental findings. Both experiment and theory ascertain the $S_0 \rightarrow S_1$ transition as both OPA and TPA

active for all of the analogues. It is evident that more theoretical studies need to be performed (i) to test other functionals and/or higher-level ab initio methods, (ii) to elucidate the effect of small structural changes on the TPA cross sections, and (iii) to examine the effects of conformational flexibility, e.g., the orientation of the sugar group mentioned previously. Further investigation of two-photon absorption of modified nucleobases by computational approaches is crucial for shedding light on the structure-photophysics interplay, which will ultimately aid in the design of better analogues.

Conclusions

In this chapter, we presented a brief discussion of the theory of TPA. With a focus on TPA in biological molecules, we reviewed the available computational methods and software packages. We then presented the applications of TPA utilizing fluorescent proteins and emissive nucleic acid base analogues. In each case, we gave a brief introduction to the topic followed by a review of the computational studies carried out on these two classes of molecules. We concluded each section with highlights of areas that require further computational investigation. What is clear is that there is a bright future for the computational study of TPA with applications to biological imaging.

Abstract

Radiotherapy is still one of the most common modalities employed in anticancer treatment. However, hypoxia, a hallmark of solid tumor cells, makes cancer significantly more resistant than the adjacent healthy tissues toward ionizing radiation. In order to overcome this detrimental situation, radiosensitizers, i.e., substances that lower the lethal dose of ionizing radiation, should be used in clinics concomitantly with radiotherapy. In the current review, one class of radiosensitizers – modified nucleosides – are discussed in terms of their mode of action. As radiosensitizers, these modified nucleosides must employ a reaction with hydrated electrons that leaves behind the reactive radicals of nucleobases in

DNA. The latter species, in turn, lead to serious DNA damage and the electron affinity of nucleosides and their ease to undergo dissociative electron attachment decide their efficiency. The mechanistic details of the process beginning from electron attachment to a nucleobase and ending with DNA damage are analyzed with the help of molecular modeling at the quantum chemistry (QM) level. First, the mechanism of action of ionizing radiation on biological matter, with particular emphasis on the formation of solvated electrons ubiquitously created under hypoxic condition, is discussed. Then, electron attachment to the modified nucleosides, to their halogen derivatives in particular, coupled to radical processes resulting in DNA damage are described in terms of the results of QM calculations. Finally, the perspectives of computer-based design of electrophilic nucleoside radiosensitizers are shortly discussed.

Introduction

The average life expectancy continuously rises due to the enormous progress in medicine observed in the last decades. Thus, the aging population is one of the reasons that increase the contribution of cancer to the variety of diseases that concern contemporary society. Indeed, as indicated in the review article published by Jemal et al. in 2011 (Jemal et al. 2011): “Cancer is the leading cause of death in economically developed countries and the second leading cause of death in developing countries.” It is therefore quite probable that, in the following years, we will witness a spectacular increase of the global burden of cancer.

Radiotherapy belongs to the most common anticancer therapies (Gaba 2011). Over 50 % of cancer patients receive radiotherapy at certain stages of their treatment. It is, however, worth emphasizing that most solid tumor cells are hypoxic, which makes them resistant toward the action of ionizing radiation (Daşu and Denekamp 1998; Oronsky et al. 2011; Williams et al. 2001). As a result, the tissues adjacent to tumor tissues that are exposed to the effects of ionizing radiation may develop secondary tumors – the most dangerous side effect of radiotherapy. This situation calls for the employment of **radiosensitizers**, i.e., chemical molecules that, when introduced into cancer cells, enable the lethal dose of ionizing radiation to be significantly reduced. Hence, the employment of radiosensitizers should make radiotherapy much more effective and safer toward healthy, nonhypoxic tissues.

The above mentioned oxygen effect – cancer cells with a decreased level of oxygen are two- to threefold less sensitive to high-energy radiation than normal cells (Oronsky et al. 2011) – provides the basis for “Trojan horse” radiotherapy. Developing such a therapy, one might employ the fact that in hypoxic cells, the DNA damaging activity of hydroxyl radicals, a common product of water radiolysis and the main cytotoxic factor under oxic conditions, is highly impaired. On the other hand, under hypoxia, the gray (Gy) of the absorbed radiation produces solvated electrons to an amount equal to the number of hydroxyl radicals (von Sonntag 2006). However, in water, the former species are not reactive toward DNA. It thus seems that a way to efficient radiotherapy under hypoxia is to “activate” solvated

electrons so that they become a DNA damaging factor. Modified nucleosides could be a solid foundation for such an anticancer therapy. After transfer to the cellular cytoplasm, the modified nucleosides must be phosphorylated by kinases to form the appropriate triphosphates (TPs). Then, if the TPs are accepted by DNA polymerases, the modified nucleosides will be introduced into the cellular DNA during replication or repair. 5-Bromouracil or 5-iodouracil, which as valence anions dissociate in an almost barrier-less manner, producing the reactive uracil-5-yl radical, are exemplar nucleosides for Trojan horse radiotherapy (Rak et al. 2015). Indeed, DNA labeled with electron affinic nucleosides that are prone to dissociative electron attachment should be, in contrast to unmodified DNA, sensitive to solvated electrons.

The remaining part of the chapter is focused on the computational approach to DNA radiosensitization with modified electron affinic nucleosides. In the next section, the formation of hydrated electrons, as they are formed during radiotherapy, is shortly characterized. Then, the process of electron attachment to a molecule, in terms of vertical and adiabatic electron affinity, as well as the stability of the formed anion in terms of detachment energy, are defined. The subsequent section is devoted to electron attachment to native DNA. Next, the Trojan horse strategy based on modified nucleosides is described in detail and the particular role of halogenated nucleosides in the development of such an approach is highlighted. Finally, the possible direction for the computational design of future, nucleoside-based radiosensitizers is briefly discussed.

Where Do the Electrons Come From?

Since cells are mostly composed of water, the main effect of their exposure to ionizing radiation (e.g., in radiotherapy treatment) is **water radiolysis**. Radiolysis of bulk water leads to the formation of a few primary species that are formed along the radiation track: genotoxic hydroxyl radicals (OH^\bullet), **hydrated electrons** (e^-_{sol}), hydrogen atoms (H^\bullet), and less harmful species such as hydrogen peroxide (H_2O_2), H_3O^+ , H_2 , and O_2 (von Sonntag 2006). The products of water radiolysis are generated in the following sequence of events:

- (i) High-energy photon (e.g., γ -rays or X-rays; photon energy ~ 1 MeV) hits a water molecule leading to its ionization ($\text{H}_2\text{O}^{\bullet+}$) or excitation (H_2O^*). “Dry” high-energy electrons are released within 1 fs (Eq. 1),

- (ii) During the physicochemical stage (fs-ps), the high-energy electron may ionize the surrounding environment – along the radiation track – creating more free electrons and producing more reactive species (OH^\bullet , H^\bullet , H_2O_2).
- (iii) Finally, high-energy electrons become thermalized, which takes place after 1 ps after their formation (Fig. 1). In contrast to UV radiation, one can observe isolated spurs (places where the concentration of radiolysis products are very

Fig. 1 Schematic representation of bulk water radiolysis induced by γ -rays

high – along the radiation track) during the irradiation of bulk water. After the physicochemical stage, the chemical stage (ps– μ s) occurs and in this time the products of water radiolysis expand from spurs to solute via diffusion. It seems important to present some of the physical properties of hydrated electron (e^-_{sol}). It is the smallest possible anion with a maximum absorbance at 720 nm, whose lifetime is on the order of microseconds in liquid water and in the order of days in ammonia (Abel et al. 2012).

It is worth emphasizing that e^-_{dry} becomes surrounded by weakly bound water molecules on the fs time scale (from -1.5 to -1 eV, Abel et al. 2012) creating **prehydrated electrons** (lifetime < 1 ps) as the precursor of hydrated (solvated) electron (Eq. 2).

Solvated electrons are bound to water in about 1 ps (Le Caer 2011) with binding energies of 3.4 eV for internally solvated electrons and 1.6 eV for surface-type electrons (Abel et al. 2012). For many years, there has been an ongoing debate about what solvated electron looks like. Kumar et al. proposed recently the minimal model of a cavity surrounded by four water molecules, inside which the electron is localized (Kumar et al. 2015). This interaction disrupts the hydrogen bonding pattern inside the liquid water. Moreover, the calculated properties of this suggested model are in good agreement with experimental data. However, this representation is proposed only in pure water, while in more biological solutions, clusters of electrons with, e.g., sodium ion $(H_2O)_n^-Na^+$ are observed, manifesting a huge impact on the electron stability and properties (Abel et al. 2012).

The most abundant and reactive products of water radiolysis are hydroxyl radicals (OH^\bullet) and solvated electrons (e^-_{sol}), which are formed almost in equal molecular yields under **hypoxic conditions** (von Sonntag 2006). However, we should rather consider the situation in the presence of molecular oxygen, as biological processes occur in an oxygenated environment. Free electrons react with oxygen leading to an increased production of hydroxyl radicals through the intermediate, superoxide, radical state ($\text{O}_2^{\bullet-}$) – the precursor of highly reactive OH^\bullet (Eq. 3) (Bielski and Richter 1977; Yamaguchi et al. 2005).

Electron Attachment and Anion Radical Stability

Once the secondary electrons are produced in the cell via irradiation-induced water radiolysis, they are willing to react with biomolecules found nearby. The willingness of the electrons to react with the other moieties is bound with those moieties through the **electron affinity** (EA).

EA can be defined as the difference in energy (or enthalpy or Gibbs free energy) between the moiety in its neutral state (A) and its electron adduct (anion radical form, $\text{A}^{\bullet-}$). Similarly, if one is trying to attach an electron to a cationic molecule B^+ , EA will be then defined as the difference in energies between this B^+ and its electron adduct – the neutral radical B^\bullet . And in the case of a neutral radical (C^\bullet), EA will be defined as the difference in energy of C^\bullet and the corresponding electron adduct, which will be then an anion, C^- . Having in mind these specific cases, we discuss the electron attachment phenomena, based on the first example, which is the pair of the neutral A and the electron adduct $\text{A}^{\bullet-}$ moieties.

The higher electron affinity means, obviously, a higher probability to catch an electron from the surrounding environment. Moreover, it is worth noting that EA is not exactly the same as **ionization potential** (IP). While EA is bound with an attaching electron, IP is bound with a detaching electron from the same neutral moiety. We consider then the following pairs: A and $\text{A}^{\bullet-}$ for EA and A and $\text{A}^{\bullet+}$ for IP. Talking about the irradiation effects on modified DNA, we will be interested in EA rather than IP values.

Three more specific terms are related to the general EA term. These are **adiabatic electron affinity** (AEA), **vertical attachment energy** (VAE, also sometimes named VEA – vertical electron affinity), and **vertical detachment energy** (VDE). AEA is the difference in energy of A and $\text{A}^{\bullet-}$ in their fully relaxed geometries, being the minimum of their potential energy surface (Fig. 2, Eq. 4). The higher (positive) AEA value, the more adiabatically stable the produced anion radical $\text{A}^{\bullet-}$.

If we are dealing with rapid electron transfer processes, when the molecular geometries have insufficient time to adjust to the changed electronic characteristics, we should discuss vertical electron stability and the two terms describing it: VEA and VDE. If the excess electron attaches to the neutral A, the electron adduct $\text{A}^{\bullet-}$

Fig. 2 How to calculate AEA, VEA, and VDE values

has no time for geometrical relaxation (thus, $A^{\bullet-}$ is still in an optimal geometry of neutral A), VEA is the difference in energy of A and $A^{\bullet-}$ (as it was for AEA), but both A and $A^{\bullet-}$ are in the relaxed A geometry (Eq. 5, Fig. 2). In parallel, for the fast detaching electron from the anion radical $A^{\bullet-}$ molecule, we allow no time for geometry relaxation of the produced A (thus, A will be still in the optimum $A^{\bullet-}$ geometry). VDE is defined then as the difference in energy of A and $A^{\bullet-}$ (as it was for AEA and VEA), but both A and $A^{\bullet-}$ are in the relaxed $A^{\bullet-}$ geometry (Eq. 6, Fig. 2).

$$\text{AEA} = E(\text{A}) - E(\text{A}^{\bullet-}) \quad (4)$$

$$\text{VEA} = E(\text{A}) - E(\text{A}^{\bullet-}, \text{ in the A geometry}) \quad (5)$$

$$\text{VDE} = E(\text{A, in the A}^{\bullet-} \text{ geometry}) - E(\text{A}^{\bullet-}) \quad (6)$$

Sometimes it may happen, for the considered molecules, that one obtains positive AEA values and negative VAE values (Li et al. 2002a). Special attention should be given then to the chosen calculation methodology level.

The last point on which we would like to draw attention in this section concerning the description of electron attachment in numbers is bound with the electron-adducts' stability. Namely, one should distinguish the **electronic stability** (both adiabatic – bound with high AEA value, and vertical – bound with a positive VDE value) from the **thermodynamic stability**. The difference is that even if $A^{\bullet-}$, produced via electron attachment, is electronically stable (does not detach its

additional electron spontaneously), it may be thermodynamically unstable if it is prone to undergo further degradation processes (like heterolytic dissociation into an anion and radical). If the kinetic barriers for all of the possible $A^{\bullet-}$ degradation processes are too high to be overcome under ambient conditions, one can conclude that $A^{\bullet-}$ is both electronically and thermodynamically stable and could be detected experimentally.

Armed with the basic terms bound with an electron attachment, we are prepared to discuss this process in the native and modified DNA fragments.

Electron Impact on Native DNA

In 2000, Sanche and coworkers showed that low-energy electrons can cause **single strand breaks (SSB)** and **double strand breaks (DSB)** in plasmid DNA (Boudaiffa et al. 2000). They irradiated DNA with an electron beam with an energy in the range of 3–20 eV and determined the yield of SSB and DSB production. The efficiency of those processes increased with the electron energy. However, the most surprising finding was the observation that electrons at energies below the ionization threshold could contribute to DNA damage, which is caused by rapid decay of transient molecular resonances located on the basic DNA units. These results suggested that secondary electrons produced by ionizing radiation can be lethal to the genome. In this manner, numerous theoretical and experimental studies on secondary electrons, carried out in many laboratories around the world, have been initiated.

One should keep in mind that the studies mentioned above were performed only for “dry” DNA under vacuum conditions, i.e., far from those encountered in cells. In fact, water plays a key role in radiation-induced DNA damage, particularly because it makes up 70–90 % of the mass of living cells. Thus, when a cell is subjected to irradiation, most of the radiation energy is absorbed by water. In aqueous solution, an excess electron swiftly becomes a e^-_{pre} and finally a e^-_{sol} .

In 2009, Lu’s group presented the mechanism of presolvated electron-induced damage to DNA nucleotides with the use of femtosecond, time-resolved, laser spectroscopy (Wang et al. 2009). The use of this technique enabled a real-time observation of the interaction of e^-_{pre} with DNA building blocks. The authors reported that bond breaking in nucleotides can be caused by transient molecular anion resonance formation induced by dissociative ultrafast-electron transfer (UET) of e^-_{pre} . Indeed, 2 years later the same group showed that the formation of DNA strand breaks induced by e^-_{pre} is even nearly twice as efficient as that induced by OH^{\bullet} radicals (Nguyen et al. 2011). These findings suggest that the UET reaction of e^-_{pre} may play a role in generating damage to DNA in aqueous environments. On the other hand, e^-_{pre} are just initial precursor states of an electron located in water with very short lifetimes and the end products are hydrated electrons (e^-_{sol}).

In 2005, Falcone et al. reported experimental studies that showed the influence of the hydration level on electron-induced DNA damage (Falcone et al. 2005). The authors investigated the yields of the products of the interaction between DNA in various hydration states and for dry or hydrated electrons: hydrogen (related

to the reaction of intra-spur electrons) and **5,6-dihydropyrimidines** (the result of electron attachment to cytosine and thymidine). In the lower tested hydration conditions (less than 22 mol of H₂O molecules per mole of nucleotide), the highest yields of 5,6-dihydropyrimidines and the lowest yields of hydrogen were found. At higher tested hydration levels (more than 22 mol of H₂O molecules per mole of nucleotide) an increase in the amount of hydrogen and decrease in yields of 5,6-dihydropyrimidines were observed.

The role of the aqueous environment was also examined by Kohanoff and coworkers (McAllister et al. 2015; Smyth and Kohanoff 2011). Using **ab initio molecular dynamics (AIMD)**, they demonstrated that in the natural DNA surroundings containing many water molecules, the excess electrons localize around the nucleobases in very short times (15 fs). Thus, they suggested that the excess electron created in close proximity to DNA (at least within 2 nm) can avoid hydration. In recent studies, McAllister et al. considered the impact of hydrogen bonding (between the bases and water molecules) and protonation by the water on the possibility of strand break production in DNA (McAllister et al. 2015). It has been shown that protonation causes a significant increase in the kinetic barrier of breaking both the C3'-O3' bond (in case of dCMPH⁻, dGMPH⁻, and dTMPH⁻) and glycosidic bond (in case of dCMPH⁻, dAMPH⁻, and dTMPH⁻) and hence it may prevent strand break production in DNA chains. It is worth noting that both hydrogen bonding to the nucleobase and the water molecule can be a donor of the proton and that the protonation preceded by electron attachment is favorable for many of the bases.

There are several experimental studies in which aqueous solutions of various DNA models, containing hydroxyl radical scavengers such as Tris-HCl or EDTA, were exposed to ionizing radiation. With the use of gel electrophoresis, Cecchini et al. demonstrated that e⁻_{sol} cannot cause strand breaks in a solution of unmodified DNA duplex in contrast to a double stranded DNA fragment labeled with 5-bromouracil (Cecchini et al. 2005). In 2013, Sanche's group reported that e⁻_{sol} generated by water radiolysis are unable to induce strand breaks in native plasmid DNA in contrast to plasmid DNA modified with cisplatin (Rezaee et al. 2013). Moreover, our data show that the electron-induced degradation of trimeric oligonucleotides (TXT) in aqueous solution occurs only if "X" is a brominated nucleobase (Westphal et al. 2015). Indeed, when the trimers contained brominated nucleosides (i.e., X = BrdU, BrdA, BrdG, BrdC), a series of products of electron-induced damage, such as bond breaks or **abasic sites**, were identified. However, when these short oligonucleotides contained native nucleosides (i.e., X = T, dA, dG, dC, dU), only the products of protonation (trimers containing 5,6-dihydrothymidine) were detected. It is worth noting that, in the past, the same trimeric model was exposed to low energy electrons under high vacuum (Park et al. 2012). Significant differences in the identified products for native trimers treated with excess electrons in the gas phase and in the aqueous solution best show the effect of the environment on the damaging potential of electrons toward DNA.

In 1982, it was proven that hydrated electrons cause a very slight inactivation of biologically active, single-stranded DNA of the bacteriophage ϕ X174 compared to

the inactivation induced by OH^\bullet and H^\bullet radicals (Nabben et al. 1982). The biological activity of ϕX174 DNA was presented as a function of gamma radiation dose (survival curves) for exposures carried out with or without an electron scavenger. The results of this experiment demonstrate a low efficiency of damage caused by the reaction of e^-_{sol} with bacteriophage DNA.

All the above mentioned findings demonstrate that e^-_{sol} exhibits a very limited reactivity toward native DNA, causing mostly just its protonation.

Why Use Modified Nucleosides of High Electron Affinity?

Knowing that native DNA is rather resistant to damage caused by irradiation-produced hydrated electrons, it is more understandable why the search for methods of sensitizing DNA to irradiation is necessary to enhance radiotherapy.

Modified nucleobases may play a key role in anticancer radiotherapy. They increase the sensitivity of DNA to ionizing radiation and are referred to as a “Trojan horse” because of their unique properties. These compounds can be readily incorporated into DNA without any modification of gene expression. This is because of their nontoxic properties, structural similarity to the native nucleobases, and the fact that they are recognized by polymerases (Goz 1977) and kinases (Lee and Cheng 1976). Before incorporation into the targeted cell or tissue, the modified nucleoside must be phosphorylated to maintain its radiosensitizing activity. Because of the fact that the nucleoside triphosphate is not chemically stable and has high polarity, the incorporation is also possible when the modified nucleoside is converted to a stable monophosphate nucleoside containing protective groups, such as carbonyloxymethyl (POM, POC), S-acyl-2-thioethyl (SATE), alkoxyalkyl (HDP, ODE), or cyclosaligenyl (cycloSal). These groups are removed inside the cell (enzymatically or chemically), which results in the release of the free nucleoside monophosphate. The resulting molecule can then be easily converted into a nucleoside triphosphate (Pradere et al. 2014).

To ensure the highest radiosensitivity, the derivative of nucleobase that increases the electron affinity, as well as facilitates the abstraction of its substituent, is required to be incorporated into the DNA strand. The substitution of a hydrogen atom with a halogen element changes the electrophilic properties of nucleobases. This results in an increase in their adiabatic electron affinity (AEA) compared to native nucleobases (Rak et al. 2015). Moreover, the highest value of AEA calculated for native nucleobases possesses uracil (Li et al. 2002a), while the 5-bromoderivative is the most radiosensitive halosubstituted 2'-deoxyuridine (Wetmore et al. 2001). The most studied modified nucleosides are 5-BrdU and 5-IdU. Undoubtedly, they are effective substitutes for thymine during replication and have been tested in the medical treatment of tumors such as head-and-neck cancer (Epstein et al. 1994), soft tissue sarcomas (Goffman et al. 1991; Robertson et al. 1995), and malignant gliomas (Greenberg et al. 1988). 5-Bromo- or 5-iodosubstituted uracil enhances the sensitivity of DNA to ionizing radiation, working as an “**electron-trap**” in the biopolymer strand (Li et al. 2002b). The probable mechanism of radiosensitization

for DNA containing 5-BrU is as follows: (i) the electron produced by ionizing radiation attaches to the modified nucleobase (which has the highest electron affinity in the strand), (ii) this is followed by formation of a bromouracil anion radical, (iii) and the **dehalogenation** of bromouracil anion radical results in the formation of a uracil-5-yl radical, whose reactivity will be discussed later in this chapter. Another derivative of nucleobases prone to increase the radiosensitivity of the nucleic acid strand is 5-fluoro-2'-deoxyuridine (5-FdU) (Gaba 2011). This analog has different cytotoxic and radiosensitizing properties than BrdU or IdU. This might be because of the size of the halogen. The van der Waals radius of Br and I are comparable to a methyl group while F is smaller and recalls a hydrogen atom, which makes the fluoroderivative similar to uracil rather than thymine and results in the limited incorporation of 5-FdU into DNA. However, this derivative is able to act as a suppressant of thymidylate synthase. 5-FdU interrupts the action of this enzyme and blocks the synthesis of thymine monophosphate, which results in the interference in DNA replication and inhibition of proliferation of tumor cells (Shewach and Lawrence 2006).

Dehalogenation of Modified Nucleobases

Independently of the final degradation reactions, most of the halogenated nucleoside induced damages begin with dehalogenation processes.

Electron attachment induced dehalogenation of **halonucleobases**, such as 5-bromouracil (5-BrU) and 5-iodouracil (5-IU), has long been a subject for theoretical studies. This is due to the discovery of their radiosensitizing properties, briefly discussed in the previous sections. It was shown experimentally that the attachment of a solvated electron to 5-bromo-2'-deoxyuridine initially leads to the formation of the respective anion radical (5-BrU^{•-}). 5-BrU^{•-} is thermodynamically unstable, therefore its creation is followed by dehalogenation as a second step, yielding bromide anion and uracil-5-yl radical (Fig. 3). This last species, being very reactive, possesses a significant potential to abstract hydrogen from adjacent sugar moieties, leading to single or double strand breaks as a result (Rak et al. 2015).

Fig. 3 Adding an excess electron to 5-BrU leads to the formation of an unstable anion radical that finally decomposes to uracil-5-yl radical and bromide anion

^aWetmore et al. (2001)^bLi et al. (2002b)^cZPE corrected^dRecalculated for this chapter at the same B3LYP/6-31 + G(d) level

Both electron attachment and **dehalogenation** can be easily described by the use of computational chemistry methods. Molecular activity towards electrons can be characterized by the AEA, VEA, VDE values, defined in the second section of this chapter.

Starting from Wetmore's work (Wetmore et al. 2001), the adiabatic and vertical electron affinities of a series of **5-halouracils**, uracil, and thymine have been calculated both in the gas phase and solution (**polarizable continuum model, PCM**) using **DFT methods** (B3LYP/6-311G(2df,p) on B3LYP/6-31 + G(d,p) or higher level gas phase geometries). Their results, later verified positively with the use of a slightly different methodology (B3LYP functional and 6-31 + G(d) basis set with isodensity PCM for water solution) (Li et al. 2002b), are summarized therein (see Table 1). As some discrepancies were found between VEAs shown in the Li et al. and Wetmore et al. papers, we recalculated them, where necessary (see Table 1). Positive EA values imply that the anionic molecule is more stable than the corresponding neutral molecule, especially for 5-CIU and 5-BrU, and the stability grows in the following order: T < U < 5-FU < 5-CIU < 5-BrU (Wetmore et al. 2001).

The second step – dehalogenation – was investigated computationally for these compounds. The study suggested that, for the series of halouracils, the barrier induced by electron attachment dissociation to X⁻ and U* goes in the opposite order: 5-BrU < 5-CIU < 5-FU, with the activation energies for dehalogenation calculated as 1.9 kcal/mol, 4.0 kcal/mol, and 20.8 kcal/mol, respectively (Wetmore et al. 2001). We can therefore conclude that 5-BrU has the largest (among other halogenated nucleobases) potential to dehalogenate itself after electron attachment and therefore 5-BrU is the most effective electron-trap for electrons produced via ionizing radiation.

It is worth mentioning that this reaction has also been widely studied experimentally – by nanosecond laser pulse radiolysis and time resolved laser spectroscopy – and all these experimental results are in good accordance with the computations

showing that EA is much higher for halogen substituted uracils than for unmodified ones or thymine (Rak et al. 2015).

5-BrU seems to have a great potential to enhance DNA sensitivity, being the major electron capturing site during irradiation, but also other derivatives have been tested, including other brominated nucleobases (BrNB) and other uracil derivatives (XU). First of all, it has been shown experimentally that not only 5-BrU but also 5-BrC is a three times better electron scavenger compared to native cytosine (Razskazovskii et al. 1997). Also 8-bromopurine analogues were proven to possess electron affinities far exceeding those for nonhalogenated ones (Flyunt et al. 2000). Knowing that, in the experiment, 8-bromo derivatives of adenine or guanine capture electrons to form the C8 radical and bromide ion (Flyunt et al. 2000; Ioele et al. 2000), Chomicz et al. compared the electron induced dissociation of four nucleobase derivatives: 8-bromo-9-methyladenine (Me-8BrA), 8-bromo-9-methylguanine (Me-8BrG), 5-bromo-1-methylcytosine (Me-5BrC), and 5-bromo-1-methyluracil (Me-5BrU) both in the gas phase and PCM model, at the B3LYP/6-31++G(d,p) level of theory (Chomicz et al. 2012). Those calculations allowed the estimation of the thermodynamic and kinetic barriers (see ΔG_{tot} and ΔG^* in Table 2) of the three following reaction steps (Eqs. 7, 8, and 9):

The survey showed that all the considered BrNBs are far better electron acceptors compared to unsubstituted ones, prone to form isolated nucleobase radicals and

bromide anion. The calculated EAs were in all cases positive (even above 2 eV in the free enthalpy scale) but for purine derivatives smaller than for native nucleobases (less than 2 eV in aqueous solution). The thermodynamic and kinetic characteristics of molecular decomposition into a nucleobase radical and bromide anion were very promising (Chomicz et al. 2012). Here, we can also observe that pyrimidines are more likely to accept an excess electron than purines, and that anionic molecules are stabilized by a polar environment, which is the reason for the much higher electron affinity in solution. These findings were proven with the use of AIMD methodology, additionally showing that brominated purine decomposition should also be barrier-free (Wieczór et al. 2014).

What Next with the Nucleobase Radicals Produced?

Radicals generated in the DNA molecule can cause a wide range of damage such as single and double strand breaks, abasic sites, cyclopurines, and interstrand cross-links.

The first process occurring after the generation of a radical is usually a **hydrogen atom transfer**. The hydrogen target for abstraction depends on the position that the radical is localized on within the nucleobase. Radicals based on the carbon atom neighboring the *N*-glycosidic bond of the nucleotide (C6 in pyrimidines, C8 in purines) are likely to abstract a hydrogen atom from their own sugar residue. Due to the structure of DNA, 2', 3', and 5' hydrogen atoms can be the target as 1' and 4' hydrogen atoms are located on the opposite side of the 2'-deoxyribose ring (Fig. 4). In the case of radicals located on the C5 atom of pyrimidines, hydrogen atom transfer from the same nucleotide is hindered by steric repulsion between the sugar ring and the C5 atom of the pyrimidine. The conformational changes that are essential for such a reaction to occur make the kinetic barrier over 40 kcal/mol – impossible to overcome under cellular conditions (Chomicz et al. 2014b). Despite that, 5-substituted pyrimidines still exhibit radiosensitizing properties.

One possible pathway for pyrimidine radicals centered on the 5-position is abstraction of a hydrogen atom from the adjacent nucleotide, where 1' and 2' positions can be targeted (Schyman et al. 2007). These radicals can also abstract a hydrogen atom from a water molecule, producing a hydroxyl radical – which is known to be genotoxic (Fig. 4). Hydroxyl radicals generated in this reaction can immediately attach to the C5 carbon atom, making the spin density move to the C6-position, or they can go on to abstract hydrogen atoms from any sugar residue in the DNA chain (Chomicz et al. 2014c). The 5' and 3' sites have the lowest kinetic barriers for such an abstraction, although they are influenced to a large extent by the ever-changing local structure of water, and the barriers for other sites within the sugar moiety are too small to prevent abstraction there (Shukla et al. 2011).

Sugar centered radicals can lead to various kinds of damage depending on the site they are localized on. 3' and 5' radicals are centered on atoms bonded with phosphate groups and, as such, they can undergo homolytic O–P bond cleavage, which is tantamount to a strand break. C–O bond breakage is impossible in this

Fig. 4 Possible targets for radical attack by 5- (marked green) and 6-uridyl (blue), as well as hydroxyl (red) radical

Fig. 5 The mechanism of 5',8-cyclo-2'-deoxyadenosine formation from 8-adenosinyl radical

case because elongating this bond leads to a phosphate radical along with a sugar centered open shell singlet, with an energy 60 kcal/mol higher than the substrate (Rak et al. 2011). When 5' radicals are located within a purine nucleotide they can also attack the C8 atom of the nucleobase to produce a **cyclopurine lesion** (Fig. 5). These reactions are more favorable kinetically and thermodynamically than 5' O-P bond cleavage (Chomicz et al. 2014a) and the lesion formed, although less cytotoxic than strand breaks, can still distort the DNA helix and thus impair cellular processes (Kropachev et al. 2014).

4' radicals can lead to strand breaks in single stranded DNA, as the 3' side C-O bond can be cleaved heterolytically to produce a cation radical, followed by hydrolysis to a new 4' radical, which can then undergo a similar reaction to break

the 5' side C–O bond (Giese et al. 1995). 2' radicals might in theory cause damage with a similar mechanism. However, there is no evidence of this pathway being feasible in DNA, as opposed to RNA, where the 2' hydroxyl group makes the 2' C–H bond weaker (Paul and Greenberg 2014). 1' radicals are known to transform into abasic sites, usually of **2-deoxyribonolactone** type, after oxidation. These alkali-labile sites can be incised by apurinic endonuclease 1 followed by forming a **Schiff base cross-link product** with DNA polymerase, which impedes further DNA repair (Greenberg 2007).

When the 5-pyrimidinyl radical is placed in a mismatched region it can also attack the opposite strand to form cross-links (Fig. 4). The mechanism proposed for the formation of this kind of lesion was based on a special zipper-like structure that the **mismatched DNA** can form (Dextraze et al. 2010). In general the conformation of DNA has a strong influence on the type of damage formed by 5-substituted pyrimidines.

Quantum Chemistry as a Tool to Search for New Therapeutics

Knowledge and experience in treating cancer and many decades of studies on the use of radiotherapy have allowed for a class of compounds referred to as radiosensitizers to be proposed for the purpose of sensitizing the DNA of tumorous cells. Radiosensitizers may become the future of modern radiotherapy, as selectively damaging tumorous cells using a lower dose of high-energy radiation ensures the highest effectiveness of treatment and limits side effects. The class includes the above mentioned 5-BrU, also in a nucleoside form 5-BrdU. The radiosensitizing mechanism of this compound on the molecular level is still not fully understood despite 50 years of studies and opportunities for clinical application.

It seems justified to search for compounds with sensitizing properties among other derivatives of nucleobases, rather than focusing on thymine derivatives or bromine modified nucleobases. This is especially true since anticancer therapy has already seen the use of analogues of pyrimidines such as 5-iodo-2'-deoxyuridine, 2',2'-difluoro-2'-deoxycitidine (gemcitabine, sold commercially as Gemzar), which increases the cytotoxicity in tumorous cells under radiation or another group: 5-fluorouracil (5-FU) or 5-fluoro-2'-deoxyuridine (5-FdU) metabolized into a monophosphate (5-FdUMP). 5-FdUMP acts as an inhibitor to thymidylate synthase and can be incorporated into DNA in the form of a triphosphate. Its radiosensitizing properties were studied clinically, too (Longley et al. 2003). Both in vitro and in vivo studies show that 4-thiothymidine has considerable potential as a photosensitizer in photodynamic therapy. Thanks to the substitution of the oxygen atom at the fourth position in thymine for a sulfur atom, the compound becomes sensitive to UVA radiation. Furthermore, experimental research shows that, despite certain reservations against clinical application due to the limited power of UVA radiation, this type of radiation is sufficient to induce the apoptosis of malignant skin cells when used with a particular concentration of the drug (Gemenetzidis et al. 2013).

Computer chemistry is a helpful tool in designing new sensitizers and understanding the mechanism of action of the known ones. Modifying a nucleobase by substituting a hydrogen atom for halogen substituents (Y: fluorine, chlorine, bromine, and iodine) at C5 (in pyrimidines) or C8 (purines) causes a change in the properties of the nucleobase as an electron acceptor and the durability of the C–Y bond (as described using DFT methods). Research has proven that the production of the 5-uridine radical due to the detachment of the electron acceptor substituent increases if the uracil is substituted with bromine. Research has also proven that modifying other bases with bromine increases their electron affinity compared to their native counterparts (Li et al. 2002b).

Chomicz et al. conducted theoretical research on the addition of an excess electron to model bromine-derived, methylated nucleobases (Me-8BrA, Me-5BrC, Me-8BrG, and Me-5BrU), which showed that all the tested nucleobases, once incorporated into a DNA strand, might sensitize the biopolymer, as indicated by the possibility of a stable valence radical anion being created both in the gas phase and the liquid phase and by the values of AEA and VDE (Table 2). The excess electron is usually located on the π^* orbital. Research shows that BrdA should undergo barrier-free degradation due to the lack of the production of a π^* radical anion. According to the authors, a C–Br bond in BrNB would break once a kinetic barrier of approximately 2.5 kcal/mol is exceeded and a stable bromine anion would be created then (Chomicz et al. 2012).

Simulations of the introduction of bromine-modified nucleotides, i.e., 3',5'-diphosphates of 8-bromo-2'-deoxyguanosine (8-BrdGDP) or 8-bromo-2'-deoxyadenosine (8-BrdADP), into a DNA strand indicate that this may sensitize the strand to high-energy radiation. The damage may occur as a result of the breaking of the O–P bond, leading to the creation of a closed-shelled carbonyl group and a phosphoryl radical or, more likely, cyclic mutations as a result of the induction of 5',8-cycloadenosine (cycloA) and 5',8-cycloguanosine (cycloG) (Chomicz et al. 2014a; Chomicz et al. 2013a).

Studies show that 5-bromine-substituted derivatives of pyrimidines are not the only compounds that may be useful in designing new anticancer drugs. Theoretical research on 8-bromo-2' deoxycytosine 3',5'-diphosphate (6-BrdCDP) and 6-bromo-2'-deoxyuridine 3',5'-diphosphate (6-BrdUDP) indicates that such modifications lead to barrier-free breakage of the C6-Br bond and the creation of a radical at the 6th carbon atom. Thanks to steric hindrance (ΔG^* activation barrier from 8.2 to 13.7 kcal/mol), this radical becomes stable by means of a hydrogen atom moving from the C3' position to C5' and similar structures forming through breaking, as reported in a study on the degradation of purine bromine nucleotides (Chomicz et al. 2014b; Golon et al. 2014).

Working under the assumption that a potential sensitizer should be a better electron acceptor than thymine, and the produced radical anion should easily degrade to a uridine radical, Rak et al. proposed two new, very promising sensitizers. The values of electron affinity (VDE and AEA) as well as thermodynamic and kinetic characteristics of reactions (Eqs. 10 and 11) were calculated for eight rationally chosen uracil derivatives (Fig. 6).

Fig. 6 5-Substituted derivatives of uracil (YU) with abbreviated names. Arrows indicate bonds that are potentially vulnerable to breakage after an excess electron is added

The results show that two of these derivatives, 5-thiocyanouracil (5-SCNU) and 5-cyanatouracil (5-OCNU), display very promising sensitizing properties, as indicated by negative values of ΔG and the activation barriers for reaction (Eq. 10) amounting to 2–3 kcal/mol only (Table 2). These calculations were confirmed experimentally using photoelectron spectroscopy (PES) for two chosen derivatives (5-SCNU and 5-CNU), for which computational studies predicted a different behavior. While it was possible to obtain the PES spectrum of the CNU^{•-} radical anion, the SCNU^{•-} anion radical spectrum was not registered, due to the SCNU^{•-} thermodynamical instability and its degradation into U[•] and SCN⁻ (Chomicz et al. 2013b) (Fig. 7).

Recent studies (Zdrowowicz et al. 2015) confirmed the sensitizing character of the uridine thiocyno derivative (SCNdU). The addition of an electron in an

Fig. 7 Energy profiles of degradation reactions for 5-substituted uracil derivatives

ESR experiment was found to lead to the production of uridine ($\text{dU}\bullet$) and $\text{dU-5-S}\bullet$ radicals. On the other hand, DFT calculations explained that the production of $\text{dU-5-S}\bullet$ and $\text{CN}\bullet$ is thermodynamically more beneficial than the creation of $\text{dU}\bullet$ and $\text{SCN}\bullet$. The activation barrier for breaking the C5-S and S-CN bonds in $\text{SCNdU}\bullet$ amounts to 8.7 kcal/mol and 4.0 kcal/mol, respectively. The computational data were confirmed by experimental research using ESR and LC-MS techniques, which observed the production of a dU-S-S-dU dimer. This suggests that SCNdU could be used as a potential radiosensitizer and would cause inter- and intrastrand cross-links within DNA.

Summary

Over 15 years have passed since the discovery that low-energy electrons are able to trigger single (SSB) and double (DSB) strand breaks in dry DNA. A number of experimental and theoretical studies aimed at explaining the mechanism of electron-induced strand break formation have been published over those years (for excellent reviews see e.g., Gu et al. 2012; Rak et al. 2008; Sanche 2005; Sanche 2009).

At first glance this phenomenon, especially the formation of DSB damage that correlates with cell death induced by ionizing radiation, has obvious practical connotations. In the current review we demonstrate, however, that as far as an aqueous environment is concerned, hydrated electrons are unable to introduce strand breaks in DNA. Although they react with nucleobases at the rate controlled by diffusion, swift and reversible proton transfer between water and the anion, resulting from electron attachment to the nucleobase, prevents the formation of SBs observed in dry DNA. On the other hand, if DNA is labeled with electron affinic, modified nucleosides, which undergo an efficient dissociative electron attachment (DEA), the nucleobase radicals formed within the DEA process are able to trigger SBs, as well as other serious DNA damage (intra- and interstrand cross-links) leading to lethal effects.

Thus, the introduction of modified nucleosides to tumor cells may constitute a foundation for a Trojan horse anticancer treatment dedicated to hypoxic conditions. Indeed, with the help of DFT modeling, we showed that bromonucleobases that swiftly release the bromide anion due to electron attachment could work as radiosensitizers. The nucleobase radicals that are left in DNA due to the DEA process to brominated nucleobases may be, in turn, involved in hydrogen transfer reactions that ultimately lead to strand breaks, cyclic purines, or cross-links.

Last, but not least, a computational approach that should result in new, efficient radiosensitizers is briefly characterized. Although radiotherapy is the most common technique employed against cancer, the number of radiosensitizers employed currently in clinics is surprisingly small. Therefore, access to new compounds sensitizing cancer cells to ionizing radiation seem to be a real obstacle for the further progress of therapy. Hence, computational chemistry methods, as demonstrated in this review, seem to be the methods of hope for solving this pressing issue.

Abstract

Excited-state molecular dynamics is a branch of theoretical physics and chemistry dedicated to simulating phenomena induced in molecules upon UV-visible

light absorption. This includes the determination of nuclei positions evolution in time along with the calculation of electronic excited-states potential energy surfaces. This chapter presents both adiabatic molecular dynamics and nonadiabatic molecular dynamics simulation methods as used in photochemistry. *Ab initio* molecular dynamics methods are briefly reviewed. A particular emphasis is on the recent developments in semiclassical algorithms and their applicability to studies of large molecular systems evolving in electronic excited states.

Introduction

Traditional molecular dynamics (MD), despite its great popularity, have few serious limitations. Among the most crucial ones is the treatment of nuclear evolution by classical equations of motion with the assumption that only a single electronic state, typically the ground state of a molecule, is occupied. In other words, MD is suitable for adiabatic processes (Marx and Hutter 2009). In classical MD, the interaction potential has to be known prior to the simulation, because the forces acting on nuclei have to be evaluated at each step of the numerical integration of equations of motions (Nowak 2012; Rydzewski et al. 2015). Despite these drawbacks (Remler and Madden 1990; Payne et al. 1992), traditional MD is well established as a tool to investigate many-body condensed matter systems, including biomolecules. The broadness and diversity of applications are documented in numerous monographs, articles, and reviews (Frenkel and Smit 2001; Sanbonmatsu and Tung 2007; Pérez et al. 2011; Orozco 2014; Perilla et al. 2015).

Gathering interaction potentials a priori is often difficult. One way to overcome this obstacle is by calculating the forces acting on the nuclei from electronic structure calculations performed “on-the-fly,” i.e., as the molecular trajectory is generated. This way, the electronic variables are considered as active degrees of freedom. For instance, in Born-Oppenheimer molecular dynamics nuclear degrees of freedom are propagated using ionic forces which are estimated at each iteration by approximately solving the electronic problem. In contrast – in the Car-Parrinello method the fictitious classical dynamics for electronic orbitals is explicitly introduced (Car and Parrinello 1985). These so-called *ab initio* MD calculations are much more computationally demanding, in contrast to traditional MD (Jasper et al. 2004a). Therefore, the study of full quantum dynamics of a polyatomic system is beyond computational possibilities, even in the next decades (Bornemann and Schütte 1998). A number of articles discussing *ab initio* MD have appeared over last years (Galli et al. 1991; Galli and Pasquarello 1993; Doltsinis and Marx 2002a; Grotendorst et al. 2002; Lorenz and Doltsinis 2012).

The interest in excited-state molecular dynamics simulations is growing, since many phenomena in modern science deal with electronic excited states: fluorescent microscopy, spectroscopy, labeling techniques, chemical lasers, photoactive enzymes, light-harvesting systems, optogenetics, photochemistry, just to name a few.

Fig. 1 Schematic comparison of nonadiabatic (orange) and adiabatic (red) reaction paths involving the ground state S_0 and first excited state S_1 . A nonadiabatic transition takes place through conical intersection (R reactants, TS transition state, P products, $*$ denoted excitation)

Among many applications of excited-state MD is computational photochemistry, which is described in a greater detail here, in order to introduce basic concepts and the formalism related to excited-state MD. Photochemical reactions can be divided into two categories: adiabatic and nonadiabatic (Fig. 1). Excited reactants R^* can overcome a potential barrier TS^* and turn into excited photoproducts P^* . After such a transition, P^* eventually return to their electronic ground state with an emission of a photon. In this process, a reaction path is on the same electronic excited state, which means that the reaction is adiabatic. On the other hand, a nonadiabatic reaction forms hot products in the electronic ground state by passing the conical intersection from the excited state to the ground state with no light emission. In other words, electronically nonadiabatic processes are defined as those in which the electronic state flips nonradiatively during dynamics (Fig. 1).

Therefore, excited-state MD is different from ground-state dynamics only when many electronic states must be considered simultaneously and can transfer a population among themselves. In such situations, the Born-Oppenheimer approximation breaks down, allowing nonadiabatic processes to take place. Nonadiabatic couplings (vibronic interactions) are well observed in molecules where two electronic states are degenerate. The nonadiabatic transition probabilities were introduced by Teller and Zener in 1930s (Zener 1932; Teller 1937). Teller also demonstrated the so-called conical crossings (also called molecular funnels or diabolic points) between potential energy surfaces in polyatomic molecules, which led to the formulation of the Jahn-Teller effect (Yarkony 1996).

Conical intersections are of high importance in a wide range of reactions, such as photoreactions, combustion reactions, and explosions (Bernardi et al. 1996; Baer and Billing 2003). Internal conversion at the conical intersections was showed by Zimmerman and Michl to be the fundamental feature to understand numerous photochemical mechanisms (Zimmerman 1966; Michl 1972a, b). In addition, the stability of DNA with respect to the UV irradiation is due to the presence of such conical intersection (Kang et al. 2002). These photochemical funnels provide pathways for ultrafast interstate crossing (in a femtosecond timescale).

This chapter presents selected main concepts and methods related to excited-state dynamics and is organized as follows. The theoretical formalism is presented in the sections “Adiabatic Molecular Dynamics” and “Nonadiabatic Molecular

Dynamics,” including the Born-Oppenheimer approximation and its limitations, the Ehrenfest dynamics, and surface hopping algorithms. In addition, the recently developed semiclassical Monte-Carlo approaches are also covered there. Selected practical calculations are presented in the **Applications** section, emphasizing advantages and drawbacks of the excited-state MD applicability to large molecular systems like proteins. The chapter ends with a **Conclusion** section, summarizing the current status of excited-state MD and pointing out the future prospects of this area of research.

Adiabatic Molecular Dynamics

Born-Oppenheimer Approximation

The Born-Oppenheimer (BO) approximation (Born and Oppenheimer 1927) is based on the assumption that the motions of nuclei and electrons in a molecule can be separated. It is usually introduced as an ansatz concerning the form of the molecular wavefunction. The BO approximation implies that the molecular wavefunction $\Psi(q, Q)$ is a product of the electronic and the nuclear factors:

$$\Psi(q, Q) = \psi(q; Q) \chi(Q) \quad (1)$$

where Q is a set of internal nuclear coordinates and q is a set of electronic coordinates. Here, $\chi(Q)$ is the nuclear wavefunction and $\psi(q; Q)$ is the electronic wavefunction, which also depends on fixed positions of the nuclei. The molecular Hamiltonian has the form (in the electrostatic approximation):

$$\mathcal{H} = -\sum_r \frac{\hbar^2}{2\mu_r} \frac{\partial^2}{\partial Q_r^2} - \frac{\hbar^2}{2m} \sum_i \frac{\partial^2}{\partial q_i^2} + V(q, Q) \quad (2)$$

where μ_r is a reduced mass for a r -th nucleus and m stands for the mass of an electron. One needs to remember that in Eq. 2 the Hamiltonian is simplified by neglecting the coupling between the rotation and the internal motions. By applying \mathcal{H} to the product $\psi(q; Q)\chi(Q)$, one gets:

$$\begin{aligned} \mathcal{H}\psi(q; Q) \chi(Q) &= \chi(Q) \left[V(q, Q) - \sum_i \frac{\hbar^2}{2m} \frac{\partial^2}{\partial q_i^2} \right] \psi(q; Q) \\ &\quad - \psi(q; Q) \left[\sum_r \frac{\hbar^2}{2\mu_r} \frac{\partial^2}{\partial Q_r^2} \right] \chi(Q) \\ &\quad - \sum_r \frac{\hbar^2}{2\mu_r} \left[2 \frac{\partial \psi}{\partial Q_r} \frac{\partial \chi}{\partial Q_r} + \chi \frac{\partial^2 \psi}{\partial Q_r^2} \right] \end{aligned} \quad (3)$$

The molecular Hamiltonian with the exclusion of the nuclear kinetic energy (electronic Hamiltonian) is the following:

$$\mathcal{H}_{el} = V(q, Q) - \frac{\hbar^2}{2m} \sum_i \frac{\partial^2}{\partial q_i^2} \quad (4)$$

$$\mathcal{H}_{el} \psi_k = U_k(Q) \psi_k \quad (5)$$

The eigenfunctions of the electronic Hamiltonian \mathcal{H}_{el} are so-called adiabatic wavefunctions. It is worth noting that, although \mathcal{H}_{el} does not contain differential operators with respect to the positions of nuclei Q , it depends on Q implicitly because its eigenvalues U_k and eigenfunctions ψ_k also depend on Q . The subscript k in the eigenfunctions and the corresponding eigenvalues is introduced to distinguish the different solutions of the Eq. 5. The ground states is for $k = 0$ and excited states are for $k > 0$.

Equation 3 now takes the form:

$$\begin{aligned} \mathcal{H} \psi_k(q; Q) \chi(Q) &= \psi_k(q; Q) \left[U_k(Q) - \sum_r \frac{\hbar^2}{2\mu_r} \frac{\partial^2}{\partial Q_r^2} \right] \chi(Q) \\ &\quad - \sum_r \frac{\hbar^2}{2\mu_r} \left[2 \frac{\partial \psi_k}{\partial Q_r} \frac{\partial \chi}{\partial Q_r} + \chi \frac{\partial^2 \psi_k}{\partial Q_r^2} \right] \end{aligned} \quad (6)$$

Finally, the definition of a nuclear Hamiltonian is following:

$$\mathcal{H}_{nuc} = U_k(Q) - \sum_r \frac{\hbar^2}{2\mu_r} \frac{\partial^2}{\partial Q_r^2} \quad (7)$$

$$\mathcal{H}_{nuc} \chi_{ku} = E_{ku} \chi_{ku} \quad (8)$$

where $U_k(Q)$ is an effective potential that constrains the nuclear motion. It is so-called the adiabatic potential energy surface (PES).

Now Eq. 3 can be written using the defined nuclear Hamiltonian:

$$\begin{aligned} \mathcal{H} \psi(q; Q) \chi_{ku}(Q) &= E_{ku} \psi_k(q; Q) \chi_{ku}(Q) \\ &\quad - \sum_r \frac{\hbar^2}{2\mu_r} \left[2 \frac{\partial \psi_k}{\partial Q_r} \frac{\partial \chi_{ku}}{\partial Q_r} + \chi_{ku} \frac{\partial^2 \psi_k}{\partial Q_r^2} \right] \end{aligned} \quad (9)$$

The BO approximation stands for neglecting the second term in Eq. 9:

$$\mathcal{H} \psi_k(q; Q) \chi_{ku}(Q) \approx E_{ku} \psi_k(q; Q) \chi_{ku}(Q) \quad (10)$$

Thus, Eq. 10 stands for the assumption that the $\psi_k \chi_{ku}$ vibronic states are approximate eigenstates of the molecular Hamiltonian.

The nonadiabatic couplings are introduced by the $H_{ku,lv}$ matrix elements:

$$H_{ku,lv} = \sum_r \frac{\hbar^2}{2\mu_r} \int_{-\infty}^{\infty} \chi_{ku}^* \left[t_{kl}^{(r)}(Q) + 2g_{kl}^{(r)}(Q) \frac{\partial}{\partial Q_r} \right] \chi_{lv} \dots dQ_s \dots \quad (11)$$

where

$$g_{kl}^{(r)} = \left\langle \psi_k \left| \frac{\partial}{\partial Q_r} \right| \psi_l \right\rangle \text{ and } t_{kl}^{(r)} = \left\langle \psi_k \left| \frac{\partial^2}{\partial Q_r^2} \right| \psi_l \right\rangle \quad (12)$$

The $g_{kl}^{(r)}$ terms do not couple different vibrational states that belong to the same electronic state. For $k = l$ in $t_{kl}^{(r)}$ a small correction is introduced to the U_k potential, which means that the approximate separation of the electronic and nuclear motions is not disrupted.

The BO approximation is based on neglecting all off-diagonal terms in nonadiabatic operators $g_{kl}^{(r)}$ and $t_{kl}^{(r)}$, i.e., neglecting interstate couplings, but keeping intrastate couplings between the electronic and nuclear terms (Eq. 12). The full adiabatic Born-Oppenheimer approximation is set by neglecting all diagonal terms too. In this approximation, the nuclei evolve on a single potential energy surface (either on the ground or the excited state), while the electrons adiabatically adjust to the nuclei.

Car-Parrinello Molecular Dynamics

The Car-Parrinello method for ab initio MD (Car and Parrinello 1985) has gained great popularity in recent years (Marx and Hutter 2009; Brunk and Rothlisberger 2015). It avoids expensive and explicit minimization of energy functionals required by the density functional theory (DFT) in the context of the Born-Oppenheimer approximation. As an alternative, it introduces a fictitious classical dynamics for the electronic orbitals (Car and Parrinello 1985). Car and Parrinello replaced the adiabatic motion of the electrons by a fictitious classical Lagrangian dynamics that oscillates around the energy minimum of the potential energy surface. In that sense, by introducing these oscillations again, the Car-Parrinello technique “undoes” the adiabatic Born-Oppenheimer approach that substituted the fast quantum-dynamically oscillatory behavior of the electronic wavefunction by the average of their motion around the minimum of the potential energy surface (Fig. 2). The fictitious classical dynamics is given by the following Lagrangian:

$$\mathcal{L}_{CP} = \frac{\mu}{2} \sum_{k=1}^N \dot{\psi}_k \cdot \dot{\psi}_k + \frac{1}{2} \sum_i M_i \dot{q}_i^2 - E_{KS}(\psi, q) + \sum_{k=1}^N \sum_{l=1}^N \Lambda_{kl} (\langle \psi_k, \psi_l \rangle - \delta_{kl}) \quad (13)$$

Here, the bracket $\langle \cdot, \cdot \rangle$ stands for the scalar product, ψ_k are the wavefunctions regarded as classical fields, M_i is the i -th ionic mass and, finally μ is the fictitious

Fig. 2 Logic of the Car-Parrinello method (Figure based on Bornemann and Schütte (1998))

electronic mass parameter. The dot denotes differentiation with respect to time. The orthonormality of the given wavefunctions ψ_k and ψ_l is ensured by introducing the Lagrange parameters Λ_{kl} .

The study of Pastore et al. (1991) proves that the fictitious mass parameter μ (usually in the range of 300–800 a.u.) constitutes a kind of a control parameter. The bigger μ is chosen, the bigger the deviation of the Car-Parrinello method from the adiabatic model is. More importantly, μ introduces a time scale of order $\sqrt{\mu}$. This requires time steps in a simulation to be proportional to $\sqrt{\mu}$. For that reason, the Car-Parrinello quantum dynamics is restricted to time steps even order of magnitude smaller than the BO adiabatic dynamics, thus it is more computationally demanding (Kühne et al. 2007). One has to establish a compromise between the computational costs and accuracy. Moreover, it is worth remembering that maintaining adiabaticity requires that the fictitious mass of electrons μ is chosen small enough to suppress a significant energy transfer from the ionic to the electronic degrees of freedom.

It is worth mentioning that the nonadiabatic Car-Parrinello molecular dynamics is also possible by coupling the restricted open-shell Kohn-Sham (ROKS) excited state to the ground state using a surface hopping scheme (Doltsinis and Marx 2002b).

Ab initio molecular dynamics is not bound to any particular electronic structure method. It is obvious that advantages and drawbacks of a particular ab initio MD are strongly connected to the underlying approximate electronic structure algorithm chosen. Over the past years, a vast spectrum of different electronic structure methods became well established, i.e., DFT, Hartree-Fock, generalized valence bond, complete active space self-consistent field (CASSCF), second-order many-body perturbation theory (MP2), or full configuration interaction (FCI), all of them may be exploited in ab initio MD simulations, but the computational cost will vary enormously, especially for larger systems.

Machine Learning Molecular Dynamics

More recent approaches to calculate force fields “on-the-fly” are based on machine learning. They use neural networks (Behler and Parrinello 2007), Gaussian

processes (Bartók et al. 2010), or the Bayesian interference (Li et al. 2015) to fit the potential energy surface, after which atomic forces are obtained by analytical differentiation (Li et al. 2015). Such implementations are not formally limited to a small number of atoms; thus, open a way for ab initio molecular dynamics of proteins. In machine learning MD, simulating dynamics is not dependent on static force fields, i.e., predefined parametrized functional forms fitted on experimental data (Laio et al. 2000). One should notice that the mentioned first principles techniques are restricted nowadays only to one potential energy surface; therefore, this kind of an approach is currently feasible only to adiabatic processes. Moreover, some of these techniques require a training set to enable learning procedure during MD simulations. The training sets can be collected to optimize an efficiency of the learning procedure either by performing the classical MD (Karplus and Petsko 1990), Monte Carlo (Duane et al. 1987), or metadynamics (Laio and Parrinello 2002; Ensing et al. 2006; Laio and Gervasio 2008) simulations.

Nonadiabatic Molecular Dynamics

For a large number of physical/chemical problems, the Born-Oppenheimer approximation can be applied with a great success. On the other hand, to properly describe phenomena beyond the BO approximation one needs to introduce the nonadiabatic couplings in MD simulations. These include, for instance, charge transfer and photoisomerization reactions. According to Barbatti and Crespo-Otero (2014) semiclassical MD methods suitable for excited states should incorporate the following criteria:

1. Be computationally nondemanding
2. Be reliable and accurate in terms of excited states of different nature
3. Be independent from human intervention and preferably not system dependent
4. Provide a computational algorithm for calculating electronic structures near intersection seams with the ground state and between the excited states

The simplest approach to include the nonadiabatic terms in MD is to treat nuclear motions by classical mechanics. In such approximation, the atomic nuclei follow a given classical trajectory, while the electronic motions are described in terms of time-dependent total wavefunction that satisfies the time-dependent electronic Schrödinger equation. The semiclassical approach is often classified as trajectory ensemble methods, where the nuclear motion of the system is simulated by a swarm of classical trajectories (Tully and Miller 1976; Tully 1998; Hack and Truhlar 2000; Jasper et al. 2004b). Such semiclassical algorithms are popular, because their only quantum requirement is that electronic structure properties have to be computed “on-the-fly.” In other words, the semiclassical methods do not require the knowledge of the full configurational space – PES is probed only along the classical motion of the nuclei. The necessary electronic structure part can be approximated

using various DFT methods, such as ROKS, time-dependent DFT (TDDFT), or wavefunction-based approaches.

For the two-state system, the nonadiabatic couplings can be examined by the so-called Massey parameter (Desouter-Lecomte and Lorquet 1979; Gersonde et al. 1994; Nikitin and Zülicke 1978):

$$\xi = \frac{\Delta E l}{\hbar \dot{R}} \quad (14)$$

where l is the characteristic length over which wavefunctions corresponding to states change significantly. For value $\xi \gg 1$ (large energy gaps ΔE and small nucleic velocities \dot{R}), the nonadiabatic effects in the system can be neglected. In the Born-Oppenheimer approximation, the electron cloud has to adjust instantly to changes between the nuclear distances. The frequency of electronic motions ω can be calculated by dividing a corresponding energy gap ΔE by \hbar :

$$\Delta E = \hbar \omega \quad (15)$$

The frequency of electronic oscillations is high when the nuclei are close to each other, i.e., where a distance between the nuclei R is small. It is clear that such distortions in the electronic clouds will influence the nuclear trajectory. Thus, these are the reasons for the significance of the nonadiabatic effects in the discussed two-state system.

The general expression for measuring nonadiabatic effects for two states k and l of a particular system can be derived from the Hellman-Feynman theorem (Feynman 1939; Hellmann 1937):

$$\left\langle \psi_k \left| \frac{\partial}{\partial Q_r} \right| \psi_l \right\rangle = \frac{\left\langle \psi_k \left| \frac{\partial \mathcal{H}_{el}}{\partial Q_r} \right| \psi_l \right\rangle}{U_l - U_k} \quad (16)$$

The nonadiabatic couplings between two states k and l are larger where their PESs get closer to each other, thus $\Delta U = U_l - U_k \rightarrow 0$. It is worth noticing that ΔU cannot be 0 for diatomic molecule systems, because two distinct solutions cannot be satisfied for the same bond length R , which means that eigenvalues corresponding to different states cannot cross (cannot become an equal value). This is sometimes called an “avoided crossing” or “noncrossing rule.”

Switching from a nonadiabatic state to the other one by a single “hop” means staying in the same adiabatic state. The probability of hopping between distinct adiabatic states $P_{a_1 \rightarrow a_2}^d$ may be estimated from the so-called Landau-Zener formula, which was formulated separately in 1932 by L. Landau (1932), C. Zener (1932), E. Stueckelberg (1933), and E. Majorana (1932):

$$P_{a_1 \rightarrow a_2}^d \approx \exp\left(-\frac{\pi^2 \Delta E^2}{\hbar v \Delta S}\right) \quad (17)$$

Here, a_1 and a_2 are the chosen adiabatic states, ΔE is the energy gap between the two potential energy surfaces at the geometry of the closest approach, ΔS is the slope difference in the region of the avoided crossing and v is the nuclear velocity along the reaction coordinate. Therefore, the probability of a “hop” from one adiabatic BO surface to another increases with an increasing difference in the surface slopes and increasing velocity of the nuclear motion but also with decreasing energy gap ΔE . The less avoided the crossing, the larger the jump probability. Some early studies of excited-state dynamics in heme proteins (Li et al. 1993; Cottone et al. 2012) and photoactive enzymes (Kubiak and Nowak 2008) employed this formula.

Ehrenfest Mean-Field Dynamics

Incorporating vibronic properties is of high importance in all systems, where the nonadiabatic effect should not be neglected. In the plain simple semiclassical approximation, the total wavefunction $\Psi(q, t)$ consists of a linear combination of adiabatic eigenfunctions $\psi_k(q, Q)$ (Eq. 5):

$$\Psi(q, t) = \sum_k C_k(t) \psi_k(q, Q) \exp\left(-\frac{i}{\hbar} \int U_k(Q) dt\right) \quad (18)$$

Here, $|C_k(t)|^2$ is the probability of the system being in the adiabatic state k at time t . The adiabatic potential energy surface U_k can be replaced by the energy expectation value:

$$U_{eff} = \langle \Psi | \mathcal{H}_{el} | \Psi \rangle = \sum_k |C_k(t)|^2 U_k \quad (19)$$

So now, all the atoms experience the effective potential U_{eff} , which represents an average over the adiabatic potential energy surfaces multiplied by their expansion coefficients $|C_k(t)|^2$. Molecular dynamics with above substitution is called the Ehrenfest dynamics, and because the idea is to perform an average over adiabatic PESs, it is also referred to as mean-field dynamics (Ehrenfest 1927). An effective potential is most appropriate for strong vibronic interactions but leaves the system in an unphysical final state that corresponds to a quantum superposition of adiabatic states. Although, this method has been successfully used to study some chemical problems, i.e., excitation lifetimes of organic molecules (Liang et al. 2010), on the other hand it suffers from serious drawbacks. When the difference between the adiabatic states is large, then the dynamics must be primarily driven by only one surface and not an average potential. Moreover, a system, which is initially in a pure adiabatic state, after a transition through strong vibronic coupling, will be in a mixed state. The most significant issue is that the pure adiabatic character of a state cannot be recovered in the configuration space even asymptotically. Yet another problem is that the Ehrenfest methods violate microscopic reversibility (Grotendorst et al. 2002).

Fig. 3 Schematic comparison of two semiclassical molecular dynamics algorithms: the Ehrenfest mean-field method (*left, blue* – single trajectory) and Tully’s surface hopping method (*right, red* – swarm of trajectories) governed by two potential energy surfaces

Surface Hopping

The quantum wavepacket evolution in time can be approximated by a swarm of semiclassical trajectories propagating on adiabatic Born-Oppenheimer potential energy surfaces of multiple electronic states. The nonadiabatic events are represented by a stochastic algorithm which allows each trajectory to “hop” between other states during the time evolution. In this class of methods, the wavepacket probability distribution should be approximated by the statistics over an ensemble of trajectories in terms of a fraction in each electronic state at any time step (Fig. 3). This method, in contrast to the Ehrenfest dynamics, does not facilitate any averaged adiabatic potentials. At any moment in time, the system is propagated using one pure adiabatic potential energy surface that is selected according to its state population.

The time-dependent electronic state is following:

$$\Psi^{(r)}(q, Q, t) = \sum_k C_k^{(r)}(t) \psi_k^{(r)}(q; Q) \quad (20)$$

where the subscript (r) is used to emphasize the dependence on the trajectory. After taking Eq. 19 to the time-dependent Schrödinger equation, a set of coupled equations of motion for the complex nuclear state amplitudes $C_k^{(r)}(t)$ emerges:

$$i\hbar \dot{C}_k^{(r)}(t) = \sum_k C_k^{(r)}(t) \left\{ U_k(Q^{(r)}) \delta_{ij} - i\hbar \sum_\gamma g_{jk}^{(\gamma)}(Q^{(r)}) \dot{Q}_\gamma^{(r)} \right\} \quad (21)$$

where the first order nonadiabatic couplings $g_{jk}^{(\gamma)}$ are given by Eq. 12. These coupled equations can be solved along a nuclear classical trajectory r , evolving adiabatically in a given electronic state j . The given trajectory r can “hop” from the state j to k during the time interval $[t, t + dt]$ with the probability:

$$p_{jk}^{(r)}(t, t + dt) = -2 \int_t^{t+dt} \Re \left[\frac{C_k^{(r)}(\tau) C_j^{(r)*}(\tau) \kappa_{kj}^{(r)}(\tau)}{C_j^{(r)}(\tau) C_j^{(r)*}(\tau)} \right] d\tau \quad (22)$$

Here, $\kappa_{kj}^{(r)}(\tau) = \sum_{\gamma} g_{ij}^{(\gamma)}(Q^{(r)}) \dot{Q}_{\gamma}^{(r)}$. A stochastically driven jump between two distinct potential energy surfaces $j \rightarrow k$ takes place when a following condition is fulfilled:

$$\sum_{l \leq k-1} p_{jl}^{(r)} < \varrho < \sum_{l \leq k} p_{jl}^{(r)} \quad (23)$$

where $\varrho \in [0, 1]$ is a randomly generated number. This algorithm is a modification of the traditional surface hopping method (Tully and Preston 1971; Tully and Miller 1976), and it guarantees minimum number of jumps along each adiabatic trajectory. Thus, it is referred to as the “fewest switches surface hopping algorithm” (Tully 1990, 1998). This algorithm has emerged as a popular platform for performing excited-state MD over the recent years (Hudock et al. 2007; Hazra et al. 2010; Jiang and Sibert III 2012).

According to Tully, surface hopping algorithms suffer from the three major inconsistencies between quantum and classical mechanics (Tully 2012). The foremost issue in semiclassical molecular dynamics comes from discrepancies in feedback between the quantum and classical degrees of freedom. The reason for this is that the motions of particles treated classically imply changes of the Hamiltonian which govern the quantum particles and, therefore, drive nonadiabatic transitions. On the other hand, such changes of a quantum state have impact on the classical motion. It is so-called quantum back-reaction.

Yet another important divergence of surface hopping algorithms from the theory can be attributed to the quantum decoherence (Hammes-Schiffer and Tully 1994). The total wavefunction for a system and its bath have a phase to which contribute both fast and slow degrees of freedom. In the case of taking the classical limit for the slow degrees of freedom, the phase information corresponding to this part of system is gone. Unfortunately, this lost phase affects the branching ratios of the trajectories. The interference between the wavefunctions of the slow degrees of freedom for the different possible trajectories exists only when time is shorter than the decoherence times. Interesting idea for handling the quantum decoherence problem is the simultaneous-trajectory surface hopping (Shenvi et al. 2011).

The last concern with treating some degrees of freedom by the laws of classical mechanics and others with quantum mechanics is properly handling the detailed balance condition. Accordingly, the quantum system driven by finite temperature classical system will in limit approach an infinite temperature. This is a well-known issue, since the energy passes from the classical system to quantum system artificially. Besides the surface hopping algorithms, which handle detailed balance approximately, the Ehrenfest dynamics does not solve this problem in any form. This approximately corrects detailed balance results from frustrated surface hops (Fig. 4). A hop is frustrated if the system does not have enough energy to make the hop. The simplest solution suggested to deal with these frustrated hops is to ignore them (Tully 1990). Another solution is not to switch the adiabatic state but

Fig. 4 Schematic comparison of the surface hopping trajectories in case of restricted total energy level (*violet line*): (*red*) omitting frustrated hop, if energy conservation condition is not fulfilled (Tully 1990); (*green*) allowing frustrated hop, even if such condition does not stand but Jasper condition stands (Jasper et al. 2002)

instead reverse the direction of the component of the velocity along the nonadiabatic coupling vector (Hammes-Schiffer and Tully 1994). One more suggestion proposed by Jasper et al. is to allow the transition to take place if an allowed hopping point is reachable within uncertainty time $\delta t = \hbar/2\Delta E$, where ΔE is the extra energy that the system needed to make the hop possible (Jasper et al. 2002).

Another recent modification of the fewest switches surface hopping was proposed in Gorshkov et al. (2013) and White et al. (2014). A part of this algorithm is similar to previous surface hopping methods. A swarm of classical trajectories is propagated, allowing the system to jump from a current pure adiabatic potential energy surface to the other state. The hopping rate is, however, arbitrary and the “hop” occurs only if the energy balance condition is fulfilled. Next, the classical trajectories are classified into groups according to their final electronic states and the numbers of jumps that occurred during their course. The gained data is used later in Monte-Carlo sampling to retain phase information and the hopping rates at the moments of hops.

Hybrid Quantum Mechanics/Molecular Mechanics (QM/MM)

The quantum mechanical approach to dynamics is much more computationally demanding than classical mechanics, thus it is not directly applicable for large biological molecules. The key idea to overcome this limitation was proposed by Warshel and Levitt (1976). The main assumption in that method is to subdivide a complex system in such a way that only a small, nevertheless chemically active region is treated quantum mechanically. The rest of the system is simulated with empirical potentials of the classical MD. In this way, even huge biological systems can be treated efficiently in terms of computational resources and for longer simulation times. This is the so-called QM/MM approximation and since its postulation the method has been applied to various complex biomolecules (Virshup et al. 2008; Beierlein et al. 2011; Shim et al. 2012; Brunk and Rothlisberger 2015).

The QM/MM methods were combined with both adiabatic and nonadiabatic quantum calculation methods (Brunk and Rothlisberger 2015).

The hybrid Hamiltonian takes the form:

$$\mathcal{H}^{QM/MM} = \mathcal{H}^{QM}(q) + \mathcal{H}^{MM}(Q) + \mathcal{H}^{QM-MM}(q, Q) \quad (24)$$

Here, \mathcal{H}^{QM} denotes the ab initio Hamiltonian, \mathcal{H}^{MM} is the classical Hamiltonian, which is described by a standard force field

$$\mathcal{H}^{MM} = \mathcal{H}_b^{MM}(Q) + \mathcal{H}_{nb}^{MM}(Q) \quad (25)$$

where \mathcal{H}_b^{MM} is the bonded term, which takes into account stretching, bending, and torsional terms, whereas \mathcal{H}_{nb}^{MM} is the nonbonded term, and it includes the van der Waals, hydrogen bonds, and electrostatic interactions. The major drawback of the QM/MM approximation is calculating the coupling term of the full Hamiltonian, \mathcal{H}^{QM-MM} . For instance, in QM/MM Car-Parrinello methods, the van der Waals interactions between QM and MM regions are described by the classical force field. The same assumption holds for the bond angles bending and dihedral distortions. In contrast, bonds between the QM and MM regions are treated with monovalent pseudopotentials.

Applications to Large Biological Systems

The most widely used approach to large biological systems, including proteins, membranes, and nucleic acids, is classical MD, dealing with a single adiabatic PES. Although, the MD method itself is very efficient, it is insufficient in describing numerous phenomena important for biological functions such as electronic excitations, bond formation and breaking, and charge transfer. Ab initio MD is, to some extent, applicable to the photophysical processes in structural biology and some representative examples of such studies are outlined here, together with an example from photoactive material science.

Photoactive Yellow Protein

Photoactive yellow protein (PYP) is a small protein that governs negative phototropism in bacteria *Halorhodospira halophila*. It contains p-coumaric acid covalently bound to the protein as a chromophore. It is a very well-characterized bacterial photoreceptor with a simple photocycle and some features in common with other photoactive proteins. The CASSCF (3-21G)-QM/MM method was applied to observe spontaneous isomerization of PYP (Groenhof et al. 2004).

This study has demonstrated that QM/MM MD with explicit surface hopping from the ground to the first excited-state can reproduce excited-state lifetimes in PYP acquired from experiments. Moreover, it helped to reveal the molecular mechanism responsible for the activity of the protein matrix on the PYP chromophore.

In another study by Isborn et al. (2012), QM/MM molecular dynamics simulations were used for computation of the absorption spectra of PYP in vacuo, aqueous solution, and protein environments. It was shown that the computed excitation energies of PYP require a QM region to be very large in order to achieve an agreement with the protein system treated entirely by quantum dynamics. The QM region consisting of the PYP chromophore, covalently linked to PYP, the layer of PYP, and water molecules, was treated with TDDFT. The dynamics of the QM region was simulated with BO dynamics. The rest of the PYP system was subject to the empirical force field. The interaction energy between the QM and MM was given by:

$$\begin{aligned}
 E^{QM-MM} = & \sum_{J=1}^{N_{QM}} \sum_{k=1}^{N_{MM}} \frac{Z_J q_k}{|\vec{r}_J - \vec{r}_k|} - \sum_{k=1}^{N_{MM}} \int q_k \frac{\rho(\vec{r})}{|\vec{r} - \vec{r}_k|} d\vec{r} \\
 & + \sum_{J=1}^{N_{QM}} \sum_{k=1}^{N_{MM}} \epsilon_{Jk} \left[\left(\frac{\sigma_{Jk}}{|\vec{r}_J - \vec{r}_k|} \right)^{12} - \left(\frac{\sigma_{Jk}}{|\vec{r}_J - \vec{r}_k|} \right)^6 \right] \quad (26)
 \end{aligned}$$

where the first term of Eq. 26 is the Coulomb interaction between the QM nuclei of charge Z_J with the MM charges q_k , the second term – the Coulomb interaction of the QM electron density $\rho(\vec{r})$ with the MM charges q_k , and the last term is the Lennard-Jones interaction of the QM atoms with the MM atoms to account for the van der Waals forces, where ϵ and σ are the interaction energy and interatomic distance for each pair of atoms, respectively (Isborn et al. 2012).

Isborn et al. observed mismatches between all the computed absorption spectra of PYP and experimental results. The authors listed possible reasons concerning this discrepancy: (i) treatment of errors by the TDDFT functional for various electronic environments, (ii) too few QM water molecules in QM/MM technique, and (iii) inaccurate molecular dynamics formulas regarding the interface between QM and MM regions (Eq. 26). Therefore, for both the ground and excited states of PYP it was suggested to include the majority of the simulated system in the QM region.

Rhodopsin

Rhodopsin is a highly specialized G protein-coupled receptor indispensable for transduction of light signals to the form of neuronal impulses. The protonated Schiff base of 11-*cis*-retinal, which is a chromophore of rhodopsin, upon absorption of light isomerizes to all-*trans* in an efficient process that takes 200 fs (Fig. 5).

Detailed mechanistic behavior of 11-*cis* to all-*trans* retinal isomerization was investigated by many hybrid molecular dynamics methods, including the QM/MM Car-Parrinello approach with ROKS of the first excited singlet state (Röhrig et al. 2004) and for a model π -electron system embedded in a real protein environment

Fig. 5 Isomerization of 11-*cis*-retinal to all-*trans*-retinal upon light excitation (Scheme prepared by J. Rydzewski, NCU, Poland)

at the advanced CASSCF level (Hayashi et al. 2003). Moreover, the conical intersection present in bacteriorhodopsin has been studied computationally and verified experimentally by ultrafast femtosecond spectroscopy with the excellent agreement between both methods (Polli et al. 2010).

Channelrhodopsin

Channelrhodopsins (ChRs, Fig. 6) are light-gated cation channels derived from algae that have shown significant utility in optogenetics. Neurons expressing ChRs can be controlled via light event in freely moving mammals (Deisseroth 2011; Kato et al. 2012). In terms of structure, ChRs have seven transmembrane part and contain the light-isomerizable chromophore all-*trans*-retinal (Fig. 6). To optimize ChRs functions, neuroscientists engineered a variety of its mutants (Lin 2011). Their success is often based on trial-and-error, rather than conclusions drawn from mechanistic insights. The exact atomistic behavior of ChRs would be of high significance in the understanding of newly emerging research field – optogenetics. Excited state molecular dynamics simulations are the perfect tools to achieve that since the structural manipulations can be examined on the atomistic level.

In the recent paper, K. Welke et al. proposed a computational approach for engineering color-shifted (characterized by a shifted absorption maximum) optimized ChRs variants acquired from homology modeling of a bacteriorhodopsin template (Welke et al. 2011). The aim of their study was to enable the search for possible targets for mutations that shift the absorption maximum. The impact from amino acid mutations near the ChR retinal binding pocket was described by the use of the QM/MM approach with the chromophore of ChR treated with the CASSCF method. The rest of the system, including ChR, was simulated by the classical molecular

Fig. 6 Schematic representation of the QM/MM approach. The whole biological system (channelrhodopsin, membrane, solvate, retinal) is divided into two regions: QM – surrounding the retinal photoactive ligand and MM – concerning the rest of the system. Visualized using Pymol (Figure prepared by J. Rydzewski, NCU, Poland)

dynamics techniques. They concluded that the large hypsochromic shift can be traced back to two origins. First, while the single mutations in the ChR binding pocket effect on a color shift is rather small, a combination of mutations covers the majority of the hypsochromic shift. Second, the other significant contribution is a stronger interaction of the retinal with its counterions. Another study regarding ChRs showed that in the visible region the circular dichroism spectrum is dominated by the exciton coupling between the retinal chromophores in the two subunits of ChR (Pescitelli et al. 2014). In that study, the QM/MM model with QM part of the system treated with TDDFT reproduces the transition energies for ChR better than any other models examined therein. The authors are not aware of any published research concerning explicitly the excited state quantum dynamics of the ChRs proteins. Filling this gap perhaps makes a perfect opportunity for understanding in the near future the time evolution of optogenetic molecular systems.

Organic Conjugated Materials

Photoactive materials require understanding of their electronic properties in order to control their photo-induced pathways. Especially, irradiative intraband relaxation of organic conjugated materials (OCMs) can lead to various complex processes challenging to model, since such processes alleviate breakdown of the

BO approximation. In the paper by T. Nelson et al. it was showed that Tully's fewest switching surface hopping algorithm can be successfully applied to large polyatomic systems involving many excited states and multiple unavoided crossings between potential energy surfaces (Nelson et al. 2014). It was proved that the highly efficient intramolecular ultrafast energy transfer in poly-(phenylene ethynylene) dendrimers, modeled by two-, three-, and four-ring PPE chromophores, is consistent with experimental measurements. Moreover, a method that allows the analysis of the distribution of radiationless transitions due to cross and hop and proper dealing with so-called trivial unavoided crossings of the potential energy surfaces has been developed (Fernandez-Alberti et al. 2012). The term "trivial" unavoided crossing describes the situation when the nonadiabatic couplings take a form of sharp peaks.

Artificial Light-Harvesting Systems

In artificial photosynthetic devices, the efficient conversion of light into electricity is believed to occur on femto- and picosecond timescales. Up to now, it was assumed that this conversion involves an incoherent electron transfer process. However, in the recent studies, there have been indications showing that the coherent motion of electrons is one of the most important stages during the conversion process (Engel et al. 2007) in photosynthetic bacteria and higher plants (Lee et al. 2007). Rozzi et al. studied quantum dynamics of a photo-excited carotene-porphyrin-fullerene triad and provided evidence that the electron energy transfer from the porphyrin moiety to fullerene is strongly correlated with wavelike motions of electrons and nuclei on timescales not exceeding hundreds of femtoseconds. Quantum dynamics was performed by combining TDDFT and the Ehrenfest mean-field approach (Alonso et al. 2008; Andrade et al. 2009). The initial photoexcitation of the molecule was modeled by a rapid perturbation in the charge density localized on the porphyrin moiety. Next, the evolution of this perturbation and its effects on the charge density on the rest of the triad were monitored in time for two different simulation scenarios: quenched ionic positions in specific regions of the molecule and nuclei not restricted to move (Fig. 7). Therefore, determination of the effect of quantum dynamics of the system on the electron transfer was possible.

The results of quantum dynamics simulations of Rozzi et al. indicate a rapid charge density flow to the fullerene moiety within approximately 70 fs, but only in case of freely moving nuclei. The initial perturbation in form of the electronic wavepacket oscillates between the carotene-porphyrin group and the fullerene moiety. It was confirmed that the ionic movement drives the charge density transfer in the molecule. By quenching all the nuclei so they do not move during the quantum dynamics, the charge transfer was greatly suppressed.

Fig. 7 Frames of the photo-induced perturbation used to model oscillations in charge density at a time of 30.48 fs the nuclei not restricted to change positions and all ions clamped. An increase in electronic charge density is colored in *magenta*, whereas a decrease is shown in *green* (Reprinted with permission of Nature Publishing Group from “Quantum coherence controls the charge separation in a prototypical artificial light-harvesting system” *Nat. Commun.* 2013, 4, 1602)

The given example shows a great importance of the quantum dynamics methods, i.e., the Ehrenfest method combined with TDDFT as a complementary tool to the ultrafast spectroscopy in probing the quantum behavior of the artificial photosynthetic devices.

Software

There are several programs suitable for performing quantum dynamics simulations, with a particular emphasis on nonadiabatic molecular dynamics or adiabatic molecular dynamics, capable of performing excited state dynamics on a single excited potential energy surface. An arbitrary list of newly emerging as well as established codes, which are appropriate for such dynamics studies for large biological systems, is presented below.

Newton-X

Newton-X (www.newtonx.org) implements a semiclassical surface hopping algorithm (see section “[Surface Hopping](#)”). It provides all steps of the nonadiabatic molecular dynamics simulation, i.e., generation of the initial conditions, computing the semiclassical trajectories and a statistical analysis of results. It must be interfaced with a program, which can calculate the potential energy surfaces by solving the Schrödinger equation for electrons, for instance: Gaussian, Turbomole,

or Gamess. Usually, the surface hopping method uses MCSCF, CC2, MRCI, or TDDFT techniques. Embedding the system in the molecular mechanics environment via the QM/MM approach is also possible.

Octopus

Octopus (www.tddft.org) employs norm-conserving pseudopotentials and real-space grid discretization (no basis sets) for performing Kohn-Sham TDDFT in real time. It can perform molecular dynamics simulations with use of Born-Oppenheimer dynamics, Ehrenfest dynamics, and Car-Parrinello dynamics. The only way to incorporate the nonadiabatic effects into the system of interest is by the Ehrenfest dynamics for nuclei, since the system evolves using a mean-field approximation. Octopus is capable of treating not only systems in three dimensions, but also in 2D and 1D for low-dimensional solids (Andrade et al. 2015; Castro et al. 2006; Marques et al. 2003).

CPMD

The CPMD program (www.cpmd.org) is an implementation of DFT based on plane waves and norm-conserving or ultra-soft pseudopotentials, particularly dedicated for both the adiabatic and nonadiabatic Car-Parrinello dynamics (see section “[Car-Parrinello Molecular Dynamics](#)”). It enables simulations of excited state molecular dynamics by the means of TDDFT (either using the density functional theory-based Ehrenfest approach or the linear response approximation to time-dependent Kohn-Sham density functional theory). It is suitable also for the hybrid QM/MM calculations with the use of the GROMOS force field. Tully’s fewest hopping algorithm is also implemented to simulate a complete swarm of classical trajectories on the potential energy surfaces. Moreover, the efficient Landau-Zener-Stückelberg theory of nonadiabatic transition has been implemented as well.

Conclusion

Excited state molecular dynamics as a tool for simulating molecular phenomena induced upon interaction with light is becoming more and more popular due to increasing computer power, implementations of new methods, and algorithm improvements. Some pilot applications in studies of biomolecules have appeared; nevertheless, there is already “plenty of space above the ground” for new applications. For instance, one can imagine the protein-ligand photo-dissociation process (Rydzewski and Nowak 2015) with a ligand capable of switching between the ground and excited potential energy surfaces during molecular dynamics simulations. Excited state molecular dynamics simulations, perhaps, will be soon mature enough for application to even larger molecular systems and more complex light-

induced phenomena in the near future. New application areas arise as biological phenomena reveal more and more their quantum nature (Arndt et al. 2009; Lambert et al. 2013).

Abstract

This chapter focuses on the computational investigations of light-induced chemical reactions in different systems ranging from organic molecules in vacuo to chromophores in complex protein environments. The aim is to show how the methods of computational photochemistry can be used to attain a molecular-level understanding of the mechanisms of photochemical and photophysical transformations. Following a brief introduction to the field, the most frequently used quantum chemical methods for mapping excited state potential energy surfaces and for studying the mechanism of photochemical reactions in isolated molecules are outlined. In the following sections, such methods and concepts are further developed to allow the investigation of photo-induced reactions in solution and in the protein environment.

Introduction

Since the early 1990s, quantum chemical methods based on *ab initio* multi-configurational wavefunctions have been used to investigate the mechanisms of photochemical organic reactions and have led to the development of the field of computational photochemistry (Bernardi et al. 1996b). As a consequence it is now possible, using available program packages (examples of which include Molcas (Andersson et al. 2009; Aquilante et al. 2009), Gaussian (Frisch et al. 2009), Gamess-US (Gordon et al. 2005; Schmidt et al. 1993), Columbus (Lischka et al. 2006), Molpro (Werner et al. 2008), and Q-Chem (Adams et al. 2009; Shao et al. 2006)), to locate excited state equilibrium structures, conical intersections, or singlet/triplet crossings, and map ground or excited state minimum energy paths at a level of accuracy that often allows for comparison with spectral data (Kutateladze 2005; Olivucci and Sinicropi 2005). This offers chemists a powerful tool to rationalize and predict such complex processes as the light-induced response of a molecule.

There are two events that may happen when light energy is absorbed by a molecule: wastage or exploitation. Some technological application may require molecules whose structures are unaffected by light absorption, those that efficiently dispose of the excess electronic energy (e.g., through light emission and internal conversion). Other applications may require molecules that exploit light to drive specific chemical, conformational and electronic changes (e.g., through photochemical reactions or light-induced energy or electron transfer). It can be easily recognized that nature provides many examples of effective light energy wastage and exploitation. Therefore, the understanding of these events can be considered a basic requirement for the rational design of efficient photochemical reactions, artificial photosynthetic systems, and molecular-level devices and machines. Below, we will present case studies from small molecules in the gas phase to molecules in complex environments such as biological photoreceptors.

The computational investigation of a light-induced reactive process requires the construction of the associated photochemical reaction path (Olivucci and Sinicropi 2005). In its simplest form, this is defined by a branched minimum energy path that connects the Franck–Condon (FC) point A^* on the potential energy surface of the light-absorbing state with one (or more) primary photoproduct (B) or original reactant (A). As illustrated in Fig. 1 left, if the relaxation of A^* leads to a stable excited state equilibrium species (structure B^*) this may form a luminescent state, for instance a fluorescent state (FS), thus leading to radiative deactivation. High fluorescence quantum yields require long excited state lifetimes that, among other factors, could be imposed by high energy barriers restraining further evolution of A^* . If this is not the case, B^* can evolve beyond a transition state (TS), to produce a different excited state species (C^*) that may also decay radiationally. If this is the case, one has an excited state conformational or chemical change that might lead to a different fluorescence emission. One of the most prominent examples of this so-called dual fluorescence is that produced by 4-(N, N-dimethylamino)benzonitrile in polar solvents (Grabowski et al. 2003). Alternatively (see Fig. 1 right), the excited state transition structure could connect B^* to a point where efficient radiationless decay (internal conversion) takes place. In the limiting case of a negligible or non-existent barrier, A^* may promptly reach such point on a picoseconds time-scale. For internal conversion, this process is usually associated with regions where there is a limited gap between ground and excited states, a large overlap between a low lying vibrational state of the photoexcited molecule and a suitable ground state vibrational mode (Simons 1983). These conditions are satisfied in the regions surrounding a

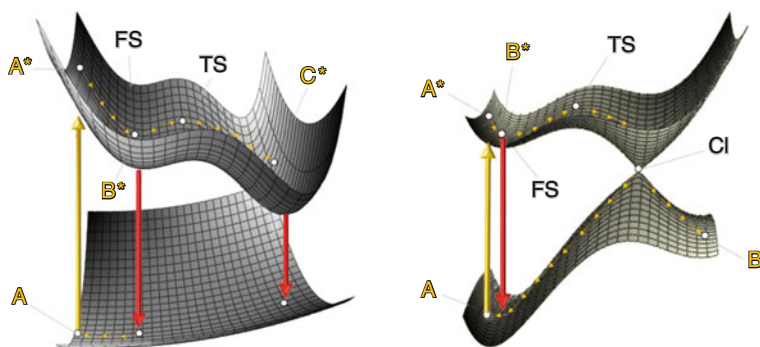

Fig. 1 Schematic structure of the photochemical reaction path. Left: general structure of the excited state energy surface in the vicinity of the Franck–Condon point. A^* is geometrically identical to the minimum on the ground state, but has the electronic wave function of the excited state. The species B^* is a relaxed form of A^* that may emit fluorescence and/or evolve towards a different region of the excited state potential energy surface through the transition state (TS), producing a different emitting or reactive species C^* . Right: intersecting ground and excited state potential energy surfaces. The arrows indicate the direction of the minimum energy path connecting A^* to the conical intersection (CI) and then to the photoproduct B or original reactant A

conical intersection (CI). Therefore, evolution towards a CI leads to an efficient decay to the ground state (decay is common in the whole region surrounding the CI). When the relaxation following decay results exclusively in reactant back-formation (CI \rightarrow A stream of arrows) one has internal conversion. In contrast, when the ground state relaxation produces a novel species B (a primary photoproduct) by following a different relaxation path, one has a photochemical event (left to right stream of arrows).

CIs provide a common key mechanistic entity for the description of a photochemical reaction and ultrafast internal conversion (Turro et al. 2009). The potential energy surface region surrounding each CI point can be seen as an efficient radiationless deactivation channel (Bernardi et al. 1996a; Migani and Olivucci 2004; Robb et al. 1995) that, in photochemistry, is called a funnel. A photochemical funnel (Braslavsky 2007) corresponds to a molecular structure in the vicinity of a CI that would decay within one half of a vibrational period. For this reason computer simulations appear to be the only “direct” source of information about the structure of a molecule in a funnel. Notice that one has a CI only when the ground and the excited state have the same spin. If this is not the case and the electronic states have different spins the process is called intersystem crossing (Simons 1983; Turro et al. 2009).

In Fig. 1 we show that the entire “photochemical reaction path” is defined and computed in terms of a set of connected minimum energy paths (MEP) corresponding to steepest descent lines. In particular, the path starting at A* on the spectroscopic state and ending at the photoproduct energy minimum B on the ground state energy surface is constructed by joining two MEPs. A first MEP connects FC point to the CI. A second MEP connects the CI to the photoproduct B. A third MEP can be computed that starts at CI and describes the reactant reconstitution process responsible for partial return of the photoexcited species to the original ground state minimum (i.e., internal conversion). The mapping of the excited state potential energy surface of chemically different organic chromophores, strongly supports the idea that the mechanistic scenario described above (i.e., involving decay at a CI), is common. This was first realized after the development of CASSCF gradients (Schlegel and Robb 1982) in the early 1980s, and through a systematic computational research effort carried out in the 1990s (Bernardi et al. 1990; 2006). Also a number of algorithms were developed in order to locate the conical intersections and characterize the associated geometries (Anglada and Bofill 1997; Bearpark et al. 1994; De Vico et al. 2005; Farazdel and Dupuis 1991; Koga and Morokuma 1985; Levine et al. 2006; Ragazos et al. 1992; Yarkony 1993). Since the conical intersections are high-dimensional entities and not single points, the algorithms minimize the energy along the intersection seam. The points with the lowest energy of the seam are referred to as minimum energy conical intersections (MECI). The decay processes that are mediated by conical intersection are ultrafast and therefore too fast to allow the molecule to travel along the seam to reach the MECI. Thus transitions can occur at intersections which are higher in energy than MECI. This idea prompted the development of advanced methods to optimize stationary points along the multidimensional seam of intersection and determine the

structure of more extended segments of the crossing (Laino and Passerone 2004; Sicilia et al. 2007, 2008). A better way of defining the conical intersection point during the decay is to perform molecular dynamics simulation, which considers the kinetic energy of the molecule and can explore different regions of the excited state surface provided a number of different initial conditions. The methods solve the classical equations of motions and use forces from electronic structure methods to move on a single potential energy surface. In order to account for non-adiabatic transitions, a variety of approaches have been produced. Trajectory surface hopping algorithms are widely used to accomplish this task. They have in common that a transition is induced, i.e., a hop between surfaces, when the non-adiabatic coupling becomes strong. There are several examples where this surface hopping algorithm has been successfully applied to study photochemical events (Barbatti and Lischka 2008; Barbatti et al. 2008; Groenhof et al. 2004, 2008; Schaefer et al. 2007; Schapiro et al. 2009; Virshup et al. 2009; Weingart 2007; Weingart et al. 2004). A more sophisticated approach that treats both electrons and nuclei quantum mechanically was implemented by Martinez and co-workers (Ben-Nun and Martinez 1998; Levine et al. 2006). Herein an additional basis function describing the nuclei is created or spawned (therefore the name “multiple-spawning”) when strong non-adiabatic coupling between different states arises.

Below we discuss selected case studies of a series of processes investigated by means of computational photochemistry. We begin with isolated molecules in vacuum and conclude with chromophores in complex environments. The first case study focuses on reduced models of the retinal chromophore of visual photoreceptors. Subsequently the photodenitrogenation, intermolecular charge transfer and hydrogen transfer in azoalkanes are described. The following section deals with chromophores in complex environments. An overview will be given starting with GFP and asFP595 which is a GFP-like protein (Fig. 2) whose fluorescence can be switched on by Z/E photoisomerization. This is followed by an extensive discussion of a simulation of the photoisomerization of rhodopsin, a membrane protein characterized by seven α -helices (Fig. 2). The cationic Rh chromophore is the 11- cis stereoisomer of the protonated Schiff base of retinal (PSB11), and is connected through one covalent bond to the Lys296 residue. Upon absorption of visible light, PSB11 undergoes a Z/E photoisomerization and produces (stereoselectively) the corresponding all- trans chromophore (PSBAT), which ultimately triggers the Rh activity (Kandori et al. 2001; Mathies and Lugtenburg 2000; Palczewski et al. 2000; Teller et al. 2001). Computational studies of bR, an archaeal rhodopsin with a red-shifted absorption maximum (λ_{\max}^a) relative to Rh, and with a PSBAT chromophore, rather than PSB11, are described. Another class of molecules that have been excessively studied by tools of computational photochemistry are the deoxyribonucleic acids (DNA). We will illustrate how quantum chemistry is applied to unveil a mechanism of photodeactivation in a cytosine-guanine base pair. In the next case study the calculation of absorption spectra, including solvent effects and a novel method for taking vibrational contributions into account, is applied to coumarin C153. Finally, we highlight molecular dynamics simulations used to understand the isomerization mechanism in retinal containing proteins (Rh and bR).

Methods in Computational Photochemistry

Multiconfigurational Quantum Chemistry

Among the possible quantum chemical methodologies (e.g., semi-empirical or *ab initio*) used to model excited state species, below we mainly deal with *ab initio* (i.e., from first principles of quantum mechanics) approaches. In particular, to describe the evolution of intermediates and species whose geometries are far from equilibrium, one employs *ab initio* multiconfigurational methods. These methods are based on the multideterminant configuration interaction ansatz (i.e., where the electronic wavefunction is represented by a linear combination of determinants rather than by a single determinant) being the methods of choice when, in a photochemical process, a molecule rapidly changes its electronic structure and enters regions of crossing between different potential energy surfaces. The favorable properties of these methods are: (1) the accuracy can be systematically improved until they provide the exact solution of the non-relativistic Schrödinger equation (when a full-configuration interaction wavefunction and basis set close to the Hartree limit are used), (2) they are unbiased in the sense that they do not contain empirical parameters, and (3) they are suitable for dealing with potential energy

surface crossings between electronic states of the same or different spin-multiplicity (e.g., when the wavefunction is written in terms of Slater determinants) and there is a rapid change of electronic structure. The drawback is that these types of calculations are computationally expensive even though, nowadays, progress is being made to extend their applicability (Aquilante et al. 2009).

The ab initio complete-active-space self-consistent-field (CASSCF) method (Roos 1987) is a multiconfigurational method that offers maximum flexibility for an unbiased description of the electronic and geometrical features of molecules in their ground and excited electronic states. This is a particularly powerful method because the orbital coefficients are optimized together with the weights of a linear combination of all possible configurations constructed from a selected set of electrons and orbitals (Roos and Taylor 1980; Schmidt and Gordon 1998; Siegbahn et al. 1981). Furthermore, the CASSCF wavefunction can be used for subsequent second-order perturbation theory computations (CASPT2) of the dynamic correlation energy, (Andersson et al. 1990) ultimately allowing for a quantitative simulation and prediction of excitation energies.

In order to illustrate the accuracy that one can reach by a CASPT2//CASSCF protocol (the ‘//’ sign indicates that the molecular structure is determined (optimized) at the CASSCF level but that the energy is computed at the CASPT2 level), we report the results of the simulation of the observed gas-phase spectra of PSBAT in Fig. 3 (Andruniw and Olivucci). The spectrum was simulated according to the procedure described in ref. Andruniw and Pawlikowski (1998). The $S_0 \rightarrow S_1$ electronic excitation is found to be 524 nm at the CASPT2//CASSCF/6-31G* level of theory (the 6-31G*) Pople-type acronym refers to the specific atomic basis set used in the calculation). In 2006 the experimental spectrum of PSBAT was measured by Andersen and co-workers showing several overlapping bands that were initially attributed to the vibrational excitations in S_1 (Nielsen et al. 2006). The most intense peak was at 590–600 nm meaning the error of the CASPT2//CASSCF protocol is nearly 6 kcal · mol⁻¹. However, very recently the same group has repeated the gas phase measurement finding a remarkably broad absorption with a flat top ranging from 530 to 610 nm (Rajput et al. 2010). By probing different retinal PSB analogues it was shown that the broadness of the band is due to a highly flexible C5–C6–C7–C8 dihedral angle. The C6–C7 bond connects the polyene chain with the β -ionone ring and has either a 6s- cis or 6s- trans conformation. The shorter wavelength of 530 nm was assigned to the 6s- cis-conformer and the longer wavelength of 610 nm to the 6s- trans-conformer. Compared to the new absorption maximum the CASPT2//CASSCF value is in very good agreement (0.6 kcal · mol⁻¹).

The general assumption underlying the validity of the CASPT2//CASSCF protocol is that the CASSCF level of theory is accurate enough to provide qualitatively correct ground and excited state equilibrium structures, and in particular, MEPs. Currently this is of practical importance since only the CASSCF energy gradient can be evaluated analytically while the analytical CASPT2 gradients are not available for molecules of the size of interest in photobiology. This approximation is still awaiting a thorough evaluation. However, in certain cases, the equilibrium structures

Fig. 3 The $S_0 \rightarrow S_1$ absorption band of gas-phase PSBAT computed on the basis of excited state CASSCF frequency calculations (the frequencies have been scaled using a 10% factor). Top: the equilibrium geometry of the PSBAT is computed at the CASSCF/6-31G* level of theory with a 12 electrons in 12 orbitals active space. Left: experimental absorption spectra recorded by Andersen and co-workers (Nielsen et al. 2006; Rajput et al. 2010). Right: simulation of the first order line spectra and of the spectral band by Lorentzian fitting. The maximum “b” is assigned to the vertical transition and it is < 600 nm (~ 590 nm). The vertical excitation energy resulting in the predicted λ_{\max}^a value is computed by single-point CASPT2/6-31G* calculation on the CASSCF equilibrium geometry. Normal modes involving mixed β -ionone ring and chain torsion and bending, as well as C-CH₃ motion in simulated spectrum are difficult to assign because of overlapping bands

on a CASPT2 potential energy surface may differ significantly from the same structure calculated at the CASSCF level. In order to illustrate this point, the energy profile along a CASPT2//CASSCF minimum energy path computed for a simplified HBDI chromophore in the excited state is compared to the CASSCF energy profile in Fig. 4 (Martin et al. 2004).

Recently (Valsson and Filippi2010) reported the photoisomerization of retinal models using high-level quantum chemical methods, among others CASPT2, which include dynamic electron correlation. The two and three double bond truncated retinal models optimized at the CASPT2 level and numerical gradients. It was found that all bonds were equally lengthened and therefore the rotation around several bonds became possible. However, not all of the rotations lead to radiationless decay to the ground state. Some of the pathways on the excited state involved single bond rotation up to 45° and ended up in energy wells on the excited state (see Fig. 1 left). This finding is in contrast with the widely accepted reaction

Fig. 4 CASSCF (green squares) and CASPT2 (blue squares) energy profiles for the electronic S_1 state for the torsional relaxation. The stream of arrows indicates the energetically favored relaxation path. A change in shape of the reaction energy profiles after dynamic electron correlation correction (i.e., passing from CASSCF to CASPT2) has also been documented in other systems. See a discussion in ref. Sinicropi et al. (2003) (Redrawn with permission from ref. Martin et al. 2004)

coordinate established at the CASSCF level which is driven subsequently by two uncoupled modes. The first mode is responsible for the inversion of the bond length alternation in the excited state whereas the second mode is mainly the rotation of the central double bond. It is shown that this path also exists in the CASPT2 potential energy surface but it is reached rather from relaxing directly out of the Franck–Condon point. These controversial results on retinal chromophore in vacuo outline the importance of the dynamic electron correlation and the choice of the QM method that need to be verified for more realistic models. The size of the chromophore models should be extended towards the full retinal. However, the lack of the analytical gradients for CASPT2 makes these calculations extremely computationally demanding.

The difference between the CASPT2 and CASSCF geometries has also been investigated for both ground and excited state models of the PSB11 chromophore. The main difference in the results between these treatments is found in the ground state equilibrium geometry, where one finds a bond length alternation (BLA) pattern along the polyene chain which is less pronounced at the CASPT2 level (indicating a more extended delocalization) than at the CASSCF level (Page and Olivucci 2003). However, these studies were carried out with limited basis sets. Recently, different quantum chemical studies of the λ_{\max}^a of biological chromophores have employed density functional theory (DFT) rather than CASSCF ground state equilibrium geometries. For PSB11 and PSBAT these levels yield significantly different BLA values. Blomgren et al. (Blomgren and Larsson 2005) have proposed that this difference originates from the dynamic electron correlation which is (partially)

included in DFT functionals. The changes in the BLA computed for PSB11 are also reflected in the magnitude of the twisting of the C6–C7 single bond with respect to the backbone (see Fig. 2) and consequently in the conformation of the β -ionone ring. The ring is nearly planar in the DFT geometry but highly twisted in the CASSCF geometry as reported by Bravaya et al. (2007). Using the PBE0/cc-pVDZ calculations these authors find that PSB11 has two conformers featuring a -39° and $+170^\circ$ twisting of the C5–C6–C7–C8 dihedral angle corresponding to *s-cis* and *s-trans* isomers of the β -ionone ring, respectively. These results can be compared with the CASSCF/6-31G* data presented by Cembran et al. (2005) for the same chromophore. The CASSCF/6-31G* level of theory yields a single highly twisted PSBAT conformer with a -69° C5–C6–C7–C8 dihedral angle.

The gas-phase λ_{\max}^a (i.e., the corresponding vertical excitation energy) of PSB11 has been computed with different protocols that are also a matter of debate. Using a modified multiconfiguration quasi-degenerate perturbation theory aug-MCQDPT2 for excitation energies and DFT optimized geometry at PBE0/cc-pVDZ level for PSB11 (Bravaya et al. 2007) yields a 599 nm λ_{\max}^a , which appeared to be a very good estimate of the experimentally observed value for the gas-phase PSB11 (~ 610 nm) (Nielsen et al. 2006). In the light of the refined experimental absorption maximum at 530 nm (Rajput et al. 2010) the deviation is $7 \text{ kcal} \cdot \text{mol}^{-1}$. The use of a computationally consistent (i.e., with geometry and energy computed using the same method) TDDFT//DFT protocol (TD-B3LYP/6-31 + G*//B3LYP/6-31G) yields a 537 nm λ_{\max}^a (Wanko et al. 2005) and therefore performs better than mixed wavefunction-based/density-functional approaches. Also the CASPT2/ANO//MP2/6-31G** calculated result is far off (606 nm) which is based on a protonated PSB11 model rather than an alkylated (N-dimethyl) like in the aug-MCQDPT2//PBE0 study, which is more consistent with the measured chromophore. In contrast the CASPT2//CASSCF/6-31G* method yields 524 nm (Andruniw and Olivucci) which appears to be close to the recent experimental excitation energy of 530 nm (Rajput et al. 2010). TDDFT is a method that has much promise in studying excited states, but currently has limitations. It has been shown to be effective when used to compute valence-excited states (Dreuw and Head-Gordon 2005). However, when the excited state being studied has charge transfer (CT) character (either intermolecular or intramolecular) or if the molecule has an extended π system, TDDFT cannot reliably predict excitation energies. It has failed to accurately describe the CT states of several biologically relevant molecules, some of which include porphyrin complexes (Dreuw and Head-Gordon 2005). The failure is extensive. Not only is the energy gap inaccurate but also the topography of the excited state potential energy surface. This can be seen from the results of a study conducted in our laboratory (Fantacci et al. 2004), the results of which are displayed in Fig. 5. A MEP was calculated for a truncated model of the retinal chromophore (only three conjugated double bonds were included) with CASSCF. Energies were then recalculated at geometries along the path using CASPT2//CASSCF and various density functionals using TDDFT//CASSCF. Near the FC point, where the wavefunction changes rapidly, a potential energy well and maximum were found using TDDFT. These are features of an excited state energy surface that would not

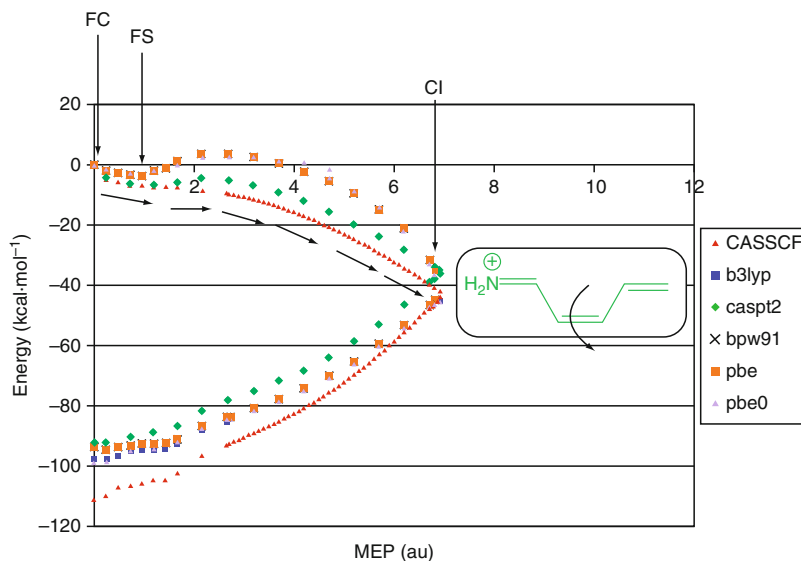

Fig. 5 Energy profiles along the S_1 photoisomerization coordinate of a simplified PSB11 model computed at the CASPT2//CASSCF/6-31 G* level. The energy at the Franck–Condon point is taken as the reference for the comparison. The fluorescent state (FS) corresponds to the local minimum along the TDDFT curve. The local maximum of the TDDFT curve corresponds to a model structure whose dihedral angle around the central isomerizing double bond measures 15° . There is no maximum or energy well along the CASSCF energy profile and these features are much less distinct along the CASPT2//CASSCF energy profile. In the PSB11 chromophore the value of the C5–C6–C7–C8 dihedral angle strongly affects the vertical excitation energy of the gas-phase retinal chromophore. By changing it one can change the excitation energy by up to 0.7 eV. The PBE0/cc-pVDZ bond alternation value is close to the value found for N-methyl-11-cis PSBR obtained by Sekharan et al. (2006) with the MP2 method. As suggested by Wanko et al. (2005) the hybrid exchange-correlation functionals like the PBE0 used in the aforementioned work, should provide BLA values very close to those computed at the CASPT2 level of theory. Also the similarity of MP2/6-31G* and CASPT2/6-31G* equilibrium geometry was directly demonstrated for short retinal chromophore models (i.e., the pentadieniminium cation) (Page and Olivucci 2003). Of course, no CASPT2 optimization of the full retinal chromophore with adequate (e.g., large ANO) basis sets has been reported up to now and in our view the issue regarding the correct ground state geometry of the retinal chromophore has still to be settled (Redrawn with permission from ref. Fantacci et al. 2004)

be expected to be exhibited by a molecule that undergoes an ultrafast femtosecond-scale photochemical reaction, so it is presumed that they are artifacts resulting from the use of TDDFT. The CASPT2//CASSCF surface is more accurate, exhibiting a plateau, with only a minuscule potential energy well. Another benchmark study came to similar conclusions, finding that the use of TDDFT led to a qualitatively incorrect description of the excited state potential at geometries distant from the FC point when the method was used on model retinal chromophores (Wanko et al. 2004). The source of the problem can be attributed to the CT nature of retinal's first excited state.

Problems with TDDFT can be found at all points of a photochemical reaction path, from the FC point to the CI. At the CI the quality of the immediately surrounding ground and excited state potential energy surface (PES) is inaccurate (Levine et al. 2006). A CI must have two branching directions (i.e., there must be two different motions that the molecule can undergo that will cause the energies of the states to separate). TDDFT, in contrast, describes a CI where only one branching direction lifts the degeneracy of states. An additional problem is that near the CI the slope of the PES along the single degeneracy-lifting coordinate is much steeper than that obtained with more reliable methods, as shown in the case of butadiene (Levine et al. 2006).

There are many reasons why TDDFT is not appropriate to study excited states, especially when double excitation or CT states are involved. For further reading we recommend the review by Dreuw et al. (Dreuw and Head-Gordon 2005). CASPT2 is much more reliable, in terms of accuracy, but cannot be used for optimizations, unless the molecule being studied is very small, in which case numerical gradients can be calculated with CASPT2. In the majority of cases, though, the best compromise will be CASPT2//CASSCF.

QM/MM Methodology

The quantum mechanical methods described above are limited in the application by the size of the molecule. In 1976 Warshel (Warshel and Levitt 1976) proposed a hybrid treatment, which allowed to treat biological macromolecules such as proteins that are too large for quantum chemical calculations. The idea is to divide the macromolecule into two or more subsystems which have different sizes and functions. The smaller subsystem, where a change of electronic structure or a chemical reaction occurs, is described by a quantum mechanical (QM) approach (i.e., by a suitable quantum chemical method), whereas the larger residual subsystem is treated using a molecular mechanics (MM) force field. Fortunately, because photochemical reactions are localized only to a specific area (i.e., the chromophore) electronic structure methods can be applied to this significantly smaller region, and the remaining part can be treated on a lower level such as a classical force field. This approach allows the study of large systems but also introduces new problems, the most important of which regards the treatment of the frontier between the two subsystems. In the past three decades much work has been done to solve this problem and for a comprehensive outline the reader is referred to the review by Senn and Thiel (2009).

Using the multiconfigurational approach combined with classical or molecular mechanics treatment of the environment a CASPT2//CASSCF/MM protocol was established (the//separator has the same meaning as above). Thus geometry optimization and molecular dynamics simulations are carried out at the CASSCF/MM level (this notation indicates that the QM part of the molecule is described at the CASSCF level while the rest is described with an MM force field such as AMBER (Case et al. 2002; Ponder and Case 2001), CHARMM, (Brooks et al. 1983)

Fig. 6 Main parts of a QM/MM model for Rh. The protein structure is usually obtained from the Protein Data Bank (Berman et al. 2000). The QM part corresponds to the chromophore plus a part of the side-chain of the amino acid that is linked to it. The QM/MM frontier region usually corresponds to a weakly polarized C–C bond that, for Rh, is chosen to correspond to the $C_\delta - C_\epsilon$ bond of the Lys296 side chain in Rh. In this bond the QM atom (C_ϵ) is capped with an H link-atom and the MM atom (C_δ) is held in place by MM potentials that are specifically parameterized for this region. This MM parameterization of the QM/MM frontier region is specific to the chromophore and the side chain

or OPLS (Jorgensen and Tirado-Rives 1988)). Of course, the application of this methodology requires the construction of a suitable protein model. In order to study the Rh pigment, a CASPT2//CASSCF/AMBER protocol based on the QM/MM link-atom electrostatic-embedding scheme (Senn and Thiel 2009) (see Fig. 6) has been implemented and successfully applied for the first time in our laboratory (Ferré and Olivucci 2003a, b; Ferré et al. 2004).

A meaningful calculation of the spectroscopic parameters can be achieved by running a long time ground state QM/MM trajectory simulation and computing CASPT2 vertical excitation energies at regular time intervals. In this way the λ_{\max}^a , fluorescence maximum (λ_{\max}^f) or phosphorescence maximum could be obtained by averaging these results (for an application of this concept using other quantum chemical methods see refs Hoffmann et al. (2006) and Pistolesi et al. (2009)). However, because of the cost of CASPT2//CASSCF calculations this strategy appears to be unpractical. The calculation of quantities such as the λ_{\max}^a and λ_{\max}^f cannot be systematically carried out using this approach. Yet, as explicitly mentioned above, the CASPT2//CASSCF level of QM treatment is required if one wants an unbiased and rigorous quantitative description of the electronic excited state of an organic chromophore/fluorophore. One possible solution to this problem is to prepare a model of the system that provides a sufficiently accurate

representation of the time-averaged configuration of the chromophore/fluorophore and its environment. Using this model the chromophore would effectively feel the average steric and electrostatic field imposed by the protein.

The case studies given in section “[Case Studies of Chromophores Embedded in a Molecular Environment](#)” show that within certain accuracy QM/MM models are viable for different proteins. Indeed, we have shown that models based on the experimental crystallographic structure (i.e., where the protein is not fully relaxed or equilibrated) allow the prediction of the spectroscopic parameters with an accuracy of a few kcal · mol⁻¹ for systems that differ in protein structure and in the chemical nature of the chromophore/fluorophore.

Case Studies of Isolated Chromophores

Photoisomerization in a Rhodopsin Chromophore Model

The protonated Schiff base of 11- cis-retinal (PSB11) is the chromophore in the visual receptor rhodopsin. A light-induced cis/trans isomerization of the chromophore triggers the primary event in vision, which is a series of conformational changes of the protein. This photoreaction is considered as the archetype of a chemical reaction optimized by nature to achieve a specific molecular response. Hence, it was in focus of numerous computational and experimental investigations.

The first detailed structure of the excited and ground state potential energy surfaces of the rhodopsin chromophore model was obtained for the three double-truncated 11- cis-retinal (3db-PSB11). In particular the structure of the excited and ground state reaction path branches has been fully elucidated. Furthermore the reduced dimension of the model (Scheme 1) has allowed for the computations of ab-initio CASSCF semi-classical trajectories and the evaluation of the excited state lifetime and time scale of the photochemical isomerization (Weingart et al. 2004).

Scheme 1 Reduced models of PSB11

Fig. 7 Branching (or g,h) plane vectors for the CI structure of 3db-PSB11. The X_1 and X_2 vectors correspond to the derivative coupling (or non-adiabatic coupling) and gradient difference vectors between the S_1 and S_0 states (Redrawn with permission from ref. Migani and Olivucci 2004)

The results demonstrated that 3db-PSB11 provides a reasonable model for more realistic structures. In particular, the two-state, two-mode nature of the reaction coordinate computed and observed (both in solution and in the protein) is maintained in the minimal model and the computed ultrafast excited state dynamics is still characterized by two different timescales corresponding to a the initial stretching relaxation (i.e., an inversion of the single bond/double bond length alternation) and to the following torsional deformation (about the central $C_2 - C_3$ bond), respectively.

In Fig. 7 we plot the branching plane vectors (X_1 and X_2) at the conical intersection of 3db-PSB11 model. The conical intersection structure features one highly twisted double bond (about 92°) and involves two electronic configurations, an ionic and a covalent state, that differ for the transfer of one electron between the $C_5 - C_4 - C_3 -$ and $-C_2 - C_1 - N$ fragments.

From the structure of the branching plane it is apparent that in this molecule X_1 and X_2 describe two types of processes. As shown in Scheme 2, motion along the X_1 corresponds to a coupled pyramidalization (wagging) modes at the C_1 and C_4 centers of the π -chain. This motion allows for a widening of the $C_4 - C_3 - C_2 - C_1$ dihedral angle leading to a π -bond breaking process. The X_2 mode is characterized by a stretching deformation (a double bond expansion and single bond contraction mode) of the $N = C_1 - C_2 = C_3 - C_4 = C_5$ chain segment. Thus, motion along the X_2 direction would ultimately yield two structures that be represented by (resonance) formulas with inverted single and double bonds and with the positive charge shifted from the N-terminal to the C_5 -terminal. These

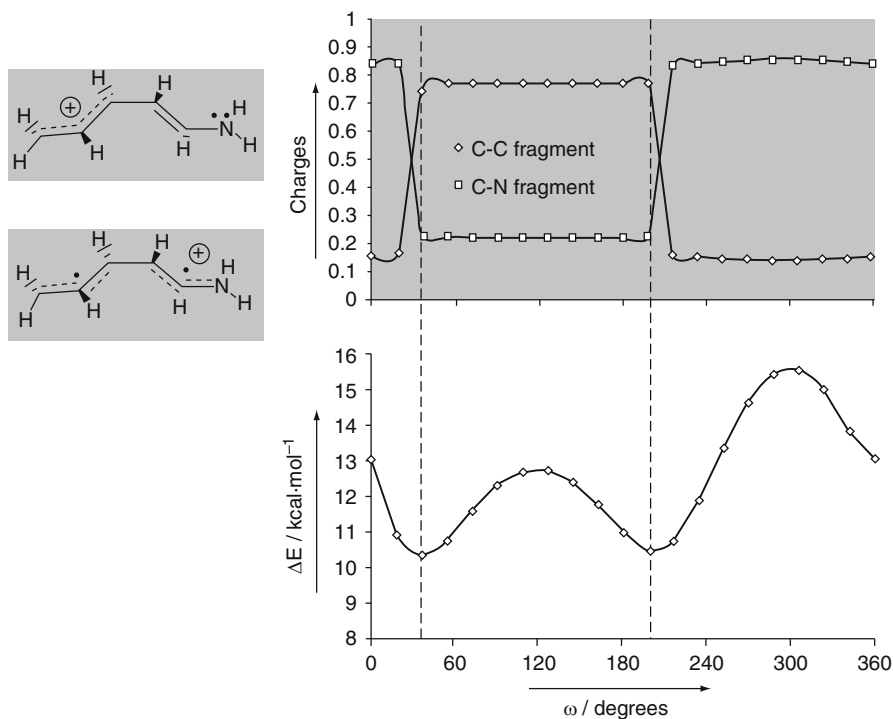

Scheme 2 Deformation of the CI geometry of 3db-PSB11 along the branching plane vectors X_1 and X_2

two 92° twisted structures will be less stable than those generated by displacement along the wagging mode since the deformation along X_1 allows for reconstitution of the central double bond providing strong coupling with the Z/E double bond isomerization coordinate. Thus, structural analysis of the branching plane suggests that upon decay from CI the molecule will generate the Z and E stereoisomers.

The analysis of the wavefunction, taken together with the analysis of the branching plane, provides the basis for the rationalization of the electronic structure of the ground state energy surface comprising the reactant and product valleys (and, eventually, the transition structures connecting them). The result of such an analysis for chromophore model 3db-PSB11 is shown in Scheme 3, where the wavefunction is analyzed in terms of point charges of the $C_5 - C_4 - C_3-$ and $-C_2 - C_1-$ N fragments along a loop centered on the CI (angle ω) and lying on the plane defined by the X_1 and X_2 modes. The charge distribution of the system demonstrates the existence of two different regions. The first region $0^\circ < \omega < 30^\circ$, $200^\circ < \omega < 360^\circ$ is characterized by a structure where the charge is mainly localized on the N-terminal part of the molecule. The second region $30^\circ < \omega < 200^\circ$ is characterized by a structure where the positive charge is mainly located on the C-terminal part of the molecule. The border between the two regions corresponds to the electron transfer events between the two fragments. Notice that the wavefunction changes are associated with the two minima in the energy gap diagram.

As we have previously underlined, the low-lying conical intersections could be only provided through the computation of the photochemical minimum energy path (MEP). However, some cases have been documented where excited state reaction path does not necessarily hit the lowest energy point belonging to the

Scheme 3 Characterization of the topology around the CI of 3db-PSB11 by charge distribution of the model chromophore and the energy profile

intersection space (IS) and the decay may not occur in this region. One of these cases concerns the excited state relaxation path of the 3db-PSB11 chromophore. Indeed, the mapping of the low-lying segments of the IS for this chromophore (see Fig. 8), by means of constrained MEP computations, demonstrated that it ends at a conical intersection with a ca. 70° (CI_{70°) twisted structure. The intersection space remains then coincident with the reaction path up to the lowest energy intersection (CI_{92°) that has a 92° twisted structure (Migani et al. 2003). Notice that in this situation the main locus of excited state (S_1) decay is predicted to be CI_{70° .

In the follow-up study an extended model with four double bonds (4db-PSB11 in Scheme 1) confirmed the topological features found in 3db-PSB11 (Migani et al. 2004). But it also shows expansion of the intersection space segment because of an increased number of double bonds. In the 4db-PSB11 model there are two central double bonds. Twisting each of them at a time and both simultaneously on the excited state can lead to CIs. One can expect a topology of the IS space where these singly twisted CIs are connected by the doubly twisted conical intersections. Indeed, two singly twisted CIs could be identified via IS steepest descent path (ISDP) calculations starting from the doubly twisted CI-geometry T,T- CI (Fig. 9). For nomenclature of these structures, the first letter describes the C2–C3 and the

Fig. 8 The excited state reaction path of the cation 3db-PSB11 intercepts the conical intersection point CI_{70° located ca. $5 \text{ kcal} \cdot \text{mol}^{-1}$ above the minimum energy conical intersection CI_{90° . The values of the relevant structural parameters are given in Å and degrees (Redrawn with permission from ref. Migani and Olivucci 2004)

second the C4–C5 double bond conformation, with T being a nearly 90° twisted dihedral. It shows that one can smoothly change the amount of twisting about the C2–C3 and C4–C5 bonds without leaving the IS.

In principle, two additional paths should also connect the complementary isomers of the singly-twisted geometries with the doubly twisted structure. Starting at the same T,T- CI point these two CIs were found (Fig. 10) pointing to T,T- CI serving as a saddle point of index 2 on the IS and not as a transition state. In Fig. 10 we show that a 3D plot of the four ISDPs suggests the existence of a low-lying, two-dimensional cross section (i.e., a surface) of the IS space spanned by CI structures characterized by different degrees of twisting of the two central bonds. This 4db-PSB11 model extends the picture of the S_1/S_0 intersection due to the fact that the bottom of the S_1 energy surface of Rh is spanned by a fairly extended IS segment along the C10–C11–C12–C13 torsion from 80° to 110° . It should be noticed that certain substituents or a suitably designed molecular environment can change the energy profile favoring one isomerization channel over the other or even stabilizing the central part of it.

A more realistic chromophore model including all five double bonds of the polyene chain of retinal (5db-PSB11 in Scheme 1) was studied by Gonzalez Luque et al. (2000). A minimum energy path (MEP) was computed at the CASSCF level

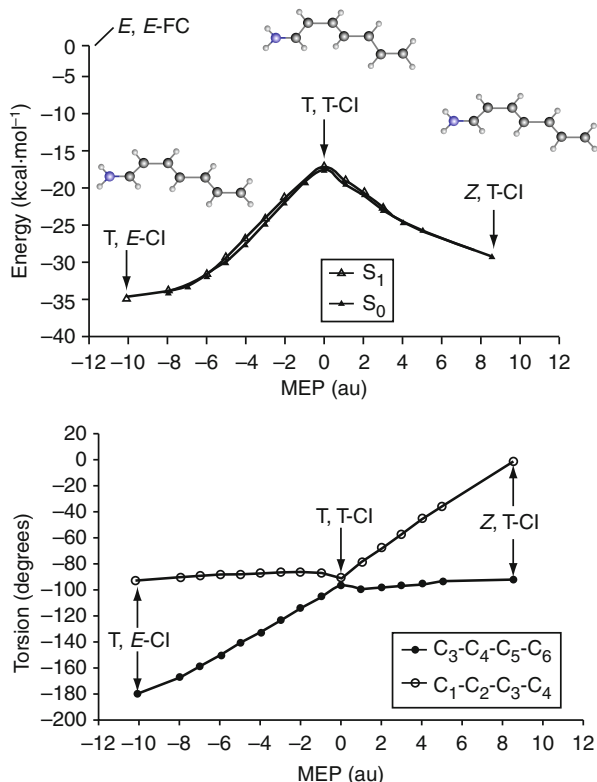

Fig. 9 Left: CASSCF energy profile along the IS coordinate connecting the chemically distinct CI minima T, E and Z,T. The energy values are relative to E, E-4db-PSB11, the most stable isomer. Right: IS coordinate analysis along the corresponding path

of theory. Ten π -electrons included in π -type orbitals with 6-31G* basis set were employed. It should provide an unambiguous cis/trans photoisomerization coordinate for PSB11 (and PSBT) under isolated conditions. This coordinate suggests the dynamic behavior illustrated in Fig. 11, where a metastable species performs many skeletal oscillations along an energy plateau before the reactive torsional modes get fully populated. The plateau may be assigned to the picosecond “fluorescent state” observed in solution and therefore drastically reduces the efficiency of the photoisomerization compared to the protein environment. A second basic feature of the computed path is the positive-charge translocation along the chromophore framework. The positive charge was found to shift partially from the N end to the C end of the models upon $S_0 \rightarrow S_1$ photoexcitation and S_1 in-plane relaxation. The following twisting deformation leads to a complete translocation of the charge that localizes on the fragment containing the C end as already demonstrated for the smaller model 3db-PSB11.

Photofragmentation Through a Conical Intersection: The Photodenitrogenation of a Bicyclic Azoalkane

Photo-induced denitrogenation of 2,3-diazabicyclo[2.2.1]hept-2-ene (DBH) has been the subject of debate ever since it was first reported by Solomon et al. (1968). The observed stereoselectivity in the nitrogen extrusion and housane formation processes was of particular interest. The conical intersection structure which mediates the C–N α -cleavage is characterized by a linear-axial arrangement at the NNC moiety where one of the two CN bonds is still intact (1.48 Å) (Page and Olivucci 2003; Yamamoto et al. 1998). The branching plane vectors X_1 and X_2 correspond to two orthogonal bending motions of the NNC angle, as illustrated in Fig. 12.

When the CI structure is displaced along X_1 and X_2 , the CNN bending motions prompt the formation of the ground state diazenyl diradical (^1DZ in the Scheme 4) either in the exo, endo, or endo-exo forms, as illustrated in Scheme 5.

Fig. 11 Shape of the FC → SP region of the S₁ energy surface of 5db-pSB11 model

Fig. 12 Gradient difference (X₁) and derivative coupling (X₂) vectors for the CI structure of DBH (illustrated schematically in the inset). The vectors correspond to two orthogonal bending motions of the NNC angle (Redrawn with permission from ref. Sinicropi et al. 2003)

Scheme 4 Photofragmentation of DBH to the Inverted Housane

Scheme 5 Formation of different isomers starting from the diradical CI structure

The electronic structure of the intersecting states of the α -CN bond cleavage of DBH is illustrated in Scheme 6. The electronic configuration of the S₁ state of the azoalkane corresponds to a tetraradical configuration where two electrons are localized in each α -CN σ -orbital, one electron in the excited nitrogen lone pair, and one electron residing in the p-orbital nitrogen bound to the α -C. On the other hand, the electronic configuration of the ground state azoalkane consists of a biradical in which the two α -CN σ -orbitals are singly occupied.

Reaction path calculations explain the observed inversion of stereoselectivity. It is ascribed to an impulsive population of a vibrational mode that triggers axial-to-equatorial ring inversion. This idea is supported by classical molecular dynamics

Scheme 6 Electronic structure of the S_0 and S_1 state

simulations. Figure 13 reveals that after a single oscillation (on a 40 fs timescale) in the direction of a transient bicyclic intermediate, the molecule reaches a strained structure that it can only relax following the initial direction of motion. After 60 fs, the exo-axial 1DZ configuration is reached, followed by the axial to equatorial transition structure on an 80 fs timescale. Within 100 fs, the inverted configuration is observed.

Charge Transfer and Intermolecular Hydrogen Transfer Mediated by a Conical Intersection: Quenching the Fluorescence of Bicyclic Azoalkanes

In contrast to DBH, the so-called “reluctant” azoalkanes are inert to photochemical denitrogenation. One representative system is the 2,3-diazabicyclo[2.2.2]oct-2-ene (DBO, Scheme 7). DBO exhibits a long-lived excited n, π^* -singlet state (on the order of μ s).

Using the 1,2-diazacyclopent-1-ene (pyrazoline) as a model of DBO allows the use of accurate yet computationally demanding (expensive) methods. In combination with experimental evidence, two mechanisms for quenching $^1n, \pi^*$ states were proposed (Sinicropi 2002; Sinicropi et al. 2000, 2001, 2002). DBO is efficiently quenched by hydrogen donors (for instance by solvents such as chloroform, methanol, and benzene) either via a concerted or a stepwise process. DBO luminescence can be quenched by electron donors (e.g., with triethylamine), however, only through a concerted process. Calculations have been carried out using CH_2Cl_2 and methanol to model hydrogen donors, and trimethylamine/dimethyl ether as

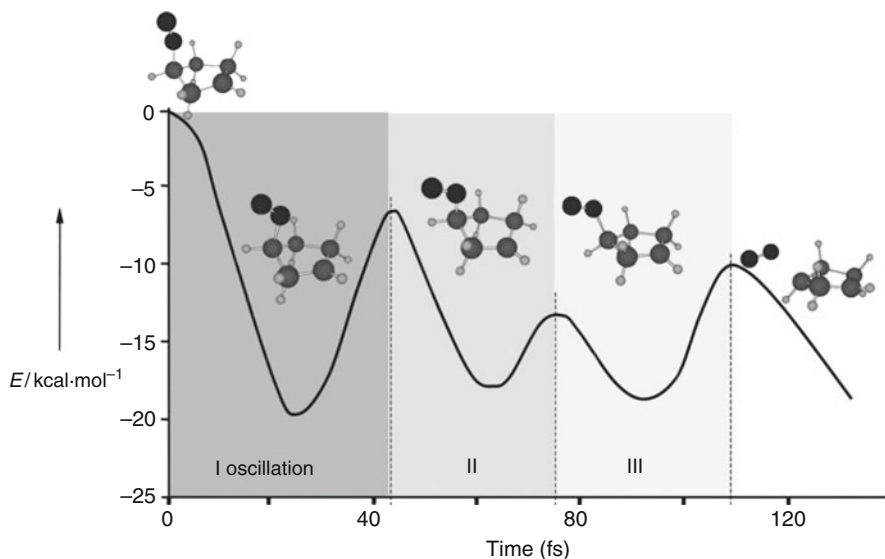

Fig. 13 Triplet DFT energy profiles along the molecular dynamics simulations started in the vicinity of the CI structure of DBH. The snapshots demonstrate the molecular changes along the trajectory (This figure is redrawn with permission from ref. Sinicropi et al. 2003)

Scheme 7 Internal conversion of DBO

strong/weak electron donor solvents on the other hand. As shown in Fig. 14, both quenching routes involve bimolecular photochemical reactions. Deactivation occurs through an S_1/S_0 CI, located halfway along the reaction coordinate, and prompting bifurcation. The first branch (represented by full arrows) resembles a photophysical transformation and has been termed an “aborted” photochemical transformation. The second branch (represented by light arrows) is associated with production of a transient species that reverts to the original starting reactants by passage through a low-lying transition state located on the ground state reaction coordinate (depicted by a dashed curve). Thus, both routes correspond to a photochemical transformation, which was initiated but never achieved.

The conical intersection for the hydrogen abstraction mechanism (in the presence of CH_2Cl_2) is characterized, with respect to the reactant pair, by shortening the H–N distance (from 2.22 to 1.02 Å) and simultaneously lengthening the C–H distance (from 1.07 to 2.01 Å). The structure on the conical intersection for this bimolecular

Fig. 14 Potential energy diagram showing the interplay between ground (S_0) and excited (S_1) state surfaces in the fluorescence quenching of ${}^1n, \pi^*$ state chromophores due to an hydrogen donor or electron donor species. The full and light arrows describe the concerted and stepwise energy wastage route

Fig. 15 The molecular structure of the characterized conical intersection that mediates hydrogen abstraction in the presence of CH_2Cl_2

reaction is given in Fig. 15, whereas the degeneracy-lifting vectors are illustrated in Fig. 16.

Motion along X_1 stretches the intermolecular N-H distance whereas displacement along X_2 causes an out-of-plane pyrazoline ring distortion, both translations lifting the degeneracy between the two states. Structural evolution along both displacements is illustrated in Scheme 8. Translation along X_1 leads to the radical

Scheme 8 Characterization of the topology around the CI of associated pyrazoline-dichloromethane model pair

pair (RP) while displacement along $-X_1$ leads to production of an unstable ion pair (IP). Evolution in the X_2 and $-X_2$ directions leads to two equivalent ground state transition structures, featuring a distorted pyrazoline ring.

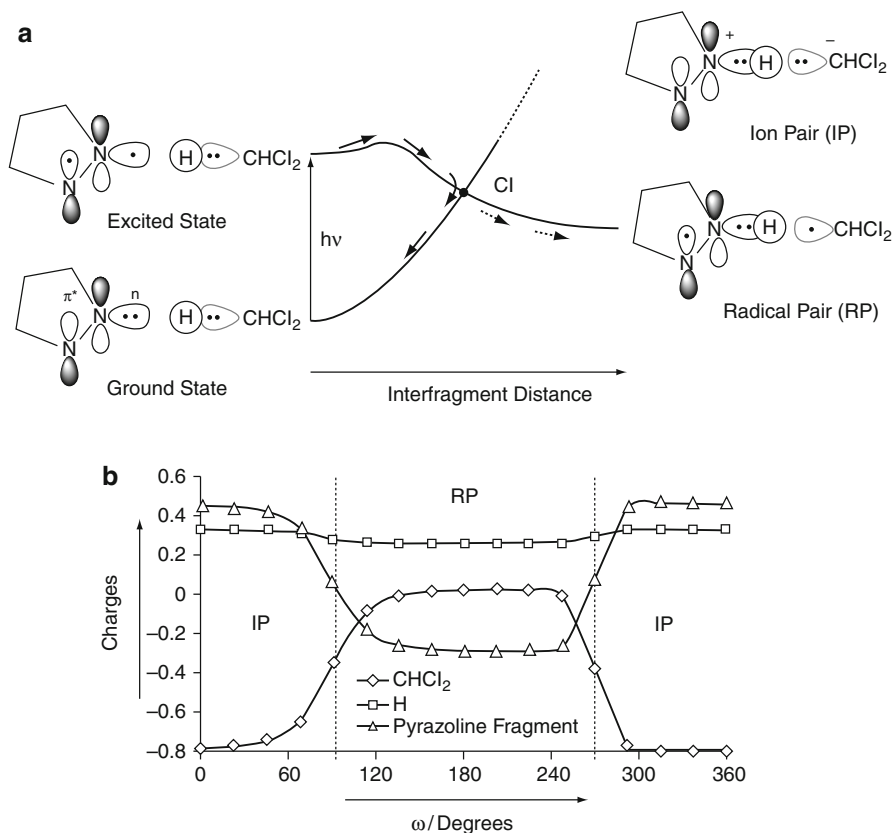

Fig. 17 (a) Modified state correlation diagram of the n, π^* -excited state (ES) of pyrazoline + CH_2Cl_2 correlating with the radical pair (RP) derived from hydrogen atom abstraction and the ground state (GS) correlating with the ion pair (IP) derived from proton abstraction. (b) S_0 fragment charges [au] along a circular cross section centered at CI and spanning the branching plane (pyrazoline fragment, open triangles; hydrogen atom, open squares; CHCl_2 fragment, open circles) (Redrawn with permission from ref. Sinicropi et al. 2001)

An analysis of the wavefunction indicates that the n, π^* -excited state correlates with the radical pair structure (derived from a complete hydrogen atom abstraction), whereas the ground state correlates with the ion pair (derived from proton abstraction), see Fig. 17a. Although this case study deals with bimolecular photochemical processes, it is in a sense similar to the retinal PSB models as the electronic configurations describing the intersecting states are interchanged by charge transfer. The charge distribution of the system along a circular cross section – spanning the plane defined by the X_1 and X_2 vectors and centered around CI – is displayed in Fig. 17b with ω expressing the rotation. It reveals the existence of two distinct regions. The first region ($0^\circ < \omega < 100^\circ$ and $290^\circ < \omega < 360^\circ$) is characterized by an ion pair structure where the charge on the pyrazoline is positive while it is

Fig. 18 X_1 and X_2 vectors for the CI structure of pyrazoline + trimethylamine involved in the charge transfer process (Redrawn with permission from ref. Olivucci and Sinicropi 2005)

negative on CHCl_2 . The second region $100^\circ < \omega < 290^\circ$ is characterized by a covalent structure. The border between the two regions corresponds to two sudden electron transfer events, one from the CHCl_2 anion to the pyrazoline cation yielding the RP configuration ($\omega = 90^\circ$) and the second in opposite direction ($\omega = 270^\circ$).

The molecular structure of the conical intersection along with the degeneracy-lifting vectors of the branching plane for the charge transfer process is given in Fig. 18. Notice that X_1 is dominated by an out of plane deformation of the pyrazoline ring whereas X_2 is dominated by the interfragment distance. The computed photochemical reaction path demonstrates that the excited state branch of the photochemical reaction path is dominated by an decrease in the distance between the pyrazoline and $\text{N}(\text{CH}_3)_3$ fragments. After a low-lying excited state barrier, the evolution along the path leads to the formation of an exciplex located in the vicinity of a conical intersection. The intersection is accessed when the distance between the pyrazoline and nitrogen atoms of the amine is ca. 2\AA . In the exciplex, the computed amount of charge transfer from the trimethylamine lone pair to the excited state half-vacant nonbonding orbital of one pyrazoline nitrogen atom is about 0.3 electrons.

Fig. 19 Modified correlation diagram for the interaction of the n, π^* -excited state of pyrazoline with an electron donor such as the trimethylamine reflecting the occurrence of an exciplexes and a conical intersection along the reaction pathway (Redrawn with permission from ref. Sinicropi et al. 2000)

The exciplex $N \dots N$ two-orbital/three-electron bond can be viewed as a mixture of a covalent ($N = N^{\bullet} \dots : NMe_3$) and an ionic ($N = N^{\bullet-} \dots ^+ NMe_3$) electronic configurations. A steep rise of the ground state energy surface towards the conical intersection is due to a destabilizing two-orbital/four-electron repulsive interaction ($N = N : \dots : NMe_3$) (see Fig. 19).

Case Studies of Chromophores Embedded in a Molecular Environment

Green Fluorescent Proteins (GFP)

In 1961 the Green Fluorescent Protein (GFP) was discovered in the jellyfish *Aequorea Victoria* and became the first representative of the same named protein family (Shimomura 2009). Its chromophore is p-hydroxybenzylideneimidazolinone (HBDI), enclosed in a β -barrel structure. It emits a green fluorescence light if exposed to blue light. The corresponding fluorescence spectrum shows a single peak at 508 nm attributed to the anionic form of the chromophore. In contrast, in water solution the HBDI anion shows a blue-shifted fluorescence that has a very short lifetime.

The GFP chromophore has been studied extensively, both by means of experimental and theoretical methods. Sinicropi et al. (2005) performed the first QM/MM simulation of GFP suitable for the quantitative evaluation of λ_{\max}^a and λ_{\max}^f . Calculations were done at the CASPT2//CASSCF/CHARMM level of theory with the 6-31G* basis set because a previous study (Martin et al. 2004) suggested that dynamic electron correlation is important to reproduce the observed quantities. The

Fig. 20 Right: Chromophore cavity of the model for the GFP fluorescent state I displaying the hydrogen bond network and the values of the computed λ_{\max}^f value. Left: The change in the hydrogen bond network by disruption of the W1–chromophore bond leads to a red shift in the predicted λ_{\max}^f

λ_{\max}^a was evaluated for the anionic ground state form in the emitting state (state I) and in a modified I state with a disrupted hydrogen bond between the chromophore and the closest water molecule (see Fig. 20).

For the full protein model of the I state the calculated peaks for absorption and emission are 468 and 507 nm, respectively, compared with the experimental values of 495 and 508 nm (Brejc et al. 1997; Chatteraj et al. 1996) resulting in an error of less than 4 kcal · mol⁻¹. A somewhat better agreement with experimental data is achieved by Altoe et al. (2007) using a similar computational protocol. The calculations were performed at the CASPT2//CASSCF/AMBER level for the chromophore with the same basis set. Prior the QM/MM excited state calculation the model was equilibrated by MD simulation. The authors calculated the absorption of 504 nm for the I state (experimentally 495 nm).

The GFP model (Sinicropi et al. 2005) shows that there is a charge translocation towards the imidazolinone moiety in the I state, indicating that the excited state is a charge transfer state. It is shown that the hydrogen bond between the proximal water molecule and the phenoxy oxygen of the chromophore localizes the negative charge on that oxygen atom. In fact, as reported in Fig. 20, removing that water molecule has a great effect on structure and energy, which leads to a less stable structure (20 kcal · mol⁻¹ higher in energy). A different effect is found when comparing a protein model with the positively charged counter-ion Arg96 to a protein model without it: the protein environment balances the counter-ion effect to the same extent in S₀ and S₁. A similar quenching effect is also observed for Rh (Strambi et al. 2007) (see below) despite its very different protein and chromophore structure.

Another member of the GFP protein family is asFP595, which was discovered in *Anemonia sulcata* (Quillin et al. 2005). It fluoresces brightly at 595 nm after intense illumination at 568 nm at room temperature. The X-ray crystal structure was obtained in 2005 for the dark state at 1.38 Å resolution. The chromophore was discovered to be the same as in GFP, and the initial hypothesis for explaining the fluorescence was a Z/E photoisomerization because the chromophore cavity can easily accommodate both the isomers, as was seen from the crystal structure. The first QM/MM study on asFP595 was carried out by Grigorenko et al. (2006). The ground state equilibrium structure was determined at the RHF/6-31G^{*} and B3LYP/6-31 + G^{*} level while the excited state properties were studied at the CASSCF/AMBER level with the 6-31 + G^{*} basis set (with a 10 electron/10 orbital active space). The QM region included the chromophore unit and the sidechains of the His197, Glu215, and Arg92 residues, all of which are involved in the hydrogen bonding to the chromophore. For the HBDI moiety three options were considered: the E anion, the Z anion, and the E zwitterion. The protein environment was shown to stabilize the zwitterion with respect to the gas phase, which confirmed the importance of evaluating the role of the protein matrix. The CASSCF vertical transition energies give support to the experimentally based hypothesis that the dark state features an anionic or zwitterionic E conformation, while the emitting state features an anionic Z-isomer formed upon light absorption by the E ground state. However, it is known that the CASSCF vertical excitation energies are far from being quantitative and may change dramatically for transitions to charge transfer states upon CASPT2 correction.

A 2007 study by Schäfer and coworkers (Schaefer et al. 2007) shed light on the photochemical reaction path in asFP595, finding many similarities with GFP. They used TDDFT to establish the general features of the photocycle: after photon absorption the zwitterionic E dark state chromophore is converted into the anionic Z form by proton transfer from the imidazolinone ring to the Glu215 side chain and E → Z isomerization. A proton wire connects the chromophore cavity to the external solution in order to achieve protonation of the phenolate oxygen, which leads to the neutral Z form. Another proton wire is able to release protons from His197 to the solution along five residues and a buried water molecule. The proton transfer seems to be important in preventing the reverse photochemical reaction that would result from absorption of a second photon. Photoisomerization leading to changes in protonation states seems to be a general principle exploited by evolution: both bR and PYP rely on the same mechanism. Subsequently, the CASSCF method (Schaefer et al. 2008) was employed to gain deeper insight into the mechanism and its features at the atomic level. A QM/MM MD simulation was performed, evaluating energies and forces of S₁ and S₀ at the CASSCF/3-21G level with a six electron/six orbital active space to reduce the computational cost. The QM region included only the chromophore, and the OPLS force field was used for the rest of the system. The results confirmed the conclusions of the previous paper in a more detailed way: the proton distribution in the active site controls the possible photochemical pathways of the protein-embedded chromophore. There are six different states, arising from the combination of E and Z conformations with a

neutral, anionic, or zwitterionic chromophore. To switch from the non-fluorescent to the fluorescent state an $E \rightarrow Z$ isomerization is required. It has been observed to happen only for the neutral chromophore which is poorly populated. The fluorescent state is the zwitterionic Z form reached upon protonation of Glu215, but this state is also sparsely populated. These two findings are in agreement with the observed low overall photoisomerization quantum yield of asFP595. Moreover, excitation of the neutral E chromophore should be performed with green light otherwise the blue-shifted Z photoproduct would isomerize back. The neutral Z state is more populated than the other Z forms, so the efficiency of the back reaction, i.e., the switching off, is very high.

Understanding the Spectral Tuning in Retinal Proteins

Rhodopsin, the dim-light photoreceptor in vertebrate retina, belongs to the G-protein-coupled receptor family. The 11- *cis*-retinal (PSB11) that is covalently bound to Lysine 296 via a Schiff-Base link serves as the chromophore (Fig. 2). Upon light absorption PSB11 undergoes a stereoselective Z/E isomerization to the all- *trans* isomer, which leads to a protein-wide conformational change that initiates light perception. As summarized in Fig. 21, this is an ultrafast photochemical reaction featuring a ~ 100 fs lifetime of the excited state and a 200 fs appearance-time of the vibrationally hot intermediate photorhodopsin (photo-Rh). The first isolable intermediate, bathorhodopsin (batho-Rh), is detected on a 2 ps time scale. Below we review the results of recent research efforts to investigate the mechanism of the excited state isomerization in Rh using a QM/MM model.

More than 30 years ago Warshel proposed, on the basis of semiempirical simulations, an isomerization mechanism that could explain how this process can occur in the restricted space of the Rh binding pocket (Warshel 1976). Since two adjacent double bonds were found to isomerize simultaneously the mechanism reveals a so-called bicycle pedal motion. Due to the concerted rotation of two double bonds in opposite directions the overall conformational change is minimized and hence this mechanism was found to be space-saving. The empirical valence bond (EVB) method (Warshel and Levitt 1976) was used to compute the excited state potential energy surface of the chromophore during a trajectory calculation where the steric effects of the protein matrix were modeled by specific restraints on the retinal atoms. Since then, Warshel and his coworkers have improved the model employing better structural data and new computational developments (Warshel and Barboy 1982; Warshel and Chu 2001; Warshel et al. 1991). The main refinement of the bicycle pedal mechanism was that the simultaneous rotation of the adjacent double bonds is aborted at a twist of 40° and leads to the isomerization of only one bond (Warshel and Barboy 1982).

Since the crystal structure of the rhodopsin protein became available in 2000, a more accurate description of the protein environment was available for computational investigation and for the interpretation of the experimental data. In 2003 Ferré and co-workers performed the first QM/MM simulations using the

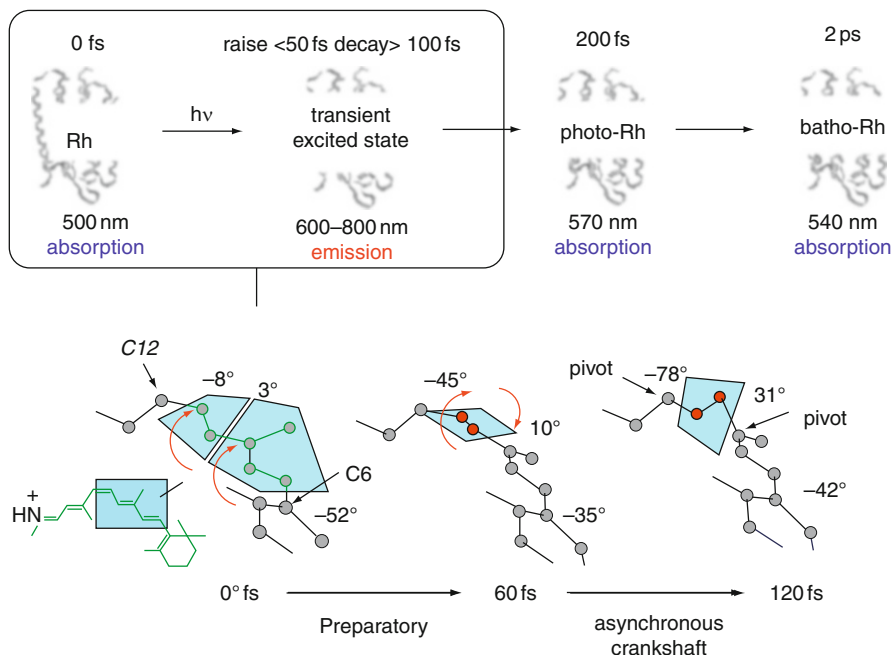

Fig. 21 Top: Observed λ_{\max}^a values and excited state lifetimes associated with the initial steps of the photoisomerization of Rh. Bottom: Schematic representation of the excited state isomerization motion of PSB11 dominated by an asynchronous crankshaft structure deformation (Frutos et al. 2007) and documented for a CASSCF/AMBER model of Rh

ab initio CASPT2//CASSCF/AMBER protocol applied to the protein-embedded retinal chromophore in the excited state (Ferré and Olivucci 2003b). In this study the authors have truncated the retinal chromophore at the QM level to make the calculation feasible. The authors used a five double-bond N to C6 retinal fragment. The CASSCF level of theory was used to determine the ground state equilibrium structure with all 10 π -electrons in 10 π -type orbitals comprising the active space. The protein was modeled with the AMBER force field.

Starting from the 1HZX (Palczewski et al. 2000) crystallographic structure, it was shown that the CASPT2//CASSCF/AMBER protocol can be used to construct a Rh model featuring the full retinal chromophore treated at the QM level. This model could reproduce the stationary spectroscopic features (see Fig. 22 top left for a comparison of the observed and computed values, given in italics and plain text, respectively) with an error similar to the one found for GFP systems described above. For instance, the λ_{\max}^a is reproduced with only 3 kcal \cdot mol $^{-1}$ error (476 versus 498 nm). But also the computation of the corresponding λ_{\max}^a in solution employing the same methodology led to an error within 2 kcal \cdot mol $^{-1}$ of the so-called opsin-shift (the 445 nm λ_{\max} observed for PSB11 in methanol is red-shifted to 498 nm in Rh).

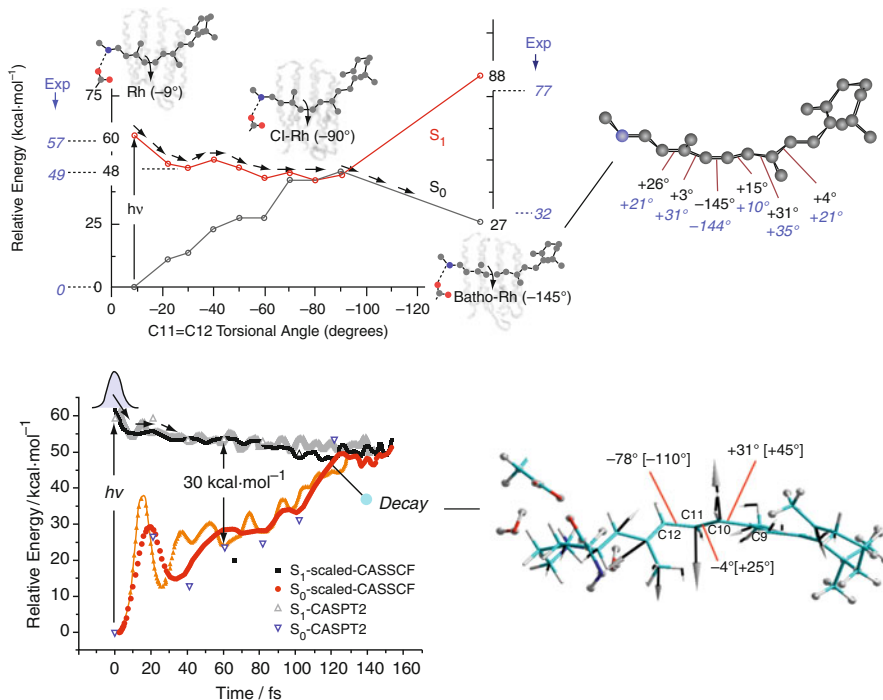

Fig. 22 Top left: Energy profiles along the S₁ photoisomerization coordinate of Rh computed at the CASPT2//CASSCF/AMBER level. The PSB11 structure on the right corresponds to the first isolable intermediate batho-Rh. The values in italics correspond to observed values (See ref. Kukura et al. 2005). Bottom: Scaled-CASSCF S₁ and S₀ energy profiles and CASPT2 points along the S₁ trajectory of Rh. The S₁ and S₀ energy profiles are reported for two Rh models based on the 1HZX (red and black lines) and 1U19 (orange and grey lines) crystallographic structures (M. M. Huntress, M. Olivucci, unpublished data). The structure on the right represents the point of decay (conical intersection structure) reached after ~ 120 fs time evolution. The vectors represent the velocities at the decay point and clearly show a crankshaft-like motion at the center of the PSB11 backbone

Furthermore we have been able to investigate the effect of water relocation inside the Rh cavity (Strambi et al. 2007). A second water (W2) had to be placed into the protein binding pocket according to qualitative space filling and electrostatic considerations since the original 1HZX crystallographic structure only showed the presence of one water molecule (W1). However, the more recent and better resolved crystallographic structure (PDB Code: 1U19) (Okada et al. 2004) points to a different location and different hydrogen bonding for W2. The sensitivity of S₀ → S₁ excitation energies with respect to the position of W2 has been investigated by constructing a new Rh model with the revised water placement. The results from the refined structure indicate a fairly low sensitivity of the λ_{\max}^a to the significant geometrical change of the salt bridge region, which suggests that there is a compensation mechanism that counteracts the effects of this change on the λ_{\max}^a . Our analysis points to a displacement of the chromophore to a cavity region

with a larger positive electrostatic potential as a means to offset the effect of the decrease in NH (+)–O1 (–) salt bridge distance. We have also compared the effect of a reduction of the full opsin model to a model with only the 27 amino acids of Palczewski's cavity (Palczewski et al. 2000), those that surround the retinal. It was found that the value predicted for the $S_0 \rightarrow S_1$ excitation energy is substantially the same indicating that for Rh the charges of distant residues are of minor importance for the optical absorption features of PSB11. Of course, we do not expect this to be a general result. Highly truncated protein models should always be applied carefully until a systematic analysis is carried out to determine their limitations and reliability.

In Fig. 22 top left, we report the S_1 branch of the photochemical reaction path of Rh computed in terms of a relaxed scan driven by the torsional deformation of the reacting bond. Using this data we have located and assigned the S_1 structure that corresponds to transient fluorescent state I. We then located the structure of the lowest lying S_1/S_0 CI (CI-Rh) that also corresponds to the local S_1 minimum. This structure displays a $\sim 90^\circ$ twisted C11–C12 bond. Starting from the CI-Rh geometry, using standard optimization, the first stable ground state intermediate bathorhodopsin (batho-Rh) has been located. It exhibits absorption at 540 nm and features an all- trans-like chromophore structure ($\sim 150^\circ$) dihedral angle around the C11–C12 double bond). The computed structure of batho-Rh can be compared with the structure that was experimentally derived by Mathies and coworkers (Kukura et al. 2005) by femtosecond resolved resonance Raman spectroscopy (see Fig. 22 top right). The comparison indicates that it is possible to predict the structure of an intermediate. Concerning the photon energy of $\sim 32 \text{ kcal} \cdot \text{mol}^{-1}$ that is efficiently stored in batho-Rh, the results of our CASPT2//CASSCF/AMBER energy profile show that we reproduce this quantity with an error of $5 \text{ kcal} \cdot \text{mol}^{-1}$.

A mechanistic picture of the space-saving isomerization mechanism is derived from the reaction path of the Rh QM/MM model and the associated structural deformation. The predominant change in the retinal geometry that occurs immediately after excitation leading to the fluorescent state I is a bond length alteration (BLA) in the $-C9 = C10-C11 = C12-C13 = C14-$ moiety. A complete inversion between single and double bonds is found at the geometry characterizing the state I. The CI-Rh displays a highly helical structure compared with Rh and FS-Rh and is mainly characterized by a large structural change in the $-C9 = C10-C11 = C12-C13 = C14-$ moiety. Thus, the motion driving the $S_1 \rightarrow S_0$ decay is mainly torsional with a rotation of $\sim 60^\circ$ ($20^\circ \rightarrow 90^\circ$) around the C11 = C12 bond, and 37° and 15° twisting around the C9 = C10 and C13 = C14 bonds, respectively. Therefore, from a general point of view, during photoisomerization the structural changes do not occur exclusively at the central double bond but also involve the other two adjacent double bonds, which lead to a global change in the helicity of the chromophore. A mechanism can be derived considering the largest changes. These involve the torsion about the reactive bond C11 = C12 and about the adjacent C9 = C10 bond. As highlighted in Fig. 21 (bottom) these twisting deformations occur in opposite directions and results in the rotation of the $-CH-CH-$ moiety with respect to the remaining framework. The mechanism confirms that the space-saving motion imposed by the tight Rh cavity is of the

crankshaft type. However, since the progression about the C9 = C10 bond is more limited, we can talk of an asynchronous crankshaft mechanism (Frutos et al. 2007). Furthermore, a comparison of the CI-Rh structure with the batho-Rh structure establishes (consistent with the experimental data) that the less twisted C9 = C10 reverts to its original stereochemistry after ground state relaxation, so we can talk of an aborted asynchronous crankshaft mechanism.

Another widely studied retinal protein is bacteriorhodopsin (bR), a light-driven ion pump discovered in *Halobacterium salinarum* in 1971 (Oesterhelt and Stoeckenius 1971). It is a membrane protein, which upon illumination generates and maintains a proton gradient across the cell membrane (Oesterhelt and Stoeckenius 1973). The gradient can be used as a source of energy, for example, by adenosine triphosphate synthase. bR shares some similarities with the visual rhodopsin: seven transmembrane α -helices and a protonated Schiff base with lysine-bound retinal as the chromophore. The X-ray crystal structure was first obtained at 3.50 Å resolution in 1996 (Grigorieff et al. 1996). By 1999, the resolution had improved to 1.55 Å (Luecke et al. 1999). The bR photocycle consists of several intermediates labeled K, L, M, N, and O, which were characterized by spectroscopy and trapped at low temperature in order to be studied by crystallography (Balashov and Ebrey 2001; Lanyi 2000). Light absorption triggers the Z/E isomerization of the C13 = C14 double bond of the PSBAT chromophore. The bond isomerization is completed at the K intermediate, yielding a 13- cis chromophore (PSB13); the following thermal relaxation leads to Schiff base proton transfer to the Asp85 counter-ion, in the L and M steps. The proton flux is completed during the remaining part of the photocycle, along with other accompanying proton transfers and protein structural changes.

The first ab initio QM/MM calculation on bR was reported by Hayashi et al. using multiconfigurational methods to evaluate the excited state properties (Hayashi and Ohmine 2000). The protein model was based on the crystal structure determined by Luecke et al. (1999) where the missing residues were taken from the PDB structures 2BRD (Grigorieff et al. 1996), 1C3W, (Luecke et al. 1999) and 1QHJ (Belrhali et al. 1999). The geometry was optimized at the HF level, using DZV and 3-21G basis sets with polarization functions on oxygen atoms. CASSCF(12,9) was employed to calculate retinal excitation energies. Five different models were built, each with different atoms included in the QM region. The results demonstrated that the protein environment affects the absorption properties of the chromophore. The side chains and the water molecules in the binding pocket affect the geometry of the retinal, forcing a twisting of the C13 = C14 double bond. The protein environment is anionic near the Schiff base, which stabilizes the ground state with respect to the excited state, causing a blue shift of the $S_0 \rightarrow S_1$ excitation energy.

Later the Schulten group (Hayashi et al. 2001) performed a further analysis to elucidate the physical mechanisms of the observed spectroscopic tuning in the rhodopsin family. A comparison between bR and the sensory rhodopsin II (sRII) was done to understand the origin of the change in λ_{\max}^a from 568 nm in bR to 497 nm in sRII. This difference was observed experimentally, in spite of the

same chromophore in both proteins and the similar protein environments. As in the previous work, a QM/MM methodology was employed, with AMBER as the MM force field. The equilibrium geometries of the QM regions were computed at the HF/DZV level. The excitation energies were evaluated with a CASSCF(10,11) wave function. The QM region included the retinal, the retinal-bound lysine (starting from C γ), and parts of the binding pocket: two aspartic acid residues (starting from C β) and three water molecules. The comparison between bR and SRII was performed by calculating the contributions to the $S_0 - S_1$ excitation energy: the total energy was rewritten as a sum of the energy of the isolated chromophore, the electronic reorganization energy arising from the modification of the wave function in the presence of the protein, and the electrostatic interaction energy between protein and chromophore. The results showed that the main contribution is electronic reorganization in the retinal and a closer inspection of the structures showed a reduced counter-ion–Schiff base distance in sRII compared with bR. This is the reason for the blue shift, consistent with the picture given in a previous paper (Hayashi et al. 2001).

Another spectroscopic feature of the bR photocycle was addressed by the same group in 2002 (Hayashi et al. 2002). The early K and L intermediate models were built using MD and refined with QM/MM optimization, following the same method as described above. The geometry optimization showed an increased chromophore distortion on passing from the ground state to the K intermediate. Moreover, the local hydrogen bond network is perturbed: a water molecule is displaced and the hydrogen bond between Thr89 and Asp85 is broken because the latter group undergoes a conformational change. Another result of that change is the reduction of the distance between the Asp85 carboxyl group and the Schiff base, which is thought to prompt the proton transfer in the following L-to-M process. Regarding the optical properties, K and L intermediates are red-shifted with respect to the initial absorption of bR. The excitation energies were evaluated at the CASSCF(12,11)//HF level, with a three state averaged calculation followed by state specific computation for S_0 and S_1 . The theoretical results are in good agreement with the experimental red shift, even though the absolute values are quite different and the spectroscopic shifts are overestimated. The reason for the shortcomings of the computational theory in this case is the failure of the CASSCF method to account for dynamic correlation. An analysis of the individual contributions to the total excitation energy allows one to pinpoint the main factors affecting the spectroscopic shift. Chromophore distortion around the C15 = N and C13 = C14 double bonds was found to be the main factor. It destabilizes S_0 more than S_1 , therefore reducing the energy gap. Another factor is the reduced electrostatic interaction between protein and chromophore, which increases the S_0 energy without affecting S_1 , where the charge is more delocalized towards the β -ionone ring. Nevertheless the geometry is optimized at the HF level, which is known to overestimate bonding character, compared with post-SCF methods, which leads to a likely underestimation of bond torsion in the chromophore.

Deactivation Mechanism in Cytosine-Guanine DNA Base Pair

Deoxyribonucleic acid (DNA) is a common biomolecule in all living organisms that contains the genetic information used for their development and functioning. It is composed of nucleotides, with backbones made of sugars and phosphate groups joined by ester bonds, forming long polymer chains. Attached to each sugar is one of only four bases: adenine (A), cytosine (C), guanine (G), and thymine (T). These bases belong to two types of organic molecules – adenine and guanine are purines that are fused five- and six-membered heterocyclic compounds, while cytosine and thymine are pyrimidines, which are six-membered rings. A pair of strands is usually arranged in the shape of a double helix by strong hydrogen bonds between the bases that stack upon each other. Due to the aromatic character of the nucleotide bases DNA absorbs in the harmful ultraviolet (UV) region of the spectrum. Hence, UV irradiation is one sort of mutagen that can damage DNA and subsequently lead to cancer. It is not surprising that DNA and its building blocks have been extensively investigated by computational quantum chemistry. The full coverage of the applications goes beyond the scope of this book chapter. Instead we are reporting an investigation using multiconfigurational *ab initio* calculations combined with AMBER force field in a QM/MM approach to study ultrafast radiationless deactivation mechanism of cytosine-guanine inter-strand base pair (Groenhof et al. 2007).

Groenhof et al. (2007) used a multiconfigurational approach as part of the QM/MM setup to study the inter-strand excited state proton transfer. One of the fastest deactivation processes in DNA was related to the cytosine-guanine base pair occurring on sub-picosecond time-scale. Therefore excited state molecular dynamics were employed to track this reaction. CASSCF with a reduced active space of eight electrons in eight orbitals and a 3-21G basis set was employed to model the molecular dynamics of the photoactivated C–G base pair. A surface hopping algorithm was used to detect a transition from the excited to the ground state. The crystal structure of the human DNA/topoisomerase I complex provided the initial coordinates for the QM/MM simulations. In total, 22 base pairs of B-DNA molecule were used. The partitioning of the system was done in a way that the cytosine-guanine base pair in the center of the molecule was described at the QM level. The remainder of the system was modeled with AMBER force field (Case et al. 2002). The chemical bonds between the bases and the deoxyribose sugar rings connecting the QM and the MM subsystems were replaced by constraints and the QM part was capped with two hydrogen link atoms. To equilibrate the DNA and the solvent prior to the QM/MM simulations, the system was equilibrated classically for 1,000 ps. The initial conditions for the excited-state simulations were obtained by taking 20 frames at equal time intervals from an additional 2 ps ground state trajectory at the CASSCF(8,8) level. In the excited state MD simulations, a time step of 0.5 fs was used.

Fig. 23 Sequence of events after the excitation. A proton is abstracted from guanine and accepted by cytosine. After the decay to the ground state via a conical intersection the proton returns to the guanine base. The excess thermal energy that is released upon returning to S_0 is responsible for spontaneous double proton transfer (at 82 fs) which leads to the formation of a different tautomeric state of the base pair (200 fs) (Redrawn with permission from ref. Groenhof et al. 2007)

In consequence, the ultrafast photodeactivation mechanism of the cytosine-guanine base pair was uncovered by the molecular dynamics simulations (see Fig. 23). The excitation to the charge transfer state induces a transfer of a proton from guanine to cytosine within a few femtoseconds. After the proton transfer, the system approaches the conical intersection seam and returns to the ground state. However, within a few femtoseconds the seam is closed again, and a second hop takes the system back to S_1 where it stays until another hop occurs. Most trajectories showed several hopping events between the S_1 and S_0 surfaces, with an average excited state lifetime of 200 fs for the entire process. This can be rationalized by the topology of the $S_1 - S_0$ intersection space (see Fig. 24). The proton transfer coordinate in the vicinity of the S_1 minimum is parallel to the extended hyperline and allows multiple transitions between the crossing states.

Absorption Spectra of a Coumarin in Solution

The calculation of absorption spectra is of great interest to chemists, since these spectra provide a wealth of information about the molecule, its environment and its properties. As a result of solvent effects and solute-solvent interactions the spectra can be quite complex. In addition, some of the information can be convoluted under the broad bands. Nowadays, computational photochemistry serves as a standard tool for spectroscopists, used to assign the experimental spectra. Until recently the calculations yield simple stick absorption spectra, which show the excitation

Fig. 24 Excited and ground state potential energy surface crossing of the cytosine-guanine base pair. The two reaction coordinates are proton transfer and skeletal deformation of the bonds. The dashed yellow and green lines schematically represent a path sampled in a typical trajectory on the S_1 and the S_0 potential, respectively. Along the proton-transfer coordinate the system moves out of Franck–Condon region to the minimum of the excited state. Due to the oscillations of the second reaction coordinate the trajectory hits the seam more than once (Redrawn with permission from ref. Groenhof et al. 2007)

energies and their relative intensities, without taking environmental effects into account. Recent advances in quantum chemistry allow researchers to treat solvents and to calculate vibrational contributions to the spectra. Here we present a case study of coumarin C153 (Scheme 9) computed by TD-DFT including solvent effects considered by polarized continuum model (PCM). Improta, Barone, and Santoro have studied the spectra in two different solvents: cyclohexane and dimethylsulfoxide (DMSO) (Improta et al. 2007). Coumarin C153 was selected to evaluate this novel methodology because it exhibits significantly different polarizabilities on its ground and electronically excited states. Therefore solvents with different polarities lead to large solvatochromic shifts that ought to be accounted for by the simulations.

In DMSO the spectrum consisting of an asymmetric broad band, extended towards the blue wing of the maximum, is correctly reproduced by the simulation (Fig. 25 right). This proves the reliability of the calculated vibrational progression hidden within the band. However, similar to the case of cyclohexane, the spectrum is found to be red-shifted by 400 cm^{-1} . The authors ascribe the latter to the effect of dynamic solvent fluctuations which are much more pronounced in polar solvents. Finally, the DMSO \rightarrow cyclohexane solvatochromic shift is estimated to be only 150 cm^{-1} smaller than its experimental counterpart.

Using this novel protocol Improta, Barone, and Santoro were able to simulate the spectrum of coumarin C153 in different solution environments with a high degree of accuracy. Complex band structures were reproduced for solvents of varying polarities with a computational procedure feasible for large molecular systems.

Scheme 9 The calculated stick absorption spectrum of the anti isomer of coumarin at 0 K in cyclohexane is shown in Fig. 25 left. The authors employ an algorithm for automatic selection of transitions between vibrational states since the full set is too computationally demanding. After harmonic analysis the algorithm was used to select $27 \cdot 10^6$ transitions out of a total of 10^{36} states. For the convolution of the spectrum the full width at half maximum of a Gaussian was chosen to match the main experimental bands. The spectrum was found to be unaltered when calculated for 300 K and also to be practically indistinguishable for the anti and syn isomers. The line shapes of the calculated spectrum resemble its experimental counterpart as shown for anti coumarin in cyclohexane (Fig. 25 middle). The two-peak structure with a spacing of $1,400 \text{ cm}^{-1}$ is qualitatively reproduced. The first band is mainly due to the 0–0 transition and a contribution from transitions to the single vibrationally excited state (C1). However, the computed spectrum is found to be blue-shifted by 400 cm^{-1} . The second band is composed of contributions from transitions to the first (C1), second (C2), and third (C3) vibrational states. The only deviation from the experimental spectrum is manifested in the relative height of these two bands

Excited State Molecular Dynamics

Tracking the Photoisomerization of Retinal in Different Environments

The first attempts to study the photoisomerization of the retinal chromophore by using ab initio excited state molecular dynamics were reported by Robb and coworkers (Vreven et al. 1997; Weingart et al. 2004) focusing on a model chromophore in the gas phase at the CASSCF level of theory. A more recent work by Weingart, again for an isolated retinal model, has shown that the quantum yield of the photoisomerization process depends critically on the initial retinal configuration (Weingart 2007). In the resting state of bovine rhodopsin, the chromophore deviates from planarity (Okada et al. 2004; Palczewski et al. 2000). By taking this retinal structure as a starting point for a series of excited state CASSCF semi-classical trajectories the author found that 70 % of the trajectories ended at the all-trans photoproduct. This result suggests that selectivity and quantum efficiency might originate from strain imposed by steric interactions between the chromophore and the protein before photon absorption.

Recently we have reported the first S_1 trajectory computation for Rh carried out with a scaled CASSCF force field that reproduces the static and transient spectroscopic parameters (Frutos et al. 2007). Because of the immense cost of the CASPT2 gradients, their application in trajectory computation is impossible

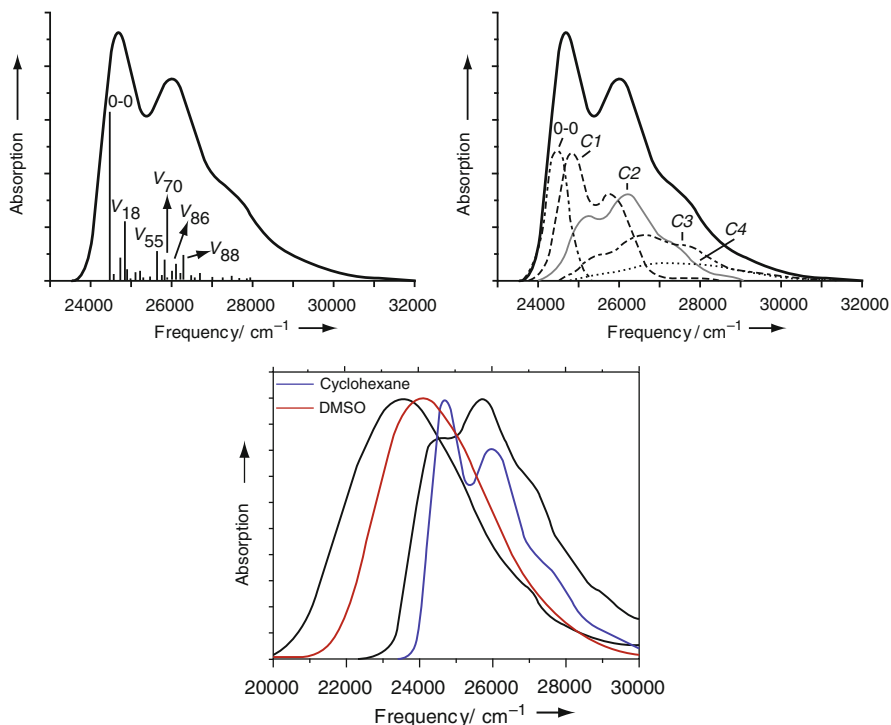

Fig. 25 Calculated spectra of C153 in cyclohexane. Left: 0 K stick spectrum and its assignment including transitions with one quantum in a single oscillator. Middle: A decomposition of the spectrum (thick line) in its components, where C_n dominates collection of transitions to vibrational states with the same number n of simultaneously excited oscillators. Right: Calculated spectra in cyclohexane (blue) and DMSO (red) compared to the experimental spectra (black) (Redrawn with permission from ref. Improta et al. 2007)

for the retinal chromophore even if such a calculation is limited to a few hundred femtoseconds. However, CASSCF energies not only fail to reproduce the observed spectroscopic properties of Rh but also yield an energy profile that is too steep. In order to overcome this problem and evaluate a realistic trajectory we noticed that scaling the CASSCF isomerization energy profile along the S_1 branch of the reaction path of Fig. 22 top left, yields a curve overlapping with the corresponding CASPT2 curve (Frutos et al. 2007). As displayed in Fig. 22 bottom left, the results show that this potential drives the chromophore to the CI on a 120 fs time scale. This time scale is in line with the observed excited state Rh lifetimes, which confirms the suitability of the scaled force field.

The assertion that a scaled CASSCF potential can approximate CASPT2 accuracy has been assessed by single point CASPT2//CASSCF/AMBER calculations along the trajectory. In Fig. 22 bottom-left we report the S_1 potential energy along the computed trajectory. Seven single point CASPT2/6-31G*/AMBER

computations have been performed to validate the scaled energy profile and to compute the correct $S_1 - S_0$ energy gap. The scaled CASSCF energies remain close to the CASPT2 energies all along the trajectory supporting the accuracy of our procedure.

Within 10 fs the S_1 system undergoes a $\sim 8 \text{ kcal} \cdot \text{mol}^{-1}$ energy decrease. Following this event the potential energy decreases slowly and monotonically until, after 110 fs, a region of degeneracy located $\sim 15 \text{ kcal} \cdot \text{mol}^{-1}$ below the Franck-Condon point is reached. Since the initial motion is dominated by simultaneous double bond expansion and single bond contraction, $\sim 8 \text{ kcal} \cdot \text{mol}^{-1}$ of vibrational energy must be initially located along this mode, which leads to complete inversion of the double bond/single bond character centered in the $-C9 = C10-C11 = C12-C13 = C14-$ moiety. The analysis of the entire 140 fs S_1 trajectory together with the resulting backbone deformation depicted in Fig. 22, points to a space saving isomerization mechanism that includes the previously proposed bicycle pedal or crankshaft coordinate. The $-C7 = C8-C9 = C10-C11 =$ segment of PSB11 twists with respect to the two remaining fragments, namely the $-NH = C15-C14 = C13-C12 =$ and the β -ionone ring, during the first 60–70 fs. Such a motion is mainly characterized by a negative twist of the reactive $-C11 = C12-$ bond and a positive twist of the $-C6-C7-$ bond. At the critical 60 fs mark the nature of the motion changes. The $-C6-C7-$ twist stops and the $-C9 = C10$ bond adjacent to the reactive $-C11 = C12-$ bond starts to twist in the positive direction. In other words, the $= C10-C11 =$ fragment rotates with respect to the backbone, leading to an 80° twisted $-C11 = C12-$ bond and to a moderately twisted ($\sim 30^\circ$) $-C9 = C10-$ bond after 110 fs. The nature of this motion is confirmed by plotting the linear momentum vectors in the 65–110 fs region. Further studies have revealed that this motion may be an intrinsic property of the retinal chromophore (Schapiro et al. 2009).

A more recent CASSCF/AMBER trajectory study of the photoisomerization of Rh was reported by Hayashi et al. (2009). The protein model was constructed based on the 1U19 crystal structure. It was equilibrated using classical MD and provided, after a 2 ns equilibration, a sample of 14 different starting points for the trajectory calculations. The polyene chain of the retinal, including the double bond of the β -ionone ring, was treated at the CASSCF level using a DZV basis set. The active space was composed of 12 π -electrons and 12 π -type orbitals. The first two roots were averaged in the CASSCF wave function. In order to describe the interaction between the QM part and the MM part, mechanical embedding was employed. This is an important difference from the excited state trajectory presented above (Frutos et al. 2007) that uses electrostatic embedding instead. In mechanical embedding the interaction between the QM and the MM region is treated at the MM level, which is less accurate. However, the transition from the excited to the ground state was initiated using the energy difference as criterion, namely when it was less than $75 \text{ kcal} \cdot \text{mol}^{-1}$. In addition, a trajectory of isolated retinal was calculated using a structure taken from the equilibrated rhodopsin.

It was found that all 14 CASSCF/AMBER trajectories decayed to the ground state within 100 fs (the shorter time could be attributed to a lack of scaling and

the unrealistically steep CASSCF energy surface), which is of the same order of magnitude as the trajectory by Frutos et al. (2007). Batho-Rh is formed in 13 cases and in one case a 9- cis isomer (isorhodopsin) is produced by a bicycle pedal isomerization of C9–C10 and C11–C12 bond. However, an accompanying rotation of 60°, on average, is found around C9–C10 in the 13 trajectories showing a crankshaft or aborted bicycle pedal-type mechanism, which is consistent with the previous findings.

The first QM/MM trajectory computation describing the photoisomerization of bR was reported by Hayashi et al. (2003). However, the selected QM part corresponded to a highly reduced PSBAT chromophore featuring only three double bonds. This was described by a three state averaged CASSCF wave function with 6 π -electrons in a 6 π -type orbitals active space with a DZV basis set. The MM part was described using AMBER for the protein and the TIP3P model for the water molecules. An ensemble of starting conditions was generated by a classical MD simulation of the resting state of bR at constant temperature (300 K). To compare the effect of the protein on the photoisomerization, trajectories of the same retinal model were calculated under vacuum. In total, 11 trajectories were performed to see if the high selectivity of the isomerization could be reproduced in the absence of the protein environment. It was found that the initial stretching relaxation is followed by a selective isomerization exclusively around the C13–C14 bond. It should be mentioned that this double bond is the central one in the investigated model. Hence, its preference for rotation compared with the terminal bonds is expected. The analysis of the isomerization dynamics of the six isolated chromophore trajectories shows that four trajectories isomerize around C13–C14 and two around the terminal C15–N16 bond. The authors concluded that the high selectivity in bR is a result of the protein environment.

Conclusion

In this chapter we have presented a few selected computational photochemistry case studies of model systems with increasing complexity, starting from isolated molecules that served as models in early works. The photochemical reaction paths of these systems were examined in mechanistic investigations, resulting in a general understanding of light-induced processes. Towards the end of the chapter we have given more recent examples of steady state spectra, minimum energy path calculations, and molecular dynamics simulations in different environments. More realistic models and rigorous simulation not only provided an explanation for the photochemical events, but also allowed a comparison with experimental data: the shape of spectra in solution can be convoluted, ab initio dynamics can predict excited state lifetimes and quantum yields, and conical intersections of chromophores in proteins can be located. All this reveals that the current stage of the tools of computational photochemistry are already providing results with accuracy comparable to experimental observables.

Nevertheless, we have also shown that some questions remain open, needing more accurate treatments which are still not feasible to date. Therefore further breakthroughs in computational photochemistry are anticipated. On one hand the development of quantum chemical methods and algorithms for effective computations is expected in the near future, whereas an increase of computational resources and computing power on the other hand ought to lead to another bloom in this research field.

Abstract

Molecular descriptors and properties are two basic forms of chemical information representing compounds in the computer. Chemical space is a structure for the mapping of these information types. It is not always easy to distinguish between descriptors and properties which are the rare annotations of chemical compounds and often need to be predicted. However, this distinction helps in understanding structure-property approaches and the possible origins for their failures. A variety of molecular descriptors is available both for storing molecules and for their processing in computers and we do not have here a sharp differentiation. The trend in property prediction goes away from pure modeling and prediction endeavors to the development of models that can also be interpreted and thus help us in increasing chemical insight and knowledge.

Introduction

Chemoinformatics is a term that has been coined to describe a discipline organizing and coordinating the application of informatics methods in chemistry. The definition of chemoinformatics evolved with the changing landscapes of informatics (computer sciences) and chemistry (Gasteiger and Engel 2003). According to Greg Paris, this “encompasses the design, creation, organization, storage, management, retrieval, analysis, dissemination, visualisation and use of chemical information, not only in its own right, but as a surrogate or index for other data, information and knowledge” (Paris 1999). Frank K. Brown describes this discipline as “the combination of all the information resources that a scientist needs to optimize the properties of a ligand to become a drug” (Brown 1998). Latest definitions broadened the scope of the area to the “the application of informatics methods to solve chemical problems” or simply to *in silico chemistry* (Gasteiger and Engel 2003; Polanski 2009).

At the semantic level, two elements constructing the designation *chemoinformatics* clearly relate this discipline to chemistry and informatics. The designation originated in the 1990s, when a new name was sought for the discipline that uses computers in drug design. This reflected the increasing potential of informatics and a large dose of the early optimism of computer applications in the field of drug design. Chemistry which originated this subdiscipline is the science of **chemical compounds and their transformations**. The maze of molecules, chemical entities, compounds, substances, and species (Woody et al. 2012) that was created by nature and chemists was not easy to be translated into machine understandable data. The human chemist is flexible enough to be aware of the problematic definitions, while a single uncertainty is already a problem for the computer. Computer understandable

chemistry is required for the machine to process the data. At the same time, it is also required to enable an interaction between chemist and computer to translate structure data of the molecular objects into a machine-readable and processable system that would be clear enough and unambiguous. Teaching computer chemistry appeared to be an enormously hard exercise.

A variety of textbooks, handbooks, and handbook chapters (Gasteiger and Engel 2003; Gasteiger 2003; Leach and Gillet 2003; Bajorath 2004; Lavine 2005; Bunin et al. 2007; Foulon and Bender 2010; Polanski 2009; Polanski and Bak 2010; Karthikeyan and Vyas 2014) is available in the field. However, we also need to make a few definitions in order to structure the field of chemoinformatics in a more precise manner. Furthermore, we want to describe still unsolved dilemma and discuss problems and concepts within this discipline.

History of Chemoinformatics

Historically, the field of chemoinformatics goes back to the 1960s although the name chemoinformatics was coined only in 1998. An illustrative historical perspective is drawn by the evolution of the journals publishing research in the discipline. Chemical information formed an important component of chemoinformatics. This was one of the reasons why the *Journal of Chemical Documentation* changed its name to *Journal of Chemical Information and Computer Sciences* in 1975. Then, in turn, this journal changed its name to *Journal of Chemical Information and Modeling* in 2005. “Computer science is now too far from the chemical core and chemists believe that they are generating their own tools for computer chemistry investigations” (Gasteiger and Engel 2003; Polanski 2009). The *Journal of Cheminformatics* has just started to appear in 2009. When the name chemoinformatics was introduced, the term *chemometrics* had already been coined. Chemometrics did not refer to all computer applications in the field of chemistry. Instead, it focused on some computer applications in analytical chemistry. This was probably the first field of computer applications in chemistry organized by a common name. Chemometrics started to deal with objectives less complex than those targeted by chemoinformatics.

In the very beginning of computer science, chemists realized its important potential for storing of chemical information, for molecular modeling, and for structure manipulation. At the same time, bringing molecules into the virtual computer world was a complex problem which had never been attempted by chemometrics. Various roots for chemoinformatics can be identified: In the mid-1960s, work was initiated on building databases on chemical information. The problem of a unique and unambiguous representation of chemical structures was addressed by Morgan (1965) which led to the construction of the Chemical Abstracts Service databases. Hansch and Fujita published their seminal work on quantitatively modeling biological activity which led to the establishment of the field of quantitative structure-activity relationship (QSAR) (Hansch and Fujita 1964). In the late 1960s, Langridge and coworkers visualized 3D molecular models

on cathode ray tubes (Lesk 1977). The DENDRAL project was initiated in 1964 at Stanford University for deriving the structure of organic compounds from their mass spectra (Lindsay et al. 1980). This work is widely considered to be the first application of artificial intelligence to organic chemistry. Other approaches to computer-assisted structure elucidation (CASE) were made in the late 1960s by Sasaki in Japan (Sasaki et al. 1968) and Munk in Arizona (Shelley et al. 1978). In the late 1960s and early 1970s, several groups at Harvard, SUNY, Brandeis, and TUM in Germany (Corey and Wipke 1969; Gelernter et al. 1973; Hendrickson 1971; Blair et al. 1974) took up the problem of computer-assisted synthesis design (CASD). Although none of the systems that were developed found general acceptance by organic chemists, the work on these systems eventually created the foundation for in-house databases on chemical structures and reactions such as MACCS, REACCS, and the Beilstein database.

Chemoinformatics, cheminformatics, molecular informatics, and chemical informatics are related names or even synonyms. In fact, *chemometrics* that uses, for example, the same techniques for analyzing data is evidently covered by chemoinformatics. However, for historical reasons, chemometricians often prefer to preserve their separate identity. For sure, however, seeing these disciplines as a unity will help much in better understanding the world of chemistry.

Scope of Chemoinformatics

Attempting to identify the scope of chemoinformatics, we can try to indicate differences in quantum chemistry and chemoinformatics. Both focus on modeling molecular effects. Hard theories with brute-force approaches are available for small objects. This decides that quantum chemistry uses *deductive learning*, providing a theory from which predictions are made. The complexity of the larger chemical and biological bodies decides that hard physical and mathematical approaches fail. Thus, cheminformatics uses *inductive learning*, trying to learn from experimental observations and data. Surprisingly, such methods are highly successful not only here but generally in science, where real progress is often accompanied by serendipity. Learning from experiments and data has been at the core of understanding chemical phenomenon from the very beginning of chemistry as a science. Cheminformatics now provides tools to do that kind of learning in a more systematic and efficient way. Quantum chemistry and cheminformatics may meet somewhere in the future for the better understanding of complex chemical and biological objects.

Accordingly, chemical data are the core issue in cheminformatics which both learning from data and focusing on data analysis for data prediction. Data prediction can be distinguished into two basic groups. First are molecular predictions, e.g., modeling 3D structures. Second, there are predictions of properties for molecular assemblies forming chemical substances. Both types of predictions are of crucial importance for drug design which is a major field of application of cheminformatics. Although drug design is still a central arena where cheminformatics is played, the scope of the discipline has included, from the very beginning, practically

Table 1 Chemoinformatics from problems to concepts

Problems	More important concepts
Chemical data documentation and searches: database searches and management	SMILES coding
Calculating molecular descriptors: 2D (chemical graphs) and 3D (molecular modeling) representations are mapped into single numbers (0D); vectors, fingerprints(1D); matrixes, surface maps (2D); surface, atomic representations, force fields, virtual or real receptor data (3D); etc.	Connectivity (graph theory) approaches Additivity concept Molecular modeling Force fields
Molecular modeling: molecular structure 3D data generation in silico from their 2D or 1D representations. This includes both predictions of molecular topography and molecular descriptors, i.e., atomic annotations data by calculated (simulated) atomic properties	Molecular mechanics Molecular dynamics Force field Molecular interaction field Partial atomic charges Lipophilic potential
Structure elucidation: (synonym: structure-spectra correlations) property to molecular structure is mapped in FCS when we are attempting to find a structure having a certain spectra or in structure to property version (VCS and FCS) we are simulating a spectra for a given molecule (substance)	RDF structure coding (2D) 2D structure – 2D spectra correlation
Mapping structure to activity (SAR): a series of structures (FCS substances) is needed to study SAR, which are usually synthesized. The real goal of SAR is usually to predict the training series for designing new structures and substances by property predictions in a qualitative or quantitative procedures	SAR QSAR QSAR domain Similarity measures Privileged structures Fragonomics
Property prediction: compounds' series (FCS) are mapped from FCS into VCS; two basic versions are available, i.e., property versus property or structure versus property. However, in the design step for novel compounds in VCS (we can design both compounds VCS or FCS where some properties can be registered in databases and/or literature), we are always to use a structure version (no property is available in VCS)	QSAR QPAR logP versus partition coefficient Fragonomics Virtual screening
Synthesis design: designing organic synthesis in product (target molecule) to reagent (synthon, reagent equivalent) mapping	Synthons Retrosynthetic analysis Synthesis tree

all computer applications in any field of chemistry. In Table 1, we are introducing chemoinformatics by basic problems and concepts developed in this discipline.

On the other hand, the trio, quantum chemistry, chemometrics, and chemoinformatics, nicely illustrates how creative is science forming different approaches, depending upon the encountered complexity of the problems, methods available, and reductionism level needed. We tried to conclude this in Table 2.

From Molecules to Substances and Compounds

Chemistry focuses on chemical compounds. But what do we mean by a chemical compound? The dictionary meaning of chemical compound is a substance formed from two or more elements chemically united in fixed proportions or in other words composed of identical molecules consisting of atoms of two or more chemical elements. Molecules and substances are precisely defined. Substantial definitions of chemistry were formulated by IUPAC. This includes especially:

- *Chemical element*
- *Chemical species*
- *Chemical substance*
- *Measurement*
- *Mixture*
- *Molecular entity*
- *Molecule*
- *Property*

A reader interested in more details should refer to the IUPAC compendium, an online version is available (IUPAC(a), goldbook.iupac.org), to precisely understand these terms. In particular, a molecule is an atomic scale body. Since the definition refers to a single entity, we are dealing in the laboratory with such objects only very rarely. In the real world, molecules agglomerate forming substances. From the

Fig. 1 The increase in information complexity from molecule to chemical compound

viewpoint of information theory, agglomeration brings a substantial complication. This process can significantly influence molecular structure and properties. Further, a single molecule (molecular entity) under experiment can form a substance arranged by an ensemble of chemically identical molecular entities. This effect of differentiation of the initial uniform molecular body is called speciation, and the resulting system is known under the term chemical species. In Fig. 1, we illustrate the increase of the system complexity from molecules to substances. Molecular agglomeration brings the problem of intra- and extramolecular interactions which changes the molecular arrangement and properties. Molecular interactions can include both original molecules and the molecules of different molecular species, and we cannot decide a priori on the importance of these interactions. Furthermore, in many experiments, we are dealing with molecules in solutions where individual molecules are surrounded by solvent molecules. The environment, concentration, pH value, etc., bring further complications influencing substances.

In fact, both chemistry and chemoinformatics deal with chemical compounds. A chemical compound is a historically formed term that covers both molecules and substances including molecular agglomeration to a single and to multiple molecular entities (chemical species). What we mean by chemical compound depends on the context and can denote:

- A *synonym of a molecule* (composed of at least two different atoms) representing a single chemical body for virtual needs (coding, in silico processing, visualization, etc.)
- A *molecule* representing a single chemical body under measurement (e.g., a single DNA strand that can be observed, e.g., under microscopy)
- A *substance* composed of a replicated but single molecular entity under measurement
- A *chemical species* under measurement when replicated is more than one molecule type

In fact, a molecule is a model of a chemical compound available both in the form of a physical representation that shows what this object looks like and as an idealized image of an atomic scale body. Formally, the term molecular descriptor has been coined by Todeschini to describe all numbers relating to molecules and obtained as “a final result of a logic and mathematical procedure transforming chemical information encoded within a symbolic representation of a molecule into a useful number” (Todeschini and Consonni 2000). However, we are still not consequent enough in differentiating molecules from substances. For example, it reads: “Molecular descriptors are divided into two main classes: experimental measurements, such as logP, molar refractivity, dipole moment, polarizability, and, in general, physicochemical properties, and theoretical molecular descriptors” (Consonni and Todeschini 2010). We should distinguish *experimental measurements*, i.e., *properties* (mainly for real substances), from other numbers describing in silico *simulated* molecules or substances, namely, molecular descriptors. By the way, this inconsequence is not a coincidence because historically in chemistry we are determined to think in the category of chemical compounds. To realize the complication of defining molecular bodies forming a single chemical compound, the reader is referred to Bobach et al. (2012).

With the development of chemical knowledge, we realized the need for measuring similarities or, alternatively, the diversity of chemical compounds that helps the systematic probing or screening of objects within the controlled molecular structure span. For example, in QSAR this problem is referred to as defining the model domain (Netzeva et al. 2005).

In sections “[Storing of Chemical Structure Information in the Computer](#)” and “[Representations for Coding Molecules](#),” we will largely concentrate on the representation of molecular structures. In section “[Chemical Compounds Beyond Structure Representation](#),” we will briefly discuss the representation of chemical compounds that cannot be specified with a molecular structure.

Chemical Space

Chemical space (CS) is a concept which appeared in the hope of organizing a whole population of chemical compounds. Chemical space is a structure for the mapping of chemical compounds by descriptors and properties. Despite widespread attention, this term has not been precisely defined. The idea was inspired by the cosmological universe populated by stars, where chemical compounds replace cosmological objects to *navigate chemical space* (Lipinski and Hopkins 2004). This was shaped by multidimensional descriptors (fingerprints) or properties, while the comparison or similarity studies are performed by the comparison with a reference compound (Medina-Franco et al. 2008). The parameters characterizing similarity to a given reference compound can also be annotated in such a space. The distribution of compounds in space and neighborhoods and relations between

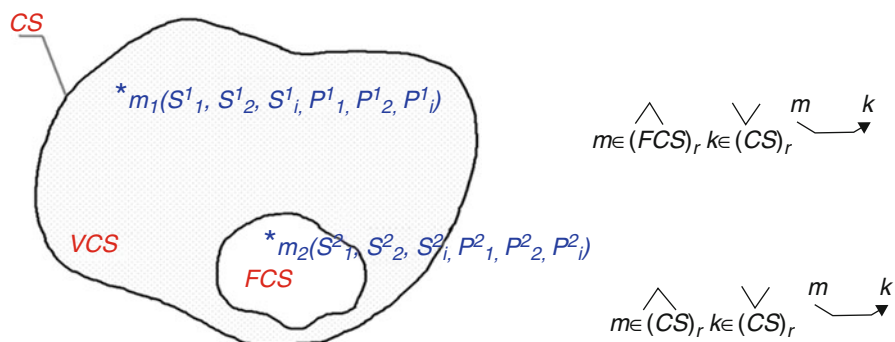

Fig. 2 Chemical space (CS). On the *right-hand side*, two basic problems of in vitro and in silico organic synthesis are defined as the mapping of molecules (chemical compounds) m into products k

the objects populating CS depend upon the molecules selected to populate CS. It was suggested that chemical space can be defined as the entire collection of all meaningful chemical compounds, typically restricted to small organic molecules (Dobson 2004). For a detailed review and discussion of the abovementioned concepts, the reader should compare reference Boehm (2011).

A definition of CS related to mathematics was attempted in Polanski (2009). In Fig. 2, we illustrate this concept. The CS is populated by chemical compounds, i.e., both molecules and substances are covered by this structure. The CS can be divided into two basic moieties, factual chemical space (FCS), described by chemical compounds that have already been obtained and registered, and virtual CS (VCS) mapping hypothetical molecular structures. We can use the mathematic formalism for mapping molecular objects, their properties, or descriptors. Accordingly, we note two common chemical problems, chemical synthesis and reaction predictions, using this structure (Fig. 2). An in vitro reagent should be a known substance of FCS, and its product can be both an FCS and a VCS element; m should be included in the reaction domain r for reagents and k in the reaction domain of products. The difference for in silico operation is that both m and k can be CS elements.

It is interesting to further analyze the structure of chemical space. If we hypothetically visualize CS as a matrix, this will include three main blocks of data. First, these will be the data coding constitution and stereochemistry of the molecules, and then come the molecular descriptors of the molecules, and, finally, the properties measured for the substances formed by the molecules. Since molecules and substances together are chemical compounds, the CS is populated by chemical compounds.

It is worth mentioning here that the differences between VCS and FCS will not be so large as could be expected. By FCS we mean that the compounds were registered in any database or a publication. But even in such cases, we usually have nothing more than melting point and ^1H NMR spectra registered. The FCS

compound collections (libraries) for actual property measurements are still available rather rarely. Thus, the CS matrix resembles a sparse matrix populated by few data even for the compounds that are already registered. On the other hand, *measured* properties are completely unavailable for virtual compounds (VCS). A number of missing values in FCS means that we are working more on virtual molecules with descriptors and predicted properties than with real property values. It means that the data flood in chemistry is a myth. It is a local effect observed for only a rather few chemical compounds and properties. We still do not have substantial information for chemical compounds. Actually, the large number of data results more from the large number of compounds registered (ca. 70 million or 10^8 compounds) than from the completeness of their properties measured. The number of chemical compounds obtained is however nothing if we compare this to the enormous number of potential chemical structures which ranges anywhere from 10^{18} to 10^{180} molecules (Boehm 2011).

Interestingly the libraries of real chemical compounds collected by pharmaceutical companies are probably the largest chemistry deposits available in FCS. It is also just in recent years that such libraries have become available in chemistry.

It is also interesting to enumerate the number of registered chemical compounds in VCS (Boehm 2011):

- Screening libraries of pharma companies 10^6
- Commercially available compounds 10^7
- Patent/literature compounds 10^8

The structure of chemical space helps us in understanding how rare are real property annotations of chemical compounds. Properties decide on substance usability and on its importance in chemistry. They allow compound identifications and comparisons. This seems trivial and chemists were aware of this very early. The FCS was described by *Chemisches Zentralblatt*, which appeared as early as 1830 and by Beilstein's *Handbuch der Organischen Chemie* which contained already in 1881 two volumes, registering 1500 compounds, with more than 2000 pages. Even such small FCS needed a system addressing chemical compounds in the compendium. Chemical formulae, chemical name (nomenclature system), and a special structure of *Systemnummers* helped in finding the compound's entry in the Beilstein Handbook. Despite this, for years, using Beilstein needed expertise in chemistry.

At the very beginning, each new compound obtained was of substantial interest exploring new chemistry areas. However, a relatively large population of 100 million compounds explored by now decides our preferences in our current chemical investigations. Nowadays, we focus not on new compounds but rather on exceptional properties in FCS (Hammond 1968). This decides that we do not care for publication of any property data for any new FCS compound. Currently, published compound properties are stored in databases available online.

Storing of Chemical Structure Information in the Computer

Two essential tasks have to be solved in chemoinformatics: the storing of chemical compound information and the prediction of properties of chemical compounds. Basically, therefore, two types of molecular descriptors can be identified. First are descriptors needed to map the structures into unique and unambiguous codes understandable for the computers. This is important both for experimental chemistry working with substances in FCS and theoretical chemistry dealing with molecules or virtual chemical substances (VCS). This type of mapping is performed especially by the descriptors discussed in sections “[Mapping Chemical Graphs into 0D Descriptors](#),” “[Mapping Chemical Graphs into 1D Descriptors](#),” “[Mapping Chemical Graphs into 2D Descriptors](#),” and “[Mapping Chemical Graphs into 3D Descriptors](#).” Then, we have a variety of molecular descriptors designed to be used for in silico molecular predictions, property prediction, or molecular visualization. In the latter case, the prediction of properties of compounds, it is more important to describe the structure of molecules in a manner appropriate for the prediction of the property of interest than to have a fully reversible mapping between molecular structures and descriptors, i.e., once we transformed the molecule into the descriptors, we often cannot easily and/or unambiguously come back to this specific molecule. We will first discuss in this section the descriptors needed for storing compound information in the computer. The derivation of descriptors for the prediction of properties will be discussed in section “[Representations for Coding Molecules](#).”

In order to control the CS (molecular management and manipulation), we need to have efficient machine-searchable databases registering all compounds that have been synthesized by chemists from the very early days to today. This problem is referred as *structure representation and searching*.

Molecules formed by atoms connected by chemical bonds can formally be represented in a simplified 2D version using graph theory which replaces an atom by a node (vertex) and a bond by an edge. The visualization of molecules by chemical graphs annotated with atomic symbols was such a successful *chemist-friendly* concept that this seems today to be a molecule archetype deciding the perception of chemistry and developing the essence of chemical knowledge. In other words, today we simply cannot imagine understanding the basic concepts of chemistry without 2D chemical graphs. In this sense, chemistry is in the lucky and highly valuable position of having a language that is internationally accepted and understood. The task is then to translate this language into a computer-readable and understandable form. The formal features of graph theory important for mapping molecules into chemical or molecular graphs will not be discussed here further, and the reader is referred to a number of available literature ranging from a very formal to more popular descriptions. A comprehensive overview is provided by Gasteiger (2003).

The storing of information on the structure of chemical compounds has to be unique, i.e., the stored information should for a given compound always be the same, and it has to be unambiguous, i.e., not two different compounds should

receive the same representation. To uniquely and unambiguously code molecules, we need to define their constitution and stereochemistry, where constitution means the connectivity pattern between atoms and stereochemistry defines the spatial arrangement of the atoms in a reduced form.

It is worth mentioning, however, that in the majority of chemical applications, the stereochemical description does not include a precise description of the real 3D molecular structure (which is known relatively rarely), but rather its rough scheme relative to a standard, e.g., two hypothetically possible 3D structures of trans-1,2-dibromocyclohexane are available, but we usually do not focus on this fact. A variety of such uncertainties decided that finding the strict rules for coding molecules for computer applications appeared to be an unexpectedly tedious problem. Moreover, molecular graphs at the early stages of computer technology development were too complex for direct application. The complex nature of molecular graphs can be illustrated by a question asked by Cayley and Schiff: what is the number of all alkanes with molecular formulae $C_{20}H_{42}$, a relatively simple chemical structure (Cayley 1875; Schiff 1875). This can be reformulated into a graph theoretical problem to the question of how many graphs can be arranged to contain 20 C and 42 H nodes with edges fulfilling chemical bonding rules. The answer is 366,319, and it took almost 60 years to answer this question by Henze and Blair (1931) and Reymond et al. (2010). Accordingly, what was done in the early stages of chemoinformatics was a simplification of the chemical graphs.

Mapping Chemical Graphs into 0D Descriptors

The most simple transformation of a chemical graph is a single real number. Mathematically, in this operation, we map chemical information into its simplest form of zero dimensionality (0D), while the calculated number (molecular descriptor) is called a global descriptor. A typical 0D descriptor used for data storage and addressing is:

- Molecular formulae (MF)

An important feature of the mapping of a molecular graph into an MF is that we do not use atom connectivity information for this. We simply sum the atoms of the certain types; in other words, we only annotate the vertexes of the graph. This has the implication that an MF is nonreversible and ambiguous. However, we are often using this notation in the course of documentation and addressing compounds, e.g., in databases or in the literature, e.g., we can use the molecular formula index to search for the appropriate section within the ACS Chemical Abstracts where the compound information can be found.

Mapping Chemical Graphs into 1D Descriptors

Mapping to a 0D representation substantially decreases information on chemical compounds, and 0D descriptors are usually too coarse to code molecules. Instead, 1D descriptors such as:

- Systematic nomenclature
- Line notation

appeared to be enough for the efficient coding of molecules and for database searching.

The concept of a systematic nomenclature scheme (chemical name) by naming rules is human-oriented, which means that easy chemical nameability and name readability by human chemists have been given high priority. However, the systematic nomenclature such as the IUPAC system quite often leads to rather complicated names reflecting the complexity of chemical structures. A human-friendly nomenclature does not necessarily meet the requirements of a computer-oriented system. For example, restricting the name generated for a single structure to a unique value is still a challenge and is to be solved by a preferred name program (PNP) currently under consideration (IUPAC(b), iupac.org). The first system that allowed the input of chemical structures in the form of their chemical names was developed by Beilstein in 1986. This was operated internally at the Beilstein Institute, and the structure input was restricted to the Beilstein notation sub-rules. Currently, the systematic nomenclature is a fully reversible system with software, allowing the mapping of a molecule to a name and a name to a molecule structure.

A line notation is another important system that maps a 2D molecular graph into a linear sequence of letters and numbers. The first systems for this mapping were developed even before computer applications, and a peak of success was in the 1960s and 1970s when this provided a rapid system for coding even large molecules. In a computer system, this was especially suitable due to the compactness of data storage requirements, an important problem at that time. Among historically important line notations:

- Wiswesser (WLN)
- ROSDAL
- SYBYL (SLN)
- SMILES

the latter one, SMILES, evidently predominates today. This is caused by its very simple semantic rules and the intuitive nature of the system. In Fig. 3, we show some illustrative examples. SMILES codes support any chemical entry in Wikipedia, and almost each molecular editor can generate SMILES. Vice versa, SMILES can replace a molecular input into a variety of databases, e.g., Reaxys and/or molecular

Fig. 3 SMILES, a simple line notation concept transforming a molecular graph (2D) into its 1D representation. In the *upper* part, the notation of some structural elements (double bond and branching at carbon atom) is shown. Below, the formation of chains and stereochemistry in SMILES coding is indicated

editors. A smell of success for this system is in the air if we realize that a Google search can be performed today directly by a SMILES input.

Mathematically, a line notation performs a reduction of information from a 2D into a 1D representation. Dimensionality reduction, while preserving 2D information, explains the success here. Lower dimension means simplification in data manipulation. An important remark is that this dimensionality reduction is fully reversible. So we can both obtain a SIMLES for any molecule and remap this back to reproduce the original molecule.

Mapping Chemical Graphs into 2D Descriptors

Molecular graphs were developed for coding molecules for the needs of human chemists; however, they appeared impractical for feeding computers with molecular

data. Matrix notations or linear codes are the methods developed for mapping molecular graphs into the computer-friendly data. A variety of matrix systems (2D descriptors) were designed, where the numeric representation depends upon the scheme used for coding atoms and bonding. Popular notations include the following matrices:

- Adjacency
- Atom connectivity
- Distance (topological or geometrical)
- Bond
- Bond electrons
- Incidence

Although a matrix system performs well, the number of entries needed to describe a molecule squares with the increase in the number of atoms in the molecule, making it impractical for storing large molecules or large datasets.

A connection table (CT) is an alternative method, allowing us to present molecular graphs in a form of lists of atoms and bonds in a molecule which increase linearly with the number of atoms. A number of CT versions are available, and the reader is referred to Gasteiger (2003) for a detailed introduction.

In Fig. 4, we illustrate an adjacency matrix and in Fig. 5 a connection table and of a simple organic molecule.

A CT notation has now become the predominant form of representing molecular structures. Standard notations such as Molfiles and SDFfiles have been developed that are globally used for information exchange, e.g., in Fig. 6, we illustrate a Molfile coding the 3D structure of salicylic acid by also giving the 3D coordinates of the atoms. In effect, the international language of chemical graphs has been translated into an internationally standardized computer-readable form. (As these representations are coded in ASCII, they can also be read by a human.) An interesting example of coding vitamin C, a chemical compound with all tautomers, by a CT can be found in Bobach et al. (2012).

Today, graphical molecule editors have been developed as tools for the direct creation, modification, or inputting of molecular graph 2D information. Vice versa tools are available for obtaining molecular graphs as outputs from computer-stored CTs.

Mapping Chemical Graphs into 3D Descriptors

A 2D molecular representation defines the molecular topology (atomic constitution and connectivity). However, this in its cleanest form does not code stereochemistry, i.e., the spatial arrangement of the atoms around an atomic center called atomic configuration. This can be coded within chemical graphs by enriching them with solid and dashed wedged bonds, indicating above-the-plane or below-the-plane pointing of the bonds. The configuration is a simplified 3D molecular representation

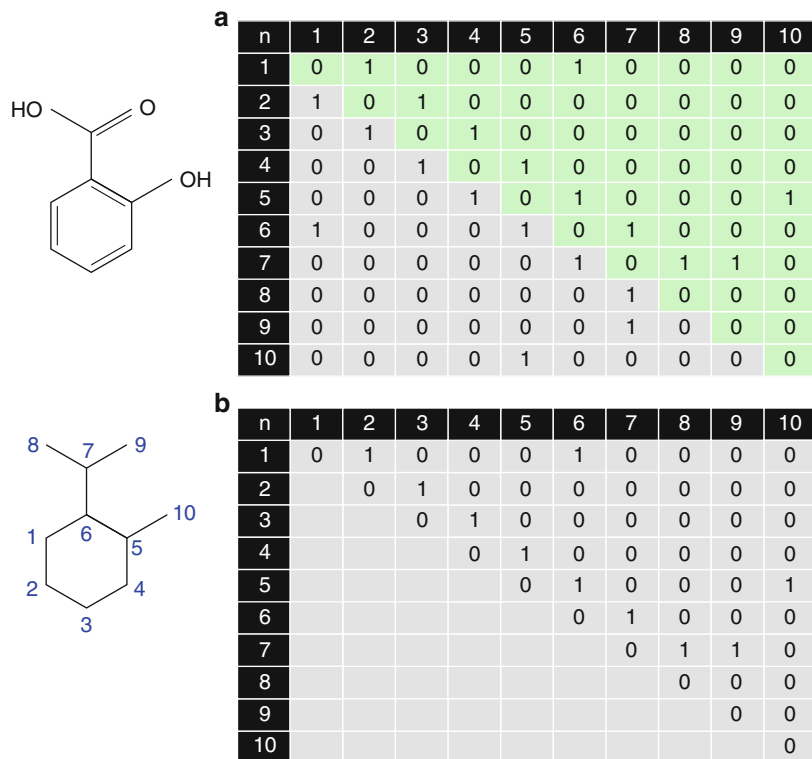

Fig. 4 Two possible forms of an adjacency matrix of salicylic acid: $a_{ij} = 1$, if i and j are bonded or 0 if not bonded

indicating a *version* of the atomic arrangement (stereoisomer) but not the real 3D atomic coordinates.

Stereochemical codes in chemistry are developed to achieve a significant simplification in the visualization of 3D molecules in 2D for the human chemist. Stereochemical information is somewhere in between topology (2D) and topography (3D). In chemistry, beside the solid and dashed wedged bond rule enriching molecular graphs, we illustrate stereochemistry using certain conventions, such as Fischer, sawhorse, or Newman projections. Basically, stereochemistry is a molecular descriptor that defines the arrangement of atoms around an atomic center relative to a standard. The reader should note that this type of molecular descriptor is different from those discussed in section “[Representations for Coding Molecules.](#)” To better understand this, we compared in Fig. 7 the Fischer and Newman projections of stereoisomers of tartaric acid (two enantiomers and one meso compound). A simple compound but a complex problem: a single constitution (chemical compound), two different enantiomers (molecular species, if present in a single substance), and potentially three substances (diastereoisomers). Actually, this is even more

Atom list		Bond list		
1 st atom	2 nd atom	bond order		
1	C	1	2	2
2	C	1	6	1
3	C	1	16	1
4	C	2	3	1
5	C	2	15	1
6	C	3	4	2
7	C	3	14	1
8	C	4	5	1
9	O	4	13	1

12	H	6	7	1
13	H	7	8	1
14	H	7	9	2
15	H	8	11	1
16	H	10	12	1

Fig. 5 A connection table of salicylic acid

complicated if we analyze the rotamers in Fig. 7c. Although rotamer I is achiral due to having a center of symmetry, rotamers II and III are in fact chiral, and the achirality of the substance is due to the compensation of chirality contributed by these two chiral conformers. To illustrate how important and complicated stereochemical problems can be if transformed into the computer, a reader can refer to Carbonell et al. (2013).

Basically, two possible representations for the real 3D structure are available. First are 3D atomic coordinates measured as the actual property of compounds (substances), e.g., through crystallography. Accordingly, such data are available in databases (compare section “[Databases and Database Searching](#)”). Second, there are predictions of 3D structures based on molecular modeling. In the second case, this operation can be explained as a mapping of a 2D (CT) or a 1D (SMILES) molecular representation into 3D (see section “[Representation of 3D Structures and Their Mapping into Lower Dimensionality](#)”).

Technically, 3D structures can be noted in several data formats:

- SDfile (Structure Data)
*.sdf
- Molfile (Connection Table Format)
*.mol

These data files can represent both descriptor and property data and can be converted into each other (compare Chemaxon, chemaxon.com).

Databases and Database Searching

It is quite clear that an overview of the flood of chemical information can nowadays only be managed by databases. With more than 100 million chemical compounds known, it is simply impossible for a human to know from memory for any compound whether it has been made and what its properties are. In this sense, chemoinformatics has delivered indispensable methods for research in chemistry and for the further development of its knowledge.

Fig. 7 The stereochemical problem of tartaric acid isomers noted in Fischer (a, b) or Newman (c) projections. Chiral molecules can arrange into chiral substances but also into an achiral one which rotamers I–III are shown in (c)

In section “[Storing of Chemical Structure Information in the Computer,](#)” we discussed the computer representation of molecules (chemical structures). These computer constructions are highly standardized for coding purposes and can be derived from molecules. Otherwise, real properties of substances that are beyond molecules cannot be calculated but are to be measured in experiments. Measured data involving chemical substances are to be eventually organized in the form of searchable and manageable databases. A search engine, the heart of a chemistry database, usually is today an intuitive user friendly system that can be operated by drawing a molecule or by inputting a SMILES code representing a substance, while the searches can be controlled by logical and/or truncation (wildcard) operators (Gasteiger and Engel 2003). In Table 3, we specified some database taxonomies found in literature.

Structure databases, e.g., Gmelin, Beilstein that are now continued by Reaxys (Elsevier) or the Cambridge Structural Database (CSD), illustrate the importance of chemical information for the development of chemical knowledge. Organic or medicinal chemistry or drug design cannot do without database systems. Internet

Table 3 Database taxonomies found in literature

Formal model	Hierarchical
	Network
	Relational
	Object-based
Content	Literature
	Factual
	Numeric
	Meta-databases (entries for other databases)
	Catalogs of chemical compounds
	Research projects databases
	Structure databases where 3D molecular structures are entries
	Small molecules
	Bioinformatics data, i.e., proteins and genetic (DNA and RNA) data
	Chemical reaction databases
	Internet, e.g., web search engine Google
Data type	Biological activity
	Spectroscopy
	Crystallography
	Genetic
	Proteomics

online access to databases is currently a common standard, while both the charged licensed and free systems are widely represented among various organization schemes.

Property data of chemical compounds stored in databases can be simple numerical and factual representations, complex records, e.g., ^{13}C , ^1H NMR, IR, MS spectra or proteomics, protein data. The PDB (protein data bank) structural data format is an example of the data standardization for such data type. The PDB data include more than 100,000 structures (2015/03/03) deposited which are freely available from PDB, www.rcsb.org where also the statistics for the PDB data is given.

The ZINC database is an interesting example of a free database of commercially available compounds for virtual screening. ZINC contains over 35 million FCS compounds that are commercially available from 235 suppliers. The data are prepared in ready-to-dock, 3D formats for a large number of substances: 95,361,026 entries. The chemical compounds (FCS) are annotated in particular with chemical properties and biological activity. The purpose of this database is an easy access to molecular data needed for high-throughput virtual screening. Technically, ZINC stores 3D information in mol2, 3D SDF, and DOCK file formats.

Interestingly, properties are available also for compounds whose molecular structures are not exactly known, e.g., polymers. The CHEMnetBASE, Polymers:

A Property Database (Chemical Databases Online, polymersdatabase.com) contains almost 1000 polymers and 1500 monomers annotated with:

- General description
- Volumetric and calorimetric properties
- Surface properties and solubility
- Transport properties
- Mechanical properties
- Electrical properties
- Optical properties
- Polymer stability
- Applications and commercial products

It is interesting to compare the population of the experimentally measured properties to the registered FCS which is ca. 10^8 (100,000,000):

- Partition coefficient data 10^4 (30,000)
- Structure (crystallographic) data 10^6 (750,000)
- Biological data for screening test (pharma) libraries 10^7

Chemoinformatics has also developed methods that allow an efficient searching for compounds in databases. One can perform searches for full structures, for compounds containing certain substructures, or for similar structures. Various definitions of structural similarity are available. Substructure and similarity searches provide lists of compounds that can be further investigated for the problem at hand.

There is, however, an interesting and important remark to be made concerning the availability of biological data for pharma libraries. The data gathered by pharma industry are not available to the general audience and/or competing companies. This important problem and obstacle in drug design was identified and the so-called *data sharing* concept has been developed to enhance the efficiency of data acquisition and use in pharma. Actually, some procedures and norms for data sharing have been developed (Bird and Frey 2013). Moreover, since we are awaiting significant innovations in medicinal chemistry and in pharma companies, the so-called *collaborative drug design* concept appeared (CDD, collaborativedrug.com). This needs a substantial collaboration and data sharing with pharmaceutical industry. Currently, we believe that this is an absolute requirement for the new era discoveries based on new targets (macromolecular drug receptors) for which personally tailored medicines can be developed in the so-called translational drug discovery approach (Littman and Krishna 2011).

The next problem is that chemical literature publishes only data for positive experiments. This means that chemical journal data are those relating to high-activity compounds. This decides that usually negative data are unavailable and the whole data statistics is skewed. For example, the average potency for the real drugs

on the market is lower than the potency of compounds published in journals (Walters et al. 2011).

Prediction of Properties

Actually measured properties are by definition not available for VCS compounds but are also rare for most FCS compounds. Thus, we often have to replace them with predicted values. Chemistry is a science describing the facts of nature by collecting data in experiments that are performed. The data provide the basis for mathematical models which can be seen as a compressing tool. For example, if the experiment probing two variables provided us with a matrix of parameters of size $10,000 \times 2$ and this can be modeled by a simple linear equation, we are replacing 20,000 numbers by two numbers (*regression*) or even a single number (*ridge regression*).

Regression is a tool developed not only for modeling data but also for predicting data by intra- or extrapolation. We will use here the concept of quantitative structure-activity relationship (QSAR) initially developed by Hansch. QSAR is of fundamental importance in drug design to explain a simple approach to property prediction. In fact, what we are doing in the Hansch approach is modeling drug transport through biological membranes by a partition coefficient (Fig. 8). A partition coefficient is a property measured in an experiment. In drug design, we need, however, to design new molecular objects for which we cannot yet perform experimental measurements. Thus, in a Hansch model, a partition coefficient is replaced by the logP value which can be formally classified as a 0D molecular descriptor. The *additivity concept* provides us with a system in which logP is calculated by summing contributions from structure fragments. These contributions were estimated based on a regression model relating the partition coefficient measured for the substances to fragmental molecular descriptors. The logP value for the whole molecule can then be calculated by simply putting together the increments describing the individual molecular fragments.

Actually, partition coefficients have been measured experimentally only for 30,000 substances (Martel et al. 2013) which is only a tiny fraction of the FCS population. On the basis of this database, we can estimate logP for millions of virtual molecules under design. In fact, even after these substances will be synthesized, the actual partition coefficient values will be measured for them only in rare cases.

This means that the mapping of partition coefficients into logP (both for unmeasured FCS and unavailable VCS compounds) is a substantial extrapolation.

Fig. 8 Schematic notation of the prediction of the partition coefficient by logP calculation. Details in text

However, a real problem of this mapping lies elsewhere. During the design step, we are replacing a substance with an isolated molecule and then come back to the substance after its actual synthesis. Below we illustrate this by the CS operator which helps to understand the problem.

Accordingly, the logP (molecular descriptor, S_{mFCS}) for the training compound series is related to the measured partition coefficient of the related substances (P_{sFCS}) that are available in FCS (mapping 1; physical chemistry in vitro), which provided a basis (regression model) for the calculation of the respective logP (S_{mCS}) for any compound in CS (mapping 2; chemoinformatics in silico). We are usually forgetting about the mapping 3 (hypothesized to be the identity mapping), which means we are using in modeling logP as a replacement for the partition coefficient (P_{sCS}) of the substance under design.

In more or less congeneric series, this replacement usually does not distort the prediction quality, and the mapping can be seen as a reasonable intrapolation, but with an increase in the extrapolation span into the structures which are not well covered by the training substances, we may neglect a variety of real inter- and intramolecular effects encoded in the actual lipophilicity, if measured for substances (Pliska et al. 1996). This effect is not well explored for logP but is very well known for the similar Hammett equation and Hammett constant, where after fascination with linearity, it is a distortion from linearity that provided us really valuable information on chemical reactivity and reaction mechanisms (Schreck 1971). We should remember that logP is not the same as the partition coefficient. Instead, logP is a fragonomics-based molecular descriptor, a correlate of the partition coefficient, aimed to mimic this property.

We can distinguish several basic scenarios for property predictions. Property prediction is based on inter- or extrapolation operation as described above for the partition coefficient. This can, however, be further divided into regression models based directly on another property measured, namely, property-property models, e.g., partition coefficients can be estimated on the substance solubility data (if real data are available for FCS compounds) and alternative models where predictions are made on the basis of molecular descriptors, known as structure-property relationships (compare paragraph 6). A single or multiple property or molecular descriptor representations can be used for this purpose. In most cases, the latter approach will be followed by representing the molecular structures by structure descriptors. Therefore, the entire section “[Representations for Coding Molecules](#)” is devoted to this theme.

From a technical point of view, modeling a dependent variable by a data analysis method usually needs independent variables where each molecule of a dataset is represented by the same number of elements. The application of a mathematical data analysis method requires each object, in this case each molecule, to be represented by the same number of independent variables, i.e., the same number of molecular descriptors. This is a serious requirement for chemistry because the molecules of a dataset usually have different sizes. If a molecule were represented by a single value for each atom, different numbers of variables would result for the various molecules. This would prevent the application of a mathematical data

Fig. 9 The two-step approach to the prediction of properties of compounds that cannot be directly calculated

analysis method such as a multi-linear regression analysis or an artificial neural network. Therefore, the specification of many molecular descriptors must include a mathematical transform of the molecular structure to give for each molecule descriptors of the same number of elements irrespective of its size. This problem is known under the name *uniform-length descriptor* (Baumann 1999). This implies at least one rule to define a fixed number of element in each vector and one rule to fill in the vector elements when the values are missing (Todeschini and Consonni 2000). A variety of mathematical operators, e.g., autocorrelation, can be used to achieve this transform of a molecule. The examples of *uniform-length descriptors* are (Todeschini and Consonni 2000):

- Autocorrelation descriptors
- EVA descriptors
- Topological charge indices
- Molecular profiles
- Spectra descriptors
- Affinity fingerprints
- Radial distribution function (RDF) descriptors

Once we have a dataset of molecules represented by molecular descriptors, a data analysis has to be applied to obtain a model for the prediction of the desired property (see Fig. 9). Thus, in essence, a two-step process is applied: first, the calculation of descriptors for all molecules in a dataset. And then, a mathematical data analysis method such as a statistical or pattern recognition method is used to build a model for property prediction. Note that we talk here about two different types of mathematical methods: one method to make sure that molecules with different number of atoms obtain the same number of descriptors and a second type of mathematical methods for data analysis or building a model. The latter is the substantial domain of chemometrics.

Below we enumerate some of the methods popular in chemoinformatics:

- Statistics, e.g., mean, sum, regression, and correlation analysis
- Neural networks
- Pattern recognition

- Dimensionality reduction (feature selection, feature reduction)
- Principal component analysis (PCA)
- Partial least squares (PLS)
- Fourier analysis
- Wavelet transformations
- Machine learning
- Experimental design

Since currently the trend in computer science goes to open source or freeware projects, also many data analysis methods are available on the Internet. A reader can find a useful online guide for this as well as useful books and manuals, free software or packages, for example, at the www site (StatPages.org, statpages.org), or more specific information on chemical applications at Milano Chemometrics (a) (michem.disat.unimib.it).

Representations for Coding Molecules

Section “[Representations for Coding Molecules](#)” only gives a concise introduction into molecular descriptors. The reader can find a more detailed presentation in the next chapter “Molecular Descriptors” in this book or alternatively in the reference Todeschini and Consonni (2000).

There are many possible molecular descriptor taxonomies. Some of possible descriptor categories are listed here.

Depending upon structure representation type:

- Coding constitution and/or stereochemistry
- Atomic representations
- Fragment codes
- Topology 2D
- Geometry (topography)
- Molecular interaction fields
- Surface annotation (properties)
- Conformational profiles

Calculated for complex molecular aggregates:

- Virtual receptor site (simulated receptor data)
- Ligand-receptor systems (real receptor data)

Substance property correlates:

- Fragment-based substance property correlates, Hansch or Hammett constants

Descriptor data type and structure:

- 0D (single number), 1D (vector), 2D (map, pixel), and 3D (volume, voxel)
- Fingerprints
- Hashed fingerprints
- Structure keys
- Boolean
- Integer number
- Real number
- Tensor
- Scalar field
- Vector field

Several descriptors important for storing chemical structure information in computers were discussed in section “[Storing of Chemical Structure Information in the Computer](#).” Below we present some other methods developed for in silico chemistry, for the prediction of properties, with an emphasis on dimensionality mapping or distortion during these transformations.

Mapping Chemical Graphs into 0D (Global) Descriptors

The simplest transform of a chemical graph is a single real number. Mathematically, in this operation, we map chemical information into its simplest form of 0D dimensionality, while the calculated number (molecular descriptor) is called a global descriptor. Some representative examples are:

- Molecular weight (MW)
- Average molecular weight
- Atom counts
- Bonds counts
- Multiple bonds
- Double bonds
- Triple bonds
- Number of atoms
- Number of rings
- Sum of atomic volumes
- Total polar surface area
- logP
- Single number connectivity indices

LogP is a classical example where we need both connectivity information and the annotation of atoms with fragmental logP (hydrophobicity) descriptors for this calculation. Some global descriptors can be calculated even without connectivity information, e.g., MF (compare section “[Storing of Chemical Structure Information](#)”

in the Computer”) or MW which does not need connectivity information but only atomic weights. Alternatively, geometric bonding information and atomic charges are needed for dipole moment calculations, while the precise 3D atomic arrangement is needed for the calculation of the moment of inertia.

In the context of the property versus descriptor differentiation, we can ask a question if atomic annotations (MW, fragmental logP) are atomic descriptors and not measured atomic properties. Fragmental logPs are property correlates, however, that means clearly a molecular descriptor but not a property. Partial atomic charges are computer-simulated values and not a measured property. We can doubt about atomic weights which were measured in experiments. Actually, the calculation of the MW descriptor is entirely analogous to the logP calculation. The only difference is that MW is obtained by summing atomic contributions so accurate a simulation that the resulting descriptor will give a 100 % correlation with the property (MW) measured for the whole molecule in a potential real-world experiment with a single molecule (MS spectroscopy) or a substance (e.g., cryometry).

Mapping 2D Molecular Graphs into 1D and 2D Descriptors

1D line notations and 2D matrix representations that are used for storing chemical structure information are also popular for *in silico* structural manipulation. In general, transforms to lower dimensions mean also a distortion of information, so we cannot fully recover the information of the original. The exclusion here are descriptors designed for addressing and storing information (paragraph 6) in which a full reversibility of information is a substantial need. In particular, mapping 2D molecular graphs into 1D or 2D can provide us with representations that do not distort information. Note especially the SIMLES (1D) descriptors which are both unambiguous and fully reversible (paragraph 6.2). The availability of these descriptor types decides that they are also used for other *in silico* application.

Technically, some important and popular 1D molecular descriptors can be classified as (Todeschini and Consonni 2000; Gasteiger and Engel 2003):

- Structure keys
 - Augmented atoms
 - Atoms pairs
 - MDL keys
 - CACTUS screen vectors
- Hash codes
 - Topology based
 - Stereochemistry based
 - Atomic charges based
- Molecular fingerprints
 - Daylight fingerprints
 - Unity fingerprints

- Holograms
- MOLPRINT-2D fingerprints
- Extended connectivity fingerprints
- Functional connectivity fingerprints

Structure keys define structure motifs or fragments in the form of a Boolean vector, i.e., whether present (1), otherwise (0). Fingerprints are Boolean vectors that define a set of patterns. A pattern can, for example, be a path of predefined length, where each path is given by the atom and bond annotations along the path. Hashed fingerprints provide fingerprint-type information of all possible paths that traverse a molecule with up to certain number of bonds. Hash structure codes are vectors developed for storing information, where hashing means to cut or chop the input into smaller information pieces of accepted number within a file length (Todeschini and Consonni 2000; Gasteiger and Engel 2003).

Representation of 3D Structures and Their Mapping into Lower Dimensionality

The representation of 3D structures was discussed in paragraph 6. 3D structure data can be both a molecular descriptor (if predicted) and a real property if measured.

The expansion of 2D molecular graphs (with stereochemical information where needed) to structures with 3D atomic coordinates can be obtained by:

- 3D structure generators, e.g., CORINA (data- and rule-driven methods)

Additionally,

- Ab initio quantum chemistry
- Semiempirical quantum chemistry
- Molecular mechanics

are available further to refine the 3D structure (e.g., as given by a Z-matrix).

Basically, two different methods can be used for coding a 3D molecular representation in complex molecular descriptors. Both are based on a Cartesian coordinate system defining atomic positions. In the first, we are supplementing this by a connection table listing the bonding between atoms. The second codes are based on internal coordinates, i.e., bond lengths, bond angles, and torsion angles. An example of such a notation is the so-called Z-matrix. Although a Z-matrix seems to be a less human-friendly option for *in silico* modeling, it offers the advantage of providing an explicit list of internal molecular data which can be directly used for *in silico* simulations.

Fig. 10 Radial distribution function (RDF). A 2D molecular descriptor for coding 3D molecular structures with atomic numbers as atom property, where f is a scaling factor, N is the number of atoms, r is the distance between atoms i and j , and B is a smoothing parameter (Hemmer et al. 1999)

Other approaches are molecular transforms of the 3D information into lower dimensionality data. Below we give some illustrative examples:

- **3D to 2D**

- 3D to 2D mapping is a 2D self-organized map of partial atomic charges. This appeared as an efficient model for the comparison of a series of bioactive molecules and a simple simulator of a biological receptor, i.e., the *receptor-like neural network* (Polanski 1997).
- 2D maps of atomic poses (3D structural data) are used in SOM-4D-QSAR mapping (Polanski and Bak 2003).

- **3D to 1D**

- Radial distribution function (RDF) is an interesting method here (Hemmer et al. 1999). This was illustrated in Fig. 10.
- Molecular Shape Spectrum in 4D QSAR (Hopfinger et al. 1997).

- **3D to 0D**

A simple transformation of the 3D structural data into the *principal moments of inertia* about any axis (most often along the X, Y, or Z coordinates) is defined as

$$I = \sum_{i=1}^A m_i \cdot r_i^2$$

where A is the atomic number, m_i is the atomic mass, and r_i is the perpendicular distance from the chosen axis.

An interesting example of a useful molecular descriptor obtained by a 3D to 0D mapping of the structural data is the *RMSD* molecular descriptor (root-mean-square deviation of atomic positions):

$$RMSD = \frac{1}{n} \sqrt{\sum_{i=1}^n (v_{ix} - w_{ix})^2 + (v_{iy} - w_{iy})^2 + (v_{iz} - w_{iz})^2}$$

$v = [v_x, v_y, v_z]$ and $w = [w_x, w_y, w_z]$ structural data for two molecular representations, n = number of atoms.

This is used for the comparison of two differently modeled 3D structures or for the comparison of the modeled structure with the real 3D structure.

Representation of Molecular Surfaces

Clearly, a molecular surface is a molecular descriptor and not a property. As this picture is very illustrative and satisfies our imagination of the molecular world, we use it to explain and understand molecular effects. Actually, this is not necessarily a true copy of a molecular body. For example, the repulsive effect of the atoms shaped into hard sphere-like entities used to explain the energy barrier between the conformers, explaining the energy preference for the staggered conformer over the eclipsed one. The sphere-like ethane can be found in any chemical textbook. However, it has been found just recently that steric repulsion is only of secondary importance for the determination of the ethane folding principles. In fact, quantum mechanics shapes the molecule into a form in which steric repulsion favors the eclipsed conformer. Instead, hyperconjugation explains the rotation of the single C-C bond into the staggered form (Weinhold 2001).

A number of digital descriptors are available for the quantification of shape effects related to the surface (Mezey 1993; Polanski 2003). Shape descriptors are:

- Molecular shape indices
- Minimal steric difference (MSD)

that can be estimated from molecular graphs, i.e., from 2D representations after their expansion into 3D structures.

Alternatively, real 3D structures can be used for the description of molecular shapes by performing direct calculations or by performing complex *in silico* simulations. Some illustrative examples are:

- Van der Waals or Connolly surfaces
- Solvent accessible surface area

- Molecular shape analysis, MSA
- Molecular volumes, STERIMOL
- Quantitative shape-activity relationship, QShAR
- Comparative molecular surface analysis, CoMSA

A molecular surface substantially reframes the digital discontinuous form of the structure view to a continuous landscape-like picture. Thus, digitalization is not always the main point in the description of shape representations illustrated by surfaces. Instead, visualization provides the data for molecular shape analyses. Illustrative examples of such analyses can be found in reference Zupan and Gasteiger (1999) or under the entry topological feature maps in reference Todeschini and Consonni (2000).

Handling of Conformational Flexibility

Molecules are dynamic objects capable of rotation along single bonds or stimulated with higher energies even along multiple bonds. The set of rotamers provides us with the so-called conformational profile space of a molecule. Rotamers is a term coined in organic chemistry which is directly connected to conformational analysis both based on an intuitive analysis or on qualitative measures called *steric effects* or quantitatively probed by precisely calculated energies values. The conformational space of rotamers usually focuses our attention on several poses. These rotamers should easily be imagined and visualized without computer-aided methods with typical values of bonding angles and/or the lowest or highest energy states. A *pose* is a less strictly defined molecular conformation populating a conformational profile space. Typically, the term pose refers to computer-generated conformations, and the number of poses can reach very high numbers. Conformational information is a molecular descriptor much like stereochemical information. However, we can measure the property of a substance composed of certain conformations if they are stable enough.

Represented by poses, a conformational profile space that is typical for each molecule can be transformed into a 3D map in a procedure that resembles the 2D mapping of molecular surfaces. Thus, if we replace a pixel (2D) of the map with a volume unit called voxel (3D), we can easily explain the analogy. Voxels can be annotated with molecular descriptors which refer to a single molecule or describe the difference between a given molecule and a reference molecule. The simplest voxel-counting type is the atom count, i.e., the number of atoms found in a unit cube. Alternatively, partial atomic charges can be summed or averaged in voxels. This method is used for the calculation of the grid cell occupancy descriptors, GCOD, 4D-QSAR (Hopfinger et al. 1997), or their fuzzy neural network equivalents, SOM-4D-QSAR (Polanski and Bak 2003), while in both methods, the pose set has been generated by molecular dynamics simulations.

Representation of Chemical Reactions

As said in the Introduction, chemistry is the science of chemical compounds and their transformations. In this sense, the computer representation of chemical reactions presented in the very beginning an essential challenge for chemoinformatics. It was soon realized that an efficient representation of chemical reactions has to go beyond the storing of starting materials and products of a reaction. To answer important questions about a chemical reaction, it is necessary to store information on the essential changes in a chemical reaction, the breaking and making of bonds in the course of a reaction. These changes are represented by the so-called reaction center, the atoms and bonds directly participating in the transformation of the starting materials into the products.

We will here not go deeper into those tasks and how they were solved. Suffice to say that indeed these tasks were solved and, thus, the basis for reaction databases and for systems on computer-assisted synthesis design has been laid in section “[Applications of Molecular Descriptors for Property Prediction](#).” More details can be found in Gasteiger (2003).

Trends in Structure Representation

It is more and more realized that chemoinformatics can help in increasing our chemical knowledge. In this endeavor, the trend in property prediction shifts from models that are good in predictive capability to models that can also be interpreted.

To this effect, molecular descriptors have to be used in the model building process that is prone to interpretation. Two types of descriptors can be used for this purpose, fragmental descriptors and descriptors that are based on physicochemistry. A variety of fragment-based descriptors are available. Recently, fragments that had been developed for toxicity alerts were extended and made publicly available (Yang et al. 2015; Chemotyper, chemotyper.org). These chemotypes can also be used for analyzing properties other than toxicity. Furthermore, the atoms and bonds of these substructures can be enriched by physicochemical effects such as partial atomic charges.

A range of physicochemistry-based descriptors are available; quite a few have been listed in section “[Representations for Coding Molecules](#).” A typical example is the logP descriptor that models the influence of lipophilicity on a property. In a more global approach, a hierarchy of structure descriptors has been developed that combines geometry with physicochemistry (Gasteiger 2006). In this approach, geometry goes from 2D through 3D to molecular surfaces. And physicochemistry encompasses a variety of effects such as partial atomic charges, electronegativity, or polarizability effects. Mathematical methods are used for combining geometry with physicochemistry including the use of mathematical transforms to obtain the same number of independent variables irrespective of the size of the molecules in the dataset.

The endeavor of obtaining models that can be interpreted also must have consequences on the choice of a data analysis method. Rather than using highly sophisticated modeling techniques that squeeze the ultimate out of a dataset – and thus quite often hide the influence of the molecular descriptors used – methods have to be employed that clearly show the effect of each descriptor used. For example, a simple multi-linear regression analysis might not produce the highest prediction power of a model, but it clearly shows the influence of each descriptor on the property under consideration.

This trend in property prediction is also reflected in publishing policies. More and more will manuscripts on QSAR studies only be accepted for publication if they also provide new data or if they lead to more insight into the effects influencing the modeled property.

From a practical point of view, a variety of descriptors can be calculated today in an online mode or by freeware packages both for individual molecules and in batch mode for a series of molecules. Just to cite as an example of mi-logP values calculated online, visit directly the web page of Molinspiration, molinspiration.com. The method is robust enough to *process* practically all organic and most organometallic molecules. The user can input a SMILES or draw a 2D molecular graph. Other molecular descriptors called here *molecular physicochemical properties* that are available from the site are:

- 3D molecular structure data
- Molecular polar surface area TPSA
- Molecular volume
- “Rule of 5” parameters
- Number of rotatable bonds

An interesting new option are databases with calculated descriptors, e.g., we can find a database of 1124 descriptors calculated for 234,773 molecules (Milano Chemometrics (a), michem.disat.unimib.it).

Applications of Molecular Descriptors for Property Prediction

Formally, property-to-property relationships are limited to FCS compounds with measured properties. The solubility or chromatographic behavior versus lipophilicity (quantitative structure-retention relationships) is an illustrative example here. As, however, properties are rare, we are often replacing a real property-property systems with property versus property mapping which are then extended to the extrapolated values (compare $\log P$ calculation discussed in section “[Prediction of Properties](#)”).

However, the most popular method here is a structure-property strategy based on using molecular descriptors as independent variables. For example, a discussion of molecular descriptors available for the prediction of oral bioavailability and their performances can be found in reference Ahmed et al. (2012). Drug design is an

example of the structure-property method aimed at predicting the biological activity of chemical compounds.

Drug Design

Drug design is a central challenge to chemistry and pharmacy. Accordingly, chemoinformatics has found many applications to this problem. The majority of drugs are molecules capable of interaction with macromolecular targets controlling processes in living organisms. This paradigm defines two basic strategies for searches for new drugs. First are structure (receptor dependent)-based methods, and second are ligand-based (receptor independent) ones.

Molecular design is often used as a synonym for *drug design*. This interchange illustrates the complex nature of the problem showing a hesitation if we are to focus on a molecule or a substance (drug). The so-called lead structure, namely, an active compound, is an essential need for starting any development project for a new drug. A lead structure can be found as a consequence of:

- Serendipitous discovery
- Natural substance screening
- Screening chemical compounds resulting from synthetic chemistry
- Computer-aided structure-based design
- Ligand-based screening of chemical libraries (both of real or virtual compounds)
- Combinatorial chemistry
- Receptor-based dynamic combinatorial chemistry (property-oriented combinatorial chemistry)
- Receptor-based chemical methods, e.g., NMR methods

A general disagreement between the lead structure-activity versus its complexity (Zartler and Shapiro 2005) is a substantial dichotomy in drug design which was realized just recently (Fig. 11). Since the development of chemical, physical, and biological technologies allowed the identification of compounds with increasingly lower activities, the population of potential lead structures significantly increased. However, the activity level drastically decreases for low molecular compounds. Just recently, this paradigm has founded fragonomics, i.e., the strategy of the identification of active small fragments (low MW molecules) and the rules for connecting them into compounds of higher complexity and activity. The potential of this method is broadly investigated now. For example, we realized that the activity and complexity of real drugs are lower, *slim pharma* than these under R&D development, *molecular obesity* (Hann 2011). What should be the advantageous range of logP values, the preferred ADMET range, etc., for fragments, are examples of problems under current diagnosis.

Once a lead structure is found, it needs to be optimized and/or modified for the requirements of an individual receptor or target system. Due to the needs for substantial simplification, we are usually using here the model of a single

Fig. 11 The complexity versus binding affinity dichotomy. Low MW ligands are more probable to be identified due to statistics, but their affinities are lower than for chemical compounds with larger complexity and higher MW (Adapted from Zartler and Shapiro 2005)

Fig. 12 The increase in complexity from conventional drug design to the synergy by replacing the single-drug to single-target interactions with the multidrug D1, D2 (mD) to multi-target T1, T2 (mT) system (Adapted from Musiol et al. 2014)

drug-single target. The challenge of information complexity increases when replacing a single by a multidrug target system as explained in Fig. 12.

The requirement for optimization is, however, not a single but a series of structures. Accordingly, the question arises: how should we modify a lead structure? There are a number of concepts and rules starting from the technical ones, e.g., Topliss schemes, through chemical ones:

- Changing of substitution type and pattern
- Homologation

- Ring and/or chain transformations (enlargements, shortening, branching, transformation, increasing system rigidity, or vice versa increasing system flexibility)
- (Bio)isosterism
- Peptidomimetics

to the chemoinformatics-based chemical information metrics targeted at measuring the design domain in CS covered by chemical compounds under the R&D project. Accordingly, we can use for this the measures of compounds':

- Similarity
or
- Diversity

QSAR is an example of the optimistic strategy aimed at drug design in which we are attempting to quantitatively predict the activity of the new substance, a potential drug. In its simplest form, this strategy can be noted as follows:

$$A = F(S)$$

where A is the activity and S is the molecular descriptors.

A Free Wilson analysis (synonyms are *additivity model* and *de novo approach*) is a property modeling method based on a truly structure-property scenario. In this method, we are searching for a regression model where the independent variable block is the so-called group contribution of two substituent series mounted at two positions of the reference compound. The resulting regression coefficients of the indicator variables are the biological activity contributions of the corresponding structural elements. The efficiency of this approach shows that, in fact, the mapping to the partition coefficient is not necessarily a requirement. An interesting comparison of the methods can be found in reference Kubiny (1993). Recently, it has been shown that structure information in structure-property scenario can be coded directly by SMILES codes (Worachartcheewan et al. 2014).

The last decades brought the idea of applying in QSAR studies rather complex molecular descriptors based on molecular interaction fields, conformational compound profiles, or even describing ligand-receptor systems (receptor-dependent) both with simulated and real receptor data. In Table 4 we present a QSAR classification according to the dimensionality that can be found in the literature (Polanski 2009b). This classification is not fully consistent because $m = 0$ and $m = 1$ refer to the data structure of molecular descriptor, i.e., one element (univariate data) vector in 0D and a vector (multivariate)-type molecular descriptor where each element can describe another global property in 1D; while in 2D to 6D, the dimensionality indicates the type of molecular representation tested. Vector type data (dimension = 0 or 1) is always needed in 0÷6D QSAR modeling. For example, a SMILES line notation is a 1D representation, but it was designed to code 2D matrix molecular graphs. The term receptor-independent or receptor-dependent notation is sometimes used to indicate if we include real receptor data, e.g., 3D structure,

Table 4 Classification of the receptor-independent QSAR, 0÷6D (Polanski 2009)

QSAR dimension m^a	Molecular representation used for molecular descriptor calculation	Information dimension	Example of S variable
0D	Single number (univariate X data) parameter referring to global descriptors	0D	logP
1D	A multivariate combination of global descriptors or 1D descriptors	1D	logP and Hammett constants, Free Wilson analysis, SMILES-based QSAR
2D	Structural patterns relating to 2D molecular representations	2D	Connectivity, 2D pharmacophores, SMILES-based QSAR
3D	Single-state 3D ligand representations	3D	Molecular interaction field (MIF) descriptor in CoMFA
4D	Multiple 3D ligand representations (conformations, orientations, protonation)	3D	Grid cell occupancy descriptor (GCOD; 4D QSAR)
5D	3D QSAR + induced fit scenarios	3D	Quasar (quasi-atomistic receptor surrogate) in 5D QSAR
6D	5D QSAR + multiple solvation scenarios	3D	Quasar in 6D QSAR

into the analysis. Below we present a possible coherent version of this approach organized according to the information complexity where:

Dimension indicates dimensionality of the molecular descriptor

- 0D Single number, global 0D property or descriptor
- 1D 1D molecular descriptor

Dimension indicates molecular representation used for molecular descriptor calculation

- 2D 2D information
- 3D Single static 3D ligand states
- 4D Multiple ligand states
- 5D Virtual or pseudoreceptor constructed from the active ligand series
- 6D 5D + multiple solvation
- 7D Real receptor data

Such an m-QSAR classification resembles somehow to the way chemists refer to the protein structures. The amino acid sequence defines the primary structure, the local organization defines the secondary structure, the overall protein shape describes the tertiary structure, and the effects resulting from the interactions with

another protein molecule are explained in the quaternary protein structure. Thus, dimension refers here more to data complexity than to real topology (topography).

There are a variety of properties that are of substantial importance in chemistry and drug design. Examples are absorption, distribution, metabolism, excretion, and toxicity (ADMET) in pharmacokinetics. Aqueous solubility can be a useful property that can be used in property-property models (Gasteiger and Engel 2003), and Caco 2 cell line membrane transport behavior has been recently applied to the prediction of substance-cell absorption (property-property approach) in pharma industry contributing to our understanding of drug efflux transporters such as P-glycoprotein (ABCB1) and BCRP (ABCG2). This proved to be an unexpectedly successful approach. Accordingly, Caco 2 behavior was simulated *in silico* in the so-called membrane interaction QSAR with 4D fingerprint descriptors to provide this property prediction (Iyer et al. 2007).

Toxicity is another of the abovementioned substance properties of key importance not only in drug design but also generally in chemistry and everyday life which can be illustrated by the Registration, Evaluation, Authorisation and Restriction of Chemicals (REACH) regulations (REACH, ec.europa.eu). The complex software based on multidimensional Quasar descriptors, including receptor dependent models, is available from Vedani group as a freeware OpenVirtualToxLab™ license for toxicity predictions (VirtualToxLab, biograf.ch).

Structure Elucidation

Currently a variety of physical methods are available for structure determination and elucidation:

- Electron diffraction
- X-ray diffraction
- ¹H and ¹³C NMR
- Mass spectrometry
- Infrared spectroscopy

For each compound synthesized in the laboratory or isolated from natural products, routinely IR, NMR, and mass spectra are taken. Interpretation of the data generated during these experiments and finding structure-spectra correlations are central problem in organic chemistry. Computer-assisted structure elucidation (CASE) is a generic name for the computer techniques used for this purpose. Generally, the strategy under CASE is a property (spectra) to structure (2D or 3D molecular descriptor data) mapping. The CASE problem was addressed by chemoinformatics already in the 1960s. However, due to the complexity of the problem, no general-purpose system is yet available.

The general problem of structure elucidation will not be discussed here any further, and the reader should consult the available literature. An interesting example

of CASE is a counter-propagation neural network that we input with the IR spectra coded by Fourier or Hadamard coefficients (2D data) and radial distribution function (RDF) for code structure representations (3D data). Due to the full reversibility of the RDF code, the IR spectrum in this method could be directly mapped into the 3D molecular structure (Hemmer et al. 1999).

Organic Synthesis Design

Several groups in the USA, Germany, England, and Japan started with the development of systems for computer-assisted synthesis design (CASD) already in the late 1960s and early 1970s (Corey and Wipke 1969; Gelernter et al. 1973; Hendrickson 1971; Blair et al. 1974). At that time, many basic problems in chemoinformatics such as storing chemical structures, unique and unambiguous coding of molecules, ring and aromaticity perception, and representation of chemical reactions had to be solved. This work laid the foundation to the development of databases on chemical structures and reactions such as MACCS, REACCS, and the Beilstein Database which can all be traced back to efforts made in the CASD groups.

On the other hand, no CASD system has yet found general acceptance by organic chemists. The reasons are manifold, not the least that organic chemists want to personally take the challenge of designing their syntheses intellectually without assistance by a computer. However, what Herbert Gelernter has said in 1973 is still valid: “The amount of information to be processed and the decisions between many alternatives suggests the use of computers in organic synthesis design.” In this sense, we can expect that some time in the future, CASD systems of global usefulness will appear and be used.

Chemical Compounds Beyond Structure Representation

There are many compounds and substances where an exact molecular structure is not known or cannot be given. Examples are plastic materials, mixtures of compounds (see Fig. 1: chemical species), many inorganic materials, etc. Nevertheless, there is definitely interest to also store such species in databases or to predict their properties. In such cases, representations other than molecular descriptors have to be chosen. These representations can be representations of the compounds that they were made of and their respective ratio and experimental conditions of their preparation. Other important descriptors are physical or chemical data for the characterization of such substances. Of particular value for property prediction are spectral data because they give important indirect information on the composition and structure of those substances. Not much work has been done in this direction, but for sure many studies will come.

Conclusions

Cheminformatics has substantially changed the availability of information on chemical compounds in databases. The present level of chemical investigations would be inconceivable without access to databases on chemical compounds and chemical reactions. Efficient database mining and knowledge discovery methods changed the way in which we are designing chemical substances and their reactions. Today there is no problem for finding selective or specific reactions among a variety of possible options. There is also no problem for finding equivalent reagents for various possible synthons and available commercial chemicals for them.

Predicting properties is the second important area of cheminformatics applications. We still need to improve our efficiency here since the available FCS data on real properties are still rare for chemical compounds. From the data analysis point of view, we have developed a variety of methods efficient in this area.

Molecular descriptors and properties are two basic forms of chemical information representing compounds in the computer. Although it is not always easy to distinguish between these information types because we often need to predict properties, this helps in understanding structure-property approaches and the possible origins for their failures. A variety of molecular descriptors is available both for storing molecules and for their processing in computers, and we do not have here a sharp differentiation.

The trend in property prediction goes away from pure modeling and prediction endeavors to the development of models that can also be interpreted and thus help us in increasing chemical insight and knowledge. However, probably the most important aspect of cheminformatics is that it is allowing us for a better understanding of chemistry. In this context, we must first clearly define a chemical problem, avoiding any possible uncertainties to be able to teach this to the computer. Secondly, the availability of chemical information at our desks improves our learning ability in this area and increases our chemical knowledge.

Abstract

Quantum chemical and molecular mechanics-generated structure and reactivity parameters comprise a part of chemoinformatics, where such parameters are stored and properly indexed for search-information of a related molecule or a set of molecular systems. The present review makes a general survey of the various computable quantum chemical parameters for molecules. These could be used

for quantitative structure activity relation (QSAR) modeling. The applicability of various quantum chemical techniques for such property (QSAR parameters) is also discussed and density functional theory (DFT)-related techniques have been advocated to be quite useful for such purposes. Molecular mechanics methods, although mostly useful for less time consuming structure calculations and important in higher level molecular dynamics and Monte-Carlo simulations, are sometimes useful to generate structure-related descriptors for QSAR analysis. A brief discussion in this connection with molecular mechanics-related QSAR modeling is included to show the use of such descriptors.

Introduction

Chemoinformatics (also known as cheminformatics and chemical informatics) is the use of computer informational techniques applied to a range of problems in the field of chemistry. These *in silico* techniques are used mostly in drug discovery but can also be used in chemical and allied industries which include paper, pulp, dyes, and such other industries. The term chemoinformatics was first properly defined by K.F. Brown in 1998 (Brown 1998), and according to this definition *it is described as the mixing of information resources to transform data into information and information into knowledge for the intended purpose of making better and faster decisions in the area of drug lead identification and optimization*. This basic definition was later extended to the other allied chemical fields. It combines the scientific working fields of chemistry, computer science, and information science in the areas of topology, chemical graph theory, information retrieval, and data mining in the chemical space (Leach and Gillet 2007).

The main goal in chemoinformatics involves storage, indexing, and search of information of the related compounds. The related search topics include unstructured data mining (information retrieval and extraction), structured data mining (database, graph, molecule, sequence and tree mining), and digital libraries. The *in silico* representation of chemicals (involving structure and properties) are usually stored in large chemical databases. They also include visual representations in two and three dimensions for studying physical interactions, modeling, and docking. These chemical databases include virtual libraries (data for real and virtual molecules) and facilities for computationally screening *in silico* libraries of compounds (commonly known as virtual screening). The results are used for the well-known quantitative structure-activity relationship (QSAR) studies for the prediction of specific activity of compounds.

Since the inception of QSAR technique (Hansch 1969), electronic parameters from molecular structures were incorporated in the correlation through Hammett substituents constants (Hammett 1937; Hansch et al. 1991). It was possible since the molecules used were aromatic systems with substituents at meta- and para-positions. Hansch (1969) used the parameters generated through such analysis as measure of the electronic characteristics of molecules. An enormous number of QSAR equations have been reported in literature, many having functional form much more complicated than the original Hansch equation. Various parameters

have been used in QSAR equations in this respect, most of which were designed to represent the hydrophobic, electronic, and steric characteristics of molecules. Extensive tables have been published with values of these common parameters for a wide variety of substituents.

Modern state of the art quantum chemical techniques provide meaningful representation of structures and are source of related physical and electronic properties of molecules from their calculated wave functions. The usual electronic descriptors of molecules are atomic charges, dipole moment, electron affinity, ionization potential, and many other electronic properties related to orbital energies and molecular surfaces (e.g., molecular electrostatic potential (MEP)), and specific and thermodynamic parameters (related to the conformational properties and reactivities). These are of potential importance in QSAR analysis and are usually stored in chemoinformatics libraries as basic molecular information. Molecular mechanics (MM) calculations are also a useful tool for the structure calculations in a less time consuming way (with lower accuracy) but are not useful for generation of electronic parameters like quantum chemical methods. The main importance of various MM approaches actually lies in higher level molecular dynamics and Monte-Carlo simulations. Still in some specific cases, MM has sometimes been used to generate structure-related descriptors for QSAR methods.

A relation between the quantum chemically/MM derivable properties (usually stored in chemoinformatics libraries) and the related mathematical modeling are shown in Fig. 1. The mathematical models are usually of statistical origin and

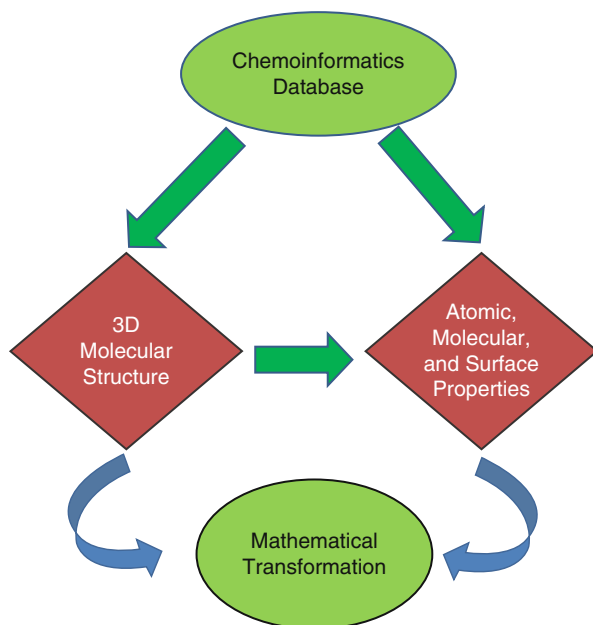

Fig. 1 The use of derived molecular properties (quantum chemical origin) for mathematical drug design is schematically shown in the flow chart. The properties are either from chemoinformatics data base or through direct calculations

correlate the observed biological activities with molecular descriptors to understand their specific properties. They are also useful to predict the properties of designed drug molecules within the statistical limitations of the derived models. In the present review, we will discuss the connection of such *in silico* databases in chemoinformatics used in drug discovery only. The present review would involve brief discussions on the usefulness of various quantum chemical parameters related to the biological properties of molecules (to be used in QSAR) and a brief résumé of the techniques in generating such quantum chemical parameters. In the last section of this review, a brief discussion has been made on the usefulness of MM-derived parameters for QSAR.

Quantum Chemical Parameters for Chemoinformatics

Atomic Charges

The quantum chemically computed atomic charges are one of the most fundamental parameters to be used in QSAR. This is because electrostatic interactions are central in controlling most of the chemical/biological reactions. The advantage of a quantum chemical technique is that it can compute the net charges on each atom in a molecule through gross population analysis. These parameters are also important to investigate surface charge characteristics of a molecule. There are various techniques to generate atomic charges through population analysis. The successful techniques amongst the oldest ones are Mulliken and Löwdin population analysis. In Mulliken's method (Mulliken 1955), the electron population (ρ_A) on an atom A of a molecule is defined in terms of one electron density matrix ($D_{\mu\nu}$) and overlap matrix ($S_{\mu\nu}$) as

$$\rho_A = \sum_{\mu \in A} \sum_v^{AO} D_{\mu\nu} S_{\mu\nu} \quad (1)$$

The diagonal term $D_{\mu\mu}S_{\mu\mu}$ represents the number of electrons in the μ^{th} atomic orbital (AO) and the off-diagonal $D_{\mu\nu}S_{\mu\nu}$ is (half) the number of electrons shared by the AOs $\mu\nu$ (there is an equivalent $D_{\nu\mu}S_{\nu\mu}$ element as the matrix is diagonal). The gross charge on atom A is defined as the sum of nuclear and electronic contributions.

$$Q_A = Z_A - \rho_A \quad (2)$$

The Löwdin technique (Löwdin 1970) uses $S^{1/2}D S^{1/2}$ matrix for population analysis. This is equivalent to a population analysis of the density matrix in the orthogonalized basis set by transforming the original set of functions by $S^{-1/2}$. The electron population associated with an atom is obtained through the equation:

$$Q_A = Z_A - \sum_{\substack{\mu=1 \\ \mu \text{ on } A}}^{AO} \left(S^{1/2} D S^{1/2} \right)_{\mu\mu} \quad (3)$$

The Mulliken and Löwdin population give different atomic charges, but mathematically there is nothing to indicate which partition gives better result. More realistic charge analysis, from a chemist's point of view, is obtained from the natural bond orbital (NBO) analysis by Weinhold and coworkers (Weinhold and Landis 2012). The method uses one-electron density matrix for defining the shape of atomic orbitals in molecular environment and molecular bonds from electron density between atoms. The density matrix D is defined in terms of blocks of basis functions belonging to a particular center. The natural atomic orbitals (NAO) in the molecular orbital are defined as those which diagonalize the original blocks in the D matrix. These NAOs are, in general, not orthogonal and are orthogonalized to achieve well-defined division in electrons. The natural atomic charges are computed as the difference of nuclear charge and the total natural population of NAOs (on the atoms). There are several other atomic charge calculation techniques, viz., electrostatic potential derived charges (Bayly et al. 1993) and populations derived from atoms in molecule (AIM) theory (Popelier 2000). They could be used in QSAR with varying successes, but the most recommended charges are the natural atomic charges through NBO analysis.

The atomic charges are usually used as the static chemical reactivity indices (Franke 1984). Since electrostatic interactions play important role in a chemical reaction, the orientations of the interacting moieties could be decided from the σ and π -electron densities and in such cases they could be used as directional reactivity indices. These orientation natures of the interacting moieties could, of course, be better interpreted from the molecular electrostatic potential (MEP) of the molecules. The atomic charges have been used to explain various other properties also. For example octanol-water partition coefficients of organic compounds (Karelson et al. 1996; Ghose et al. 1988), prediction of anti-HIV-1 activities of HEPT-analog compounds (Alves et al. 2000), hydrogen-bond donor strengths (Schwöbel et al. 2009), and atomic charge selectivity for optimal ligand-charge distribution at protein binding sites (Bhat et al. 2006) are a few to be mentioned. Atomic charges are also used as descriptors of molecular polarity but again charge derived properties like electrostatic moments would be a better choice.

Other Charge-Related Properties

These properties include frontier orbital densities, superdelocalizability, dipole moment, polarizability, and hyperpolarizability. The highest occupied molecular orbital (HOMO) and the lowest unoccupied molecular orbital (LUMO) are usually termed as frontier orbitals (Fukui 1971). These orbitals are the key factors in explaining many organic reactions. Specifically, pericyclic reactions (Woodward

and Hoffmann 1969) were explained from symmetries of the HOMO–LUMO orbitals. The frontier orbital densities were designed later as QSAR descriptor for electrophilic (f_r^E) and nucleophilic (f_r^N) centers in terms of HOMO ($C_{HOMO,n}$) and LUMO ($C_{LUMO,n}$) coefficients of the atomic orbital of the n th atom X and were defined as $\sum(C_{HOMO,n})^2$ and $\sum(C_{LUMO,n})^2$, respectively. The superdelocalizabilities and atom–atom polarizabilities are originated through Hückel theories and are not of much use in recent times in regular quantum chemistries, although they are sometimes used as reactivity descriptors in QSAR analysis (Karelson et al. 1996).

Dipole moment (μ) of a molecule could be used as a polarity descriptor in chromatographic observations of molecular polarity accounts for chromatographic retention on a polar stationary phase (Grunenberg and Herges 1995). Dipole moment of a molecule has several other importance, viz., it is an important parameter to account for the solvation properties of molecules (Milischuk and Matyushov 2002; Jensen 1999). In the case of directional orientation of molecules during interactions, the dipole–dipole interactions become quite important in total electrostatic interactions, if the components have non-zero dipole moments. The higher moments of the molecular systems also play important role in shaping the orientation as well as the nature of interactions in specific cases. The importance of higher moments is seen in cation- π interactions (Ma and Dougherty 1997). It is a very widely studied biological phenomena and the nature of interactions are believed to be controlled through electrostatics. Interactions through charge-dipole (C-D) and charge-quadrupole (C-Q) were believed to be the controlling features in such interactions. Recent studies on model cation- π interactions have shown (Kim et al. 1994; Kadlubanski et al. 2013) that octopole moments also have an important role in such interactions.

The model interactions were investigated for Mg^{2+} , Ca^{2+} , and NH_4^+ ions (acceptors) interacting with benzene, *p*-methylphenol, and 3-methylindole (donors) (Kadlubanski et al. 2013). The calculated strong electron sharing in the complexes showed that they might have considerable influence in shaping the contribution of total electrostatic interactions between the donors and acceptors. Figures 2 and 3 represent the natures of three of such multipolar components of the electrostatic interaction energies in Mg^{2+} , Ca^{2+} , and NH_4^+ complexes as a function of various interaction distances. The total electrostatic interaction energies (T-EI) together with charge-charge (C-C), dipole-charge (D-C), quadrupole-charge (Q-C), and octopole-charge (O-C) components were found to be important and presented in the figures. The influences of the other multipolar components were found to be negligible. The results show that the total interaction energy curves, with few exceptions, are either repulsive or dispersive in nature. The T-EI curves of Mg^{2+} complexes are bound (i.e. having a minimum) while the similar curves for the Ca^{2+} -complexes are dispersive for benzene and 3-methylindole (Fig. 2a, c). In this respect, the interactions of *p*-methylphenol... Ca^{2+} show a weak minimum (Fig. 2c). The nature of the curves representing the Q-C and O-C components of both the complexes as represented in Fig. 2b, d show that they have either repulsive or attractive contributions to the total electrostatic interactions in a significant way around the equilibrium distances and thus revealing the importance of such interactions in strong cation- π complexes.

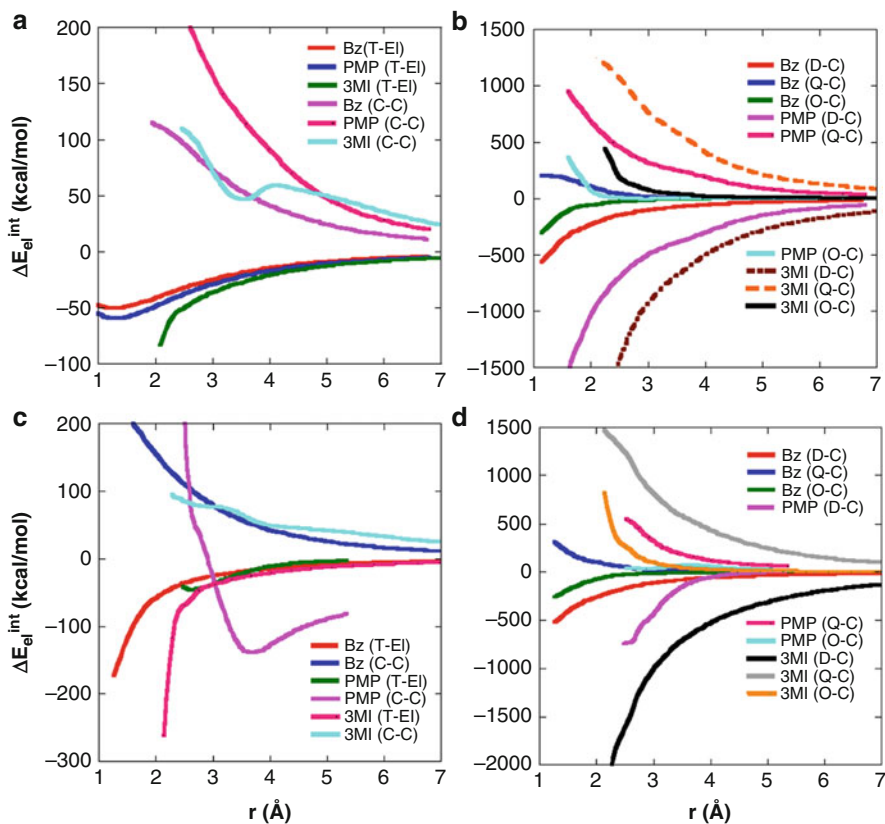

Fig. 2 Plots of total electrostatic interaction energies (*T-EI*) and their multipolar components as a function of *r* (interaction distance) for the complexes of Mg^{2+} and Ca^{2+} ions with benzene (*Bz*), *p*-methylphenol (*PMP*), and 3-methylindole (*3MI*). Panels (a) and (b) represent the curves for the Mg^{2+} complexes, while panels (c) and (d) are for the Ca^{2+} ion complexes. In the figures, C-C, D-C, Q-C, and O-C represent the multipolar electrostatic interaction energy components (C-C charge-charge, D-C dipole-charge, Q-C quadrupole-charge, O-C octopole-charge) (Reproduced from Kadlubanski et al. 2013, with the kind permission of the American Chemical Society 2013)

The D-C and (C-C) components of these metal complexes also behave similarly (Fig. 2a–d) to mostly offset the attractive components to generate overall shape of the T-EI curves.

The curves representing the electrostatic components of the cation- π complexes of NH_4^+ ion show an altogether different nature (Fig. 3). The D-C components are bound around the equilibrium interaction distances (*r*) (Kadlubanski et al. 2013). The rest of the components around the equilibrium *r* behave in such a way that the T-EI curves are dispersive, although such components sometimes show bound character at larger *r* (not of much significance here). The differences of the nature of the curves of NH_4^+ . . . aromatic complexes (Fig. 3) with respect to those of

Fig. 3 Plots of total electrostatic interaction energies (*T-EI*) and their multipolar components as a function of interaction distances for the complexes of NH_4^+ ion with benzene (*Bz*) (panel **a**), *p*-methylphenol (*PMP*) (panel **b**), and 3-methylindole (*3MI*) (panel **c**). See Fig. 2 for the definition of the curves representing the cases of C-C, D-C, Q-C and O-C (Reproduced from Kadlubanski et al. 2013, with the kind permission of the American Chemical Society 2013)

the metal ion complexes could be due to the anisotropic potential expansion of the NH_4^+ ion. Similar studies were carried out using the dihydrated species of the metal cations (Kadlubanski et al. 2013). Although dihydrated metal ions are expected to have some anisotropic character in this respect, the curves showed they are not strong enough to make too much difference with respect to non-hydrated cases (where the metal ions are strictly isotropic). Thus it is evident from these curves that the multipolar components of electrostatic interactions play a major role in the formation as well as controlling the nature of interactions in the cation- π complexes. The rationale of this discussion is that although dipole moment is

common descriptor in QSAR studies, the higher moments should also be treated as effective descriptors in many important biological phenomena.

The quadrupole moment gives a rough approximation of the molecular volume, but this volume parameter can be observed through the effect of electric field on dipole moment (induced dipole moment) of a molecule. Generally the induced dipole moment μ could be written as:

$$\mu = \mu^0 + \alpha_{ij} V_j + \frac{1}{2} \beta_{ijk} V_j V_k + \frac{1}{6} \gamma_{ijkl} V_j V_k V_l \dots \quad (4)$$

The terms μ^0 and α denote dipole moment and polarizability, β and γ are the higher order polarizabilities. The $V_j, V_k \dots$ are the components of the applied field V . The term β and γ are not known to make contributions in QSAR studies, but the term α is an important descriptor. There are two such descriptors, isotropic and anisotropic α and they could be written as (Martin et al. 1979):

$$\alpha_{\text{isotropic}} = \frac{1}{3} (\alpha_{xx} + \alpha_{yy} + \alpha_{zz}) \quad (5)$$

and

$$\alpha_{\text{anisotropic}} = \frac{1}{\sqrt{2}} \left[(\alpha_{xx} - \alpha_{yy})^2 + (\alpha_{xx} - \alpha_{zz})^2 + (\alpha_{yy} - \alpha_{zz})^2 + 6(\alpha_{xy}^2 + \alpha_{xz}^2 + \alpha_{yz}^2) \right]^{1/2} \quad (6)$$

The $\alpha_{\text{isotropic}}$ is in a sense related to the molar volume (as it is expressed in terms of \AA^3) and has been found to be related to hydrophobicity and thus to other related biological properties (Hansch and Coats 1970). Furthermore, the electronic polarizability of molecules shares common features with the electrophilic superdelocalizability (Lewis 1987). This parameter also contains information regarding the inductive effects in a molecule (Gaudio et al. 1994). The anisotropic term is also expressed in volume units (\AA^3) and characterizes the properties of a molecule as an electron acceptor (Cartier and Rivail 1987).

Total and Orbital Energies and Related Properties

The total energy (E) of a molecule is generally used to account for several important molecular properties which include ionization potential (IP), electron affinity (EA), protonation energy, etc. The thermochemistry of a system is also important and the related parameters are computed in quantum chemical calculations as part of vibrational frequency calculations, as the partition functions needed for Gibbs free energy (G), enthalpy (H), and entropy (S) calculations are related to the molecular vibrations. The changes of these thermodynamic parameters, viz., ΔG , ΔH , ΔS , are important in accounting for experimental interaction energies between two

molecular systems, for heat of reactions, and to calculate reaction rates. The last parameter is not probably that important in QSAR, but the two others are quite important. The IP and EA of a molecule are computed as the difference of energy between the neutral and the corresponding cationic and anionic species, respectively. The HOMO (E_{HOMO}) and LUMO (E_{LUMO}) energies also account for the IP and EA of a molecule (Koopman's theorem), but the accuracies of such results are very low and are not used any more.

The important applications of E_{HOMO} and E_{LUMO} are to account for reactivity of molecules has already been discussed in connection with frontier electron densities. But the conception of hardness and softness are considered as more reliable descriptors for reactivities and they are also derived through E_{HOMO} and E_{LUMO} . Parr and Pearson provided the analytical definitions of hardness (η) and softness (S) as (Parr and Pearson 1983):

$$\eta = \frac{1}{2} \left(\frac{\partial^2 E}{\partial N^2} \right)_{v(\bar{r})} = \frac{1}{2} \left(\frac{\partial \mu}{\partial N} \right)_{v(\mathbf{r})} \quad (7)$$

$$S = \frac{1}{2} = \left(\frac{\partial N}{\partial \mu} \right)_{v(\mathbf{r})} \quad (8)$$

where E is the total energy, N is the number of electrons of the chemical species, and μ represents the chemical potential, which is identified as negative of the electronegativity (Parr and Pearson 1983), and $v(\mathbf{r})$ is the external electrostatic potential of an electron at \mathbf{r} due to the nuclei. The operational form of η and S could be written in terms of IP and EA as (Parr and Pearson 1983; Roy et al. 1998):

$$\eta = \frac{IP - EA}{2}; S = \frac{1}{IP - EA} \quad (9)$$

These definitions of hardness and softness lead to the hard and soft acid–base theory, which is quite useful to explain chemical reactions. According to this principle, all factors being equal, hard bases prefer to react with hard acids and soft bases prefers to react with soft acids, and atomic and molecular systems were classified as hard and soft systems based on equation (9). The concept was further extended to explain site-specific nucleophilic, electrophilic, and radical reactions through development of the concepts of local softness and hardness ($\eta_D(\mathbf{r})$ and Fukui functions ($f(\mathbf{r})$). The local softness ($s(\mathbf{r})$) is defined as (Roy et al. 1998):

$$s(\mathbf{r}) = f(\mathbf{r})S = \left(\frac{\partial \mu}{\partial v(\mathbf{r})} \right)_N S \quad (10)$$

Three types of $f(\mathbf{r})$ can be defined, which when multiplied by S generates three types of local softness, viz., s_k^+ , s_k^- , and s_k^0 for the nucleophilic, electrophilic, and radical attack, respectively, on the atom center k of a molecule.

$$\left. \begin{aligned} s_k^+ &= [\rho_k(N_0 + 1) - \rho_k(N_0)] S \\ s_k^- &= [\rho_k(N_0) - \rho_k(N_0 - 1)] S \\ s_k^0 &= \frac{1}{2} [\rho_k(N_0 + 1) - \rho_k(N_0 - 1)] S \end{aligned} \right\} \quad (11)$$

$\rho_k(N_0)$ represents electronic population on atom k for N_0 electron system. The local hardness ($\tilde{\eta}(\mathbf{r})$) is defined using electron density $\rho(\mathbf{r})$ as:

$$\tilde{\eta}(\mathbf{r}) = \left[\frac{\partial \mu}{\partial \rho(\mathbf{r})} \right]_{v(\mathbf{r})} \quad (12)$$

The local hardness is usually derived in working form ($\eta_D(\mathbf{r})$) from this formula using Thomas-Fermi-Dirac (TFD) approach to DFT using the electron density ρ as:

$$\eta_D(\mathbf{r}) = \frac{V_{el}(\mathbf{r})}{2N} \quad (13)$$

where $V_{el}(\mathbf{r})$ is the electronic part of the electrostatic potential. The electron density ρ is embedded in the explicit expression of $\eta_D(\mathbf{r})$ (Roy et al. 1998) and is not shown here.

The applicability of hard and soft acid–base (HSAB) principle together with their local counterparts (hardness and softness) has been discussed in details by Roos et al. (2009). The authors have discussed the use of these parameters in enzyme catalysis, which include phosphoenolpyruvate (the cofactor of several syntheses), the disulfide cascade mechanism in arsenate reductase, the preferential attack of cys10 on dianionic arsenate, mixed disulfide dissociation mechanism of thioredoxin, and hydride transfer in flavoenzymes. The local softness and electrophilicity parameters were found to be quite effective in explaining site-specific reactivity involved in these complex reactions. QSAR combined with DFT concepts have been applied in histone deacetylase (HDAC) inhibitors as they are very promising targets as anticancer drugs. The active site HDAC consists of Zn^{2+}

Fig. 4 Ribbon diagram of the active site of human histone deacetylase (HDAC8) (PDB: 1 W22) with a bound hydroxamic acid inhibitor (Reproduced from Roos et al. 2009, with the kind permission of the American Chemical Society 2009)

ion (Fig. 4). The general QSAR analysis in this respect was found to be qualitative in nature (Chattaraj et al. 2006). The introduction of electrophilicity concept in QSAR (Chattaraj et al. 2006) increased the interpretative character and chemical hardness was found to be useful descriptor in this respect, as the hardness of the zinc binding group of HDAC correlated well with the calculated relative interaction energies of these inhibitors (Roos et al. 2009). In a recent review (Schwöbel et al. 2011), the importance of chemical hardness descriptors has been discussed for the electrophilic reactivity in toxicity prediction. An electrophilic index ω_{el} ($= \mu^2/2\eta$) has been proposed to be important descriptor for the QSAR analysis of such reactions.

Hardness and electronegativity parameters have been further used to develop descriptors for hydrogen bond basicity and acidity for applications in QSAR. Two theoretical scales, quantifying the hydrogen bond ability of compounds, are proposed: hydrogen bond basicity, B^* , and hydrogen bond acidity, A^* (Oliferenko et al. 2004). Both of these scales are based on clear physical considerations and use molecular topology and orbital valence-state energetic characteristics as parameters. These parameters are quantitatively defined including the geometric features originating through molecular graphs. The total hydrogen bond basicity B^* is defined as:

$$B^* = \frac{\eta^{lp}}{\chi^{lp} n^*} \sum_i^D \frac{\chi_i^\sigma - \chi_1^{ref}}{\eta_i^\sigma d_i^2 n^*} \quad (14)$$

where χ^{lp} and η^{lp} are the lone pair electronegativity and corresponding hardness values, n^* is the effective principal quantum number, χ_1^{ref} is the reference electronegativity of the basic center, χ_i^σ , η_i^σ represent electronegativity and hardness of the σ -orbitals, and d_i is the topological distance for the i th substituent atom. The summation runs over all atoms positioned at particular topological distances from the basic center D , where D is the diameter (the shortest maximum length) of the corresponding molecular graph. The total hydrogen bond acidity A^* is defined using a similar set of parameters in the following way:

$$A^* = \frac{\chi_i^\sigma - \chi_1^{ref}}{\eta_i^\sigma D_{1H}^2} + \sum_{i=2}^N \frac{\chi_i^\sigma - \chi_i^{ref}}{\eta_i^\sigma d_{iH}^2} \quad (15)$$

where χ_i^σ and η_i^σ are the electronegativity and hardness of the sigma orbital of the acidic center and the i th atom, respectively, χ_i^{ref} is reference electronegativity of the i th atom, D_{1H} is the geometric distance between the hydrogen and the nearest atom, and d_{iH} is the topological distance between i th and the hydrogen atom. These new HB descriptors were found to significantly improve the performance of QSAR software and be useful in molecular modeling and drug design. The latter becomes possible if one considers A_i^* and B_i^* values of each atom in the molecule rather than the overall molecular features. Two sets of such atomic values, $\{A_i^*\}$ and

$\{B_i^*\}$, define two scalar potential fields of hydrogen bonding which can be used as molecular fields in comparative molecular field analysis (CoMFA) and/or scoring functions in ligand docking.

Molecular Surface-Related Properties

Molecular Electrostatic Potential

Molecular complementarity plays a central role in the molecular recognition process, and molecular electrostatic potential (MEP) is one of the oldest known properties of molecular systems to interpret such interactions. Since the introduction of the MEP by Scrocco et al. (Scrocco and Tomasi 1973), different investigators have applied this property for predicting biological recognition processes and it has been shown that an MEP profile leads to direct inferences about the nature of the corresponding binding site (Scrocco et al. 1973) and about interaction between these sites and an approaching molecule. The MEP of molecule $V(\vec{r})$ at a point \vec{r} is defined as:

$$V(\vec{r}) = \sum_A \frac{Z_A}{|\vec{R}_A - \vec{r}|} - \int \frac{\rho(\vec{r}_1)}{|\vec{r}_1 - \vec{r}|} d\vec{r} \quad (16)$$

The MEP has been used for molecular recognition process of drug molecules and to investigate the nature of long-range interactions with the corresponding drug-binding/receptor sites (Scrocco and Tomasi 1978). This approach was used to account for the binding properties of the neurotransmitter γ -aminobutyric acid (GABA) (Guha et al. 1992), cardiotonic drugs (Bhattacharjee et al. 1992), various nucleic acid bases (Weiner et al. 1982), and various other molecular systems (Scrocco and Tomasi 1978; Weiner et al. 1982). In recent times, MEP analysis have been found to be quite useful to interpret the difference in the nature of binding of acetylcholine (Ach) and various toxic nerve agents to the acetylcholinesterase (ACHE) binding sites (Majumdar et al. 2006). A typical example in this respect could be found in the interaction natures of Ach and R- and S-sarin enantiomers to the ACHE binding site (Fig. 5).

The ACHE(I) and ACHE(II) represents two forms of ACHE active cavity due to the two different orientations of the tautomeric His-440 moiety. The interactions in the ACHE(I) . . . Ach and ACHE(II) . . . Ach complexes (Fig. 5a, b) are dominated by the two-body electrostatic interactions between Tyr-121 residue and Ach. The orientation of the $-N^+(\text{CH}_3)_3$ group over the aromatic ring is ideal for cation- π interaction. However, it cannot be classified as purely cation- π , as MEP maps of Fig. 5a, b show that there is a possibility of electrostatic interactions of the $-N^+(\text{CH}_3)_3$ electron density with the side chain and the $-\text{OH}$ group of the Tyr-121 residue. This electrostatic effect together with the dispersion interactions makes this interaction more attractive than the normal cation- π interaction. The electrostatic interactions with the rest of the fragments are repulsive.

Fig. 5 Calculated MEP on the isodensity surfaces of the (a) ACHE(I)...Ach, (b) ACHE(II)...Ach, (c) ACHE(I)...(*S*)-sarin, and (d) ACHE(II)...(*S*)-sarin complexes. The various colored regions on the surfaces are *deep blue* (highly positive, >0.1 au), *light blue* (<0.1 au and >0.05 au), *green* (0.0 au), *yellow* (<-0.1 au and >-0.05 au), and *red* (>0.1 au). The minimum negative MEP values of the substrate are within the range -20 to -10 kcal/mol (*greenish yellow region*), while it is around -50 kcal/mol (*reddish yellow region*) for the inhibitor (Reproduced from Majumdar et al. 2006, with the kind permission of the American Chemical Society 2006)

The MEP map of the ACHE(I)...(*S*)-sarin complex (Fig. 5c) indicates strong hydrogen bonding interactions with the Ala-201, Ser-200, Glu-199 (X1), His-440, and Glu-327 (X3) fragments of ACHE (Majumdar et al. 2006). However, these are not pure hydrogen bonding interactions. The MEP isopotential surface of the ACHE(I)...(*S*)-sarin complex shows that the attractive interactions are also possible from the other parts of the X1-Ach and X3-Ach fragments. These effects make the two-body interactions more attractive than an ordinary hydrogen bond. The nature of interactions is totally changed in the ACHE-(II)...(*S*)-sarin complex (Fig. 5d). Since the interaction of P = O [of (*S*)-sarin] with the -N-H of the His-400 residue is lost in this case, the complex becomes a weakly bound system. The MEP map further shows that the electrostatic terms are quite important.

The MEP properties could be used as QSAR descriptor and important development in this direction was made by Carbo and coworkers (1980) and later by Good

et al. (Good and Richards 1996). These are concerned with molecular similarity and are used in 3D-QSAR modeling. The Carbo index for molecular similarity (C_{AB}) is defined as:

$$C_{AB} = \frac{\int P_A P_B dv}{\left(\int P_A^2 dv\right)^{1/2} \left(\int P_B^2 dv\right)^{1/2}} \quad (17)$$

where P_A and P_B are electron density dependent structural properties. The numerator measures property overlap while the denominator normalizes the similarity result. Initially, electron density was used as the structural property P , and later MEP was used to evaluate P (Eq. 18).

$$P_r = \sum_{i=1}^n \frac{q_i}{(r - R_i)} \quad (18)$$

where P_r is the electrostatic potential at point r associated with the charge q_i of the i th atom and the summation runs over the total n atoms. R_i is the nuclear coordinate of the atom i . In order to avoid singularities at the atomic nuclei, where $1/(r - R_i)$ tends to infinity, the MEP is normally determined outside the van der Waals (VDW) volume of the molecules in the calculation. The Carbo index was sensitive to the shape of property distribution rather than to its magnitude. Hodgkin and Richards (Good and Richards 1996) introduced the following modified index (H_{AB}) to increase the sensitivity of the formula to property magnitude:

$$H_{AB} = \frac{2 \int P_A P_B dv}{\int P_A^2 dv + \int P_B^2 dv} \quad (19)$$

When considering receptor drug binding, the electrostatic interaction energy of the system is proportional to the electrostatic potential exerted by the drug. The drug molecule similarity is related to the difference in binding energies (ignoring entropy and solvent effects), and this disparity is proportional to the difference in drug electrostatic potentials. Richards et al. (Good and Richards 1996) further developed two similarity indices based on this premise. They are known as exponential (E_{AB} , Eq. 20) and linear (L_{AB} , Eq. 21) indices.

$$E_{AB} = \frac{\sum_{i=1}^n \exp\left(-\frac{|P_A - P_B|}{\max(|P_A|, |P_B|)}\right)}{n} \quad (20)$$

$$L_{AB} = \frac{\sum_{i=1}^n \left(1 - \frac{|P_A - P_B|}{\max(|P_A|, |P_B|)} \right)}{n} \quad (21)$$

The term $\max(|P_A|, |P_B|)$ ($= P_{\max}$) equals larger MEP magnitude between P_A and P_B at grid point where similarity is being calculated. Although C_{AB} indices were used in QSAR studies, this was later replaced by the indices developed by Richard and coworkers. They were used to study dopamine agonistic properties as well as studies on hypoglycemic agents and np-apomorphine molecules and were employed in QSAR studies of steroids (Good and Richards 1996). These 3D-QSAR indices were also extended in graphical structure activity analysis using neural networks (Good and Richards 1996) and QSAR models from partial least squares [PLS] studies (Good and Richards 1996). Klebe et al. (1994) further developed MEP based comparative molecular similarity indices analysis technique for 3D-QSAR studies. The method was used to examine the correlations between calculated physicochemical properties and in vitro activities of a series of human immunodeficiency virus type 1 (HIV-1) integrase inhibitors (Makhija and Kulkarni 2001).

The more advanced studies of the MEP properties of molecules have been directed to macromolecular systems. In recent times, average electrostatic potential (ξ_k) have been computed using Markov model to study indirect interaction between amino acids placed at a topological distance (k) within a given protein backbone. A specific example in this context is the case of Arc repressor, which is a model protein of relevance for biochemical studies on bioorganics and medicinal chemistry. It was used to model the effect of alanine scanning on thermal stability (González-Díaz and Uriarte 2005). The potential ξ_k is defined as:

$$\xi_k = \sum_{j=1}^n p_k^A(j) \cdot V(j) \quad (22)$$

The potential ξ_k , in this definition, is dependent on the absolute probability $p_k^A(j)$ with which the amino acids interact with other amino acids placed at a distance k . The potential also depends on the initial unperturbed MEP $V(j)$ of the amino acid. The detailed mathematical analysis is available in González et al. (2005), and we do not need to elaborate it here further. Recently Murray, Politzer, and coworkers (Murray et al. 2014, 2015) have designed reactivity index of molecules based on their MEP surface properties and have applied to account for several interactions, but the applications of such indices as descriptor in QSAR are not yet available.

Atoms in Molecule (AIM) Theory Based Descriptors

The 3D molecular structure representation based on Bader's quantum topological Atoms in Molecules (AIM) theory for use in QSAR have been developed by Alsberg et al. (2000). Critical points located on the electron density distribution of the molecules are central to this structure representation using quantum topology

(StruQT). Other gradient fields such as the Laplacian of the electron density distribution can also be used. The type of critical point of particular interest is the bond critical point (BCP), which is characterized by using the three parameters, viz., electron density (ρ), the Laplacian ($\nabla^2\rho$), and the ellipticity (ϵ). This representation has the advantage that there is no need to probe a large number of lattice points in 3D space to capture the important parts of the 3D electronic structure as is necessary in, e.g., comparative field analysis (CoMFA). The details of AIM parameters are well documented (Popelier 2000) and need not be discussed here within the short span of this review. Interested readers are advised to go through the cited references for details.

Alsberg et al. (2000) used the structure representation through AIM to compute the wavelength of the lowest UV transition for a system of 18 anthocyanidins. Different QSAR models were also constructed using several chemo-metric/machine learning methods such as standard partial least squares regression (PLS), truncated PLS variable selection, genetic algorithm-based variable selection, and genetic programming (GP). These models identified bonds that either took part in decreasing or increasing the dominant excitation wavelength (Alsberg et al. 2000). The models also correctly emphasized on the involvement of the conjugated π system for predicting the wavelength through flagging the BCP ellipticity parameters as important for this particular data set. One advantage of AIM formalism is that it can be used to compute various electrostatic moment terms (up to octopole moment) and the MEP generated by molecular electron distribution can be expanded using multipole moments to represent the potential accurately. The AIM has further advantage of generating transferable atomic contribution of electrostatic potential in the total MEP of a molecule. This enables construction of potential maps of macromolecules (e.g., proteins) using the results of smaller fragments (Popelier 2000). The applications of AIM formalism, although promising, are still in developing stage and not used yet on regular basis.

Quantum Chemical Techniques as Source of Parameter Generations

The quantum chemical techniques to compute the parameters described above are quite large in number and still many new techniques are emerging to meet the challenges of breaking the molecular size barrier together with accuracy of the parameters. The guide to the accuracy of the computed parameters lies in the reproducibility of the experimental observables (e.g., dipole moment, vibrational spectra, binding energies, etc.) through the techniques used. In earlier days of QSAR, mostly Hückel's method was used and the molecular systems were restricted to planar π -systems (Hansch 1969; Hansch and Coats 1970; Hansch et al. 1991). The development of various semiempirical techniques broke this barrier from the mid-1970s through the development of complete neglect of differential overlap (CNDO) (Jensen 1999), intermediate neglect of differential overlap (INDO) (Jensen 1999), and modified intermediate neglect of differential overlap (MINDO group of

techniques) (Jensen 1999) of atomic orbitals in a molecule. These methods were developed through approximations (attached to the name of the techniques) from Hartree-Fock (HF) equations. The other variants CNDO/S and ZINDO (Jensen 1999) were not used unless spectral parameters were needed in QSAR. The later developments of these semiempirical techniques, viz., modified neglect of diatomic differential overlap (MNDO), its AM1 version, and the PM3-PM6 (Jensen 1999) group of techniques are still in use, especially PM6, for some specific cases. These methods were mostly generated from their earlier version of neglect of diatomic differential overlap (NDDO) technique (Jensen 1999). Most of the semiempirical techniques are not considered as the state of the art after the early 1990s due to their inability to reproduce experimental observables within accuracy limit. The systematic error embedded in the approximations used in such techniques is the responsible factor and development of various HF theory-based ab initio methods from the mid-1960s started to replace the semiempirical computations.

The simple HF-theory based ab initio techniques were later improved further to include high electron-correlations. These include Möller-Plesset second-order perturbation (MP2) and its higher versions (MP3, MP4), configuration interactions (CI), and multiconfiguration self-consistent field (MCSCF) techniques; their variants at the multireference levels; and various coupled cluster theory based methods (viz., CCSD, CCSD(T), and their multireference models) (Jensen 1999). These are highly accurate methods for computing molecular properties for both the ground and excited states but are enormously time consuming and need large computer memories even for small molecules. Thus their usage is not very much welcome in QSAR as such analysis needs substantial number of molecular data set for a specific property analysis of mostly small and mid-sized molecules. Sometimes the molecular systems are quite large and the properties are not easily extractable through such higher-order techniques.

The compromise between accuracy and molecular size could be resolved through the use of density functional theory (DFT) (Jensen 1999). The Kohn-Sham variational principle for DFT is quite old (Kohn and Sham 1965), but real computational approach of DFT in molecular quantum chemistry started in the mid-1980s. At present this is one of the cheapest and reliable techniques and quite a large number of functionals have been designed (and still under development) in this context to resolve diverse molecular problems. DFT could be used for fairly large molecular systems with affordable computational time and the technique is ideal for generating reliable parameters for QSAR. Several quantum chemical parameters for QSAR, discussed earlier, have either no semiempirical version or are not so accurate after computation. DFT technique is also very much desirable in this context. The semiempirical techniques are still directly used for very large molecular systems or systems where use of QM/MM (Jensen 1999) type of formalism is essential. The QM/MM technique, which divides a molecule/molecular system into two or three regions (called layers), e.g., methods like ONIOM (Svensson et al. 1996), mostly uses semiempirical formalism as second layer in the total computational strategy. This layer distribution is, of course, flexible and depends on the level of ab initio technique chosen for the first layer and the accuracy of computations needed for the

second and third layers. The final choice of the use of quantum chemical techniques in QSAR depends on the requirements for the model and, of course, user's intuition.

Molecular Mechanics and QSAR

The molecular mechanics (MM) as such is a tool for generating structure of molecules through much cheaper way than quantum chemical techniques using classical potentials. There are various forms of such potentials and they are formulated through transferable parameters called force-fields. The details of such potentials cannot be discussed in this short review, but the general views on it are well documented. The interested readers can refer to more recent books in this area (Schlick 2002; Warshel 1991). The most important aspect is that these potentials and related force-field parameters are the important essential step in designing strategies for large molecular structure simulations. The large structures are usually proteins, enzymes, DNA, and RNA like molecules and the simulation strategies involve classical molecular dynamics (MD) and Monte-Carlo (MC) techniques. The literature involving such calculation strategies as well as their use in large structure simulations, simulations involving their free energy surfaces (involving phase transition from one form to the other, free energy of interactions with large and small molecular units, etc.) have been accumulating for the last 50 years with various levels of sophistications. It is out of scope to discuss such topics here, but they are well documented (Schlick 2002) for interested readers. The MM calculations could also be used as an initial step to calculate the structures of larger species, like metal nanoclusters in desired symmetry (Majumdar et al. 2012).

The other important part of MM calculations is that the methods are sometimes used as a cheap way to generate structure dependent descriptor in QSAR analysis. Such descriptors could be generated from other sources also (Stanon et al. 2002), and we will wrap up this discussion by citing one important example of MM applications in this direction. The example is related to the generation of surface area of molecule from the van der Waals radii of atoms from the force-field data (MMFF94 force-field) after optimizing the geometry through MM calculations. For a given numerical property P_i for each atom i in a molecule, the descriptor $P_VSA(u, v)$ (VSA: van der Waals surface area) for a specific range $[u, v]$ was defined using sum of atomic VSA contribution of each atom i as (Labute 2000):

$$P_VSA(u, v) = \sum_i V_i \delta(P_i \in [u, v]) \quad (23)$$

where V_i is the atomic contribution of atom i to the VSA of the molecule. For a set of n descriptors associated with a property P ,

$$P_VSA_k = \sum_i V_i \delta(P_i \in [a_{k-a}, a_k]) \quad k = 1, 2, \dots, n \quad (24)$$

where $a_0 < a_k < a_n$ are interval boundaries such that $[a_0, a_n]$ bound all values of P_i in any molecule. The mathematical expression shows that VSA-type of descriptors correspond to a subdivision of the molecular surface area. The concept was used to construct QSAR/QSPR models for boiling point, vapor pressure, free energy of solvation in water, solubility in water, receptor class, and activity against thrombin, trypsin, and factor Xa (Labute 2000).

Conclusions

Quantum chemical parameters are getting more and more useful in QSAR as they are quite reliable because of the proper reproducibility of many key molecular observables with respect to experiments. In the present review, we have discussed various quantum chemical parameters involving atomic charges in molecules; electrostatic moments and their implications; orbital-related properties like hardness, softness, and their implications in reactivities; surface-related properties like MEP; and the related important QSAR indices. AIM properties are also discussed and examples have been cited regarding the usage of all these parameters in QSAR to model drug-related molecular properties. The sources of generating such quantum-chemical parameters are also discussed in terms of semiempirical and ab initio-related methods. DFT techniques have been suggested to be the most suitable ones after considering the pros and cons of these methods. The discussion on molecular mechanics (MM) also constitutes a part of the review and although it is mostly used to construct molecular structures, the structural parameters generated through MM are also sometimes used in QSAR/QSPR-related modeling. Such possibilities are also discussed in terms of van der Waals surface-related parameters. Various parameters for QSAR are still emerging through various quantum chemical/MM-related techniques, but ultimately it depends on the intuition of the user to generate meaningful structure-activity correlations for practical use in chemoinformatics.

Abstract

Despite the number of available chemicals growing exponentially, testing of their toxicological and environmental behavior is often a critical issue and alternative strategies are required. Additionally, there is the need to predict properties of not yet synthesized compounds to reduce the costs of synthesis, selecting only those that have the maximal potential to be active and nontoxic compounds. In order to evaluate chemical properties avoiding chemical synthesis and reducing expensive and time-demanding laboratory testing, it is necessary to build *in silico* models

establishing a mathematical relationship between the structures of molecules and the considered properties (quantitative structure–activity relationships, QSARs). Molecular descriptors play a fundamental role in QSAR and other *in silico* models since they formally are the numerical representation of a molecular structure. Molecular descriptors can be classified using different criteria. Among them, there are two main categories, experimental and theoretical descriptors. The basis to understand and perform molecular descriptor calculation, the different theoretical descriptor categories together with their perspectives are described in this chapter.

Introduction

The overall number of chemicals synthesized, isolated, or marketed is increasing exponentially. The CAS REGISTRYSM database (www.cas.org) currently contains more than 93 million unique organic and inorganic chemical substances; it is updated daily and approximately includes 15,000 new substances each day.

Combinatorial chemistry and dynamic combinatorial chemistry (DCC) (Lehn 1999; Corbett et al. 2006) allow the synthesis of a large number of compounds in a single process, fastening the synthesis of different molecules with predefined characteristics.

At the same time, techniques like molecule structure generation and computer-assisted structure elucidation (CASE) of chemical compounds (Kind and Fiehn 2010; Elyashberg et al. 2011) give the possibility to design virtual molecules using *in silico* methods and potentially allow researchers to design millions of molecules in seconds.

Unfortunately, testing of physicochemical, toxicological, environmental, and other properties of chemicals is growing more slowly, hence, there is the need to have tools able to estimate chemical properties without performing experimental tests.

Quantitative structure–activity relationships (QSARs) and the similar quantitative structure–property relationships (QSPRs) (Hansch et al. 1996) are chemoinformatic techniques that allow establishing a relationship between the molecular structure and a defined endpoint. In order to apply these techniques, it is necessary to define, from a chemoinformatic point of view, what a molecular structure is. The molecular structure is a set of parameters able to describe a molecule in quantitative terms. Unfortunately, this set of parameters is not unique, that is, different mathematical representations of a molecular structure are available. Depending on the selected molecular representation, we can describe a molecule by means of experimental descriptors or theoretical descriptors. Experimental descriptors are all the experimental measurements such as octanol–water partition coefficient, molar refractivity, polarizability, and, in general, any physicochemical property obtained applying a well-specified experimental procedure. On the contrary, theoretical molecular descriptors are those descriptors obtained by a well-specified chemoinformatic algorithm applied to an unequivocal molecular representation.

Research on molecular descriptor is growing fast during the last years; the major drives that foster this development are essentially two. The first one is the rapid growth of number of available chemicals together with freely accessible databases collecting experimental data (Irwin and Shoichet 2005; Bolton et al. 2008; Pence and Williams 2010; Williams and Tkachenko 2014). Data availability changes the approaches to QSAR models (Cherkasov et al. 2014). While the first QSARs were based on few congeneric compounds possibly having the same mode of action (MoA) (Bobra et al. 1985; Vighi and Calamari 1985), the increased data availability enables researchers to develop more complex and global models based on hundreds of heterogeneous chemicals (Mannhold et al. 2009; Kühne et al. 2013; Cassotti et al. 2014a; Gissi et al. 2015).

The second stimulus comes from institutions. REACH regulation on the registration, evaluation, authorization, and restriction of chemicals in Europe (Worth 2010) promotes the use of QSAR methodologies to predict not available experimental data. There are analogous perspectives in the US EPA (Zeeman et al. 1995) and governmental agencies including Health Canada (Hughes et al. 2009).

In this scenario, molecular descriptors play a crucial role. Although until the 1960s–1970s, the study of relationships between experimentally measured quantities and molecular structure was based on experimental descriptors; nowadays, this analysis is more focused on the recognition of the relationships among theoretical descriptors and the considered experimental property. Thousands of molecular descriptors have been proposed in literature (Todeschini and Consonni 2009); this impressive amount of work is just one of the evidences of the scientific community interest in this field.

The huge amount of available molecular descriptors requires the delineation of few basic rules that molecular descriptors should comply with (Randić 1996; Guha and Willighagen 2012).

A molecular descriptor must:

1. Be invariant to atom labeling and numbering
2. Be invariant to the molecule roto-translation
3. Be defined by an unambiguous algorithm
4. Have a well-defined applicability on molecular structures

Additionally, in order to be potentially useful, a molecular descriptor should meet the following requirements:

5. Should have structural interpretation
6. Should have a good correlation with at least one experimental property
7. Should not have trivial relation with other molecular descriptors
8. Should not be based on experimental properties
9. Should preferably be continuous
10. Should preferably show minimal degeneracy
11. Should preferably be simple
12. Should preferably be applicable to a broad class of molecules

13. Should preferably be able to discriminate among isomers
14. Should preferably have calculated values in a suitable numerical range for the set of molecules where it is applicable to

Basically, the first rules can be used to understand if a molecular descriptor is well defined, but they do not permit to realize if a descriptor is useful or not to predict a defined property. Molecular descriptors should be invariant to all the operations related to molecule manipulation, which do not affect the molecular structure. Additionally, a molecular descriptor should have an applicability domain; it means that it should be clear to which class of molecules can be applied. Most of the first proposed molecular descriptors have been thought of for small organic molecules. Recently, one of the major challenges that molecular descriptors should face with is the possibility to be applied on different classes of compounds like salts, ionic liquids, peptides, polymers, and nanostructures.

The second set of rules are more related to the usefulness of a descriptor that should be interpretable, possibly related to an experimental property, but not excessively related to already existing molecular descriptors. A molecular descriptor should be a continuous variable and show a low degeneracy; it means that a molecular descriptor should be able to account for variations in molecular structure, even if variation is small.

Regardless of the molecular descriptor definition, the information gatherable by a molecular structure depends on the selected molecular representation.

How to Represent Molecules

Chemical compounds can be represented in different ways using different rules and criteria. Depending on the molecule representation, different information, codified in molecular descriptors, can be collected (Testa and Kier 1991; Jurs et al. 1995).

The simplest molecule representation is the chemical formula that codifies the atom types and their occurrences within a molecule. Chemical formula does not carry any information about atom connections, and molecular descriptors obtained by this kind of representation are referred to as 0D molecular descriptors.

The substructure list consists of a partial list of structural fragments included in a molecule. Molecular descriptors derived from this representation are usually cited as 1D molecular descriptors. They cannot represent the whole topology of the chemical structure, can be easily calculated and interpreted, and are typically used for similarity/diversity analysis and virtual screening of large chemical databases.

The topological representation is the most popular one. This is a two-dimensional representation that, in addition to the atomic composition, includes the information about connectivity of atoms in the molecule in terms of a molecular graph. Molecular descriptors derived from two-dimensional representation of molecule are referred to as 2D molecular descriptors.

3D molecular descriptors derive the molecular representation where the spatial information about atom positions is added to atom connectivities; in other words,

every atom of the molecule is associated with a set of three-dimensional coordinates determining its own position in the three-dimensional space. This representation is referred to as geometrical representation of a molecule where the molecule is considered as a rigid geometrical structure.

Additional representations of molecular structures have been defined. For example, 4D representation takes also into account molecular properties deriving from electron distribution and the interactions of the molecules with probes.

How to Codify Chemical Structures

Molecular structure information is usually stored in the so-called chemical files. Despite the huge number of chemical file formats (Boyle et al. 2011), all of them represent molecular structure focusing on specific atomic or molecular information and cannot store all possible chemical data.

With regard to the topic of this chapter, two main types of chemical files can be distinguished, one concerning the topological representation and the other the geometrical representation of molecules.

Typically, the former includes all types of linear notations; among them the most used is the SMILES file format (Weininger 1988). The latter includes all chemical file formats that can store the three-dimensional coordinates of the atoms, such as MDL and SYBYL file formats. An attempt to provide a standard format to store chemical data based on an XML dialect is the Chemical Markup language (CML) (Murray-Rust 1999; Murray-Rust and Rzepa 2001).

Molecular Structure Curation

The fundamental assumption at the basis of molecular descriptor calculation is the correctness of the molecular structures on which calculation algorithms are applied. Unfortunately, chemical structure annotation, both in chemistry publications and in public and commercial databases, is not exempt from errors.

Molecular structure curation has been severely emphasized in the last years in many publications highlighting problems and consequences related to the use of incorrect data in chemoinformatic and QSAR analysis (Young et al. 2008; Tropsha 2010). Data curation is usually composed of different steps to be applied to a whole dataset. Chemical structure curation has been recently detailed and has been split in five main steps (Fouches et al. 2010):

1. Removal of chemical structures that cannot be treated by the considered application or software, typically inorganics, mixtures, and eventually organometallics
2. Structural conversion and cleaning
3. Standardization and normalization of specific chemotypes
4. Removal of duplicates
5. Final manual checking

In this chapter, we will focus on second, third, and fifth steps. The second step is related to the preparation of the dataset. To calculate molecular descriptors, chemical structures must be encoded into a specific computational format, such as SMILES, SYBYL, or MDL. This conversion can be performed drawing the molecular structure by a molecule editor or directly querying a chemical database. Once this operation has been done, a consistency check must be performed on the generated molecular files finding out not realistic or incorrect molecular structures.

The third step of the curation procedure takes into account the fact that a molecule, or even a single fragment, can be represented in different ways. For example, aromatic rings can be represented either in Kekulé (i.e., bond configuration double–single–double) or aromatic form (i.e., conjugated bonds); since the representation is different, in principle it can affect the molecular descriptor values even if the chemical information is identical. Also some functional groups can have alternative representations; this is the case of nitro groups, which have multiple mesomers and can be represented using different bond notations (e.g., neutral and charged). The choice of one form with respect to another can affect significantly the performance of the models built with such data. Much more important is that the same normalization procedure is applied to all the molecular structures regardless of their specific representation.

The last step concerns the final check of all the codified molecular structures, which has to be done manually and, consequently, could be tedious and time demanding especially for big datasets. Nevertheless, it is crucial in order to identify issues not properly handled by automatic curation and to fix, if possible, the problems raised during the aforementioned steps.

Constitutional Descriptors

Constitutional descriptors are the simplest molecular descriptors that can be calculated starting from a molecular structure. Constitutional descriptors comprise all those descriptors representing a molecular structure, which take into account only chemical composition and do not encode information about the overall topology and geometry.

Typical constitutional descriptors are the molecular weight, the number of atoms and bonds, absolute and relative occurrence frequency of specific atom and bond types, and ring descriptors obtained considering only molecular structure composition.

The cyclomatic number (c), also known as circuit rank, is the most known ring descriptor and it is defined as:

$$c = |E| - |V| + D$$

where $|E|$ is the number of bonds, $|V|$ is the number of atoms, and D is the number of disconnected fragments in the molecular structure. The cyclomatic number is the minimum number of edges to be removed from a molecular graph in order to

remove all its cycles, making it into a forest, that is, an acyclic graph. It is widely used in the description of ring systems and gives the cardinality of the Smallest Set of Smallest Rings (SSSR).

Topological Indices (TIs)

Topological indices are two-dimensional descriptors derived from the topological representation of molecular structures (i.e., molecular graph); no information about spatial distribution of the atoms is considered in the calculation of these descriptors.

There exist different categories of topological indices; some of them will be described in the following paragraphs.

Molecular Graph

The typical 2D representation of a molecule is the molecular graph. A graph, $G = (V, E)$, is a representation of a set V of objects, called vertices, and a set E of links between vertices, called edges (Cormen et al. 2001). The molecular graph is a graph where the atoms are the vertices and the chemical bonds between atom pairs are the edges.

The molecular graph is typically an undirected, weighted, sparse graph. A graph is defined as undirected if the edges have no orientation and is defined as weighted if a number (i.e., the weight) is assigned to each edge. A sparse graph is a graph for which the number of edges $|E|$ is much less than the square of the number of vertices $|V|^2$. The weights associated to edges are typically the bond orders.

Application of graph theory on molecular structure (Balaban 1985) permits to handle chemical graphs adopting well-defined algorithms useful to explore structural properties of the molecules. Typically, graph theory can be used to extract information from the molecular graph, such as the calculation of matrices depending on graph connections and the definition of graph invariants that are those properties that depend only on the abstract structure of the graphs and do not depend from graph representations. Graph invariants are numerical representations of a graph; they can be a single number, a sequence of numbers, or a characteristic polynomial derived from the graph by a well-defined numerical manipulation of the graph structure. Graph invariants can be used for fast recognition of graph isomorphism since, for any invariant, two graphs with different values cannot be isomorphic. Anyway, two graphs with the same invariant value may or may not be isomorphic; a graph invariant is complete if it has equal values only for isomorphic graphs.

Graph invariant theory is the basis for the definition of topological indices.

A graph is commonly represented in two standard ways, as a collection of adjacency lists or as an adjacency matrix.

The adjacency lists are a collection of $|V|$ lists, one for each atom i , where every list $Adj[i]$ includes the atoms connected to the i -th atom together with the corresponding bond orders.

The adjacency matrix \mathbf{A} is essentially a $|\mathbf{V}| \times |\mathbf{V}|$ symmetric square matrix where the element a_{ij} is equal to one if atoms i and j are adjacent, zero otherwise:

$$[\mathbf{A}]_{ij} \equiv a_{ij} = \begin{cases} 1 & \text{if } (i, j) \in \mathbf{E} \\ 0 & \text{otherwise} \end{cases}$$

Atoms are adjacent if there exists a chemical bond connecting them.

Matrix-Based Representation

Adjacency matrix is just one of the possible matrices that can encode information about a molecular graph. Many matrices can be calculated from a graph extracting different information. These matrices, known as the graph-theoretical matrices, are the starting point to derive lots of molecular descriptors depending on the information included in the considered matrix.

Graph-theoretical matrices can be classified as vertex matrices, edge matrices, or incidence matrices. Vertex matrices are those matrices whose rows and columns refer to graph vertices, the atoms, and each element of the matrix encodes a property associated to a pair of vertices. Vertex matrices are square matrices whose dimension is $|\mathbf{V}| \times |\mathbf{V}|$. Edge matrices are $|\mathbf{E}| \times |\mathbf{E}|$ square matrices whose elements encode information on pair of edges, the bonds. Incidence matrices contain information about the relationships between two different sets of objects, such as atoms, bonds, cycles, substructures, or molecular paths. Usually incidence matrices are not square matrices and their dimension depends on the considered objects.

Most of the graph-theoretical matrices are calculated on a graph that does not include the hydrogen atoms, the so-called H-depleted molecular graph; however, they can be also derived from the H-filled molecular graph, if hydrogens are required to better represent the molecular structure.

Despite a large number of graph-theoretical matrices have been proposed in the literature (Ivanciuc and Ivanciuc 2000; Todeschini and Consonni 2009), only some of them along with the corresponding molecular descriptors will be here described with some details.

Vertex matrices are more used to derive molecular descriptors than edge and incidence matrices. Among them, the most important are the adjacency matrix and the topological distance matrix.

One of the first molecular descriptors derived from the adjacency matrix \mathbf{A} is the Lovasz–Pelikan index, which is defined as the leading eigenvalue (i.e., the largest eigenvalue) of the adjacency matrix (Lovasz and Pelikan 1973):

$$\lambda_1^{LP} \equiv \max_i \{\lambda_i\}$$

The topological distance matrix \mathbf{D} is a symmetric square $|\mathbf{V}| \times |\mathbf{V}|$ matrix whose element d_{ij} is equal to the topological distance between vertices i and j :

$$[\mathbf{D}]_{ij} \equiv d_{ij} = \begin{cases} |\min p_{ij}| & \text{if } i \neq j \\ 0 & \text{if } i = j \end{cases}$$

where $|\min p_{ij}|$ is the number of edges along the shortest path between i and j .

One of the most known topological indices is the Wiener index (W), which is defined as the half-sum of all the elements d_{ij} of the distance matrix (Wiener 1947):

$$W = \frac{1}{2} \cdot \sum_{i=1}^{|\mathbf{V}|} \sum_{j=1}^{|\mathbf{V}|} d_{ij}$$

The Laplacian matrix \mathbf{L} , also known as Kirchhoff matrix, is a symmetric square $|\mathbf{V}| \times |\mathbf{V}|$ matrix (Merris 1994) defined as an augmented matrix, it being obtained as the result of a square matrix and a diagonal matrix whose diagonal elements are the atomic properties. More specifically the Laplacian matrix is defined as the difference between the vertex degree matrix and the adjacency matrix. The vertex degree matrix is a diagonal matrix whose diagonal elements are the vertex degrees, the vertex degree δ_i being the number of non-H atoms adjacent to atom i :

$$[\mathbf{L}]_{ij} = \begin{cases} \delta_i & \text{if } i = j \\ -1 & \text{if } (i, j) \in \mathbf{E} \\ 0 & \text{if } (i, j) \notin \mathbf{E} \end{cases}$$

Vertex degrees can be calculated as the row sums of the adjacency matrix \mathbf{A} :

$$\delta_i = \sum_{j=1}^{|\mathbf{V}|} a_{ij}$$

The Laplacian spectrum is the set of eigenvalues derived from the diagonalization of the Laplacian matrix. These eigenvalues are real nonnegative numbers; the last eigenvalue is always equal to zero, and, if the graph is connected, the eigenvalues, except for the last one, are greater than zero.

Quasi-Wiener index (W^*) is calculated as the product of the number $|\mathbf{V}|$ of vertices of the graph and the sum of the reciprocal non-zero eigenvalues of the Laplacian matrix (Mohar et al. 1993):

$$W^* = |\mathbf{V}| \cdot \sum_{i=1}^{|\mathbf{V}|-1} \frac{1}{\lambda_i}$$

where $|\mathbf{V}|-1$ is the number of positive eigenvalues and λ_i the i -th eigenvalue of the Laplacian matrix. The quasi-Wiener index coincides with the Wiener index for acyclic graphs.

The detour matrix Δ , also known as maximum path matrix, is a symmetric vertex matrix defined as (Harary 1969; Trinajstić et al. 1997):

$$[\Delta]_{ij} = \begin{cases} |\max p_{ij}| & \text{if } i \langle \rangle j \\ 0 & \text{if } i = j \end{cases}$$

where $|\max p_{ij}|$ is the number of edges along the longest path between vertices i and j , that is, the detour distance.

The maximum path sum (MPS) index (Ivanciuc and Balaban 1994), also known as the detour index and usually denoted as w , is a Wiener-type index defined as the half-sum of the detour distances between every pair of vertices included in the molecular graph:

$$w = \frac{1}{2} \cdot \sum_{i=1}^{|V|} \sum_{j=1}^{|V|} [\Delta]_{ij}$$

From the standard graph-theoretical matrices, additional matrices can be calculated applying mathematical operators to a single or a set of matrices, hence obtaining, for instance, augmented matrices, reciprocal matrices, and weighted matrices.

Reciprocal matrices are obtained by raising to different powers the elements of the considered matrix. A typical example of these matrices is the reciprocal distance matrix \mathbf{D}^{-1} , also known as Harary matrix \mathbf{H} :

$$[\mathbf{D}^{-1}]_{ij} = \begin{cases} 1/d_{ij} & \text{if } i \langle \rangle j \\ 0 & \text{if } i = j \end{cases}$$

The Harary index H is calculated from the reciprocal distance matrix as a Wiener-type index:

$$H = \frac{1}{2} \cdot \sum_{i=1}^{|V|} \sum_{j=1}^{|V|} d_{ij}^{-1}$$

Weighted matrices are usually vertex or edge matrices describing a molecular graph containing heteroatoms or multiple bonds. Weighted matrices are obtained associating to each vertex or edge a defined property, the weight, which is used to differentiate the diverse atom or bond types. The set of weights is the weighting scheme associated to the molecular graph. Typically vertex weights are atomic properties such as atomic numbers, mass, or any physicochemical property that can be associated to the atoms. The edge weights are bond properties like the conventional bond order, the bond length, some combination of the properties of the connected atoms, or any other property that can be associated to the considered bond.

The atom connectivity matrix **C** is the most known example of weighted matrices. This is a weighted adjacency matrix whose elements c_{ij} are defined as follows:

$$[\mathbf{C}]_{ij} \equiv c_{ij} = \begin{cases} \pi_{ij}^* & \text{if } (i, j) \in E \\ 0 & \text{otherwise} \end{cases}$$

where π^* is the conventional bond order.

Another example of weighted matrices is the χ matrix (Randić 1992) that is defined as follows:

$$[\chi]_{ij} = \begin{cases} \frac{1}{\sqrt{\delta_i \cdot \delta_j}} & \text{if } (i, j) \in E \\ 0 & \text{otherwise} \end{cases}$$

where δ is the vertex degree of the two connected atoms.

Randić connectivity index (χ_R) is among the first proposed topological indices (Randić 1975, 2001); it can be calculated from the χ matrix as a Wiener-type index:

$$\chi_R \equiv {}^1\chi = \frac{1}{2} \cdot \sum_{i=1}^{|V|} \sum_{j=1}^{|V|} [\chi]_{ij} = \frac{1}{2} \cdot \sum_{i=1}^{|V|} \sum_{j=1}^{|V|} a_{ij} (\delta_i \cdot \delta_j)^{-1/2}$$

where a_{ij} are the adjacency matrix elements, which equal 1 for pairs of connected atoms, 0 otherwise.

Burden matrix **B** is another weighted matrix, which provides the well-known Burden eigenvalue descriptors (Burden 1989). Burden matrix is defined as follows:

$$[\mathbf{B}]_{ij} = \begin{cases} \pi_{ij}^* \cdot 10^{-1} & \text{if } (i, j) \in E \\ Z_i & \text{if } i = j \\ 0.001 & \text{if } (i, j) \notin E \end{cases}$$

A generalization of Burden matrix has been proposed in Dragon software (Mauri et al. 2014).

Among the edge matrices, the most common is the edge adjacency matrix. This is a symmetric matrix whose dimension is $|E| \times |E|$, which collects information about the connectivities of molecular bonds. Formally, it is defined as:

$$[\mathbf{E}]_{ij} \equiv e_{ij} = \begin{cases} 1 & \text{if } (i, j) \text{ are adjacent bonds} \\ 0 & \text{otherwise} \end{cases}$$

Analogously to the calculation of the vertex degree δ , the edge degree ε can be calculated from the edge adjacency matrix as:

$$\varepsilon_i = \sum_{j=1}^{|\mathbf{E}|} [\mathbf{E}]_{ij}$$

Edge adjacency matrix has been used to derive different graph-theoretical invariants, such as the edge connectivity index (Estrada 1995) defined as:

$$\varepsilon = \frac{1}{2} \cdot \sum_{i=1}^{|\mathbf{E}|} \sum_{j=1}^{|\mathbf{E}|} e_{ij} (\varepsilon_i \cdot \varepsilon_j)^{-1/2}$$

where e_{ij} are the elements of the edge adjacency matrix.

The advantage of the matrix representation of a molecular graph is that a lot of matrix operators and manipulations can be applied to graph-theoretical matrices allowing the calculation of different sets of descriptors highlighting diverse information depending on the considered representation.

Generalized Topological Indices

Topological indices are single graph invariants derived from a graph-based representation of a molecular structure. Topological indices are usually calculated on an H-depleted molecular graph, and depending on their definition, they are responsive to one or more structural features of the molecule, like size, shape, symmetry, and ring system characteristics. Topological indices taking only into account the structural information of the molecule are referred to as topostructural indices, whereas topological indices taking also into account the chemical information of the molecule such as the atom types or the hybridization states are named topochemical indices (Basak et al. 1997).

Topological indices can be derived applying mathematical operators directly to graph-theoretical matrices, such as the Wiener operator that consists in the half-sum of the matrix elements, or applying mathematical functions to local vertex invariants (LOVIs). Local vertex invariants are those numerical quantities of graph vertices (i.e., the atoms) used to characterize specific properties of the molecule's atoms. In analogy with the local vertex invariants, local edge invariants are those invariants calculated on graph edges and codifying bond properties.

Local vertex invariants can be derived taking into account only the topological representation of the molecule or considering also the physicochemical properties of the atoms associating a weight, the considered physicochemical property, to each atom in the molecule. This approach enables the topological indices to discriminate among heteroatoms.

Typical local invariants are the vertex degree δ , the valence vertex degree, and the bond vertex degree ε .

Local invariants can be calculated from any graph-theoretical matrix. One of the most common approaches is to sum the values of a generic symmetric graph-theoretical matrix along a row:

$$\mathcal{L}_i = \sum_{j=1}^A [\mathbf{M}]_{ij}$$

where \mathbf{M} is the considered matrix of dimension $A \times A$.

Applying this operator to the adjacency matrix \mathbf{A} results in the calculation of the most common local vertex invariant, the vertex degree δ_i :

$$\delta_i = \sum_{j=1}^{|\mathbf{V}|} a_{ij}$$

Most of the topological indices proposed in the literature have been studied to be applied on a specific graph-theoretical matrix; for instance, the Wiener index is defined as the sum of the topological distances between all the atom pairs, but it is commonly calculated as the half-sum of the distance matrix entries.

One of the characteristics of the most common topological indices is that they can be easily generalized in order to be applied on almost any graph-theoretical matrix. This generalization allows the evaluation of the behavior of these indices when applied on matrices including different types of information.

Let \mathbf{M} be a generic $A \times A$ symmetric graph-theoretical matrix, then a collection of generalized topological indices can be defined.

The formula $D1$ is a generalization of the Wiener index:

$$D1_{(\mathbf{M})} = \alpha \cdot \sum_{i=1}^A \sum_{j=1}^A [\mathbf{M}]_{ij}^\lambda$$

where two parameters have been added to the original formula, a scale parameter α and a power parameter λ . If the matrix \mathbf{M} coincides with the distance matrix (\mathbf{D}), $\alpha = 1/2$ and $\lambda = 1$, then the formula $D1$ corresponds to the Wiener index. Analogously, if matrix \mathbf{M} is the distance matrix (\mathbf{D}), $\alpha = 1/2$ and $\lambda = -1$, then the Harary index is obtained.

An additional parameter a_{ij} can be introduced in formula $D2$ to restrict the summation to adjacent elements, a_{ij} being the elements of the adjacency matrix:

$$D2_{(\mathbf{M})} = \alpha \cdot \sum_{i=1}^A \sum_{j=1}^A a_{ij} [\mathbf{M}]_{ij}^\lambda$$

Based on generic local vertex invariants \mathcal{L} , a general formula for the calculation of generalized topological indices is defined as the following:

$$D3_{(\mathcal{L};\alpha,\lambda)} = \alpha \cdot \sum_{i=1}^A \sum_{j=1}^A a_{ij} (\mathcal{L}_i \cdot \mathcal{L}_j)_{ij}^\lambda$$

The original Randić-connectivity index is obtained substituting \mathcal{L}_i with the vertex degree of the i -th atom and setting $\alpha = 1/2$ and $\lambda = -1/2$. Analogously, the Balaban index J (Balaban 1982) is obtained setting $\alpha = |E|/2(c + 1)$, where r is the cyclomatic number, and $\lambda = -1/2$ and considering the \mathcal{L}_i as the sum of all entries of the i -th row of the distance matrix \mathbf{D} .

A further generalization of the formula $D3$ to be applied on any type of graph fragments can be written as:

$$D4_{(\mathcal{L};\alpha,\lambda,k)} = \alpha \cdot \sum_{k=1}^K \left(\prod_{i=1}^{n_k} \mathcal{L}_i \right)_k^\lambda$$

where \mathcal{L} is a generic local vertex invariant, K is the total number of selected graph fragments, and n_k is the number of vertices in the k -th fragment. Function $D4$ is the basis for the calculation of Kier–Hall connectivity indices (Kier and Hall 1977). Kier and Hall proposed a general scheme to calculate connectivity indices based on the Randić index formula but considering larger fragments than bonds (i.e., pairs of adjacent atoms):

$${}^m\chi = \sum_{k=1}^K \left(\prod_{i=1}^{n_k} \delta_i \right)_k^{-1/2}$$

where δ_i is the vertex degree of the i -th atom.

Unlike Randić-connectivity index that is calculated on all pairs of adjacent vertex, Kier and Hall connectivity indices are calculated on all the subgraphs, of a predefined order m , constituting the molecule. Zero-order subgraphs ($m = 0$) are all the atoms in the molecule; it means that the summation goes over all vertex degrees, K is equal to the number of atoms, and $n_k = 1$. Analogously, 1-order subgraphs ($m = 1$) are all pairs of adjacent atoms, that is, all paths of length one (i.e., bonds), and for $m = 1$ the Randić-connectivity index is obtained, with K equal to the number of edges $|E|$ and n_k equal to 2. Second-order connectivity indices ($m = 2$) are calculated on all paths of order 2, K is equal to the number of path of length 2 in the graph, and n_k is equal to 3 since any path of length two involves three atoms.

As described, topological indices can be easily derived from a molecular graph. The collected information depends on the considered graph-theoretical matrix, on the chosen invariants, and on the operators applied to the examined matrix. This approach, besides being a theoretical generalization of existing and well-known topological indices, enables the definition of an extremely large number of theoretical topological indices whose tangible usefulness must be verified both analyzing their chemical meaning and applying them on real cases evaluating their ability to properly correlate physicochemical, biological, or other experimental properties.

Autocorrelation Descriptors

Autocorrelation descriptors denote a heterogeneous class of molecular descriptors whose general mathematical formalization is the following:

$$D5_{(\mathcal{L};\alpha,\lambda,k)} = \alpha \cdot \sum_{i=1}^A \sum_{j=1}^A (\mathcal{L}_i \cdot \mathcal{L}_j)_{ij}^\lambda \cdot \delta(d_{ij};k)$$

where \mathcal{L} is a generic local vertex invariant; α and λ are a scaling and a power parameter, respectively; and $\delta(d_{ij};k)$ is a Kronecker delta function equal to one for pairs of substructure centers at topological distance $d_{ij} = k$ and zero otherwise; A is the number of substructure centers that typically are the molecule atoms.

Autocorrelation descriptors are related to the spatial distribution of a generic molecular property, the local vertex invariant \mathcal{L} , on the molecular structure space and measure the strength of a relationship between atoms at a predefined distance equal to k .

The most known autocorrelation descriptors are the Moreau–Broto (1980; Broto et al. 1984), Moran (1950), and Geary (1954) autocorrelation descriptors.

Moreau and Broto applied for the first time the spatial autocorrelation function to a molecular graph to measure the distribution of atomic properties on the molecular graph. They named the proposed descriptors as the autocorrelation of a topological structure (ATS); these can be derived from the general equation $D5$ setting $\alpha = 1/2$ and $\lambda = 1$ and substituting the generic local vertex invariant \mathcal{L}_i with any atomic property w_i as:

$$ATS_k = \frac{1}{2} \cdot \sum_{i=1}^{|V|} \sum_{j=1}^{|V|} w_i \cdot w_j \cdot \delta(d_{ij};k)$$

where V is the set of vertices of the H-filled molecular graph.

Moreau–Broto autocorrelation calculated for path length zero is defined as the sum of the squares of the atomic properties:

$$ATS_0 = \sum_{i=1}^{|V|} w_i^2$$

The weight w can be defined arbitrarily. Common atomic properties are the atomic masses, electronegativities, polarizabilities, ionization potentials, and van der Waals volumes. Atomic properties should be properly centered in order to obtain uncorrelated autocorrelation descriptors (Hollas 2003).

Moran and Geary autocorrelation functions have been originally applied in ecological studies to evaluate the spatial distribution of environmental properties

and later proposed in Dragon software to evaluate the spatial distribution of atomic properties as alternative functions to ATS descriptors. Unlike Moreau–Broto autocorrelation descriptors (ATS), they explicitly take into account the mean and the standard deviation of the properties used as the atom-weighting scheme. Both Moran and Geary coefficients can be derived from the general equation *D5* just replacing the scaling and power parameters and the local vertex invariants.

Moran autocorrelation descriptors (MATS) have been defined as:

$$\text{MATS}_k = \frac{\frac{1}{\Delta_k} \cdot \sum_{i=1}^{|V|} \sum_{j=1}^{|V|} (w_i - \bar{w}) \cdot (w_j - \bar{w}) \cdot \delta(d_{ij}; k)}{\frac{1}{|V|} \sum_{i=1}^{|V|} (w_i - \bar{w})^2}$$

where w_i is any atomic property, \bar{w} is the property mean on the molecule, and Δ_k is the sum of the Kronecker deltas, that is, the number of atom pairs at distance equal to k . Moran coefficient usually takes value in the interval $[-1, +1]$. Positive values of the coefficients reflect positive spatial autocorrelation, whereas negative values of the coefficients reflect negative spatial autocorrelation; values around 0 mean that there is no specific pattern in the atom property distribution in the molecule.

Geary autocorrelation descriptors (GATS) can be calculated using the following equation:

$$\text{GATS}_k = \frac{\frac{1}{2\Delta_k} \cdot \sum_{i=1}^{|V|} \sum_{j=1}^{|V|} (w_i - w_j)^2 \cdot \delta(d_{ij}; k)}{\frac{1}{(|V|-1)} \sum_{i=1}^{|V|} (w_i - \bar{w})^2}$$

where w_i , \bar{w} , and Δ_k have the same definition as for MATS descriptors. Geary coefficient is a distance-type function whose values vary from zero to infinite. Small values of Geary autocorrelation coefficients reflect strong spatial autocorrelation; values between 0 and 1 reveal positive autocorrelation, while values larger than 1 are associated to negative spatial autocorrelation.

A particular case of autocorrelation descriptors is the atom-type autocorrelation (ATAC). Atom-type autocorrelation descriptors are discrete descriptors, while Moreau–Broto, Moran, and Geary descriptors are continuous functions. Atom-type autocorrelation descriptors count the occurrences of atom pairs, where atom pairs are defined as any pair of atoms having particular features at a predefined topological distance k . Also in this case, the formula of atom-type autocorrelation descriptors can be derived from the general equation *D5* as the following:

$$\text{ATAC}_k(u, v) = \frac{1}{2} \cdot \sum_{i=1}^{|V|} \sum_{j=1}^{|V|} \delta(i; u) \cdot \delta(j; v) \cdot \delta(d_{ij}; k)$$

where u and v represent two different atom types and $\delta(i; u)$, $\delta(j; v)$, and $\delta(d_{ij}; k)$ are three Kronecker delta functions equal to one if atom i is of type u , atom j is of

type v , and the topological distance d_{ij} is equal to k , respectively, zero otherwise. Atom types can be defined using one or more atomic properties; typical properties are the element type, connectivity, hybridization state, and pharmacophore properties.

Atom pair descriptors are usually calculated on a predefined set of atom types and a defined range of topological distances, the number of which determines the length of the resulting descriptor vector. Since atom pair descriptors are alignment-free, they enable fast calculation of similarity even on large databases.

Carhart descriptors are atom pair descriptors where atom types are defined using the chemical element of atoms, their connectivity calculated on the H-depleted molecular graph and the number of π electrons (Carhart et al. 1985). Alternatively, atoms can be labeled as the center of a predefined list of functional groups or structural features; the resulting descriptor vector will represent the frequencies of the occurrences of every defined atom pair on the defined range of topological distances.

Another type of well-known atom pair descriptors are the CATS (Chemically Advanced Template Search) descriptors (Schneider et al. 1999; Renner et al. 2006). The atom-type definition in CATS is related to the concept of “potential pharmacophore points” (PPP), where a PPP is a generalized atom type defined considering some physicochemical aspects. Five PPP have been originally proposed for the calculation of CATS: hydrogen-bond donor (D), hydrogen-bond acceptor (A), positive (P), negative (N), and lipophilic (L). Any atom of the molecule can be assigned to none, one, or two atom types, resulting in 15 possible atom pairs (DD, DA, DP, DN, DL, AA, AP, AN, AL, PP, PN, PL, NN, NL, LL). CATS are calculated on a topological distance varying from 0 to 9 resulting into a vector of 150 frequencies. CATS descriptors can be used as a vector of occurrences or they can be scaled. Scaling is usually performed dividing the occurrences by the number of non-hydrogen atoms or dividing each of the 15 possible PPP pairs by the sum of the occurrences of the two PPP belonging to the atom pair. The relative scaling, using the sum of the occurrences of the PPP, highlights rare PPP considering them as possible important contributors of the pharmacophoric aspect of the molecules with respect to abundant PPP pairs like the lipophilic atom types.

Autocorrelation descriptors can be extended to be calculated on a three-dimensional structure. Three-dimensional autocorrelation descriptors are based on Euclidean interatomic distances, while the property is still defined as an atomic property.

An example of three-dimensional autocorrelation descriptors is the CATS3D descriptors (Fechner et al. 2003) that are the three-dimensional counterpart of the CATS descriptors. Since distances are not calculated on the topological structure but in the real 3D space, they are not integer values, and consequently, Euclidean interatomic distances have to be partitioned into a defined set of distance bins. CATS3D have been defined using 20 distance bins from 0 to 20 Å in steps of 1 Å. The formula for these descriptors is the following:

$$\text{CATS3D}_k(u, v) = \frac{1}{2} \cdot \sum_{i=1}^{|\mathbf{V}|} \sum_{j=1}^{|\mathbf{V}|} \delta(i; u) \cdot \delta(j; v) \cdot \delta(r_{ij}; k)$$

where k is the considered distance bin, u and v represent two different atom types, and $\delta(i; u)$, $\delta(j; v)$, and $\delta(r_{ij}; k)$ are three Kronecker delta functions equal to one respectively if atom i is of type u , atom j is of type v , and their interatomic distance r_{ij} is comprised in the k -th bin, zero otherwise.

Geometrical Descriptors

Geometrical descriptors are those molecular descriptors calculated taking into account the three-dimensional structure of the molecule, i.e., the position of the atoms in the three-dimensional space. Geometrical descriptors derived from a three-dimensional graph representation of the molecule, taking into account not only the positions of the atoms but also the connections among them, are usually named as the topographic indices. The calculation of geometrical descriptors can be performed only for molecular structures whose three-dimensional description is available. Three-dimensional structure can be retrieved from crystallographic data or as the result of molecular optimization.

Geometrical descriptors potentially have higher information content than two-dimensional descriptors, but they have to be treated carefully since their values vary modifying the molecule conformation. Their application is therefore bound to those cases for which a specific conformation is selected or diversity among conformations has to be evaluated. Despite this, many geometrical descriptors have been satisfactorily used to model physicochemical and toxicological properties.

The geometrical distance matrix \mathbf{G} is the common representation of the distance relationships between all of the atom pairs in the 3D space; this is a symmetric $|\mathbf{V}| \times |\mathbf{V}|$ matrix whose entries r_{ij} are the Euclidean distances between every pair of atoms i and j in the molecule:

$$\mathbf{G} \equiv \begin{bmatrix} 0 & \cdots & r_{1|\mathbf{V}|} \\ \vdots & \ddots & \vdots \\ r_{|\mathbf{V}|1} & \cdots & 0 \end{bmatrix}$$

The 3D-Wiener index (${}^3D W_H$) is a topographic index calculated by analogy with the Wiener index from the geometrical distance matrix as:

$${}^3D W_H = \frac{1}{2} \cdot \sum_{i=1}^{|\mathbf{V}|} \sum_{j=1}^{|\mathbf{V}|} r_{ij}$$

Other topographic indices can be derived from the geometrical distance matrix applying the proper matrix operators.

A local vertex invariant that can be calculated from the geometrical distance matrix is the geometric distance degree, which is calculated as the row sum of the geometrical distance matrix as:

$$G_{\sigma_i} = \sum_{j=1}^{|V|} r_{ij}$$

where r_{ij} is the Euclidean distance between atoms i and j .

In analogy to the connectivity indices, the 3D connectivity indices ($\chi\chi$) have been defined substituting the vertex degree δ with the geometric distance degree G_{σ} :

$${}^m\chi\chi = \sum_{k=1}^K \left(\prod_{i=1}^{n_k} G_{\sigma_i} \right)_k^{-1/2}$$

where K is the number of m -th order subgraph constituted by n_k vertices.

Two additional examples of descriptors calculated using the geometrical distance matrix as a basis are the Euclidean connectivity (χ^E) index (Balasubramanian 1995):

$$\chi^E = \sum_{i=1}^{A-1} \sum_{j=i+1}^A (G_{\sigma_i} \cdot G_{\sigma_j})^{-\frac{1}{2}}$$

and the 3D Balaban index (Mihalic et al. 1992):

$${}^{3D}J = \frac{|E|}{c+1} \cdot \sum_{i=1}^{A-1} \sum_{j=i+1}^A a_{ij} (G_{\sigma_i} \cdot G_{\sigma_j})^{-1/2}$$

where c is the cyclomatic number, that is, the number of independent cycles in the structure.

Matrices used to encode information about a molecular structure can be combined in different ways in order to obtain novel matrices taking into account different features of the structure. An example of matrix combination is the distance/distance matrix $\mathbf{G/D}$, which is a $|V| \times |V|$ symmetric vertex matrix whose values are defined as the ratio between the geometrical distance and the topological distance:

$$[\mathbf{G/D}]_{ij} = \begin{cases} \frac{r_{ij}}{d_{ij}} & \text{if } i \neq j \\ 0 & \text{if } i = j \end{cases}$$

where r_{ij} and d_{ij} are the Euclidean and the topological distance between atoms i and j , respectively.

Two of the most known classes of three-dimensional descriptors are the WHIM (Weighted Holistic Invariant Molecular) descriptors (Todeschini et al. 1994; Todeschini and Gramatica 1997) and the GETAWAY (Geometry, Topology, and Atom-Weights Assembly) descriptors (Consonni et al. 2002a, b).

Unlike the topographic indices, which combine information on the topological and 3D structure of molecules, WHIM descriptors do not take into account the connections among atoms but only their position in the three-dimensional space. WHIM descriptors encode three-dimensional information on size, shape, symmetry, and atomic property distribution. Their calculation exploits the eigenvalues and eigenvectors of a weighted covariance matrix of the centered Cartesian atomic coordinates derived from a three-dimensional representation of the molecular structure: eigenvectors define the principal axes of the molecule and, accordingly, the unique reference frame for the considered molecular structure. WHIM descriptors are invariant to roto-translation: they are invariant to translation as a result of the centering of the atomic coordinates and to rotation as long as the principal axes are unique. These characteristics are fundamental in order to define molecular descriptors independent of prior molecule alignment.

The weighted covariance matrix for a generic atomic weighting scheme w is defined as:

$$s_{jk}^2 = \frac{\sum_{i=1}^A w_i (q_{ij} - \bar{q}_j) (q_{ik} - \bar{q}_k)}{\sum_{i=1}^A w_i}$$

where the summations run over the molecule atoms, s_{jk} is the weighted covariance between the two sets of atomic coordinates j and k ($j, k = x, y, z$), w_i is the atomic property of atom i , and q_i , q_j , and \bar{q} represent the coordinates of the i -th and j -th atoms and the corresponding average value, respectively.

Different weighting schemes have been proposed and accordingly different covariance matrices and hence different principal axes were obtained. WHIM descriptors have been divided in two classes, directional WHIM descriptors and global WHIM descriptors.

The three eigenvalues of the weighted covariance matrix play a crucial role in the WHIM descriptor calculation. Each eigenvalue represents a dispersion measure of the projected atoms along the considered principal axis. Directional WHIM descriptors consider the three eigenvalues separately providing information on the molecular size, shape, density, and symmetry along the principal axis, while global WHIM descriptors consider the relationships among the eigenvalues to describe molecular properties along the three principal directions in the molecule.

GETAWAY descriptors are three-dimensional descriptors that encode information about the influence that each atom has in determining the whole shape in the molecule and evaluate the interactions among atoms with respect to their

geometrical position in the three-dimensional space. For their calculation molecular matrix, representations are considered.

The first matrix is called molecular influence matrix \mathbf{H} , which is an $A \times A$ symmetric matrix, defined as:

$$\mathbf{H} = \mathbf{M} \times (\mathbf{M}^T \times \mathbf{M})^{-1} \times \mathbf{M}^T$$

where \mathbf{M} is the molecular matrix of the centered Cartesian coordinates (x, y, z) calculated on the H-filled three-dimensional molecular graph for a defined conformation. Centering the atomic coordinates is done with respect to the geometrical center of the molecule and assures the translational invariance. Influence matrix \mathbf{H} is invariant to rotation of the molecular coordinates, granting that GETAWAY descriptors are independent of any alignment.

Elements of the influence matrix can be split, with respect to their meaning, in two sets. The former comprises the diagonal elements of \mathbf{H} , denoted as h_i and called leverages, whose range is from 0 to 1. Leverages represent the contribution of each atom in defining the molecule shape; atoms located near the molecular surface have higher leverages than atoms near the molecule center. The latter includes the off-diagonal elements h_{ij} that reflect the capability of the j -th atom to interact with the i -th atom. Positive values of h_{ij} mean that atoms i and j are positioned in the same molecular region revealing possible atomic interactions, while negative values of h_{ij} mean that the two considered atoms i and j are positioned in opposite molecular region with respect to the center of the molecule reflecting low possibility of interaction.

The second matrix to be considered for GETAWAY calculation is the influence/distance matrix \mathbf{R} , an $A \times A$ symmetric matrix determined combining the elements of the influence matrix \mathbf{H} with the elements of the geometrical distance matrix \mathbf{G} :

$$[\mathbf{R}]_{ij} = \begin{cases} \frac{\sqrt{h_i \cdot h_j}}{r_{ij}} & \text{if } i \neq j \\ 0 & \text{if } i = j \end{cases}$$

where h_i and h_j are the leverages of atoms i and j , respectively, and r_{ij} is the Euclidean distance between them. Diagonal elements are set to zero by definition while off-diagonal elements represent the interactions between pairs of atoms, which decrease as the interatomic distance increases. This matrix has been defined to emphasize the interactions between atoms that are near each other and located on the molecular surface.

Unlike WHIM descriptors that allow a holistic description of the molecular properties, GETAWAY descriptors have been developed in order to exploit local information of molecular structures.

Structural Keys and Molecular Fingerprints

All the molecular descriptors presented in the previous sections derive from a mathematical manipulation of a molecular structure representation, typically a matrix-based representation, using a well-defined set of mathematical operators. Those descriptors have been defined in order to highlight different chemical aspects of a molecular structure starting from a holistic representation of the chemicals.

On the contrary, structural keys and molecular fingerprints try to describe a chemical capturing different local aspects of a molecular structure. Specifically, these approaches identify a set of structural fragments participating in the molecule composition.

Typically, structural keys are a predefined set of structural features, atom pairs, functional groups, ring systems, and atom-centered fragments that have been prepared in order to be able to discriminate among molecules and eventually be able to highlight chemical properties of a molecule. Structural keys can be defined as occurrence frequency or binary vector depending on whether the structural features identified in the molecules are counted or denoted only as present or absent.

Several structural key sets have been defined; the most known are the two sets of MACCS keys (Durant et al. 2002) comprising 960 and 166 structural features, respectively, and the PubChem structural keys, which include 881 bits reflecting the presence or absence of 881 structural features. PubChem service uses PubChem fingerprints for similarity neighboring and similarity searching (Bolton et al. 2008).

Unlike the structural keys that are a well-defined set of molecular features (i.e., fragment dictionary), the molecular fingerprints are identified exploring the molecular structure in all possible substructure patterns following a set of rules. Depending on the rules used to identify the molecular patterns, different types of fingerprint can be calculated.

Substructure patterns can be identified increasing or lowering the discriminatory power just defining the rules to be used to recognize and differentiate the patterns. The first rule to be considered is related to the kind of patterns that can be identified during the fingerprint calculation process. Two major types of patterns can be identified: paths and atom centered, also known as circular patterns. Then two classes of fingerprints can be calculated, path and extended connectivity fingerprint, also known as Morgan or circular fingerprint (Rogers and Hahn 2010).

Exhaustively enumerating all linear fragments of a molecular graph up to a given size generates a path fingerprint, while exhaustively enumerating all circular patterns grown radially from each heavy atom of the molecule up to the given radius size generates a circular fingerprint.

The first parameter to be set once the type of fingerprint has been defined is the maximum path length or the maximum radius of the patterns to be identified. Then, additional options can be set in order to increase or decrease the discrimination power of substructures. Patterns can be differentiated defining the atom properties encoded in the atom identifiers; typical properties that can be considered during the pattern identification are the atomic number, the number of neighbor atoms (i.e., atom connectivity), the number of bonded hydrogens, the formal charge, and the atom aromaticity.

Since recognized substructures are not included in a defined list, the number of identified substructures varies depending on the considered molecules affecting the fingerprint vector length. Typically, molecular fingerprint is a Boolean vector coding the presence or absence of structural features. On the contrary, some molecular fingerprints have been defined as a set of occurrences of different molecular fragments generated by breaking down all considered molecules; an example of this kind of fingerprint is the ISIDA descriptors (Ruggiu et al. 2010).

Alternatively, in order to obtain a fixed-length vector of molecular fragments, the Boolean vector constituting the fingerprint is processed using hash functions. A hash function is any function that can be used to reduce a variable-length Boolean vector to a fixed-length one. Specifically, each identified pattern is used as pseudorandom number generator seed, and the output of the hash function is a set of bits. The set of bits produced by hashing all the patterns identified in the molecule is added using the logical OR operator to produce the fingerprint of the whole molecule. This means that every bit associated to a substructure pattern will be set in the molecule fingerprint enabling Boolean operations on fingerprints to screen molecule databases; Boolean operations allow fingerprint comparison extremely fast for substructure searching. Fingerprint hashing is introduced when it is not possible to assign a particular bit to each pattern, as for structural keys, due to the huge number of possible identifiable patterns.

Hashing functions enable the definition of a fixed-length vector but introduce the so-called bit collision; this means that, under a predefined set of rules, a specific fragment will always be associated to a defined set of bits in the fingerprint, but two different fragments may share one or more bits among their bit sets.

Unlike structural keys that reveal with certainty the presence or absence of a particular pattern, fingerprints are not so accurate since if a fingerprint indicates the absence of a pattern then that particular substructure is certainly missing; on the contrary, a fingerprint can only indicate a pattern's presence with some probability. Nevertheless, fingerprints encode an almost exhaustive set of patterns with respect to structural keys, resulting in a more detailed description of a molecular structure in almost all situations.

Molecular fingerprints have been originally introduced for fast database searching since they are able to identify common substructures; however, molecular fingerprints are currently more and more used for building QSAR models, especially those based on local similarity as in the kNN approach (Cassotti et al. 2014b).

Future Perspectives

Despite the research on molecular descriptors and QSAR is quite recent, it is now able to provide solid answers to real problems. Molecular descriptor theory is facing new challenges requiring both chemical and mathematical skills. The description of structures not considered before, like disconnected structures and nanomaterials, is one of these challenges.

Molecular Descriptors for Disconnected Structures

Molecular descriptors have been widely used in order to deploy accurate models for the prediction of toxicological and physicochemical properties of organic compounds. The increasing number of available chemical data together with the progress in molecular descriptor theory and chemoinformatic techniques are the reasons for this successful approach.

One of the challenges that molecular modeling is facing is the capability to be applied not only on small organic molecules but also on different kinds of chemicals, like disconnected structures. Disconnected structures comprise salts, mixture, and ionic liquids. Recently, several studies approached this problem focusing on the prediction of nonadditive physicochemical properties like density, bubble temperature, and azeotropic behavior (Ajmani et al. 2006). Toxicological properties of mixtures have been studied too (Roy et al. 2014).

Besides data availability, one of the relevant issues concerning modeling of disconnected structures is the representation of these structures through appropriate molecular descriptors (Oprisiu et al. 2013). Most of the existing molecular descriptors have been developed to catch molecular structure information of small, full connected, organic molecules. Recent studies are evaluating the feasibility to apply these classical descriptors to disconnected structures. Considering the calculation algorithm, the classical descriptors can be divided into two classes. The former comprises all the descriptors whose mathematical definition does not require that the molecule is full connected; the latter includes those descriptors that can be calculated only on a fully connected graph. Trivial examples of molecular descriptors that can be calculated, preserving their chemical meaning on disconnected structures, are most of the constitutional descriptors; molecular weight is a molecular descriptor whose meaning is preserved on disconnected structures; a cyclomatic number is another descriptor whose definition comprises the possibility to be calculated on disconnected structures. Functional groups, atom-centered fragments, fingerprints, and structural keys are additive descriptors whose interpretation is identical for fully connected and non-fully connected structures.

While this first class of descriptors can be directly calculated on disconnected structures, the second class requires a deeper evaluation on how these descriptors can be calculated on disconnected structures. One approach is to calculate molecular descriptors on every full connected constituent of the compound and then perform a linear combination of the calculated values. Linear combinations typically are the average, the sum, or the absolute difference of the descriptor values (Oprisiu et al. 2013).

Obviously, the characterization of disconnected structures using molecular descriptors is a complex field since, in addition to the traditional issues, interaction among mixture constituents should be taken into account.

Data availability will be, as for traditional QSAR, the drive that will permit to evaluate the possibility to describe disconnected structures with molecular descriptors. Simultaneously, the advance in molecular descriptor theory could give

the instruments to develop and test molecular descriptors devoted to the description of disconnected structures.

Molecular Descriptors for Nanostructures

Nanomaterials are usually defined as those materials of which a single unit size is between 1 and 1000 nanometers. Besides the need to evaluate physicochemical properties of this class of chemicals, an emerging issue, related to the increasing use of engineered nanomaterials, is the assessment of their potential toxicological effects toward biological and environmental systems (Haasch et al. 2005; Buzea et al. 2007).

As well as for disconnected structures, the chance to use a quantitative structure–activity relationship approach is being widely evaluated during the last years (Puzyn et al. 2009; Oksel et al. 2015). QSAR applied to nanomaterials, named nano-QSAR or QNAR (quantitative nanostructure–activity relationships), is an emerging research field whose preliminary steps have been moved (Fourches et al. 2010, 2011).

As well as for disconnected structures also for nanomaterials, the fascinating aspect that needs to be studied is the definition of proper molecular descriptors able to properly delineate a nanostructure. High structural complexity and diversity among nanomaterials increase the difficulties to develop quantitative parameters capable to encode their structural information.

Due to the lack of theoretical descriptors, currently most of the molecular descriptors used to provide nanostructure description are experimental descriptors. Experimental molecular descriptors are usually derived from images captured by electron microscopy, transmission electron microscopy, and atomic force microscopy. These descriptors define size distribution, agglomeration state, shape, porosity, and surface area (Puzyn et al. 2009). Besides experimental descriptor usage, some researches attempt to describe nanomaterials using traditional theoretical descriptors (Kar et al. 2014).

So far, the data availability is one of the major bottlenecks for the advancement in nano-QSAR studies. The study and definition of theoretical molecular descriptors accomplishing the requirements defined in the introduction, such as structural interpretation, good correlation with at least one experimental property, and especially a well-defined applicability on nanostructures, is one of the biggest challenges that nano-QSAR should face.

Conclusions

In this chapter an overview of the different molecular structure representations along with the theoretical basis of molecular descriptors has been presented. The intention was to provide the readers not only with a detailed description of some of the most known molecular descriptors proposed during the last 40 years but also, above all,

with the theoretical fundamentals to understand the generation process of molecular descriptors.

The molecular graph is the most common representation of the molecular structure, and from it, applying a finite set of operators, a huge number of descriptors can be derived. Most of them have clear chemical interpretation but others rather seem to be the outcome of some mathematical trick. In conclusion, when dealing with molecular descriptors, one should keep in mind that molecular descriptors are numbers that can be easily generated through different combinations of structure representations, atom/bond weighting schemes, and mathematical functions, but in order to produce useful descriptors, some basic rules should be fulfilled not only related to their mathematical definition but also to their chemical interpretation and the correlation with one or more experimental property.

Abstract

In this chapter, we present an overview of various chemometric methods, appropriate for analyzing and interpreting data from social media, industry, academia, medicine, and other sources. We discuss unsupervised machine-learning techniques used for grouping (hierarchical cluster analysis, *k*-means) and exploring (principal component analysis, self-organizing Kohonen maps) all types of data, both quantitative and qualitative. For each method described in this chapter, we explain the basic concepts, provide a rudimentary algorithm, and present practical applications. All the examples are based on a set of molecular descriptors calculated for a selected group of persistent organic pollutants (POPs).

Introduction

The vast amount of digital information generated every day in social media, industry, and academia necessitates the use of advanced techniques appropriate for processing, analysis, and interpretation of data.

There are two main types of data analysis algorithms, namely, supervised and unsupervised machine-learning methods. A simplified schematic of machine-learning methods is presented in Fig. 1. Supervised learning is used for modeling, i.e., making predictions with the help of a calibration, discrimination, or classification model, depending on the research problem. Unsupervised learning Principal component analysis (PCA), used for exploring the hidden data structures and relationships between variables, helps us find groups (clusters) of objects (samples) similar to each other or, conversely, significantly dissimilar from the rest, as defined by a selected metric. The main difference between the two methods is that when constructing a model, the unsupervised learning method utilizes only the explanatory (independent) variable matrix (\mathbf{X}), while the supervised learning method takes also the response (dependent) variable (y) into account (Brown et al. 2009).

This chapter discusses methods of unsupervised machine learning, or pattern recognition, which are often used in problem solving in various fields of research such as chemistry, economics, forensic science, and medicine (Skwarzec et al. 2011; Li et al. 2013; Kountchev and Iantovics 2013; Golebiowski et al. 2014; Petushkova et al. 2014; Schnegg et al. 2015). It is meant as a brief overview of the most popular methods, along with examples, so as to facilitate an easier understanding of the topic.

Fig. 1 An overview of data mining methods

Data

All examples given in this chapter are based on a data set on persistent organic pollutants (POPs). This data set contains 21 molecular descriptors (Table 1) calculated for 1436 chloro (“C”) and bromo (“B”) analogues of dibenzo-*p*-dioxins (PXDDs, where X stands either for C or B), dibenzofurans (PXDFs), biphenyls (PXBs), naphthalenes (PXNs), diphenyl ethers (PXDEs), and benzenes (XBs) (Gajewicz et al. 2010). Most of the examples in this chapter will be based on a reduced set of POPs, namely, polychlorinated naphthalenes PCNs, polychlorinated dibenzo-*p*-dioxins PCDDs, and polychlorinated dibenzofurans PCDFs (Fig. 2).

As the POP class membership of each sample is known beforehand, the authors chose to use this data as a tool for comparing the effectiveness and the performance of each clustering method presented in this chapter.

Data Preparation

In order to ensure the reliability and accuracy of the results, we must first evaluate the quality of the raw data. The purpose of such evaluation is identifying possible mistakes (errors) made during data collection and reducing the risk of propagating

Table 1 Molecular descriptors

Symbol	Definition of molecular descriptor	Unit
nAT	Number of atoms	—
nX	Number of halogen substituents	—
nO	Number of oxygen atoms	—
MW	Molecular weight	u
HOF	Standard heat of formation	kcal·mol ⁻¹
EE	Electronic energy	eV
Core	Core-core repulsion energy	eV
TE	Total energy	eV
TEp	Total energy of the corresponding cation	eV
VIP	Vertical ionization potential	eV
HOMO	Energy of the highest occupied molecular orbital	Hartree
LUMO	Energy of the lowest unoccupied molecular orbital	Hartree
D	Dipole moment	Debye
SAS	Solvent accessible surface	Å ²
MV	Molecular volume	Å ³
Qm	Lowest negative Mulliken partial charge on the molecule	—
Qp	Highest positive Mulliken partial charge on the molecule	—
P	Polarizability derived from the dipole moment	Å ³
EN	Mulliken electronegativity	Hartree
Hard	Parr and Pople’s absolute hardness	Hartree
Shift	Schuurman MO shift alpha	Hartree

n

Fig. 2 A schematic representation of the example POP data set used in this chapter with m samples (molecules) and n variables (descriptors)

those errors during the next stages of analysis. Data control also allows us to assess whether any variable transformations (preprocessing) are necessary. In order to use pattern recognition methods presented in this chapter, we must first perform a specific type of data transformation, called standardization, autoscaling, or Z-transformation. Standardization is a way of centering and scaling data in such a way (Eq. 1) that the resulting variables have a mean value equal to 0 and the standard deviation equal to 1.

$$z_i = \frac{x_i - \mu}{\sigma} \quad (1)$$

where x_i is the sample value, z_i is the standardized sample value, μ is the mean value for all samples in the column, and σ is the standard deviation of all the values in the column.

It should be noted that, after this transformation, all the variables have mean value equal to 0 and variance equal to 1 (see Fig. 3). Thusly, the effect of unequal value ranges, caused by differing variable units, and has been nullified, as the standardized data are unitless. Each variable has equal significance (weight) and influence on the analysis results (Livingstone 2009).

Clustering

In order to explore the data, to identify and visualize their underlying structure, and to understand the relationships between objects (samples), we should employ clustering methods. Clustering is a way of looking for natural patterns or groups in the data, in other words, a way of determining the relative positions of

Fig. 3 Data transformation during autoscaling (a) raw data; (b) centered data, where $\mu = 0$; and (c) centered and scaled data, where $\mu = 0$, $\sigma = 1$

all objects in the multidimensional variable space. It is an unsupervised machine-learning method, that is to say, the size and membership of the groups are not known in advance. The groups are formed as a result of a clustering algorithm and are extracted from the data set accordingly to criteria selected by the user.

As all clustering methods are built on the concept of similarity, not only do they allow us to determine group membership but they also help us identify outliers. Ways of measuring similarity will be discussed in depth later in this chapter.

There are two main approaches to clustering. The first one, called *hierarchical*, produces levels of rank-ordered clusters. The second one, called *partitive*, sorts the data into a predefined number of clusters of equal importance (Everitt et al. 2011).

Similarity and Distance

Similarity can be expressed in terms of distance between two objects in the variable space. This space can be one-, two-, three-, or multidimensional, proportionally to the number of variables. It is quite intuitive to interpret similarity and distance as inverse concepts: the greater the distance between objects, the lesser their similarity. Two objects are considered to have similar properties and, consequently, belong to the same group, if the distance between them is sufficiently small (Brereton 2003).

The perception of similarity through distance, the way we interpret objects as similar or not, depends on the distance metric selected, variables used, and data transformation method applied.

Examples of different approaches to defining distances between objects, that is, different *similarity metrics*, are shown in Fig. 4. The *Euclidean distance* between the two objects, $i(1)$ and $j(2)$, denoted by line C, can be calculated according to Eq. 2:

$$D_{\text{Euclidean}} = \sqrt{\sum_{j=1}^J (x_{ij} - x_{kj})^2} \quad (2)$$

where i, j are sample indices, n is the variable number, x_i is the i -th sample value of n -th variable, and x_j is the j -th sample value of n -th variable.

Fig. 4 Different approaches to defining distance metrics

In the presented example, the Euclidean distance between objects 1 and 2 is given as:

$$C = \sqrt{B^2 + A^2}$$

$$C = \sqrt{(5 - 1)^2 + (4 - 1)^2} = 5$$

The second distance metric represented in Fig. 4, known as *Manhattan* or *city block distance*, is calculated as follows (Eq. 3):

$$D_{\text{Manhattan}} = \sum_{j=1}^J |x_{ij} - x_{kj}| \tag{3}$$

In the example:

$$D_{\text{Manhattan}} = 4 + 3 = 7$$

The last distance metric, *Chebyshev*, can be determined according to Eq. 4:

$$D_{\text{Chebyshev}} = \max |x_{ij} - x_{kj}| \tag{4}$$

In our example, $|A| < |B|$; thus,

$$D_{\text{Chebyshev}} = |B| = 4$$

Table 2 Most popular distance metrics

No.	Metric	Equation	Type	Data type
1	Euclidean	$\sqrt{\sum_{j=1}^J (x_{ij} - x_{kj})^2}$	Dissimilarity	Interval/binary
2	Manhattan (city block)	$\sum_{j=1}^J x_{ij} - x_{kj} $	Dissimilarity	Interval
3	Chebyshev	$\max x_{ij} - x_{kj} $	Dissimilarity	Interval
4	Minkowski(order n)	$\sqrt[n]{\sum_{j=1}^J (x_{ij} - x_{kj})^n}$	Dissimilarity	Interval
5	Canberra	$\sum_{j=1}^J \frac{ x_{ij} + x_{kj} }{x_{ij} + x_{kj}}$	Dissimilarity	Interval
6	Mahalanobis	$\sqrt[n]{\sum_{j=1}^J (x_{ij} - x_{kj})^n S^{-1}(x_{ij} - x_{kj})^n}$	Dissimilarity	Interval
7	Cosine(Ochiai)	$\frac{\sum_{j=1}^J x_{ij} x_{kj}}{\sqrt{\sum_{j=1}^J x_{ij}^2 \sum_{j=1}^J x_{kj}^2}}$	Similarity	Interval/binary
8	Pearson correlation coefficient	$\frac{\sum_{j=1}^J (x_{ij} - \bar{x}_i)(x_{kj} - \bar{x}_j)}{\sqrt{\sum_{j=1}^J (x_{ij} - \bar{x}_i)^2 \sum_{j=1}^J (x_{kj} - \bar{x}_j)^2}}$	Similarity	Interval/binary
9	Squared Pearson correlation coefficient	$\left[\frac{\sum_{j=1}^J (x_{ij} - \bar{x}_i)(x_{kj} - \bar{x}_j)}{\sqrt{\sum_{j=1}^J (x_{ij} - \bar{x}_i)^2 \sum_{j=1}^J (x_{kj} - \bar{x}_j)^2}} \right]^2$	Similarity	Interval/binary

Distance measures can emphasize similarity, as well as dissimilarity between the objects. The abovementioned metrics highlight the differences between samples and quantify dissimilarity. It should be noted that the choice of the distance measure depends also on the type of data available. A list of the most popular (dis)similarity metrics can be found in Table 2.

The measure of proximity between two clusters, or an object and an already formed cluster, is called *linkage* (Varmuza and Filzmoser 2009). Let us assume there are three clusters called C_1 (with n_1 objects), C_2 (with n_2 objects), and C_3 (with n_3 objects). If clusters C_2 and C_3 are aggregated to form a new single cluster called C_4

Table 3 Linkage types

Linkage type	Equation
Single [nearest neighbor]. Distance between two clusters is the minimum distance between any single observation in one cluster and any single observation in the other cluster	$D_{C_1C_4} = \min(D_{C_1C_2}, D_{C_1C_3})$
Complete [furthest neighbor]. Distance between two clusters is the maximum distance between any single observation in one cluster and any single observation in the other cluster	$D_{C_1C_4} = \max(D_{C_1C_2}, D_{C_1C_3})$
Centroid [unweighted pair group method centroid, UPGMC]. Euclidean distance between two clusters is the distance between the cluster centroids (means, middle points)	$D_{C_1C_4} = \ c_1 - c_4\ $
Average [unweighted pair group method with arithmetic mean, UPGMA]. Distance between two clusters is the mean distance between all observations in one cluster and all observations in the other cluster	$D_{C_1C_4} = \frac{n_2}{n_2+n_3} (D_{C_1C_2}) + \frac{n_3}{n_2+n_3} (D_{C_1C_3})$
McQuitty [weighted pair group method with arithmetic mean, WPGMA]. Distance between the newly formed cluster and any other cluster is the mean value of the distances from each of the two merged clusters to that cluster	$D_{C_1C_4} = \frac{1}{2} (D_{C_1C_2}, D_{C_1C_3})$
Ward [minimum variance]. The proximity of two clusters is calculated as the Euclidean distance between their centroids multiplied by a correction factor, thus minimizing the within-cluster sum of squares	$D_{C_1C_4} = \ c_1 - c_4\ \frac{\sqrt{2n_1n_4}}{n_1+n_4}$

(with $n_2 + n_3 = n_4$ objects), the distance between cluster C_1 and the new cluster C_4 is calculated according to one of the approaches listed in Table 3.

The *single linkage* method is a good choice for identifying the most homogenous (similar) groups. The *complete linkage* method tends to highlight the differences between samples – the resulting groups are similar in size but very diverse. The *furthest neighbor* method can be sensitive to outliers. While the single or complete linkage methods are based on single-pair distances, the *average* and *centroid linkage* methods use a more central measure of location.

Hierarchical Clustering

Hierarchical clustering is an iterative method of grouping objects into a tiered, ordered structure, where all individuals are assigned to a specific, mutually exclusive subgroups. There are two approaches to hierarchical clustering:

- (a) *Agglomerative* (bottom-up), which starts with each of the n objects forming separate, single-member clusters and recursively merges the two most similar

groups or individuals into one of a higher level until all objects have been combined into a single cluster

- (b) *Divisive* (top-down), which starts with all n objects forming one single cluster and with each iteration splits it into two smaller groups until all objects form separate, single-member clusters

The agglomerative methods are widely used in various areas of science: medicine, environmental science, computer vision, and analytical chemistry, which is why the authors choose to focus on them in this section.

Advantages

- Wide range of similarity metrics and cluster linkage techniques
- Applicability to a variety of data types (interval, binary, and count data)

Disadvantages

- Ambiguity in selecting the final number of clusters
- Irreversibility of the merge at each level

Clustering Algorithm

The workflow of agglomerative hierarchical clustering is presented below. In this example, the variables were all measured on different scales; therefore, prior to the analysis, a data transformation is necessary. In order to convert data variables into ones with comparable units, all the sample values were standardized, that is, mean centered and variance scaled (Fig. 5).

Agglomerative hierarchical clustering consists of the following steps:

1. Computing the pairwise distance matrix (Fig. 6). Using a selected metric, the distances between each point and all other objects in the data set are calculated. Here, the Euclidean distance is used.
2. Forming clusters (Fig. 7). The first step is to find two objects with smallest distance to each other (A and B). These objects will be merged into the first cluster (C_1).
3. Determining intercluster distances. Using a selected linkage technique, the relative proximity of the new cluster C_1 to all the remaining objects (C, D, E, and F) is calculated. When estimating linkage, all unmerged objects are considered to be single-member clusters or *singletons*. Here, the single linkage (nearest neighbor) approach has been used.
4. Merging the previously formed cluster (C_1) and the closest object C, into a new cluster (C_2) (Fig. 8).
5. Iterating step 3 thru 4 until all objects have been incorporated into a single cluster with nested subclusters (Fig. 9). In our example, cluster C_1 contains only objects A and B. Cluster 3 contains only objects E and D. One tier up in the hierarchy, cluster C_2 contains cluster C_1 and object C. Up another tier, Cluster C_4 contains cluster C_2 and C_3 . The final tier the cluster C_5 comprises all objects, formed by merging cluster C_4 and object F.

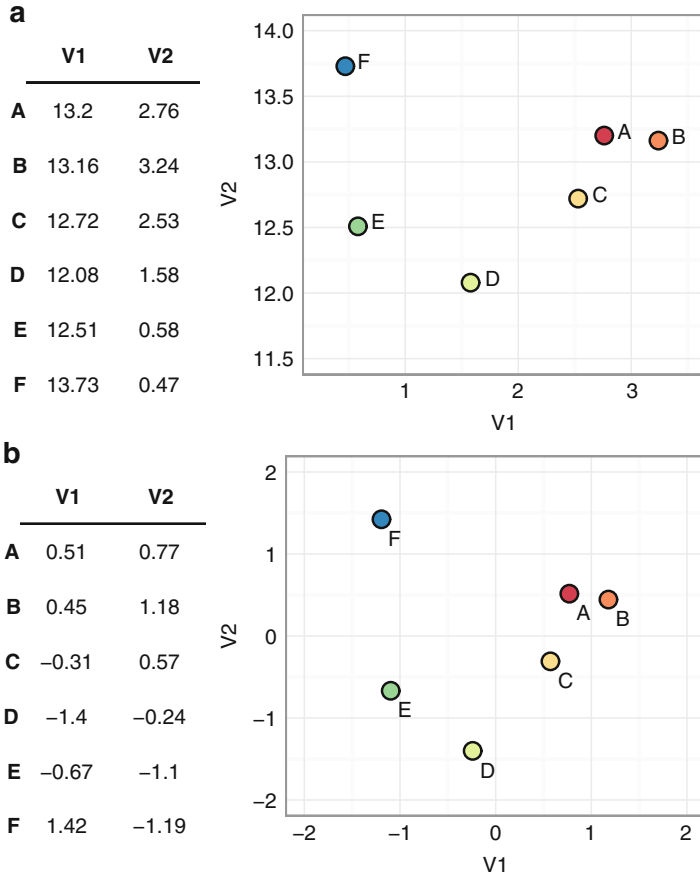

Fig. 5 The effect of autoscaling on a randomly generated data set; (a) original (raw) data, (b) autoscaled data

The hierarchical clustering results can be visualized as a tree-like diagram, called the *dendrogram* plot (Fig. 10). Typically, the y-axis indicates the distance at each successive split (or join) or branch height. On the x-axis, the objects are shown as leaves.

There are three main types of dendrograms to choose from: rectangular, triangular, or circular, although the rectangular is most popular (see Fig. 11). Regardless of the choice of the dendrogram type, the interpretation remains the same. Objects belonging to the same cluster are always more similar to each other than to the objects from other clusters.

Depending on the distance metric and linkage method used, the tree diagram will be different (Fig. 12). For example, using the Canberra distance metric instead of the

Fig. 6 Example of (a) Euclidean distance matrix, where the smallest distance between the two has been highlighted, (b) visualization of the Euclidean distance between the closest objects – A and B

Fig. 7 Forming the first cluster C_1 by merging two closest objects A and B, based on the single linkage approach

standard Euclidean distance will result in greater distance value ranges and distinct cluster separation; see Fig. 12a.

Selecting appropriate distance and linkage parameters will help answer the questions about the data structure and facilitate the correct interpretation of results. When looking for similarities between samples, one should use the single linkage method instead of the complete linkage approach (Fig. 12b).

Let us now turn to the POP data set. As we are trying to cluster the objects into most diverse groups in order to find the common characteristics for POP samples

Fig. 8 Forming the second cluster by merging cluster C_1 with the closest object C, based on the single linkage approach

Fig. 9 Final clustering results, with showing hierarchical (nested) cluster structure

from the chemical groups of polychlorinated naphthalenes PCNs, polychlorinated dibenzo-*p*-dioxins PCDDs, and polychlorinated dibenzofurans PCDFs, we used the Euclidean distance metric. For comparison's sake, we applied the three types of linkage metrics to build a dendrogram: complete (Fig. 13a), Ward's (Fig. 13b), and single (Fig. 13c). Depending on the linkage method used, the number of main

Fig. 10 An example of a rectangular dendrogram, created using Euclidean distance and complete linkage

Fig. 11 Different types of dendrograms (a) rectangular, (b) triangular, and (c) circular

branches varies significantly, e.g., for the complete method, four main clusters can be identified; for Ward's method, three main clusters are visible; and for the single linkage method, two main cluster groups are noticeable. The preliminary assumptions on cluster number are very subjective and depend on the person analyzing the plots. Another scientist may see a completely different ramification to the one presented by the authors.

Choosing Number of Clusters

The dendrogram resulting from agglomerative hierarchical clustering does not explicitly specify group structure. Based only on the tree diagram, we are unable to identify the number of groups and their memberships or size. That information can, however, be obtained by “cutting” the dendrogram at a certain height (h) or by specifying the desired number of groups (k). Choosing the cutoff point or a default

Fig. 12 Comparison of distance metrics and linkage methods: (a) Euclidean versus Canberra distance, complete linkage; (b) single versus complete linkage, Euclidean distance

cluster number is not an easy task, especially considering the variety of data types, units, and ranges, as well as differing needs and expectations of individual analysts.

A substantial number of approaches to determining the branch cut height can be found in the literature (Milligan and Cooper 1985). The simplest one, a *rule of thumb* really, is to use the square root of half of the sample number (Eq. 4):

$$g = \sqrt{\frac{n}{2}}$$

where n is the number of samples and g is the cutoff value.

In order to verify the number of main groups (clusters) identified through different linkage methods, we use the rule of thumb approach. The number of POP samples n equals to 288; therefore, the cutoff height $g = 12$. The resulting groups for all three linkage methods, colored for better identification, are shown in Fig. 14. When using the complete linkage method, after visual inspection, we identified four main clusters. This verified when using the rule of thumb approach, as shown in Fig. 14a. Curiously, the three main clusters initially identified in the second dendrogram (Ward’s method) were later disproved by the rule of thumb, which showed 11 subclusters (Fig. 14b). Interestingly, while we initially identified

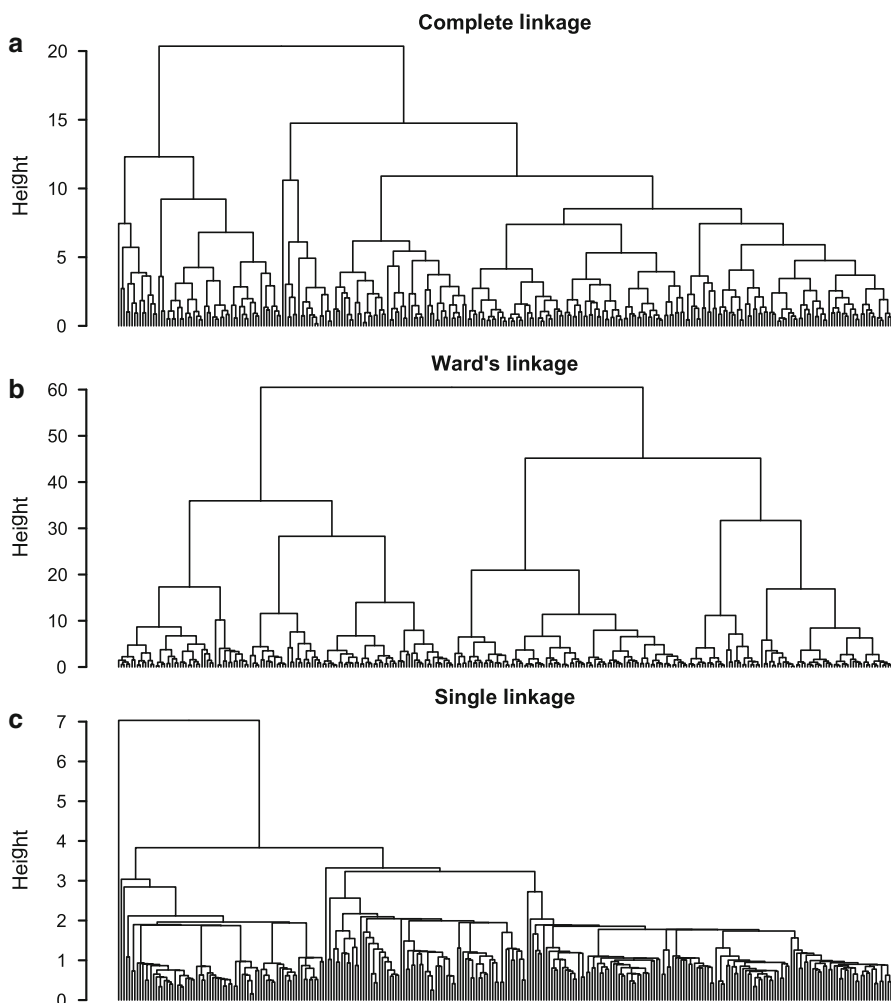

Fig. 13 Hierarchical clustering results for three POP groups (PCNs, PCDDs, and PCDFs) using the Euclidean distance: (a) complete linkage, (b) Ward's linkage method, (c) single linkage

two main subgroups in the third dendrogram (single linkage), according to the rule of thumb, there is only one, all-encompassing cluster (Fig. 14c).

Other, more complex means of selecting the number of clusters are also available. Most of them are automated in nature (i.e., those for which user input is not necessary), such as the C_{index} (Eq. 5):

$$C_{index} = \frac{S - S_{min}}{S_{max} - S_{min}} \quad (5)$$

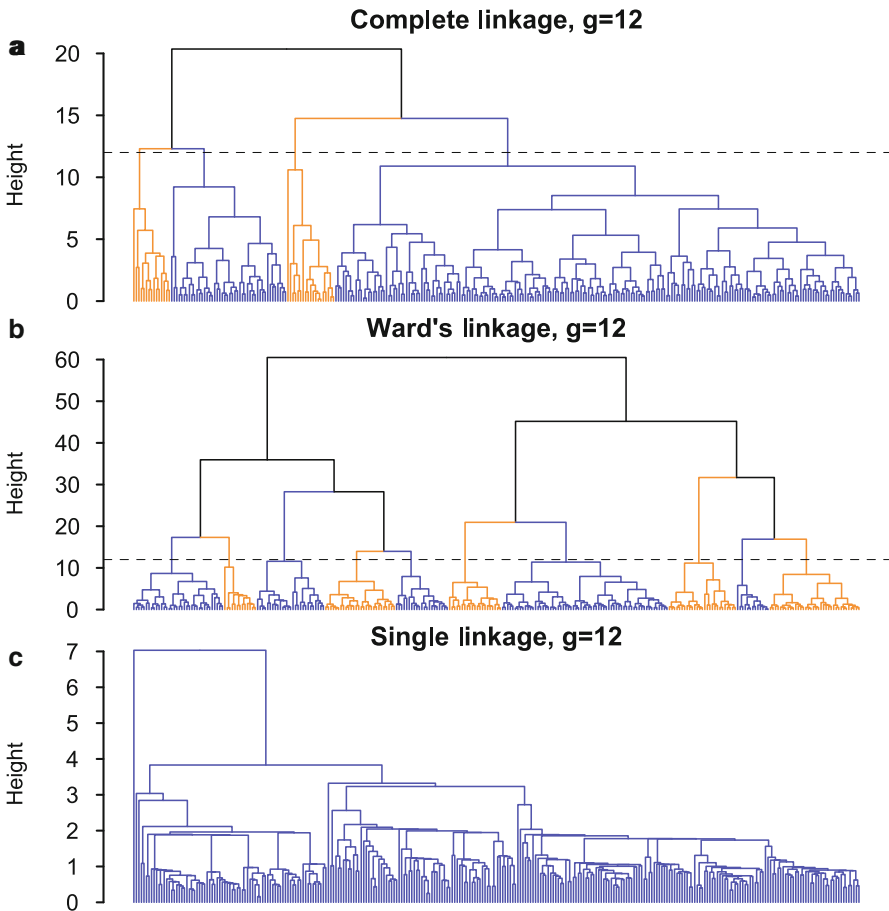

Fig. 14 Varying number of clusters depending on the linkage method used: (a) complete linkage, (b) Ward's linkage method, (c) single linkage. The dashed vertical line shows the cutoff tree height ($g = 12$)

where NC is the total number of pairs of objects from the same cluster, S is the sum of distances for the total number of object pairs in the same cluster (NC), S_{min} is the sum of the NC smallest distances between all the pairs of points in the entire data set, and S_{max} is the sum of the NC largest distances between all the pairs of points in the entire data set.

The C_{index} takes values between 0 and 1, where a small value indicates good clustering. In the case of the POP data set, there are 287 cluster sets ($k = n - 1$ values) possible, ranging from 2 to 287. When comparing C_{index} values for all the possibilities (Fig. 15), we can see that the lowest C_{index}^{287} value is 0, for a grouping consisting practically only of 287 one-element clusters. Such a grouping is, of course, meaningless and unusable. Therefore, in practice, we look for a global

Fig. 15 Number of clusters versus C_{index} value

minimum and the lowest possible number of clusters at the same time. In our case, when taking both of those condition into account, we arrive at $C_{index}^2 = 0.346$, found for $k = 2$. Therefore, two is the optimal cluster number.

Another numerical technique to determine the optimal cluster number is the silhouette index S_i , which is calculated individually for each sample (Eq. 6):

$$S_i = \frac{b_i - a_i}{\max \{a_i, a_i\}} \quad (6)$$

where a_i – is the average dissimilarity of i -th object to all other objects in the same cluster, and b_i – is the minimum of average dissimilarity of i -th object to all objects in other, closest cluster.

The silhouette width S_i can take values between -1 and 1 . For objects with high S_i value (close to 1), the cluster assignment is correct and accurate. For samples with silhouette value close to zero, the cluster assignment is ambiguous and imprecise. That is, the sample may have very well been assigned to another cluster instead, as it is equidistant from both clusters. Objects with S_i , value close to -1 , were wrongly classified (assigned cluster membership) and lie somewhere in between all the possible clusters.

The overall silhouette width is simply the average S_i value over all objects in the data set. When assessing the optimal number of clusters, the one with the maximum average silhouette width should be chosen. The silhouette index should be visualized in the form of a bar graph (silhouette plot), which, in addition to S_i values, shows cluster membership for each object (Fig. 16).

We used the silhouette plot to verify and compare the clustering for two different linkage methods: complete (Fig. 16a) and Ward's (Fig. 16b). In the case of complete linkage, 71 out of 288 POP samples (24.65% of the data) have S_i values below 0, meaning they could be considered as "misclustered" samples. Such a high number

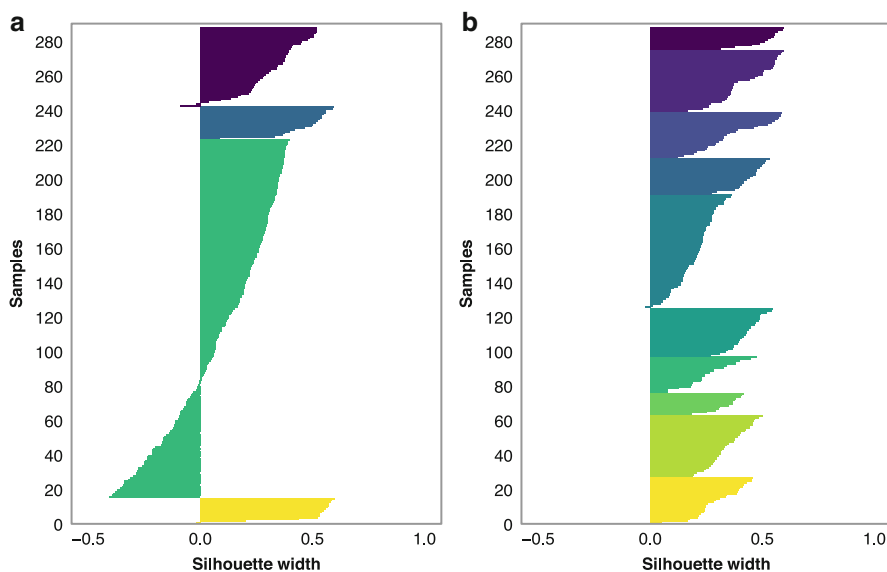

Fig. 16 Silhouette plots for three POP groups (PCN, PDDD, and PCDF). Comparison of the cluster number resulting from cutting dendrograms at height $g = 12$; (a) complete linkage, (b) Ward's linkage method. Groups have been color-coded for easier interpretation

of samples with negative silhouette values may suggest that the selected linkage method may not be the most suitable for the data at hand. This conclusion is further confirmed when looking at the silhouette plot for Ward's method (Fig. 16b). There is only one POP sample with the S_i value below 0, suggesting that this linkage method gives a more accurate separation of samples (grouping). It is worth noting that, if a data set contains a significant number of samples with S_i values below 0, it may also suggest that the selected features (variable) do not describe the underlying data structure in an appropriate manner.

There is also another way of comparing the cluster membership with the original POP group, illustrated in Fig. 17. Cluster 1 consists of several PCNs and two PCDFs. Cluster 2 contains the bulk of the data set, that is, the majority of samples from all three POP groups (PCNs, PCDDs, and PCDFs). Cluster 3 and 4 contain a small number of PCDDs and PCDFs. We see now why the silhouette analysis yielded 71 "misclustered" samples. The reason for such misclustering might be the use of too many variables (in this case, all 21 molecular descriptors), some of which might be redundant.

Despite the great number of cluster selection methods available, there is no single, universally applicable technique regarded as a golden standard. The silhouette index is a potential candidate for an effective and simple way of verifying the quality and performance of the selected clustering algorithm. Sadly though, even the most sophisticated cluster selection and identification method needs to be augmented by

Fig. 17 Hierarchical clustering grouping versus the original chemical groups. Euclidean distance and complete linkage method were used

user expertise and experience. No two research problems are alike; therefore, no universal, unambiguous approach to all of them can be found.

***k*-means**

The *k*-means algorithm is one of the most popular partitioning methods, mainly because of its ease of use. It groups data into a user-defined number of clusters, *k*. Each observation is assigned to the nearest cluster, the center of which is defined by the arithmetic mean (average) value of its points, the centroid (Myatt 2007). Among many available distance metrics (see Table 1) used in *k*-means, the Euclidean distance is the most popular one. The main advantage of this method is its clarity and simplicity, making its implementation an easy task.

Partitioning Algorithm

The algorithm consists of the following steps:

1. Setting up initial positions of the *k* cluster centers. This can be by supplying a set of predefined centroid coordinates or by random generation of cluster centers.

2. Calculating distances from each i -th element to each of the initial cluster centers using a selected distance metric.
3. Based on sample-center distances, assigning each i -th element to the nearest cluster.
4. Calculation of new cluster means (centroids) after object reassignment.
5. If the distance from the sample to the new cluster center is smaller than the distance to the prior cluster center, assignment of the sample to a new cluster with the closer centroid.
6. Iterating steps 2 thru 5 until permanent cluster assignment for all elements, i.e., until no element changes its cluster membership. It is possible to define the maximum number of iterations regardless of group reassignment.

When applying the k -means method to the POP data set, we observed some cluster overlap, as was the case with HCA results (Fig. 18).

In order to compare the clustering results from both the hierarchical and partitioning method, we calculated the silhouette for each sample (Fig. 19). We found that the overall performance of the k -means algorithm was better in terms of cluster homogeneity; only 7 out of all 288 samples (2.43 % of all data) have S_i below 0, which means only seven of them have been “misclustered.” It is a great improvement over the HCA clustering, which yielded 71 “misclustered” samples.

All partitioning methods divide the data into a set number clusters in a way that optimizes an objective function, that is, meets specific criteria set for the results prior

Fig. 18 The results of k -means clustering for selected POP groups (PCNs, PCDDs, PCDFs)

Fig. 19 The silhouette plot of k -means clustering results for the selected POP groups (PCNs, PCDDs, PCDFs)

to the analysis. In case of k -means, the algorithm minimizes the sum of squared errors, SSE (Han et al. 2012), the within-cluster sum of squared distances between each sample and cluster center (Eq. 7).

$$\text{SSE} = \sum_{k=1}^K \sum_{x_i \in C_k} \|x_i - c_k\|^2 \quad (7)$$

where k is the number of clusters, C_k is the k -th cluster, c_k is the centroid of the k -th cluster, and x_i is the sample.

It is important to note that a different choice of initial centroid positions may result in a different final assignment of points to clusters. Therefore, it is advisable to run the k -means algorithm a number of times, each with a different set of starting parameters, and then compare the results. This will ensure that the algorithm will reach the global optimal cluster configuration and will not get “stuck” at a local minimum of the objective function.

Advantages

- Effective when working with well-separated, compact clusters
- Computationally faster and more appropriate for large data sets than agglomerative hierarchical clustering
- Intuitive use and ease of interpretation, simplicity of implementation

Disadvantages

- The number of groups must be prespecified prior to running the algorithm
- Not robust to noisy data and outliers – might create nonoptimal clusters (solution: use k -medoids)
- Not applicable for categorical data (solution: use k -modes)

k -medoids

While the k -means algorithm is a very simple and useful tool, it is quite susceptible to extreme values or noise, which distort the mean value of the cluster. The k -medoids algorithm is a modified version of the k -means approach, where rather than averaging all objects in the cluster to find the center, the middle point, or medoid, is selected from among the samples in the cluster (Everitt et al. 2011). Thusly, the clusters are represented by their most centric element, instead of a numerical value that may not belong to the cluster at all. Medoids are defined as data points, whose average dissimilarity to all the objects in a cluster is minimal.

Both the k -means and k -medoids algorithms minimize the distance between all points inside a cluster and its designated center. The difference being that, unlike the k -means algorithm, k -medoids work with pairwise dissimilarities instead of Euclidean distances.

The k -medoids algorithm is analogical to that of the k -means method:

1. Selection of an initial set of k -medoids among the n objects in the data set.
2. Assignment of each object in the data set to the nearest (least dissimilar) medoid.
3. Searching for more optimal medoids. Iteratively for every medoid m , swapping (replacing) it with each one of the non-medoid objects o_i to check if it improves the total distance of the resulting clustering.

The suitability of the medoid “candidate” o_i is assessed by computing its average dissimilarity to all remaining non-medoid data points $o_{n \neq i}$. The objective function is the total cost of the new configuration, which is the sum of candidate-no-medoid differences E (Eq. 8).

$$E = \sum_{i=1}^n d(o_i, m) \quad (8)$$

where d is the dissimilarity measure, o_i is the non-medoid object, m is the medoid, and n is the number of objects in the data set.

4. Selection of new medoids o_i with the lowest cost of the configuration (Fig. 20).

k -modes

The k -means clustering algorithm cannot be applied to categorical data, as it relies on means to represent cluster centers, and nonnumerical data have no defined mean value. The k -modes, a variant of k -means, enables grouping categorical data by using the mode as the cluster center point. Moreover, it replaces the Euclidean

Fig. 20 The results of k -medoid clustering for the selected POP groups (PCNs, PCDDs, PCDFs)

distance metric from k -means with matching dissimilarity measure and a frequency-based approach to update cluster modes.

The k -modes algorithm consists of the following steps (Khan and Kant 2007):

1. Selecting k initial modes, one for each of the cluster.
2. Assigning every data object to the cluster whose mode is nearest to it. The proximity (dissimilarity) measure is based on the total number of mismatches d (Eq. 9). The smaller the number of mismatches, the more similar the two elements are.

$$d(X, Y) = \sum_{j=1}^m \delta(x_j, y_j) \quad (9)$$

$$\begin{cases} 0, & x_j = y_j \\ 1, & x_j \neq y_j \end{cases}$$

where X and Y are two categorical objects and m is the number of categorical attributes; x_j, y_j are categories for attribute j .

3. Computing new modes for all clusters.
4. Repeating step 2 thru step 3 until no data object has changed its cluster membership (Fig. 21).

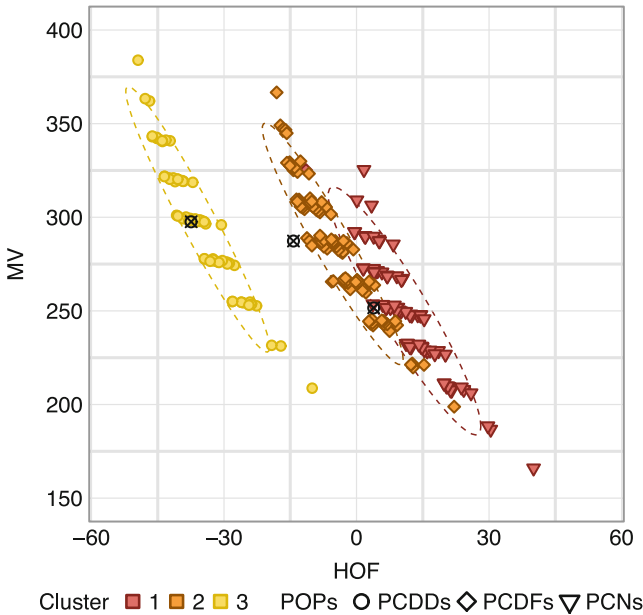

Fig. 21 The results of *k*-modes clustering for the selected POP groups (PCNs, PCDDs, CDFs)

PCA

When faced with a large, multidimensional set of variables, the sheer volume may make it difficult to see patterns and relationships hidden in its structure. Principal component analysis allows us to visualize and describe this structure by means of reducing the dimensionality of the data. This method is based on principal components (PCs), which are linear combinations of the original variables (PCs) and form a new multidimensional space onto which the original data set is projected.

The main applications of principal component analysis are:

- Projecting multidimensional (multivariate) data onto 2D and 3D scatterplots
- Wining out important information from data noise
- Converting data with high inter-variable correlation into a set of uncorrelated latent variables suitable for predictive modeling

In data mining, information content is measured in terms of data variance (Eq. 10).

$$\sigma^2(x) = \frac{\sum_{i=1}^m (x_i - \mu)^2}{n - 1} \tag{10}$$

where σ is the variance of variable x , μ is the mean value of variable x , n is the number of samples, and x_i is the i -th sample of variable x .

Variables with very little difference in values (low variability) are in fact non-informative and have little bearing on the clusters present in the data set. These variables are inadequate to the task of describing and explaining the underlying data structure, as they have very little influence on it.

In order to describe the linear relationship of two variables, we can calculate their covariance:

$$\text{cov}(x_k, x_l) = \frac{\sum_{j=1}^n (x_{jk} - \mu_k)(x_{jl} - \mu_l)}{n - 1}$$

where x_k and x_l are k -th and l -th variables, μ_k and μ_l are variable means, and n is the number of samples.

The covariance parameter is the measure of how much the values of two variables change together. If values of one variable change (e.g., increase) in the same direction as values of the other, i.e., the variables tend to show similar behavior, the covariance value is positive. Although, the covariance parameter, while a good indicator of whether two variables correspond to each other, is not suitable for a pairwise comparison of multiple variables with differing units and value ranges. In other words, the same numerical value of covariance might mean a highly proportional relationship for one pair of variables, whereas for another pair, it might signify a completely random one.

In order to unambiguously assess and compare the relationships between variables, we must calculate the correlation coefficient r (Eq. 11):

$$r(x_k, x_l) = \frac{\text{cov}(x_k, x_l)}{\sqrt{\text{var}(x_k)}\sqrt{\text{var}(x_l)}} \quad (11)$$

where x_k , x_l are k -th and l -th variables, σ_k^2 , σ_l^2 are variable variances, and cov is variable covariance.

The Workflow

Prior to the analysis, the data matrix \mathbf{X} requires preprocessing and the preferred data transformation methods is standardization (autoscaling). In the resulting autoscaled matrix \mathbf{Z} , all the variables have mean value μ equal to 0 and the standard deviation value σ equal to 1. Thus, any distorting effects caused by differing variable units have been negated.

The principal component analysis consists of the following steps (Jolliffe 2002; Brereton 2009):

1. Calculating the correlation-covariance (*corr-cov*) matrix \mathbf{C} . The diagonal elements of a covariance matrix are the variable variances, and the non-diagonal

elements are their covariance. For standardized (autoscaled) data, the covariance matrix is equivalent to the correlation matrix, and the diagonal elements are in fact the Pearson's correlation coefficients (Eq. 12):

$$\begin{aligned} \text{var}(x_k) &= 1 \\ \text{var}(x_l) &= 1 \\ r(x_k, x_l) &= \text{cov}(x_k, x_l) \end{aligned} \tag{12}$$

where x_k, x_l are k -th and l -th variables, cov is the variable covariance, and r is the variable correlation coefficient.

2. Computing the eigenvalues and eigenvectors of the correlation-covariance matrix. The eigenvalues λ indicate the amount of variance in data explained by their corresponding principal component. Each eigenvector contains a set of variable coefficients, i.e., loadings, \mathbf{P} . The resulting eigenvectors \mathbf{P} are arranged in descending order of their eigenvalues. The loadings express the variables' contributions to the principal components.
3. Calculating the scores. In order to obtain the positions of all data objects in the new principal component space, we must calculate the principal component scores, \mathbf{T} . The scores matrix is a product of autoscaled matrix \mathbf{Z} and the eigenvector matrix \mathbf{P} .
4. Determining the number of significant principal components, k . All principal components are mutually orthogonal – each one contains unique information that none of the others represent. Yet not all of the PCs are equally important. Considering that they are sorted in a descending order of information content, only a first selected few principal components will be useful in representing the data set.

The essence of the mathematical operations performed in order to obtain the principal components can be distilled into the scheme shown in Fig. 22. The rows in matrix \mathbf{Z} represent samples and the columns represent variables. The product \mathbf{TP} is an approximation of to the original data set, i.e., a model, the error of which is being represented by matrix \mathbf{E} .

Fig. 22 A schematic of PCA decomposition. k is the number of significant principal components, \mathbf{Z} is the $n \times m$ standardized data matrix, \mathbf{T} is the $n \times k$ scores matrix, \mathbf{P} is the $k \times m$ loadings matrix, and \mathbf{E} is the $n \times m$ error matrix

Table 4 Eigenvalues and explained variance of the principal components – POP data set

PC	Eigenvalue	Explained variance [%]	Cumulative explained variance [%]
1	11.36	54.07	54.07
2	5.75	27.40	81.48
3	2.25	10.70	92.18

19	0.00	0.00	100.00
20	0.00	0.00	100.00
21	0.00	0.00	100.00

Let us review the results of the principal component analysis of the POP data set. There are various methods of selecting the significant number of principal components (Jolliffe 2002):

1. The Kaiser criterion, which states that the significant PCs have eigenvalue greater than or equal to 1. In our case (Table 4), we would choose the first three principal components (PC1 thru PC3).
2. The minimum cumulative variance criterion is PC significance only for values over a certain arbitrary threshold, here 90%. Again, according to this rule, we should use the first three principal components (PC1 thru PC3, Table 4).
3. The “elbow method” based on the scree plot (Fig. 23a). The “elbow” in question is the point of the plot where the line reaches a plateau. We would make use of the first four principal components (PC1 thru PC4).

We choose to obey the Kaiser criterion, that is, to consider PC1, PC2, and PC3 as the most significant.

The next step is to visualize the data set in the space created by the principal components (Fig. 24), i.e., the *scores*. The principal component scores show the position of all samples projected onto the PC hyperspace. When analyzing the scores for the first three principal components, we noticed that PC1 and PC2 separate the

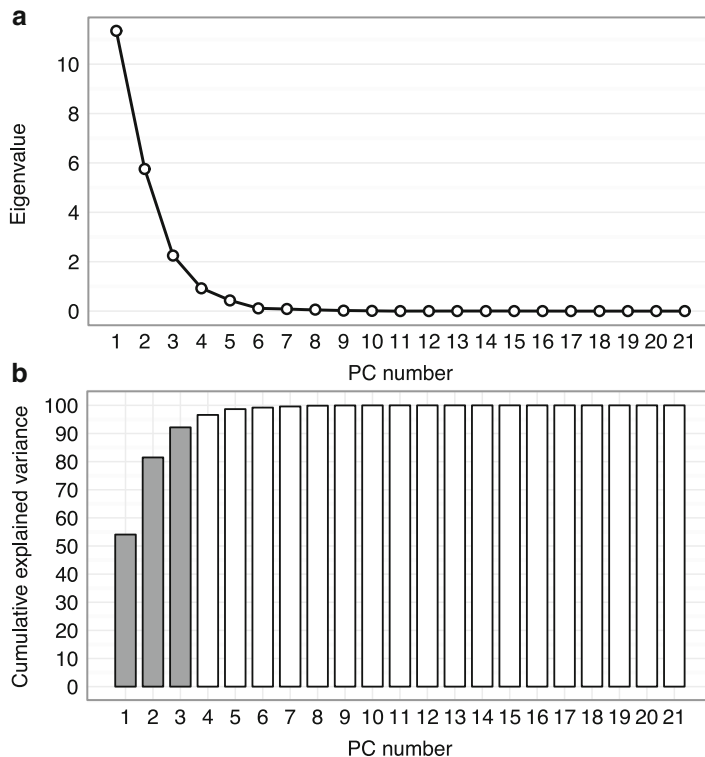

Fig. 23 Explained variance of principal components for selected POP groups (PCNs, PCDDs, PCDFs): (a) scree plot of the principal components (b) cumulative explained variance

three selected POP groups (PCNs, PCDDs, PCDFs) quite well (Fig. 24a), whereas PC1 in combination with PC3 (Fig. 24b) seems to highlight possible outliers. When juxtaposing PC2 and PC3, we see highly condensed group made up of PCN and PCDF samples as well as highlight one possible outlier (Fig. 24c).

Knowing that each principal component is a linear combination of all variables (descriptors) in the data set, we can use loadings to investigate which variables influence them most. A variable is considered to be highly influential on the principal component if the absolute value of its standardized loading is greater than 0.7 (Jolliffe 2002). What this means is that in reality, only the “highly influential” variables dictate the internal data structure.

According to PC1’s loading vectors presented in Fig. 25, the first principal component is determined by the size and bulk of the molecules. The contributing structural descriptors (nX, MW, MV, and SAS) are all correlated with PC1, that is the greater the PC1 values, the higher the number of chlorine atoms, molecular mass, volume, and surface. The polarizability (P) of a molecule and the core-core repulsion energy (Core) between two atoms are proportional to molecular size, which is expressed by the high loading values of these descriptors. Another characteristic dependent on the size of the molecular is its energy. Here, the proportion is inverse,

Fig. 24 Scatterplots of the first three principal component scores (PC1, PC2, PC3) – POP data set

as values of energy and heat are expressed in negative numbers, so the bigger the molecule, the lower (“more negative”) the energy value. This is expressed through a set of descriptors: the heat of formation (HoF), the electronic energy (EE), the total energy (TE) and the total energy of the corresponding cation (TEp), and the LUMO energy and Parr and Pople’s absolute hardness (Hard). All of them have negative loading values and are inversely correlated with PC1.

PC2 is determined by the molecule’s ability to donate and accept electrons. The higher the number of oxygen atoms (nO) and the overall number of atoms in the molecule (nAT), the more difficult it is to detach an electron, which is expressed by the inverse proportion between those two descriptors and the vertical ionization potential (VIP). VIP itself is calculated as the difference between the energy of a neutral molecule and the energy of the corresponding cation. According to the Koopmans’ theorem, the negative value of HOMO can be used as an approximation of the first ionization energy, so in fact, both descriptors express the same molecular feature. Conversely, the bigger the number of electronegative atoms (i.e., oxygen) in the molecule, the greater the overall electronegativity (EN). The chemical shift (Shift) is the equivalent of the electronegativity but with an opposite sign.

Fig. 25 First three principal component loadings (PC1, PC2, PC3) – POP data set

PC3 represents the symmetry of a molecule, expressed through the highest positive Mulliken charge on the molecule (Qp). The more symmetrical the structure of a molecule, the lower the partial charge.

SOM

Self-organizing (or Kohonen) maps, SOMs (Kohonen 2001), are a type of unsupervised partitive clustering methods. They are a quick and easy way of simultaneous data grouping and visualization, inspired by the biological information transport and processing system – neurons and synapses. SOMs are an ideal tool for analyzing large, complex data sets for which the standard scatterplot would be unreadable due to overlapping data points, the so-called overplotting.

SOMs preserve the topology, i.e., the relative distances between objects, of a high-dimensional variable space while mapping it onto a low-dimensional representation, usually a two-dimensional grid or plane.

Building SOMs

Determining the Structure

A Kohonen neural network consists of two layers (Kohonen 2001; Vesanto and Alhoniemi 2000):

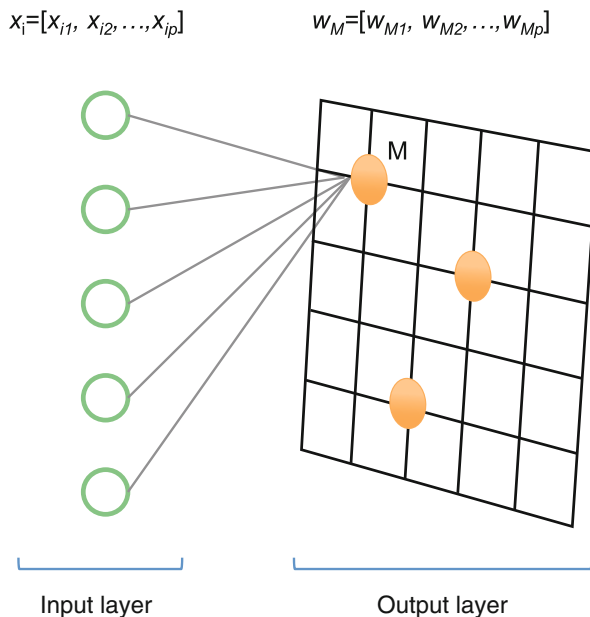

Fig. 26 A schematic representation of a SOM network

1. *Input layer* – an array of input vectors, each of length p , based on the original data matrix; every sample (object) is represented by an input vector containing its coordinates in the original p -dimensional variable space (Fig. 26).
2. *Output layer* – a grid with M nodes (neurons), where M is a number of nodes determined by the user; each node is represented by a *weight vector*, or *codebook vectors*, of length p , containing *weights*, i.e., values defining its location in the original p -dimensional variable space (Fig. 26).

In order to set up the computations, one must first define and select a number of parameters describing the shape, topology, and size of the network:

- (i) Number of neurons in the output layer
- (ii) Network shape: planar (1D line, 2D square or rectangle), cylindrical, and toroidal
- (iii) Neighborhood type: square, rectangular, or hexagonal
- (iv) Neighborhood radius
- (v) Neighborhood function: rectangular, Gaussian, cut Gaussian, triangular, and exponential
- (vi) Learning rate
- (vii) Number of iterations during the training process

All of these parameters influence the network's learning capabilities, quality of grouping, and computation time.

The *number of neurons* (i) defines the number of grid nodes present in the output layer. The greater the number of neurons in the network, the more complex problems it can solve and sharper the divide between resulting groups (clusters) – at the cost of computational resources. Choosing too many neurons may mean that a part of them will go unused when applied to low-complexity problems. Conversely, employing an insufficient number of neurons produces overlapping clusters and loss of information about class structure (Gemperline 2006).

The *network shape* (ii) describes the arrangement of the nodes in the network. The simplest possible shape resembles a 1D chain, where each link is a node. The more complex form can be a 2D map (arranged in a square or rectangular grid), 3D cylinder to a toroid. To ensure the equal number of neighbors for every neuron, it is best to use infinite, edgeless, toroidal form (Brown et al. 2009).

The *neighborhood type* (iii) is a method of counting the neighboring nodes. A square neighborhood means that a neuron has four nearest neighbors, a hexagonal neighborhood means that the neuron has six nearest neighbors, and a rectangular neighborhood means that a neuron has nine nearest neighbors.

The *neighborhood radius* (iv) is the number of surrounding nodes associated with the *winner neuron* or the *best matching unit*, *BMU*. This group of neurons, along with the BMU, is called a *neighborhood set*. The radius value decreases during each training cycle and is ultimately limited only to the winning neuron (Maimon and Rokach 2005).

The *neighborhood function* (v) controls the intensity of change of the weights in the codebook vectors from the neighborhood set, that is, the vectors closest to the winner neuron. The most popular is the Gaussian function, through which the winner neuron's weight adjustment is greater than that of the remaining neurons (Kohonen 2001; Brereton 2009; Brown et al. 2009).

The *learning rate* (vi) is responsible for the network's performance. It's a coefficient which can take values between 0 and 1 and determines how similar the neuron weight vectors will be to the *input pattern* or *sample vector*. The sample vector is a randomly chosen object (sample) from the original data matrix, serving as a reference point for the training vector at each iteration. The initial value of the learning rate decreases with each iteration, the increment determined by a linear or exponential function. Choosing a too small number may result in an insufficient weight correction and therefore limited adjustment of codebook vectors in the p -dimensional space. As a consequence, some of the map units may never get a chance to fully learn the input pattern and sufficiently represent all the samples (Brereton 2009; Brown et al. 2009; Hastie et al. 2009).

The *number of iterations* (vii) defines the amount of repetitions in the training cycle. Too small a number may result in an undertrained network, which in turn leads to incorrect clustering. On the other hand, a too large number may lead to waste of computational time and resources on redundant cycles when an optimal solution had been found a few repetitions prior. The recommended number of iteration samples is the number of map units multiplied by a factor of 500 (Brereton 2009).

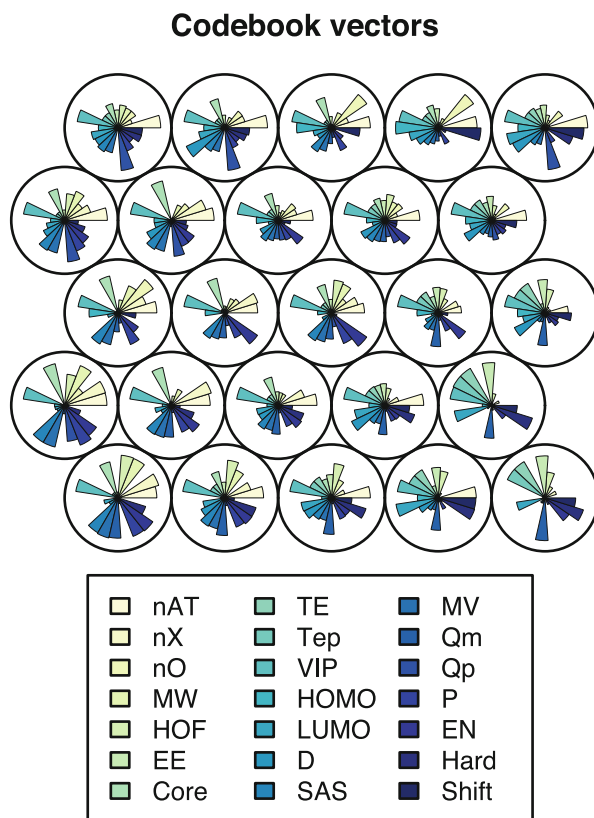

Fig. 27 Optimal weight vectors of the output neurons (*codebook vectors*) for the POP data set

Training

After establishing all the necessary parameters, it is time to begin training the network, that is, performing an iterative search of optimal weight vectors of the output neurons (Fig. 27). The steps of this iterative process are as follows (Vesanto and Alhoniemi 2000; Brereton 2009; Brown et al. 2009):

1. Initializing the network – selecting the initial weights for M neuron. The most common method is a random assignment of a value from a min-max range. The number of weights in the codebook vector is equal to the number of variables (features) in the original data set.
2. Selecting, usually at random, a single input vector.
3. Calculating the distances between the input vector and the neurons described by the codebook vector in the p -dimensional variable space. The choice of distance metric is left to the user – a list of the most commonly used one can be found elsewhere in this chapter.

Fig. 28 SOM U-matrix for the POP data set

4. Identifying the winner neuron, or best matching unit, the most similar, i.e., the closest, to the input vector.
5. Adjustment of neuron positions. There are two methods of repositioning the nodes in the variable space:
 - (a) *Winner takes all, WTA* – where only the winner neuron is relocated in the direction of the input vector
 - (b) *Winner takes most, WTM* – where the winner neuron and the associated neurons are repositioned in the vector space
6. Until the user-defined number of cycles has been reached, repeat the cycle starting from step 2.

Visualization

Once we have determined the optimal weights of the output layer neurons, we can graphically represent the relationships between them and the original data. There are several aspects of SOMs to visualize (Brereton 2009):

1. Unified distance matrix, or U-matrix, which illustrates the similarity between neurons (map units), color-coded by distance (Fig. 28). Based on the U-matrix, it is possible to identify outliers as well as clusters, as neurons representing similar samples are positioned at adjacent regions of the map.
2. Hit histogram, where the size of the map unit is proportional to the number of points (objects) represented by that neuron (Fig. 29).
3. Component planes, which demonstrate how a specific variable influences the SOMs (Fig. 30). Each variable from the data set can be represented on a separate component plane.

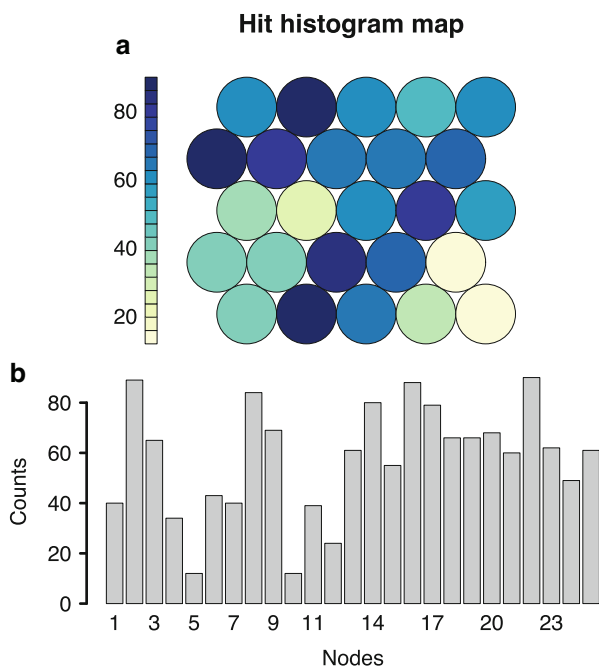

Fig. 29 Two ways of representing SOM hit histogram: (a) a 2D histogram, (b) a “classical” barplot

Fig. 30 SOM component planes: (a) molecular weight, MW, (b) vertical ionization potential, VIP

Quality Assessment

In order to assess the quality of the SOM training, there are a number of measures that can be employed. Among the most popular are the (Brereton 2009):

- MQE, mean quantization error. The average distance between each input vector and its best matching unit, calculated according to Eq. 13:

$$\text{MQE} = \frac{\sum_{i=1}^n d(x_i, w_c)}{n} \quad (13)$$

where $d(x_i, w_c)$ is the distance between input vector (x_i) and weight vector of the winner neuron; n is a number of input patterns.

- TE, topographic error. The ratio of all input vectors for which the first and second BMUs are not adjacent, calculated according to Eq. 14:

$$\text{TE} = \frac{\sum_{i=1}^n l(x_i)}{n} \quad (14)$$

where $l(x_i)$ is a function equal to 1 when the first and second most similar codebook vector of a particular sample is from adjacent units; otherwise, the function is 0.

Summary

In this chapter, we present selected unsupervised methods of data grouping and exploration. Each of them allows the user to focus on different aspects of the data. Hierarchical cluster analysis enables the initial exploration of the data structure and determining which objects are similar to each other in the context of various complexity levels. The k -means approach allows the user to more precisely identify group membership by an iterative search of the variable space and real-time improvement of clustering results. Thanks to modified versions of k -means, such as k -medoids and k -modes, we are able to handle outliers and categorical data with ease. With the help of robust exploratory methods, such as the principal component analysis and self-organizing Kohonen maps, it is possible to examine large data sets and determine which of the variable is crucial in describing underlying data structure.

Each of the presented techniques has some drawbacks and limitations, which is why user expertise and experience, as well as extensive knowledge on the inner workings of these approaches, are essential for effective data analysis. We hope that this chapter will serve as an overview and a starting point for further pursuit of knowledge in this field.

Abstract

The development of quantitative structure–activity relationship (QSAR) methods is going very fast for the last decades. OSAR approach already plays an important role in lead structure optimization, and nowadays, with development of big data approaches and computer power, it can even handle a huge amount of data associated with combinatorial chemistry. One of the recent developments is a three-dimensional QSAR, i.e., 3D QSAR. For the last two decades, 3D-OSAR has already been successfully applied to many datasets, especially of enzyme and receptor ligands. Moreover, quite often 3D QSAR investigations are going together with protein–ligand docking studies and this combination works synergistically. In this review, we outline recent advances in development and applications of 3D QSAR and protein–ligand docking approaches, as well as combined approaches for conventional organic compounds and for nanostructured materials, such as fullerenes and carbon nanotubes.

Introduction

The methodology of quantitative structure–activity relationship (QSAR) is very well described in various publications (Hansch et al. 1995; Kubinyi 1997a, b; Eriksson et al. 2003). In short, QSAR is a method to find correlations and mathematical models for congeneric series of compounds, affinities of ligands to their binding sites, rate constants, inhibition constants, toxicological effect, and many other biological activities, based on structural features, as well as group and molecular properties, such as electronic properties, polarizability, or steric properties (Klebe et al. 1994; Hansch et al. 1995; Karelson et al. 1996; Kubinyi 1997a, b; Perkins et al. 2003; Isayev et al. 2006; Martin 2009; Rasulev et al. 2010; Puzyn et al. 2011).

Thus, QSAR approaches have been used for many types of biological activities to describe correlations for series of drugs and drug candidates (Kubinyi 1997a, b; Veber et al. 2002). In addition, in case of available crystallographic data on the proteins, the QSAR models can be developed with the additional information from the three-dimensional (3D) structures of these proteins, interacting with drug candidates, by applying protein–ligand docking data for further QSAR analysis, or, if there is no data on 3D structure of protein, then developing QSAR based on three-dimensional features of investigated molecules (Moro et al. 2005; Ragno et al. 2005; Gupta et al. 2009; Hu et al. 2009; Sun et al. 2010; Araújo et al. 2011; Ahmed et al. 2013). The second approach was named as 3D3D QSAR approach (Wise et al. 1983; Cramer and Bunce 1987; Cramer et al. 1988; Clark et al. 1990). There are also many other multidimensional approaches, including 4D QSAR and 5D QSAR, but all of them are just extension of QSAR analysis to a number of conformations (orientations, tautomers, stereoisomers, or protonation states) per molecule, number of concentrations (dosages) per compound, etc (Lill 2007). In overall, when talking about 3D QSAR, computational chemists usually assume that the QSAR analysis takes into account a three-dimensional structure of the compound in minimal energy conformation and builds QSAR model based on various 3D fields generated (Kubinyi 1997a, b).

A first similar to 3D QSAR approach was developed by Cramer in 1983, which was the predecessor of 3D approaches called dynamic lattice-oriented molecular modeling system (DYLOMMS) that involves the use of PCA to extract vectors from the molecular interaction fields, which are then correlated with biological activities (Wise et al. 1983). Later authors improved this approach and by combining the two existing techniques, GRID and PLS, has developed a powerful 3D QSAR methodology, so-called comparative molecular field analysis (CoMFA) (Cramer et al. 1988; Clark et al. 1990). Soon after, CoMFA has become a prototype of 3D QSAR methods (Kim et al. 1998; Todeschini and Gramatica 1998; Podlogar and Ferguson 2000). CoMFA approach was then implemented in the Sybyl software (Tripos 2006) from Tripos Inc.

As it was mentioned before, a good and fruitful approach is a combination of molecular docking and 3D QSAR pharmacophore methods (Patel et al. 2008; Gupta et al. 2009; Araújo et al. 2011; Ahmed et al. 2013). Molecular docking and 3D QSAR model are the two potent methods in drug discovery process. Thus,

Fig. 1 A number of 3D QSAR-related papers for a period of 1990–2014 (Source – Web of Science)

virtual screening using 3D QSAR approaches followed by docking has become one of the reputable methods for drug discovery and enhancing the efficiency in lead optimization (Oprea and Matter 2004). The main advantage of this combined approach of 3D QSAR and pharmacophore-based docking is to focus on specific key interaction for protein–ligand binding to improve drug candidates. Ameliorate the selection of active compounds; it is optimal to use both methods like molecular docking and 3D QSAR modeling (Gopalakrishnan et al. 2005; Klebe 2006; Perola 2006; Pajeva et al. 2009; Yang 2010).

Since the time of development of 3D QSAR approach, a number of papers and methods' developments were published within 3D QSAR methodology. Let's briefly list and explain these methods here and then discuss recent developments and applications of these 3D QSARs in the assessment of the properties of biologically active compounds and development of drugs and drug candidates. As can be seen from Fig. 1, the number of publications related to 3D QSAR approach is increasing every year, from 3 to 5 publications in the beginning of 1990s to about 150 publications per year in 2014. It confirms the increasing importance of the method and successful application in many drug design projects.

Ligand-Based 3D QSAR Methods

To give some view on a number of 3D QSAR methods developed for the last three decades, we listed below the ligand-based 3D QSAR methods and very short description per each of them.

CoMFA – Comparative molecular field analysis is the method which correlates the field values of the structure with biological activities. CoMFA generates an

equation correlating the biological activity with the contribution of interaction energy fields at every grid point (Cramer et al. 1988). The method was developed in the 1988 and still one of the most popular ones for 3D QSAR modeling.

CoMSIA – Comparative molecular similarity indices analysis (CoMSIA) method, where the molecular similarity indices calculated from steric and electrostatic alignment (SEAL) similarity fields and applied as descriptors to encode steric, electrostatic, hydrophobic, and hydrogen bonding properties (Klebe et al. 1994). This is a development of CoMFA method and also gets very popular in drug design.

GRID – This method and program was designed as an alternative to the original CoMFA approach. It is actually a force field which calculates the interaction energy fields in molecular-field analysis and determines the energetically favorable binding sites on molecules of known structure. The method to some extent is similar to CoMFA, and it computes explicit nonbonded (or non-covalent) interactions between a molecule of known 3D structure and a probe (i.e., a chemical group with certain user-defined properties). The probe is located at the sample positions on a lattice throughout and around the macromolecule. The method offers two distinct advantages, one of them is the use of a 6–4 potential function for calculating the interaction energies, which is smoother than the 6–12 form of the Lennard-Jones type in CoMFA, and another advantage is the availability of different types of probes (Goodford 1985). Moreover, the program in addition of computing the regular steric and electrostatic potentials also calculates the hydrogen bonding potential using a hydrogen bond donor and acceptor, as well as the hydrophobic potential using a “DRY probe.” Later on, a water probe was included to calculate hydrophobic interactions (Kim et al. 1998; Kim 2001).

MSA – Molecular shape analysis (MSA) is a ligand-based 3D QSAR method which attempts to merge conformational analysis with the classical Hansch approach. The method deals with the quantitative characterization, representation, and manipulation of molecular shape in the construction of a QSAR model (Hopfinger 1980).

HASL – Inverse grid-based approach represents the shapes of the molecules inside an active site as a collection of grid points (Doweyko 1988). The methodology of this approach begins with the intermediate conversion of the Cartesian coordinates (x, y, z) for superposed set of molecules to a 3D grid consisting of the regularly spaced points that are (1) arranged orthogonally to each other, (2) separated by a particular distance termed as the resolution (which determines the number of grid points representing a molecule), and (3) all sprawl within the van der Waals radii of the atoms in the molecule.

Thus, the resulting set of points is referred to as the molecular lattice and represents the receptor active site map (like in CoMFA). Quite important that the overall lattice dimensions are dependent on the size of the molecules and the resolution chosen.

GRIND – This is the method that uses *grid-independent descriptors* (GRIND) which encode the spatial distribution of the molecular interaction fields (MIF) of the studied compounds (Pastor et al. 2000). In the anchor-GRIND method (Fontaine

et al. 2005), to compare the MIF distribution of different compounds, the user defines a single common position in the structure of all the compounds in the series, so-called anchor point. This anchor point does not provide enough geometrical constraints to align the compounds studied; however, it is used by the method as a common reference point, making it possible to describe the geometry of the MIF regions in a more precise way than GRIND does. The anchor point is particularly easy to assign in datasets having some chemical substituents well known as being crucial for the activity. In the anchor-GRIND approach, the R groups are described with two blocks of variables: the anchor-MIF and the MIFMIF blocks (Fig. 2). The first one describes the geometrical distribution of the R MIF relative to the anchor point, while the second one describes the geometrical distribution of the MIF within each R group. These blocks are obtained after the following steps: (i) every R group is considered as attached to the scaffold, (ii) the anchor point is set automatically on an atom of the scaffold, (iii) a set of MIF are calculated with the program GRID (Goodford 1985) as well as the shape field implemented in the program Almond (Cruciani et al. 2004), and (iv), as the last step, the blocks of descriptors

Fig. 2 Calculation of the anchor-GRIND descriptors for an ACE inhibitor with the anchor point set on the zinc binder sulfur atom (Reproduced with permission from reference (Fontaine et al. 2005) Copyright, American Chemical Society, 2005)

are computed from the anchor point and the filtered MIF. Authors also were able to incorporate a molecular shape into the GRIND descriptors (Fontaine et al. 2004).

GERM – Genetically evolved receptor model (GERM) is a method for 3D QSAR and also for constructing 3D models of protein-binding sites in the absence of a crystallographically established or homology-modeled structure of the receptor (Walters and Hinds 1994). As for many 3D QSAR datasets, the primary requirement for GERM is a structure–activity set for which a sensible alignment of realistic conformers has been determined. The methodology is the following: it encloses the superimposed set of molecules in a shell of atoms (analogous to the first layer of atoms in the active site) and allocates these atoms with explicit atom types (aliphatic H, polar H, etc., to match the types of atoms found in the investigated proteins).

CoMMA – Comparative molecular moment analysis (CoMMA) is one of the unique alignment-independent 3D QSAR methods, which involves the computation of molecular similarity descriptors (similar to CoMSIA) based on the spatial moments of molecular mass (i.e. shape) and charge distributions up to second-order as well as related quantities (Silverman and Platt 1996).

COMBINE – Comparative binding energy analysis (COMBINE) method was developed to make use of the structural data from ligand–protein complexes, within a 3D QSAR methodology. The method is based on the hypothesis where free energy of binding can be correlated with a subset of energy components calculated from the structures of receptors and ligands in bound and unbound forms (Ortiz et al. 1995; Lushington et al. 2007).

CoMSA – Comparative molecular surface analysis (CoMSA) is a non-grid 3D QSAR method that utilizes the molecular surface to define the regions of the compounds which are required to be compared using the mean electrostatic potentials (MEPs) (Polanski et al. 2002, 2006). In overall, the methodology proceeds by subjecting the molecules in the dataset to geometry optimization and assigning them with partial atomic charges.

AFMoC – Adaptation of fields for molecular comparison (AFMoC) is a close to 3D QSAR method that involves fields derived from the protein environments (i.e. not from the superimposed ligands as in CoMFA); therefore, it is also known as a “reverse” CoMFA (=AFMoC) approach or protein-dependent 3D QSAR (Gohlke and Klebe 2002). The methodology is the following: a regularly spaced grid is placed into the receptor binding site, followed by mapping of the knowledge-based pair potentials between protein atoms and ligand atom probes onto the grid intersections resulting in the potential fields. Thus, based on these potential fields, specific interaction fields are generated by multiplying distance-dependent atom-type properties of actual ligands docked into the active site with the neighboring grid values. In result, these atom-type-specific interaction fields are then correlated with the binding affinities using PLS technique, which assigns individual weighting factors to each field value.

CoRIA – Comparative residue interaction analysis (CoRIA) is a 3D QSAR approach which utilizes the descriptors that describe the thermodynamic events involved in ligand binding, to explore both the qualitative and the quantitative features of the ligand–receptor recognition process. The CoRIA methodology is

the following: initially it simply consisted of calculating the nonbonded (van der Waals and coulombic) interaction energies between the ligand and the individual active site residues of the receptor that are involved in interaction with the ligand (Datar et al. 2006; Dhaked et al. 2009). By employing the genetic algorithm-supported PLS technique (G-PLS), these energies then correlated with the biological activities of molecules, along with the other physiochemical variables describing the thermodynamics of binding, such as surface area, lipophilicity, molar refractivity, molecular volume, strain energy, etc.

SOMFA – Self-organizing molecular-field analysis, where firstly the mean activity of training set is subtracted from the activity of each molecule to get their mean-centered activity values. The methodology is the following:

- A 3D grid around the molecules with values at the grid points signifying the shape or electrostatic potential is generated.
- The shape or electrostatic potential value at every grid point for each molecule is multiplied by its mean-centered activity.
- The grid values for each molecule are summed up to give the master grids for each property.
- Then the so-called $SOMFA_{property,i}$ descriptors from the master grid values are calculated and correlated with the log-transformed molecular activities (Robinson et al. 1999).

kNN-MFA – This relatively new method was developed and reported in 2006 by Ajmani et al. (2006). kNN-MFA is a k-nearest neighbor molecular-field analysis. kNN-MFA adopts a k-nearest neighbor principle for generating relationships of molecular fields with the experimentally reported activity. This method utilizes the active analogue principle that lies at the foundation of medicinal chemistry. Like many 3D QSAR methods, kNN-MFA requires suitable alignment of a given set of molecules. This is followed by generation of a common rectangular grid around the molecules. The steric and electrostatic interaction energies are computed at the lattice points of the grid using a methyl probe of charge +1. These interaction energy values are considered for relationship generation and utilized as descriptors to decide nearness between molecules.

3D-HoVAIFA – This method based on three-dimensional holographic vector of atomic interaction field analysis (Zhou et al. 2007). Initially the holographic vector for 3D QSAR methods was developed by Zhou et al. in 2007 (Zhou et al. 2007). Proceeding from two spatial invariants, namely, atom relative distance and atomic properties on the bases of three common nonbonded (electrostatic, van der Waals, and hydrophobic) interactions which are directly associated with bioactivities, 3D-HoVAIF method derives multidimensional vectors to represent molecular steric structural characteristics.

CMF – This is a recently introduced continuous molecular-field approach (Baskin and Zhokhova 2013). This is a novel approach that consists in encapsulating continuous molecular fields into specially constructed kernels. It is based on the application of continuous functions for the description of molecular fields instead

of finite sets of molecular descriptors (such as interaction energies computed at grid nodes) commonly used for this purpose. The feasibility of using molecular-field kernels in combination with the support vector regression (SVR) machine learning method to build 3D QSAR models has been demonstrated by the same authors earlier (Zhokhova et al. 2009). Authors claim that by combining different types of molecular fields and methods of their approximation, different types of kernels with different types of kernel-based machine learning methods, it is possible not only to present lots of existing methods in chemoinformatics and medicinal chemistry as particular cases within a single methodology but also to develop new approaches aimed at solving new problems (Baskin and Zhokhova 2013). The example of application of this approach is described later in this chapter.

PHASE – This is a flexible system (engine) (Dixon et al. 2006) for common pharmacophore identification and assessment, 3D QSAR model development, and 3D database creation and searching (within Schrodinger Suite, Schrodinger, LLC). It includes some subprograms, for example, LigPrep, which attaches hydrogens, converts 2D structures to 3D, generates stereoisomers, and, optionally, neutralizes charged structures or determines the most probable ionization state at a user-defined pH. It also includes MacroModel conformational search engine to generate a series of 3D structures that sample the thermally accessible conformational states. For purposes of 3D modeling and pharmacophore model development, each ligand structure is represented by a set of points in 3D space, which coincide with various chemical features that may facilitate non-covalent binding between the ligand and its target receptor. PHASE provides six built-in types of pharmacophore features: hydrogen bond acceptor (A), hydrogen bond donor (D), hydrophobic (H), negative ionizable (N), positive ionizable (P), and aromatic ring (R). In addition, users may define up to three custom feature types (x, y, z) to account for characteristics that don't fit clearly into any of the six built-in categories. To construct a 3D QSAR model, a rectangular grid is defined to encompass the space occupied by the aligned training set molecules. This grid divides space into uniformly sized cubes, typically 1 Å on each side, which are occupied by the atoms or pharmacophore sites that define each molecule.

APF – In 2008, Totrov M (Totrov 2008) introduced atomic property fields (APF) for 3D QSAR analysis. APF concept is introduced as a continuous, multicomponent 3D potential that reflects preferences for various atomic properties at each point in space (Fig. 3). The approach is extended to multiple flexible ligand alignments using an iterative procedure, Self-Consistent atomic Property Fields by Optimization (SCAPFOld). The application of atomic property fields and SCAPFOld for virtual ligand screening and 3D QSAR is tested on published benchmarks. The new method is shown to perform competitively in comparison to current state-of-the-art methods (CoMFA and CoMSIA).

Thus, there are studies with comparative analysis of these two methods, PHASE and Catalyst (HypoGen). In 2007, Evans et al. (2007) provided a comparative study of PHASE and Catalyst methods for their performance in determining 3D QSARs and concluded that the performance of PHASE is better than or equal to that of Catalyst HypoGen, with the datasets and parameters used. Authors found that within

Fig. 3 An overall scheme of APF potentials visualized for an example of a drug molecule. Transparent blobs are the equipotential contours of various APF components (Reproduced with Permission from reference (Totrov 2008). Copyright John Wiley and Sons, 2008)

PHASE, the atom-based grid QSAR model generally performed better than the pharmacophore-based grid, and by using overlays from Catalyst to build PHASE grid QSAR models, they found evidence that better performance of PHASE on these datasets was due to the use of the grid technique.

Recent Advances in 3D QSAR Studies of Organic Compounds

In this part of the review, we discuss the new developments in the methods and in applications of 3D QSARs for various chemicals, including nanostructured materials.

For the last 10 years, there was mainly improvement of the 3D QSAR approaches which were developed before 2005. As it was discussed above, all these methods as CoMFA, CoMSIA, GRID, SOMFA, etc., were developed in late 1990s and early 2000s. Some of the recently introduced methods are just improvements of old approaches. However, if we take a look at applications, we can see many interesting publications and novel ligand developments which were designed by 3D QSAR and docking methods.

Recently, a quite interesting study was performed by Virsodia et al. (2008) on antitubercular activity of 23 substituted *N*-phenyl-6-methyl-2-oxo-4-phenyl-1,2,3,4-tetrahydropyrimidine-5-carboxamides by application of 3D QSAR using CoMFA and CoMSIA methods. Authors synthesized and assessed the antitubercular activity of all investigated compounds followed by comprehensive 3D QSAR modeling. Authors were able to get good models with $r^2 = 0.98$ and 0.95 , with cross-validated $q^2 = 0.68$ and 0.58 , respectively. Authors stated that CoMFA and

CoMSIA contours helped them to design some new molecules with improved activity (Virasodia et al. 2008).

Another CoMFA and CoMSIA study was performed by Ravichandran et al. (2009) by analysis of anti-HIV activity of 96 1,3,4-thiazolidine derivatives. Authors were able to get good models by CoMFA and CoMSIA with r^2 values 0.931 and 0.972, respectively. The predictive model was evaluated using a test set comprising of 17 molecules, and the predicted r^2 values of CoMFA and CoMSIA models were 0.861 and 0.958, respectively.

With the use of CoMSIA method, Kumar et al. (2009) were able to investigate novel Bignelli dihydropyrimidines with potential anticancer activity. The developed model based on 32 compounds showed a good statistical data – for training set $q^2 = 0.51$, while for the test set $r^2 = 0.93$.

Raparti et al. in 2009 (Raparti et al. 2009) reported a study based on a novel kNN-MFA 3D QSAR which was discussed above, where authors synthesized, assessed for antimycobacterial activity, and investigated by 2D and 3D QSAR approaches a series of ten compounds (4-(morpholin-4-yl)-N0-(arylidene)benzohydrazides). Authors were able to get satisfactory for this size of dataset statistical results for 3D QSAR model against *M. tuberculosis* (Raparti et al. 2009), with $r^2 = 0.910$ and $q^2 = 0.507$, respectively.

Another kNN-MFA 3D QSAR study was conducted and published by Kishore Jha et al. in 2010 (Jha et al. 2010). Authors evaluated the antimicrobial activity of 21 compounds by kNN-MFA combined with various selection procedures. As selection methods, authors were using simulated annealing (SA), genetic algorithms (GA), and stepwise (SW) forward–backward methods. The developed model showed satisfactory results for this kind of studies, with $q^2 = 0.696$ and $r^2_{pred} = 0.615$. Authors concluded that the 3D QSAR study has shown that less electronegative substituent would be favorable for the activity, and therefore the future molecules should be designed with less electronegative group to result in potentially active molecules.

Thus, recently, Araújo et al. (2011) studied acetylcholine inhibitors (AChEIs) by application of combined approach, so-called receptor-dependent 3D QSAR (RD 3D QSAR) where they investigated a series of 60 benzylpiperidine inhibitors of human acetylcholinesterase. They received two models with $r^2 = 0.86$, $q^2 = 0.74$ and $r^2 = 0.90$, $q^2 = 0.75$, which were validated by a combined GA-PLS approach. Based on those models, authors have proposed four new benzylpiperidine derivatives and predicted the pIC_{50} for each molecule. The good predicted potency of one of the benzylpiperidine derivatives indicated a promising potency for this candidate as a new HuAChE inhibitor (Araújo et al. 2011).

In another similar study, in 2009 Gupta et al. (2009) conducted an interesting combined study with protein–ligand docking-based 3D QSAR study of HIV-1 integrase inhibitors. They were using protein–ligand docking to identify a potential binding mode for 43 inhibitors at HIV-1 IN active site, and best docked conformation of certain molecule was used as a template for alignment. The docking was followed by CoMFA and CoMSIA modeling, and authors developed very good models with r^2_{cv} values of 0.728 and 0.794, respectively, and non-cross-

validated ones $r_{ncv}^2 = 0.934$ and 0.928 . This combined docking-based 3D QSAR methodology showed really good predictive abilities and can be employed further in the development of better inhibitors for various proteins.

One more study is worth to discuss where authors applied a combination of docking and 3D QSAR to reveal the most important structural factors for the activity. Here, Hu et al. (2009) applied a receptor- and ligand-based 3D QSAR study for a series of 68 non-nucleoside HIV-1 reverse transcriptase inhibitors (2-amino-6-arylsulfonylbenzotrioles and their thio and sulfinyl congeners). Authors were applying docking simulations to position the inhibitors into RT active site to determine the most probable binding mode and most reliable conformations. This complex receptor-based and ligand-based alignment procedure and different alignment modes allowed authors to obtain reliable and predictive CoMFA and CoMSIA models with cross-validated q^2 value of 0.723 and 0.760 , respectively. Authors concluded that the CoMFA steric and CoMSIA hydrophobic fields support the idea that bulkier and hydrophobic groups are favorable to bioactivity in the 3- and 5-positions of the B (benzene)-ring. At the same time, these groups are unfavorable in the 4-position. Also, the CoMSIA H-bond donor and acceptor fields suggest that the sulfide and sulfone inhibitors are more active than the sulfoxide ones due to H-bonding with protein residues.

It is good to mention here another interesting study where combination of methods is used, including molecular docking and 3D QSAR to develop a predictive QSAR model. Moro et al. (2006) suggested the use a combination of molecular electrostatic potential (MEP) surface properties (autocorrelation vectors) with the conventional partial least-square (PLS) analysis to produce a robust ligand-based 3D structure–activity relationship (autoMEP/PLS). They applied this approach to predict human A3 receptor antagonist activities. First of all, the approach was suggested as an efficient and alternative pharmacodynamic-driven filtering method for small-size virtual libraries. For this, authors generated a small-sized combinatorial library (841 compounds) that was derived from the scaffold of the known human A3 antagonist pyrazolo-triazolo-pyrimidines (Moro et al. 2005). This is another successful example of combined approach of docking and 3D QSAR to investigate and design active analogue compounds. Authors were using MULTIDOCK code that is part of MOE suite (Molecular Operating Environment (MOE) 2016) to get a conformational sampling and then calculate interaction energies using MMFF94 (Halgren 1996) and use it for further steps. The MEPs were derived from a classical point charge model: the electrostatic potential for each molecule is obtained by moving a unit positive point charge across the van der Waals surface, and it is calculated at various points j on this surface (Moro et al. 2006). Authors were able to test the approach by synthesizing several predicted potent compounds, and they found that all the newly synthesized compounds are correctly predicted as potent human A3 antagonists (Moro et al. 2006).

As a continuation of development of pharmacophore- and docking-based methods for QSAR, the novel PHASE code was developed. This updated code then was used by Amnerkar and Bhusari (2010) to investigate by 3D QSAR approach the anticonvulsant activity of some prop-2-eneamido and 1-acetyl-pyrazolin derivatives

Fig. 4 Common pharmacophore generated from the best PHASE hypothesis. Pharmacophore features are *red sphere* for hydrogen bond acceptors (A) with the *arrows* pointing in the direction of lone pair, *blue sphere* for positively charged group (P), and *orange torus* for aromatic rings (R). Compound 52 aligned to the pharmacophore for which *blue* indicates nitrogen, *yellow* refers to sulfur, *green* indicates chlorine, *gray* indicates carbon, and *white* refers to hydrogen (Reproduced with Permission from reference (Amnerkar and Bhusari 2010). Copyright Elsevier, 2010)

of aminobenzothiazole. They received a statistically significant 3D QSAR model with r^2 of 0.922 and q^2 of 0.814. The model was analyzed in order to understand the trends of investigated molecules for their anticonvulsant properties. Authors found the influence of electron withdrawing, hydrogen bond donor, and negative/positive ionic and hydrophobic groups to anticonvulsant activity. Authors believe that the derived 3D QSAR as well as clues for possible structural modifications will be of interest and significance for the strategic design of more potent molecules in the benzothiazoles as anticonvulsant agents. The pharmacophore hypothesis generated from PHASE-based 3D QSAR analysis can be seen in Fig. 4.

Another PHASE application for 3D QSAR study is published by Pulla et al. (2016). Authors applied a 3D QSAR approach to investigate silent mating-type information regulation 2 homologue 1 (SIRT1) which is the homologous enzyme of silent information regulator-2 gene in yeast. SIRT1 was believed to be overexpressed in many cancers (prostate, colon) and inflammatory disorders (rheumatoid arthritis); that is why it has good therapeutic importance. Authors conducted both structure-based and ligand-based drug design strategies with utilizing high-throughput virtual screening of chemical databases. Then an energy-based pharmacophore was generated using the crystal structure of SIRT1 bound with a small molecule inhibitor and compared with a ligand-based pharmacophore model that showed four similar features. A 3D QSAR model was developed and applied to generated structures. Among the designed compounds, Lead 17 emerged as a promising SIRT1 inhibitor with IC_{50} of 4.34 μ M and, at nanomolar concentration (360 nM), attenuated the proliferation of prostate cancer cells (LnCAP) (Pulla et al. 2016). The 3D QSAR model was developed using PHASE 3.4 module in Maestro 9.3 software

package developed by Schrodinger, LLC (Dixon et al. 2006). Docking studies were executed using Glide 5.8 module (Halgren et al. 2004). Authors were validating the pharmacophore model by set composed of 1055 compounds, consisting of 1000 decoys and 55 known inhibitors. The drug-like decoy set of 1000 compounds was obtained from the Glide module (Halgren et al. 2004). A final 3D QSAR model was developed based on dataset of 79 molecules reported as SIRT1 inhibitors in various literatures. To develop QSAR model, PHASE module relied on PLS regression applied to a large set of binary-valued variables. Each independent variable in the model originated from the grid of cubic volume elements spanning the space occupied by the training set ligands. Each training ligand in the training set was represented by binary code consisting of set of bit values (0 or 1) indicating the volume of elements occupied by van der Waals model of the ligand. Authors were able to get a very good 3D QSAR model with $r^2 = 0.953$, $q^2 = 0.908$, and $r^2_{ext} = 0.941$. A validated 3D QSAR model (for ADHRR 802) authors used to generate contour maps could help in understanding the importance of functional groups at specific positions toward biological activity. These insights could be known by comparing the contour maps of the most and least active compounds, as shown in Fig. 5 represented in Pulla et al. (2016). The blue and red cubes indicated the favorable and unfavorable regions, respectively, of the hydrogen bond donor effect, while light-red and yellow cubes indicated favorable and unfavorable regions, respectively, of the hydrophobic effect, and the cyan and orange cubes indicated favorable and unfavorable regions, respectively, of the electron-withdrawing effect. From Fig. 5a, it can be seen that the blue favorable regions of the hydrogen bond donor effect were nearer to the donor feature (D5) of the active molecule; however, it could also be observed that blue boxes were also concentrated at the amide group beside thiophen, thus illustrating that additional donor groups at these regions (blue cubes) could increase biological activity. At the same time, in the inactive molecule, red unfavorable boxes were observed around the donor feature (D5), inferring the biological inactiveness of the molecule. In the case of the hydrophobic effect, the light-red color cubes were seen surrounding the hydrophobic feature (H8, piperidine) of the active molecule, whereas the presence of few yellow unfavorable cubes indicated that these hydrophobic groups were not in the right position in the inactive molecule, illustrating the weak biological activity. Next, in the case of the electron-withdrawing effect of the active molecule, the favorable cyan cubes were seen around the acceptor feature (A3), and cyan cubes were also seen near the pyrimidine ring. It inferred that the acceptor features near the pyrimidine ring could further increase the bioactivity of the molecule. However, in the case of the inactive molecule, mostly unfavorable orange cubes were observed around the acceptor feature (A3), illustrating the importance of the electron-withdrawing group in the activity of lead molecules.

Thus, another new combined docking-based 3D QSAR study (Sun et al. 2010) was published with the analysis of influenza neuraminidase inhibitors. The study was based on novel 3D-HoVAIFA method which is based on three-dimensional holographic vector of atomic interaction field analysis (Zhou et al. 2007). As it was mentioned above, initially the holographic vector for 3D QSAR was developed by

Fig. 5 Contour maps of the most active and inactive molecules: (a) the hydrogen bond donor effect (most active), (b) the least active (*blue* denotes favorable, *red* denotes unfavorable), (c) the hydrophobic effect (most active), (d) the least active (*light red* denotes favorable, *yellow* denotes unfavorable), (e) electron-withdrawing effect (most active), and (f) the least active (*cyan* denotes favorable, *orange* denotes unfavorable) (Reproduced with Permission from ref (Pulla et al. 2016). Copyright, American Chemical Society, 2016)

Zhou et al. in 2007 (Zhou et al. 2007). The method uses atomic relative distance and atomic properties on the bases of three common nonbonded (electrostatic, van der Waals, and hydrophobic) interactions which are directly associated with bioactivities, and then 3D-HoVAIF method derives multidimensional vectors to represent molecular steric structural characteristics for further 3D QSAR analysis. Similarly to previous study, authors conducted a docking study to find the best docking pose and template for alignment. Then authors were able to get good models for a large dataset of 124 compounds and received the following correlation coefficients, $r^2 = 0.789$ and $r^2_{cv} = 0.732$. Authors claim that 3D-HoVAIFA can be applicable to molecular structural characterization and bioactivity prediction. In addition, it was showed that HoVAIFA and docking results are corresponding (Sun et al. 2010), which illustrates that HoVAIFA is an effective methodology for characterization of complex interactions of drug molecules.

One more docking-based 3D QSAR study was published in 2010 by Sakkiah et al. (2010), where authors conducted 3D QSAR pharmacophore-based virtual screening and molecular docking for the identification of potential HSP90 inhibitors. Authors were using HYPO and HYPOGEN (Li et al. 2000) 3D-based pharmacophore models. Based on the training set of 16 compounds, they were able to develop a good model using pharmacophore generation module in Discovery Studio (Accelrys) and then apply it for test set of 30 compounds. For predicting activity, the correlation coefficients of the model for training and test sets were 0.93 and 0.91, respectively. Authors then applied the model to virtual screening of about 160,000 compounds (Maybridge and Scaffold databases) and finally selected 1150 compounds for docking studies. Finally, 36 selected compounds were reported that were showing high activity based on 3D QSAR model and docking analysis. The developed HYPOGEN pharmacophore model that was used for virtual screening of 160,000 compounds from the databases is represented in Fig. 6.

Recently introduced and discussed previously the CMF approach for 3D QSAR analysis was successfully applied for several datasets (Baskin and Zhokhova 2013). Authors applied CMF approach to build 3D QSAR models for eight datasets through the use of five types of molecular fields (the electrostatic, steric, hydrophobic, hydrogen bond acceptor and donor ones). The 3D QSAR models were developed for the following datasets: 114 angiotensin converting enzyme (ACE) inhibitors, 111

Fig. 6 Catalyst HypoGen pharmacophore model, where H and HBA are illustrated in cyan and green, respectively (For interpretation of the references to color in this figure legend, the reader is referred to the web version of this article) (Reproduced with Permission from reference Sakkiah et al. 2010) Copyright Elsevier, 2010)

acetylcholinesterase (AChE) inhibitors, 163 ligands for benzodiazepine receptors (BZR), 322 cyclooxygenase-2 (COX-2) inhibitors, 397 dihydrofolatereductase (DHFR) inhibitors, 66 glycogen phosphorylase b (GPB) inhibitors, 76 thermolysin (THER) inhibitors, and 88 thrombine (THR) inhibitors. Authors were able to get good models and then compare statistical characteristics of the developed models with the same characteristics built earlier for the same datasets using the most popular 3D QSAR methods, CoMFA and CoMSIA, based on the use of molecular fields. Almost for all cases authors received better statistics than in original works. For example, for ACE inhibitors, CMF approach showed $q^2 = 0.72$, while CoMFA and CoMSIA showed 0.68 and 0.65, respectively. 3D QSAR for AChE inhibitors showed for CMF $q^2 = 0.58$, while for CoMFA and CoMSIA, it was 0.52 and 0.48, respectively. 3D QSAR for DHFR inhibitors showed for CMF $q^2 = 0.67$, while for CoMFA and CoMSIA, it was only 0.49 and 0.53, respectively. Other datasets also showed better results. The only one dataset, for BZR receptors, showed not so high values ($q^2 = 0.40$) but comparable with previous data received by CoMFA and CoMSIA – 0.32 and 0.41, respectively. As follows from the results presented in this paper, this particular implementation of the CMF approach provides an appealing alternative to the traditional lattice-based methodology. This method provides either comparable or enhanced predictive performance in comparison with state-of-the-art 3D QSAR methods, such as CoMFA and CoMSIA. Authors also discussed advantages and disadvantages of this approach. The potential advantages of this approach result from the ability to approximate electronic molecular structures with any desirable accuracy level, the ability to leverage the valuable information contained in partial derivatives of molecular fields (otherwise lost upon discretization) to analyze models and enhance their predictive performance, the ability to apply integral transforms to molecular fields and models, etc. The most attractive features of the CMF approach are its versatility and universality. At the same time, of the most serious limitations of the CMF approach, at least in its present form, comes from the mere nature of kernel-based machine learning methods. The amount of computational resources needed to calculate a kernel matrix scales as a square of the number of compounds in the training set. The mean amount of computational resources needed to calculate each element of a kernel matrix also scales as a square of the average number of atoms in molecules. As a result, it becomes impractical to build 3D QSAR models using a training set with more than 300 medium-sized compounds (Baskin and Zhokhova 2013).

Another interesting combination approach, Shih et al. (2011) in 2011 proposed a combination of 3D QSAR methods in order to get better predictivity for the dataset. Authors proposed for the first time a combination approach to integrate the pharmacophore (PhModel) (Taha et al. 2008), CoMFA, and CoMSIA models for B-RAF (RAF family of serine/threonine kinases). The PhModel was implemented by the program Accelrys Discovery Studio 2.1. First, authors established ten PhModels and used them to align diverse inhibitor structures for generating the CoMFA and CoMSIA models. Then the partial least-square (PLS) method was used and known B-RAF inhibitors to validate the prediction ability of CoMFA and CoMSIA models. Finally, the goodness of hit (GH) test score was used as a

benchmark for appraising the prediction ability of CoMFA and CoMSIA models to screen a compound database. Thus, ten PhModels were generated based on the 27 training set inhibitors. Each PhModel included four features: hydrogen bond acceptor (A), hydrogen bond donor (D), hydrophobic (HY), and ring aromatic (RA). The correlation coefficients for ten PhModels were very good and ranged from 0.964 to 0.902. Authors claim that this approach could be applied to screen inhibitor databases, optimize inhibitor structures, and identify novelty potent or specific inhibitors (Shih et al. 2011).

One more combination study for RAF inhibitors is worth to mention, was performed by Yang et al. (2011) which was applied as a combination of docking, molecular dynamics (MD), molecular mechanics Poisson–Boltzmann surface area (MM/PBSA) calculations, and 3D QSAR analysis to investigate the detailed binding mode between B-RAF kinases with the series of inhibitors and also to find the key structural features affecting the inhibiting activities. Considering the difficulty in the accurate estimation of electrostatic interaction, the QM-polarized ligand docking and GBSA rescoring were applied to predict probable poses of these inhibitors bound into the active site of B-RAF kinase. To obtain the rational conformation for developing 3D QSAR models, authors applied the docking-based conformation selection strategy. Moreover, the detailed interactions were analyzed on the basis of the results from MD simulation and the free energy calculation for two inhibitors with much difference in their activity. Authors investigated 61 B-RAF inhibitors and developed CoMFA and CoMSIA models with $r^2 = 0.917$ and 0.940, respectively. In result, the structure-based 3D QSAR models provided a further structural analysis and modifiable information for understanding the SARs of these inhibitors. The important hydrophobic property of the 3-substitution of B-ring was required to be type 2 inhibitors. The five substitutable positions of the C-ring could be further modified. Authors concluded that the results obtained from the combined computational approach will be helpful for the rational design of novel type 2 RAF kinase inhibitors.

Recently, a group of computational scientists is proposed to apply a protein–protein interaction (PPI) analysis to target small molecules. Since currently in worlds life science, research is going on the booming of interactome studies, a lot of interactions can be measured in a high-throughput way, taking into account that large-scale datasets are already available. Studies show that many different types of interactions can be potential drug targets. This boom of HTS studies greatly broadens the drug target search space, which makes the drug target discovery difficult. In this case, computational methods are highly desired to efficiently provide candidates for further experiments and hold the promise to greatly accelerate the discovery of novel drug targets. Thus, Wang et al. (2016) published a study where they suggested a new method, where inhibition of protein–protein interaction (PPI) analysis offered as a promising source to improve the specificity of drugs with fewer adverse side effects. They proposed a machine learning method to predict PPI targets in a genomic-wide scale. Authors developed a computational method, named as PrePPItar (Wang et al. 2016), to predict PPIs as drug targets by uncovering the potential associations between drugs and PPIs (Fig. 7). Authors investigated the

databases and manually constructed a gold-standard positive dataset for drug and PPI interactions. Their effort leads to a dataset with 227 associations among 63 PPIs and 113 FDA-approved drugs and allowed them to build models and learn the association rules from the data. Also, authors were able to characterize drugs by profiling in chemical structure, drug ATC-code annotation, and side-effect space and represent PPI similarity by a symmetrical S-kernel based on protein amino acid sequence. At the end, a support vector machine (SVM) is used to predict novel associations between drugs and PPIs. The PrePPiTar method was validated on the well-established gold-standard dataset. Authors found that all chemical structures, drug ATC code, and side-effect information are predictive for PPI target. Authors claim that PrePPiTar can serve as a useful tool for PPI target discovery and provide a general heterogeneous data-integrative framework.

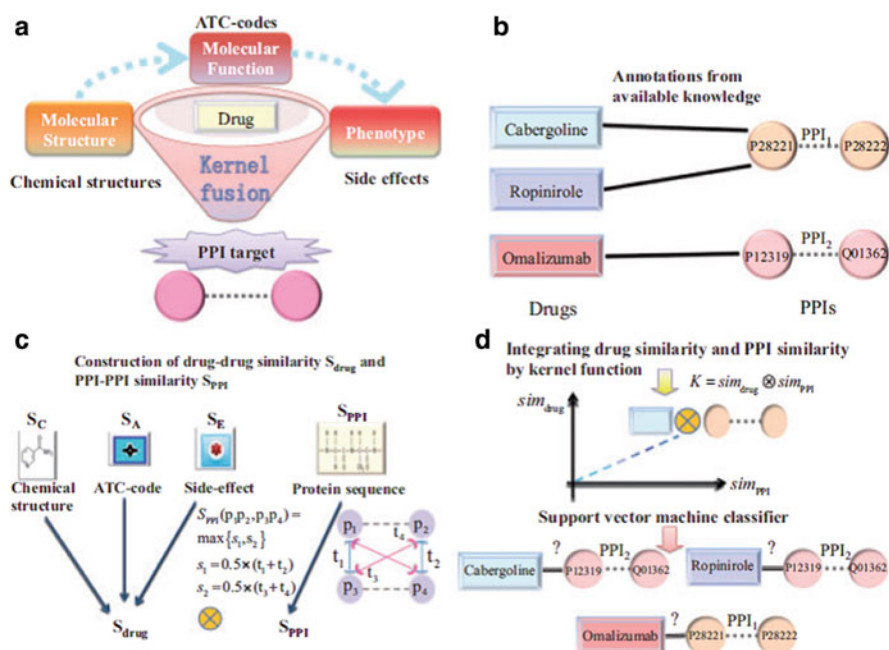

Fig. 7 The proposed flowchart for the PrePPiTar. **(a)** The schematic plot for our PrePPiTar method. PrePPiTar applies the kernel fusion method to integrate multiple information about drug, including chemical structure, ATC code, and drug side effect to detect the interactions between drugs and PPIs. **(b)** Collecting known associations between drugs and PPIs as gold-standard positives in a bipartite graph. **(c)** Calculating drug–drug and PPI–PPI similarity metrics, where t_i ; $i = 1; 2; 3; 4$ are the sequence similarity among proteins. **(d)** Relating the similarity among drugs and similarity among PPIs by Kronecker product kernel and applying SVM-based algorithm to predict the unknown associations between drugs and PPIs (Reproduced with Permission from reference (Wang et al. 2016). 3D QSARs and Combined Docking Studies of Nanostructured Materials

Nanomaterials are becoming an important component of the modern life and have been the subject of increasing number of investigations involving various areas of natural sciences and technology. However, theoretical modeling of physicochemical and biological activity of these species is still very scarce. The prediction of properties and activities of “classical” substances via correlating with molecular descriptors is a well-known procedure, by application QSAR and 3D QSAR methods. In spite of this, the application of QSAR for the nanomaterials is a very complicated task, because of “nonclassical” structure of these materials. Here, we would like to show first applications of the 3D QSAR and docking methods for nanostructured materials, which are nevertheless possible and can be useful in predicting their various properties and activities (toxicity).

Thus, one of the first 3D QSAR studies for nanostructured materials was provided in 2008. Durdagi et al. 2008a have investigated novel fullerene analogues as potential HIV PR inhibitors. It was the first work where authors analyzed nanostructured compounds for anti-HIV activity using protein–ligand docking and 3D QSAR approaches. Moreover, authors conducted MD simulations of ligand-free and the inhibitor bound HIV-1 PR systems to complement some previous studies and to provide proper input structure of HIV-1 PR in further docking simulations. Then, five different combinations of stereoelectronic fields of 3D QSAR/CoMSIA models were obtained from the set of biologically evaluated and computationally designed fullerene derivatives (where training set = 43 and test set = 6) in order to predict novel compounds with improved inhibition effect. The best 3D QSAR/CoMSIA model yielded a cross-validated r^2 value of 0.739 and a non-cross-validated r^2 value of 0.993. Authors stated that the derived model indicated the importance of steric (42.6%), electrostatic (12.7%), H-bond donor (16.7%), and H-bond acceptor (28.0%) contributions (Fig. 8). In addition, the derived contour plots together with applied de novo drug design were then used as pilot models for proposing the novel analogues with enhanced binding affinities. Interestingly, the investigated by authors the nanostructured compounds have triggered the interest of medicinal chemists to look for novel fullerene-type HIV-1 PR inhibitors possessing higher bioactivity. Later this year, authors published a second study for the same type of fullerene-based nanomaterials (Durdagi et al. 2008b).

The same group published in 2009 another study for fullerene derivatives but functionalized by amino acids (Durdagi et al. 2009). Authors used in silico screening approach in order to propose potent fullerene analogues as anti-HIV drugs. Two of the most promising derivatives showing significant binding scores were subjected to biological studies that confirmed the efficacy of the new compounds. The results showed that new leads can be discovered possessing higher bioactivity. Authors used docking approach together with MD simulations to get the best hits during the virtual screening.

Fig. 8 (i) CoMSIA steric/electrostatic contour maps of template compound 23 (template compound; has best binding affinity in training set, *left* on the figure) and compound 36 (has worst binding affinity in training set, *right* on the figure). Sterically favored areas are shown in *green* color (contribution level of 80 %). Sterically disfavored areas are shown in *yellow* color (contribution level of 20 %). Positive potential favored areas are shown in *blue* color (contribution level of 80 %). Positive potential disfavored areas are shown in *red* color (contribution level of 20 %). (ii) CoMSIA H-bond donor/H-bond acceptor contour maps of compounds 23 and 36 (on the *left* and *right* of the figure, correspondingly). The individual contributions from the H-bond donor and H-bond acceptor favored and disfavored levels are fixed at 80 % and 20 %, respectively. The contours for H-bond donor favored fields have been shown in *cyan* color, while its disfavored fields have been shown in *purple* color. H-bond acceptor favored fields have been shown in *orange* color, while its disfavored fields have been shown in *white* color (Reproduced with Permission from ref (Durdagi et al. 2008a). Copyright Elsevier, 2008)

In 2011, the same group provided further analysis to design better anti-HIV fullerene-based inhibitors (Tzoupis et al. 2011). In this study authors employed a docking technique, two 3D QSAR models, MD simulations and the MM-PBSA method. In particular, authors investigated (1) hydrogen bonding (H-bond) interactions between specific fullerene derivatives and the protease, (2) the regions of HIV-1 PR that play a significant role in binding, (3) protease changes upon binding, and (4) various contributions to the binding free energy, in order to identify the most significant of them. The CoMFA and CoMSIA methods were applied too, to build 3D QSAR models, where good correlation coefficients were received, for both methods, $r^2 = 0.842$ and 0.928 , respectively. Authors claim that the computed binding free energies are in satisfactory agreement with the experimental results.

Fig. 9 The binding site interactions. H-bonds formed by the ligand 42 in the binding site (Glide) (Reproduced with Permission from reference (Ahmed et al. 2013). Copyright, Royal Society of Chemistry, 2013)

Another group published in 2013 a study that conducted a comprehensive investigation of fullerene analogues by combined computational approach including quantum chemical, molecular docking, and 3D descriptors-based QSAR (Ahmed et al. 2013). Authors stated that the protein–ligand docking studies and improved structure–activity models have been able both to predict binding affinities for the set of fullerene- C_{60} derivatives and to help in finding mechanisms of fullerene derivative interactions with human immunodeficiency virus type 1 aspartic protease, HIV-1 PR. Protein–ligand docking revealed several important molecular fragments that are responsible for the interaction with HIV-1 PR (Fig. 9). In addition, a density functional theory method has been utilized to identify the optimal geometries and predict physicochemical parameters of 49 studied compounds. The five-variable GA-MLRA-based model showed the best predictive ability ($r^2_{train} = 0.882$ and $r^2_{test} = 0.738$), with high internal and external correlation coefficients.

Calvaresi and Zerbetto (2010) published a study where they investigated a fullerene binding with a set of proteins. Authors investigated about 20 proteins that are known to modify their activity upon interaction with C_{60} . The set was examined using PatchDock (Schneidman-Duhovny et al. 2005) software with an algorithm that appraises quantitatively the interaction of C_{60} and the surface of each protein. The redundancy of the set allowed them to establish the predictive power of the approach that finds explicitly the most probable site where C_{60} docks on each protein. About 80 % of the known fullerene-binding proteins fall in the top 10 % of scorers. The close match between the model and experiments vouches for the accuracy of the model and validates its predictions. Authors identified the sites

of docking and discussed them in view of the existing experimental data available for protein – C60 interaction. In addition, authors identified new proteins that can interact with C60 and discussed for possible future applications as drug targets and fullerene derivative bioconjugate materials.

Later, Calvaresi and Zerbetto (2011) published another study, where they investigated the binding of fullerene C60 with 1099 proteins. They one more time confirmed that hydrophobic pockets of certain proteins can accommodate a carbon cage either in full or in part. Since the identification of proteins that are able to discriminate between different cages is an open issue, they were interested in investigating much larger library than in Calvaresi and Zerbetto (2010). Prediction of candidates is achieved with an inverse docking procedure that accurately accounts for (i) van der Waals interactions between the cage and the protein surface, (ii) desolvation free energy, (iii) shape complementarity, and (iv) minimization of the number of steric clashes through conformational variations. A set of 1099 protein structures is divided into four categories that either select C60 or C70 (p-C60 or p-C70) and either accommodate the cages in the same pocket or in different pockets. Thus, authors also confirmed the agreement with the experiments, where the KcsA potassium channel is predicted to have one of the best performances for both cages.

Recently, in 2015 Xavier et al. (Esposito et al. 2015) published a QSAR study of decorated carbon nanotube investigation for toxicity using 4D fingerprints. In this study, authors proposed detailed mechanisms of action, relating to nanotoxicity, for a series of decorated (functionalized) carbon nanotube complexes based on previously reported QSAR models. Possible mechanisms of nanotoxicity for six endpoints (bovine serum albumin, carbonic anhydrase, chymotrypsin, hemoglobin along with cell viability, and nitrogen oxide production) have been extracted from the corresponding optimized QSAR models. The molecular features relevant to each of the endpoint respective mechanism of action for the decorated nanotubes are also discussed in the study. Based on the molecular information contained within the optimal QSAR models for each nanotoxicity endpoint, either the decorator attached to the nanotube is directly responsible for the expression of a particular activity, irrespective of the decorator's 3D geometry and independent of the nanotube, or those decorators having structures that place the functional groups of the decorators as far as possible from the nanotube surface most strongly influence the biological activity.

A docking study, together with comprehensive DFT analysis was conducted by Saikia et al. (2013). Authors made a simulation to analyze the interaction of nanomaterials with biomolecular systems, where they performed density functional calculations on the interaction of pyrazinamide (PZA) drug with functionalized single-wall CNT (fSWCNT) as a function of nanotube chirality and length, followed by docking simulation of fSWCNT with pncA protein. The functionalization of pristine SWCNT that facilitates in enhancing the reactivity of the nanotubes and formation of such type of nanotube-drug conjugate is thermodynamically feasible. Docking studies predicted the plausible binding mechanism and suggested that PZA loaded fSWCNT facilitates in the target-specific binding of PZA within the protein

following a lock and key mechanism. Authors noticed that no major structural deformation in the protein was observed after binding with CNT, and the interaction between ligand and receptor is mainly hydrophobic in nature. Authors anticipate that these findings may provide new routes toward the drug delivery mechanism by CNTs with long-term practical implications in tuberculosis chemotherapy.

In another study, Turabekova et al. (2014) published a comprehensive study of carbon nanotube and pristine fullerene interactions with Toll-like receptors (TLRs), which are responsible for immune response. Having experimental data on hands and conducting comprehensive protein–ligand investigation, authors were able to show that CNT and fullerenes can bind to certain TLRs. Authors suggested a hypothetical model providing the potential mechanistic explanation for immune and inflammatory responses observed upon exposure to carbon nanoparticles. Specifically, authors performed a theoretical study to analyze CNT and C60 fullerene interactions with the available X-ray structures of TLR homo- and heterodimer extracellular domains. This assumption was based on the fact that similar to the known TLR ligands, both CNTs and fullerenes induce, in cells, the secretion of certain inflammatory protein mediators, such as interleukins and chemokines. These proteins are observed within inflammation downstream processes resulting from the ligand molecule-dependent inhibition or activation of TLR-induced signal transduction. The computational studies have shown that the internal hydrophobic pockets of some TLRs might be capable of binding small-sized carbon nanostructures (5,5 armchair SWCNTs containing 11 carbon atom layers and C60 fullerene). High binding scores and minor structural alterations induced in TLR ectodomains upon binding C60 and CNTs further supported the proposed hypothesis (Fig. 10). Additionally, the proposed hypothesis is strengthened by the indirect experimental

Fig. 10 5,5 CNT-bound TLR1/TLR2 ECDs: (a) 5,5 CNT is bound to the TLR1 and TLR2 ECD interface dimerization area, (b) aligned structures of TLR2 ECDs before (*green* carbon atoms) and after (*blue* carbon atoms) the impact OPLS2005 refinement upon binding 5,5 CNTs. The orientation of two parallel entrance loops and the side chains of hydrophobic Phe349, Phe325, and Leu328 preventing the nanotube from intrusion are shown to be optimized (Reproduced with Permission from reference (Turabekova et al. 2014). Copyright, Royal Society of Chemistry, 2014)

findings indicating that CNTs and fullerenes induce an excessive expression of specific cytokines and chemokines (i.e., IL-8 and MCP1).

Later, this kind of interaction was confirmed by MD simulation provided by Mozolewska et al. (2014). In this study, authors made an attempt to determine if the nanotubes could interfere with the innate immune system by interacting with TLRs. For this purpose, authors used the following TLR structures downloaded from the RCSB Protein Data Bank: TLR2 (3A7C), TLR4/MD (3FXI), TLR5 (3V47), TLR3 (2A0Z), and the complexes of TLR1/TLR2 (2Z7X) and TLR2/TLR6 (3A79). The results of steered molecular dynamics (SMD) simulations have shown that nanotubes interact very strongly with the binding pockets of some receptors (e.g., TLR2), which results in their binding to these sites without substantial use of the external force.

Concluding Remarks

In this chapter, we discussed 3D QSAR and protein-ligand docking methods, recent applications of them for conventional organic compounds design and for nanostructured materials. Despite of all pitfalls, the 3D QSAR approach confirmed the importance and value in drug design and medicinal chemistry. Moreover, the combination of 3D QSAR approach with other techniques, including protein–ligand docking study gives much better improvement in predictions of biologically active compounds and drug candidates. The development of methods for 3D QSAR still continues, giving improved predictions for conventional organic compounds. Thus, we believe that 3D QSAR methods in the near future will be able to encode and model various organic and nanomaterials for important biological and physicochemical property improvement.

Abstract

Ontologies are structured controlled vocabularies which encode domain knowledge, backed by sophisticated logic-based computational tools. They enable knowledge-based applications which harness automated reasoning for inference and knowledge discovery. They also enable the semantic and standard annotation of large-scale data, which is ever relevant in the modern age of increased high-throughput data generation and sharing in scientific research. Established chemical ontologies include ChEBI, which encodes the structural classification of chemical entities of biological interest together with their roles. More recently, the chemical information ontology was created to standardize the annotation of cheminformatics software and descriptors. In this chapter, the technology, structure and applications of ontologies within cheminformatics will be described.

Introduction

Computational methods have become essential to filter, annotate, classify, and discover patterns within large-scale scientific data. *Ontologies* are frequently a core component of such large-scale data management platforms: computable logic-based representations of human domain knowledge in the form of structured controlled vocabularies with metadata, relationships, and other logical axioms (Courtot et al. 2011; Harland et al. 2011), which are used to annotate the data around those entities which are key to the domain of investigation.

Ontologies serve several distinct purposes in research data management. Firstly, ontologies provide standardized terminology and identifiers for entities in a domain, enabling different sources of data to be aggregated, e.g., across distinct databases. This is crucially important as the number of databases covering a domain of interest is proliferating. Secondly, they organize their entities hierarchically, which enables flexible aggregation around scientifically meaningful groupings. Such aggregation is an essential component in several approaches to data-driven scientific discovery. Thirdly, they facilitate browsing and searching, driving the interfaces of several bioinformatics databases. Further, their underlying representation in logical languages allows intelligent applications to perform complex reasoning tasks such as checking for errors and inconsistencies in the represented knowledge.

In the next section, we will introduce ontologies and describe the range of technologies that support and enable their representation. The following section will focus on several examples of ontologies within cheminformatics and chemistry and the application scenarios they are being used in. Finally, the last section will discuss limitations and currently open technological research areas.

What Are Ontologies?

Historically, ontology was a branch of philosophy concerned with studying the nature of existence or *what is*. More recently, the term “ontology” was conscripted as a name for the computational artifacts that were created to represent human domain knowledge for artificial intelligence within computer science, where the objective was to enable logic-based reasoning processes to derive inferences that simulate human reasoning processes (Gruber 2009). In parallel to these developments in computer science, within biology, the genomics revolution that followed the Human Genome Project saw the creation of ontologies as terminological artifacts to solve challenges in the integration of database content relating to genetic discoveries (The Gene Ontology Consortium 2000; Hunter 2002). These different intellectual paradigms all feed into the modern discipline of biomedical ontology or *bio-ontology* (Smith 2003).

Where large-scale data are labeled and populated using unconstrained text, different terminology is often used for similar or identical things. This is a feature of natural human language, and usually humans are easily able to resolve ambiguous

usages of terms and discrepant labels. However, due to the sheer volumes of research data being generated, it is necessary to develop computational methods of aggregating and aligning like with like. One approach to addressing this issue is to adopt shared standards for reference such that the same thing is always referred to by the same identifier. Harnessing such a standard across multiple different databases increases the value of the standard, allowing for easier cross-database integration and querying. Increasingly, computational research in the life sciences requires data integration across multiple disparate fields and methodological approaches in order to gain insight into underlying mechanisms. This is the case, for example, in the development of predictive models to enable personalized and translational medicine. Research results from diverse disciplines such as genetics, molecular biology, physiology, chemistry, psychology, and medicine have to be integrated in order to build a coherent picture of what is known in order to address key research gaps, and ontologies are meeting this need.

Ontologies are the structure in which the meaning of terminology used in a domain can be formalized around identifiers that can be embedded into databases. Bio-ontologies represent biological, medical, or chemical entities of scientific interest together with their properties and the relationships between them in a computationally processable language, enhanced with metadata such as definitions, synonyms, and references to databases. The longest-standing example of a successful ontology of this type is the Gene Ontology (GO) (The Gene Ontology Consortium 2000), which is used *inter alia* to unify annotations between disparate biological databases and for the statistical analysis of large-scale genetic data to identify genes that are significantly enriched for specific functions. The Gene Ontology describes the functions, processes, and cellular components of genes and gene products such as proteins.

Ontology Languages and Logical Expressivity

Bio-ontologies are developed and exchanged in a shared ontology language such as the Web Ontology Language (OWL), version 2 (Grau et al. 2008) or the OBO format (The Gene Ontology Consortium 2012). The OBO language was originally developed within the Gene Ontology project (The Gene Ontology Consortium 2000) in order to provide a more human-readable language than the then available technical alternatives that were the precursors of the OWL language. Many tools still rely on the OBO language with its relatively simple graph-based ontology structure, but the OBO and OWL languages are now largely interconvertible (Hoehndorf et al. 2010), and increasingly the community has moved toward OWL for ontology maintenance in order to harness better performance and expressivity.

OWL ontologies consist of several distinct components. These include classes, which are entities in the domain, known as “terms” in the OBO language, and properties, which are called “relations” in OBO. Metadata such as names and synonyms are included as annotations in OWL and have no impact on the logical

statements of the language. In OWL, properties represent relationships between individuals that belong to classes rather than classes themselves. As such, it is necessary to specify a quantification of each relationship for the members of the class represented by a property axiom. There are two options: a property axiom can express an *existential quantification*, which means that all members of the first class are related to *some* member of the other class, or a *value restriction*, which means that all members of the first class are *only* related to members of that other class (for the specified type of property). For example, you would capture the knowledge that organic molecules have as atomic parts some carbon atom with an existential quantification, since the molecules should have as atomic part some carbon atoms but may have parts of other types, while on the other hand you would capture the knowledge that hydrocarbons have only carbon and hydrogen as atomic parts with a value restriction, since such molecules may only have atomic parts of these types and not other types.

OWL is based on description logics (Baader et al. 2003), a family of decidable logical languages which has been developed specifically for the representation of large-scale terminological knowledge such as is found within large biomedical vocabularies. Logical languages are defined by the types of logical axioms that they support. OWL supports many different types of logical axiom, and the combination of axiom types that is used in a given ontology defines the expressivity of that ontology. There is a trade-off between expressive power and the tractability of a logic-based language. Increasing the expressivity of the language usually means that it takes longer to perform reasoning tasks.

The axiom types available in the OWL language include:

- Declaring and naming atomic classes
- OWL: Thing, the “top” class that is a superclass of every other class in an ontology
- OWL: Nothing, the “bottom” class that is a subclass of every other class in an ontology and is used to highlight inconsistent classes when there are errors in the ontology
- Intersection (AND)
- Union (OR)
- Negation (complement, NOT)
- One of (enumeration)
- Restriction on object property: some values
- Restriction on object property: all values
- Restriction on object property: minimum cardinality
- Restriction on object property: maximum cardinality
- Restriction on data property: value or value range

A powerful feature of OWL is the ability to perform *automatic classification* using fast-performing OWL reasoners. Reasoners are software toolkits that are able to compute inferences on the underlying logic used by the ontology – i.e.,

to logically deduce the consequences of the knowledge that is expressed, including inconsistencies. Examples of reasoners that work with OWL ontologies are Fact++ (Tsarkov and Horrocks 2006), Pellet (Sirin et al. 2007), and HermiT (Shearer et al. 2008), each of which supports different ranges of operators and may have different performance profiles on different reasoning tasks. For an example of OWL reasoning, given the following axioms:

IronAtom subclassOf MetalAtom (1)

MetallicCompound equivalentTo Compound and hasAtom
some MetalAtom (2)

IronOxide subclassOf Compound and hasAtom some IronAtom (3)

An OWL reasoner can automatically infer by 1–3 that IronOxide is a subclass of MetallicCompound.

OWL has *open-world* semantics, which means that inferences can only be drawn based on what is explicitly captured in the knowledge base and that absence of additional information has no implication that the information does not exist. For example, given a statement that *Square* and *Circle* are subclasses of *Shape* in a particular knowledge base, together with the knowledge that some entity *A* has_shape *C*, we nevertheless cannot infer that *C* is either a *Square* or a *Circle*, as we do not know anything about which other shapes may exist that have not been specified (i.e., in the open world). If this type of inference is desired, it is necessary to add an axiom specifying that all shapes are either squares or circles. This is called a *closure axiom*.

The primary editor that is used to maintain OWL ontologies is Protégé (2013). Protégé provides an extensive framework for ontology development, allowing editing of classes and properties, reasoner integration, and ontology visualization, as well as being supported by additional custom plug-ins.

Ontology Content and Metadata

Typically, modern bio-ontologies harness a relatively simple logical expressivity for a relatively large number of axioms (classes and relationships). In this fashion, they are able to encode a broad range of scientific knowledge in these domains – including chemistry – while remaining tractable for the reasoners and other applications, such as editors and visualizations. Alongside the classification hierarchy and the interrelationships between classes, each class typically contains some or all of the following metadata.

- A unique, usually alphanumeric, identifier. Each class is assigned an identifier which is persistent and unique. The identifier is usually stable with regard to changes in the remainder of the metadata associated with the class.

- A label which is also unique across the ontology and unambiguous with regard to what the class means. For an example of disambiguation that might be useful in assigning the label for a class, “nucleus” in an ontology of cellular components differs from “nucleus” in an ontology of atomic parts; thus, they might better be labeled “cell nucleus” and “atomic nucleus,” respectively.
- A definition, which should clearly indicate the intended meaning of the class, the way in which it is to be used, and how it differs from its immediate parent class.
- One or more synonyms or alternative labels. Synonyms may be used to capture short-hand descriptions which are in common use for reference to that class even if the synonym is not unambiguous. They may also capture acronyms or other ways in which the class may be referred to in text. Having a rich set of such synonyms for each class enhances the use of ontologies for automated text and data mining algorithms.
- One or more cross-references to databases and other ontologies. Cross-references enable broader data integration options than are supported by labels and synonym sets alone.

Chemical Ontologies and Their Uses

With an increase in availability of open, large-scale chemical data through public domain projects such as PubChem (Bolton et al. 2008), making sense of and effectively organizing the knowledge in databases for search and retrieval have become a challenge. Traditional large-scale data management methods in chemistry include chemical structure-based algorithmic and statistical methods for the construction of hierarchies and similarity landscapes. These techniques are essential not only for human interaction for effective browsing and searching but also in computational methods for interpreting raw data, such as for evaluating bioactivity patterns associated with chemical structural features (Wegner et al. 2012). Ontology-based classifications provide a complementary method for organizing data which is more text and knowledge oriented than algorithmic clustering methods (Hastings et al. 2012).

The Chemical Entities of Biological Interest (ChEBI) ontology (Hastings et al. 2013) was initially developed as a dictionary for chemical knowledge within biology, to enable standardization of chemical references within bioinformatics databases. This was facilitated by the use of semantics-free, stable identifiers for chemical entities, by the inclusion of extensive synonyms and cross-references, and through striving to represent community agreement about the entities in a given domain such that the ontology could be widely used. ChEBI is the primary chemical annotation and identification standard in many databases including MetaboLights (Haug et al. 2012), UniProt (The UniProt Consortium 2015), BioModels (Li et al. 2010), and Reactome (Matthews et al. 2009) and in the Gene Ontology (Hill et al. 2013). ChEBI is also listed as a secondary identifier for chemical information

in many additional databases such as KEGG (Kanehisa et al. 2006), DrugBank (Wishart et al. 2006), and HMDB (Wishart et al. 2009), enabling ontology-based data integration. As of August 2015, ChEBI contained just over 46,000 fully annotated entities.

ChEBI provides both a structure-based and a role-based sub-ontology, with roots “chemical entity” and “role,” respectively. The “chemical entity” sub-ontology of ChEBI classifies molecular entities into structure-based classes by virtue of shared structural features. Included in the chemical entity ontology are fully specified molecules such as transplatin and erythromycin A and structure-based classes such as steroid and macrolide. These molecules may be furthermore interrelated with structural relationships such as “is enantiomer of” and “is tautomer of” which are appropriate between entities with closely related chemical structures. Included in the “role” sub-ontology are drug usage classes such as antidepressant and antifungal; chemical reactivity classes such as solvent, acid, and base; and biological activity classes such as hormone (Batchelor et al. 2010). Where specific targets are known, the role ontology includes classes which refer to the target specifically, such as “cyclooxygenase inhibitor” for paracetamol. Chemical entities are linked to roles using the “has role” relationship.

An overview of the content of ChEBI showing selected classes from the structure-based and role-based classifications is illustrated in Fig. 1.

Fig. 1 Core divisions in content in the ChEBI ontology between chemical entities and roles. Fully specified chemical entities such as the vitamin pyridoxal are assigned role categories with the “has role” relationship and structure-based classes with the “is a” relationship. The “has part” relationship may be used to specify important parts of structure-based classes

Chemical Text Mining

ChEBI has been applied to many different use cases outside of its original remit as a dictionary for chemical references in biological databases. The extensive annotation of synonyms and other metadata has made it an important resource for chemical text mining – the automated identification of chemical mentions in text – as implemented in tools such as OSCAR (Jessop et al. 2011).

Results across many different research areas are reported in text in the primary scientific literature. However, the body of literature is growing at such a rate that it is not possible to read all the relevant articles in any field as the volumes are too. Computational processing to identify articles of interest or to amass all the literature in which specific entities are mentioned is increasingly necessary. In the literature, classes of chemical entities are often referenced rather than individual fully specified molecules. Biological knowledge such as the actions of enzymes in biological pathways is also often described in terms of classes or patterns of behavior rather than individual molecules. For this reason, ChEBI's extensive ontology of chemical classes has proved very useful in chemical text mining (Corbett and Murray-Rust 2006).

A closely related task is that of calculating systematic names for chemical structures and calculating structures from systematic chemical names. IUPAC naming rules for chemicals, as described in the “Gold Book” (McNaught and Wilkinson 1997) and implemented in tools including the open source Opsin (Lowe et al. 2011), provide a method for obtaining a systematic name from a given chemical structure and for interpreting a name to yield an appropriate chemical structure. However, it should be noted that systematic names can be unwieldy and lengthy and that chemists in many cases prefer to use shorter trivial names such as “caffeine.” Such trivial names cannot typically be automatically computed and need to be stored in a knowledge base such as ChEBI.

Text processing and knowledge discovery has been enhanced by implementations of ontology-based similarity for improved classification and text mining (Ferreira and Couto 2010). Similarity has many important applications in life science research. Most importantly, similar entities can be expected to behave similarly in similar contexts (Wegner et al. 2012). We can learn something about unknown entities and make predictions about their behavior, by examining knowledge about similar entities. But for this endeavor to yield the best results, the measures used for similarity must have real domain relevance.

Semantic Similarity

Semantic similarity is named as such because it encodes a measure of similarity that uses knowledge over and above the purely structural features of an entity. For example, the two words “cell” and “cell” are structurally identical, but can have very different semantics – the one means “cell” as in organism parts and the other

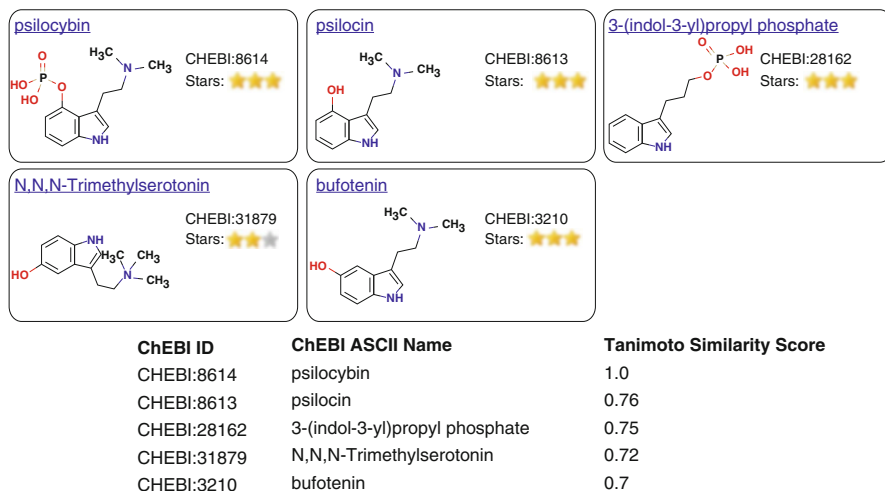

Fig. 2 The chemical structures for psilocybin (CHEBI:8614) and those structures in ChEBI which are similar including psilocin (CHEBI:8613) and 3-(indol-3-yl)propyl phosphate (CHEBI:28162)

“cell” as in for prisoners. Ontologies aim to encode relevant information about the meaning of the entities they represent, through the relationships which are captured for a given class and, in the case of more expressive OWL ontologies, additional features of the logical axioms. In chemistry, the most commonly used measure for calculating similarity between chemical entities uses features of the chemical structure to compute a similarity metric. Representations of chemical structures include the atoms and bonds which constitute the entity, with information about their types and how they are locally arranged. Similarity algorithms pick out features from such representations and binarize them into a fixed-length bit array (a string of 1’s and 0’s) or “fingerprint,” which is then able to be rapidly compared for similarity with the fingerprint from another structure using, for example, a Tanimoto score.

Psilocybin (CHEBI:8614), psilocin (CHEBI:8613), and 3-(indol-3-yl)propyl phosphate (CHEBI:28162) are structurally very similar, and their Tanimoto score along with other similar structures is given in Fig. 2.

ChEBI’s similarity search function gives the similarity score between psilocybin and psilocin at 76 % and between psilocybin and 3-(indol-3-yl)propyl phosphate at 75 %.

Different databases might give different pairwise scorings depending on the underlying features used in the comparison. A human chemist may also give different judgments about the relative similarity of two pairs of compounds depending on the application they have in mind. However, it is clearly not possible to algorithmically make a significant distinction based on a 1 % difference in a similarity metric. While 3D shape-based similarity measures may yield better results in some cases, many organic molecules are flexible and thus may adopt multiple conformers, hindering computation of shape-based similarities. In terms of a semantic similarity

using the ontology relationships captured in ChEBI, however, we can immediately observe rather strong differences between these two pairs. While psilocybin and psilocin are both classified as tryptamine alkaloids (CHEBI:48274) and as having the role hallucinogen (CHEBI:34599), 3-(indol-3-yl)propyl phosphate has immediate structural parent monoalkyl phosphate (CHEBI:25381) and no role annotated. In terms that have strong biological relevance, then, the first pair is much closer in similarity than the second pair. This is not reflected in the structural similarity measure, but would be reflected in a semantic similarity measure using the relationships asserted in the ChEBI ontology. A hybrid similarity metric for chemical entities, called Chym, has been developed, which combines a structure-based similarity measure with a semantic similarity measure based on ChEBI (Ferreira and Couto 2010). In application of Chym to several classification problems, the authors have shown that their hybrid measure yields better (more biologically meaningful) results than a purely structural similarity measure. Recently, the enhanced logical expressivity (disjointness axioms) within ChEBI has been harnessed to implement an improved semantic similarity metric for chemicals (Ferreira et al. 2013).

CMPSim (Grego et al. 2010) is another web tool that also uses the information contained in the ChEBI ontology in order to calculate similarity. In this case, the tool is used to quantify similarity between metabolic pathways. This tool can be used to quickly find the semantic similarity between KEGG pathways. To do so, a pathway is mapped into the ChEBI compounds that participate in it, and then the two pathways are compared by comparing the ChEBI similarities. Within systems biology in general, ChEBI is extensively used for model and pathway annotations (Courtot et al. 2011), and the ontology relationships have furthermore been used to help automate gap filling in the process of the creation of whole-genome metabolic models (Swainston et al. 2011).

Enrichment Analysis

Data that are annotated with ontologies are organized by the structure of the ontologies into groupings which can serve as the categories around which several statistical data mining techniques can operate. One technique that makes use of the structure of ontologies in that way is *ontology-based enrichment analysis*. In an ontology enrichment analysis, an annotated dataset is compared to a background set to find whether some ontology categories are statistically overrepresented in the annotated data as compared to the background. This technique has found widespread use in functional genomics, in which sets of genes annotated in the Gene Ontology are compared to the full set of GO annotations to determine which functional ontology categories are over- or underrepresented in the experimental sample. There are many variations on this theme in different implementations. For example, the genes of interest may be selected as those overexpressed in a particular microarray experiment, and the background reference set may be the full set of genes present in the microarray experiment or may be the full set of genes annotated for a given species (Huang et al. 2009).

It is possible to perform ChEBI role enrichment for metabolic data with MBRole (Chagoyen and Pazos 2011). MBRole performs enrichment analysis from ChEBI role annotations which are grouped into biological roles, chemical roles, and applications. MBRole is also able to perform pathway enrichment analysis using KEGG pathways. Data mining approaches have also been used to establish links between drugs and pathways (Hoehndorf et al. 2012). In this utility, a large-scale mapping between disease pathways and chemicals that may be used to perturb them is provided through the integration of information about drugs, genes, diseases, and pathways. The approach uses a multi-ontology enrichment analysis with a human disease ontology and a chemical ontology in combination.

To aid in the analysis of chemicals in large-scale metabolomics or other -omics measurements, ChEBI has been used to implement a web-based enrichment analysis tool, BiNChE (Moreno et al. 2015). The tool provides the option of doing enrichment analysis with the ChEBI role branch, structure branch, or both. It allows three main types of enrichment analysis: weighted, plain, and fragment. The plain analysis takes as input a list of ChEBI identifiers and uses a binomial test to determine ontology class enrichment. For the weighted analysis, the tool takes as input a list of ChEBI identifiers together with an accompanying set of numbers from 0 to 1, which can represent intensities or any measurement that reflects differential relevance of the small molecules in an experiment. This type of enrichment uses an implementation of the SaddleSum algorithm to compute differential enrichment based on not only the input ChEBI entries but also their weights. Fragment analysis is a special case of weighted analysis, in which only the chemical structure branch of the ontology is used; the input data for this type of analysis would typically come from fragmentation mass spectrometry experiments. In all cases, results are corrected for multiple hypothesis testing. The results of the analysis are displayed in an interactive graph that can be exported as a high-resolution image or in network formats. An example is illustrated in Fig. 3.

Cheminformatics and the Semantic Web

The Semantic Web is a worldwide technological movement which aims to bring data online in readily interpretable, semantically annotated, integrated, and interlinked form. Underlying this effort are a series of technologies including a standard format for representing data as triples (subject-predicate-object, RDF), a standard web-enabled identifier formats (URIs), and the OWL ontology technology for embedded semantics. In this context, chemical and cheminformatics data are becoming available in large interlinked repositories. For example, the PubChem database has recently been made available as linked data in the RDF format (Fu et al. 2015), as was the ChEMBL database (Willighagen et al. 2013) and various other EBI databases (Jupp et al. 2013). Aggregate stores of linked data on the semantic web include Bio2RDF (Belleau et al. 2008) and Chem2Bio2RDF (Chen et al. 2010). Publishing data in this fashion allows for remote usage, without the additional burden of heterogeneous data integration across different database models. Semantic

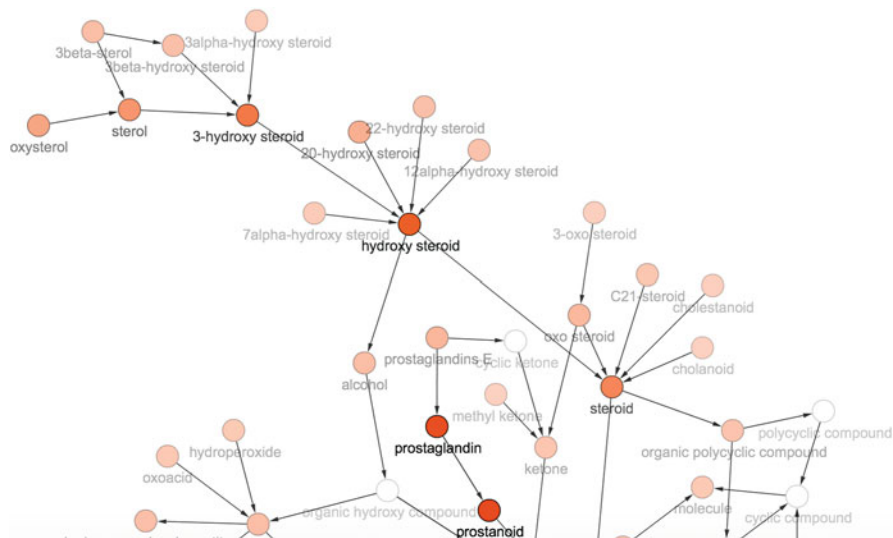

Fig. 3 A portion of a sample output graph of a BiNChE plain enrichment analysis in the structure classification branch of the ontology

web-enabled software is able to fetch the desired data from distributed repositories that support cross-resource query answering over multiple sources.

Annotation of the data using standard vocabularies is key to the success of semantic integration. This is because different vocabularies or data models may refer to the same data types with different labels or identifiers. For example, in cheminformatics, molecular weight as a property of a molecule may be referred to in one database as “MWEIGHT,” while in another it is referred to as simply “WEIGHT” or even “MASS” and in another as “MOLWEIGHT” and so on. These different labels obscure the fact that the data is comparable and should be integrated, thus “hiding” portions of such data from algorithmic processes or forcing a tedious manual disambiguation step. On the other hand, multiple implementations of an algorithm may use the same terminology while nevertheless producing different outputs due to differing heuristics, optimizations, errors, or differences in the interpretation of relevant concepts. This can lead to incorrect deductions when the results of calculations are made available under the same terminological label without further provenance as to which implementation was used to generate the data. A key challenge that arises in this context is thus managing all aspects of the provenance of information published online.

To standardize the annotation of calculated or measured chemical data in the context of the semantic web, the chemical information (CHEMINF) ontology was developed (Hastings et al. 2011). Both measurement and prediction of property values are ways to derive information about chemical or biological properties and represent them so that they can be accessible for further research. Openly published on the semantic web, such values can be reused for diverse subsequent

analyses. It is important, however, to fully detail the algorithms which were used to generate calculated property values and/or the experimental conditions under which the data were generated. To address this need, the CHEMINF ontology includes entities representing chemical graphs and the various formats for encoding them; descriptors, with definitions and axioms describing what they are specifically about; algorithms and their software implementations, with axioms describing their inputs and outputs; and chemical qualities, which are needed to specify exactly which quality a chemical descriptor is describing.

CHEMINF was one of the ontologies used in the semantic annotation of the large-scale PubChem database in RDF (Fu et al. 2015). As a deposition-based aggregation archive database, PubChem calculates and represents many different types of chemical property, identifier, and other attributes, organized around a standardized chemical structure. For example, PubChem calculates 3D coordinates, physical properties (e.g., molecular weight, XLogP3), and descriptors (e.g., InChI, SMILES, IUPAC names). Furthermore, all such information that is provided by depositors from their own data collections are faithfully represented in PubChem. There is thus a pertinent need for the standard representation of, firstly, the type for each data item, taken from the CHEMINF descriptor classification; secondly, the algorithm and toolkit used (where applicable) to calculate the descriptor in question, taken from the CHEMINF software and algorithm classification; and, finally, the source of the data (where not internally calculated), taken from a CHEMINF vocabulary of database names. All entries in CHEMINF have dereferenceable URIs, that is, their identifiers are themselves linked data ready.

Other ontologies used in the PubChem RDF implementation include ChEBI for chemical classification, the Units Ontology (UO) (Gkoutos et al. 2012) for the accurate representation of standard units of measure, and the Citation Typing Ontology (CiTO) (Shotton 2010) for the representation of associated references from the literature.

Limitations and Research Areas

There is a fundamental challenge for the comprehensive integration of chemical structure-based algorithms with logic-based OWL reasoning, in that the OWL language is not able to represent the full detail of cyclic structures, including therefore the actual structures of molecular entities containing rings (Magka et al. 2011). Given this limitation, progress has been made to partially represent aspects of chemical structure and expose those to OWL-based reasoning. One of the first applications of OWL for chemical classification was Villanueva-Rosales and Dumontier (2007), in which functional groups were encoded within an OWL ontology used for group-based automated ontology classification. Care, however, had to be taken to only encode the detail of the functional group structures insofar as they were not cyclic. The same team extended this work to include axiomatic definitions of lipid classes in the Lipid Ontology (Chepelev et al. 2011). In both of these cases, the detection of specific functional groups in molecular structures

is done using normal algorithmic approaches (Wegner et al. 2012). A prototype of a self-classifying ontology for chemicals in ChEBI was presented in Chepelev et al. (2012), which includes an algorithm for the discovery of shared features among groups of chemical structures, the representation of such features in an OWL ontology, and the automatic classification of that ontology using OWL reasoning. The features which are detected include common functional groups and additionally the presence of charges and cycles.

Different types of structural features used in chemical class definitions were identified in Hastings et al. (2012). These include:

- Presence or absence of specific parts. In the general case for chemical structures which may include cycles, in order to classify molecules based on the detail of the parts of their structures, a different formalism to OWL is needed for the chemical ontology. Description graphs have been proposed as one such formalism (Magka et al. 2011).
- The number or count of specific parts. While ChEBI does not capture this information at present, it is within the scope of the OWL formalism through capturing *cardinality* constraints on the “has part” relationships. For example, a cardinality constraint could capture the fact that a tricarboxylic acid is a class of chemical entities that has three carboxy groups as part. The algorithms reported in Chepelev et al. (2012) were capable of discovering such constraints on classes. However, within that approach, it is not possible to exclude the inference that a tricarboxylic acid – with three carboxy groups – is also a dicarboxylic acid, with *at least two* carboxy groups. OWL is capable of representing this constraint accurately, but the performance of the reasoning over a knowledge base including many such constraints is still an open challenge.
- Calculated properties of the chemical such as overall charge or molecular weight. OWL is capable of handling data properties such as integers or strings. These allow the definition of classes referring to particular values or value ranges. For example, it is possible to define *small* molecules as the molecules whose molecular weight is less than 800 daltons. These data restrictions are supported by OWL reasoners just as are object property restrictions.
- Topological features, such as polycyclic cages or molecular knots. Topological features such as overall regularity or cage structure falls outside the expressivity of OWL, although some previous work has investigated the use of higher-order logics for that purpose (Kutz et al. 2012).
- Structural formulae, e.g., hydrocarbons, strictly defined, excluding heteroatoms. Due to the open-world semantics of OWL, everything that is not explicitly stated in the ontology is assumed to be *not known to hold* rather than *known not to hold*. For example, ChEBI contains “organic molecule” and “inorganic molecule” as two classes. However, if it is not explicitly stated in the ontology that *all* molecules are either organic or inorganic and none are both, the ontology cannot infer that a molecule is inorganic simply from a statement to the effect that it is not organic. This open-world property of the semantics is a challenge for strict and exclusive class definitions. This is an area where the closed-world semantics

of alternative formalisms such as the description graphs formalism described in Magka et al. (2011) may be more practical. A particularly challenging class to define within a logic-based formalism is one captured by a parameterized molecular formula, such as alkenes which are described by the formula C_nH_{2n} . Constraints on number of atoms of particular sorts can be expressed using OWL cardinality restrictions, but this facility does not allow the relationship between the number of carbons and the number of hydrogens to be expressed.

Another open research area in the context of text and data mining is the prediction of novel ontology annotations for as yet unannotated data. The Gene Ontology annotation team use a set of rules for automatically predicting ontology annotations for as yet unannotated data, but these are mainly based on knowledge about the orthology of genes rather than data mining existing annotations or examining the structure of the ontology (Camon et al. 2004). Ontologies provide categories for data to be aggregated into which categories can then form the input into machine learning algorithms and statistical models of various sorts that can in turn provide predictions for novel data. Supervised methods, such as Bayesian classifiers, decision trees, and support vector machines, can be used to classify compounds for a particular functional activity class. However, these approaches result in binary output for a particular class membership rather than allocation of compounds to the ontology dataset. Supervised machine learning for prediction of chemical class membership based on an existing hierarchy would require large training sets of chemicals that are already classified into such a hierarchy. Although ChEBI could in principle act as such a training set, the size of the classified data is still a tiny fraction of the enormous chemical space, and the problem is further exacerbated by the fact that many of the ChEBI leaf nodes thus far contain a fairly low number of representative classified structures. Manually constructed classifications may furthermore be far from complete in the sense that an arbitrary compound belongs to a vast number of classes yet will only have been classified under those deemed to be the most *relevant* – a judgment which remains, for the foreseeable future, highly subjective.

Conclusions

We have given some background to ontologies as they are being used in cheminformatics to support standardization, knowledge discovery, and data annotation. In general, the use of ontologies for standardized annotations reduces the overhead of data integration, sharing, and reuse.

An exciting direction that life sciences ontology development is currently expanding into is that of increasing interrelationships between the ontologies themselves. For example, relationships link from the Gene Ontology to the ChEBI ontology are being created to explicitly represent chemical participation in biological processes (Hill et al. 2013). This shows potential for enabling whole-systems modeling that is needed to enable truly translational research in which structural chemistry informs biological research and discovery in real-world applications.

Abstract

Force fields are empirical energy functions that are designed to compute the properties of molecular systems at a relatively low cost, subject to the condition that there are no chemical changes in a system. A force field is a sum of various energy contributions which were developed and parameterized using small model systems. A long-sought goal in designing a force field is that the simulation of a biomolecular system (mainly globular proteins) reproduces the native structure(s) and the folding/assembly process of the system. A systematic way to achieve this goal is to train a force field using a number of macromolecules (e.g., proteins) to determine the balance among constituting energy terms by adjusting force-field parameters so that the force field properly reproduces the native structures of the training molecules. In this chapter, we discuss the principles and methods used for the calibration of a force field suitable for various applications.

Introduction

Empirical force fields to treat biological macromolecules, including proteins, have a long history of development (Mackerell 2004). Initially, they were defined as sums of neoclassical expressions that include bond stretch, bond angle, torsional angle, point-charge electrostatics, and van der Waals terms. Parameters for bond lengths, bond angles, torsional angles, and van der Waals terms were determined based on various spectroscopic experimental data (crystal, infrared, NMR, and microwave spectroscopy data) of small molecules. Point charges were determined by fitting to the molecular electrostatic potentials of model molecules calculated by using molecular quantum mechanics methods. These parameters were subsequently adjusted to reproduce the geometry, infrared frequencies, heats of associations, etc., of small molecular systems (Némethy et al. 1992; Pearlman et al. 1995; Brooks et al. 2009). Thus-generated force fields were reasonably good to study the dynamics of proteins near their experimental structures, but the computational resources and simulation techniques available at that time did not allow one to use them to study protein folding from unfolded structures. Therefore, the capacity of these early force fields to fold proteins could not be properly assessed. Nevertheless, some of them, e.g., the ECEPP force field developed by Scheraga and coworkers, were successfully used to predict structures of rigid cyclic peptides such as gramicidin S (Dybert et al. 1975) ahead of experiment.

In late 1970s and early 1980s, coarse-grained force fields for proteins began to emerge. Levitt and Warshel (Levitt and Warshell 1975; Levitt 1976) developed a physics-based force field for proteins, representing the protein backbone by three pseudo-atoms (identified with C^α , N, and O) and the side chain by one extended atom. The interaction potentials were defined and determined as Boltzmann-averaged energies over approximate energy surfaces of a model system calculated with all-atom empirical potentials and partially by taking empirical hydration

energies of amino acid residues. A few years later, an alternative approach to develop coarse-grained force fields was proposed by Crippen and coworkers, which was based on the statistical potentials determined from a database of known protein structures (Obatake and Crippen 1981; Crippen and Wiswanadhan 1984). When these researchers applied then-available global optimization methods to explore the energy surface of protein sequences with known 3D structures, their force fields produced protein-like structures, but not native-like structures.

In the early 1980s, a protein structure prediction approach known as threading or fold recognition was proposed. In this approach, the native structure of a protein is sought among decoys generated from known protein structures (Bryant and Lawrence 1993; Miller et al. 1996). This approach was developed for both on-lattice and off-lattice representation of protein conformations. The decoy which gives the lowest energy (or equivalently the best score) is considered as the prediction of the native fold. For the success of this approach, the corresponding energy/score function was trained on a large number of known protein structures. The training was achieved usually by optimizing the parameters so that the most native-like structure corresponds to the lowest Z-score one. The Z-score is a quantity taken from statistics and is defined as the ratio of the difference between the energy of a structure and the average energy of sampled structures to the standard deviation of the sample.

The first method to determine a force field with folding properties (i.e., operating in the conformational search space not restricted to a fixed set of decoys) was developed by Crippen and Snow (Crippen and Snow 1990). The method was based on the maximization of the energy gap between the lowest-energy simulated native-like structure and the lowest-energy simulated nonnative structure. The physics-based justification of such an approach was provided by Shakhnovich and coworkers (1991) and Sali et al. (1994) who, based on their lattice model studies of proteins, concluded that the larger the energy gap is, the quicker the folding happens. Even though the original Crippen's results did not survive long because it turned out very quickly that their energy-embedding method used to generate the decoys was insufficient to find the global energy minimum (Snow 1992) and it was found later that a large energy gap is neither a necessary nor a sufficient condition for foldability (Camacho and Thirumalai 1996; Klimov and Thirumalai 1996), the energy-gap maximization still remains as one of the principles of force-field training. It was later demonstrated based on on-lattice model studies (Camacho and Thirumalai 1996; Klimov and Thirumalai 1996) that a large energy gap is insufficient to assure folding and that folding transition should precede collapse of a polymer chain into compact but unorganized structures. A few years later (Liwo et al. 2004), this result was generalized to the requirement that for a foldable energy landscape, the formation of native-structure elements should occur in an ordered manner, which observation provided the basis for the hierarchical method of force-field optimization (Liwo et al. 2002, 2007; Ołdziej et al. 2004a, b). Wolynes and coworkers, on the other hand, provided a physical justification of Z-score optimization by relating this quantity to the difference between the folding and glassy transitions of proteins (Brungelson and Wolynes 1987; Goldstein et al. 1992).

For a protein to fold, its folding-transition temperature should be well above its glassy-transition temperature. The ratio of the difference of these two temperatures to the glassy-transition temperature is related to Z-score. Z-score optimization also is a principle that underpins many successful force-field optimization approaches.

This chapter summarizes the force-field calibration methods, starting from the two initial concepts outlined above.

Force-Field Calibration for Fold Recognition

As outlined in Introduction, the fold-recognition problem is defined as finding the most native-like structure among a given set of decoys. The scoring function is usually based on energy or pseudo-energy. Therefore, depending on whether Z-score or energy gap is the scoring function, the force-field optimization problem can be defined as the minimization of the target function given by Eqs. 1 or 2, respectively:

$$\Delta E = E_{nat} - \min_{i \neq nat} E_i \quad (1)$$

$$Z = \frac{E_{nat} - \frac{1}{N} \sum_{i \neq nat} E_i}{\sqrt{\frac{1}{N} \sum_{i \neq nat} E_i^2 - \left(\frac{1}{N} \sum_{i \neq nat} E_i \right)^2}} \quad (2)$$

where *nat* is the index of the native structure of the training protein and *N* is the number of decoys, excluding the native structure.

The energy function, *E*, is usually a linear function of parameters which makes the optimization problem a linear programming problem if the score function is the energy gap (Eq. 1) or nonlinear programming problem when the Z-score function is used (Eq. 2). Examples of successful force fields developed using this principle are the force field used in the LOPP server (Meller and Elber 2001) and that developed by Zhang and Skolnick (2004).

Optimization of a force field for fold recognition is relatively easy because the set of decoys is fixed. However, the accuracy of fold recognition depends on the completeness of the decoy set (threading database). Therefore, the method inevitably fails if the database does not include the appropriate fold. Often, it is difficult to identify the correct fold in the database if it is of less common type. A variant of threading, in which the energy of decoys is minimized with the target sequence before the score function is calculated, was developed in our laboratory and applied to the optimization of the early version of the UNRES force field (Liwo et al. 1997). This approach was subsequently further studied by Schug and Wenzel (2006). In this case, the force-field optimization requires iterations because the minimized geometry of decoys depends on force-field parameters. On the other hand, the resulting force fields are applicable not only to the folds used in training but also to new-fold proteins for de novo folding studies; a prediction made with

Fig. 1 *Top panel:* the predicted structure of the 25–85 fragment of HDEA (red ribbon) superposed on the experimental structure (PDB code 1BG8) Yang et al. (1998) (yellow ribbon); the C α rmsd is 4.2 Å. *Bottom panel:* same for the 16–42 fragment; the C α rmsd is 2.9 Å (Reproduced with permission from Figs. 1 and 2 of Liwo et al. (1999))

the UNRES force field optimized in this way coupled with the global optimization conformational space annealing (CSA) method (Lee et al. 1997, 1999) successfully generated the best protein model for target T0063 of CASP3 (Fig. 1) (Liwo et al. 1999).

Energy Gap and Z-Score Optimization for Ab Initio Protein Structure Prediction and Folding Simulations

The target functions of this optimization are the same as for force-field optimization for fold recognition; however, instead of using a fixed set of decoys, we need to generate many diverse low-energy decoys using the energy function under consideration. Because of high cost of such computations, the number of training proteins is much less than that used in optimization for fold recognition (where the set of decoys is fixed). In the very first approach developed by Crippen and Snow, the energy-embedding method was used. They also used the experimental structure to compute the native reference (Crippen and Snow 1990; Seetharamulu and Crippen 1991). However, this method failed to include many low-energy structures, and for this reason, the resulting force field worked only with the energy-embedding method. When a more powerful Monte Carlo minimization (MCM) search method (Li and Scheraga 1987) was applied with the identical force field, nonnative structures with lower energies than the native reference structure were found (Snow 1992).

In our laboratory, we developed a variant of energy-gap and Z-score optimization method (Lee et al. 2001; Pillardy et al. 2001) in which decoys are generated with the powerful CSA conformational search technique (Lee et al. 1997; Lee and Scheraga 1999). The experimental structure was not used as the native reference; instead, an approach called local CSA was developed to perturb the experimental structure in order to generate low-energy near-native structures. Therefore, the target functions given by Eqs. 1 and 2 had to be redefined by Eqs. 3 and 4, respectively.

$$\Delta E = \min_{i \in \{nat\}} E_i - \min_{i \notin \{nat\}} E_i \quad (3)$$

$$Z = \frac{\frac{1}{N_{nat}} E_i - \frac{1}{N_{nonnat}} \sum_{i \notin \{nat\}} E_i}{\sqrt{\frac{1}{N_{nonnat}} \sum_{i \notin \{nat\}} E_i^2 - \left(\frac{1}{N_{nonnat}} \sum_{i \notin \{nat\}} E_i \right)^2}} \quad (4)$$

where $\{nat\}$ denotes the set of native-like decoys (generated by restrained or unrestrained simulations with the current energy function parameters), N_{nat} is the number of native-like decoys, and N_{nonnat} is the number of nonnative-like decoys. The optimization involves iterating cycles, each of which consists of decoy generation and target function optimization, as shown in Fig. 2.

Using this approach, we managed to produce a version of the UNRES force field that folded proteins of all structural classes (Pillardy et al. 2001). However, the transferability of this force field was not well established. Later, the method was formulated as a sequence of linear programming problems and applied to the optimization of the united-residue UNRES and the all-atom CHARMM force fields (Lee et al. 2002, 2004a, b, 2008).

Wolyne and coworkers used the Z-score optimization method with the umbrella sampling Brownian dynamics as a search engine to optimize their force field based on associative-memory Hamiltonian (Eastwood et al. 2002, 2003; Fujitsuka et al. 2004). The resulting force field had some success in protein structure prediction (Prentiss et al. 2006).

When using a flexible decoy set, regardless of the target function to optimize (e.g., Eq. 3 or 4), two problems are encountered: (i) instability of the iterative process and (ii) glassiness of the resulting force field. The reason for the glassiness is that although local CSA or umbrella sampling Brownian dynamics generate reasonable low-energy near-native structures, there is no guarantee, especially with complex training proteins, that the optimization will provide accessible pathways for the proteins to fold starting from the unfolded state to the folded structures. The numerical instability problem results from the fact that the target function optimized in a given cycle can produce a force field with which qualitatively distinct decoys are generated; these new decoys often have very low energies and are usually nonnative. The reason for this is that the largest contribution to the target function comes from the native-like structure or the lowest-energy nonnative structures, while the other

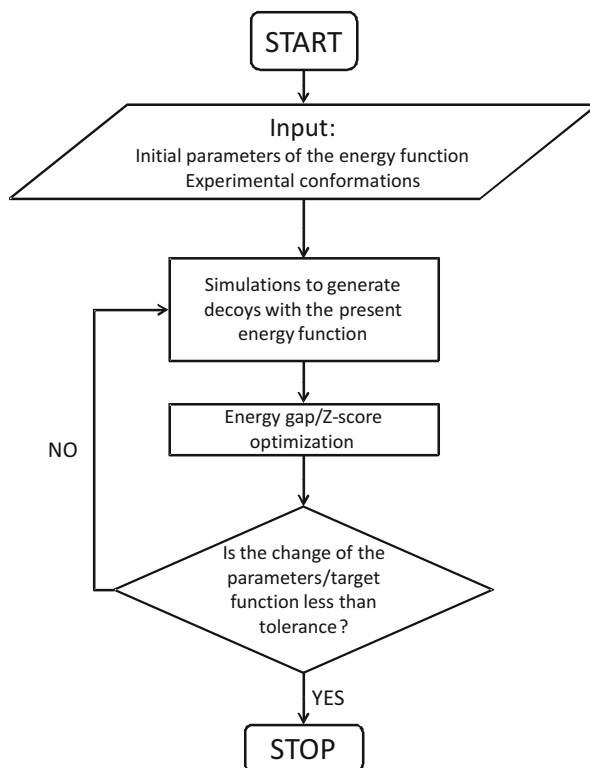

Fig. 2 A general iterative scheme of force-field optimization

structures are largely ignored. Therefore, the optimization of a force field is possible only for training proteins with simple folds (e.g., the three- α -helix bundle (Lee et al. 2001) or a three-stranded β -sheet fold (Pillardiy et al. 2001)). The development of a transferable force field that can fold proteins with more complex α -helical folds or $\alpha + \beta$ proteins still remains a challenge. Methods to consider in order to overcome the drawbacks in the energy-gap and/or Z-score optimization methods are described in the next sections.

Funnel Sculpting

Funnel sculpting is an approach developed by Micheletti and coworkers (2001) and Fain and Levitt (2003), which is based on the Wolynes' concept that the energy landscape of a foldable protein should look like a funnel; the lower the energy is, the fewer accessible conformational states should appear. As pointed out in the previous section, neither the energy-gap nor the Z-score optimization method guarantees a funnel-like energy landscape; instead, the *Schott-funnel* landscape with a flat and

rugged bottom is often obtained, resulting in the *glassiness* of the force field. The method of funnel sculpting is based on the maximization of the correlation between energy and native likeness. Although it never reached beyond the testing stage, this idea was a big step forward in the field of energy function optimization.

Hierarchical Optimization

The idea that the (free) energy should decrease with increasing native likeness was implemented in the hierarchical optimization method (Liwo et al. 2002). In this approach, the conformational space of a training protein is divided into levels, each of which consists of conformations with common native-structure element(s) (e.g., a native α -helix, a native β -hairpin, a native supersecondary structure motif, etc., or combinations thereof). The more native-like elements a level has, the higher rank it is assigned; the native structure has all native-like elements and, consequently, has the highest rank. The idea is to optimize the energy function so that the lower free energy a level has, the higher its native likeness is. The free energy of each level can be calculated from the results of simulations with a given force field. The levels and their hierarchy should follow the experimental thermal folding/unfolding pathway, as outlined in Fig. 3.

In the initial version of the hierarchical optimization approach (Liwo et al. 2002; Ołdziej et al. 2004a, b), the CSA global optimization method was implemented to generate decoys. To assign a particular conformation to a level, a binary number was assigned to each conformation, depending on the conformity of its segments (including the whole conformation) with the native structure; this number increases with increasing native likeness (Ołdziej et al. 2004b). To account for gradual folding, decoys were collected from various stages of CSA, i.e., after 8,000, 16,000, and 64,000 energy-minimized conformations, for stages 1, 2, and 3, respectively. The conformations of stage 1 usually contained only one native-structure element, and the conformations of stage 3 were all native-like. The target function consisted of quartic penalty terms to maintain the free energy gaps between levels above the preassigned values, Δ (see Eq. 5). As in the energy-gap and Z-score optimization approaches, hierarchical optimization is an iterative process that consists of decoy generation and target function minimization. The target function is defined as

$$\Phi = \sum_{\substack{\text{training} \\ \text{proteins}}} \sum_{\beta} \sum_{i < j} w_i g[F_j(\beta) - F_i(\beta); \Delta_{ij}^{(1)}, \Delta_{ij}^{(2)}(\beta)] \quad (5)$$

where

$$F_i = -\frac{1}{\beta} \ln \sum_{i \in \{i\}} \exp(\omega_i - \beta E_i) \quad (6)$$

Fig. 3 Schematic illustration of the energy-ordering of the conformational-hierarchy levels, which is the goal of the algorithm for optimizing the potential function by hierarchical approach, using the 1FSD peptide (Dahiyat and Mayo 1997) as an example. The energies of the conformations should decrease with their increasing “native-likeness”. The highest energy level (*Level 0*) is occupied by structures with either no or nonnative secondary structure. Next (*Level 1*) is occupied by the structures with one native secondary structure element (the N-terminal β -hairpin or the C-terminal α -helix; the native-like structure fragments are indicated by thicker lines). Yet lower energy (*Level 2*) have structures with both α -helix and β -hairpin, but no or incorrect packing of these two substructures and/or shifted turn in the β -hairpin. Finally, the native-like structures, with α -helix and β -hairpin packed correctly occupy the lowest energy level (*Level 3*). Because the number of structures with more and more defined native-like elements decreases, such ordering of structures leads to diminishing conformational entropy following the energy decrease, which is highly desirable in order to find the native structure quickly in a spontaneous energy-driven search of the conformational space. Reproduced with permission from Figure 1 of Liwo et al. (2002)

$$g(x; x_{\min}, x_{\max}) = \begin{cases} \frac{1}{4}(x - x_{\min})^4 & x < x_{\min}, \\ \frac{1}{4}(x - x_{\max})^4 & x > x_{\max}, \\ 0 & \text{otherwise.} \end{cases} \quad (7)$$

The indices i and j indicate level numbers ($\{i\}$ denoting the conformations of level i). The absolute temperature is denoted by T and the inverse temperature $\beta = 1/k_B T$, where k_B is the Boltzmann constant. T runs from below to above the folding temperature. $\Delta_{ij}^{(1)}$ and $\Delta_{ij}^{(2)}$ are the lower and the upper bounds, respectively,

of the free energy gap between levels i and j , The first sum is taken over all training proteins. For each conformation, ω_i is the logarithm of the frequency with which a conformation is to be counted; it is 0 for canonical simulations, and for multicanonical simulations, it is calculated by the weighted histogram analysis method (WHAM) (Kumar et al. 1992; Liwo et al. 2007).

With this version of hierarchical optimization method, more complex training proteins could be treated that contained α , β , and $\alpha + \beta$ folds (Ołdziej et al. 2004a, b). A transferable force field was produced with the use of four training proteins, which are identified by their PDB codes: 1GAB (a three- α -helix bundle), 1E0L (a three-stranded antiparallel β -sheet), 1E0G, and 1IGD ($\alpha + \beta$ proteins) (Ołdziej et al. 2004a). This force field produced reasonably good results in CASP5 and CASP6 blind-test protein-structure prediction experiments and performed well even in coarse-grained molecular dynamics simulations. However, while the glassiness problem was effectively eliminated by the introduction of a hierarchy of gradually folded structures, the instability problem mentioned in the previous section still remained, and the force field with the parameters obtained by minimizing the target function in a given iteration generated usually nonnative decoys in the subsequent CSA simulations. This problem was somewhat alleviated (but not completely resolved) by including the representatives of the decoys from all iterations in computing the free energies.

While the force field optimized as described above performed well in finding native-like structures and pathways of protein folding, it was not good in reproducing folding thermodynamics. Therefore, the hierarchical optimization method was further modified. The first modification was to require that the free energy of a level decreases with increasing native likeness below the folding-transition temperature, it increases above the folding-transition temperature, and the free energies of all levels become equivalent at the folding-transition temperature. The folding-transition temperatures of the training proteins were taken from the experiment, and the free energy gaps at different temperatures were estimated from the experimental temperature dependence of the free energy of the unfolding of the training proteins. The second modification was made to use replica-exchange molecular dynamics (Hansmann and Okamoto 1994; Pande et al. 2003) to generate decoys and the weighted histogram analysis method (Kumar et al. 1992) to compute free energy gaps; at early optimization stages, umbrella sampling replica exchange was used in order to generate native-like structures in the conformational ensemble (Liwo et al. 2007).

The revised hierarchical optimization method resulted in versions of the UNRES force field which reproduced reasonably good thermodynamics of the protein folding (Liwo et al. 2007). To alleviate the iteration instability problem, a Shannon entropy term was added to the target function to keep the shape of the probability distribution of the conformations of a given level close to the initial one and, therefore, to avoid the appearance of a handful of *lead* conformations on which the target function is focused (Liwo et al. 2007). With this approach, the UNRES force field was parameterized with the 1GAB (three- α -helix-bundle) protein, which proved very reliable in predicting the structures and folding pathways of α -helical

proteins; when distance restraints were implemented, it was successfully used to study functionally important *open-to-closed-conformation* transitions of a bacterial Hsp70 chaperone (Golas et al. 2012) and to study the association of the iron-sulfur-binding (Isu1) protein with the Jac1 Hsp40 co-chaperone (Mozolewska et al. 2015). Another version of UNRES was obtained by using 1E0L, and it was successfully used to study amyloid formation from the A β 42 peptide (Rojas et al. 2010, 2011).

Even with the modifications mentioned above, the optimization procedure was not sufficiently stable. Therefore, an alternative method of scanning the parameter space with the use of two small proteins, tryptophan cage and tryptophan zipper, was implemented (He et al. 2009), which bypassed the local minimization stage. The resulting force field turned out to be quite successful, as proved in the CASP10 exercise (He et al. 2013), although the predicted secondary-structure information needs to be provided for more reliable predictions. This force field was also used to study biological processes such as Pick1 binding to the Bar1 domain (He et al. 2011).

Maximum Likelihood Optimization

Although the hierarchical method performs much better in the optimization of the energy functions for free simulations, its disadvantage is a large degree of arbitrariness of the assignment of conformations to levels. Cutoffs on the number of native contacts, the root-mean-square deviation (RMSD) of the respective fragment from the experimental structure, etc., must be applied to assign conformations to particular hierarchy levels, and cases when two very similar conformations are assigned to different structural levels occur frequently. Moreover, experimental NMR structures often contain ensembles of conformations with quite flexible parts, which must be deleted from comparison.

In addition to this, the idea of hierarchical optimization conforms strictly only with the nucleation-condensation mechanism of protein folding. However, experimental and theoretical studies of protein folding demonstrated that the folding process occurs through a molten globule stage (Ptitsyn 1995). In particular, in our simulations of the N-terminal part of the B-domain of staphylococcal protein A (PDB code: 1BDD) (Maisuradze et al. 2010), we observed that the protein preserves its overall shape even at temperatures higher than the folding-transition temperature, with the native contacts in place or shifted by a few residue, and only the secondary structure is melted. This observation was confirmed by a detailed NMR study of tryptophan cage (Hałabis et al. 2012) (Fig. 4).

On the basis of the facts pointed out above, we recently developed a new method of energy function optimization, which is based on achieving maximum similarity between calculated and experimental ensembles at the temperatures at which the experimental ensembles were determined (Zaborowski et al. 2015). The maximum likelihood method is a natural way to solve this problem: each conformation determined experimentally can be considered as a point in the conformational space, at which the Boltzmann probability calculated from the energy function could be

Fig. 4 NMR-determined ensembles of the tryptophan cage miniprotein at $T = 280$ K (a), $T = 305$ K (b), and $T = 313$ K (c). The pictures were drawn based on the data of Hałabis et al. (2012)

evaluated and the sum of logarithms of probabilities maximized. However, to do so, the exact method to calculate the partition function would be needed. Simulations provide only the relative probabilities of the conformations from the simulated set, and these calculations cannot be extended beyond this set. To overcome this difficulty, an approach has been recently designed in our laboratory, in which each experimental conformation is assigned with contributions from all of the simulated conformations with Gaussian weights depending on the distance from the experimental conformation. The target function is defined as

$$l_N^* = \ln Q(T) - \sum_{j=1}^N a_j \left(\omega_j - \frac{U_j}{RT} \right) \quad (8)$$

where U_j denotes the energy of the j th simulated conformation, ω_j is defined below Eq. 6, $Q(T)$ is the partition function computed from simulations, and the coefficients $a_i, i = 1, 2, \dots, n$ are defined by Eq. 9; it should be noted that these quantities comprise the similarity of the simulated conformations to the experimental conformations. It should also be noted that we made use of the fact that by Eq. 9, the coefficients a_i are normalized to 1.

$$a_j = \frac{1}{A} \sum_{i=1}^n \frac{\exp\left(-\frac{\|\mathbf{X}_i - \mathbf{Y}_j\|^2}{2s^2}\right)}{\sum_{k=1}^N \exp\left(-\frac{\|\mathbf{Y}_j - \mathbf{Y}_k\|^2}{2s^2}\right)} w_i \quad (9)$$

$$A = \sum_{j=1}^N \sum_{i=1}^n \frac{\exp\left(-\frac{\|\mathbf{X}_i - \mathbf{Y}_j\|^2}{2s^2}\right)}{\sum_{k=1}^N \exp\left(-\frac{\|\mathbf{Y}_j - \mathbf{Y}_k\|^2}{2s^2}\right)} w_i \quad (10)$$

Here, \mathbf{X}_i is the i th experimental conformation, \mathbf{Y}_j is the j th simulated conformation, and s is the overlap radius, which is the parameter of the method.

In the zero temperature limit, using a single reference experimental conformation and replacing the soft Gaussian similarity function with a hard cutoff on the distance of the calculated from the experimental structure, the maximum likelihood method becomes equivalent to the energy-gap maximization method (Zaborowski et al. 2015).

The method was tested with optimization of the UNRES force field based on the experimental ensembles of conformations of the tryptophan cage determined at three temperatures, including the folding-transition temperature. Hamiltonian replica exchange molecular dynamics with restraints derived from the mean experimental conformation corresponding to each temperature was used to generate decoys. As opposed to the energy-gap, Z-score, or hierarchical optimization methods discussed in the previous sections, the iteration process was very stable, and a fast convergence was observed. The reason for this is that the target function expressed by Eq. 8 contains energies, not the exponents of energies as in the case of the hierarchical optimization method or the minimum energies as in the case of the energy-gap/Z-score optimization. Therefore, provided that the set of simulated conformations is dense enough near the experimental conformations (which can always be achieved when umbrella sampling Hamiltonian replica exchange is used), no lead conformations appear to bias the results of local minimization of the target function. The UNRES force field obtained by maximum likelihood optimization described above was transferable to other α -helical proteins, although it was trained with only one small protein. It could even reproduce some $\alpha + \beta$ folds (Zaborowski et al. 2015).

Very recently, maximum likelihood optimization was applied to calibrate the NARES-2P force field for nucleic acids. In this application of the maximum likelihood optimization method, the target function was extended by the addition of the sums of squares of the differences between the calculated and experimental heat capacity and the fraction of paired nucleic acid base profiles (He et al. 2015). With the experimental data of only two small DNA molecules, the resulting force field was able to reproduce the experimental melting temperatures, enthalpies, and entropies of 18 small DNA molecules with good accuracy.

Conclusions and Outlook

Calibration of macromolecular energy functions is a new frontier in force-field development. The methods used for the energy function calibration presented in this chapter (Bryant and Lawrence 1993; Miller et al. 1996; Brungelson and Wolynes 1987; Goldstein et al. 1992; Meller and Elber 2001; Schug and Wenzel 2006; Lee et al. 2001, 2002, 2004a,b, 2008; Pillardy et al. 2001; Liwo et al. 2002, 2007; Ołdziej et al. 2004a,b; Zaborowski et al. 2015) demonstrate the importance of a close interaction between theory and experiment. Apparently, experimental structures alone are not sufficient to obtain force fields that can

reproduce structures, dynamics, and thermodynamics of the folding of proteins and other biological macromolecules, protein-ligand and protein-protein association, DNA hybridization, etc.

The modified maximum likelihood function defined by Eq. 8 (Zaborowski et al. 2015) appears to be the best one for the optimization of force fields for free simulations. With this approach, both the instability of a single interaction of the optimization process and the arbitrariness of splitting the set of decoys into the subsets with various native-like elements (or just native-nonnative if energy-gap optimization is pursued) are avoided. On the other hand, the procedure itself is computationally very demanding because only convergent decoy sets can be accepted to start a new iteration. Therefore, the method seems to be the most appropriate to optimize coarse-grained force fields in which the number of degrees of freedom is much reduced (e.g., only two per residue in the UNRES and NARES-2P force fields) compared to all-atom force fields.

Abstract

In this chapter, we present a brief description of compound datasets and programs developed to serve chemoinformatics as well as, more specifically, nanoinformatics purposes. Emphasis has been placed on publicly available tools and particularly on KNIME (Konstanz Information Miner), the most widely used freely available platform for data processing and analysis. Among a multitude

of studies that have demonstrated the usefulness of chemoinformatics tools to chemical and medicinal applications, herein we present indicative cases of five successful KNIME-based approaches. The first two studies include the risk assessment of nanoparticles (NPs) through the Enalos InSilicoNano platform, namely, (1) the prediction of the toxicity of iron oxide NPs and (2) the cellular uptake prediction of computationally designed NPs with the aid of reliable quantitative nanostructure–activity relationships (QNAR) models. The third case study deals with the recognition of organic substances as corrosion inhibitors through the construction of predictive quantitative structure–property relationships (QSPR) models with Enalos KNIME nodes. Finally, two more cases are briefly described and involve the accurate prediction of yellow fever inhibitors from the ChEMBL database and the *de novo* design of compounds with the reaction vectors methodology. The aim of this work is to familiarize the interested reader with the freely available *in silico* tools in KNIME analytics platform and to demonstrate their value and effectiveness toward specific computational applications.

Introduction

Chemoinformatics employs computational methods and information technology to deal with chemical problems (Leach and Gillet 2007). Current efforts in the field of drug discovery are particularly concerned with the handling of chemical structural information so that properties of a ligand are optimized to address the multiple demands of a potent drug (Brown 1998). Chemoinformatics mainly emerged due to the enormous amount of data that has been generated by recent drug discovery attempts, including high-throughput screening and combinatorial chemistry methodologies (Russo 2002). Chemoinformatics include several modeling approaches aiming at successful drug design. For instance, the development of quantitative relationships between the observed biological activities and the chemical structures through construction of quantitative structure–activity relationships (QSARs) models and the prediction of ligand–protein structures via docking approaches are among the most widely used techniques. It is important to highlight that the methods employed in chemoinformatics are usually developed to handle large sets of chemical structures and their different properties (usually referred as molecular descriptors) and thus should be appropriate for big data analysis.

Through the course of the years, the development of chemoinformatics approaches has been greatly assisted by data mining tools and open-source software. The recently released curated small-molecule databases are valuable assets for testing and validating chemoinformatics algorithms and tools (Hu and Bajorath 2012). There are many databases (either publicly available or proprietary) containing a number of chemical substances. The size of typical databases ranges between tens of thousands and millions of compound entries (Leach and Gillet 2007). The most well used public databases are PubChem (Wang et al. 2009), ZINC (Irwin et al. 2012), BindingDB (Liu et al. 2007), and

ChEMBL (Gaulton et al. 2012). ZINC contains the three-dimensional structures of commercially available compounds, which were constructed to be used in structure-based virtual screening, while PubChem, BindingDB, and ChEMBL also include (bio)activity information. Additionally, PubChem provides screening information data sets (SIDS) and the three-dimensional structures of the majority of the compounds, and in BindingDB and ChEMBL databases the activities of compounds can be assembled into relevant classes. Activity classes are of particular usefulness toward benchmarking of new computational methodologies (Hu and Bajorath 2012).

Recently, virtual databases have been built. Virtual compounds are substances that have not been observed/synthesized so far, but they could be synthesized. This broader consideration allows for the construction of even larger virtual libraries containing billions of compounds (Leach and Gillet 2007).

The release of these important sources of information that can be systematically explored have boosted the development of many software tools for chemoinformatics that make extensive use of datasets. Among others, software tools have been particularly emerged to tackle research practices, such as data mining, virtual screening and machine learning, molecular selectivity analysis, and visualization of structure-activity relationships (SARs).

In this chapter, we briefly review some of the most popular chemoinformatics tools with particular emphasis on programs that are either publicly available or at least free for academic purposes. Since KNIME is the most widely used, freely available platform for chemoinformatics applications, we will specifically present tools that have been integrated into KNIME and are offered as KNIME nodes to execute several important tasks for chemoinformatics analysis. Such applications include CDK, Indigo, RDKit, Vernalis, CACTVS, Enalos, Lhasa, OpenBabel, OCHEM, Chemical Identifier Resolver, ErlWood, EMBL-EBI Nodes, and CheS- Mapper.

Popular Software Tools for Chemoinformatics

Konstanz Information Miner (KNIME) is an open-source analytics platform, which is the leading tool for wide-ranging data processing, integration, analysis, and exploration (Berthold et al. 2008). It enables the visual creation of data flows (so-called pipelines), the selective execution of specified analysis steps, and the presentation of the results via interactive views on models and data. KNIME offers intuitive use and high level of scalability, which currently render it the most popular platform for chemoinformatics applications. Therefore, as already mentioned, this chapter will be mostly devoted to the description of software tools that employ KNIME to accomplish their functions.

The Chemistry Development Kit (CDK) is an open-source and development chemoinformatics software (Steinbeck et al. 2003). In collaboration with the KNIME group, the CDK nodes for KNIME have been recently developed. These nodes provide features regarding chemical compound handling, such as several file conversion applications for molecules, calculation and drawing of 2D and 3D

structures, symmetry group calculations, fingerprint calculation, proper handling of hydrogen atoms, and molecular property estimations, among others.

Indigo (developed by GGA Software Services LLC) is a software tool for organic chemistry (<http://lifescience.opensource.epam.com/indigo/>). Manipulation and functionality of organic structures with the Indigo nodes for KNIME can be obtained through conversions to Kekulé and aromatic states, handling of hydrogen, molecular properties generation, fingerprint comparison, R-group decomposition, stereochemistry calculation, and component separation. Additional functionalities include file conversions among SDF, SMILES, and CML formats; detection of drawing errors in structures; 2D structure generation; and structure matching.

RDKit (<http://www.rdkit.org/>) also provides chemoinformatics applications through KNIME, for instance, substructure filtering and searching, 2D and 3D structure generation, chemical reactions, molecular fingerprinting, salt separation from compounds, and R-group decomposition.

Vernalis Research (<http://www.vernalis.com/research>) employs its KNIME nodes to assist structure-based and fragment-based drug discovery. It includes several functionalities, such as flow control, PDB and sequence tools, I/O applications, matched molecular pairs, and fingerprint properties.

Lhasa Limited nodes for KNIME offer additional operations on the evaluation of binary classification models and table manipulation (<http://www.lhasalimited.org/>).

The OpenBabel chemoinformatics package (<http://openbabel.org/>) is primarily a file converter toolbox (KNIME chemistry nodes). It can also filter molecular files with SMARTS and has a wide applicability in analyzing molecular modeling and bioinformatics data (O'Boyle et al. 2011).

The Online Chemical Modeling Environment (OCHEM) is a platform, which aims to simplify the procedures for performing QSAR calculations (Sushko et al. 2011). This is achieved through combination of experimental results taken from a database and a modeling procedure. The database contains thousands of entries and a user-friendly application environment. The use of current KNIME nodes for OCHEM is restricted to some running predictions and the data export/import.

KNIME nodes development from ErlWood also offers interpretation and handling of structure-activity relationship data, as well as various compound viewing facilities (<https://tech.knime.org/community/erlwood>).

The European Bioinformatics Institute (www.ebi.ac.uk) provides the EMBL-EBI KNIME nodes, which make use of the Chemical Entities of Biological Interest (ChEBI) database to obtain database files via ChEBI IDs, substructure, or keyword searches. ChEBI is a publicly available depository of small chemical molecules.

The visualization node CheS-Mapper (Gutlein et al. 2012) employs the characteristics of small molecule structures to perform clustering according to feature similarity criteria. 3D structure depiction and embedding of compound datasets are also supported.

The Chemical Identifier Resolver (CIR, developed by the CADD group at the National Cancer Institute) nodes for KNIME enable the recognition of a chemical structure provided that an identifier is known (<http://cactus.nci.nih.gov/chemical/>

Fig. 1 Freely available Enalos KNIME nodes

structure). CIR is a resolver for various structure identifiers and can also convert a particular structure identifier into another one.

Finally, the functionality of the Enalos KNIME nodes (<https://tech.knime.org/community/enalos-nodes>) developed by NovaMechanics Ltd will be briefly described. Enalos nodes for the KNIME platform are associated with several important aspects regarding data analysis and curation for chemoinformatics and nanoinformatics. The Enalos nodes (Fig. 1) among others provide (1) domain-similarity based on (i) euclidean distances or (ii) leverages, (2) fit quality and predictive power of a QSAR model with the Model Acceptability Criteria node, (3) the newly developed fast generation of all possible substitutions of a lead compound, and (4) calculation of important molecular descriptors with the Mold2 node. Mold2 is able to evaluate large and diverse sets of molecular descriptors from two-dimensional chemical structure information (Hong et al. 2008). Comparison of Mold2 descriptors with descriptors calculated from commercial software on several published datasets showed that Mold2 descriptors yield models with higher quality than other packages and also produce sufficient structural information.

In the following section, we present three case studies of *in silico* approaches developed by our group that involve the utilization of Enalos KNIME nodes for building predictive models.

Chemoinformatics Studies Using the Enalos KNIME Nodes and Enalos Cloud Platform

The KNIME analytics platform contains a multitude of processing nodes for data I/O, modeling, analysis, and data mining. It integrates well with Weka programming language for machine learning applications. Over the last 30 years, a vast amount of data has been generated within the areas of chemo-, bio-, and nanoinformatics. KNIME has emerged as one of the most reliable open-source data mining tools for the prediction of chemical properties and applications, such as virtual screening of chemicals and nanoparticles (NPs), chemical library enumeration, virtual library creation, building QSAR/QSPR, ADMET, and pharmacokinetics models, as well as prediction of various biological effects of organic compounds and NPs.

In this section, we present three case studies that involve the use of Enalos KNIME nodes in predicting (i) the toxicity of iron oxide NPs, (ii) the cellular uptake of organic NPs (virtual screening is also demonstrated), and (iii) the inhibitory potency of organic substances against corrosion.

In the first two case studies Enalos InSilico platform is also introduced. Enalos InSilico platform is a Cloud platform built to host a variety of predictive models to address the need for risk assessment and virtual screening. Workflows included in Enalos InSilico platform are constructed based on reliable data information, and each workflow combines advanced in silico tools to yield accurate predictions. Predictive workflows are available in a user-friendly format and include toxicity, biological activity, and property evaluation models.

Risk Assessment Tool for the Toxicity Prediction of Iron Oxide Nanoparticles Through Enalos InSilicoNano Cloud Platform

Nanoparticles (NPs) are known for their unique optical, electronic, and mechanical properties, which have led to the rapid evolution of nanotechnology materials being applied in a wide range of commercial, technological, and therapeutic applications in fields such as environment, industry, defense, electronics, and biomedicine. The latter has enjoyed great scientific, technological, and commercial progress in different NP applications (Gajewicz et al. 2012; Cohen et al. 2013).

Along with the apparent increasing use of NPs, concerns on their effect upon the environment and human health have been raised. Since toxicity assessment of NPs via traditional experimental routes often require expensive and time-consuming procedures, computational approaches such as quantitative nanostructure–activity relationships (QNARs) have been successfully used to predict the toxic effects of NPs (Vrontaki et al. 2015; Kleandrova et al. 2014a, b; Speck-Planche et al. 2015; Winkler et al. 2013, 2014; Shao et al. 2013; Toropov et al. 2013). However, the computational investigation of NP toxicity is seriously hindered by the lack of available NP descriptors, organized datasets, and systematic experimental data for NPs. Only few organized datasets on NP toxicity are available so far. Among these toxicity datasets on nanostructures, metal oxide NP data have been investigated in several computational studies (Fourches et al. 2010; Liu et al. 2011, 2013a; Puzyn et al. 2011; Zhang et al. 2012).

A fully validated QNAR model is presented, which was constructed based on toxicity data of iron oxide NPs with different core, coating, and surface modifications (Melagraki and Afantitis 2015; Shaw et al. 2008; Liu et al. 2013). The initial dataset was constructed with 44 iron oxide NPs that comprised a core with either Fe₂O₃ or Fe₃O₄ coating, including cross-linked dextran, PVA, or other, and various surface modifications (Shaw et al. 2008; Liu et al. 2013). Values for descriptors such as the size, R1 and R2 relaxivities, and zeta potential along with a coating-indicative parameter were considered as independent variables for the model development. The values of the input variables for each NP and the corresponding toxicity class are shown in Table 1.

Table 1 NP properties, bioactivity, and predictions

ID	NP ^b	Size	ZP	R1 ^c	R2	Coating	NHit ^d	Class	Prediction	Domain

^aTest Set

^bThe 44 NPs were obtained from the following studies (Liu et al. 2011; Epa et al. 2012)

^cR1: spin-lattice relaxivity; R2: spin-spin relaxivity

^dNHit: the number of hits identified for each NP across the 64 bioactivity measures (4 cell lines X 4 assays X 4 concentrations)

NPs were evaluated with different assays in various cell types and concentrations that produced a 64-component vectorial metric. Each NP was characterized either active or inactive according to the number of hits obtained across the 64 bioactivity measures. For the QNAR developed KNIME workflow, the following steps have been integrated: (1) data preprocessing, (2) variable selection, (3) model development and (4) validation, and (5) determination of domain of applicability [via the Enalos Domain – Similarity node that defines applicability domain (APD) based on euclidean distances]. The publicly available set of Enalos KNIME nodes can be accessed through either the KNIME Community or NovaMechanics website (www.novamechanics.com/knime.php or www.insilicotox.com/index.php/products/enalos-knime-nodes-community-contributions/) (Melagraki and Afantitis 2013).

Before model running, the available data were separated into training set and test set with the partitioning node in KNIME. According to the data in the training set, the most significant descriptors were selected (Witten et al. 2005; Hall et al. 2009). The NPs used in the validation set were not further employed during model development. Among all available techniques, the J48 modeling method yielded the most predictively powerful model for the available data.

The proposed predictive model was validated internally and externally regarding goodness-of-fit, robustness, and predictivity, thus totally meeting the criteria recommended by the Organization for Economic Cooperation and Development (OECD).

To validate the performance of the model, the following parameters were considered (Afantitis et al. 2011; Mouchlis et al. 2012):

$$\text{Precision} = \text{TP} / (\text{TP} + \text{FP})$$

$$\text{Sensitivity} = \text{TP} / (\text{TP} + \text{FN})$$

$$\text{Specificity} = \text{TN} / (\text{TN} + \text{FP}) \text{ and}$$

$$\text{Accuracy} = (\text{TP} + \text{TN}) / (\text{TP} + \text{FP} + \text{FN} + \text{TN}),$$

where TP true positive, FP false positive, TN true negative, and FN false negative.

The confusion matrix is presented below:

	Positive predicted	Negative predicted
Positive observed (Active)	TP	FN
Negative observed (Inactive)	FP	TN

Table 2 Confusion matrix (training set)

	Positive predicted	Negative predicted
Positive observed (Inactive)	16	0
Negative observed (Active)	4	11

Table 3 Confusion matrix (test set)

	Positive predicted	Negative predicted
Positive observed (Inactive)	7	1
Negative observed (Active)	1	4

Additionally, the Y-randomization test demonstrated the robustness and the statistical significance of the predictive model.

The ability to perform virtual screening of NPs that were not originally included in the dataset is particularly important, especially if there is an indication on its reliability. For this purpose, it is crucial to determine the limits of the model's domain of applicability. This will identify NPs that are excluded from the area of reliable predictions of the proposed model.

In this work, the Enalos Domain-Similarity node calculated the domain of applicability using euclidean distances to estimate the similarity between NPs belonging to the training and test sets. More details on the domain of applicability calculation can be found elsewhere (Melagraki and Afantitis 2013; Afantitis et al. 2008; Tropsha 2010).

Based on the reported toxicity data for the 44 iron oxide NPs used in this study, 31 compounds were included in the training set while the other 13 in the test set. As mentioned above, subsequent model development was based on the NP structures of the training set. For the NPs, experimental parameters such as the size, R1 and R2 relaxivities, and zeta potential were combined with a coating-specific parameter and were used as inputs for the model development. The three coating categories which have been considered are: PVA, cross-linked dextran, and other. Among the above descriptors, the subset that best describes the variation of toxicity with NP properties (as demonstrated by the variable selection algorithm) includes the R1 and R2 relaxivities and coating.

After the model development from the training data was achieved, the toxicity prediction for the test set followed. Observed classes and predictions for the 44 NPs of the initial set are shown in Table 1. Confusion matrices for the training and the test sets are shown in Tables 2 and 3, respectively. The evaluation of the

performance of the training set yielded: precision = 80 %, sensitivity = 100 %, specificity = 73.3 %, and accuracy = 87.1 %. Regarding the test set, the respective parameters are: precision = 87.5 %, sensitivity = 87.5 %, specificity = 80 %, and accuracy = 84.6 %.

The applicability domain was defined for NPs within the test set and the cutoff value was estimated to be 0.906. For all structures of the test set, values range from 0 to 0.448, therefore, all predictions are considered reliable. The above set of validation measurements highlights the accuracy, significance, and robustness of the produced model.

The predictive workflow is publicly available via the Enalos Cloud platform. In silico design and screening may be performed through the Enalos Cloud platform by visiting the iron oxide model web page (enalos.insilicotox.com/QNAR_IronOxide_Toxicity/). The user can initiate a prediction by either manually entering the selected NP properties (e.g., zeta potential, size etc.) or by importing a CSV file (.csv) with NP properties for high-throughput virtual screening (HTVS) (Scheme 1).

When properties are uploaded for a set of NPs and the input values have been included, the predictive model is used and a prediction is obtained. The generated

output provides a summary of the results in a pdf-like format or a CSV file, which contains all relevant information for further analysis (Scheme 2). The results include predicted values for each nanostructure and a notification on the reliability of predictions based on the domain of applicability limits.

As already mentioned, the Enalos Cloud platform allows the performance of a preliminary *in silico* testing by virtually screening a set of NPs, based on the validated model. The predictive QNAR model described here can be accessed at the web page of Enalos QNAR Iron Oxide Toxicity Platform (http://enalos.insilicotox.com/QNAR_IronOxide_Toxicity/).

This study outlines Enalos InSilico platform as a useful tool to facilitate the computer-aided NP design by acting as a source of toxicity prediction for novel NPs.

Cellular Uptake Prediction and Virtual Screening of Nanoparticles via Enalos InSilicoNano Platform

In this section, a validated quantitative nanostructure–activity relationships (QNAR) model that can predict the cellular uptake of organic nanoparticles is presented (Melagraki and Afantitis 2014). The model is publicly available through Enalos InSilico Cloud platform in the QNAR_PaCa2 web page (http://enalos.insilicotox.com/QNAR_PaCa2/) and can be used for new-structure predictions that are designed and/or uploaded to the server. The Enalos InSilico web service functionality was successfully used for the virtual screening of a set of PubChem structures, which were selected to recognize structures similar to that of a known active compound. The model was based on Mold2 descriptors and the k-nearest neighbors (kNN) algorithm.

The selected engineered NPs (ENPs) used for model development, possess the same metal core but different organic coating (Weissleder et al. 2005). The model building was based on a KNIME workflow, especially designed for this purpose. Initially, for the development of the model, all data including organic molecules and cellular uptake values were preprocessed and randomly divided into training set (89 compounds, which were used in the model development) and validation (25 compounds) set. The Enalos Mold2 KNIME node was used for the calculation of 777 descriptors for each compound. During the correlation analysis some descriptors were eliminated, thus leaving 382 of them to be used as inputs for the QNAR model development.

Next, the CfsSubset variable selection with BestFirst evaluator method was applied to identify nine descriptors as the most representatives of the structural features that define the biological profile of the studied NPs.

The nine descriptors are: (D461) Geary topological structure autocorrelation length-7 weighted by atomic van der Waals volume, (D467) Geary topological structure autocorrelation length-5 weighted by atomic Sanderson electronegativities, (D599) number of total quaternary C-sp³, (D649) number of group secondary aliphatic amines, (D712) number of group donor atoms for hydrogen bonds, (D714) number of group CH₃R and CH₄, (D753) number of group phenol or enol or carboxyl OH, (D758) number of group Al₂-NH, and (D775) hydrophilic factor index. The physical meaning of the above descriptors can be found in the original publication (Melagraki and Afantitis 2014). The optimized value of k within kNN application was 2 (Franco-Lopez et al. 2001).

The proposed model was successfully validated with the methodology applied in the previous section. The validation results are shown in Fig. 2.

The R²_{LOO} was calculated to be 0.74. Also, the Y-randomization test verified the model's robustness and statistical significance. The decreased values of the correlation coefficient indicate the low possibility of chance correlation.

After the model was validated, the reliability of a given prediction was suggested through domain of applicability calculations (cutoff value = 2.153) (Mouchlis et al.

Criterion	Assessment	Result

Fig. 2 Model evaluation summary results

2012; Zhang et al. 1995; Papa et al. 2009). It was concluded that the proposed model requires only the structural information from the organic compounds involved and was confirmed to be accurate and reliable within applicability limits. Thus, the model could be considered a useful tool toward cellular uptake determination of NPs.

The model was made available online through Enalos InSilico platform for fast in silico predictions for a set of given compounds. Screenshots of the Enalos InSilico web service and the results page are presented in Schemes 3 and 4.

Scheme 4 Screenshot of Enalos InSilico platform results for QNAR_PaCa2 model

As shown in Schemes 3 and 4, the user can design or enter a chemical structure and obtain a prediction. The aforementioned workflow will calculate the descriptors and the output will be rapidly generated (within seconds). One may experiment with different scaffolds and structures and observe the structural features that induce a certain effect. Also, the user can exploit the proposed QNAR model and then scan specific structures for a preliminary *in silico* testing. In this way, it is possible to offer QSAR/QNAR results for immediate sharing and implementation. It was recently pointed out (Tetko 2012) that the use of predictive models as software tools will probably increase in the future, and this will activate the reuse of knowledge, which in turn will result in further developments.

As already mentioned, the proposed model and web platform can be used in virtual screening studies for the prioritization of new compounds. To demonstrate the usefulness of the produced model, potent compounds from the PubChem database were identified using similarity calculations based on molecular quantum numbers (MQNs) (Melagraki and Afantitis 2014). The virtual screening procedure was employed for the recognition of the first 1000 neighbors of **compound 36** (isatoic anhydride), in terms of chemical similarity. The 1000 resulting compounds were tested with the online tool through Enalos InSilico platform (via an sdf file, which contains all the structures) regarding their cellular uptake. Compounds were next classified by increasing potency and the most promising ones were selected for screening. The predictions for the first 20 compounds are shown in Table 4.

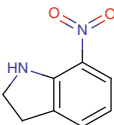

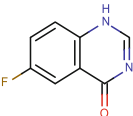

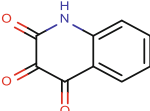

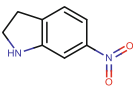

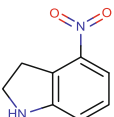

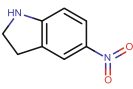

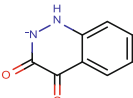

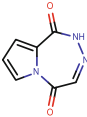

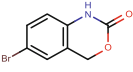

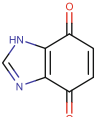

Within the proposed framework, the Enalos InSilico platform emerges as an invaluable application for the evaluation of novel NPs, which have not been experimentally tested or synthesized. An additional, important aspect of the approach is that the above tools can be further expanded and applied to polymer–NP structures that are currently gaining increasing attention.

Identification of Organic Materials as Corrosion Inhibitors Based on Enalos KNIME Nodes

One of the most efficient ways to prevent metal corrosion in acidic media is the development of novel corrosion inhibitors (Ebenso et al. 2012). Organic inhibitors, which contain heteroatoms (e.g., oxygen, nitrogen, sulfur) and possess multiple bonds, have been considered for various corrosion systems, metals, and alloys. Inhibition is obtained with creation of physical and/or chemical absorption film on the surface of the metal (El Ashry et al. 2012). The planarity of heterocycles and the presence of lone electron pairs on the heteroatoms are crucial factors that control the absorption of these compounds on the metallic surface.

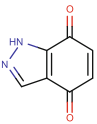

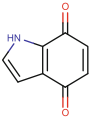

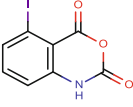

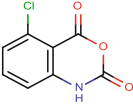

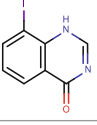

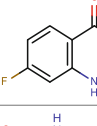

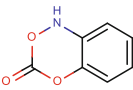

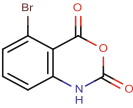

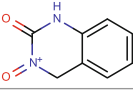

One drawback regarding the design of corrosion inhibitors is the time-consuming and costly nature of the process. On the other hand, computational techniques, such as the quantitative structure–property relationships (QSPR) methodology has greatly advanced the efficient modeling and prediction of new or modified corrosion inhibitors (Lee et al. 2012; Toropov et al. 2012).

In this study, the modeling and prediction of corrosion inhibition for steel in acidic environment through the development of QSPR with the aid of the Enalos KNIME nodes is described (Berthold et al. 2008; Melagraki and Afantitis 2013). The development of a predictive kNN model was realized by first calculating Mold2 molecular descriptors for the organic inhibitors with the Enalos Mold2 KNIME node. The predictive model was assessed with the Enalos Model Acceptability Criteria KNIME node. The domain of model applicability was determined using the Enalos Domain KNIME nodes.

Corrosion inhibition data for steel in acidic medium from various organic chemicals were collected from the literature (El Ashry et al. 2012) and were assembled in a single database. Inhibitors involve triazole, oxadiazole, and thiadiazole derivatives; aromatic hydrazides and Schiff bases; benzimidazole and 2- substituted derivatives; as well as pyridine derivatives. A set of 55 organic inhibitors in different concentrations yielded a total of 186 inhibition data.

The structural features of the studied corrosion inhibitors were evaluated with the Mold2 software. A total of 777 descriptors were initially calculated for each compound based on topological, geometrical, and structural criteria. From these, only 320 descriptors were used as possible inputs for the construction of the QSPR model, since the remaining descriptors were filtered out due to poor discrimination power (Ojha and Roy 2011).

Among the different modeling methodologies screened in KNIME platform, the k-nearest neighbors (kNN) technique (with an optimized value $k = 3$) was selected as the most appropriate for the specific data (Hall et al. 2009). Details on the kNN algorithm and methodology can be found elsewhere (Franco-Lopez et al. 2001).

The predictive model was validated internally and externally according to the standards of QSAR model acceptance, as imposed by the OECD. The complete dataset was randomly split into 70:30 ratio (training set: validation set) with the partitioning KNIME node. The combinations in the test set did not participate in the training procedure. The statistical criteria that were used to determine the robustness, reliability, and predictive ability of the model are: the coefficient of determination between experimental values and predicted values (R^2), validation via external test set, leave-one-out cross validation procedure and quality of fit and predictive ability of a continuous QSAR model based on Tropsha's tests (Tropsha 2010). The statistics of the validation procedure are shown in Table 5.

Table 5 Statistical parameters of the QSPR model

R^2 training (n = 131)	0.96
RMSE training	4.90
R^2_{LOO}	0.73
R^2_{pred} (n=55)	0.84
RMSE _{pred}	9.83

The predictive scheme included a KNIME workflow, which operated the following actions:

1. Compounds along with corrosion inhibition data were uploaded and preprocessed.
2. The calculation and selection of descriptors was realized.
3. The kNN methodology was carried out.
4. The produced model was validated.
5. The domain of applicability was determined.

The initial dataset of 186 corrosion inhibitors was randomly divided into 131 training set compounds and 55 validation set compounds (ratio 70:30). As mentioned above, only compounds from the training set were used to develop the QSPR models, and 320 descriptors were selected as possible inputs during the development.

The CfsSubset variable selection with the BestFirst evaluator method (Witten et al. 2005) was next applied on the training set to identify the most significant among the 320 descriptors. Thus, the concentration along with seven descriptors was selected as the most important parameter for the model development.

The selected descriptors include number of oxygen (D026), structural information content order-1 index (D282), Geary topological structure autocorrelation length-8 weighted by atomic Sanderson electronegativities (D470), Moran topological structure autocorrelation length-7 weighted by atomic polarizabilities (D509), lowest eigenvalue from Burden matrix weighted by van der Waals order-6 (D545), highest eigenvalue from Burden matrix weighted by van der Waals order-4 (D575), number of group Ar-CH=X (D741), and the concentration (C in mM).

The description of the selected descriptors will be briefly discussed below (Todeschini and Consonni 2009).

A combination of the descriptors offers a unified representation of the compound and high selective power. Descriptors D026 and D741 indicate the number of oxygen atoms and Ar-CH=X groups that may be present in the compound. Descriptor D282 encodes the structural information content order-1 index. This descriptor represents a graph theoretical invariant, which considers the molecular graph as being a source of different probability distributions, to which the information theory is applied (Todeschini and Consonni 2009). D470 encodes information as described by Geary topological structure autocorrelation length-8 weighted by atomic Sanderson electronegativities. The Geary index denotes spatial autocorrelation and is a distance-type function which varies from zero to infinite. D509 encodes information regarding the atomic polarizabilities combined with Moran topological structure autocorrelation length-7. Moran coefficient (value range between -1 and +1) indicates the spatial autocorrelation and is associated with atomic properties, the number of atoms, and the topological distance between them. Descriptors D545 and D575 represent the lowest eigenvalue from Burden matrix (Burden 1989) weighted by van der Waals order-6 and the highest eigenvalue from Burden matrix weighted by van der Waals order-4, respectively (Burden et al. 2009). Burden descriptors

weighted by van der Waals have been shown to be very selective descriptors and in turn useful for similarity searching (Todeschini and Consonni 2009).

The above descriptors are associated with different weights that affect the corrosion inhibition across compounds. Therefore, according to the positive or negative impact of each descriptor, novel compounds with specified properties may be designed.

After comparison with the results from other methodologies (Melagraki and Afantitis 2013), it was concluded that the kNN approach yielded an accurate and powerful model that reliably predicts the efficiency of corrosion inhibition. Then, one may safely conclude that the selected descriptors encode the structural characteristics of the substances related to corrosion inhibition.

The experimental vs. predicted corrosion inhibition values for the training set and test set compounds are shown in Fig. 3. Outliers have been indicated and presented in the original article (Melagraki and Afantitis 2013).

The Enalos Model Acceptability Criteria KNIME node has been applied to the data (Fig. 4) and the model passed Tropsha's requirements for predictive ability.

R^2 is the determination coefficient between experimental and predicted values and model prediction on the test set (R^2_{pred}). The model was particularly stable with respect to the inclusion/exclusion of compounds measured by the leave-one-out (LOO) cross validation procedure ($R^2_{\text{LOO}} = 0.73$).

Another measure of robustness and statistical significance of a QSPR model is the Y-randomization test, which further validated our approach. An additional validation test was conducted to evaluate the predictive power of the method independently of the partitioning of the dataset (Melagraki and Afantitis 2013).

Fig. 3 Experimental vs. predicted values for the training and test set

Criterion	Assessment	Result
$R^2 > 0.6$	PASS	$R^2 = 0.842$
$R_{cv}^2 > 0.5$	PASS	$R_{cv}^2 = 0.826$

Model Predictive

Fig. 4 Enalos Model Acceptability Criteria KNIME node screenshot

Fig. 5 Distribution of the RMSE values (100 random splits)

The distribution of the root mean squared error (RMSE) values is shown in Fig. 5.

The applicability domain cutoff value was estimated to be 3.774 and 0.183 for similarity (Mouchlis et al. 2012) and leverage (Afantitis et al. 2008) calculations, respectively. Similarity calculations for all compounds in the test set had values which range between 0.015 and 1.23. However, the leverage predicted response of a simple pyridine (0.378) resulted from a significant model extrapolation, and it is the only prediction that may be considered unreliable.

The present approach, due to its high predictive power and the minimal requirement of only 2D structure information of a compound, could be a very useful tool for the determination of the corrosion inhibition. Moreover, this modeling method considerably decreases the time and cost required to experimentally design corrosion inhibitors. Also, the method may be applied to the screening of regular or virtual chemical databases, thus seeking new organic compounds with specific

properties. For this purpose, the applicability domain will be an invaluable tool for discarding “divergent” chemical structures.

KNIME-Based Design and Prediction of Compound Structures

The broad applicability of KNIME in the area of medicinal and pharmaceutical chemistry has also rendered it a valuable tool for structure prediction and analysis. Thus, KNIME workflows have been implemented over the years to perform drug design, virtual screening, molecular modeling, QSAR, QSPR, structure classification, and clustering applications among others.

In this section, we present two KNIME applications regarding the prediction of yellow fever inhibitors and a knowledge-based method for the de novo design of novel compounds.

Prediction of Yellow Fever Inhibitors from ChEMBL Database Through KNIME Classification Analysis

Yellow fever (YF) is an acute infection, which is transmitted by arthropods and mosquitoes to humans (Agnihotri et al. 2012), and is caused by the mosquito-borne yellow fever flavivirus (YFV). The family of flaviviruses also includes other RNA viruses, such as the hepatitis C virus (HCV), the dengue virus (DENV), the West Nile virus (WNV), the Japanese encephalitis virus (JEV), and the bovine viral diarrhea virus (BVDV) among others (Agnihotri et al. 2012; Julander 2013).

YFV is a major health risk in particular regions of South America and Africa since almost 200,000 new infections and 30,000 deaths are observed every year (Chatelain et al. 2013); importantly, the fatality rate may reach 60 % in severe cases.

Currently, several regular antiviral drugs have been tested against YF disease, but no chemotherapeutic medication has been developed to specifically target YFV. An anti-YFV vaccine (17D) is used to prevent the infection; however, it has been observed to cause systemic infections and side effects in some patients (Julander 2013).

Therefore, computational approaches, such as virtual screening and modeling are particularly suitable to assist the discovery of new anti-YFV compounds. In this context, Moorthy and Poongavanam collected a number of compounds from the literature that were found (experimentally or computationally) to inhibit the YFV and employed them for the development of KNIME classification models using the Naive Bayes approach (Narayana Moorthy and Poongavanam 2015).

For this purpose, a set of 379 YFV inhibitors were collected from the ChEMBL database (<https://www.ebi.ac.uk/chembl/>). After the initial treatment of the data (namely, salt removal, 3D structure generation, and energy minimization of the structures), 30 two-dimensional descriptors of the compounds were calculated with the CDK tool as implemented in KNIME (Berthold et al. 2008; Beisken et al. 2013). In total, 16 classification models were developed using the Weka

data mining software (Hall et al. 2009). The first 12 models refer to individual datasets, while models 13–16 were developed from a combined dataset, which contained 309 compounds. Before the development of the models, the dataset was partitioned into training (65 %) and test (35 %) set based on a sampling consideration that distributes the inhibitors and noninhibitors evenly between sets. The inhibitor definition was restricted to specific activity criteria (i.e., $IC_{50} \leq 10 \mu\text{M}$ for inhibitors; $IC_{50} > 10 \mu\text{M}$ for noninhibitors). The quality of models was investigated through various activity thresholds (10, 30, 50, and 100 μM) and statistical parameters, such as the sensitivity, specificity, G-mean, Matthew's correlation coefficient (MCC), and overall accuracy.

Principal component analysis (PCA) revealed that the dataset does not contain distinct clusters and its diversity is adequately represented by the training set. Despite the presence of some outliers, it was observed that they were not structurally similar whatsoever. Additionally, it was shown that the majority of inhibitors is highly affected by the topological polar surface area (TPSA) and polar bonds. This indicated the more hydrophobic nature of noninhibitors compared to inhibitors.

The BestFirst attribute selection module of Weka was employed to select a set of 24 physicochemical descriptors in order to construct the Naive Bayes classification models for YFV inhibition. It was shown that the six datasets (activity cutoff 30 μM) perform equally well with an overall accuracy for the test set being >75 %.

The model quality (based on MCC) was higher for all datasets except for one, which performed poorly. Models derived from all datasets were statistically significant with MCC and G-mean values >0.7. The significance of the dataset was also verified by the high F-score values (>0.8), while sensitivity and specificity parameters were >0.75 for most models. The F-score is calculated through the following equation:

$$\text{F-score} = \frac{\text{Precision} \times \text{Sensitivity}}{\text{Precision} + \text{Sensitivity}} \quad (1)$$

Also, the predictive ability of the scheme was investigated by combining all the datasets into one. Thus, 70 compounds (Krečmerová et al. 2007) were used in the test set, while the remaining 309 compounds were combined into one dataset to train the model. It was observed that an activity cutoff of 50 μM yields a relatively good accuracy. Despite that models developed by different activity thresholds (10 or 30 μM) were successful in distinguishing inhibitors (>90 %) from noninhibitors (65 %), they lacked a balanced class distribution (predicting adequately both classes instead of predicting accurately only one), which clearly affects the quality of the model. Therefore, new models were constructed based on the 309 compounds set (200 compounds in the training set, 109 compounds in the test set). From the models for each activity threshold (10, 30, 50, and 100 μM), one model (at 50 μM) displayed superior performance over the others. That is, it predicted 92 % of inhibitors and 78 % of noninhibitors with a MCC coefficient of 0.71, and a G-mean score (0.84), which reflects the high quality. Finally, the best YFV inhibition model

(at 50 μM) was implemented into KNIME workflow to become freely available for use in medicinal chemistry applications.

De Novo Design of Synthetically Feasible Compounds Through the Reaction Vectors Approach

Early attempts to develop successful de novo design programs for compounds have been seriously hampered by the unfeasible synthesis of the proposed structures (Boda and Johnson 2006; Lewis and Leach 1994; Schneider and Fechner 2005; Gillet and Johnson 1998). More recent approaches that may facilitate synthetic routes generate a fixed set of transformations, which are in turn applied to starting structures to generate new molecules (Fechner and Schneider 2006, 2007; Lameijer et al. 2006; Schürer et al. 2005; Vinkers et al. 2003). However, these methods are usually restricted by the limited number of “reactions” that can be performed.

Reaction-like methodologies have been used in QSAR and data mining studies. For instance, the “matched molecular pairs” scheme (Leach et al. 2006) evaluates the change of a property with respect to a single structural change. Similar approaches perform clustering of molecule pairs according to descriptor difference vectors, which are constructed by subtracting the vector representation of the “product” molecule from the vector representation of the “reactant” molecule (Sheridan et al. 2006). Therefore, the pairs of molecules which belong to the same cluster represent similar transformations. Thus, changes in activities associated with the pairs may be used to estimate the effect of a particular transformation on activity.

A knowledge-based approach regarding the de novo design of compounds based on reaction vectors has been proposed by Patel et al. (Patel et al. 2009). The method of reaction vectors is related to the descriptor difference vectors approach (Sheridan et al. 2006) and characterizes the structural changes, which occur at the reaction center.

The authors’ flexible procedure enabled the automatic collection of ever-increasing data on reactions, which are available in several databases. Reaction vectors could be applied to novel starting molecules through a structure generation algorithm to predict new structures. Each applied transformation is derived from a reactions database, and since it is associated with a reaction from the literature, one may be confident toward the synthetic feasibility of the proposed molecules. The vectors are automatically collected from a set of reactions, which is not restricted by size or reaction type, therefore without involving any complex reaction strategy.

The principle of the method is the utilization of the information taken from a set of reactions (parent reactions) in deriving reaction vectors. Reaction vectors are used to describe the reaction environment as well as changes at the reaction center. Then, the reaction vectors are extracted from the knowledge base and may be applied to input starting materials in order to predict new product compounds for synthesis. In some cases, successful predictions may require the operation of a reaction vector to a second starting molecule.

In the past years, reaction vectors have been used to search and classify chemical reactions (Broughton et al. 2003). As already mentioned, a reaction vector represents the changes that occur during a reaction. This is described in a descriptor scheme that is enhanced in the products (positive descriptors, they represent bonds gained in products) and is diminished from the reactants (negative descriptors, they represent bonds lost from reactants). In de novo design, the practical role of reaction vectors is to propose synthetic ways to new compounds by achieving a balance between specificity and generality. Namely, the reaction vectors should be specific enough in order to avoid their application in environments which disfavor the course of a reaction, but encoding part of the environment will hamper their ability to generate novel structures. It was shown that such a balance may be obtained by combining atom pairs separated by one and two bonds (Patel et al. 2007). The reaction vectors employed by Patel et al. are modifications of the original descriptors developed by Carhart et al. (1985). More detailed information on reaction vectors can be found in Patel et al. and references therein (Patel et al. 2009).

The authors revealed that many reactions in the Lilly database are incomplete, and they implemented a reaction cleaning algorithm to overcome this drawback. The reaction cleaning algorithm is applied to the reactions before calculating the atom pair descriptors for the reactants and products. The reaction vector is next calculated as follows:

$$D = P - R \quad (2)$$

where D is the reaction vector, P is the product vector (the sum of the vectors of individual products), and R is the reactant vector (the sum of the vectors of individual reactants). The algorithms have been implemented with the aid of the JoeLib toolkit (joelib.sourceforge.net/) with the de novo design tool available in KNIME.

The de novo design algorithm was validated internally by reproducing reactions in the Lilly database and externally by reproducing the already known synthetic pathways of two drugs. Internal validation was achieved by generating 90 % of the known parent products for each reaction in a dataset containing 5695 reactions and 2866 reaction vectors. The external validation involved the syntheses of the intermediate of the antithrombotic drug (S)-(+)-clopidogrel bisulfate (Wang et al. 2007) and the antidepressant venlafaxine (Kavitha and Rangappa 2004). In each case, the products were successfully generated using a 5839 reagents set and a dataset, which comprised 24,418 reactions and 16,859 reaction vectors. The reaction vectors procedure was successful in reproducing the known synthetic routes for both drugs; however, it was suggested that this approach also yields quite a few alternative products.

The applicability of the algorithm to de novo design was demonstrated in three cases: (1) the ability of a reaction vector to generate novel and diverse products as regards the parent reaction, (2) prediction of analogs of a lead compound, and (3) application to the enumeration of a compound library.

In the first case, 10 reactants were randomly selected from the smaller (2866 vectors/5695 reactions) dataset and were input to the de novo design tool. Products were generated employing the 16,859 reaction vectors from the larger dataset. Structures containing more functional groups than others usually yielded more solutions, therefore, the number of products that were created lies within 0 and 44. Moreover, the average similarities between predicted compounds and products of the parent reactions vary significantly (0.15–0.96). It is therefore suggested that the diversity of the products depends on both the starting molecule and the entries in the reaction database.

Next, the predictive power of the algorithm in lead optimization cases was explored by considering drugs as starting compounds and generating products after single-step transformations. The products were assumed to be synthetically feasible if they were identified upon search in SciFinder Scholar. The procedure was based on penicillin G, Prozac, and aspirin (starting structures) and was performed with the larger set of reaction vectors (16,859) and the 5839 reagent set as described above. Penicillin G was associated with the most potential products (24), while 20 and 12 products were generated for Prozac and aspirin, respectively. The reaction vector methodology was shown to realize the generation of synthetically accessible molecules that share close structural similarities with a parent compound. Thus, this approach could be particularly valuable in structure-activity relationship (SAR) studies by proposing structures for synthesis that explore sufficiently the conformational space around a known lead compound.

Finally, the proposed methodology can be used to construct a virtual library of products by listing all possible products from a single reaction employing a specific set of reagents. For instance, the authors used 6-bromoquinoxalin-2-one as starting material, 628 boronic acids as the reagents (extracted from the ACD), and a Suzuki coupling reaction to construct an enumerated library with 292 compounds. It was shown that this scheme may be used to direct a parallel synthesis route according to a single reaction with varying reagents.

Moreover, the way the reaction vector methodology recognizes the environment of a reaction is clearly demonstrated. For the transformation that is applied, there is a literature precedence, and thus a high level of confidence is achieved regarding the completion of the reaction. However, this requires that complete coverage of a generic reaction has been obtained through adequate examples in the reaction database.

The approach has been implemented in KNIME and this allows the facile customization of the procedure for a variety of applications. Overall, the usefulness of the proposed algorithm is to provide sets of molecules, which are associated with multiple purposes, and at the same time being synthetically feasible.

Abstract

Several different chemical properties/activities must be contemporaneously taken into account to prioritize compounds for their hazardous behavior. Examples of application of chemoinformatic methods, such as principal component analysis for obtaining ranking indexes and hierarchical cluster analysis for grouping chemicals with similar properties, are summarized for various classes of compounds of environmental concern. These cumulative endpoints are then modeled

by validated quantitative structure–activity relationships, based on theoretical molecular descriptors, to predict the potential hazard of new chemicals.

Introduction

The chemical universe is huge and is rapidly enlarging every day: the number of chemicals registered in the Chemical Abstract Service (CAS) registry (www.cas.org) gets nowadays over 100 million of chemicals, the majority of them are commercially available, and almost 345,000 are regulated and listed in various inventories (for instance, EU-EINECS, US-EPA TSCA, Canada-DSL). While many new chemicals are being developed continuously (many thousands each year), with increasing possibility to interact with humans and wildlife, information on physicochemical properties, reactivity, and biological activities are more slowly produced. The problem of lack of data and slow assessment procedures is highly significant: in fact, so far, we have extensive information about only a few chemicals, but the majority of compounds (>95 %), even high production volume (HPV) compounds, have been not sufficiently well characterized for their environmental behavior and potential to cause human or ecologic toxicity (Judson et al. 2009; Arnot et al. 2012). The filling of this data gap, in order to assess and control the chemicals effectively, is one of the main aims of several legislations worldwide, in particular of the recent European legislation REACH (Registration Evaluation Authorization and restriction of Chemicals) (EC Regulation 2006).

However, it is clearly impossible to measure all chemicals in all media to which humans and ecological receptors are exposed, as well as to test a plethora of endpoints. In order to reduce costs, time, and sacrificed animals, there is an urgent need to prioritize the use of testing resources toward those chemicals and endpoints that present the greatest potential of risk to human health and environment. Therefore, it is highly evident that the prioritization of chemicals is nowadays a big challenge, mainly for the identification of new emerging pollutants.

Chemoinformatic analysis has a clear and fundamental role in dealing with this issue. By chemoinformatic methods, it is possible to analyze and model the experimental information, which is already available for tested chemicals, and to exploit this information applying the developed tools to chemicals without experimental data or even before their synthesis. The main aim is to better use the existing knowledge for preventing, as soon as possible, potential dangerous properties of not yet tested compounds and also for planning *a priori* the synthesis of safe chemicals.

In recent years, many scientists have faced this important problem, studying various endpoints by different chemoinformatic approaches, but with the same common aim: to highlight the most hazardous chemicals by screening data sets of several compounds (here some representative of more recent examples: Gramatica and Di Guardo 2002; Salvito et al. 2002; Sanderson et al. 2003, 2004; Schmieder et al. 2003; Tong et al. 2003; Gramatica et al. 2004a, b, 2015, 2016a, b; Knekta et al. 2004; Öberg 2004, 2005, 2006; Muir and Howard 2006; Klasmeier et al. 2006; Hansson and Rudén 2006; Liu et al. 2006, 2007; Dix et al. 2007; Gramatica and

Papa 2007; Brown and Wania 2008; Papa and Gramatica 2008, 2010; Wegmann et al. 2009; Judson et al. 2009; Stenberg et al. 2009; Kavlock and Dix 2010; Li and Gramatica 2010a, b; Bhatarai and Gramatica 2010, 2011a; Howard and Muir 2010; Kovarich et al. 2011, 2012; Öberg and Iqbal 2012; Stempel et al. 2012; Roos et al. 2012; Sanderson 2012; Zarfl et al. 2012; Scherlinger et al. 2012; Arnot et al. 2012; Guillen et al. 2012; Singh et al. 2014; Cassani and Gramatica 2015; Wedebye et al. 2015; Sangion and Gramatica 2016a, b).

In this chapter, the crucial topic of screening chemicals of heterogeneous molecular structure is faced, studying some specific endpoints and focusing on compounds of environmental concern. These screening studies have two different aims: (1) to rank, highlight, and prioritize the most hazardous compounds among the already used chemicals, also those without experimental data, and (2) to predict the potential dangerous behavior of not yet synthesized compounds, in an *a priori* approach of the “benign by design” strategy of green chemistry. The focus here will be on the potential hazard intrinsically related to the chemical structure, thus on the utility of QSAR (quantitative structure–activity relationship) modeling, in particular based on a preliminary chemoinformatic analysis. A chemometric method of explorative analysis, such as principal component analysis (PCA), is applied for defining trends and ranking indices, as well as for the *a priori* data set splitting for external validation of QSAR models. Hierarchical cluster analysis (HCA) is used for grouping chemicals, according to some properties, and for defining the *a priori* classes for a subsequent classification by various classification methods. Particular emphasis is here devoted to multivariate linear regression (MLR) models, in particular ordinary least squares (OLS) models, based on genetic algorithm (GA) for variable selection and developed by the software QSARINS (QSAR-INSubria) for QSAR model development and validation (Gramatica et al. 2013). Some of the QSAR models of cumulative ranking endpoints here presented, applied to several classes of chemicals of emerging concern (CEC), are implemented in the module QSARINS-Chem (Gramatica et al. 2014) for easy applicability. Moreover, results of prioritization of endocrine disruptors (EDs), performed by various classification models, are also here commented.

A previous review of these chemoinformatic approaches, presenting the basis of externally validated QSAR modeling, illustrated according to the OECD principles for QSAR in regulation (OECD 2004) was published in Chapter 12 of the book *Recent Advances in QSAR Studies* (Gramatica 2009), edited by the same editors of the present book. Therefore, this chapter is mostly an updating of the previous one on the approaches widely applied in the Insubria QSAR research group, with special emphasis on the QSAR modeling of ranking indices obtained by PCA.

QSAR Modeling for Prioritization

QSAR (quantitative structure–activity relationship) modeling is based on the assumption that the molecular structure of a chemical (i.e., its geometric, steric, and electronic properties) contains the features responsible for its physical, chemical, and biological properties. Such modeling techniques are the best chemoinformatic

approaches for finding and exploiting the information inherent in the molecular structure related to the intrinsic hazard of any chemical. In fact, by QSAR models, based on theoretical molecular descriptors and validated chemometric methods, both of regression and classification, the biological activity (or property, reactivity, etc.) of new or untested chemicals can be inferred from the molecular structure of compounds whose activities (properties, reactivities, etc.) have already been assessed.

There is no need, in this chapter, to enter into details on QSAR modeling, commented elsewhere in this book; this has been also the topic of my chapter of the above-cited book (Gramatica 2009) and of all my papers in these last 20 years, some cited also here.

However, it is important to stress the point that, particularly for prioritization aim in screening big data sets, it is not sufficient to be able to reproduce well the available data and it should not be of primary importance to understand underlying mechanisms. To know the real predictivity of QSAR models and to which chemicals the model could be more reliably applied is of crucial and fundamental relevance. For this reason, all my QSAR works, which are mainly devoted to screening and prioritization, are focused on external validation on chemicals never used for model development and on model applicability domain (AD) check (Gramatica 2007, 2014; Gramatica et al. 2012). The proposal of concordance correlation coefficient (CCC) as validation parameter for QSAR models and its comparison with other used statistical parameters (Chirico and Gramatica 2011, 2012), highlighting some drawbacks and proposing intercomparable thresholds for real predictivity, were also done for this purpose. Recently, all these compared external validation parameters, and the Insubria graph for checking the applicability domain of QSAR models to chemicals without experimental data, have been implemented in our software QSARINS, freely available on request (www.qsar.it) for academia and research centers.

Ranking Indexes: PC Scores as New Cumulative Endpoints for QSAR Models

The behavior of chemicals in the environment and their impact on humans and wildlife are dependent on many different variables such as physicochemical properties, chemical reactivity, biological activity, etc. of the compounds. Since many parameters could be of contemporary importance, it is crucial to understand, rationalize, and interpret the covariance, which is inherent in this environmental complexity. Explorative methods of multivariate analysis, applied to various topics of environmental concern, give a combined view that generates ranking of the studied chemicals and highlight variable relationships. Then, based on these chemoinformatic tools, a more focused investigation can be made into chemicals of higher concern, guiding experimental tests on the prioritized compounds.

A multivariate explorative technique, such as principal component analysis (PCA), is used by several researchers (e.g., Knekt et al. 2004; Öberg and Iqbal

2012) to visualize the distribution of chemicals, represented by structural descriptors or environmental properties, with the aim to select representative compounds for experimental testing or to highlight the structural properties more related to specific hazardous behavior.

Some of my researches, summarized in this chapter, led to the proposal of a cumulative index, based on the outcome of the application of PCA for chemical screening and ranking. This index (the PC1 score) condenses the main information related to the studied properties. If it explains a reasonably significant variance of the studied variables, it can be usefully modeled as a new aggregate endpoint by QSAR approaches. The developed QSAR models exploit the already available information and can be used to predict the potential behavior of chemicals without experimental values or of new chemicals even before their synthesis. In fact, the QSAR approach, which is based on theoretical molecular descriptors that can be calculated for whatever drawn chemicals, can be applied without knowledge of any experimental parameter.

Similarly, another chemoinformatic method, such as hierarchical cluster analysis, can be applied for grouping chemicals according to their similarity based on several properties. The obtained groups can then be modeled by QSAR classification methods.

Many studies and published papers of the author 20-year researches at Insubria University are focused on this combined approach of chemoinformatic analysis (ranking indexes from PCA plus regression QSAR models of these cumulative indexes; groups modeled as classes by classification QSAR models) for prioritization aims. These will be summarized in the following paragraphs, organized according to the studied endpoints.

Multivariate Explorative Methods: PCA and HCA

The multivariate explorative techniques have the principal aim to condense the information, present in any multivariate data set, into a more easily interpretable view.

Principal component analysis (PCA) (Jackson 1995; Jolliffe 2002) is probably the most widely known and used explorative multivariate method. In PCA, the studied variables are linearly combined so that the obtained combinations (the principal components, PCs) explain the variation in the original data with decreasing explained variance. The first principal component (PC1) condenses the maximum amount of possible data variance in a single variable, while the following orthogonal PCs account for successively smaller quantities of the original variance.

To be useful and be considered sufficiently representative of the main information included in the data, it is desirable that the first two PCs account for a substantial proportion of the variance in the original data, while the remaining PCs condense irrelevant information and noise and could be disregarded. The more common representations of PCA are score plot, loading plot, and biplot, defined as the joint representation of the rows and columns of a data matrix: the points (scores) represent

the chemicals, while the vectors or lines represent the variables (loadings). The length of each vector indicates the information associated with that specific variable, while the angle between the vectors reflects their correlation.

Hierarchical cluster analysis (HCA) (Kaufman and Rousseeuw 1990) is a clustering technique with the purpose to build a binary tree of the data that successively merges similar groups of points. HCA creates clusters according to the measure of distance or similarity between data points, based on measured characteristics, connecting, in an iterative process, the nearest groups of objects. It is based on the idea that objects are more related to nearby objects than to objects farther away. The main output of the HCA is the dendrogram that summarizes the relationships between objects in a visual binary tree. Clusters can be identified cutting the dendrogram at different similarity levels. Hierarchical cluster analysis is one of the best ways to observe how homogeneous groups of objects with similar properties are formed and to identify classes.

QSAR Modeling of Ranking Indexes and Classes

In our environmental chemistry studies, PCA for obtaining ranking indexes and regression QSAR modeling of these ranking indexes, as new cumulative endpoints, and HCA for obtaining *a priori* classes and classification QSAR models have been widely used in my group for screening, ranking, and priority setting in many contexts. I'll cite here and comment below only some of the most significant and/or recent: (a) environmental partitioning and leaching of pesticides (Gramatica and Di Guardo 2002; Gramatica et al. 2004a) and benzotriazoles (Bhatarai and Gramatica 2011b), (b) degradability of volatile organic compounds (VOCs) by tropospheric oxidants (Gramatica et al. 2004b), (c) persistence of POPs by global half-life index (GHLI) (Gramatica and Papa 2007; Papa and Gramatica 2008), (d) rat/mouse toxicity of perfluorinated compounds (PFCs) (Bhatarai and Gramatica 2010, 2011a), (e) aquatic toxicity of personal care products (PCPs) (Gramatica et al. 2016b) and pharmaceuticals (Sangion et al. 2015; Sangion and Gramatica 2016b), and (f) PBT screening of various compounds by PBT Index (Papa and Gramatica 2010; Gramatica et al. 2015, 2016a; Cassani and Gramatica 2015; Sangion and Gramatica 2016a).

Environmental Behavior

Leaching of Pesticides

The tendency of pesticides to pollute groundwaters and, in general, the partitioning of pesticides into different environmental compartments depend mainly on physicochemical properties, such as soil organic carbon partition coefficient (K_{oc}), *n*-octanol/water partition coefficient (K_{ow}), water solubility (S_w), vapor pressure

Fig. 1 (a) PCA of environmental physicochemical properties of 135 pesticides and definition of leaching index (*LIN*) and volatility index (*VIN*). (b) Scatter plot of the OLS model of *LIN* (Permission from Gramatica and Di Guardo, *Chemosphere*, 2002)

(VP), and Henry's law constant (H). We have applied PCA on these various environmental partitioning properties of a heterogeneous and highly representative data set of 135 pesticides of different chemical classes (acetanilides, carbamates, dinitroanilines, organochlorines, organophosphates, phenylureas, triazines, triazoles) to study the tendency to leach from soil into the surface and subsurface waters (Gramatica and Di Guardo 2002) (Fig. 1a).

The resultant macrovariables, the PC1 and PC2 scores, were called leaching index (*LIN*) and volatility index (*VIN*) and were proposed as cumulative partitioning indexes in different environmental media. The component *LIN* tends to discriminate between the relatively more sorbed/less soluble (on the left of Fig. 1a) and the less sorbed/more soluble pesticides (on the right), while *VIN* appears to differentiate between volatile (upper part of Fig. 1a) and nonvolatile compounds.

Both indexes were modeled by OLS QSAR model, using theoretical DRAGON molecular descriptors (Talete 2007) selected by genetic algorithms: they are mainly atom and group count parameters as a number of halogens, nitro groups and sulfur, plus Ms the mean electrotopological state of the molecule related to the polarizability, and a topological descriptor ICR (the radial centric information index) (Bonchev and Rouvray 1991). The model robustness and internal predictive power are satisfactory; below the QSAR model equation for LIN, the cumulative index which explains 65 % of the data variance and the corresponding plot in Fig. 1b are reported:

$$\text{LIN} = -3.04 - 0.96nX - 2.28n\text{NO}_2 + 3.42\text{Ms} - 1.74\text{ICR} - 0.45n\text{S}$$
$$n = 135, R^2 = 87.0 \%, Q^2_{\text{LOO}} = 85.8 \%, Q^2_{\text{LMO}} = 85.7 \%,$$
$$s = 0.66, F = 172.22, \text{SDEP} = 0.68 \text{ and } \text{SDEC} = 0.65.$$

A combination of two chemoinformatic methods, principal component analysis for ranking and hierarchical cluster analysis for the definition of four *a priori* classes (Fig. 2a), according to the environmental behavior as soluble, sorbed, volatile, or nonvolatile/medium class, was applied to the environmental physicochemical properties of 54 pesticides of various chemical categories (Gramatica et al. 2004b). The pesticides were finally assigned to the defined four classes by three different classification methods (classification and regression tree (CART, the classification tree in Fig. 2b), k-nearest neighbors (k-NN), and regularized discriminant analysis (RDA)) with misclassification risk in cross validation ranging from 17 % to 18 %. The discriminant variables were simple theoretical molecular descriptors, such as MW, nHDon, and topological Balaban Index (Balaban 1983) (named J in DRAGON). MW, which encodes information on molecule dimension, is able to discriminate the chemicals that are contemporaneously most sorbed in organic soils and least soluble in water; in fact it is well known that biggest molecules have the greatest tendency to bind, by van der Waals forces, to the organic component of the soil (mainly humic acids). The more soluble pesticides, which have the higher possibility to form hydrogen bonds with water molecules, are discriminated by nHDon, the number of groups able to donate hydrogen in the hydrogen bonds. Furthermore, the chemicals with fewer intramolecular hydrogen bonds are the most volatile.

Similar PCA ranking was also useful to highlight which benzotriazoles could be most dangerous for the aquatic compartment (Bhatarai and Gramatica 2011a): these chemicals, used in the past mainly as pesticides, are now recognized as new contaminants of emerging concern (CEC) for the environment. In fact they are nowadays used as deicing additives and are a major source of pollution predominantly of aquatic resources near the airports of major cities.

The presented chemoinformatic approaches allow the screening of the environmental distribution of pesticides and a rapid predetermination of their possibility to

Fig. 2 (a) Hierarchical cluster analysis of the environmental physicochemical properties of 54 pesticides for the definition of four *a priori* classes. (b) Classification tree of CART model of the four classes (Permission from Gramatica et al. *Int. J. Environ. Anal. Chem.*, 2004b)

pollute both surface and groundwaters, starting only from the molecular structure without any *a priori* knowledge of the physicochemical properties.

Persistence

Persistence in the environment is an important criterion in prioritizing hazardous chemicals and in identifying new persistent organic pollutants (POPs).

Various studies, based on various approaches, have been performed on this topic (Öberg 2005, 2006; Muir and Howard 2006; Klasmeier et al. 2006; Wegmann et al. 2009; Howard and Muir 2010; Puzyn et al. 2011; Scheringer et al. 2012). Here some

of my studies regarding the screening and prioritization using cumulative indexes are summarized.

Degradability of Volatile Organic Compounds (VOCs) by Tropospheric Oxidants

An indirect measure of the persistence of volatile organic compounds (VOCs) in the atmosphere, and therefore a necessary preliminary parameter in environmental exposure assessment, is the degradability, measured by the reaction rates with the main tropospheric oxidants: hydroxyl radical and ozone during the daytime and nitrate radical at night. The contemporaneous variation and influence of the rate constants of the degradation by three oxidants (kOH, kNO₃, and kO₃) of several VOCs, in determining their inherent tendency to degradability, were explored by principal component analysis (Fig. 3a). The first component, along which the variables are grouped in the same direction, discriminates between the less degradable compounds, so the relatively more persistent (chemicals to the right in the PCA graph) and the more degradable chemicals (chemicals to the left).

Thus, the PC1 score, which explained 81 % of the data variance for 399 chemicals, was defined as ATDIN, an atmospheric degradability index, and was modeled by OLS, based on theoretical molecular descriptors and externally validated (Gramatica et al. 2004a) (scatter plot in Fig. 3b).

It is also interesting to note that the PC2 is able to highlight the different reactivity of chemicals with ozone and with OH and NO₃ radicals, respectively.

$$\text{ATDIN} = -17.59 - 1.80\text{HOMO} + 2.87\text{nBnz} - 0.51\text{BEHe4}$$

$$n_{\text{training}} = 227, R^2 = 93.9 \%, Q^2_{\text{LOO}} = 93.7 \%, Q^2_{\text{LMO}(50\%)} = 93.5 \%;$$

$$n_{\text{prediction}} = 172; Q^2_{\text{EXT}} = 92.3 \%;$$

$$s = 0.387; \text{SDEC} = 0.384; \text{SDEP} = 0.391$$

The molecular descriptors of this model are informative of different aspects of the studied reaction. The best descriptor is the energy of the highest occupied molecular orbital (HOMO), as a measure of the molecular reactivity. The number of aromatic rings (nBnz) is probably selected in the model to encode for the different reactivity of aliphatic and aromatic chemicals in relation to the attack sites for the three different oxidants. 2D-BCUT descriptors, BEHe4, weighted by the atomic electronegativity of Sanderson (Burden 1989) encode for charge distribution factors.

This model can be useful in avoiding the release into the environment of potential persistent volatile compounds which are not inherently degradable in troposphere, causing risk to humans and wildlife for their persistence at that atmospheric level. Moreover, these chemicals could reach the stratosphere with potential dangerous behavior on the ozone layer.

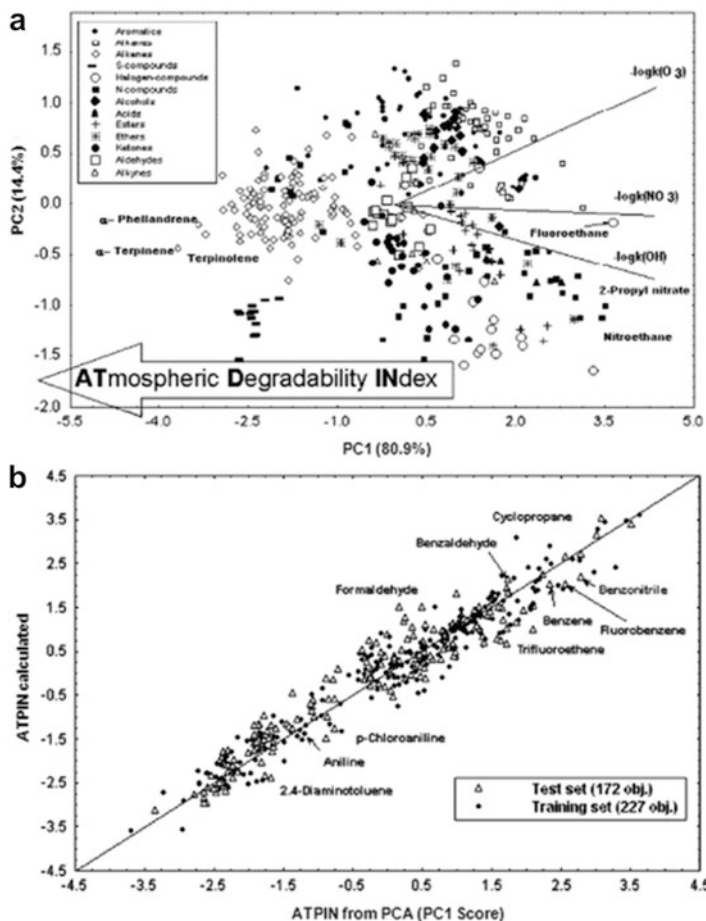

Fig. 3 (a) PCA of the kinetic rate constants of degradation by tropospheric oxidants of 399 VOCs and definition of ATDIN. (b) Scatter plot of QSAR model of ATDIN (Permission from Gramatica et al. *Atmos Environ*2004a)

Screening of POPs by Environmental Half-Life (HL)

The degradation half-lives in various compartments are among the more commonly used criteria for studying environmental persistence. Available half-life data for degradation in air, water, sediment, and soil, for a set of 250 organic chemicals, were combined in multivariate approach by principal component analysis. A ranking of the studied organic pollutants according to their relative overall half-life is obtained in this way: we named this global half-life index (GHLI) (Gramatica and Papa 2007).

The biplot relative to the first and second components is reported in Fig. 4a, where the chemicals (points) are distributed according to their environmental persistence, represented by the linear combination of their half-lives in the four selected

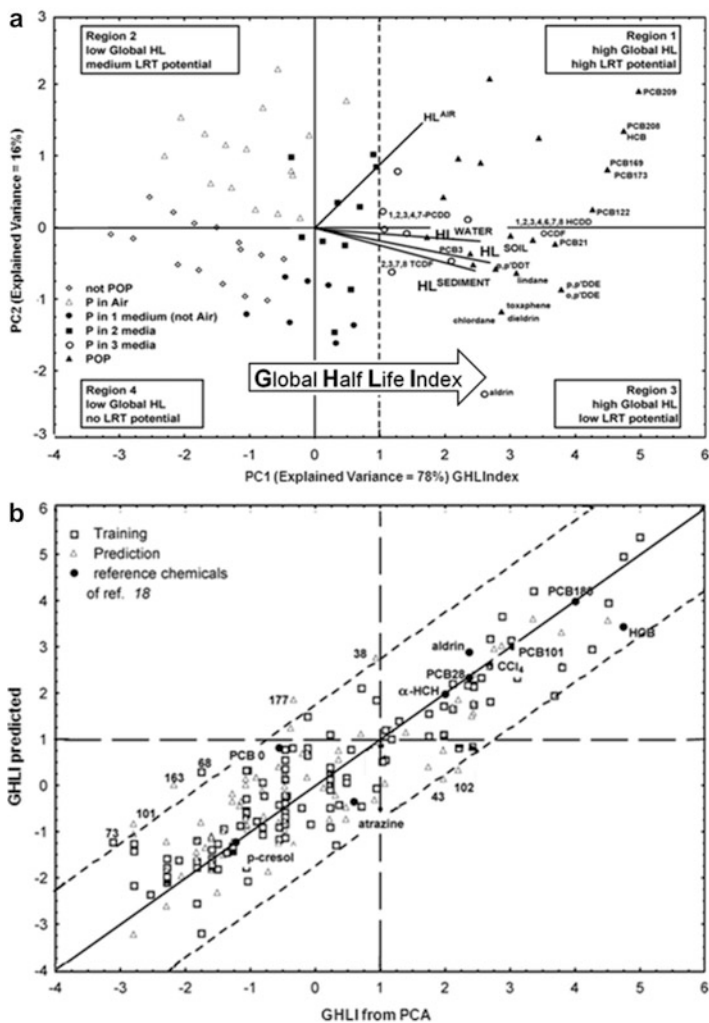

Fig. 4 (a) PCA of the half-lives in four environmental compartments of 250 heterogeneous chemicals and definition of global half-life index (*GHLI*) for POPs. (b) Scatter plot of the QSAR model of *GHLI* (Permission from Gramatica and Papa, *Environ. Sci. Technol.*, 2007)

media (the loading lines show the importance of each variable in the first two PCs). The cumulative explained variance of the first two PCs is 94 %; the PC1 alone providing a very significant part of the total information is 78 %. Since all the half-lives in different media (the lines) are oriented in the same direction along the first principal component, PC1 is a new macro-variable representing cumulative half-life and condensing chemical tendency to environmental persistence. Therefore, PC1 is useful to discriminate chemicals with regard to persistence: chemicals with high

half-life values in all the media are located to the right of the PCA plot (Fig. 4a), in the zone of global higher persistence (very persistent chemicals anywhere); chemicals with a lower global half-life fall to the left of the graph, not being persistent in any medium.

PC2, although less informative (E.V. 16 %), is also interesting: it separates the compounds more persistent in air (upper parts in Fig. 4a, region 1), i.e., those with higher long-range transfer (LRT) potential, from those more persistent in water, soil, and sediment (region 3 in Fig. 4a).

A deeper analysis of the distribution of the studied chemicals confirms experimental evidences: to the right, among the very persistent chemicals in all the compartments (full triangles in Fig. 4a), most of the compounds recognized as POPs by the Stockholm Convention (UNEP 2014) are located. Highly chlorinated PCBs and hexachlorobenzene are among the most persistent compounds in this reference scenario; they are grouped in region 1 owing to their global high persistence, especially in air. The less chlorinated PCBs (PCB 3 and PCB 21), p,p'-DDT, p,p'-DDE and o,p'-DDE, highly chlorinated dioxins and some dioxin-like compounds, as well as pesticides toxaphene, lindane, chlordane, dieldrin, and aldrin fall in region 3 of highly persistent chemicals, mainly in compartments different from air.

This global index GHLI was then modeled as a cumulative endpoint using a QSAR approach based on theoretical DRAGON molecular descriptors. The original set of available data was first randomly split into training and prediction sets: 50 % of the compounds (125 compounds) were used for OLS model development, while the other 50 % was put into the prediction set to validate the QSPR model. Given below is the best model, selected by statistical approaches, and its statistical parameters, which confirm model robustness and real external predictivity. Figure 4b shows the plot of GHLI values from PCA versus the predicted GHLI values:

$$\text{GHL Index} = -3.12 + 0.33X_{0v} + 5.1Mv - 0.32MAXDP - 0.61nHDon \\ - 0.5CIC0 - 0.61O - 060$$

$$n_{\text{training}} = 125; R^2 = 0.85; Q^2_{\text{LOO}} = 0.83; Q^2_{\text{BOOT}} = 0.83,$$

$$\text{RMSE} = 0.76; \text{RMSE}_{\text{cv}} = 0.70;$$

$$n_{\text{prediction}} = 125, R^2_{\text{EXT}} = 0.79; \text{RMSEP} = 0.78.$$

A similar highly predictive model for GHLI, based on PaDEL-Descriptors (Yap 2011), has been recently implemented in the module QSARINS-Chem of the software QSARINS (www.qsar.it) for easy applicability on new compounds, in order to help in avoiding the synthesis of chemicals that have, inherent in their molecular structure, the potentiality to be POPs.

The chemical environmental half-lives were also used for POP pre-screening (Papa and Gramatica 2008) developing predictive classification models, based on k-NN, CART, and counter-propagation artificial neural networks (CP-ANN). In this approach, the three *a priori* classes of different degrees of persistence (high, medium, and low) were determined by hierarchical cluster analysis (Fig. 5a) applied

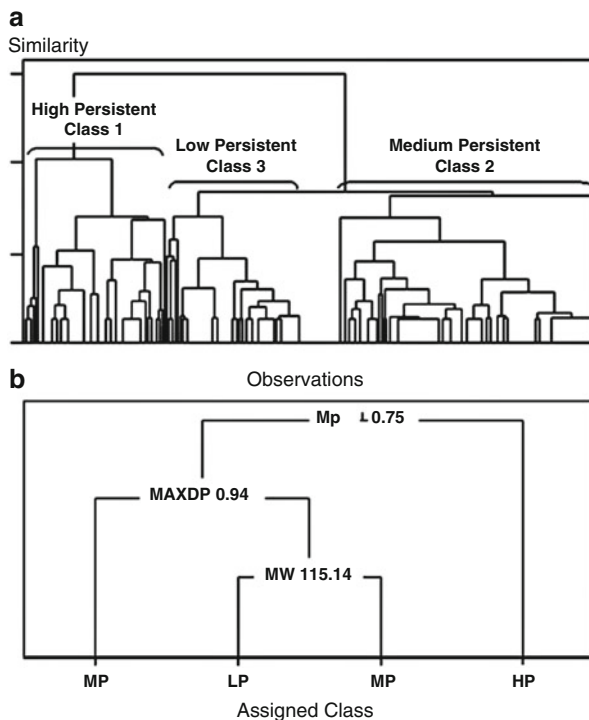

Fig. 5 (a) Hierarchical cluster analysis of environmental half-lives for defining three classes of persistence; (b) CART tree of three classes for POP ranking (Permission from Papa and Gramatica *J. Mol. Graph. Mod.*, 2008)

to environmental half-lives. The range of overall external predictivity of the three classification models was high, 75–85 %. The three discriminant structural variables selected in this study (mean polarizability, Mp; maximum electrotopological variation, MAXDP; and molecular weight, MW, in the decision nodes of the CART tree in Fig. 5b) are all bidimensional descriptors independent of chemical conformation, thus easily calculable from the bidimensional structural graph of a compound. The calculations of these variables can be performed starting from the simple SMILES string of a chemical.

The application of both kind of models, regression of GHLI and classification of persistence classes, using only a few structural descriptors, could allow a fast preliminary identification and prioritization of not yet known POPs, just from the knowledge of their molecular structure. The proposed multivariate approach is particularly useful not only to screen and to make an early prioritization of environmental persistence for pollutants already on the market, but also for not yet synthesized compounds, which could represent safer alternative and replacement solutions for recognized POPs. No method other than QSAR is applicable to detect the potential persistence of completely new compounds.

Toxicity

Endocrine Disruptors (EDs)

A large number of environmental chemicals are suspected to disrupt endocrine systems by mimicking or antagonizing natural hormones. Such chemicals, named endocrine disruptors (EDs), may have dangerous effects on the health of humans and wildlife. Under REACH, the chemicals with demonstrated endocrine disruption activity require authorization to be produced and used; in addition, safer alternatives should be proposed. However, it is practically impossible to perform a variety of toxicological tests on all potential EDs; thus, QSAR modeling for prioritization has been applied by many authors in these last years (e.g., Shi et al. 2001; Hong et al. 2002; Fang et al. 2003; Schmieder et al. 2003; Tong et al. 2003; Roncaglioni et al. 2004; Asikainen et al. 2004, 2006; Saliner et al. 2006; Devillers et al. 2007, 2015; Dybdahl et al. 2012; Vuorinen et al. 2013; Browne et al. 2015) providing promising methods for the screening of a set of chemicals for potential estrogenic activity.

QSAR models of the estrogen receptor binding affinity of a data set of 128 NCTR heterogeneous compounds (Ding et al. 2010) were built also in our laboratory by OLS method using theoretical DRAGON descriptors (Liu et al. 2006), giving full consideration to the OECD principles regulating QSAR acceptability (OECD 2004) during model construction and assessment.

The results of several validation paths using different splitting methods (D-optimal design, self-organizing maps (SOM), random on activity sampling) give proof that the proposed QSAR model is robust and satisfactory (Q^2_{pred} range, 0.76–0.81), thus providing a feasible and practical tool for the rapid screening of the estrogen activity of organic compounds, supposed EDs. A similar regression model, based on the same training set, and on PaDEL-Descriptors (Yap 2011), is now available in the QSARINS-Chem module of the QSARINS software for easy application on new chemicals (www.qsar.it).

On the same topic, satisfactory predictive models for EDs' classification, based on different classification methods, were proposed (Liu et al. 2007). In this study, QSAR models, based on 232 structurally diverse chemicals from the NCTR database as training set and on theoretical structural descriptors, were developed to quickly and effectively identify possible estrogen-like chemicals by using nonlinear classification methodologies (least squares support vector machine (LS-SVM), counter-propagation artificial neural network (CP-ANN), and k-nearest neighbor (k-NN)). The main descriptor, able to classify alone, with a concordance percentage near 80 %, was nArOH, the number of phenolic groups. Therefore, chemicals with phenolic groups have a great potentiality to be endocrine disruptors. The models were externally validated on 87 chemicals (prediction set) not included in the training set. All three methods gave satisfactory prediction results both for training and prediction sets (accuracy range, 82.8–89.7 %); the most accurate model was obtained by the LS-SVM approach. In addition, our models were also applied for screening a big data set from US-EPA (more than 58,000 discrete organic chemicals)

Fig. 6 Classification obtained by consensus of three methods on the screening of more than 50,000 chemicals as potential EDs

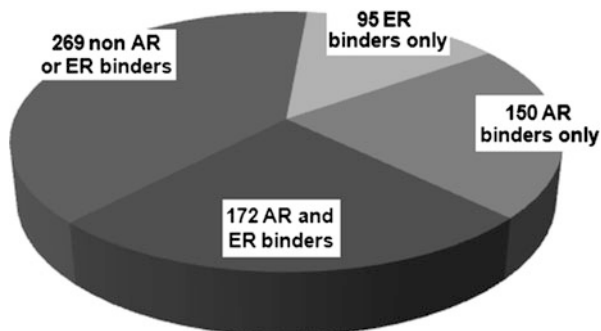

to verify the predictions by consensus: about 76 % of the screened chemicals were predicted not to bind to an estrogen receptor (Fig. 6). The obtained results indicate that the proposed QSAR models could provide a feasible and practical tool for the rapid screening of huge data sets and a very useful prioritization approach for focusing experimental tests only on potential estrogens. In fact, the common 40,300 negative compounds could be excluded from the potential ED list without experiments, because the models have high accuracy and low false-negative rate (3–9 %), while costly and lengthy experimental tests should be concentrated on the common positives (7.8 %, meaning >4000) and eventually on the disagreements, which are predicted as EDs by one classification method and not by the others.

An additional screening work was done to classify a big data set of EDs, both estrogen receptor (ER) binders and androgen receptor (AR) antagonists, mainly aiming to improve the external sensitivity in comparison to the literature models (Vinggaard et al. 2008) and to screen for potential AR binders (Li and Gramatica 2010a). The k-NN, the local lazy method and alternating decision tree methods, and the consensus approach were used to build different models, which improved the sensitivity on external chemicals from 57.1 % (Vinggaard et al. 2008) to 76.4 %. The models' predictive abilities were further validated on a blind data set: the sensitivity was even higher >85 %. Then the proposed classifiers were used: (i) to distinguish a set of AR binders into antagonists and agonists, (ii) to screen a combined estrogen receptor binder database to find out possible chemicals that can bind to both AR and ER, and (iii) to virtually screen our in-house environmental chemical database. The *in silico* screening results suggested that: (i) some compounds can affect the normal endocrine system through a complex mechanism because they could bind both to ER and AR; (ii) new EDs, which are non-ER binders, are recognized *in silico* as binders to AR; and (iii) about 20 % of compounds in a big data set of environmental chemicals are predicted as new AR antagonists. Therefore, the priority should be given to them for experimentally testing their binding activities with AR. The results of this complex screening study are summarized in Fig. 7.

Other QSAR models for screening and prioritization of potential EDs were also developed in Insubria group on brominated flame retardants (Kovarich et al. 2011), on perfluorinated chemicals (Kovarich et al. 2012), as well as on other heterogeneous chemicals (Li and Gramatica 2010b, c).

Ecotoxicity

A lot of chemicals that enter into the environment could have dangerous toxic impact on different wild species. Aquatic organisms, such as algae, crustacean, and fish, are normally used as test organism to determine ecotoxicological data. However, also in relation to ecotoxicity, there is a relevant lack of experimental data; therefore, several chemoinformatic approaches have been, and are continuously, applied to model the existing data and to predict ecotoxicological endpoints for various classes of chemicals of high concern (e.g., Vighi et al. 2001; Salvito et al. 2002; Sanderson et al. 2003, 2004; Öberg 2004; Lo Piparo et al. 2006; Roy 2006; Mazzatorta et al. 2006; Sanderson and Thomsen 2009; Gramatica et al. 2012; Sanderson 2012; Kar and Roy 2012; Cassani et al. 2013, 2014; Singh et al. 2014; Roy et al. 2015). The majority of chemical regulators apply ECOSAR models (US EPA 2012), but these models are not always applicable with satisfactory reliability to all kind of chemicals. This problem, related to applicability domain, has been recently highlighted for an important class of emerging environmental pollutants, the pharmaceuticals (Madden et al. 2009), but it is relevant also for other chemicals, such as personal care products (PCPs). Below, some examples of new ecotoxicity studies, recently performed by the Insubria group on these contaminants of emerging concern for the environment (PCPs and pharmaceuticals), are reported.

Aquatic Toxicity of Personal Care Products

PCP ingredients, widely used all over the world, during the last years became chemicals of increasing environmental concern, mainly because they are detected in water and may harm wildlife. Due to their high structural heterogeneity, to the big number of endpoints and the huge lack of experimental data, *in silico* tools, as QSAR models based on structural molecular descriptors, are highly useful to quickly highlight the most hazardous and toxic compounds, prioritizing existing or even not yet synthesized chemicals. In a recent study (Gramatica et al. 2016a), new externally validated QSAR models, specific to predict acute PCP toxicity in three key organisms of aquatic trophic level, i.e., algae (*Pseudokirchneriella subcapitata*), crustacean (*Daphnia magna*), and fish (*Pimephales promelas*), were

developed according to the OECD principles for the validation of QSARs, using the QSARINS software (Gramatica et al. 2013). These OLS models, based on theoretical molecular descriptors calculated by free PaDEL-Descriptor, selected by genetic algorithm, are statistically robust and externally predictive (CCC range:89–95 %). They were applied to predict the three modeled acute toxicities for 534 PCPs without experimental data, verifying the wide structural applicability domain of each model by the Insubria graphs (more than 95 % of 534 screened PCPs were into the AD). The root mean squared error (RMSE) of each model for chemicals in the prediction sets, not used for model development, was compared with the corresponding RMSE of the ECOSAR models (US EPA 2012): the RMSE of the Insubria models is always around half logarithmic units, while ECOSAR models exhibit always RMSE values higher than one logarithmic unit. Then, according to the consolidated approach in our group, a trend of cumulative acute aquatic toxicity was highlighted by PCA of the three endpoints of ecotoxicity, allowing the ranking of the overall most toxic for all three trophic levels of the aquatic compartment with more than 90 % of data explained variance (Fig. 8). In the biplot of Fig. 8, the most dangerous PCPs, in the right zone, are highlighted as filled squares, using the multi-criteria decision making (MCDM), included in QSARINS-Chem (Gramatica 2014). MCDM is a technique that summarizes the performances of a certain number of criteria simultaneously, as a single number (score) between 0 and 1. This is done associating to every criteria, in our case different predictions for the studied endpoints, a desirability function which values range from 0 to 1 (where 0 represents the less toxic compound and 1 the most toxic), and giving different weights to the selected criteria. The sum of the weights of the criteria must be 1, and in our case, we used the same weight for each criterion: 0.333, which is 1/3 (total/number

Fig. 8 PCA of experimental and predicted aquatic toxicity data for 484 PCPs and definition of the aquatic toxicity index (ATI) (Permission from RCS: Gramatica et al., Green Chem. 2016b)

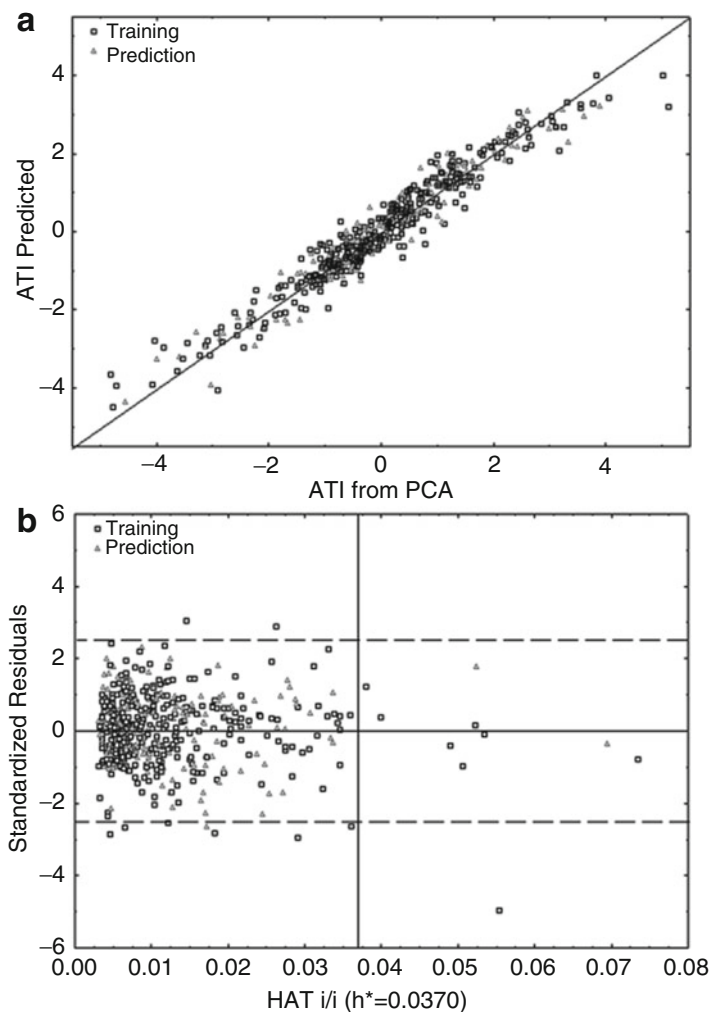

Fig. 9 (a) Scatter plot of the OLS model of ATI; (b) Williams plot for the AD of ATI model (Permission from RCS: Gramatica et al., Green Chem. 2016b)

of criteria). The geometric average of all the values obtained from the desirability functions gives the MCDM value (i.e., the ranking).

A priority list of 40 most hazardous PCPs was then proposed: it includes mainly UV filters (in particular benzotriazoles), some phthalates, and also some fragrances.

Finally, the trend of PC1, which explains about 80 % of the data variance, was proposed as an aquatic toxicity index (ATI). A QSAR model for the prediction of ATI was developed, by OLS on 484 data and using the PaDEL descriptors (scatter plot in Fig. 9a), to be applicable in QSARINS (www.qsar.it) for the *a priori* detection of not yet tested PCPs and also for the preliminary chemical design

of possibly not environmentally hazardous PCPs. The model, with the following equation, is highly predictive and has a good applicability domain verified by the Williams plot of Fig. 9b:

$$\text{ATI} = -14.27 + 0.33 \text{ XlogP} + 18.33 \text{ Mp} + 0.02 \text{ TIC1}$$

$$n_{\text{training}} = 324; R^2 = 0.94; Q^2_{\text{LOO}} = 0.93; Q^2_{\text{LMO}} = 0.93, \text{ RMSE} = 0.40;$$

$$\text{RMSE}_{\text{cv}} = 0.40;$$

$$n_{\text{prediction}} = 160; Q^2_{\text{Fn}} = 0.93 - 0.94; \text{CCC}_{\text{EXT}} = 0.97; \text{RMSE}_{\text{EXT}} = 0.39.$$

The model is mainly driven by LogP descriptor, here represented by XlogP, which has, as expected, a positive sign in the equation, increasing the toxicity of a chemical. The remaining two descriptors, Mp and TIC1, both with a positive sign in the model equation and thus with a positive impact on the cumulative toxicity trend of PCPs, encode respectively for mean atomic polarizability and total information content index (neighborhood symmetry of 1 order). These three descriptors are mainly related to the complexity and the dimension of the molecule, but also to the presence of electronegative atoms, giving higher values for big and halo-substituted compounds.

Aquatic Toxicity of Pharmaceuticals

Similarly to the modeling and screening developed for PCPs, active pharmaceutical ingredients (APIs) were also studied. Pharmaceuticals have become ubiquitous present in the environment; for this reason in 2006, the European Medicines Evaluation Agency (EMA) published guidelines for the environmental risk assessment of human pharmaceuticals. Every environmental risk assessment (ERA) requires large amounts of data for each chemical, but, unfortunately, information on ecotoxicological data is available only for a little percentage of APIs in literature and databases. From literature, we collected and carefully curated data sets for the limited quantity of ecotoxicity data of species at different trophic levels (algae, *Daphnia*, fish). For each species, we developed *ad hoc* QSAR acute toxicity models, based on PaDEL molecular descriptors, using the OLS method and genetic algorithm for variable subset selection in QSARINS software (www.qsar.it). All models are robust ($R^2 > 0.75$, $Q^2_{\text{LOO}} > 0.70$) and externally validated ($\text{CCC} > 0.85$) on different splitting schemes, thus allowing reliable application to new pharmaceuticals. The structural applicability domain (AD) of the proposed models to pharmaceuticals without experimental data was verified and demonstrated to be very high with 74 % of chemicals inside the AD for all the toxicity models. The predictions from Insubria models were always better than those obtained by ECOSAR (US EPA 2012) (average RMSE of 0.5 for Insubria models against an average RMSE of 1.3 for ECOSAR). Moreover, reliable predictions from the different models, applied on a set of more than 1000 pharmaceuticals, were combined by PCA to find an ecotoxicity trend representative of the pharmaceuticals' toxicity in the

whole aquatic ecosystem. This trend, called overall aquatic toxicity index (ATI) for pharmaceuticals, was then modeled by molecular descriptors to obtain a QSAR model useful to highlight, directly from the chemical structure, the pharmaceuticals potentially most hazardous for the environment. This index, and the predictions obtained by it, could be used to refine procedures of input prevention and control at consumer level as well as *a priori* in the rational design of environmentally safer pharmaceuticals (Sangion et al. 2015; Sangion and Gramatica 2016b; Fig. 10).

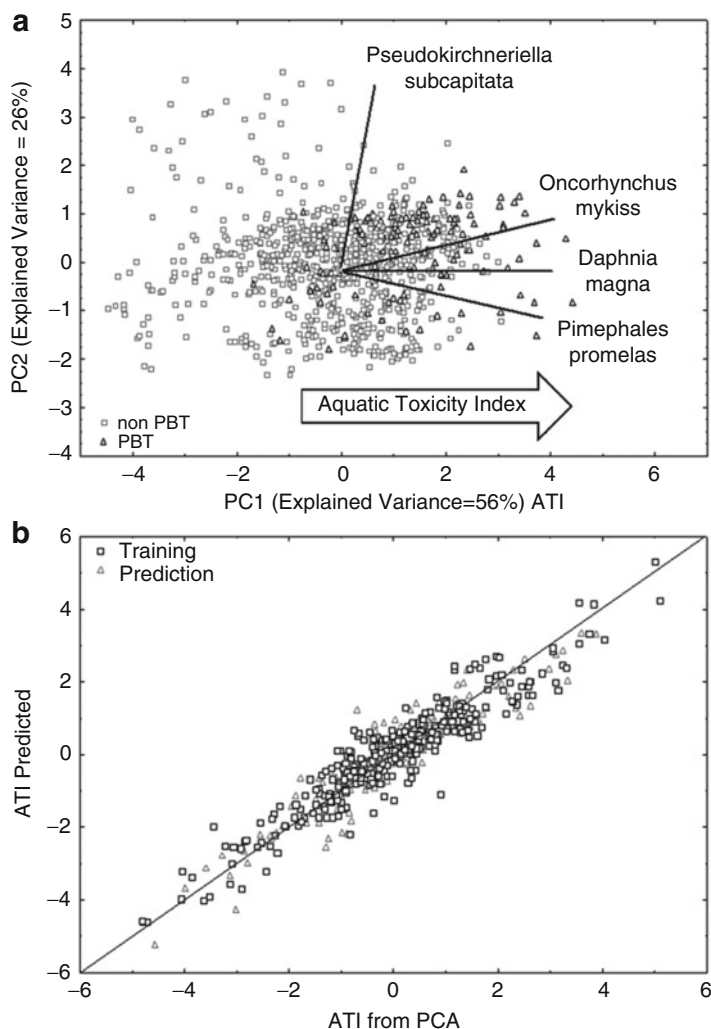

Fig. 10 (a) PCA of experimental and predicted aquatic toxicity data for 984 pharmaceuticals and definition of the aquatic toxicity index (*ATI*); (b) scatter plot of the OLS model of *ATI* for pharmaceuticals

Mammalian Toxicity on Rodents of Fluorinated Chemicals

Fully or highly fluorinated compounds, known as per- and polyfluorinated chemicals (PFCs), are widely distributed and released in the environment, because of their use in different household and industrial products. Some long-chain PFCs are classified as emerging pollutants; in fact, they are found undegraded worldwide and even in polar regions, but their environmental and toxicological effects are mostly not well known. In our lab, under the CADASTER FP7 EU Project (www.cadaster.eu), QSAR models of the mammalian toxicity of PFCs on two species of rodents, rat and mouse, were developed, on two endpoints: LC50 data for inhalation (Bhhatarai and Gramatica 2010) and LD50 oral toxicity (Bhhatarai and Gramatica 2011b).

The OLS models, based on DRAGON molecular descriptors selected by genetic algorithm, were always developed on data sets split in different ways (random, by structural similarity using self-organizing maps (SOM)) to verify the satisfactory external predictivity.

Furthermore, to understand the contribution of each toxicity endpoint and the mutual effect of rodent toxicity, the four models were applied individually to a combined data set of 376 compounds, obtaining predictions for those without experimental data. The compounds were checked for their belonging to the structural AD of each model by Insubria graphs, and 204 compounds were found to be within AD. The PCA of experimental and predicted inhalation and oral toxicity on both rodents (rat and mouse) of PFCs, within the AD of all the four models, allowed to rank PFCs according to their cumulated toxicity on rodents. In Fig. 11 the biplot

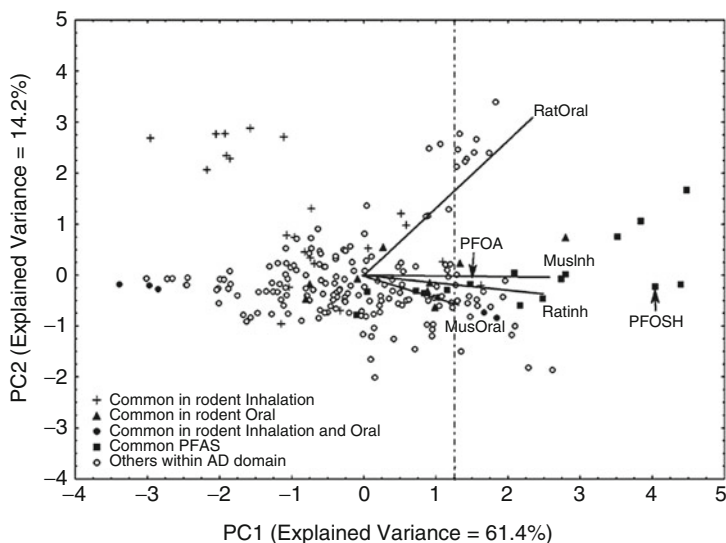

Fig. 11 PCA of inhalation and oral toxicity for two rodent species of 204 PFCs (Permission from Bhhatarai and Gramatica *Mol. Divers.* 2011b)

of this PCA, which explains 75.6 % of data variance, is reported. The compounds with experimental values of rodent inhalation (cross), rodent oral (filled triangles), both rodent inhalation and oral (filled circles), and most common alkylated PFCs (filled squares) are tagged. PC1 ranks the PFCs according to their cumulative rodent toxicity, while PC2 differentiates the PFCs more toxic for rat oral toxicity from those more toxic on the other endpoints. In the right zone of the PCA, the most dangerous and already banned PFCs, as perfluorooctanoic acid (PFOA) and perfluorosulfonic acid (PFSOA), are correctly located: this is a proof of the reliability of the obtained screening and ranking results. Therefore, some other PFCs, which are located in the same zone of concern, should be considered of potential toxicity and prioritized for experimental tests.

Persistence Bioaccumulation Toxicity (PBT)

The chemicals that are contemporaneously persistent, bioaccumulative, and toxic (PBT) are priority chemicals due to the potential risk they pose to humans and ecosystems; therefore, they are considered substances of very high concern (SVHC), which require authorization for use and plan for safer alternatives by REACH. Therefore, in accordance to the precautionary principle, chemicals have to be screened and evaluated for their overall PBT behavior. Unfortunately, for many of the existing substances, even for high production volume (HPV), it is not known, currently, if they could have a potential PBT-like behavior.

Several screening works (Muir and Howard 2006; Howard and Muir 2010; Öberg and Iqbal 2012; Stempel et al. 2012) have highlighted that, among commercial chemicals, many might be PBTs. Therefore, it is evident that not only different approaches for priority setting should be compared to identify the existing potential PBTs but also the “benign by design” approach of green chemistry should be applied for planning the synthesis of safer alternatives to these dangerous compounds (Papa and Gramatica 2010; Stempel et al. 2012; Gramatica et al. 2015, 2016a; Cassani and Gramatica 2015; Sangion and Gramatica 2016a).

Currently, identifying substances as potential PBT or POP candidates relies mainly on determining if specific properties of a chemical exceed threshold values for each property related to PBT behavior (commonly, half-life in various compartments for P, BCF for B, and a number of toxicity evidences for T) (Muir and Howard 2006; Howard and Muir 2010). The most widely used tool for PBT assessment is the US-EPA PBT Profiler (2006), because it is easily applicable from the web (US EPA 2006). The PBT Profiler screens chemicals on the basis of individual P, B, and T properties, calculated by QSAR models and compared to cut off values for each endpoint.

As an alternative approach for PBT prioritization, we developed and proposed a new tool for the screening of chemicals for their potential cumulative PBT behavior (Papa and Gramatica 2010), as an inherent property of a compound that makes it potentially hazardous. PCA of overall half-life in various compartments (the global half-life index, commented above (Gramatica and Papa 2007)), for taking into

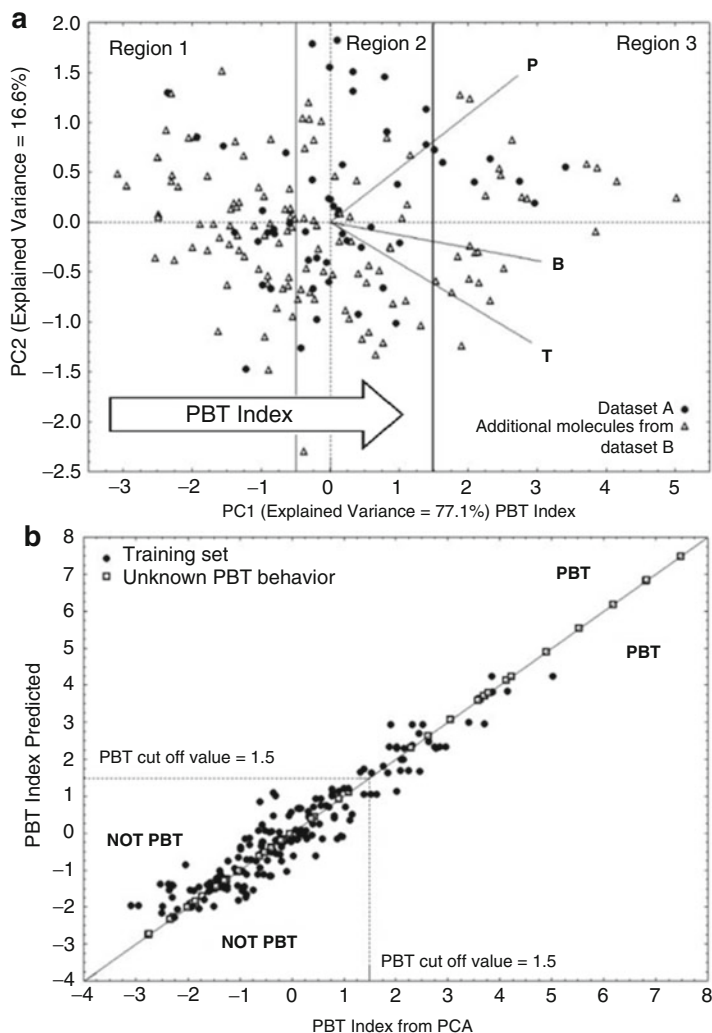

Fig. 12 (a) PCA of persistence, bioaccumulation, and toxicity for 180 heterogeneous chemicals and definition of the PBT Index; (b) scatter plot of the QSAR model of the PBT Index (Permission from Papa and Gramatica, *Green Chem.* 2010)

account the chemical persistence (P), bioconcentration factor (BCF) (Gramatica and Papa 2005) for bioaccumulation (B), and aquatic toxicity on *Pimephales promelas* (Papa et al. 2005) for toxicity (T), allowed to rank 180 representative non-PBT and PBT chemicals according to their cumulative PBT behavior. In fact, since the loadings of the three properties (P, B, and T) are oriented in the same direction in the PCA biplot (Fig. 12a), the PBTs are ranked on the right of the plot. Therefore, the

PC1 score, which explains more than 77 % of the data variance, can be considered as a PBT Index. The cutoff for PBTs was arbitrary fixed at 1.5 score value, by comparison with the thresholds of the criteria normally applied for PBTs and very P very B (vPvB). It is interesting to note that this Index is precautionary; in fact, also some chemicals with only two thresholds of criteria exceeded are located in the right zone (>1.5 of PC1 score): these compounds would be not recognized as PBT by the normally applied criteria (as those in the US-PBT Profiler), while all the chemicals located in region 3 are considered PBTs by the PBT Index.

This Insubria PBT Index was then modeled by OLS QSAR model, using four simple molecular descriptors, with high verified external predictivity ($Q^2_{\text{EXT}} = 80\%$). Thus, our work was based on two different steps according to our consolidated approach: (a) the application of a multivariate tool, such as PCA, for screening chemicals according to their cumulative PBT properties and for the definition of the PC1 score as a PBT Index (biplot in Fig. 12a) and (b) the development of a QSAR model of the PBT Index (scatter plot in Fig. 12b).

Our PBT Index model was recently redeveloped using the PaDEL-Descriptor (Yap 2011), freely calculable online: therefore, the model is now easily applicable in the module QSARINS-Chem of the software QSARINS (Gramatica et al. 2013, 2014) (www.qsar.it).

$$\text{PBT Index} = -1.42 + 0.65 \text{ nX} + 0.22 \text{ nBondsM} - 0.41 \text{ nHBDon_Lipinski} \\ - 0.09 \text{ MAXDP2}$$

$$n_{\text{training}} = 92, R^2 = 0.89, \text{RMSE} = 0.52, Q^2_{\text{LOO}} = 0.88, Q^2_{\text{LMO30\%}} = 0.87, \\ \text{RMSE}_{\text{CV}} = 0.55,$$

$$n_{\text{prediction}} = 88, Q^2_{\text{FI}} = 0.89; \text{CCC}_{\text{EXT}} = 0.94; \text{RMSE}_{\text{EXT}} = 0.49.$$

The descriptors, selected for the best model by the genetic algorithm procedure, are (in descending order of importance) nX (number of halogen atoms), nBondsM (number of multiple bonds), nHDon_Lipinski (number of donor atoms for H bonds), and MAXDP2 (maximal electrotopological positive variation). All of these parameters are mono- or bidimensional and independent of chemical conformation, thus easily calculable from the topological graph (2D sketch) or even from the SMILES code. These variables take into account different chemical properties. The most important descriptors, nX and nBM, which encode for substitution with halogens and unsaturation, are known to increase the PBT behavior of chemicals. On the contrary, MAXDP and nHDon are inversely related to the PBT Index. These last two descriptors are related to a compound's ability to form electrostatic and dipole-dipole interactions, as well as hydrogen bonds in the surrounding media.

Recently, we have extensively applied our PBT Index model for the screening of large data sets of hundreds of heterogeneous chemicals (part 1 of the series

“Early PBT assessment and prioritization of emerging environmental contaminants” in Gramatica et al. 2015), to personal care product (PCP) ingredients (part 2 in Cassani and Gramatica 2015), to flame retardants (part 3 in Gramatica et al. 2016a), and to pharmaceuticals (part 4 in Sangion and Gramatica 2016a). In all these screening studies, we have compared the PBT Index results with those obtained by the US-EPA PBT Profiler, and we have proposed to consider as highly reliable the predictions obtained in agreement by two methods (plot for flame retardants in Fig. 13a).

It is interesting to note that in the screening of flame retardants (FRs), some supposed “safer alternatives” to the banned FRs, which are already in commerce, are detected as intrinsically hazardous for their PBT properties. They are “regrettable substitutions.” If reliable predictive models, based on the chemical structure, would be more often applied *a priori* in a green chemistry approach, from the very beginning of the product development process, it would be possible to avoid the continuous placing on the market, and consequently in the environment, of compounds that will be identified as PBTs, only several years after their use.

Regarding the Insubria PBT Index, we have verified that it is, in the majority of the screenings, more precautionary in highlighting more compounds as PBTs, and the analysis of the disagreements, based on experimental evidences, supports our results for the majority of the cases. It is also important to highlight that the prediction by PBT Index for new chemicals can be verified for the model applicability domain by the Insubria graph (Fig. 13b).

From these screening and prioritization studies, we have verified the reliability of the Insubria PBT Index and, in general, the satisfactory agreement with the PBT Profiler (always >70 %). Main interesting results are:

- (a) In the screening of the Insubria data set of 2780 chemicals of environmental concern (Gramatica et al. 2015), included in the QSARINS-Chem module of the software QSARINS (Gramatica et al. 2013, 2014) (www.qsar.it), the compounds predicted as PBTs by consensus (agreement >82 %) are more than 300.
- (b) In the screening of 534 PCP ingredients, only eight are prioritized as PBTs by consensus of two methods: they are mainly UV filters as benzotriazoles (Cassani and Gramatica 2015).
- (c) In the screening of 128 flame retardants (FRs) (Fig. 13), some already banned and some on the market as substitutes, 30 FRs, which are supposed “safer alternatives,” are predicted as PBTs by both modeling tools in agreement (Gramatica et al. 2016a).
- (d) In the screening of 1267 pharmaceutical ingredients, only 35, of various therapeutic categories, were included in a priority list of potential PBTs, while 83 % of the screened pharmaceuticals are predicted as non-PBTs by consensus (Sangion and Gramatica 2016a).

Hazard. Mater.* 2016a), (b) Insubria graph for the AD of Flame Retardant model

Conclusions

In this chapter, a review of the most recent and significant studies performed for prioritization of chemicals in the Insubria QSAR research group is presented. These studies are based on the fundamental assumption that the hazard of any chemical is an inherent property of the molecular structure; therefore, that QSAR models are an incomparable tool to extract and exploit the information related to any physicochemical or biological property of compounds with available experimental data. The application of externally validated predictive QSAR models to chemicals without experimental data, which are into the model applicability domain, is useful

for highlighting the potentially most hazardous compounds in the screening and priority setting of big data sets of chemicals. This prioritization can allow to concentrate experiments on prioritized chemicals, thus reducing time, costs, and animal test, but also to avoid the synthesis, and introduction to the market and into the environment, of harmful compounds, which could be recognized dangerous only after evidence of human health concerns has been manifested. This is the basis of the “benign by design” approach of green chemistry.

In these studies, we have demonstrated that, taking into account that the chemical behavior derives from a contemporaneous combination of variables, the application of various chemoinformatic methods, such as explorative analysis by PCA and HCA, is useful in ranking and grouping chemicals according to their cumulative behavior, based on more than a single property or activity. In this way, ranking indexes can be proposed for priority-setting purposes and can be also modeled by QSAR to exploit the fundamental information inherent in the chemical structure. The possibility to continuously contaminate the environment with “regrettable substitutions” could be highly reduced if *a priori* screenings, by combining QSAR models and other chemometric approaches, will be more widely applied. Unfortunately, so far, we do not learn enough from the past knowledge, and we do not take advantage, in an extensive way, from the existing information on the inherent hazard that is included in the chemical structure. This should be done, but more expertise on chemoinformatic method for prioritization should be present also at chemical regulation level.

Acknowledgments All my collaborators in the researches performed at the QSAR Research Unit of Insubria University are greatly acknowledged, in particular now Alessandro Sangion for his help in the preparation of the manuscript.

Abstract

Since many drug development projects fail during clinical trials due to poor ADME properties, it is a wise practice to introduce ADME tests at the early stage of drug discovery. Various experimental and computational methods have been developed to obtain ADME properties in an economical manner in terms of time and cost. As *in vitro* and *in vivo* experimental data on ADME have accumulated, the accuracy of *in silico* models in ADME increases and thus, many *in silico* models are now widely used in drug discovery. Because of the demands from drug discovery researchers, the development of *in silico* models in ADME has become more active. In this chapter, the definitions of ADME endpoints are summarized, and *in silico* models related to ADME are introduced for each endpoint. Part I discusses the prediction models of the physicochemical properties of compounds, which influence much of the pharmacokinetics of pharmaceuticals. The prediction models of physical properties are developed based mainly on thermodynamics and are knowledge based, especially QSAR (quantitative structure activity relationship) methods. Part II covers the prediction models of the endpoints in ADME which include both *in vitro* and *in vivo* assay results. Most models are QSAR based and various kinds of descriptors (topology, 1D, 2D, and 3D descriptors) are used. Part III reviews physiologically based pharmacokinetic (PBPK) models.

Introduction

ADME describes the disposition and fate of pharmaceutical compounds within an organism, especially in the human body. The primary cause of failure during the drug development phase is poor pharmacokinetics (PK) and toxicity rather than poor efficacy of the candidate compound. In particular, PK has been a major source of failure in drug development (Cheng et al. 2013). Termination of drug development during the clinical phase results in significant losses of both time and cost. The overview of ADME of a chemical compound in the human body is described in Fig. 1. The integration of all components of ADME, and the introduction of time and concentration of chemicals (mother compound and its metabolites) as variables, leads to the development of a PK model. A PK model can be used to determine the proper dose and dosing interval (Gleeson et al. 2011) of a drug to avoid excess administration that can lead to undesirable side effects.

The recent trend in drug discovery has been to optimize both efficacy and PK properties concurrently to reduce the failures aforementioned. Therefore, to obtain ADME or PK properties of a large number of compounds during the early stage of drug discovery, both high-throughput experimental and computational (*in silico*) methods have been developed and have become popular in current drug discovery. Each method has pros and cons. *In vitro* assays are faster than *in vivo* assays; however, the results of both methods do not always correlate. *In vivo* assays performed with surrogate animals have relatively good correlation with results from humans; however, they are slow and expensive. *In silico* models are easy to use,

Fig. 1 This figure illustrates ADME for oral administration of drugs. Orally administered tablets or capsules are disintegrated in the gastrointestinal (GI) tract. Dissolved drug molecules can be absorbed through the gut wall, while precipitated drug particles are excreted through the GI tract. When the drug molecules pass through the gut wall, it can be expelled by transporters or metabolized by enzymes. Drugs that successfully pass the gut wall will reach the liver. The liver has many enzymes that metabolize foreign compounds. Reactions can be classified into phase I and phase II according to the enzymes involved. As a result of both reactions, the hydrophilicity of xenobiotics is increased and easily excreted through the kidney. Drugs that are not chemically modified during the metabolism process enter the systemic circulation. A portion of drugs are unable to be delivered to the target organ, tissue, or cell because they are caught by proteins in the blood. The unbound free form of drugs and metabolites can be delivered to the target cell and target biomolecules, and some are rapidly removed through the kidney. Therapeutic effects can be achieved when the concentration of drug is adequate at the site of action after the drugs go through the interplays with the physiological system

fast, and inexpensive, and an important advantage is that one can predict ADME properties using only the molecular structure, even before synthesis of the molecule.

Most *in silico* models developed for ADME endpoint prediction are data-driven (knowledge-based) models that use experimental data as training objects. As a consequence, the quality (predictability and robustness) of the model depends on the quality of the data and the physical feasibility of the model. The model is the mathematical representation of the relationship between the molecular structure and the target property, but in a qualitative or quantitative way. These methods are commonly designated as quantitative structure activity relationships (QSARs), which are widely used for the prediction of chemical toxicity in both humans and in the environment. REACH (Registration, Evaluation, Authorisation and Restriction of Chemical), a regulation of the European Union, adopted to improve the protection of human health and the environment from the risks that can be posed by chemicals while enhancing the competitiveness of the EU chemical industry. It

also promotes alternative methods for the assessment of hazards in substances in order to reduce the amount of animal testing. For this purpose, it is necessary to provide detailed guidance that explains the validation principles of the different types of QSAR models. In an OECD-published book, (Guidance document on the validation of (Quantitative) Structure Activity Relationships [(Q)SAR] Models 2007), the principles for the construction of QSAR models, computational methods, and model validation methods are described in detail.

Due to the increase in demand of QSAR models in various research and regulatory fields, many researchers have been working on developing models for new endpoints, expanding chemical space (application domain), and increasing the accuracy of *in silico* models. The growing market of ADME software is evidence of the increased use of *in silico* models in the pharmaceutical industry.

This chapter will explain the prediction of ADME properties of chemicals in three parts. Part I covers the prediction models of physicochemical properties, which influence much of the pharmacokinetics of pharmaceuticals; Part II covers the prediction models of the endpoints of ADME, which include both *in vitro* and *in vivo* assay results; and Part III covers physiologically based pharmacokinetic (PBPK) models. Details of the methods of model development can be found in Tao et al. (2015) as it is beyond the scope of our work.

PART I: Physicochemical Property Prediction Models

Certain physical properties of compounds have a high correlation with the endpoints of ADME – for example, $\log P_{w/oct}$ (the partition coefficient of a compound between water and 1-octanol). These highly correlated physical properties frequently appear in QSAR models as an important variable, the descriptor. The Lipinski rule of five is a popular rule-based method to check whether chemicals have pharmacological activity. The Lipinski rule is as follows: Molecular weight <500 Da, $\log P_{w/oct} < 5$; with no more than 5 hydrogen bond donors, and no more than 10 hydrogen bond acceptors. The physical properties in the Lipinski rule can be replaced with other physical properties, for example, surface area, polar surface area fraction, solubility, solvation free energy, and so forth, because most physical properties of a compound can be described with other physical properties of the compound. For this reason, the set of variables, or descriptors, of one QSAR model may differ from that of another QSAR model despite both models using the same data set for model construction. Here, we introduce the physical properties that are very important variables to construct ADME endpoint models – solvation free energy, ionization constant, lipophilicity, and solubility of compounds. Available software that predicts physical properties is summarized in Table 1.

Solvation Free Energy (ΔG_{solv})

Solvation free energy is used for the estimation of the ionization constant, lipophilicity, and solubility of compounds and is one of the most frequently appearing

descriptors in QSAR models. Based on explicit or implicit expressions of the solvent, various methods have been developed for calculating the solvation free energy of compounds and solutes. Since explicit solvent models have excessively high computational costs, less expensive and practical models based on free-energy relationship or continuum solvation method have been intensively developed and widely used.

The solvent-accessible surface area (SASA) model is the simplest and most widely used model for the ΔG_{solv} calculation of large molecules like proteins (Lee and Richards 1971). SASA is the surface of a molecule that is accessible to a solvent. The solvation free energy of a solute is given by

$$\Delta G_{solv} = \sum_i \sigma_i ASA_i \quad (1)$$

where σ_i is the empirical parameter of the solvation free energy of the i th atom and ASA_i is the SASA of the i th atom.

The linear free energy relationship (LFER)-based model is simple and described in a realistic physical way. The linear term contributing to free energy is described by the product of the properties of the solvent and the solute of a solution. The Abraham LFER (Abraham et al. 1988) model is expressed as:

$$\log SP = c + eE + sS + aA + bB + IL \quad (2)$$

where SP is a free energy-related physical property; E is excess molar refraction; S is the ability of a solute to stabilize a neighboring dipole; A and B are the

solute's effective hydrogen bond acidity and basicity, respectively; and L is the gas–liquid partition constant of the solute. The linear coefficients, c , e , s , a , b , and l are determined with experimental data through an optimization procedure, and the coefficients represent the magnitude of interaction of the solvent with the solute, for example, “sS” represents the magnitude of the contribution to $\log SP$ by the interaction of the solvent with solute dipole, “S.”

Continuum solvation models (Cramer and Truhlar 1995) calculate solvation free energy considering the following three terms:

$$\Delta G_{\text{solv}} = \Delta G_{\text{cav}} + \Delta G_{\text{vdw}} + \Delta G_{\text{pol}} \quad (3)$$

ΔG_{cav} is the free energy to form a cavity in the solvent with the SASA of solute, ΔG_{vdw} is the van der Waals interaction between the solute and solvent, and ΔG_{pol} is the electrostatic interaction between the polar solute with polarizable solvent. Continuum solvation models describe a solute as a collection of point charges, and solvent as a dielectric continuum medium. The charge distribution of the solute electrically polarizes the solvent, and the electric field of induced dipole of the polarized solvent interacts with the dipole of the solute. In the classical approaches, the Poisson-Boltzmann (PB) equation is used to calculate ΔG_{pol} .

In quantum mechanical approaches, the self-consistent reaction field (SCRF) (Tomasi et al. 2005) is applied to account for the mutual polarization. It is further applied in a polarizable continuum model (PCM) (Mennucci 2012). PCM uses SCRF equations in a boundary element problem with apparent surface charges spread on the cavity surface. SMx models (Marenich et al. 2013) calculate solvation energy with this equation:

$$\Delta G_{\text{solv}} = \Delta E_E + G_P + G_{\text{CDS}} + \Delta G_N + \Delta G_{\text{conc}} \quad (4)$$

ΔE_E is the solute's internal electronic energy change upon transfer of the solute from the gas to the liquid. G_P is the polarization energy of the solute-solvent system from introduction of the solute; it is defined by the general Born (GB) approximation. G_{CDS} is the energy for cavitation, dispersion, and solvent structure. ΔG_N is energy variation due to change in nuclear coordinates. ΔG_{conc} is the difference in concentration between the gas phase standard state and the solution phase.

In the conductor-like screening model for realistic solvation (COSMO-RS) (Klamt et al. 2010), the polarization charges of the continuum are estimated from scaled-conductor approximation. COSMO-RS derives the polarization charges from the continuum, caused by distribution of screening charges (σ -profile) of the solute, from a scaled-conductor approximation. In the model, the hydrogen bonding term $E_{hb}(\sigma, \sigma')$ is considered as one component of the interaction between solute and solvent,

$$E_{hb}(\sigma, \sigma') = c_{hb}(T) \max[0, \sigma_{acc} - \sigma_{hb}] \min[0, \sigma_{don} + \sigma_{hb}] \quad (5)$$

where σ and σ' refer to the screening charge densities of the two surface patches in contact, and σ_{acc} and σ_{don} are the screening charge densities of the hydrogen bond acceptor and donor, respectively. The hydrogen-bonding threshold σ_{hb} and the prefactor c_{hb} are adjustable parameters.

The generalized solvation free energy density (G-SFED) model (Lee et al. 2013) calculates ΔG_{solv} as:

$$\Delta G_{solv} = \Delta G_{inter} + \Delta G_{HB} + \Delta G_{cav} \quad (6)$$

The solute molecule is considered as a point charge, and SASA is discretized into small polarizable fractions. The summation of interactions between SASA and solute gives interaction energy (ΔG_{inter}) between the solvent and solute. ΔG_{HB} is the contribution of a hydrogen bond described with the acidity and basicity of both solute and solvent. ΔG_{cav} is calculated based on the surface tension of the solvent.

Ionization Constant (pK_a)

pK_a is the negative logarithm of the acid dissociation constant, K_a , which is a quantitative measurement of the strength of acid in solution. pK_a prediction models have been developed by many researchers because it is one of the most important features of molecules in water solution, e.g., proteins in water. Broadly, pK_a can be estimated using the thermodynamic cycle or QSAR. In the thermodynamic approach (Fig. 2), the Gibbs free energy changes of a system is used as

$$pK_a = \Delta G_{aq}/2.303RT \quad (7)$$

In the thermodynamic cycle, ΔG_{aq} is calculated through

$$\begin{aligned} \Delta G_{aq} = & [\Delta G_{acid \text{ or base}} - \Delta G_{water} (H - OH_2^+)] \\ & + [\Delta G_{solv} (A^- \text{ or B}) - \Delta G_{solv} (HA \text{ or } BH^+)] \\ & + [\Delta G_{solv} (H_3O^+) - \Delta G_{solv} (H_2O)] \end{aligned} \quad (8)$$

The first term, $\Delta G_{acid} - \Delta G_{water} (H - OH_2^+)$, is the free energy of bond dissociation. The second and third terms relate to the solvation energy difference between neutral and ionized species.

Ionization of a molecule in the gas phase can be predicted using gas phase acidity (GPA) and gas phase basicity (GPB) prediction models (Gasteiger and Hutchings 1983). Several models were developed with expanded application domains. Recently, a GPA/B prediction model was developed and published with a brief introduction to other GPA/B models (You et al. 2014).

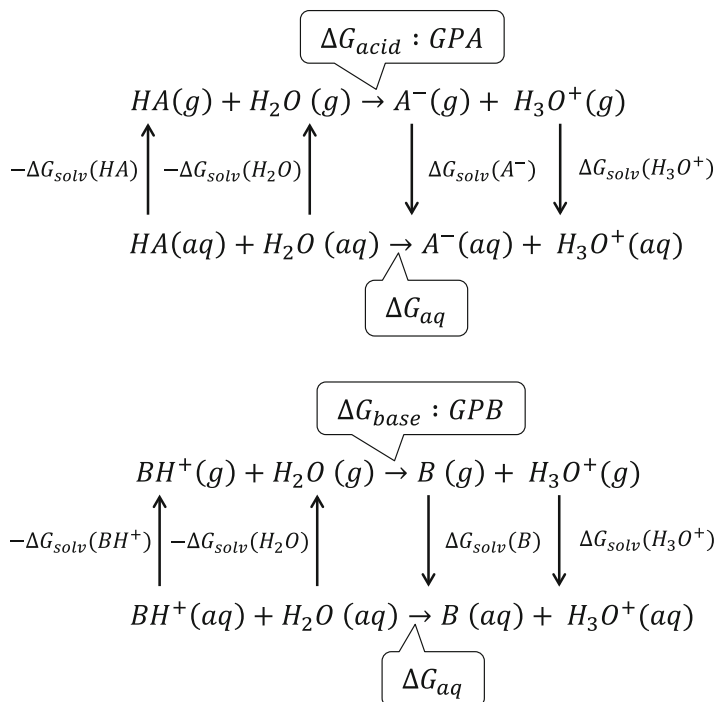

Fig. 2 The thermodynamic cycle is applied to calculate the Gibbs free energy difference in proton dissociation in water. GPA and GPB is gas phase acidity and basicity

LFER-based models are developed to predict pK_a using an experimental database. This approach is based on the discovery that similar molecular fragments have similar pK_a values. Databases that contain the pK_a of simple molecules and their molecular fragments are used to predict pK_a by searching the experimental pK_a of the closest molecular structure. Recent work in this approach used ab initio equilibrium bond length as a descriptor. In this model, the closest neighbor of the input molecule is searched in the database, then pK_a is predicted based on the experimental pK_a of the closest neighbor and bond lengths of the input molecule (Alkorta and Popelier 2015).

QSAR models for pK_a prediction mainly introduce QM descriptors and some thermodynamic descriptors for building models – HOMO, polarizability, free energies, relative proton transfer energy, minimum surface local ionization energy, partial atomic charges, group philicity, and molecular electrostatic potential (Svobodova Varekova et al. 2011). Simulations Plus, commercial software, updated their pK_a prediction model with Bayer's data to expand the application domain of QSAR. This model covers both public and industrial domains (Fraczkiewicz et al. 2015) and gives generally good prediction results on test sets. Several *in silico* models are now available. Details of pK_a prediction software can be found in the paper by Fraczkiewicz (Fraczkiewicz 2013).

Lipophilicity (logP)

To predict lipophilicity, three main approaches were used – group contribution methods, QSAR, and solvation energy-based models. Group contribution methods use additivity contribution approximation as follows:

$$\log P_{w/oct} = \sum a_i f_i + \sum c_i f_i + \text{constant} \quad (9)$$

f_i is the number of i th fragments in a molecule, and a_i is the coefficient for i th fragments. These coefficients show the magnitude of contribution of each fragment of the molecule to $\log P_{w/oct}$. c_i is the correcting factor for the i th fragment. These group contribution methods are broadly applied in available software.

QSAR approaches are applied with various descriptors, such as lattice energy, QM descriptors, Abraham's descriptors, and so forth. Details of descriptors and methods applied to predict $\log P$ were reviewed by Mannhold et al. (Mannhold et al. 2009). The solvation energy-based model predicts $\log P$ by estimating the solvation Gibbs free energies of a molecule in two solvents. The $\log P_{w/oct}$ is calculated directly from the difference between solvation free energies in water (ΔG_w) and in 1-octanol (ΔG_{oct}):

$$\log P_{w/oct} = -(\Delta G_{oct} - \Delta G_w) / 2.303RT \quad (10)$$

In physiological conditions, pH differs from compartment to compartment in the body. The Henderson-Hasselbach (HH) (Hansen et al. 2006) equation is used for the calculation of the $\log P$ of ionizable species, $\log D$,

$$\text{pH} = \text{p}K_a + \log_{10} \frac{[A^-]}{[HA]} \quad (\text{for acids}) \quad (11)$$

using the HH equation, $\log D$ is expressed as,

$$\log D = \log P_{w/oct} + \log \left[1 / \left(1 + 10^{\text{pH} - \text{p}K_a(\text{acid})} \right) \right] \text{ pag} \quad (12)$$

Solubility (logS)

For solubility prediction models, group contribution methods are broadly used for $\log P$ calculation. Recently, a deep learning algorithm has been adopted to build a solubility prediction model (Lusci et al. 2013). The thermodynamic approach to predict solubility requires the following additional parameters: crystalline molar volume (V_m) (Skyner et al. 2015), vapor pressure (VP) (Thompson et al. 2003), and melting point (MP) (Ran and Yalkowsky 2001).

A model using V_m calculates ΔG_{solv} with intrinsic solubility (S_o),

$$\Delta G_{solv} = -RT \ln (S_o V_m) \quad (13)$$

A model using vapor pressure,

$$S_o = (P_{VP} / P_{ideal}) \cdot \exp (-\Delta G_w / RT) \quad (14)$$

P_{ideal} is the pressure of an ideal gas (24.45 atm). The model using MP is known as the general solubility equation (GSE), and it uses estimated $\log P_{w/oct}$ with the model.

$$\log S_o = 0.5 - 0.01 (MP - 25) - \log P_{w/oct} \quad (15)$$

Solubility of ionized species is also calculated using the HH equation (Hansen et al. 2006).

$$\log S_{pH} = \log S (1 + 10^{pH-pK_a}), \log S_{pH} = \log S (1 + 10^{pK_a-pH}) \quad (16)$$

and the HH equation is applied twice in the equation for an ampholyte

$$\log S_{pH} = \log S \left(1 + 10^{pH-pK_a(\text{acid})} + 10^{pK_a(\text{base})-pH} \right) \quad (17)$$

The HH equation is applied to describe the ionization of species, although accuracy issues have been raised (Bergstrom et al. 2004). GSE also can be used to predict $\log S_{pH}$ by applying logD.

$$\log S_{pH} = 0.5 - 0.01 (MP - 25) - \log D \quad (18)$$

PART II: ADME Prediction Model

In the past several decades, a significant amount of in vitro and in vivo assay data has been accumulated as a byproduct of pharmaceutical development. This accumulated data enabled the development of ADME prediction software with high reliability and accuracy. In Part II, we will explain the endpoints of ADME and introduce prediction models of each endpoint. Various ADME prediction softwares are currently available thanks to the efforts of many model and software development groups. A list of widely used ADME prediction software is presented in Table 2.

Absorption

Absorption in drug PK refers to the process of how drugs go through the organs of the body to reach the systemic circulation. Drugs have various routes of administration – oral, intravenous, intramuscular, intraperitoneal, ocular, nasal, rectal, intratracheal, and subcutaneous. In this chapter, we focus mainly on the oral administration route since it is the most common route of administration.

The most popular in vitro absorption assays are the parallel artificial membrane permeability assay (PAMPA), the cell-based assay, and the human intestinal absorption (HIA) assay. Several QSAR models have been developed using experimental data from in vitro methods. Since PAMPA uses artificial lipid membranes, it is convenient and offers good reproducibility; therefore, it is broadly used for absorption tests. However, the membrane does not have transporters or drug metabolizing enzymes (DMEs). Thus, it is an adequate assay method for testing passive transport but it cannot be used for the prediction of active transport. Since transporters and DMEs are expressed on the cell membrane, cell-based assays, to some extent, reflect active transport as well as passive transport. Caco-2 cells derived from human colon adenocarcinomas are broadly used for drug absorption assays. Caco-2 cells exhibit transporters like OCT, OAT, and PEPT1 and CYP3A enzymes. Another popular cell-based assay is the Madin-Darby canine kidney (MDCK) cell assay. Absorption (or permeation) is represented by the permeability coefficient (P_{eff}) defined as,

$$P_{eff} = C_t / (A \cdot C_i \cdot t) \quad (19)$$

P_{eff} is obtained by dividing the amount of drug transported through the membrane (C_t) by the product of the surface area (A) of the membrane monolayer, the time (t) taken until the system reaches steady state, and the initial concentration of the drug (C_i).

HIA is measured by dividing the absorbed drug by the drug dose. In vitro cell assays, such as those in caco-2 cells, show good correlation with human absorption. In vivo animal studies are also used to predict HIA.

$$\text{HIA (\%FA)} = \text{total mass absorbed/dose} \quad (20)$$

Bioavailability (BA) is the fraction of drug absorbed into the systemic circulation. BA is calculated based on the blood concentration profile obtained through in vivo testing.

$$\text{BA (\%F)} = [AUC_{\text{oral}} \times \text{dose}_{IV} / AUC_{IV} \times \text{dose}_{\text{oral}}] \times 100 \quad (21)$$

AUC is the area under the curve of the blood concentration profile in oral administration (AUC_{oral}) and in intravenous (IV) administration (AUC_{IV}), respectively, and dose_{IV} and $\text{dose}_{\text{oral}}$ represent the dose with IV and oral administration, respectively.

The major method used for the prediction of absorption is QSAR. Various regression QSAR models have been developed to predict the PAMPA assay (Akamatsu et al. 2009), cell-based assay (Hou et al. 2006), and BA (Hou et al. 2009). Since the absorption of cell-based assay results vary depending on how the cells are cultured, these results are not suitable for quantitative model construction; therefore, the assay results are converted to qualitative data with certain criteria in order to combine data from several laboratories (Pham The et al. 2011). The interaction of drugs with the membrane is studied and applied in the MDCK permeation prediction model (Chen et al. 2005). Information from drug interactions with transporters (Kim et al. 2014a) and DMEs (Xu et al. 2012) modifies the results of BA prediction. For BA prediction, Zhu (Zhu et al. 2011) reviewed the relationship between physical properties and oral BA. Not only physicochemical and structural properties but also in vitro data (in vitro permeability, intrinsic clearance, and animal data) and *in silico* prediction results (permeability and intrinsic clearance) were used to build the model (Wang and Hou 2015).

Distribution

Distribution in PK is defined as the transportation of drugs from one tissue/organ to another tissue/organ. Among all tissues, blood delivers drugs mainly into other tissues in affinity-dependent manner. Generally, drugs interact with proteins in the blood and membranes of the tissues. These interactions are crucial for determining the amount of drug delivered to the site of action; therefore, assay systems are

designed to measure free drug in the blood and in the volume of tissue, where drugs can be transferred. These two measurements are the parameters that predict drug distribution.

The blood brain barrier (BBB) is the set of endothelial cells that protect the brain by allowing the absorption of only those chemicals that are necessary for brain metabolism. The BBB fills cell margins with tight junctions; therefore, it blocks penetration of hydrophilic or charged compounds. Distribution of drugs into the brain is an important focus in the discovery of drugs that target the central nervous system (CNS). QSAR and molecular modeling have been applied to predict BBB penetration.

Plasma Protein Binding (PPB)

The measured percentage of a drug bound to plasma protein (%PPB) can be converted to the binding parameter, logK,

$$\log K = \log \left(\frac{\%PPB}{101 - \%PPB} \right) = \log \%bound - \log \%free \quad (22)$$

The constant value 101 is used based on the definition that log K is two for a 100 % bound compound. Most QSAR models for PPB are focused on human serum albumin (HSA) binding because serum albumin is the most abundant plasma protein in human blood. The binding parameter for HSA ($\log K_{HSA}$) can be obtained with the above equation as,

$$\log K_{HSA} = \log K - \log [HSA] = \log K + 3.22 \quad (23)$$

The value of 3.22 is calculated based on the concentration of HSA, $0.6 \times 10^{-3} M$. Normally, three PPB parameters (%PPB, logK, and $\log K_{HSA}$, measured by high performance affinity chromatography specifically for HSA) are used as endpoints in the QSAR model. Various QSAR models have been developed and details of the descriptors of these models are explained by Colmenarejo (Colmenarejo 2007). Even though the HSA binding prediction model uses a major part of the QSAR model, few α_1 -acid glycoprotein (AGP) binding prediction models have been developed. Molecular modeling is also applied to study drug binding with HSA and AGP using crystal structures. Details of the QSAR model description and molecular modeling with available crystal structures for HSA and AGP are reviewed by Lambrinidis (Lambrinidis et al. 2015).

Volume of Distribution (VD)

VD is the ratio between the total amount of drug in the body and the concentration of drug in blood plasma. The unit of VD is the liter. Several types of VD have been defined. The volume of the central compartment (VD_c) is defined as:

$$VD_c = D/C_0 \quad (24)$$

D is the IV administered dose, and C_0 is the initial plasma concentration. In a system that has multiple compartments in distribution, VD decays multiexponentially. In this case, two types of VD can be used: VD_{area} and steady-state volume of distribution (VD_{ss}).

$$VD_{area} = \frac{CL}{\beta} = \frac{D}{\beta AUC}, VD_{ss} = VD_c \left(1 + \frac{k_{12}}{k_{21}}\right) \quad (25)$$

VD_{area} is the ratio between plasma clearance (CL) and the elimination rate constant β . VD_{ss} is the equilibrium distribution of a drug between the systemic circulation and tissue compartments. k_{12} and k_{21} are the constants of distribution between the systemic circulation and tissues.

VD_c and VD_{ss} are used as endpoints in ADME prediction models. In a VD_c prediction model, plasma protein binding information can be used, since VD_c is the volume of the systemic circulation. Taravat Ghafourian et al. established models for all data, acids, and bases (Ghafourian et al. 2006). VD_{ss} per unit weight (VD_{ss}/MW) (Zhivkova and Doytchinova 2012) is used as an endpoint for acidic drugs. In another work, the Øie-Tozer equation (Øie and Tozer 1979) was applied to calculate VD_{ss} with immobilized artificial membrane (IAM) partitioning coefficients ($\log k_{IAM}$), the predicted fraction unbound in tissues (f_{ut}), and the experimental fraction unbound in plasma (f_u) (Sui et al. 2009).

$$VD_{ss} = V_P (1 + R_{E/I}) + f_u V_P \left(\frac{V_E}{V_P} - R_{E/I}\right) + \frac{V_R f_u}{f_{ut}} \quad (26)$$

$R_{E/I}$ is the ratio of binding proteins in the extracellular fluid to those in plasma. V_P , V_E , and V_R are the volumes of plasma, extracellular fluid, and the remaining fluid, respectively. These are considered as constants in the human body. The $\log f_{ut}$ prediction model was built to predict VD_{ss} .

Blood Brain Barrier (BBB)

In vitro assays for BBB prediction are focused on membrane penetration using PAMPA, caco-2 cell, and MDCK cell lines. For the QSAR model, the log scale of the brain/plasma ratio obtained by in vivo assay is used as:

$$\log BB = AUC_{brain}/AUC_{plasma} \quad (27)$$

where AUC_{brain} and AUC_{plasma} are the areas under the curve for brain and plasma concentrations, respectively. $\log BB$ is also used to classify compounds as BBB+ (BBB permeable) and BBB- (not permeable), based on certain standards. A classification model has been developed to predict the BBB permeability of drug (Mensch et al. 2009). Molecular dynamics (MD) simulations are applied to study BBB penetration of protonated sumatriptan (pSMT) using NAMD2 (Wood and

Pickholz 2013). In the simulation, 1-palmitoil-2-oleoil-sn-glicero-3-phosphatidylcholine (POPC) is used as the BBB. Interactions between POPC and pSMT are investigated under physiological conditions.

Metabolism

Metabolism is the biotransformation or chemical modification of exogenous compounds to increase their hydrophilicity and water solubility to facilitate their excretion. A compound that increases in hydrophilicity is removed from the circulatory system through the kidney. Metabolism can be classified into two main phases, phase I and phase II. Phase I metabolism is governed mainly by cytochrome P450 enzymes (CYP) and includes oxidation, reduction, and hydrolysis reactions. The CYP enzymes involved in phase I drug metabolism are summarized in Table 3 (Dowty et al. 2011). Phase II metabolism consists mainly of conjugation reactions. Moieties increasing hydrophilicity are added to exogenous compounds or its metabolites. Metabolites obtained as a result of phase-I and/or phase-II reactions in the liver may go through further biotransformation reactions by interacting with other enzymes. Tissue distribution of phase II enzymes is summarized in Table 4, and their substrates, inhibitors, and inducers have been well summarized elsewhere (Jancova et al. 2010). The phase I reaction usually generates the conjugation reaction sites for phase II; however, phase I does not necessarily precede phase II.

Drugs and their metabolites from phase I and/or phase II metabolism interact with transporters and/or nuclear receptors. Transporters are expressed in various organs and pump compounds into or out of the cell across the cell membrane, a process also called active transport. The major organs of transporter expression are summarized in Table 5 (Matsson and Bergström 2015). In the liver, transporters pump drugs into hepatocytes and pump out drugs and metabolites into the systemic circulation or bile duct. Drugs and metabolites are pumped out through transporters into the systemic circulation, and then circulate through blood vessels, are distributed among organs, and are finally excreted through the kidney. Drugs and metabolites transferred to the bile duct are excreted through the gastrointestinal (GI) tract.

Nuclear receptors in the liver are activated by the binding of drugs or metabolites and then transferred into the nucleus where they increase gene expression of phase I and phase II enzymes and transporters. This pathway leads to the increase of the metabolic reaction rate due to the increase of the concentration of enzymes.

In vitro methods of drug metabolism are performed mainly with hepatic microsomes that contain hepatic CYP enzymes in order to test the metabolic stability of a drug to the CYP enzymes. Liquid chromatography/mass spectrometry (LC/MS) or liquid chromatography/tandem mass spectrometry (LC/MS/MS) allows identification of the site of metabolism (SoM). NMR is used to elucidate the structure of metabolites. However, these techniques cannot be performed in high-throughput screening (HTS); therefore, it is necessary to develop *in silico* methods for rapid screening of compounds with moderate metabolic stability.

Table 3 Tissue distribution of CYP enzymes (Anzenbacher and Anzenbacherova 2001) and their substrates (Lewis and Ito 2009)

CYP	Organ	Substrates
1A1	Lung, liver, brain, GI, heart, lymphocytes	Polycyclic aromatic hydrocarbons
1A2	Liver	Small, planar lipophilic compounds
1B1	Skin, brain, heart, lung, liver, kidney, GI, spleen, placenta	Polycyclic aromatic hydrocarbons
2A6	Liver	Relatively small neutral molecules
2B1/2	Brain	Morphine (typical substrate)
2B6	Liver, heart	Unionized basic compounds
2C8	Liver, kidney	Medium to large molecular weight acidic and lipophilic compounds
2C9	Liver	Hydrophobic and weakly acidic compounds
2C10	Liver	Tolbutamide, diclofenac (typical substrate)
2C19	Liver, heart	Medium to large molecular weight lipophilic amines and amides
2D6	Liver, brain, heart	Ionized basic compounds
2E1	Liver, lung, brain, endothelium, heart, bone marrow	Small neutral molecules
2 F	Lung	Coumarins (typical substrate)
3A4/5	Liver, GI, kidney, lung, brain, endothelium, placenta, lymphocytes	Broad substrate specificity
3A7	Fetus, placenta, liver	Broad substrate specificity
4A9/11	Kidney	Fatty acids
4B1	Lung, placenta	?
4 F2/3	Kidney	Arachidonic acid derivatives

Phase I Metabolism

Phase-I metabolic reactions are well studied because CYPs play a major role in drug metabolism. *In silico* models have been developed to predict enzyme selectivity, to predict the SoM, to predict metabolite structure, and to illuminate the interaction of a compound with CYP enzymes (Andrade et al. 2014).

Classification models give yes or no answers to the question of whether a compound is a substrate or inhibitor of a certain enzyme. The models mainly use machine learning algorithms like SVM (Yap and Chen 2005) or decision tree (Choi et al. 2009).

Various methods have been introduced to develop models for SoM prediction. The most widely used methods are: (i) calculation of the activation energy (representative of reactivity) of phase-I metabolism reactions with the molecular orbital calculation or empirical rule and (ii) knowledge-based training of SoM with topological and electronic descriptors. Reactivity can be scored using a model developed by semiempirical MO-derived descriptors (Hennemann et al. 2009). Activation energies (E_a) calculated at SoMs are good estimators of the activity

Table 4 Tissue distribution of phase II enzymes in isoform level

Enzymes	Isoforms	Organ
UGTs	1A1, 1A3, 1A4, 1A6, 1A9, 2B7, 2B15	Liver
	1A7, 1A8, 1A10	GI
SULTs	1A subfamily (1A1: highest expression)	Liver, brain, breast, intestine, jejunum, lung, adrenal gland, endometrium, placenta, kidney, blood platelets.
	1B1	Liver, small intestine, colon, leukocytes
	1C subfamily	Fetal kidney, lung, heart, GI
	1E1	Liver, jejunum, fetal liver, lung, kidney
	2A1	Liver, adrenal, duodenum, fetal adrenal gland
	2B	Prostate, placenta, adrenal gland, ovary, lung, kidney, colon
	4A1	Brain
	6B1	Testis, kidney
NATs	NAT1	Ubiquitous tissue distribution
	NAT2	Liver, colon, intestinal epithelium
GSTs	Alpha, Kappa, Mu, Pi, Sigma, Theta, Zeta, Omega	Soluble GSTs : cytoplasm, nucleus, mitochondria, peroxisomes
TPMP		Liver, kidney (highest) / brain, lung (low)
COMTs	Cytoplasmic soluble form	Peripheral tissues
	ER membrane-bound form	Brain

UGTs uridine diphosphate (UDP)-glucuronosyltransferases, *SULTs* sulfotransferases, *NATs* N-acetyltransferases, *GSTs* glutathione S-transferases, *TPMT* thiopurine S-methyltransferase, *COMT* catechol O-methyl transferase

of substrate. The activation energy of the reaction between heme in CYP and a substrate bound to the reaction pocket/pockets of CYP can be calculated with the transition state (TS) MO calculation. EaMEAD is an empirical model developed to estimate E_a of the reactions using ab initio MO transition states as constraints for training the model (Kim et al. 2009). SmartCyp uses density functional theory (DFT) to calculate transition state and to build a E_a prediction model with 2D descriptors (Rydberg et al. 2010). Prediction models for CYP1A2 (Jung et al. 2008) and CYP3A4 (Oh et al. 2008) were developed by using both CYP-substrate docking and E_a s at SoMs. In MetaSite, a grid of pockets is considered (Cruciani et al. 2006). DR-predictor (Huang et al. 2013) and IDSite (Li et al. 2011) introduced docking for activity prediction. FAME is a reactivity-based SoM prediction model that is not limited to specific enzymes and is applicable to both phase I and phase II metabolism (Kirchmair et al. 2013).

For training QSAR, database of both parent and metabolite structures (containing SoM information) must be constructed. MetaPrint2D uses fingerprints to predict SoM. Simulations Plus developed the artificial neural network ensembles (ANNe) model. PASS uses labeled multilevel neighborhoods of an atom (LMNA) in the

Table 5 The distribution of transporters among organs that contribute mainly to ADME and their expression level. The expression level is quantified (3: high, 2: moderate, 1: low, 0: no data or not detected)

compound descriptors to predict probability of SoM (Rudik et al. 2014). Xenosite applied a deep learning algorithm to predict SOM (Hughes et al. 2015). Expert systems predict metabolic sites and products of metabolism using dictionaries of biotransformation according to rules in the system. MetabolExpert, Metabolizer, and Meteor are examples of expert systems. Metaprint2D-React is a QSAR model with fingerprint descriptors to predict metabolite structures.

The interaction of compounds with enzymes was studied using crystal structures of CYP enzymes. Recently, Kirchmair (Kirchmair et al. 2015) reviewed metabolism prediction models and recently available CYP crystal structures. Increased information of CYP crystal structures enables us to use various computer simulation methods, such as protein-ligand docking, molecular dynamics (MD), and quantum mechanics/molecular mechanics (QM/MM) (Lonsdale et al. 2013).

Phase II Metabolism

The number of phase II prediction models is significantly fewer than that of phase I prediction models since CYP enzymes play a major role in drug metabolism. Despite the relatively minor role of phase II metabolism, it was found that some toxicants are produced by phase II metabolism.

Uridine diphosphate (UDP)-glucuronosyltransferases (UGTs) are key enzymes in phase II metabolism, and ligand-based approaches like 2D-, 3D-QSAR, pharmacophore models, and classification models are applied to predict UDP-mediated

metabolism (Miners et al. 2004). Recently, a SoM by UGT prediction model was published. In this model, data are grouped into four classes according to reactions: aliphatic hydroxyl, aromatic hydroxyl, carboxylic acid, or amino nitrogen. The SVM model has been trained on each data set (Peng et al. 2013).

The experimentally identified UGT crystal structure is available; however, the binding domain is not resolved in the crystal structure (Miley et al. 2007). A number of human sulfotransferase (SULTs) crystal structures are known (1A1, 2, 3, 4/1B1/1C1, 2, 3/1E1/2A1/2B1a, b/4A1/6B1) (Moroy et al. 2012). However, studies on SULTs crystal structures like docking, MD (Stjerschantz et al. 2010), and virtual screenings (Campagna-Slater and Schapira 2009) are few due to difficulties in handling flexible binding pockets of SULTs.

Transporter

Hepatic transporters have a major role in determining drug concentration in hepatocytes. However, few *in silico* models are available to predict whether a compound's role is a substrate, inhibitor, or has no interaction. As listed in Table 3, though several transporters are working as hepatic transporters, no human transporter structures are known. An even more difficult point is that the data reported from different laboratories on the classification between substrate and inhibitor does not match. Therefore, it is difficult to develop a QSAR model with high reliability. P-glycoprotein (P-gP), also known as multidrug resistance protein 1 (MDR1) and ABCB1, is one of the most important transporters in drug resistance; however, its x-ray structure is unknown and the drug pumping mechanism is unclear. Human P-gP structure was obtained by homology modeling using mouse P-gP crystal structure, and this structure was used for the study of the docking of the P-gP substrate with P-gP (Pajeva et al. 2009). P-gP has several binding sites, and defining binding sites from a large pocket is a formidable task. Homology model-based study provides theoretical suggestions on probable binding poses and sites (Klepsch et al. 2011). Recently, with the binding pocket structure obtained from the homology modeled P-gP structure, four probable binding sites were proposed (Kim et al. 2014b).

The classification model which determines whether a compound is binder or nonbinder of OATP, OAT, and OCT was developed; however, the predictability is not satisfactory because of the high ambiguity of the training data set (You et al. 2015).

Nuclear Receptor

Pregnane X receptor (PXR) and constitutive androstane receptor (CAR) are the major nuclear receptors (NRs) in hepatocytes. These NRs are activated by drugs or metabolites and work with other proteins to regulate gene expression, especially the genes of the proteins that are related to drug metabolism. Such protein expression variation is related to drug-drug interactions (DDI).

Very few *in silico* methods have been applied for PXR and CAR. PXR ligand classification model was developed with known PXR binders as constraints (Ma et al. 2012). Crystal structures of PXR have been used for pharmacophore modeling (Chen et al. 2011) and docking (Ai et al. 2015). Two CAR crystal structures of

ligand-binding domains have been identified, and a homology modeled ligand-binding domain of CAR based on PXR and the vitamin D receptor (VDR) was used for MD simulations (Windshugel et al. 2005).

Half-Life of Drug

Drug half-life is the time required to reach 50 % of plasma concentration after reaching pseudoequilibrium, not half of the administered dose. Therefore, the half-life is influenced by each ADME endpoint of a drug. The half-life is an important guideline for dosing regimens. The half-life prediction model was built using experimental physicochemical properties of drugs. A local QSAR model was developed where data were divided into classes according to pK_a values, and a multiple linear regression model was trained with the data from each class of drugs (Durairaj et al. 2009). Self-organizing molecular field analysis (SOMFA) was used to get contribution of 3D conformations and electrostatic potential unto half-life (Goel et al. 2011).

Excretion

Excretion is the removal of chemicals from the body, and clearance (Cl) is a parameter to measure the elimination of drug. QSAR models have been developed for clearance prediction. Endpoints of these models are intrinsic (Cl_{int}), hepatic (Cl_H), renal (Cl_R), biliary (Cl_b), and total clearance in animals or humans (Cl_{animal} or Cl_{human}) (Yu 2010). Cl_{int} is measured using in vitro microsomal assay, and Cl_H is calculated using Cl_{int} as (Varma et al. 2015):

$$Cl_H = Q_H \cdot \frac{f_{ub} \cdot (PS_{influx} + PS_{diff}) \cdot Cl_{int}}{Q_H \cdot (PS_{efflux} + PS_{diff} + Cl_{int}) + f_{ub} \cdot (PS_{influx} + PS_{diff}) \cdot Cl_{int}} \quad (28)$$

where Q_H is the blood flow in liver, f_{ub} is the unbound fraction of drug, PS_{influx} , PS_{efflux} , and PS_{diff} are transportation of drug by efflux, influx, and passive diffusion, respectively. The above equation can be reduced to predict clearance by CYPs and other enzymes without considering transporters as follows:

$$Cl_H = Q_H \cdot [f_{ub} \cdot Cl_{int} / (Q_H + f_{ub} \cdot Cl_{int})] \quad (29)$$

Cl_R is dependent on the activity of glomerular filtration (GFR) and of transporters. It is defined as (Varma et al. 2015):

$$Cl_R = (f_{ub} \cdot GFR + Cl_{sec}) \cdot (1 - F_{reabs}) \quad (30)$$

Cl_{sec} is renal clearance by secretion and F_{reabs} is the fraction of reabsorbed drugs. Influx and efflux transporters govern these processes. To consider the mechanism of excretion in the kidney, the Cl_R prediction model was developed by considering

Table 6 Available software for PBPK models

Distributor	Program
Bayer Technology Services	PK-Sim
Cyprotex	chemPK
Certara	Simcyp
Simulations Plus	PBPKPlus™

the elimination mechanism (net secretion and net reabsorption) and information from 5 transporter subfamilies (P-glycoprotein (P-gP), multidrug resistance associated proteins (MRP) 1/2/4, organic anion transporters (OAT) 1/3, organic cation transporters (OCT) 2, and multidrug and toxin extrusion (MATE) 1/2 K) (Dave and Morris 2015).

Cl_b is calculated as,

$$Cl_b = X_{\text{bile}}/AUC_{\text{plasma}} \quad (31)$$

X_{bile} is the amount of drug excreted into bile, and AUC_{plasma} is the area under the curve of plasma concentration profile. A prediction model that was trained with two types of hepatocyte transporters (MRP2 and P-gP) was published to make prediction more reasonable (Yang et al. 2009).

Total clearance is the sum of all aforementioned CIs. CI can be described as:

$$Cl = Cl_{\text{liver}} + Cl_{\text{kidney}} + Cl_{\text{other}} \quad (32)$$

QSAR models were developed to directly predict Cl_{human} with descriptors. Interspecies correlation in clearance is also an important research topic to predict Cl_{human} from preclinical results. QSAR models using Cl_{animal} and molecular descriptors together to predict Cl_{human} have also been developed (Huang et al. 2015).

PART III: Physiologically Based Pharmacokinetic (PBPK) Models

PBPK models describe an organism as a closed circulatory system composed of organs that contribute to the PK of drugs (Edginton et al. 2008). Figure 3 shows the architecture of the PBPK model. In this model, organs are described with differential equations to calculate the changes of drug concentration in each organ as a function of time. PBPK model architecture is varied according to the modeling purpose and hypothesis. To develop the model, one needs information on: (i) physical properties of the drug molecule and formulation properties; (ii) properties of the biological system interacting with the drug molecule (physiological property); and (iii) the anatomical structure of tissues and organs (Rowland et al. 2011). Here, we introduce the organ-based simulation models, which are necessary for PK prediction of oral administration. Available software for PBPK models is listed in Table 6. Details for implementation of the PBPK model were explained by Peters (Peters 2012).

Fig. 3 In the physiologically based pharmacokinetic (PBPK) model, organs important for ADME are included. The organs in PBPK can be defined by a differential equation. For deterministic organs for the blood concentration profile, such as the gut, liver, and kidney, details of the mechanism are considered to implement the model. Additional tissues and organs can be added according to modeling purpose and hypothesis

Gut Physiological Model

The gut physiological model is broadly composed of three types of prediction models: dissolution, permeation, and absorption. The dissolution rate (DR) is the starting point of gut simulation models of orally administered drugs that are formulated as a tablet or capsule (Fig. 4). Various models have been developed for predicting the dissolution profile. Each model considers various formulation conditions to predict varied dissolution profile (Costa and Lobo 2001). Noyes-Whitney coined the DR equation first, and models are modified by defining the dissolution constant (k) differently (Dokoumetzidis and Macheras 2006).

$$dC/dt = k(C_S - C) \quad (33)$$

C_S is saturation solubility and C is the concentration at time t . The concentration gradient is the driving force in dissolution, and it is described by the difference between C_S and C .

DR varies based on the condition of the GI fluid. GI fluid properties are influenced by factors such as agitation strength, pH, bile concentration, and food. These factors influence the diffusion coefficient and pH-dependent solubility of

Fig. 4 Tablets or capsules that are orally administered are disintegrated into particles. Depending on the pH condition, drug molecules are either dissolved or precipitated. Drug particles are excreted through the gastrointestinal (GI) tract. Free drugs interact with micelles. Micelle-free drugs can be transported through the gut wall. In the gut wall, drug transporters and drug metabolizing enzymes (DMEs) are expressed. A portion of absorbed drugs are pumped out by transporters or metabolized by the DMEs. Drug molecules that safely cross the gut wall reach the portal vein

the formulated drug. Basic compounds and salts are highly soluble at a lower pH, but they are precipitated again at higher-pH conditions, such as in the intestines. Drug particles that are not fully dissolved act as the seed of nucleation of drug molecules and the amount of precipitated drug molecule is increased. Absorption varies between fasting and fed states. Certain foods inhibit transporters and DMEs, for example, grapefruit juice is an inhibitor of P-gP and CYP3A4, and black pepper is an inhibitor of CYPs 1A, 2B, and 2E1.

Physiological properties are related to the gut wall. Drugs need to cross various barriers to reach the portal vein. The mucus layer is composed of mucus secreted by the mucus membrane and forms a slippery cover on the gut wall. Drug permeation of the gut wall has the following three types of pathways: passive transcellular, active transcellular, and paracellular pathways. The passive transcellular pathway goes through the cell; the active transcellular pathway is permeation using a transporter; and the paracellular pathway is the passing through the tight junction between the cells. During the process of active transportation, drugs interact with DMEs and

transporters. CYPs, UGTs, Esterases, and SULTs are major DMEs in the human gut wall. Regarding transporters, P-gP, MRP2, and BCRP are efflux transporters, and OATP, OCT1, MCT1, ASBT, and PEPT1 are uptake transporters.

In gut physiological models, the anatomy of the gut is described in two ways, the compartmental model and the dispersion model. In the compartmental model, the intestine is a series of compartments that have different permeation properties in each compartment, though in reality, the small intestine cannot be clearly divided according to physiological properties. The dispersion model considers the intestine as a continuous tube. In this model, the velocity of intestinal fluid is taken into consideration. Mass balance is considered in the equation of GI tract transition. The process of flowing in and out and dissolution and precipitation is implemented in differential equations. The details of the physics applied in the absorption simulation are reviewed by Sugano (Sugano 2009).

Tissue Physiological Model

Drugs that reach the portal vein begin interaction with proteins in the blood and tissues in the circulation system. The ionization state and lipophilicity of the drug influences the interaction. Therefore, physical properties of drugs are the most important descriptors for defining the partitioning of the drug between blood and tissue. In describing distribution, protein binding is important because it represents the amount of drug not available for tissue distribution. Acidic drugs bind to albumin, lipophilic neutral drugs bind to lipoproteins, and basic drugs bind to AGP. The unbound fraction of drug interacts with membranes. Poulin and Thiel published models for the tissue/plasma partition coefficient based on the assumption that plasma and tissue is composed of water, lipids, and phospholipids (Poulin and Thiel 2001).

$$K_{T(\text{nonadipose}):P} = \frac{P_{OW} (f_{nl,T} + 0.3 f_{pl,T}) + (f_{w,T} + 0.7 f_{pl,T})}{P_{OW} (f_{nl,P} + 0.3 f_{pl,P}) + (f_{w,P} + 0.7 f_{pl,P})} \cdot \frac{f_{uP}}{f_{uT}} \quad (34)$$

$$K_{T(\text{adipose}):P} = \frac{D_{OW} (f_{nl,T} + 0.3 f_{pl,T}) + (f_{w,T} + 0.7 f_{pl,T})}{D_{OW} (f_{nl,P} + 0.3 f_{pl,P}) + (f_{w,P} + 0.7 f_{pl,P})} \cdot \frac{f_{uP}}{1} \quad (35)$$

Partition coefficients for partitioning between tissue and plasma are defined differently on nonadipose ($K_{T(\text{nonadipose}):P}$) and adipose tissues ($K_{T(\text{adipose}):P}$). P_{OW} is the octanol-water partition coefficient of a drug, and D_{OW} is that of an ionizable drug. f_{pl} , f_{nl} , and f_w are the fractional volume contents of phospholipids, neutral lipid, and water in plasma (P) or in tissue (T), respectively. f_{uP} and f_{uT} are the unbound fractions of drug in plasma and tissue. In the case of adipose tissue, f_{uT} is assumed to be one.

The drug concentration change in tissues that are not eliminating drugs is described as:

$$dC_T/dt = \frac{1}{V_T} \left(Q_{ART} \times C_{ART} - Q_{VEN} \frac{C_T \cdot f_{uT} \cdot R}{f_{uP} K_{T:P}} \right) \quad (36)$$

where V_T is the volume of the tissue, and Q_{ART} and Q_{VEN} are the blood flow rates of the artery and vein, respectively. C_T and C_{ART} are the drug concentrations in the tissue and the artery. $K_{T:P}$ is the partition coefficient for tissue and plasma. R is the blood-plasma ratio.

Liver Physiological Model

After drugs reach the portal vein, they are transported into the liver, which is composed of tissues rich in blood vessels called lobules. These physiological structures of the liver are important because metabolism occurs in a zone-dependent manner. Sinusoids are capillaries in the liver in which drug molecules are transferred through to hepatocytes and metabolized (Fig. 5).

Zone-dependent metabolism cannot be studied through in vitro assay because the architecture of the liver cannot be considered in the assay. For simulating zonation of metabolic processes in a lobule, various simulation models have been applied – multicompartment models, distribution-based models, agent-based models, interconnected parallel tubes, (Lerapetritou et al. 2009), and lattice models (Rezania et al. 2013a, b).

Elimination kinetics occurring in the liver does not always occur by one enzyme alone; sometimes various enzymes work together in biotransformation (Isin and Guengerich 2007). Therefore, various metabolites can be derived from a single drug. CYP enzyme reaction networks are modeled to calculate whole human liver clearance ($CL_{H.liver}$) by considering the clearance of each recombinantly expressed CYP enzyme with a number of metabolic pathways (Rostami-Hodjegan and Tucker 2007).

$$CL_{H.liver} = \left[\sum_{j=1}^n \left(\sum_{i=1}^n a_{ji} \times \frac{V_{\max i} (CYP_i) \times CYP_j}{K_{mi} (CYP_j)} \right) \right] \times MPGL \times \text{Liver weight} \quad (37)$$

Here, i th metabolic pathway for each j th CYP is considered together in the calculation. $V_{\max i}$ and K_{mi} are the maximum rate of metabolism and the Michaelis constant for an individual CYP, respectively. $MPGL$ is the amount of microsomal protein per gram of liver. a_{ji} is a scaling factor to compensate for differences in activity for each enzyme between recombinant systems and hepatic enzymes.

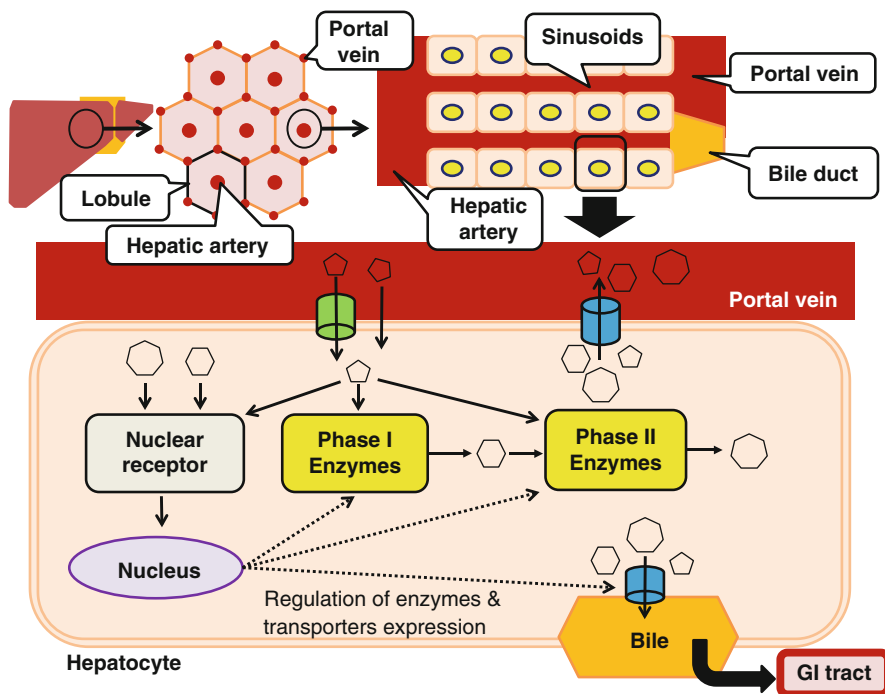

Fig. 5 The structural unit of liver tissue is the lobule. Lobule tissue is richly entangled with arteries and portal veins. Hepatic arteries in lobules are branched out through sinusoids, which are surrounded by hepatocytes. Drug molecules are transferred into hepatocytes while blood is flowing through sinusoids. Drug molecules enter into hepatocytes through passive diffusion or hepatic transporters. Phase I and phase II metabolites are transported by transporters into the portal vein and excreted through the kidney, or into bile, where the metabolites are subsequently excreted through the GI tract. Nuclear receptors (NRs) interact with drug molecules and their phase I and phase II metabolites. NRs regulate gene expression of DMEs and transporters in the nucleus

A single-cell-based simulation has been introduced. In this model, the biochemical network of hepatocytes is modeled; eight models of hepatocytes interact with sinusoids. This model can simulate the influence of the variation in gene expression levels to macroscopic character variations (Ohno et al. 2008).

Hepatosys is a project to develop a virtual liver network (General concept and deliverables of phase II “integration” 2007). This project is comprised of four networks (detoxification, endocytosis, regeneration, and iron regulation of hepatocytes) and two platforms (experiment platform and modeling platform). A mathematical model for each network is examined by genome data from microarrays, proteome and metabolome data, and kinetics of protein interactions. The ultimate goal of the Hepatosys project is to understand drug metabolism in individual patients.

Kidney Physiological Model

Parent drugs and metabolites in the systemic circulation are removed through the kidney. The physiological kidney has been modeled in the Physiome Project (Thomas et al. 2006). This model describes glomerular filtration, tubular transport, tubuloglomerular feedback, renal microcirculation, the renal medulla, and the urine-concentrating mechanism with equations.

In the multicompartiment model, the kidney is assumed to be composed of vascular, interstitial, tubule lumen, and intracellular compartments. Glomerular filtration and urine flow is a parameter in the differential equation for drug concentration. Passive reabsorption and passive permeability are considered between the tubule lumen and interstitial compartments. Clearance by DMEs and transporters is considered in the intracellular compartment (Fig. 6). The Guyton model is an attempt to simulate the physiology of humans. In this model, the physiological model of kidney is implemented. The C++ library of the Guyton model was released (Hernandez et al. 2009; Thomas et al. 2008) and has been actively applied in high blood pressure simulations.

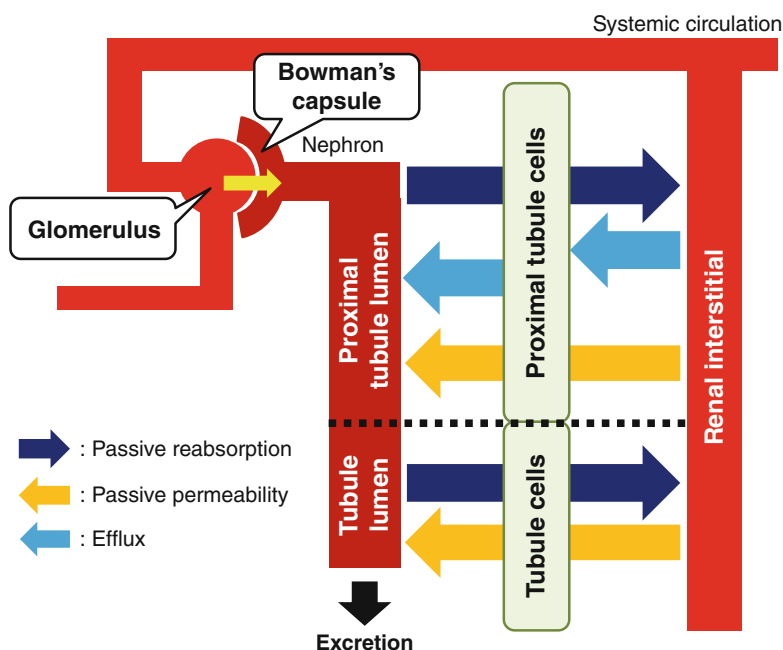

Fig. 6 In the kidney, drugs and their metabolites are eliminated from the body. Drugs and metabolites are filtered at the glomerulus and transported by reabsorption and passive permeation. Reabsorbed drugs and metabolites can be moved into the proximal tubule lumen again by transporters expressed in proximal tubule cells. Drugs and metabolites remaining in the tubule lumen are excreted

Summary

In silico models for ADME predictions were divided into three parts and reviewed. The physical properties of chemicals are important for describing ADME, ADME endpoints, and PBPK models. The number of *in silico* models is growing rapidly. Each model is improved with increased data for model construction and by introducing advanced modeling techniques. These improvements have led to an increase in utilization of *in silico* models in drug discovery and development. Despite the remarkable developments of ADME models, there are several limitations in reproducing experimental results with *in silico* models. These shortcomings are mainly due to: (i) not enough data for the endpoint to be modeled, (ii) lack of full understanding of the biological phenomena of the endpoint, and (iii) the biological complexity of the endpoint is too complicated to be modeled. More research on the molecular level of the interaction between pharmaceuticals and biomolecules is required to improve *in silico* models. Moreover, an understanding on the molecular level of the interactions in ADME could make it possible to simulate individual ADME properties. ADME properties of drugs in individuals are varied since each person manifests with different expression patterns of biomolecules interacting with drugs. This uniqueness in individuals has brought about the concept of personalized medicine. In the future, a deeper understanding upon the mechanisms of ADME in the molecular level may lead to personalized ADME predictions.

Abstract

Quantitative structure–activity relationship (QSAR) modeling is the major cheminformatics approach to exploring and exploiting the dependency of chemical, biological, toxicological, or other types of activities or properties on their molecular features. QSAR modeling has been traditionally used as a lead optimization approach in drug discovery research. However, in recent years QSAR modeling found broader applications in hit and lead discovery by the means of virtual screening as well as in the area of drug-like property prediction, and chemical risk assessment. These developments have been enabled by the improved protocols for model development and most importantly, model validation that focus on developing models with independently validated external prediction power. This chapter reviews the predictive QSAR modeling workflow developed in this laboratory that incorporates rigorous procedures for QSAR model development, validation, and application to virtual screening. It also provides several examples of the workflow application to the identification of experimentally confirmed hit compounds as well as to chemical toxicity modeling. We believe that methods and applications considered in this chapter will be of interest and value to researchers working in the field of computational drug discovery and environmental chemical risk assessment.

QSAR Methodology: Summary of Approaches for Model Building and Validation

In order to find new leads in the process of drug design and discovery, there is a need for efficient and robust computational procedures that can be used to screen chemical databases and virtual libraries against molecules with known activities or properties. For this purpose, quantitative structure–activity relationship (QSAR) analysis is widely used. QSAR modeling provides an effective way for establishing and exploiting the relationship between chemical structures and their biological actions toward the development of novel drug candidates. Theoretically, QSAR analysis is the application of mathematical and statistical methods for the development of models for the prediction of biological activities or properties of compounds. Formally, a QSAR model can be expressed in the following generic format:

$$\text{Predicted Biological Activity} = \text{Function} (\text{Chemical Structure}) \quad (1)$$

A QSAR procedure tries to minimize the error of prediction, for example, in the form of the sum of squares between predicted and observed activities.

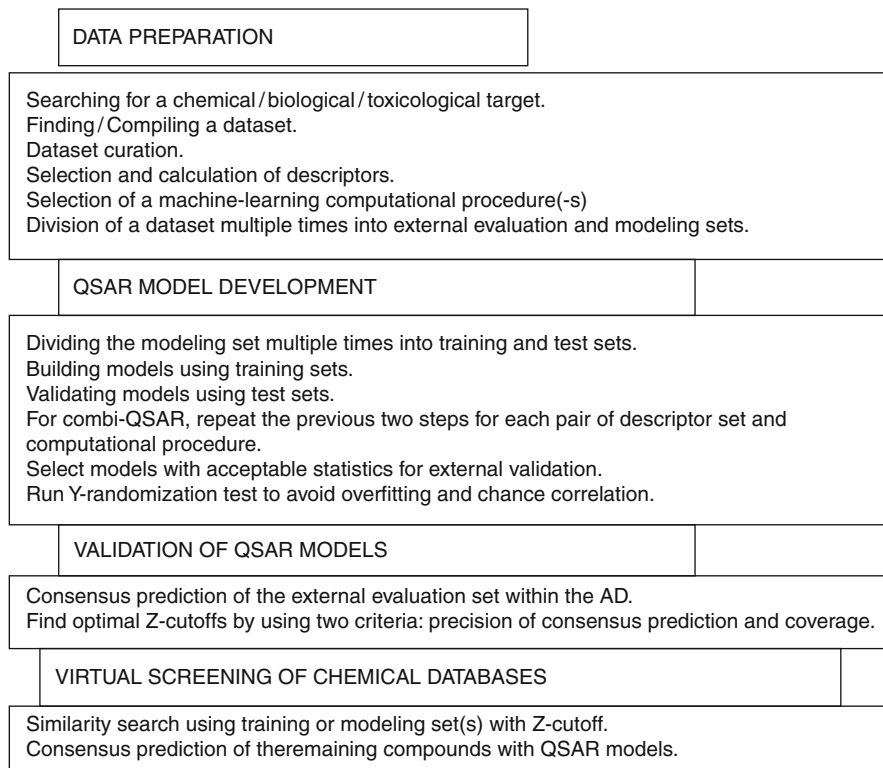

Fig. 1 Major steps of QSAR modeling

The process of QSAR model development can be divided into three parts: data preparation, data analysis, and model validation (Fig. 1). Model validation should include establishment of model applicability domain (AD). Recently, the European Organization for Economic Co-operation and Development (OECD) developed a set of principles for the development and validation of QSAR models, which, in particular, requires “appropriate measures of goodness-of-fit, robustness, and predictivity” (Organisation 2008). The OECD guidance document especially emphasizes that QSAR models should be rigorously validated using external sets of compounds that were not used in the model development.

Data Preparation

The first part of QSAR analysis includes selection of a molecular dataset for QSAR studies, acquiring or calculation of molecular descriptors (quantities characterizing molecular structures), and selection of a QSAR (statistical analysis and correlation) method. Datasets for QSAR studies can be found in research papers or electronic

databases available either publicly (PubChem 2010; BindingDB (Liu et al. 2007); ChEMBL 2010; DSSTox 2008; NIMH Psychoactive Drug Screening (PDSP) 2010) or commercially (e.g., Wombat (Olah et al. 2007) or MDDR 2009); more examples are given in a recent review (Oprea and Tropsha 2006). The dataset should include biological activity values for all compounds (e.g., binding energies to a receptor, or inhibition constants IC_{50} , or in case of toxicity modeling, lethal concentration in water LC_{50} , or lethal dose LD_{50} , etc.) preferably measured in the same lab using the same experimental method. If these experimental data are not available from one lab or one source, and the correlation between measurements made in different labs or by different methods cannot be established, they may not be used directly in QSAR studies. Instead, compounds in the dataset should be given a rank or assigned to categories of activities: for example, a compound can be very active, moderately active, or inactive. In the majority of such cases, binary classification is used, in which a compound is classified as either active or inactive. Another situation may arise, when compounds in the dataset naturally belong to different classes, for example, they are ligands to different receptors. In this case, the types of ligand specificity for a target can be considered as classes of compound activities, and the goal of QSAR analysis becomes to achieve accurate prediction of the target specificity for a new compound.

According to the nature of the activity data, QSAR studies can be divided into continuous (activities, i.e., response variable, takes many different values from within some interval), category (activities are represented by ranks or ordinal numbers), and classification (activities are different types of biological properties which cannot be rank ordered) approaches.

Prior to QSAR modeling, a dataset should be curated, that is, all structures should be verified with respect to their correct representation in the dataset; structures containing atoms, for which there are no parameters for descriptor calculation should be removed; structures consisting of several disconnected parts should be removed; salts should be removed; a problem of isomerism should be addressed; and duplicate structures should be removed. There are different tools available for dataset curation. For example, Molecular Operating Environment (MOE) (2008) includes DatabaseWash tool. It allows changing molecules' names, adding or removing hydrogen atoms, removing salts and heavy atoms, even if they are covalently connected to the rest of the molecule, and changing or generating the tautomers and protomers (cf. the MOE manual for more details). Various database curation tools are included in ChemAxon (2008) as well. If commercial software tools such as MOE are unavailable (notably, ChemAxon software is free to academic investigators), one can use standard UNIX/LINUX tools to perform some of the dataset cleaning tasks (Tropsha and Golbraikh 2010). It is important to have some freely available molecular format converters such as OpenBabel (2010) or MolConverter from ChemAxon (2008). Major procedures for database curation are discussed in our recent paper (Fourches et al. 2010).

After the dataset is selected and curated, the next task is the acquisition or calculation of descriptors. According to an excellent monograph titled Handbook of Molecular Descriptors by Roberto Todeschini and Vivian Consonni (2000)

molecular descriptors can be grouped into zero-dimensional [0D] (sometimes referred to as constitutional descriptors), one-dimensional [1D] (e.g., counts of different molecular groups, physicochemical properties of compounds, etc.), two-dimensional [2D] (invariants of molecular graphs, e.g., connectivity indices, information indices, counts of paths and walks, etc.), three-dimensional [3D], which are based on geometrical spatial properties of molecules [e.g., Comparative Molecular Field Analysis (CoMFA) descriptors (Tripos 2010) which are values of steric and electrostatic fields around aligned molecules, and different CoMFA-like descriptors (Klebe 1998; Kubinyi et al. 1998; Robinson et al. 1999)], and some other descriptors. Some descriptors can be experimental or calculated physicochemical properties of molecules such as molecular weight, molar refraction, energies of HOMO and LUMO, normal boiling point, octanol/water partition coefficient, molecular surface, molecular volume, etc.

Herein, we will not discuss different types of descriptors in detail but mention briefly major descriptor software. Most of descriptors included in the Handbook of Molecular Descriptors (Todeschini and Consonni 2000) can be calculated by the Dragon software (Dragon 2007). Molconn-Z (2007) is another widely used descriptor calculation software which calculates more than 800 descriptors. A relatively small, but diverse set of molecular descriptors can be calculated by the MOE (2008) software. Chirality molecular topological descriptors (CMTDs) developed in our laboratory append 2D descriptors by conformation-independent chirality and ZE-isomerism topological indices (Golbraikh and Tropsha 2003; Golbraikh et al. 2001, 2002). Another group of descriptors frequently used in our laboratory is atom-pair (AP) descriptors (Carhart et al. 1985). Each descriptor is defined as a count of pairs of atoms of certain types being away from each other on a certain topological distance (2D AP descriptors) or a Euclidean distance within certain intervals (3D AP descriptors); chirality AP descriptors can be calculated as well (Kovatcheva et al. 2005).

Many descriptors calculated from the knowledge of 3D structure of molecules (3D descriptors) have been developed and published as well. Although these are inherently more rigorous, one should keep in mind that their calculation is much more time and resource consuming. In many QSAR applications, the calculation of 3D descriptors should be preceded by conformational search and 3D structure alignment. However, even for rigid compounds, it is not generally known whether the alignment corresponds to real positions of molecules in the receptor binding site (Cherkasov 2008). There are different conformational analysis and pharmacophore modeling tools included in molecular modeling packages such as MOE (2008), Sybyl (there are LINUX and MS Windows versions) (Tripos 2010), Discovery Studio (2010), LigandScout (2010), etc. It has been demonstrated that in many cases QSAR models based on 2D descriptors have comparable (or even superior) predictivity than models based on 3D descriptors (Bures and Martin 1998; Golbraikh et al. 2001; Hoffman et al. 1999; Zheng and Tropsha 2000). Thus when 3D QSAR studies are necessary, if possible, 3D alignment of molecules should be preferably obtained by docking studies. VolSurf (Crivori et al. 2000; Cruciani et al. 2000) and GRIND (Pastor et al. 2000) descriptors are examples of alignment-free

3D descriptors. But their calculation still requires extensive conformational analysis of molecules. Both VolSurf and GRIND descriptors are available in Sybyl (VolSurf and Almond modules) (Tripos 2010). Various types of descriptors can be calculated by different modules of Schrodinger software (2010). Virtually, any molecular modeling software package contains sets of its own descriptors and there are many other descriptors not mentioned here that can be found in the specialized literature.

There are sets of descriptors that take values of zero or one depending on the presence or absence of certain predefined molecular features (or fragments) such as oxygen atoms, aromatic rings, rings, double bonds, triple bonds, halogens, and so on. These sets of descriptors are called molecular fingerprints or structural keys. Such descriptors can be represented by bit strings and many are found in popular software packages. For instance, several different sets of such descriptors are included in MOE (2008), Sybyl (Tripos 2010), and others, and examples of their use can be found in the published literature (McGregor and Pallai 1997; Waller 2004). Molecular holograms are similar to fingerprints; however, they use counts of features rather than their presence or absence. For example, holograms are included in the Sybyl HQSAR module (Tripos 2010). There are also more recent approaches when molecular features are not predefined a priori (as fingerprints discussed above) but are identified for each specific dataset. For example, frequent subgraph mining approaches developed independently at the University of North Carolina (Huan et al. 2006) and at the Louis Pasteur University in Strasbourg (Horvath et al. 2007) can find all frequent closed subgraphs (i.e., subgraph descriptors) for given datasets of compounds described as chemical graphs. A large and diverse set of 2D descriptors can be generated by MOLD2 software (Hong et al. 2008) available from FDA. A wide variety of descriptors are included in ADRIANA software (Gasteiger 2006).

Prior to QSAR studies, processing of descriptors is required. It includes: exclusion of descriptors having the same value for all compounds in the dataset as well as duplicate descriptors. To avoid higher influence on QSAR models of descriptors with higher variance, all descriptors are usually normalized (in most cases, range scaling or autoscaling is used). Molecular holograms or AP descriptors do not need to be normalized. Molecular field values around molecules are also not normalized. Preferably, descriptors with low variance and one of the highly correlated pair of descriptors should be excluded as well.

Finally, data for QSAR model development can be represented in a form of a table (see Table 1), in which each compound is a row and each descriptor as well as activity is a column.

The Problem of Outliers

Success of QSAR modeling depends on the appropriate selection of a dataset for QSAR studies. In a recent editorial of the *Journal of Chemical Information and Modeling*, Maggiora (2006) noticed that one of the main deficiencies of many chemical datasets is that they do not fully satisfy the main hypothesis underlying all

Table 1 QSAR table

Compound	Descriptor 1	Descriptor 2	...	Descriptor N	Activity
1	X ₁₁	X ₁₂	...	X _{1N}	Y ₁
2	X ₂₁	X ₂₂	...	X _{2N}	Y ₂
...
M	X _{M1}	X _{M2}	...	X _{MN}	Y _M

QSAR studies: Similar compounds are expected to have similar biological activities or properties. Maggiora defines the “cliffs” in the descriptor space where the properties change so rapidly, that, in fact adding or deleting one small chemical group can lead to a dramatic change in the compound’s property. In other words, small changes of descriptor values can lead to large changes in molecular properties. Generally, in this case there could be not just one outlier, but a subset of compounds properties of which are different from those on the other “side” of the cliff. In other words, cliffs are areas where the main QSAR hypothesis does not hold. So cliff detection remains a major QSAR problem that has not been adequately addressed in most of the reported studies.

There are two types of outliers we must be aware of: leverage (or structural) outliers and activity outliers. In case of activity outliers the problem of “cliffs” should be addressed as well. Recently, different approaches to find activity outliers have been published (Bajorath et al. 2009; Guha and Van Drie 2008a, b; Sisay et al. 2009). We have suggested that Grubb’s (Environmental Protection Agency 1992) and Dixon’s (Fallon et al. 1997) statistical tests can be used to find activity outliers (Tropsha and Golbraikh 2010). Structural outliers can be defined as compounds that are largely dissimilar to all other compounds in the descriptor space. The methods of finding them are similar to finding compounds out of QSAR model applicability domains (Tropsha and Golbraikh 2010) that is discussed below.

QSAR Model Development

The ultimate goal of QSAR analysis is the development of validated models for accurate and precise prediction of biological activities of compounds which could be potential leads in the process of drug discovery. Eventually, predictions should be confirmed by experimental validation. The general QSAR modeling workflow is represented in Fig. 2. Following the data curation step, we start by randomly selecting a fraction of compounds (typically, 10–20%) as an external evaluation set. The Sphere Exclusion protocol implemented in our laboratory (Golbraikh and Tropsha 2002; Golbraikh et al. 2003) is then used to rationally divide the remaining subset of compounds (the modeling set) multiple times into pairs of training and test sets that are used for model development and validation, respectively. We employ multiple QSAR techniques based on the combinatorial exploration of all possible pairs of descriptor sets and various supervised data analysis techniques

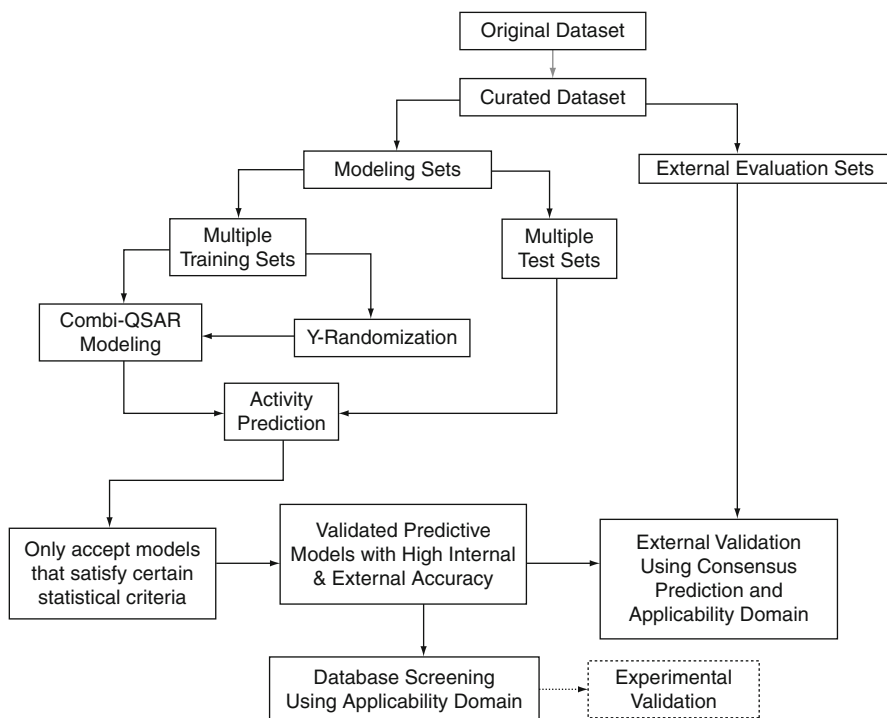

Fig. 2 Predictive QSAR modeling workflow

(combi-QSAR) (Fig. 3) and select models characterized by high accuracy in predicting both training and test sets data. Validated models are finally tested using the external evaluation set. The critical step of the external validation is the use of applicability domains (ADs). If external validation demonstrates the significant predictive power of the models, we employ them for virtual screening of available chemical databases (e.g., ZINC (Irwin and Shoichet 2005)) to identify putative active compounds and work with collaborators who could validate such hits experimentally. The entire approach is described in detail in several recent papers and reviews (Tropsha 2005; Tropsha and Golbraikh 2007).

QSAR Methods

QSAR modeling techniques employ various methods of multidimensional data analysis as well as supervised machine learning used in different areas of research in natural and social sciences such as biological sciences, geography, psychology, medicine, economics, signal processing, speech recognition, forensic studies, etc. Herein, it is impossible to discuss all the methods used in QSAR analysis. Instead, we will name only some of them. All these methods can be classified into linear and

Fig. 3 Combinatorial QSAR modeling

nonlinear approaches. Linear methods include simple and multiple linear regression (MLR), principal component regression (PCR), partial least squares (PLS), etc. The main distinctive characteristic of these methods is the linearity of the function approximating the biological activity (see Eq. 1) of their arguments (which are molecular descriptors). In linear discriminant analysis (LDA), linear combinations of descriptors are built, which define hyperplanes that separate representative points of different classes of compounds in the multidimensional descriptor space.

Nonlinear methods can be based derived from linear or based on more complex approaches that predict compound activities from their descriptors by the means of nonlinear relationships. For example, if nonlinear terms (like squares, products, or logarithms of some descriptors) are added to a linear regression, it becomes nonlinear regression. Many nonlinear methods are derived from linear methods via transforming them by a so-called kernel trick. Calculations are executed in a so-called feature space where linear methods are applied. The advantage of these methods is that there is no need to directly calculate the transformation functions. Examples of such methods include non-linear support vector machines (SVMs) and support vector regression (SVR) methods (Berk 2008; Vapnik 2000), nonlinear discriminant analysis, kernel-PCA, kernel-PLS, etc. In the multidimensional feature

space, SVM builds a soft margin hyperplane, which separates points belonging to two different classes, or more hyperplanes to separate points of larger number of classes. In contrast, SVR builds a hyperplane such that as many points as possible are within the margin. Good SVM tutorial was written by Burges (1998), and SVR tutorial by Smola and Schoelkopf (2004). Other non-linear methods include k-nearest neighbors QSAR, in which the activity of a compound is predicted as a (weighted) average of activities of its nearest neighbors. k-nearest neighbor methods can include stochastic (Zheng and Tropsha 2000) or stepwise variable (descriptor) selection (Ajmani et al. 2006).

Another large group of generally nonlinear methods are artificial neural networks (ANNs) (Neural Networks 1996; Salt et al. 2006; Zupan and Gasteiger 1999). Ensembles of ANNs can make use of bagging and boosting approaches (Agrafiotis et al. 2002). ANNs consist of groups of artificial neurons. In feed-forward back-propagation neural networks (Neural Networks 2010), neurons are organized in input, hidden, and output layers. Input layer neurons receive descriptor values of compounds, which are passed with different weights to the hidden layer neurons. A neuron activation function is then applied at each neuron to the sum of weighted inputs, and the results are passed to the output layer neurons, which calculate predicted activities of compounds. During training process, parameters of neuron functions and weights are adjusted so that the total error of predictions is minimized. There are network architectures with multiple hidden layers.

Recursive partitioning (RP) methods build decision trees in order to precisely assign compounds to their classes. The tree consists of one root node containing all objects (compounds), intermediate (or decision), and leaf (terminal) nodes. A measure of node purity is introduced; for example, it could be the ratio of counts of compounds belonging to majority and minority class in a node. At each node, the procedure tries to partition the data to increase the purity measure, that is, to make the difference between sum of child node purities and parent node purity as higher as possible. Analysis is based on descriptor value distributions between classes at the node. If such a partition at the node is impossible, it becomes a leaf node. Additional criteria may be imposed on the minimum number of compounds in a leaf node, etc. Compounds in each node satisfy certain descriptor criteria. After growing, some leaves are consecutively removed based on the improvement of classification at them (so-called pruning of a tree). Without pruning, the tree could be overfitted. Prediction process consists of moving a query compound up the tree (based on its descriptor values) until it reaches a leaf node. Predicted class of a compound is defined as that of the majority class in this node. There are also RP regression methods which are used, if response variable is continuous. There are several RP algorithms widely used such as Classification and Regression Trees (CART (Berk 2008)), C4.5 (Quinlan 1993), C5.0 (2008), etc.

Random Forest methods (Breiman 2001; Random Forests 2001) construct ensembles of trees based on multiple random selections of subsets of descriptors and bootstrapping of compounds. The compounds not selected in a particular bootstrapping are considered as a so-called out of bag set, and used as the test

set. The trees are not pruned. Best trees in the forest are chosen for consensus prediction of external compounds. The method can include bagging (Berk 2008; Breiman 1996) and boosting (Berk 2008; Breiman 1998) approaches.

Target Functions

Based on the nature of the response variable, QSAR approaches can be grouped into classification, category, or continuous QSAR (vide infra). Classes are different from categories in a sense that the former cannot be ordered in any scientifically meaningful way, while the latter can be rank ordered.

Continuous QSAR Models

We suggested that the following validation criteria should be used for continuous QSAR models (Tropsha and Golbraikh 2010): (1) leave-one-out (LOO) cross-validated q^2 (which is also used as the target function, that is, it is optimized by the QSAR modeling procedure) (2) square of the correlation coefficient $R(R^2)$ between the predicted and observed activities of the test set; (3) coefficients of determination (predicted versus observed activities (R_0^2), and observed versus predicted activities ($R'_0{}^2$) for the test set) for regressions through the origin; (4) slopes k and k' of regression lines through the origin (predicted versus observed activities, and observed versus predicted activities for the test set). In our studies, we consider models acceptable, if they have (1) $q^2 > 0.5$; (2) $R^2 > 0.6$; (3) $(R^2 - R_0^2)/R^2 < 0.1$ and $0.85 \leq k \leq 1.15$ or $(R^2 - R'_0{}^2)/R^2 < 0.1$ and $0.85 \leq k' \leq 1.15$; (4) $|(R_0^2 - R'_0{}^2)| < 0.3$. Sometimes, stricter criteria are used (Tropsha and Golbraikh 2010).

In some papers, other criteria are used. For example, sometimes standard error of prediction is used instead of (or together with) R^2 . Standard error of prediction itself makes no sense until we compare it with the standard deviation for activities of the test set, which brings us back to the correlation coefficients. If used, mean absolute error (MAE) should be compared with the mean absolute deviation from the mean. Sometimes, F-ratio is calculated, which is the variance explained by the model divided by the unexplained variance. It is believed that the higher is the F-ratio, the better is the model. We suppose that when F-ratio is used, it must be always accompanied by the corresponding p-value.

Frequently, especially for linear models such as developed with multiple linear regression (MLR) or partial least squares (PLS) the adjusted R^2 is used:

$$R_{adj}^2 = 1 - (1 - R^2) \frac{n - 1}{n - c - 1}, \quad (2)$$

where n is the number of compounds in the dataset, and c is the number of variables (descriptors or principal components) included in the regression equation. It should

be recognized that $R_{adj}^2 \leq R^2$. The higher the number of explanatory variables c is, the lower R_{adj}^2 is. R_{adj}^2 is particularly important for linear QSAR models developed with variable selection. R_{adj}^2 is not a good criterion for variable selection k NN QSAR models, since contrary to regression methods, in the k NN algorithm descriptors are just selected or not selected, that is, their weights are either zero or one. As a result, much larger set of descriptors is selected by the k NN procedure than, for example, by stepwise regression.

Target Functions and Validation Criteria for Classification QSAR Models

We consider a classification QSAR model predictive, if the prediction accuracy characterized by the correct classification rate (CCR) for each class is sufficiently large:

$$CCR_{\text{class}} = \frac{N_{\text{class}}^{\text{corr}}}{N_{\text{class}}^{\text{total}}} \quad (3)$$

and the p-value for each CCR_{class} value is not higher than a predefined threshold (in case of two classes, the CCR_{class} threshold should not be lower than 0.65–0.70, and generally, for any number of classes, p-value should not be higher than 0.05 for each class).

For the classification QSAR with K classes, we shall use the following criterion

$$CCR = \frac{1}{K} \sum_{i=1}^K CCR_i = \frac{1}{K} \sum_{i=1}^K \frac{N_k^{\text{corr}}}{N_k^{\text{total}}} \quad (4)$$

along with the correct classification rate for each class (see Eq. 2). Criterion 4 is correct for both balanced and imbalanced (biased) datasets (i.e., when the number of compounds of each class is different). For imbalanced datasets, formula $N(\text{corr})/N(\text{total})$, where $N(\text{corr})$ and $N(\text{total})$ are the number of compounds predicted correctly and the total number of compounds in the dataset) is incorrect. QSAR procedure should maximize the CCR value calculated according to Eq. 4, and at the same time it should be penalized by too high differences between CCR values for different classes.

Target Functions and Validation Criteria for Category QSAR Models

Category QSAR with more than two classes should use target functions and validation criteria other than those used in classification QSAR. These target functions and validation criteria should consider errors as differences between

predicted and observed categories, or increasing functions of these differences. The total error of prediction over all compounds is the sum of all errors of predictions for individual compounds. Let n_{ij} be the number of compounds of category i assigned by a model to category j ($i, j = 1, \dots, K$). Then the total error is calculated as follows:

$$E = \sum_{i=1}^K \sum_{j=1}^K n_{ij} f(|i - j|). \quad (5)$$

where $f(|i - j|)$ is the increasing function of errors. In case of biased datasets, it would be important to normalize the errors for compounds of category i on the number of compounds in this category:

$$E = \sum_{i=1}^K \frac{1}{N_i} \sum_{j=1}^K n_{ij} f(|i - j|). \quad (6)$$

where N_i is the number of compounds of category i . QSAR procedure should minimize the total error of prediction calculated with 5 or 6. In practice, the accuracy can be defined as $A = 1 - E/E_{\text{exp}}$, where E_{exp} is the expected total error. Thus, QSAR procedure should maximize the target function A penalized by too high differences between CCR values for different classes.

More detailed consideration of target functions and validation criteria as well as different aspects of cost-sensitive learning, weighting, penalties, as well as threshold moving in QSAR studies are discussed in our recent review (Tropsha and Golbraikh 2010). General aspects of cost-sensitive learning are discussed by Elkan (The Foundations 2001) and Chen et al. (2004). Oversampling of the minority class, that is, inclusion of compounds of the minority class in the dataset more than once, is considered by Yen and Lee (2006), and Kubat and Matwin (1997). The opposite approach, called undersampling, that is, removing part of the majority class from the dataset, is considered by Japkowicz (2000). Using moving threshold for dividing compounds into active and inactive classes when continuous property values are available but one desires to use classification modeling approaches is considered by Zhou and Liu (2006). In QSAR studies, threshold is usually moved toward the larger class, which is easier to predict correctly.

Applicability Domains

Here we are approaching an extremely important problem of QSAR studies: model applicability domain (AD). Formally, a QSAR model can predict the target property for any compound for which chemical descriptors can be calculated. However, if a compound is highly dissimilar from all compounds of the modeling set, reliable prediction of its activity is unlikely to be realized. A concept of AD was

developed and used to avoid such an unjustified extrapolation in activity prediction. Applicability domains are one of the areas of intensive research. Different methods of defining AD exist. Among others, the following definitions are considered by Jaworska and colleagues (2005, 2008).

AD is defined as a hyperparallelepiped in the descriptor space in which representative points are distributed (Netzeva et al. 2006; Nikolova-Jeliazkova and Jaworska 2005; Saliner et al. 2006). Dimensionality of the hyperparallelepiped is equal to the number of descriptors, and the size of each dimension is defined by the minimum and maximum values of the corresponding descriptor or it stretches beyond these limits to some extent up to predefined thresholds.

AD is defined as a convex hull of points in the multidimensional descriptor space (Fechner et al. 2008).

The drawbacks of these definitions are as follows. Generally, the representative points are distributed not in the entire hyperparallelepiped or convex hull, but only in a small part of it. Another drawback is that structural outliers in the dataset can enormously increase the size of the hyperparallelepiped, and the area around the outlier will contain no other points. Consequently, for many compounds within the hyperparallelepiped or convex hull, prediction will be unreliable. Besides, if the number of linearly independent descriptors exceeds the number of compounds, the convex hull is not unique.

Leverage for a compound is defined as the corresponding diagonal element of the hat matrix (Afantitis et al. 2006). A compound is defined as outside of the AD, if its leverage L is higher than $3 K/N$, where K is the number of descriptors and N is the number of compounds. The drawbacks of the leverage-based AD are as follows. (a) for each external compound, it is necessary to recalculate leverage; (b) if there are cavities in the representative point distribution area, a query compound the representative point of which is in this area will be considered to be within the AD, while in fact it is far from all other compounds (Tropsha and Golbraikh 2010).

In our studies, the AD is defined as the Euclidean distance threshold DT between a query compound and its closest k -nearest neighbors of the training set. It is calculated as follows:

$$DT = \bar{y} + Z\sigma \quad (7)$$

Here, \bar{y} is the average Euclidean distance between each compound and its k -nearest neighbors in the training set k is optimized in the course of QSAR modeling, and the distances are calculated using descriptors selected by the optimized (model only), σ is the standard deviation of these Euclidean distances, and Z is an arbitrary cutoff parameter defined by a user (de Cerqueira et al. 2006; Hsieh et al. 2008; Kovatcheva et al. 2005; Zhang et al. 2008). We set the default value of this parameter Z at 0.5, which formally places the allowed distance threshold at the mean plus one-half of the standard deviation. We also define the AD in the entire descriptor space. In this case, the same Eq. 7 is used, $k = 1$, $Z = 0.5$, and Euclidean distances are calculated using all descriptors. Thus, if the distance of the external compound from its nearest neighbor in the training set within either the entire descriptor space or

the selected descriptor space exceeds these thresholds, the prediction is not made. We have also investigated changes of predictive power by changing the values of Z-cutoff. We have found that in general, starting from some Z-cutoff value, predictive power decreases while Z-cutoff value increases (Zhu et al. 2009), as expected. Instead of Euclidean distances, other distances and similarity measures can be used.

The predicted activity of a query compound by an ensemble of QSAR models is calculated as the average over all predicted values. In binary QSAR modeling, each model will predict the compound category as either 0 (inactive) or 1 (active); however, different models used in an ensemble may yield inconsistent predictions. Consequently, the averaged predicted activity value for an external compound resulting from the use of an ensemble of models may fall anywhere within the [0;1] range. For classification and category QSAR, the average predicted value is rounded to the closest integer (which is a class or category number); in the case of imbalanced datasets, rounding can be done using the moving threshold (*vide supra*). Predicted average classes or categories (before rounding) that are closer to the nearest integers are considered more reliable since such value indicates higher concordance between different models. For example, before rounding, one compound has the predicted value of 0.2, but the other has 0.4. Hence, both compounds are predicted to belong to class 0 but the prediction for the first compound is considered more reliable. Using these prediction values, additional constraint on the AD can be defined by a threshold of the absolute difference between the predicted and the rounded predicted activity. There are several other definitions of AD (Jaworska and Nikolova-Jeliazkova 2008; Tetko et al. 2006) based on probability density distributions, distances to models, etc.

Y-randomization

To establish model robustness, Y-randomization (randomization of the response variable) test should be used. This test consists of repeating all the calculations with scrambled activities of the training set. Ideally, calculations should be repeated at least five (better, more) times. The goal of this procedure is to establish whether models built with real activities of the training set have good statistics not due to overfitting or chance correlation. If predictive power for the training or the test set of all models built with randomized activities of the training set is significantly lower than that of models built with real activities of the training set, the latter ones are considered reliable. Using different parameters of the model development procedure, multiple QSAR models are built which have acceptable statistics. Suppose, the number of these models is m . Y-randomization test can also give n models with acceptable statistics. For acceptance of models developed with real activities of the training set, the condition $n \ll m$ should be satisfied. In (Kovatcheva et al. 2005) and (de Cerqueira et al. 2006), we have introduced the measure of robustness $R = 1 - n/m$. If $R > 0.9$, the models are considered robust and their high predictive accuracy cannot be explained by the chance correlation or overfitting. Y-randomization test is particularly important for small datasets.

Unfortunately, in many publications on QSAR studies, Y-randomization test is not carried out but all QSAR practitioners must be strongly encouraged to use this simple procedure.

External Validation

Our previous experience suggests that the consensus prediction, which is the average of predicted activities over all predictive models, always provides the most stable results (Zhang et al. 2008; Zhu et al. 2008), and thus naturally avoids the need for (the best) model selection based on the statistics for the training and test sets. The consensus prediction of biological activity for an external compound on the basis of several QSAR models is more reliable and provides better justification for the experimental exploration of hits.

External evaluation set compounds are predicted by models that have passed all validation criteria described above. Each compound is predicted by models for which the compound is within the AD. Actually, each external compound should be within the AD of the training set within the entire descriptor space as well (*vide supra*). A useful parameter for consensus prediction is the minimum number (or percentage) of models for which a compound is within the AD; it is defined by the user. If the compound is found within the AD of a lower number of models, it is considered to be outside of the AD. Prediction value is the average of predictions by all models. If a compound is predicted by more than one model, standard deviation of all predictions by these models is also calculated. For classification and category QSAR, the average prediction value is rounded to the closest integer (which is a class or category number); in case of imbalanced datasets, rounding can be done using the moving threshold.

Predicted average classes or categories (before rounding), which are closer to the nearest integers are considered more reliable (Zhang et al. 2008). Using these prediction values, AD can be defined by a threshold of the absolute difference between predicted and rounded predicted activity. For classification and category QSAR, the same prediction accuracy criteria are used as for the training and test sets. The situation is more complex for the continuous QSAR. In this case, if the range of activities of the external evaluation set is comparable to that for the modeling set, criteria (1)–(4) are used (see section “[Target Functions](#)”). Sometimes, however, the external evaluation set may have a much smaller range of activities than the modeling set, so it could be impossible to obtain sufficiently large R^2 value (and other acceptable statistical characteristics) for it. In this case, we recommend using the mean absolute error (MAE) or the standard error of prediction (SEP) as discussed in one of our previous publications (Tropsha and Golbraikh 2010).

We have used consensus prediction in many studies (de Cerqueira et al. 2006; Kovatcheva et al. 2005; Shen et al. 2004; Votano et al. 2004; Zhang et al. 2007, 2008; Zhu et al. 2008) and have shown that in most cases it gives better prediction and coverage than most of the individual predictive models. Thus, we recommend using

consensus prediction for virtual screening of chemical databases and combinatorial libraries for finding new lead compounds for drug discovery.

“Good Practices” in QSAR Modeling: Examples of Models and Their Application to Virtual Screening and Lead Identification

As discussed above, our experience in QSAR model development and validation has led us to establishing a complex but straightforward workflow summarized in Fig. 2. The last critical component of this workflow is the use of models to identify tentative active hits that should be validated in experimental laboratories, and we strongly encourage every computational scientist to use this ultimate model validation strategy. We note that this approach shifts the emphasis from ensuring good (best) statistics for the model that fits known experimental data toward generating testable hypotheses about purported bioactive compounds. Thus, the output of the modeling has exactly same format as the input, that is, chemical structures and (predicted) activities making model interpretation and utilization completely seamless for medicinal chemists. In our recent studies, we have been fortunate to recruit experimental collaborators who have validated computational hits identified through our modeling of anticonvulsants (Shen et al. 2004), HIV-1 reverse transcriptase inhibitors (Medina-Franco et al. 2005), D1 antagonists (Oloff et al. 2005), antitumor compounds (Zhang et al. 2007), beta-lactamase inhibitors (Hsieh et al. 2008), geranylgeranyltransferase inhibitors (Peterson et al. 2009), and others. The discovery of novel bioactive chemical entities is the primary goal of computational drug discovery, and the development of validated and predictive QSAR models is critical to achieve this goal. We note that such studies could only be done if there is sufficient data available for a series of tested compounds such that robust validated models could be developed using the workflow described in Fig. 2. We present several examples of these studies below to illustrate the use of QSAR models as virtual screening tools for lead identification.

QSAR-Aided Discovery of Novel Anticonvulsant Compounds

We have applied kNN (Zheng and Tropsha 2000) and simulated annealing – partial least squares (SA-PLS) (Cho et al. 1998) QSAR approaches to a dataset of 48 chemically diverse functionalized amino acids (FAAs) with anticonvulsant activity that were synthesized previously, and successful QSAR models of FAA anticonvulsants have been developed (Shen et al. 2002). Both methods utilized multiple descriptors such as molecular connectivity indices or atom-pair descriptors, which are derived from two-dimensional molecular topology. QSAR models with high internal accuracy were generated, with leave-one-out cross-validated $R^2(q^2)$ values ranging between 0.6 and 0.8. The q^2 values for the actual dataset were significantly higher than those obtained for the same dataset with randomly shuffled

activity values, indicating that models were statistically significant. The original dataset was further divided into several training and test sets, and highly predictive models providing q^2 values for the training sets greater than 0.5 and R^2 values for the test sets greater than 0.6.

In the second phase of modeling, we have applied the validated QSAR models to mining available chemical databases for new lead FAA anticonvulsant agents. Two databases have been explored: the National Cancer Institute (nci 2007) and Maybridge (2005) databases, including (at the time of that study) 237,771 and 55,273 chemical structures, respectively. Database mining was performed independently using ten individual QSAR models that have been extensively validated using several criteria of robustness and accuracy. Each individual model selected some number of hits as a result of independent database mining, and the consensus hits (i.e., those selected by all models) were further explored experimentally for their anticonvulsant activity. As a result of computational screening of the NCI database, 27 compounds were selected as potential anticonvulsant agents and submitted to our experimental collaborators. Of these 27 compounds, our collaborators chose two for synthesis and evaluation; their choice was based on the ease of synthesis and the fact that these two compounds had structural features that would not be expected to be found in active compounds based on prior experience. Several additional compounds, which were close analogs of these two were either taken from the literature or designed in our collaborator's laboratory. In total, seven compounds were resynthesized and sent to the NIH for the Maximum Electroshock (MES) test (a standard test for the anticonvulsant activity, which was used for the training set compounds as well). The biological results indicated that upon initial and secondary screening, five out of seven compounds tested showed anticonvulsant activity with ED_{50} less than 100 mg/kg, which is considered promising. Interestingly, all seven compounds were also found to be very active in the same tests performed on rats (a complete set of experimental data on rats for the training set were not available, and therefore no QSAR models for rats were built).

Mining of the Maybridge database yielded two additional promising compounds that were synthesized and sent to the NIH for the MES anticonvulsant test. One of the compounds showed moderate anticonvulsant activity of ED_{50} between 30 and 100 mg/kg (in mice), while the other was found to be a very potent anticonvulsant agent with ED_{50} of 18 mg/kg in mice (ip). In summary, both compounds were found to be very active in both mice and rats. Figure 4 shows chemical structures of experimentally confirmed hits that were identified by using validated QSAR models for virtual screening as applied to the anticonvulsant dataset. It is important to note that none of the compounds identified in external databases as potent anticonvulsants and validated experimentally belong to the same class of FAA molecules as the training set. This observation was very stimulating because it underscored the power of our methodology to identify potent anticonvulsants of novel chemical classes as compared to the training set compounds, which is one of the most important goals of virtual screening.

Fig. 4 Uniqueness of scaffolds for QSAR-based experimentally confirmed virtual screening hits (a) as compared to training set compounds; (b) for the anticonvulsant dataset

QSAR-Enabled Discovery of Novel Anticancer Agents

A combined approach of validated QSAR modeling and virtual screening was successfully applied to the discovery of novel tylophorine derivatives as anticancer agents (Zhang et al. 2007). QSAR models have been initially developed for 52 chemically diverse phenanthrene-based tylophorine derivatives (PBTs) with known experimental EC_{50} using chemical topological descriptors (calculated with the Molconn-Z program) and variable selection k-nearest neighbor (kNN) method. Several validation protocols have been applied to achieve robust QSAR models. The original dataset was divided into multiple training and test sets, and the models were considered acceptable only if the leave-one-out cross-validated $R^2(q^2)$ values were greater than 0.5 for the training sets and the correlation coefficient R^2 values were greater than 0.6 for the test sets. Furthermore, the q^2 values for the actual dataset were shown to be significantly higher than those obtained for the same dataset with randomized target properties (Y-randomization test), indicating that models were statistically significant. Ten best models were then employed to mine a commercially available ChemDiv Database (ca. 500 K compounds) resulting in 34 consensus hits with moderate to high predicted activities. Ten structurally diverse hits were experimentally tested and eight were confirmed active with the highest

experimental EC_{50} of 1.8 μM implying an exceptionally high hit rate (80 %). The same ten models were further applied to predict EC_{50} for four new PBTs, and the correlation coefficient (R^2) between the experimental and predicted EC_{50} for these compounds plus eight active consensus hits was shown to be as high as 0.57.

QSAR Enabled Discovery of Novel Geranylgeranyltransferase I Inhibitors (GGTIs)

The proper functioning of proteins often relies on posttranslational modification of the polypeptide leading to changes in chemical characteristics. Found at the extreme carboxyl terminus of the protein, one posttranslational “program” utilized for over 140 proteins is the so-called CaaX box, where “C” is a cysteine, “aa” is any aliphatic dipeptide, and “X” is the terminal residue that directs which of two prenyl groups is added (Cox and Der 2002; Zhang and Casey 1996). Protein geranylgeranyltransferase type I (GGTase-I) transfers the 20-carbon geranylgeranyl group to proteins including critical signaling molecules from many classes, for example, the Ras superfamily (including K-Ras, Rho, Rap, Cdc42, and Rac), several G-protein gamma subunits, protein kinases (rhodopsin kinase, phosphorylase kinase, and GRK7), and protein phosphatases (Casey and Seabra 1996; Sebti and Hamilton 2000). Several GGTIs have been developed that inhibit C20 lipid modification of GGTase-I substrates. GGTIs have been primarily developed for use as cancer therapeutics, particularly in cancers that have high levels, or activating mutations of geranylgeranylated proteins (Sebti and Hamilton 2000; Winter-Vann and Casey 2005).

The pharmacological data for 48 GGTIs reported in (Peterson et al. 2009) were generated as part of an iterative drug discovery program that led to GGTI-DU40 (Peterson et al. 2006). The structure of GGTI-DU40 can be discussed in the context of the CaaL peptide framework. There is a free amide group, a spacer domain relating to the dialiphatic motif, and critical sulfur as found in the requisite cysteine residue of GGTase-I’s substrates. Four additional GGTIs included in the data set were peptidomimetics as well. Importantly, the modeling set included compounds with different (chemical scaffolds), which in theory (and as we have established in our study, in practice) should have enabled the identification of chemically diverse hits from virtual screening.

Three different modeling techniques have been used to model GGTIs following our general combi-QSAR strategy (Fig. 3); the specific workflow as applied to the GGTI dataset is shown in Fig. 5. As the first step of our QSAR-based virtual screening, the preliminary filtering of the 9.5 million compounds in our screening library yielded 79 initial hits. This was done by using the global applicability domain of all 48 GGTIs in the modeling set. After consensus predictions by 104 validated kNN models, their predicted activities (pIC_{50}) were found ranging from 4.51 to 5.96. Only 47 hits, including two pairs of stereoisomers, showed high predicted activity ($pIC_{50} > 5.50$) as well as high model coverage and were designated as the final hits. Concurrently, two additional QSAR models were employed to reevaluate

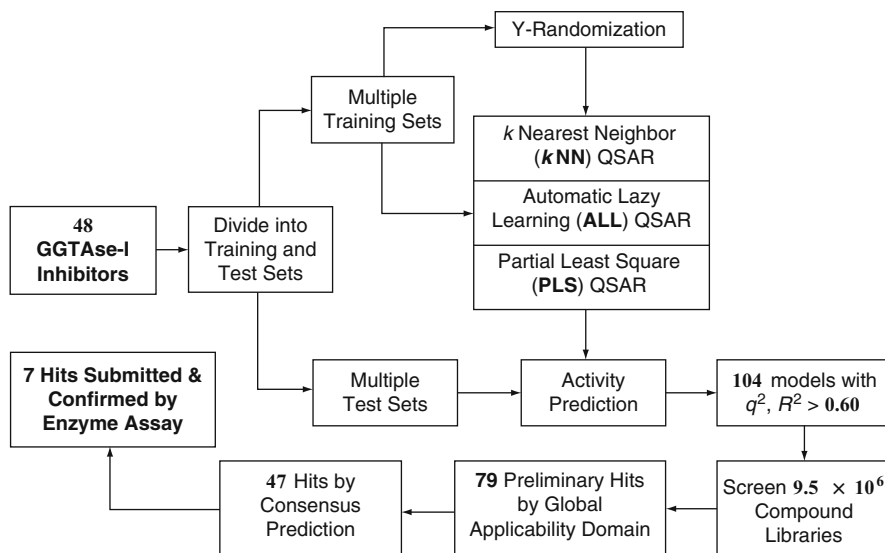

Fig. 5 The predictive QSAR modeling workflow illustrated for GGTIs Using purified recombinant GGTase-I as an enzyme source and GGpp and Ras-CVLL as substrates, seven hit compounds were tested in vitro as a matter of the experimental validation. The selection was based on high predicted activity, availability, and structural uniqueness. All tested compounds showed inhibition of GGTase-I with the pIC_{50} ranging from 3.63 to 5.44 (cf. Fig. 6)

those 79 hits in order to identify the consensus hits among all three methods. In the end, seven compounds were prioritized for experimental validation based on high predicted activity, uniqueness of structure, and availability.

The unexpected result was to identify several predicted actives that did not have a common ring feature in their structure. In fact, seven highly ranked hits had no apparent relationship with any of the training set molecules. They had furan, triazole, tetrazole, and pyridine cores in their scaffolds while all non-peptidomimetic compounds of the training set were based on a pyrazole core. Therefore, the seven hit compounds appeared to be the structurally novel hits. Figure 6b shows chemical structures of the three representative confirmed hits with novel scaffolds highlighted. This study reconfirmed the observation that we already emphasized earlier with anticonvulsant compounds that contrary to the common belief, QSAR-based virtual screening is capable of identifying experimentally confirmed hit compounds with novel scaffolds.

“Good Practices” in QSAR Model Development: Applications to Toxicity Modeling

Many compounds entering clinical studies do not survive as a good pharmacological lead to become a marketed drug. Chemical toxicity and safety have been regarded

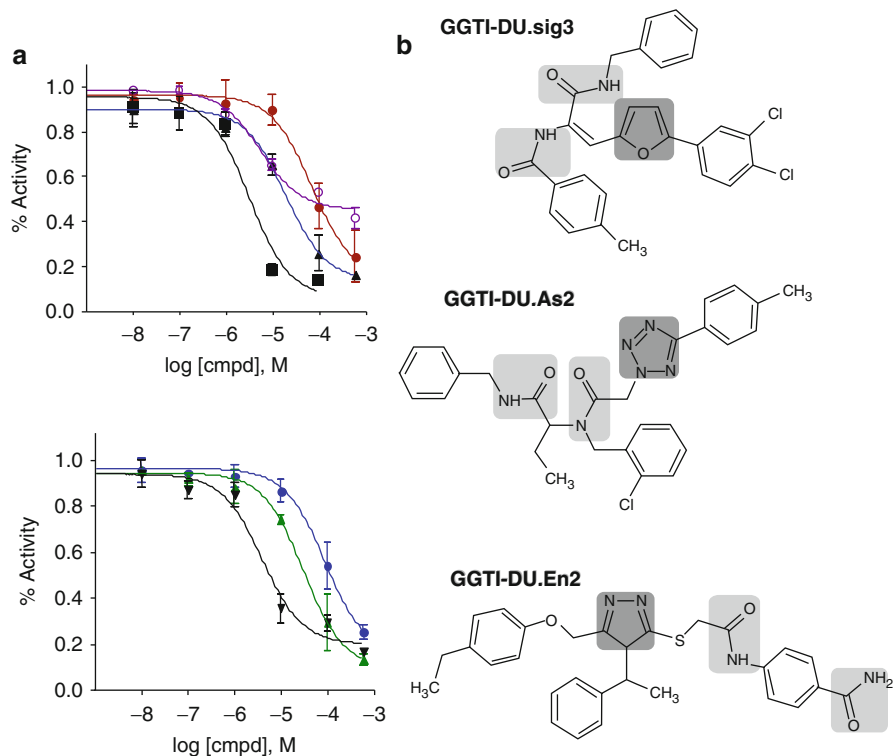

Fig. 6 Experimental validations of computational GGTI hits using GGTase-I in vitro activity assay. **(a)** Inhibition curves; **(b)** Chemical structures of three representative confirmed hits; the novel scaffolds in the structures are highlighted

as the major reason for attrition in the past decades (Kola and Landis 2004). However, evaluation of chemical toxicity and safety in vivo at the early stage of drug discovery process is expensive and time consuming. To replace the traditional animal toxicity testing and to understand the relevant toxicological mechanisms, many in vitro toxicity screens and computational toxicity models have been developed and implemented by academic institutes and pharmaceutical companies (Cheeseman 2005; Dash et al. 2009; Dix et al. 2007; Inglese et al. 2006; Park et al. 2009; Riley and Kenna 2004; Valerio 2009; Yang et al. 2009). In the past 15 years, innovative technologies that enable rapid synthesis and high throughput screening of large libraries of compounds have been adopted for toxicity studies. As a result, there has been a huge increase in the number of compounds and the associated testing data in different in vitro screens. With this data, it becomes feasible to reveal the relationship between the high throughput in vitro toxicity testing results and the low throughput in vivo low dose toxicity evaluation for the same set of compounds. Understanding these relationships could help us delineate

the mechanisms underlying animal toxicity of chemicals as well as potentially improve our ability to predict chemical toxicity using short-term bioassays.

The unique advantage of using a computational toxicity model in risk analysis is that a chemical could be evaluated for its toxicity potential even before it is synthesized. The computational toxicity tools based on QSAR models have been used to assist in predictive toxicological profiling of pharmaceutical substances for understanding drug safety liabilities (Durham and Pearl 2001; Jacobson-Kram and Contrera 2007; Muster et al. 2008; Valerio 2009), supporting regulatory decision making on chemical safety and risk of toxicity (Bailey et al. 2005), and are effectively enhancing an already rigorous US regulatory safety review of pharmaceutical substances (Valerio 2008). Predictive QSAR models of chemical toxicity are beginning to be used to evaluate compounds' safety in the pharmaceutical industry and environmental agencies (Durham and Pearl 2001; Snyder 2009). However, it has been reported that most QSAR models do not work well for evaluating *in vivo* toxicity, especially for external compounds (Zvinavashe et al. 2008, 2009). Several reviews were published recently that challenge the feasibility and reliability of QSAR models of chemical toxicity (Johnson 2008; Stouch et al. 2003). At the same time, experimental data resulting from short-term high throughput screening assays are emerging prompting the development of novel modeling approaches that can combine short-term assay data and conventional chemical descriptors of molecules to develop enhanced QSAR models of animal toxicity. We briefly review these emerging approaches and applications below.

Quantitative Structure In Vitro–In Vivo Relationship Modeling

To stress a broad appeal of the conventional QSAR approach, it should be made clear that from the statistical viewpoint QSAR modeling is a special case of general statistical data mining and data modeling where the data is formatted to represent objects described by multiple descriptors and the robust correlation between descriptors and a target property (e.g., chemical toxicity *in vivo*) is sought. In previous computational toxicology studies, additional physicochemical properties, such as water partition coefficient (logP) (Klopman et al. 2003), water solubility (Stoner et al. 2004), and melting point (Mayer and Reichenberg 2006) were used successfully to augment computed chemical descriptors and improve the predictive power of QSAR models. These studies suggest that using experimental results as descriptors in QSAR modeling could prove beneficial. The already available and rapidly growing HTS data for large and diverse chemical libraries makes it possible to extend the scope of the conventional QSAR in toxicity studies by using *in vitro* testing results as additional biological descriptors. Therefore, in some of the most recent toxicology studies, the relationships between various *in vitro* and *in vivo* toxicity testing results were generated (Forsby and Blaauboer 2007; Piersma et al. 2008; Schirmer et al. 2008; Sjoström et al. 2008). Based on these reports, we proposed a new modeling workflow called Quantitative Structure In vitro–In vivo Relationship (QSIIRQuantitative structure in vitro–in vivo relationship (QSIIR)

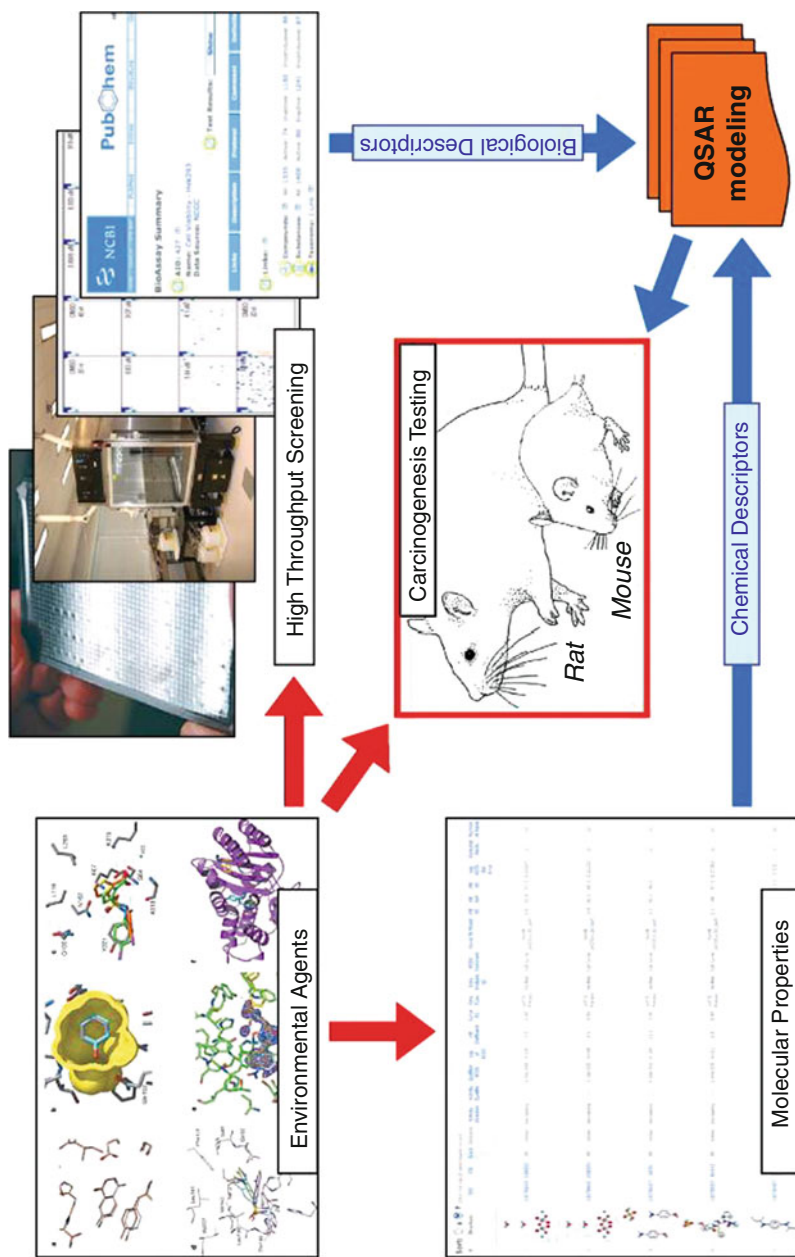

Fig. 7 Combining chemical and biological profiles as descriptors in QSAR modeling of chemical carcinogenicity

modeling) and used it in animal toxicity modeling studies (Zhu et al. 2008, 2009). The target properties of QSIIR modeling were still biological activities, such as different toxicity end points, but the content and interpretation of “descriptors” and the resulting models is different. This focus on the prediction of the same target property from different (chemical, biological, and genomic) characteristics of environmental agents affords an opportunity to most fully explore the source-to-outcome continuum of the modern experimental toxicology using cheminformatics approaches. Figure 7– provides visual illustration of the integrated QSIIR approach to in vivo toxicity modeling.

Using “Hybrid” Descriptors for QSIIR Modeling of Rodent Carcinogenicity

To explore efficient approaches for rapid evaluation of chemical toxicity and human health risk of environmental compounds, the National Toxicology Program (NTP), in collaboration with the National Center for Chemical Genomics (NCGC) has initiated an HTS Project (Inglese et al. 2006; Thomas et al. 2009). The first batch of HTS results for a set of 1,408 compounds tested in six human cell lines was released via PubChem. We have explored this data in terms of their utility for predicting adverse health effects of the environmental agents (Zhu et al. 2008). Initially, the classification k-nearest neighbor (kNN) QSAR modeling method was applied to the HTS data only for the curated dataset of 384 compounds. The resulting models had prediction accuracies for training, test (containing 275 compounds together), and external validation (109 compounds) sets as high as 89 %, 71 %, and 74 %, respectively. We then asked if HTS results could be of value in predicting rodent carcinogenicities. We identified 383 compounds for which data were available from both the Berkeley Carcinogenic Potency Database and NTP-HTS studies. We found that compounds classified by HTS as “actives” in at least one cell line were likely to be rodent carcinogens (sensitivity 77 %); however, HTS “inactives” were far less informative (specificity 46 %). Using chemical descriptors only, kNN QSAR modeling resulted in the overall external prediction accuracy of 62 % for rodent carcinogenicity. Importantly, the prediction accuracy of the model was significantly improved (to 73 %) when chemical descriptors were augmented by the HTS data, which were regarded as biological descriptors (Fig. 8). Thus, our studies suggested, for the first time, that combining HTS profiles with conventional chemical descriptors could considerably improve the predictive power of computational approaches in chemical toxicology.

Using “Hybrid” Descriptors for the QSIIR Modeling of Rodent Acute Toxicity

We used the cell viability qHTS data from NCGC as mentioned in the above section for the same 1,408 compounds but in 13 cell lines (Xia et al. 2008).

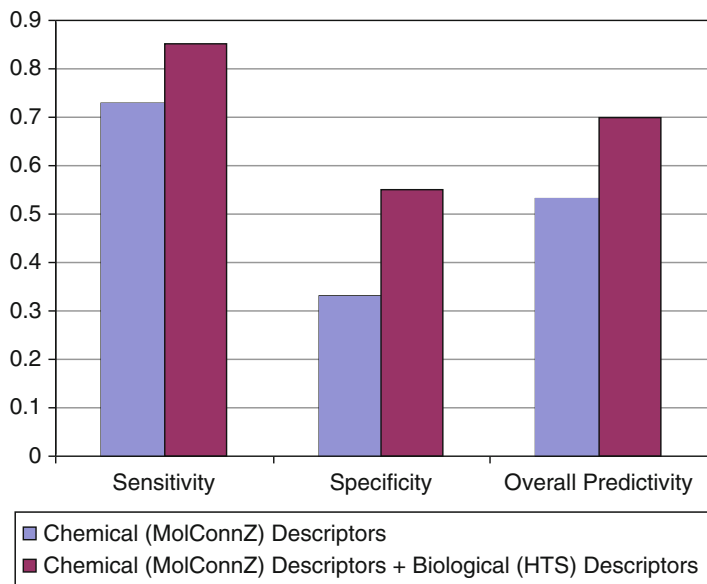

Fig. 8 Comparison of the prediction power of QSTR models of chemical carcinogenicity for the independent validation set using conventional versus hybrid descriptors

Fig. 9 Acute toxicity modeling. The ROC curves for conventional QSAR model (bold line) and different hybrid models for the same external compounds.

Besides the carcinogenicity, we asked if HTS results could be of value in predicting rodent acute toxicity (Sedykh et al. [in press](#)). For this purpose, we have identified 690 of these compounds, for which rodent acute toxicity data (i.e., toxic or nontoxic) was also available. The classification kNN QSAR modeling method was applied to these compounds using either chemical descriptors alone or as a combination of chemical and qHTS biological (hybrid) descriptors as compound features. The external prediction accuracy of models built with chemical descriptors only was 76 %. In contrast, the prediction accuracy was significantly improved to 85 % when using hybrid descriptors. The receiver operating characteristic (ROC) curves of conventional QSAR models and different hybrid models are shown in Fig. 9. The sensitivities and specificities of hybrid models are clearly better than for conventional QSAR model for predicting the same external compounds. Furthermore, the prediction coverage increased from 76 % when using chemical descriptors only to 93 % when qHTS biological descriptors were also included. Our studies suggest that combining HTS profiles, especially the dose–response qHTS results, with conventional chemical descriptors could considerably improve the predictive power of computational approaches for rodent acute toxicity assessment.

Collaborative and Consensus Modeling of Aquatic Toxicity

We discuss below the results of a recent important study of aquatic toxicity (Zhu et al. 2008). In our opinion, this particular study may serve as a useful example to illustrate the complexity and power of modern QSAR modeling approaches and highlight the importance of collaborative and consensual model development.

The combinational QSAR modeling approach has been applied to a diverse series of organic compounds tested for aquatic toxicity in *Tetrahymena pyriformis* in the same laboratory over nearly a decade (Aptula et al. 2005; Netzeva and Schultz 2005; Schultz 1999; Schultz and Netzeva 2004; Schultz et al. 2001, 2002, 2003, 2005a, 2005b). The unique aspect of this research was that it was conducted in collaboration between six academic groups specializing in cheminformatics and computational toxicology. The common goals for our virtual collaboratory were to explore the relative strengths of various QSAR approaches in their ability to develop robust and externally predictive models of this particular toxicity end point. We have endeavored to develop the most statistically robust, validated, and externally predictive QSAR models of aquatic toxicity. The members of our collaboratory included scientists from the University of North Carolina at Chapel Hill in the United States (UNC); University of Louis Pasteur (ULP) in France; University of Insubria (UI) in Italy; University of Kalmar (UK) in Sweden; Virtual Computational Chemistry Laboratory (VCCLAB) in Germany; and the University of British Columbia (UBC) in Canada. Each group relied on its own QSAR modeling approaches to develop toxicity models using the same modeling set, and we agreed to evaluate the realistic model performance using the same external validation set(s).

The *T. pyriformis* toxicity dataset used in this study was compiled from several publications of the Schultz group as well as from data available at the Tetratox database Web site of (<http://www.vet.utk.edu/TETRATOX/>). After deleting duplicates as well as several compounds with conflicting test results and correcting several chemical structures in the original data sources, our final dataset included 983 unique compounds. The dataset was randomly divided into two parts: (1) the modeling set of 644 compounds; (2) the validation set including 339 compounds. The former set was used for model development by each participating group and the latter set was used to estimate the external prediction power of each model as a universal metric of model performance. In addition, when this project was already well underway, a new dataset had become available from the most recent publication by the Schultz group (Schultz et al. 2007). It provided us with an additional external set to evaluate the predictive power and reliability of all QSAR models. Among compounds reported in (Schultz et al. 2007) 110 were unique, that is, not present among the original set of 983 compounds; thus, these 110 compounds formed the second independent validation set for our study.

Universal Statistical Figures of Merit for All Models

Different groups have employed different techniques and (sometimes) different statistical parameters to evaluate the performance of models developed independently for the modeling set (described below). To harmonize the results of this study, the same standard parameters were chosen to describe each model's performance as applied to the modeling and external test set predictions. Thus, we have employed Q_{abs}^2 (squared leave-one-out cross-validation correlation coefficient) for the modeling set, R_{abs}^2 (frequently described as coefficient of determination) for the external validations sets, and MAE (mean absolute error) for the linear correlation between predicted (Y_{pred}) and experimental (Y_{exp}) data (here, $Y = pIGC_{50}$); these parameters are defined as follows:

$$Q_{abs}^2 = 1 - \frac{\sum_Y (Y_{exp} - Y_{LOO})^2}{\sum_Y (Y_{exp} - \langle Y \rangle_{exp})^2} \quad (8)$$

$$R_{abs}^2 = 1 - \frac{\sum_Y (Y_{exp} - Y_{pred})^2}{\sum_Y (Y_{exp} - \langle Y \rangle_{exp})^2} \quad (9)$$

$$MAE = \frac{\sum_Y |Y - Y_{pred}|}{n} \quad (10)$$

Many other statistical characteristics can be used to evaluate model performance; however, we restricted ourselves to these three parameters that provide minimal but sufficient information concerning any model's ability to reproduce both the trends

in experimental data for the test sets as well as mean accuracy of predicting all experimental values. The models were considered acceptable if R_{abs}^2 exceeded 0.5.

Consensus QSAR Models of Aquatic Toxicity; Comparison Between Methods and Models

The objective of this study from methodological prospective was to explore the suitability of different QSAR modeling tools for the analysis of a dataset with an important toxicological end point. Typically, such datasets are analyzed with one (or several) modeling techniques, with a great emphasis on the (high value of) statistical parameters of the training set models. In this study, we went well beyond the modeling studies reported in the original publications in several respects. First, we have compiled all reported data on chemical toxicity against *T. pyriformis* in a single large dataset and attempted to develop global QSAR models for the entire set. Second, we have employed multiple QSAR modeling techniques thanks to the engagement of six collaborating groups. Third, we have focused on defining model performance criteria not only using training set data but most importantly using external validation sets that were not used in model development in any way (unlike any common cross-validation procedure) (Gramatica 2007). This focus afforded us the opportunity to evaluate and compare all models using simple and objective universal criteria of external predictive accuracy, which in our opinion is the most important single figure of merit for a QSAR model that is of practical significance for experimental toxicologists. Fourth, we have explored the significance of applicability domains and the power of consensus modeling in maximizing the accuracy of external predictivity of our models.

We believe that results of our analysis lend a strong support for our strategy. Indeed, all models performed quite well for the training set with even the lowest Q_{abs}^2 among them as high as 0.72. However, there was much greater variation between these models when looking at their (universal and objective) performance criteria as applied to the validation sets.

Of 15 QSAR approaches used in this study, nine implemented method-specific applicability domains. Models that did not define the AD showed a reduced predictive accuracy for the validation set II even though they yielded reasonable results for the validation set I. On average, the use of applicability domains improved the performance of individual models although the improvement came at the expense of the lower chemistry space coverage.

For the most part all models succeeded in achieving reasonable accuracy of external prediction especially when using the AD. It then appeared natural to bring all models together to explore the power of consensus prediction. Thus, the consensus model was constructed by averaging all available predicted values taking into account the applicability domain of each individual model. In this case, we could use only 9 of 15 models that had the AD defined. Since each model had its unique way of defining the AD, each external compound could be found within

the AD of anywhere between one and nine models so for averaging we only used models covering the compound. The advantage of this data treatment is that the overall coverage of the prediction is still high because it was rare to have an external compound outside of the ADs of all available models. The results showed that the prediction accuracy for both the modeling set and the validation sets was the best compared to any individual model. The same observation could be made for the correlation coefficient R_{abs}^2 . The coverage of this consensus model II was 100 % for all three data sets. This observation suggests that consensus models afford both high space coverage and high accuracy of prediction

In summary, this study presents an example of a fruitful international collaboration between researchers that use different techniques and approaches but share general principles of QSAR model development and validation. Significantly, we did not make any assumptions about the purported mechanisms of aquatic toxicity yet were able to develop statistically significant models for all experimentally tested compounds. In this regard it is relevant to cite an opinion expressed in an earlier publication by T. Schultz that “models that accurately predict acute toxicity without first identifying toxic mechanisms are highly desirable” (Schultz 1999). However, the most significant single result of our studies is the demonstrated superior performance of the consensus modeling approach when all models are used concurrently and predictions from individual models are averaged. We have shown that both the predictive accuracy and coverage of the final consensus QSAR models were superior as compared to these parameters for individual models. The consensus models appeared robust in terms of being insensitive to both incorporating individual models with low prediction accuracy and the inclusion or exclusion of the AD. Another important result of this study is the power of addressing complex problems in QSAR modeling by forming a virtual collaboratory of independent research groups leading to the formulation and empirical testing of best modeling practices. This latter endeavor is especially critical in light of the growing interest of regulatory agencies to developing most reliable and predictive models for environmental risk assessment (Yang et al. 2006) and placing such models in the public domain.

Conclusions: Emerging Chemical/Biological Data and QSAR Research Strategies

In the past 15 years, innovative technologies that enable rapid synthesis and high throughput screening of large libraries of compounds have been adopted in almost all major pharmaceutical and biotech companies. As a result, there has been a huge increase in the number of compounds available on a routine basis to quickly screen for novel drug candidates against new targets or pathways. In contrast, such technologies have rarely become available to the academic research community, thus limiting its ability to conduct large-scale chemical genetics or chemical genomics research. The NIH Molecular Libraries Roadmap Initiative has changed this situation by forming the national Molecular Library Screening

Centers Network (MLSCN) (Austin et al. 2004) with the results of screening assays made publicly available via PubChem (2010). These efforts have already led to the unprecedented growth of available databases of biologically tested compounds [cf. our recent review where we list about 20 available databases of compounds with known bioactivity (Oprea and Tropsha 2006)].

This growth creates new challenges for QSAR modeling such as developing novel approaches for the analysis and visualization of large databases of screening data, novel biologically relevant chemical diversity or similarity measures, and novel tools for virtual screening of compound libraries to ensure high expected hit rates. Application studies discussed in this chapter have established that QSAR models could be used successfully as virtual screening tools to discover compounds with the desired biological activity in chemical databases or virtual libraries (Hsieh et al. 2008; Oloff et al. 2005; Shen et al. 2004; Tropsha 2005; Tropsha and Zheng 2001; Zhang et al. 2007). The discovery of novel bioactive chemical entities is the primary goal of computational drug discovery, and the development of validated and predictive QSAR models is critical to achieve this goal. Due to the significant recent increase in publicly available datasets of biologically active compounds and the critical need to improve the hit rate of experimental compound screening there is a strong need in developing widely accessible and reliable computational QSAR modeling techniques and specific end-point predictors.

Acknowledgments The studies described in this chapter were supported in parts by the NIH research grants R01GM066940 and R21GM076059 and EPA grants EPA (RD832720 and RD833825).

ture and biological activity has received considerable attention in recent years because it allows one to predict theoretically bioactivity without an inordinate amount of experimental time and effort. In this chapter we collect and discuss critically published results concerning the QSAR research on antimicrobial compounds. Finally, we present an updated perspective about the future trends in this area.

Introduction

Antimicrobial drugs are drugs designed to kill, or prevent the growth of microorganisms (bacteria, fungi, and viruses). The development of antimicrobial agents for clinical use has brought unquestionable benefit to individuals and society. Infectious diseases that were formerly often fatal became curable (Lerner 1998). However, antibiotics ultimately have lost their original effectiveness as they have been used over time and resistant strains of bacteria have been developed and there is thus an urgent need to identify novel, active chemotypes as leads for better drug development (Cragg et al. 1997; Hall 2004; Mcdermott et al. 2003).

The versatility of bacterial populations to adapt to environmental toxicity and associated facilities for transferring genetic material show that the antibiotic resistance a biological phenomenon is inevitable and will continue to be a chronic medical condition. The appropriate employment of antimicrobials in use and the continued development of new ones are vital to protect the health of men and animals from pathogens (Mcdermott et al. 2003).

Natural products could play a crucial role in meeting this demand (Cragg and Newman 2001). The use of natural products for the treatment of human diseases is a practice that has been used for a long time. It is estimated that 40 % of medicines available for the current treatment of diseases have been developed from natural sources (Cragg and Newman 2001; Shu 1998). The knowledge generated as a result of the use of natural product derivatives of the higher plants, microorganisms, and toxins animals was essential in the discovery of new drugs for modern medical treatment.

In medicine, natural products provide high number of drugs useful in case of complex chemical synthesis and can also serve as basic compound models of synthetic drugs or suitable modifications that reduce its toxicity (Demain 1999).

The quantitative relationship between chemical structure and biological activity has received considerable attention in recent years because it allows one to predict theoretically bioactivity without an inordinate amount of experimental time and demanding efforts.

Computational methods for predicting compounds with specific pharmacodynamic, pharmacokinetic, or toxicological properties are useful for facilitating drug discovery and drug safety evaluation. The quantitative structure-activity relationship (QSAR) and quantitative structure–property relationship (QSPR) methods are the most successfully used statistical learning methods for predicting compounds with specific properties.

More recently, other statistical learning methods such as neural networks and support vector machines have been explored for predicting compounds of higher structural diversity than those covered by QSAR and QSPR approaches. These methods have shown promising potential in a number of studies. Many attempts have been made to elucidate the QSAR of antimicrobials by using different physicochemical parameters.

This chapter is intended to review some of the strategies and current progresses in using statistical learning methods for predicting compounds with specific desired properties in antimicrobial activity.

General Overview of Methods Used in QSAR of Antimicrobial Compounds

Antimicrobial Activity Determination

As microbiological methods incorporate viable test microorganisms, predictability of the outcome is not always clear and subject to many environmental influences that may impact on a given response. Hence, it is of the utmost importance that parameters such as plant collection, validation of laboratory equipment, chemical analysis, and various intricacies of antimicrobial investigations be carefully defined.

Although several methods are used to assess antimicrobial activity, the two most common methods used are disk diffusion and minimum inhibitory concentration (MIC) assays. Generally disk diffusion studies are the method of choice due to their simplicity and capacity to analyze a large number of test samples. Even though disk diffusion methodology is a quick simple means of screening for antimicrobial activity, it is a qualitative assay because it shows if there is antimicrobial activity or not. The MIC measurement to determine antimicrobial activity is a quantitative method based on the principle of contact of a test organism to a series of dilutions of test substance. Assays involving MIC methodology are widely used and an accepted criterion for measuring the susceptibility of organisms to inhibitors (Lambert and Pearson 2000).

Quantitative Structure–Activity Relationship (QSAR)

Quantitative structure–activity relationship (QSAR) analysis is in constant development since the works of Hansch (Hansch and Fujita 1964) in early 1960s. The QSAR methodology focuses on finding a model, which allows one for correlating the activity to structure within a family of compounds. QSAR studies can reduce the costly failures of drug candidates in clinical trials by filtering the combinatorial libraries. Virtual filtering can eliminate compounds with predicted toxic or poor pharmacokinetic properties (Hodgson 2001; van de Waterbeemd and Gifford 2003) early in the pipeline.

Considering activity optimization, building target-specific structure-activity models based on identified hits can guide high throughput screening (HTS), a recent technological improvement in drug discovery pipeline, by rapidly screening the library for most promising candidates (Dudek et al. 2006). Such focused screening can reduce the number of experiments and allows for use of more complex and low throughput assays (Bajorath 2002). Interpretation of created models gives insight into the chemical space in proximity of the hit compound. Feedback loops of high-throughput and virtual screening, resulting in sequential screening approach (Lewis 2005), allow therefore for more rational progress toward high quality lead compounds. Later in the drug discovery pipeline, accurate QSAR models constructed on the basis of the lead series can assist in optimizing the lead (Prado-Prado et al. 2008).

Main stages of a QSAR study can be divided into three groups, i.e., extracting descriptors from molecular structure, choosing those informative in the context of the analyzed activity, and, finally, using the values of the descriptors as independent variables to define a mapping that correlates them with the activity in question (Dudek et al. 2006).

Generation of Molecular Descriptors from Structure

Compounds are defined by their structure, encoded as a set of atoms and covalent bonds between them. However, the structure cannot be directly used for creating structure-activity mappings because it does not usually contain in an explicit form the information that relates to activity. Molecular descriptors accentuate different chemical properties implicit in the structure of the molecule and so those properties may correlate more directly with the activity. Such properties range from physicochemical and quantum-chemical to geometrical and topological features.

On the other hand, most methods of statistical data analysis employed to predict the activity require as input numerical vectors of features of uniform length for all molecules. Chemical structures of compounds are diverse in size and nature and as such do not fit into this model directly. Molecular descriptors convert the structure to the form of well-defined sets of numerical values.

Selection of Relevant Molecular Descriptors

Although it is possible to generate hundreds or thousands of different molecular descriptors, only some of them are significantly correlated with the activity. Furthermore, many of the descriptors are intercorrelated. This has negative effects on several aspects of QSAR analysis. Some statistical methods require that the number of compounds is significantly greater than the number of descriptors and using large descriptor sets would require large datasets. Other methods, while capable of handling datasets with large descriptors to compounds ratios, nonetheless

suffer from loss of accuracy. Large number of descriptors also affect interpretability of the final model. To tackle these problems, a wide range of methods for automated narrowing of the set of descriptors to the most informative ones is used in QSAR analysis.

Mapping the Descriptors to Activity

Once the relevant molecular descriptors are computed and selected, the final task of creating a function between their values and the analyzed activity can be carried out. The value quantifying the activity is expressed as a function of the values of the descriptors. The most accurate mapping function from some wide family of functions is usually fitted based on the information available in the training set, i.e., compounds for which the activity is known. A wide range of mapping function families can be used, including linear or nonlinear ones, and many methods for carrying out the training to obtain the optimal function can be employed.

Descriptors Used in Antimicrobial Activity Studies

The QSAR techniques involve correlating the logarithm of the reciprocal molar concentration of a bioactive compounds required for a specific biological response such as ED_{50} (dose of a drug that is pharmacologically effective for 50 % of the population exposed to the drug or a 50 % response in a biological system that is exposed to the drug) or LD_{50} (Lethal Dose 50 %, dose that kills half population tested) values with linear free energy constants such as the Hammett constant σ , a measure of aromatic substituent electronic effects; Taft polar constant σ^* , a measure of substituent polar effects; the logarithm of the 1-octanol/water partition coefficient ($\log P$), a measure of hydrophobic-hydrophilic effects; and the Taft steric constant E_s , a measure of substituent steric effects, etc.

A very important role may be played by computer aided drug design techniques based on multi-target quantitative structure–activity relationships (mt-QSAR) studies. It means that they are models connecting the structure of drugs with the biological activity against different targets (microbial species in the case of antimicrobial drugs) (Prado-Prado et al. 2008, 2009). This kind of study may also help in a multi objective optimization (MOOP) of desired properties or activity of drugs against different targets; see for instance the recent works carried out by Cruz-Monteagudo in the topic (Cruz-Monteagudo et al. 2008a, b). In principle, up to date there are over 1,500 molecular descriptors that may be generalized and used to solve the former problem (González et al. 2004; Kubinyi 1990; Marrero-Ponce et al. 2005; Todeschini and Consonni 2002).

Many of these indices are known as topological indices (TIs) or simply invariants of a molecular graph, whose vertices are atoms weighed with physicochemical properties (mass, polarity, electro negativity, or charge) (Estrada and Molina 2001).

QSAR Studies of Antimicrobial Compounds

Coumarins

As a result of the continuously growing interest for antimicrobial activity of coumarins (Al-Haiza et al. 2003; Althaus et al. 1988; Galm et al. 2004; Hoult and Paya 1996; Kulkarni and Patil 1981, 1983; Laurin et al. 1999; Reusser and Dolak 1986; Rodighiero and Antonello 1958; Vieira et al. 2001), a few coumarin antibiotics became candidates for human and veterinary medicine applications. The most important representative is the 3-aminocoumarin derivative novobiocin, the antibiotic that has been relatively recently approved for medical use in the USA for SA infection treatment (Schmutz et al. 2003). Besides novobiocin, other coumarin derivatives like eskuletin, umbelliferon, and related compounds possess antibacterial properties as well (Heinrich et al. 2004). Antifungal activity has been attributed to some of the coumarin derivatives, including coumarin (1,2-benzopyranone) itself (Mares 1987). Antimicrobial activity of 3-nitrocoumarins and related compounds against *Candida albicans* and *Staphylococcus aureus* has been shown recently (Tisi et al. 2001).

Debeljak et al. (2007) studied 3-nitrocoumarins and related compounds, in order to explore their activity and molecular properties that determine their antimicrobial effects. QSAR models involved most of the 64 descriptors extracted from semiempirical and density functional theory (DFT) founded calculations have been proposed. For the study, literature data containing results of microbiological activity screening of 33 coumarin derivatives against selected clinical isolates of *Candida albicans* and *Staphylococcus aureus* were selected. Candidate molecules were checked by cross-validated models, and selected derivatives were synthesized. Their antimicrobial activities were compared to antimicrobial activities of the representative derivatives from the original set in terms of minimal inhibitory concentration (MIC). High ranking of descriptors consistent with the degree of hydrolytic instability of selected compounds is common to models of antimicrobial activity against both microorganisms. However, descriptor ranking indicates different antimicrobial mechanisms of action of chosen coumarin derivatives against selected microbial species.

A set of 68 coumarins and coumarin derivatives with already reported antifungal activities was selected and eleven attributes were generated in order to represent a relationship between the physicochemical properties and their biological activities. The descriptors were used to perform artificial neural network (ANN) and to build a model for predicting effectiveness of the new ones. With good correlation between the experimental and the predicted MIC values pertaining to all the coumarins, the study paves the way for further researches about antifungal activity of coumarins, and offers a powerful tool in modeling and prediction of their bioactivities (Soltani et al. 2009).

A series of new coumarin derivatives has been synthesized and the *in vitro* antimicrobial activity against thirteen strains of bacteria and three fungal/yeast strains were screened. They were shown to possess a wide range of activities from almost completely inactive compounds to medium active ones (Dekić et al. 2010).

Benzamides

Benzamides are an important class of compounds that show various types of biological activities (Itaru et al. 1973; Mrozik et al. 1969). Oxiclozanide was reported as an antihelmintic agent effective against *Fasciola hepatica* for the treatment of liver fluke infection (Mrozik et al. 1969). The synthesis of some *N*-(hydroxyphenyl) benzamides and phenylacetamides as possible metabolites of antimicrobial active benzoxazoles has been reported (Sener et al. 2000).

A series of substituted benzamides were synthesized by Kumar et al. (2007). The synthesized compounds were evaluated for in vitro antibacterial activity against Gram-positive *Staphylococcus aureus*, *Bacillus subtilis* and Gram-negative *Escherichia coli*, and in vitro antifungal activity against *Aspergillus ficcum* and *Aspergillus parasiticus*. In antibacterial assay minimum inhibitory concentrations (MIC) were determined, and the antifungal activity against the fungal species was determined by serial dilution method. The structural characteristics governing antibacterial activities of substituted benzamides were studied using QSAR methodology. The results obtained indicate that the benzamides are effective against the microbial species tested, and that the *N*-(2-hydroxyphenyl)-3-methoxy-2-nitrobenzamide and *N*-(2-hydroxy-6-carbomethoxyphenyl)-2-benzyloxybenzamide are the most effective ones. A general trend showed that the presence of electron-withdrawing groups (NO₂, Cl) leads to an increase in the activity in comparison to the presence of electron releasing group. The results showed that the antimicrobial activity could be modeled using the topological descriptors, molecular connectivity indices (${}^2\chi^v$ and ${}^2\chi$), and Kiers shape index ($\kappa\alpha_1$). The low residual activity and high cross-validated r^2 values (r^2_{cv}) observed indicated the predictive ability of the developed QSAR models.

Cinnamic Acid

Cinnamic acid plays an important role for the antimicrobial activity (Ahluwalia et al. 1986; Christine et al. 1984; Cremllyn et al. 1984, 1986). Derivatives of cinnamic acid, displaying a broad spectrum of biological activity and low toxicity, are of interest for the purposes of creating new effective drugs based on them (Simonyan 1993). There are several studies on cinnamic acid derivatives with antibacterial and antifungal activity (Ahmed et al. 1995; Lee and Ahn 1998; Ovale et al. 1996; Ramanan and Rao 1987; Srivastava et al. 1999; Tawata et al. 1996). Potential antimicrobial activity of sorbic, cinnamic, and ricinoleic acid derivatives was reported some time ago (Narasimhan et al. 2003). The synthesis and the correlation between physicochemical properties and biological activity were carried out. Later, the evaluation of the in vitro antimicrobial activity of over 30 compounds belonging to a series of esters, substituted derivatives, and amides of cinnamic acid was performed by Narasimhan et al. and the investigation of the relationship between their physicochemical properties and microbiological effects have been widely discussed (Narasimhan et al. 2004). Quantitative structure–activity relationship investigation with multiple linear regression analysis was applied to find a correlation between

different calculated physicochemical parameters of the compounds and biological activity. All the compounds showed a good antibacterial activity against Gram-negative *Escherichia coli* than Gram-positive *Staphylococcus aureus* and *Bacillus subtilis*. The chemical structure of each compound was described by three groups of parameters: steric, electronic and hydrophobic which were selected due to their encouraging effect in describing antimicrobial activity (Narasimhan et al. 2003). The quantitative models relating the structural features of cinnamic acid derivatives and their antimicrobial activity showed that Gram-negative *Escherichia coli* and *Candida albicans* (fungus) were the most sensitive microorganisms. The regression equations obtained for the bacterial species showed the importance of constitutional parameter unsaturation index (U_i), global topological charge index (JGT), and the lipophilic parameter log P in contribution to antibacterial activity.

Flavonones

Among the drugs approved between 1983 and 1994 by either the United States Food and Drug Administration (FDA) or comparable entities in other countries, drugs of natural origin predominated (78 %) in the area of antibacterials (Cragg and Newman 2001). A large number of homoisoflavanones have been isolated from several hyacinthaceous genera including *Eucomis* L'Hér., *Merwillia* Speta, *Ledebouria* Roth, *Veltheimia* Gled. and *Drimiopsis* Lindl. and Paxton (Pohl et al. 2000). Homoisoflavanones belong to a small homogeneous group of naturally occurring oxygen heterocycles which, within the Hyacinthaceae, are largely but not exclusively restricted to the subfamily Hyacinthoideae. The few reports on the biological activity of homoisoflavanones describe anti-inflammatory, antibacterial, antihistaminic, antimutagenic, and angioprotective properties, and potent phosphodiesterase inhibition (Amschler et al. 1996; Della Loggia et al. 1989; Heller and Tamm 1981).

Du Toit et al. (2007) determined the antibacterial activity of thirteen homoisoflavanones isolated from six Hyacinthaceae species against *Staphylococcus aureus*. They also developed a set of physicochemical parameters that would describe antibacterial activity for these and future compounds. Stepwise multiple linear regression analysis of the data yielded a statistically significant two-component model ($R^2 = 0.81$, $p < 0.003$).

Phenolic Compounds

Natural and synthetic phenolic compounds were evaluated against oral bacteria. Thus, many antimicrobial agents have been developed for the inhibition of halitosis bacteria and thus for the treatment of oral malodor (Giertsen 2004; Greenstein et al. 1997; Hayashi et al. 2007; Loesche 1979). Antibacterial compounds such as chlorhexidine, cetylpyridinium chloride, triclosan, and chlorine dioxide have been

tested either alone or in different combinations. However, most compounds have been known to induce undesired side effects (Rule et al. 2005).

Greenberg et al. performed a systematic evaluation of various phenolic compounds to develop a quantitative structure-active relationship (QSAR) (Greenberg et al. 2007). They observed that a number of phenolic compounds in natural botanic extracts and flavors demonstrated antimicrobial activity. Among them, eugenol, magnolol, honokiol, thymol, and xanthorrhizol showed strong activity against oral bacteria. Magnolia bark extract, a traditional Chinese medicine isolated from the stem bark of *Magnolia officinalis*, consists primarily of magnolol and honokiol, the two phenolic isomers, and has a strong germ-kill activity against oral bacteria.

In the QSAR approach applied for a range of about 20 phenolic compounds the lipophilicity and steric effects were found to be two key factors in determining germ-kill activity (Greenberg et al. 2008). The optimum lipophilicity, measured by the logarithm of the octanol/water partition coefficient, or log P, was found to be 5.5 for *Fusobacterium nucleatum*, a Gram-negative type of oral bacteria that causes bad breath. The optimum log P was found to be 7.9 for *Streptococcus mutans*, a Gram-positive type of oral bacteria that causes tooth decay.

The steric effect of substituents ortho to the phenolic group was found to be critical in reducing antibacterial activity despite having increased lipid solubility approaching the optimum lipophilicity value. The antibacterial activity of phenolic compounds is likely exerted by multiple functions, primarily comes from its capability to act as a nonionic surface-active agent therefore disrupting the lipid–protein interface.

Furan Derivatives

Furan derivatives, both obtained from synthetic and natural sources, have much interest due to the wide range of pharmaceutical applications they have shown (Hofnung et al. 2002; Khan et al. 2005; Kupchan et al. 1971; Shevchenko 1999). A series of synthetic nitrofuranyl amides showed good in vitro inhibitory activity against *Mycobacterium tuberculosis* (Tangallapally et al. 2006; Tomlin 1994) especially 5-nitro-furan-2-carboxylic acid *N*-[4-(4-benzylpiperazin-1-yl)-benzyl]-5-nitro-furan-2-carboxamide and 2-methyl-*N*-phenylfuran-3-carboxamide.

Preparation of furan-3-carboxylic acid and derivatives and their assessment against a panel of microorganisms including yeast-like fungi, bacteria, and algae were reported (Zanatta et al. 2004). Because some of the furan-3-carboxamides exhibited significant in vitro antimicrobial activity, the synthesis and characterization of an extended and planned series of new furan-3-carboxamides was carried out (Zanatta et al. 2007). The obtained furan-3-carboxamides were assessed against a panel of microorganisms including yeast, filamentous fungi, bacteria, and algae. Preliminary antimicrobial activity assays of some of the furan-3-carboxamides exhibited significant in vitro antimicrobial activity. QSAR investigation was applied to find a correlation between the different physicochemical parameters of the compounds studied and their biological activity. Yeasts showed a negative cor-

relation with the indicator variables I_R , but *Saccharomyces cerevisiae* showed a better correlation with the steric and polarity descriptors, Gram-positive and Gram-negative bacteria correlate with the increase of the steric volume and the polarizability parameter and negatively correlated with hardness, and filamentous fungi correlate with the increase of the steric volume and the polarity of groups.

An interesting QSAR study of diacyl-hydrazine derivatives containing furan rings was conducted and compared with the DFT method and AM1-MOPAC method (Zhang et al. 2010). The DFT-optimized conformations and ESP-fitting charges of the target compounds were also used for 3D-QSAR analysis, including CoMFA and CoMSIA. The QSAR results were consistent with the 3D-QSAR results, indicating that the electrostatic and hydrophobic properties of the target compounds were significant to the biological activity.

mt-QSAR Studies

One limitation of almost QSAR models is that they predict the biological activity of drugs against only one species of fungi, virus, bacteria or parasite species. Consequently, the development of multitasking QSAR models (mt-QSAR) to predict drugs activity against different species of antimicrobial agents is of vital importance. These mt-QSARs offer also a good opportunity to construct drug–drug Complex Networks (CNs) that can be used to explore large and complex drug-viral species databases. In very large CNs it is possible to use the Giant Component (GC) as a representative sub-set of nodes (drugs) and but the drug–drug similarity function selected may strongly determines the final network obtained. Several mt-QSAR models were reported to predict the antimicrobial activity against different fungi (González-Díaz et al. 2006), bacteria (Prado-Prado et al. 2007), parasite (Prado-Prado et al. 2008), and virus species (Prado-Prado et al. 2009) and to calculate the parameters for RNAs of both parasites and hosts (González-Díaz et al. 2011).

For example, the most important limitation of antifungal QSAR models is that they predict the biological activity of drugs against only one fungal species due the fact that most of the up-to-date reported molecular descriptors encode only information about the molecular structure. Prado-Prado et al. calculated, within a unifying framework, the probabilities of antifungal action of drugs against many different species based on spectral moment's analysis (Prado-Prado et al. 2009). They calculated new multi-target spectral moments to fit a QSAR model that predicts the antifungal activity of more than 280 drugs against 90 fungi species. Linear discriminant analysis was used to classify drugs into two classes as active or non-active against the different tested fungal species. Moreover, it was developed one single unified equation explaining the antifungal activity of structurally heterogeneous series of compounds against as many fungus species as possible (González-Díaz and Prado-Prado 2008; González-Díaz et al. 2006).

In fact, other mt-QSAR approaches, with demonstrated usefulness, have been introduced recently in medicinal chemistry (González-Díaz et al. 2006; Marrero-

Ponce et al. 2004; Molina et al. 2004). A Markov Model encoding molecular backbones information was introduced in the method named the MARCH-INSIDE, MARKovian CHEmicals IN SILico DESign (González-Díaz et al.). This method allows one to introduce matrix invariants such as stochastic entropies, potentials, and spectral moments for the study of molecular properties (González-Díaz et al. 2005; Ramos de Armas et al. 2004) and they have been largely used for small molecule mt-QSAR problems including the design of flucicidal, anticancer, and antihypertensive drugs (Prado-Prado et al. 2007). Applications to macromolecules have been restricted to the field of RNA without applications to proteins (González-Díaz and Uriarte 2005; González-Díaz et al. 2003, 2007; Saiz-Urrea et al. 2005).

The QSAR models based on different MARCH-INSIDE indices may be very useful to optimize important aspects such as activity, toxicity, or pharmacokinetics using one single model in many bioorganic and medicinal chemistry problems such as estimation of anticocccidial activity, modeling the interaction between drugs and HIV-packaging-region RNA, and predicting proteins and virus activity (González-Díaz et al. 2004, 2006). In recent studies, the MARCH-INSIDE method has been extended to encompass molecular environment, interesting information in addition to molecular structure data (Cruz-Monteagudo et al. 2007).

Multiple applications of MARCH-INSIDE to classic QSAR, macromolecular QSAR, and specially mt-QSAR were discussed (González-Díaz et al. 2007, 2008a, b; Mahiwal et al. 2010).

Finally, with the mt-QSAR methodology it is possible to predict the biological activity of drugs in more general situations than with the traditional QSAR models, whose greatest limitation is predicting the biological activity of drugs against only one microbial species. Then, this methodology improves models and allows one to predict biological activity of many organic compounds against a very large diversity of pathogens microorganisms.

Conclusion

During the last decade an increasing number of reports describe the antimicrobial activity of several compounds. A review of the literature reveals the existence of a broad-spectrum of research activity in the development practices that are used to treat a variety of diseases and significant current progresses in using statistical learning methods for predicting compounds of specific property in antimicrobial activity.

The quantitative relationship between chemical structure and biological activity allows one to predict theoretically bioactivity without resorting to an inordinate amount of time and effort making the experimental determinations. Many attempts have been performed to elucidate the QSAR of antimicrobials by using different physicochemical parameters.

In this review we have discussed published results concerning the QSAR research on antimicrobial properties of synthetic and natural compounds. Antifungal and antimicrobial activity of some coumarin derivatives, various types of biological

activities of benzamides, several studies on cinnamic acid derivatives with antibacterial and antifungal activity, reports on the biological activity of homoisoflavanones and phenolic compounds, as well as pharmaceutical applications of furan derivatives have been shown.

The actual capabilities of multitasking QSAR methodology and mt-QSAR models to predict drugs activity against different species of antimicrobial agents have also been revised.

It was been demonstrated that with the mt-QSAR methodology it is possible to predict the biological activity of drugs in more general situations than with the traditional QSAR models, predicting biological activity of many organic compounds against a very large diversity of pathogens microorganisms.
