Within this methodology, we can compute the photosensitizing effectiveness, regarding the generation of singlet oxygen, of other furocoumarins and other photosensitizers in general, analyzing the effectiveness of populating T_π as well. Since molecules (donors) that share the same basic structure are known to possess almost the same electronic coupling (against a common acceptor), the first part of this study may well be more interesting if different families of compounds are compared. On the contrary, we should rely on the different way to populate the lowest-lying triplet excited state. In studies performed on the family of furocoumarins (psoralen, 8-MOP, 5-MOP, khellin, TMP, and 3-CPS), the latter, 3-carbethoxypsoralen, was found with the largest ISC rate.

Practical Aspects

The Basis Set Superposition Error (BSSE) for Excited States

The use of finite basis sets derives in a specific defect of the quantum-chemical calculation known as the Basis Set Superposition Error (BSSE). The majority of the contribution to the energy of a system comes from the internal electrons. If the basis set of an atom is deficient in the core region, a molecular method recovers a large amount of energy correcting this deficient area with the basis set of the other atoms. The BSSE is therefore related with the improper inclusion of the correlation energy in a quantum-chemical calculation. Although present in all practical cases, as BSSE strongly depends on the separation between the different centers, its effects only become crucial in dimers and aggregates, that is, when energies at large internuclear distances are compared to those at short distances. In general, the result of ignoring BSSE is both a shortening of bond lengths and an increasing of bond energies because the net effect is an increase of the energy in absolute value. This error is a purely mathematical artifact owing to the fact that the supermolecule possesses a larger basis set than the isolated monomers and as a result the potential energy surface is altered. There are some methods to correct this error like the counterpoise (CP) or the Chemical Hamiltonian Approach (CHA) procedures.

In the previous study on the formation of the excimer of the cytosinedimer, the correction of the BSSE effect was necessary. Figure 31 displays the same PECs as in Fig. 25, but excluding the BSSE correction. All states seem now to be bound, including the ground state, and compared to the BSSE-corrected results, the vertical emission takes place at 3.19 eV instead of 3.40 eV. Table 6 collects the numerical results on the system.

The CASPT2 ground-state binding energy in the uncorrected result is substantial, 0.62 eV, but the system becomes unbound by -0.15 eV when the BSSE is included, that is, the ground state dimer at 3.416 \AA is 0.15 eV above the sum of two ground-state monomers. The CP-BSSE corrections seem to be large. With inclusion of the BSSE, both S_1 and S_2 are bound ($CP - E_b$ is positive). Because of the cancelation

Fig. 31 CASPT2 (12,12) potential energy curves built with respect the distance cytosine–cytosine arranged in a face-to-face way without the inclusion of the CP correction for BSSE

Table 7 Binding energies (E_b), basis set superposition error (BSSE) obtained through the counterpoise method (CP-BSSE), and the corrected binding energy (CP- E_b), computed at the CASPT2 level

State	Geometry	R	E_b	CP-BSSE	CP- E_b
S_0	S_0	3.416	0.62	0.77	-0.15
S_1^a	S_1	2.954	1.51	0.97	0.54
S_0	S_1	2.954	0.29	0.97	-0.68
S_2	S_2	3.376	0.99	0.74	0.25

^aTheCASPT2 vertical emission (fluorescence), including the CP-BSSE correction leadsto 3.19 eV, as the result of (4.41 eV - 0.54 eV - 0.68 eV)

of BSSE corrections, the vertical emission remains like the direct CASPT2 result once that the BSSE has been taken into account.

The corrected minimum for S_1 is obtained at $R = 3.076 \text{ \AA}$, with a vertical emission of 3.40 eV and a binding energy CP- E_b of 0.58 eV. Thus, our best estimate has a difference of 0.18 eV with respect to the emission maximum datum obtained experimentally. It is worth recalling that the computed vertical transition does not have experimental counterpart, and for a truly correct comparison with experiment, vibrational resolution of the band should be computed in order to determine the band maximum (Table 7).

The CP procedure has been followed here to take into account the BSSE, a strategy that is known to slightly overestimate the effect. The method corrects the energy at each geometry by subtracting from the full energy of the supermolecule twice the difference between the energy of the fragment using its own basis set and the energy of the fragment using the full basis, but placing the basis functions of the opposite fragment in ghost centers, that is, at the same position as the atoms but with no atoms on them. This subtracted energy is what is known as the BSSE in the CP correction procedure. Obviously the error will decrease when the distance between the fragments decreases, therefore at large internuclear distances the BSSE vanishes. The uncorrected binding energies will then be larger than they should

because they are computed as differences between the energy of the minimum of the supermolecule (with large and stabilizing BSSE effects) and the summed energy of the independent fragments (with no BSSE). The CP method was developed for ground states, and it can be directly extended to excited states only in those cases in which the excitation is clearly localized in one of the fragments. For delocalized situations, it is not possible to define a consistent procedure. As observed in Table 6, however, BSSE values are the same for ground and excited states at a common geometry, for instance here, 0.97 eV both for the S_0 and S_1 states at the S_1 geometry. This is a systematic behavior, in particular for methods like CASPT2, in which a previous common set of State-Average MOs has been used for both states. Therefore, it can be concluded that it is safe to assign the same BSSE correction for ground and excited states at the same geometry, considering also that the inter-fragment distance is the most important parameter to modulate the extent of the BSSE. Let's finally add that ANO basis sets, large and flexible, produce larger BSSE effects than lower quality basis sets.

Computation of Electronic Couplings

The calculation of the electronic coupling matrix element H' is the crucial part in the determination of ET rates and lifetimes. The extent of the coupling controls the energy transfer process, specifically the passage from one state to another, and it can be taken as a measure of the efficiency of the ET process. Different procedures to estimate the ET coupling have been developed based on diabatic localized dimer calculations, monomer transition densities or transition dipole moments, and a supermolecule ansatz of the dimer, whereas generalization of such approaches to determine TET couplings are also available. From all procedures, an energy gap based method such as the supermolecule dimer approach, in which the value of the coupling is obtained as half of the splitting or perturbation between the interacting states, has been shown to be convenient and accurate, and it will be valid in the weak regime where the interaction is not strong. It is clear that its accuracy strongly relies on the quality of the quantum-chemical method used to perform the electronic structure calculations, something guaranteed by the highly reliable and accurate CASPT2 method. It has also the additional advantage that their results are not affected by the BSSE because they are obtained as energy differences at the different internuclear distances.

Conclusions

Quantum Mechanics helps in explaining natural phenomena from theoretical physics (particles, strings) and theoretical chemistry (chemical reactions, intermolecular forces) to the most complex theoretical biology. The complexity level increases as the simplicity of models decrease due to the growing number of variables to be dealt with and the difficulty in simulating the environment. The challenge lies in the ascertainment that life takes place into hierarchically structured matter (macromolecules, cells, tissues, organs, and entities), and it requires the

action of several physical properties of its constituent elements on the whole: the interactions among them and with the environment.

Interaction of light with tissues or, in general, living or nonliving entities is a complex phenomenon which lies on the borders among physics, chemistry, and biology. Specifically, the quantum chemistry of the excited state has experienced an outstanding development in the last decades. Improved algorithms and computational strategies, and obviously faster computers, have contributed to increasing the accuracy of the theoretical description of the photochemical phenomena. Although quantitative determinations in realistic biological systems are still far into the future, medium-size systems and their processes are already at reach of quantum-chemical models. Even more, state-of-the-art experimental techniques, such those related to femtosecond lasers, cannot be properly interpreted without the support of accurate calculations, in a way that a constructive interplay between theory and experiment shows particularly rewarding.

We are witnesses of how the walls which blocked our understanding of photochemical and photophysical processes are being slowly demolished. Step by step larger systems and more complex processes can be studied with accuracy. In fact, it has been theory which has provided modern photochemistry with the proper framework formed by the potential energy hypersurfaces, their interaction through conical intersections and states coupling, and the molecular evolution along such potentials. Unfortunately there are not many methods able to compute properly excited states, and the available ones are complex and sometimes of limited applicability. Multiconfigurational approaches (MRCI, MRPT, and MRCC) give the most general and unbiased description of all types of excitations and situations, either valence, Rydberg or anionic states, bound and dissociated situations, involving open and closed-shell ground states. Among the available approaches, the CASPT2 method has proved to better balance applicability and accuracy at a relatively low computational cost, although new developments and refinements are soon to come, like RASPT2. Single configurational methods (CC, TDDFT, CIS . . .) must be used with caution because they do not give a balanced treatment of all situations in excited-state chemistry, for instance, for degenerate cases like conical intersections. Apart from having proper methods, they must be provided with the required tools, like geometry optimizers, algorithms to search for conical intersections, to compute state couplings or trajectories for the nuclei. One-electron basis sets must be also selected with caution. The simultaneous calculation of valence and Rydberg states is necessary in those regions where both types of states are present, and properly solving valence-Rydberg mixing requires specific strategies. The calculation of anionic excited states requires their own cautions, such as checking the convergence of the resonance solutions by means of different stabilization methods. On the other hand, when dealing with finite one-electron functions and comparing fragment energies with bonded situations, the problem of BSSE arises. In such a situation, the BSSE corrections may well be very important and the phenomenon should be taken into account.

In summary, the excited state quantum chemistry cannot be undertaken routinely because of its complexity. Some of the tools available for the ground state are not

even developed yet for the excited state. In order to get accurate and predictive results, one has to calibrate carefully the computational procedure and determine the requirements in each situation. In this manner, an accuracy of 0.2–0.1 eV is currently expected for the excitation energies, almost an order of magnitude larger than previously. Undoubtedly, the development and refinement of quantum-chemical methods (the software) and computers (the hardware) are making easier the study of the interaction radiation-matter, a still unfinished task with fascinating challenges in the foreseeable future.

Acknowledgments The authors thank to all the members of the Quantum Chemistry for the Excited State (QCEXVal) group from the University of Valencia for their valuable contributions and to all their coworkers along the years. Abstract

The properties of a molecule may change quite substantially when passing from the isolated state to a solution, and computational chemistry requires the possibility of taking into account the effects of a solvent on molecular properties. These changes are mainly due to long range interactions, and electrostatics involving a large number of solvent molecules play the major role in the phenomenon and free energy changes have to be evaluated. Statistical calculations by means of usual Monte Carlo or molecular dynamics coupled with a full quantum chemical description of a sample representative of the solution is still out of reach for standard molecular modeling computations nowadays. Nevertheless, several simplified approaches are available to evaluate the free energy changes which appear when an isolated molecule, as described by standard quantum computations, undergoes the influence of a solvent and to predict the changes in

the molecular properties which are the consequences of solvation. In this chapter, we develop the principles of the most usual methods that a computational chemist can find in standard codes or can implement more or less easily to approach the solvent effects in quantum chemistry investigations.

Introduction: Importance of Solvent Effects in Chemistry

Most of the chemical reactions as well as experimental structure determinations are performed in solutions. On the contrary, usual quantum chemical computations usually deal with isolated chemical species. This may lead to erroneous conclusions. For instance, the addition of bromine to an ethylenic hydrocarbon is known for having a different mechanism in the gas phase and in solution. In this example, the velocity constant vary by a factor of 10^{10} when going from carbon tetrachloride to water as a solvent (Reichardt 1979), although the mechanism is the same. These features are confirmed by appropriate quantum chemical computations which show that the transition state of ethylene-bromine would be dissymmetric and 55 kcal/mol above the van der Waals complex in the case of the isolated species (Yamabe et al. 1988), while with a simple simulation of the solvent effect one finds a symmetric transition state lying 30.79 kcal/mol above the van der Waals complex in a non dipolar solvent and 0.02 kcal/mol in water (Assfeld 1994).

A full quantum mechanical treatment of a sample containing the solute and a number of solvent molecules large enough to simulate the solution is still out of reach of usual quantum chemical computations not only because the system of interest should be pretty large but also because the free energy computations would require a statistical treatment on millions of configurations of this system. One is therefore led, in general, to use model systems, simplified expressions of interatomic interactions allowing either statistical simulations or the derivation of molecular distribution functions or some semi-empirical approaches. In this vade mecum, we summarized different ways of modeling solvent effects in quantum chemistry. This includes the supermolecule model, the continuum and semi-macroscopic models, the full quantum description of liquids, the QM/MM methods (see Fig. 1), and the use of analytical molecular distribution functions (Hirata 2003). All these approaches have their limits, and one is led to choose one or the other according to the kind of problem being addressed.

The Supermolecule Model

In some cases, in particular that of aqueous solutions, the specific interactions may be modeled by means of a supermolecule made of an aggregate of the solute and a limited number of solvent molecules treated as an isolated single molecular system at the desired quantum chemical level. This approach may give useful information on strong intermolecular interactions (Catak et al. 2009; Harb et al. 2004) but cannot model correctly the effect of the solvent because the long-range electrostatic

Fig. 1 The different approaches for modeling a solute molecule in a solvent. From *top left to bottom right*: (a) the isolated molecule (gas phase); (b) the supermolecule (solute with a few solvent molecules); (c) the continuum approach (the molecule is inserted in a cavity surrounded by a dielectric continuum); (d) the fully solvated system (the solute is inserted in a periodic box filled with solvent molecules)

interactions, which play an important role in a liquid (Buckingham 1967, 1978), are not taken into account. An efficient way to model these long-range electrostatic interactions is to use a continuum model.

Continuum Models

These models are by far the most widely used in current computational chemistry nowadays, and several review articles give an overview of them (Rivail and Rinaldi 1996; Tomasi 2004; Tomasi et al. 2005). They are based upon the consideration of the solvent as a continuous medium characterized by its macroscopic properties: bulk dielectric permittivity, possibly surface tension. The solute is assumed to occupy a cavity surrounded by this continuum. The free energy of interaction

between this molecule and its surrounding may be analyzed as the sum of three contributions:

- The free energy variation of the system when the cavity is created in the bulk of the liquid. This can be considered as an increase of its free area and is a positive free energy variation.
- The dispersion-repulsion energy arising between a polarizable solute and the solvent molecules of finite size, which is always a negative contribution.
- The electrostatic free energy arising from the polarization of the solvent by the charge distribution of the solute. The result of this polarization is a non zero electrostatic potential within the cavity which perturbs the charge distribution of the solute, leading to changes in the solute's structure, compared with the isolated molecule (Luque et al. 2003).

The earlier attempt to approach the electrostatic contribution to the free energy of solvation is due to Kirkwood (1934). This model is based on a multipole expansion of the charge distribution of the solute at the center of a spherical cavity surrounded by a continuum represented by the dielectric permittivity of the solvent. When this expansion is limited to rank 1 which corresponds to a pure dipole μ , one finds the Onsager model (Onsager 1936) in which the electrostatic contribution to the free energy of solvation by a solvent of dielectric constant ε of a molecule having a dipole moment μ in a cavity of radius a takes the expression:

$$\Delta G = -\frac{1}{2a^3} \frac{2(\varepsilon - 1)}{2\varepsilon + 1} \mu^2. \quad (1)$$

Onsager has shown, in the case of a pure liquid made of dipolar, polarizable molecules, that the dielectric constant of the liquid is fairly well predicted when the volume of the cavity is equal to the apparent molecular volume in the liquid. This finding gives a hint to the estimate of the volume of the cavity which is a parameter in the Kirkwood model. In the case of a non neutral solute, the charge q corresponds to the multipole of rank 0 and the corresponding term in the multipole expansion is the well-known Born formula (Born 1920) giving the free energy of solvation of charged solutes:

$$\Delta G = -\frac{1}{a} \frac{\varepsilon - 1}{\varepsilon} q^2. \quad (2)$$

This approach which has the advantage of giving an analytical formula of the free energy of solvation has been extended to ellipsoidal (Rinaldi and Rivail 1973) and spheroidal cavities (Rivail and Terryn 1982) and has been applied long ago to quantum chemical computations, at various levels of approximation (Rinaldi et al. 1983). As the perturbation to the wavefunction depends on the charge distribution of the solute which is defined by the wavefunction to be computed, the computational scheme requires self consistency combined with the usual self

consistent computational algorithms for quantum chemistry. This is frequently referred as the Self Consistent Reaction Field (SCRF) where the solute is polarized by the solvent which is, in return, polarized by the solute. Nowadays, this model has been extended to cavities of any shape using a multicentric multipole expansion on all the atoms of the solute (Rinaldi et al. 2004). In all these approaches, the first and second derivatives of energy are computed allowing a full geometry optimization and the determination of the stationary points in the potential energy surface and the computation of the harmonic vibrational frequencies (Rinaldi et al. 2006).

A closely related approach, using the same kind of molecular cavity has been developed by Tomasi et al. (1981). In this model, the multipole expansion is replaced by a numerical computation of the electrostatic potential inside the cavity, due to the polarization of the boundary by the solute. This model also has been improved along the years. It has various versions all known under the acronym of PCM (Cancès et al. 1997) which are implemented in the Gaussian suites of programs, and a closely related model is available in the Jaguar package (Marten et al. 1996; Tannor et al. 1994).

Rather, different approaches are based on the so-called generalized Born model in which the charge distribution of the solute is represented by point charges on all atoms and the solute–solvent interaction is defined by a sum of the Born contributions of each atom in which the reciprocal of the sphere radius in Eq. 2 is replaced by a parameterized empirical formula. The most elaborated applications of this model is found in the series of SM x models of Cramer and Truhlar ($x = 1$ to 8 nowadays, corresponding to successive improvements) (Cramer and Truhlar 1991, 2008).

Finally, to simplify the electrostatic algorithm some methods start with a dielectric permittivity $\varepsilon = \infty$ corresponding to a conductor like solvent and then correct the result either by the ratio $2(\varepsilon - 1) / (2\varepsilon + 1)$ of the Onsager factor of the actual dielectric permittivity of the solvent to the limiting value when $\varepsilon = \infty$, or by the ratio of the Born factors: $(\varepsilon - 1) / \varepsilon$. It is noteworthy that the difference may not be negligible for low dielectric constants. This approximation has first been introduced in the COSMO model (Klamt and Schüürmann 1993). A version of the PCM model, known as C-PCM (Barone and Cossi 1998) uses the same approximation to evaluate the electrostatic solvation term.

The importance of any kind of solvents, including the non polar ones has to be emphasized because some people claim that the properties in a non polar solvent should be close to the gas state. The experimental results mentioned in (Reichardt 1979) show that it is not true, and this can also be seen in the case of the Born or Onsager models. If one considers a solvent such as cyclohexane with a dielectric permittivity close to 2, one sees that the electrostatic free energy of solvation is for the former and the latter model respectively 50 % and 40 % of the limiting value at infinite permittivity. Similarly, one also notices that for high dielectric permittivities, these terms do not vary noticeably when this constant varies, justifying the COSMO-type models in particular in the case of water and highly polar solvents.

The quantitative use of continuum models requires care. The absolute values of free energies of solvation depend on many parameters. The electrostatic contribution

mainly depends on the shape and volume of the cavity. The most widely used shapes are defined by the “molecular surface” (Pascual-Ahuir and Silla 1990; Silla et al. 1991) defined after the atomic radii (Bondi 1964) multiplied by a factor of the order of 1.3. A test for the choice of this parameter can be the comparison of the volume of the cavity with the apparent molecular volume of the solute (when known) in the liquid state or in the solution like in the Onsager’s theory of the dielectric permittivity of pure polar liquids.

The non electrostatic contributions are far more difficult to model. Usually, they are evaluated by empirical formulae which, in the most favorable cases, introduce some error bars. The models parameterized on a large number of experimental data, such as SM8 (Cramer and Truhlar 1991, 2008), are probably rather reliable although one may deal with a case which is an exception. Conversely, variations of solvation energy for systems in which the non electrostatic terms are assumed not to vary significantly, such as conformational equilibria, may be approached rather safely by means of these computational efficient models.

The Full Quantum Approaches of Liquids

A reliable computation of free energies in a molecular system requires the use of statistical mechanics on a sample which can be considered as macroscopically representative. In the case of solutions, this requires more than one hundred solvent molecules and the computation of an enormous number of different configurations. Full quantum chemical studies are now possible thanks to some specific algorithms but they are still lengthy. An efficient approach uses a standard semi-empirical code, reparameterized to account properly for intermolecular energies (Bernal-Uruchurtu and Ruiz-López 2000; Bernal-Uruchurtu et al. 2000), coupled with a linear scaling divide and conquer algorithm (Dixon and Merz 1996, 1997), which allows the simulation of a set of 216 water molecules in a quite affordable computer time (Monard et al. 2005). The use of fast DFT methods can now replace the semi-empirical ones (Hu et al. 2007) and one may anticipate that in the near future, the theoretical and algorithmic improvements will make possible the use of non empirical treatments. The use of plane wave basis sets (Todorova et al. 2006; VandeVondele et al. 2005) is another attempt to improve the efficiency of the codes.

In contrast with the previous approaches in which the energy and the forces calculated at each configuration of the system are computed within the usual Born-Oppenheimer approximation (BOMD), the Car-Parrinello unified approach for molecular dynamics and DFT (Car and Parrinello 1985) is an efficient alternative to the simulation of macroscopic samples although it requires rather large computational facilities and time. The CPMD package is available for such computations which require some expertise to be ran safely (Marx and Hutter 2000). A comparison of CPMD and BOMD simulations may be useful to determine the best computational procedures (Kuo et al. 2006). Car-Parrinello computations are widely applied to the simulation of liquids, mainly water (Izvekov and Voth 2002) but other liquids are also considered (Bakó et al. 2006). All these full QM approaches are, for

the time being, mainly limited to the understanding of the structural properties of pure liquids.

The Quantum Mechanical/Molecular Mechanical (QM/MM) Models

Chemical studies usually deal with a solute which can be a single molecule or a molecular complex or transition state in a chemical reaction. In such systems, the role of the solvent is mainly a physical perturbation which can be simulated at a lower theoretical level than that required for the study of the subsystem of chemical interest. The success of continuum models confirms this statement. In order to describe the solution at the molecular level and to perform full statistical mechanics computations on a model of macroscopic sample, one may set up some computationally efficient approaches by limiting the quantum chemical study to the solute and using one of the usual classical force-fields to represent the solvent molecules. The computation of the statistical averages can be done by means of either Monte Carlo or molecular dynamics algorithms. The so-called QM/MM models are now widely used in such chemical studies.

The Hamiltonian is a sum of three terms: H_{QM} , the usual quantum Hamiltonian of the solute, H_{MM} , the classical Hamiltonian corresponding to the configuration of the solvent $H_{QM/MM}$, which corresponds to the interaction energy between the classical solvent molecules and the quantum solute (Monard et al. 2003). The first two Hamiltonians are well defined by the choice of the quantum methodology and the classical force field chosen to model the liquid. The definition of the interaction Hamiltonian is far more difficult. It is usually made of a sum of van der Waals interaction energies between the classical atoms of the solvent and the quantum atoms of the solute, the long-range electrostatic interactions between the classical solvent molecules and the electron distribution and the nuclei of the solute and the possible specific interactions (hydrogen bonds). This is the most delicate part of the methodology, which requires specific parameterizations for each kind of quantum chemical method used as well as each classical force field. A large number of papers have been published on this problem (Freindorf and Gao 1996; Freindorf et al. 2005; Giese and York 2007; Luque et al. 2000; Riccardi et al. 2004). For specific problems, useful methodologies have been set up to determine the most appropriate parameters (Martín et al. 2002).

Once the methodology has been defined, running a computation requires the usual molecular dynamics or Monte Carlo codes, but the necessity of taking into account a large number of configurations makes any improvements which accelerate the process very valuable. One of the time consuming step is the computation of the long-range electrostatic interactions for which some algorithms, such as the use of Ewald sum (Nam et al. 2005) or periodic boundary conditions (Laino et al. 2006), may become very efficient to compute accurate free energies (Gao et al. 2005).

Various methods and levels of approximation can be used for the QM part of the studies, from semi-empirical (Cummins and Gready 1997; Geerke et al. 2008),

empirical Valence Bond (Sumner and Iyengar 2008) to correlated levels (Kongsted et al. 2003; Woods et al. 2008). QM/MM simulations also work with the Car-Parrinello methodology (Laio et al. 2002).

QM/MM methods have now reached a good level of achievement and have opened the way to refined studies of molecular structure and reactivity in the liquid state (Hu and Yang 2009). However, may be one of the last remaining challenges for QM/MM methods is to correctly and efficiently handle reactivity problems where one or more solvent molecules are directly implied in the chemical mechanism. The usual solution found in literature is to choose among all solvent molecules the unique molecule which will react with the solute. Some solutions which take into account the dynamical nature of the first solvation shell have been suggested so far (Kerdcharoen and Morokuma 2002, 2003; Tongraar et al. 1998; Tongraar and Rode 2004), but they have not been applied to reactivity problems yet.

Other Statistical Approaches of the Solvent

Reference Interaction Site Model (RISM)

Integral equations of the liquid state provide us, in principle, with a rigorous statistical description of the liquid, although, to solve them, one is forced to use several approximations, in particular various closure conditions to get pair correlation functions (Hansen and McDonald 1976). These approaches have been successfully used to describe simple liquids. In the case of polyatomic molecules, the difficulty increases rapidly with the number of sites and the nature of the interatomic potential. Nonetheless, a Reference Interaction Site Model (RISM) has been proposed to extend the treatment to polyatomic liquids (Chandler and Andersen 1972) and has been successfully applied to several problems dealing with molecular solutions (Hirata and Rossky 1982). Some routines are now available to solve the RISM equations. These equations have also been coupled with a quantum computation of the solute (Ten-no et al. 1993). The interatomic potentials have the standard Lennard-Jones expression in which the electrostatic interactions are developed on a basis of point charges. Therefore, the electronic distribution of the solute is limited to effective partial charges q_λ located on the atoms (denoted by a greek index here λ). The Hartree-Fock equations are modified by introducing a perturbative potential on each atom λ of the solute:

$$V_\lambda = \rho \sum_{j \in S} q_j \int_0^\infty r^{-1} g_{\lambda j}(r, q_\lambda) 4\pi r^2 dr, \quad (3)$$

where ρ is the solvent density and $g_{\lambda j}(r, q_\lambda)$ is the radial distribution function of the j th site of solvent molecules S relative to the λ th site of the solute molecule. This function is given by the RISM equations. The RISM-SCF cycle simultaneously optimizes the pair correlation functions and the electronic wavefunctions. This

approach has been successfully applied to the study of solvent effects on the electronic spectra of carbonyl compounds (Ten-no et al. 1994).

Langevin Dipole Model (LD)

Between a macroscopic description of the solvent represented by the continuum models and a microscopic approach where all solvent atoms are explicitly represented, there exists an alternative semi-macroscopic approach: the Langevin Dipole model. This model treats the solvent (usually water) explicitly but in a simplified way. It represents the time average polarization of the solvent molecules by a cubic grid of polarizable dipoles (Warshel 1991; Warshel and Russel 1984). According to the Langevin equation (Langevin 1905), the electrostatic field of the solute reorients and polarizes the grid point dipoles. While this method has been successfully applied to the computation of the free energy of solvation of small neutral and ionic molecular solutes at a quantum level (Florián and Warshel 1997, 1999; Kongsted et al. 2009), the Langevin Dipole model has been mostly used to represent the electrostatic interactions between water as a solvent and proteins through the Protein Dipoles/Langevin Dipoles (PDL) method (Roca et al. 2007; Warshel et al. 2006).

The Future of Studies in the Liquid State

The number of selected papers dealing with various approaches of the liquid state and solutions clearly indicate that taking into account the influence of the solvent in quantum chemical studies will soon become quite usual. The large variety of methods allows us to adapt the level of modeling to the accuracy required to get useful chemical information. The methodology is still expected to improve in the near future. In particular, the full quantum treatment of a solution which takes advantage of the advances in quantum modeling of pure liquids seems to be at hand, especially when one can use different quantum levels for the solute and for the solvent. Like in the case of QM/MM the key feature is the proper treatment of the interaction between both subsystems but one can be confident to the quantum chemists to find the proper solutions to this problem.

Abstract

Theoretical background and applications of methods for the calculation of solvent effects on molecular electric properties are reviewed. Macroscopic linear and nonlinear susceptibilities are defined, and their relationship to microscopic properties, i.e., (hyper)polarizabilities, is described. The role of specific intermolecular interactions in property calculations is demonstrated in terms of interaction-induced properties. Two categories of models for the description of solvent effects are presented. The first category comprises continuum models, in which the solvent is described as a homogeneous medium with the solute molecule located inside a cavity. Within this category, the polarizable continuum model and the multipole expansion method are described in more detail. The second group of approaches is based on discrete solvent models in which the solvent molecules are explicitly considered. Selected representative methods such as the supermolecular approach, polarizable embedding, and frozen-density embedding are presented. The possibility to combine explicit and implicit methods is demonstrated on the discrete reaction field and the Langevin dipole approaches. Finally, two illustrative examples (liquid water and *p*-nitroaniline in 1,4-dioxane) of the application of the presented methods for (non)linear property calculations are given.

Glossary

AIM	Atoms in molecules approach
ALDA	Adiabatic local density approximation
BSSE	Basis set superposition error
CAMM	Cumulative atomic multipole moments
COSMO-RS	Conductor-like screening model for real solvents
DIM	Dipole interaction model
DMA	Distributed multipole analysis
DRF	Discrete reaction field
DSA	Differential shell approach
EFISH	Electric field induced second harmonic generation
FDE	Frozen density embedding
FF	Force field
FF/FDE	Finite field/frozen density embedding
GSAM	Global search algorithm of minima
HRS	Hyper Rayleigh scattering

IDRI	Intensity dependent refractive index
KS	Kohn Sham
LIM	Localized dipole interaction model
MBP	Many-body corrected molecular polarizabilities
MC	Monte Carlo
MM	Molecular mechanics
MPE	Multipole expansion method
ND-FF	Numerical derivative using finite fields
NDO	Neglect of differential overlap
NLO	Nonlinear optical (properties)
pABA	<i>p</i> -aminobenzoic acid
pNA	<i>p</i> -nitroaniline

SHG	Second harmonic generation
SM	Supermolecule, supermolecular
SMx	Solvation model
SOPPA	Second order polarization propagator approximation
SCRf	Self-consistent reaction field
TCNE	Tetracyanoethylene
THG	Third harmonic generation

Introduction

The electronic and optical response properties of materials represent important characteristics playing a crucial role in many practical applications in (opto)electronics (e.g., optical information processing, telecommunication, data storage, FETs, photovoltaic cells, LEDs), chemical analysis, and bioimaging (e.g., multiphoton fluorescence microscopy). In order to understand the response of materials in various (non)linear optical and electro-optical processes, the concepts relating the macroscopic response properties (susceptibilities) to molecular (hyper)polarizabilities are introduced. Computational techniques for the calculation of electric properties of isolated molecules are already quite advanced, as shown, e.g., by Jaszuński et al. (2015) in this handbook. However, for most applications as well as for the experimental determination of these properties, condensed phases are much

more relevant. Accurate methods to compute the corresponding properties of condensed phases, the electric susceptibilities, are less developed than those for isolated species. The effect of the environment on molecular electric properties is correspondingly to some extent unknown. For solid phases, such as molecular crystals or surfaces, it is often a good approximation to consider a rigid structure of the phase, possibly undergoing harmonic vibrations. The dynamic nature of the liquid phase is much more pronounced, but its effect on the electric properties is difficult to model accurately. Thus, it is still not well understood and is under active investigation.

In this chapter, we present a few selected models which can be applied to obtain electric susceptibilities of liquids, or the electric properties of a molecule in solution, which is not the same, as we will show below. The selection is far from complete and was made mainly to present the many different aspects of the problem, which may have to be considered for a successful calculation.

We start our overview with introducing the applied terminology, notation, and definition of macroscopic and microscopic electric properties. Then, we describe the most important aspects of solute–solvent interactions together with the concept of interaction-induced properties which are relevant for the solvent models outlined in subsequent sections. The models for the description of solvent effects can be divided into two groups. In continuum models the solvent is described as a structureless homogeneous medium that is characterized by its macroscopic dielectric properties. The solute molecule is located inside a cavity in this medium, and its properties are treated at a chosen quantum-mechanical (QM) level of theory. In these models, the averaging over different solvent configurations as well as molecular polarization effects is implicitly taken into account. Approaches which are physically more appropriate rely on discrete solvent models and are presented in section “Explicit Molecular Models,” together with selected combined discrete/continuum methods.

Definition of Macroscopic and Microscopic Quantities

Any attempt to connect macroscopic quantities with microscopic ones requires a clear definition of the corresponding properties. We consider here only electric properties, and the macroscopic quantity generally used to describe the effect of external electric fields (be it static or dynamic, e.g., in the form of light) is the polarization $\underline{P}(t)$, as it appears in the usual Maxwell equations of electromagnetism, while its microscopic counterpart is the electric dipole moment $\underline{\mu}(t)$. For weak fields, both quantities may be written as an expansion with respect to the corresponding field strengths. The treatment of the microscopic dipole moment is shown in detail in Jaszuński et al. (2015) in this handbook; thus, we will concentrate here on the macroscopic polarization. Although the treatment is essentially analogous, there are some differences, which are often the cause of some confusion.

The macroscopic susceptibility tensors with components $\chi_{\alpha\alpha_1,\dots,\alpha_n}^{(n)}(-\omega_\sigma; \omega_1, \dots, \omega_n)$ can be defined via the expansion terms of the polarization with respect to the macroscopic field, $P_\alpha^{(n)}(t) \sim [E(t)]^n$ as

$$P_{\alpha}^{(n)}(t) = \epsilon_0 \sum_{\omega_1 \dots \omega_n} \chi_{\alpha\alpha_1 \dots \alpha_n}^{(n)}(-\omega_{\sigma}; \omega_1, \dots, \omega_n) E_{\alpha_1}(t) \dots E_{\alpha_n}(t) \quad (1)$$

where $\omega_{\sigma} = \sum_i \omega_i$, the sum over frequencies runs over all distinctive sets of frequencies $\omega_1, \dots, \omega_n$, and the permittivity of vacuum ϵ_0 occurs in the SI system of units. For the Cartesian indices $\alpha_i = x, y, z$, the Einstein summation convention is applied. A similar expression for the dipole moment is employed to define the molecular (hyper)polarizabilities (see Eq. 11.84 in Jaszuński et al. 2015). The latter, however, is written as a Taylor expansion instead of the power expansion used in Eq. 1. Thus, the corresponding equation defining the (hyper)polarizabilities $\alpha^{(n)}$ via the field expansion terms of the dipole moment $\mu_{\alpha}^{(n)}(t) \sim [F(t)]^n$ is

$$\mu_{\alpha}^{(n)}(t) = \frac{1}{n!} \sum_{\omega_1 \dots \omega_n} \alpha_{\alpha\alpha_1 \dots \alpha_n}^{(n)}(-\omega_{\sigma}; \omega_1, \dots, \omega_n) F_{\alpha_1}(t) \dots F_{\alpha_n}(t) \quad (2)$$

with $\alpha^{(n)} = \alpha, \beta, \gamma$ for $n = 1, 2, 3$. This leads to the appearance of factors $n!$ in equations expressing the susceptibilities in terms of (hyper)polarizabilities. In a condensed phase the field $\underline{F}(t)$ in Eq. 2 may not be the macroscopic field $\underline{E}(t)$ used in Eq. 1. In fact, it turns out that a much more convenient choice is the so-called *local* (or *exciting*) field, which is effective on a molecule and which may differ substantially from $\underline{E}(t)$.

The macroscopic or Maxwell field may be written as a superposition of a homogeneous static and a dynamic, monochromatic field:

$$\underline{E}(t) = \underline{E}^0 + \underline{E}^{\omega} \cos(\omega t). \quad (3)$$

This is not the most general expression to describe all nonlinear optical effects, but it covers many cases of experimental interest.

With such a field, the expansion terms $\underline{P}^{(i)}(t)$ can be expressed as a Fourier series:

$$\underline{P}^{(i)}(t) = \underline{P}_0^{(i)} + \underline{P}_{\omega}^{(i)} \cos(\omega t) + \underline{P}_{2\omega}^{(i)} \cos(2\omega t) + \underline{P}_{3\omega}^{(i)} \cos(3\omega t) + \dots \quad (4)$$

Inserting Eq. 3 in Eq. 1 and employing trigonometric identities, the expansion terms in the Fourier series can be connected with the susceptibilities. This leads to

$$P_{0,\alpha}^{(1)} = \epsilon_0 \chi_{\alpha\beta}^{(1)}(0; 0) E_{\beta}^0 \quad (5)$$

$$P_{0,\alpha}^{(2)} = \epsilon_0 \left[\chi_{\alpha\beta\gamma}^{(2)}(0; 0, 0) E_{\beta}^0 E_{\gamma}^0 + \frac{1}{2} \chi_{\alpha\beta\gamma}^{(2)}(0; -\omega, \omega) E_{\beta}^{\omega} E_{\gamma}^{\omega} \right]$$

$$P_{0,\alpha}^{(3)} = \epsilon_0 \left[\chi_{\alpha\beta\gamma\delta}^{(3)}(0; 0, 0, 0) E_{\beta}^0 E_{\gamma}^0 E_{\delta}^0 + \frac{3}{2} \chi_{\alpha\beta\gamma\delta}^{(3)}(0; -\omega, \omega, 0) E_{\beta}^{\omega} E_{\gamma}^{\omega} E_{\delta}^0 \right] \quad (6)$$

$$P_{\omega,\alpha}^{(1)} = \epsilon_0 \chi_{\alpha\beta}^{(1)}(-\omega; \omega) E_{\beta}^{\omega} \quad (7)$$

$$P_{\omega,\alpha}^{(2)} = 2\epsilon_0 \chi_{\alpha\beta\gamma}^{(2)}(-\omega; \omega, 0) E_\beta^\omega E_\gamma^0 \quad (8)$$

$$P_{\omega,\alpha}^{(3)} = \epsilon_0 \left[3\chi_{\alpha\beta\gamma\delta}^{(3)}(-\omega; \omega, 0, 0) E_\beta^\omega E_\gamma^0 E_\delta^0 + \frac{3}{4}\chi_{\alpha\beta\gamma\delta}^{(3)}(-\omega; \omega, -\omega, \omega) E_\beta^\omega E_\gamma^\omega E_\delta^\omega \right] \quad (9)$$

$$P_{2\omega,\alpha}^{(2)} = \frac{1}{2}\epsilon_0 \chi_{\alpha\beta\gamma}^{(2)}(-2\omega; \omega, \omega) E_\beta^\omega E_\gamma^\omega \quad (10)$$

$$P_{2\omega,\alpha}^{(2)} = \frac{3}{2}\epsilon_0 \chi_{\alpha\beta\gamma\delta}^{(3)}(-2\omega; \omega, \omega, 0) E_\beta^\omega E_\gamma^\omega E_\delta^0 \quad (11)$$

$$P_{3\omega,\alpha}^{(3)} = \frac{1}{4}\epsilon_0 \chi_{\alpha\beta\gamma\delta}^{(3)}(-3\omega; \omega, \omega, \omega) E_\beta^\omega E_\gamma^\omega E_\delta^\omega \quad (12)$$

These expansions may be compared with the analogous expressions for the molecular dipole moment in Jaszúński et al. (2015). The linear susceptibility $\underline{\chi}^{(1)}$ is related to the relative permittivity tensor by $\underline{\epsilon} = \underline{\chi}^{(1)} + \underline{I}$, where \underline{I} is the 3×3 identity tensor. Another related quantity is the refractive index: If α is a direction parallel to a principal axis of the indicatrix of the material, the refractive index $n_\alpha(\omega)$ is given by $n_\alpha(\omega) = (\epsilon_\alpha(\omega))^{1/2}$. For an isotropic liquid, for which $\chi_{\alpha\beta}^{(1)} = \delta_{\alpha\beta}\chi^{(1)}$ and $\epsilon_{\alpha\beta} = \delta_{\alpha\beta}\epsilon$, these relationships simplify to $\epsilon = \chi^{(1)} + 1$ and $n(\omega) = (\epsilon(\omega))^{1/2}$.

We note that the conventions used here to define the (hyper)polarizabilities and susceptibilities are probably the most popular in the field of computational chemistry. There are other conventions used, for example, by several experimentalist groups but also by theoreticians (for more details, see Reis (2006) and references therein).

The connection between the polarization of a liquid composed of n_I components and the induced dipole moments of the molecules of component I is given by

$$P_{\omega,\alpha} = \epsilon_0 \sum_{I=1}^{n_I} N_I \langle \mu_\alpha^I(\omega) \rangle, \quad (13)$$

where $\langle \dots \rangle$ denotes averaging over the sample, and N_I is the particle density for the component I . Different models can be invoked to approximate the property on the right-hand side, e.g., a continuum model, a discrete model, or mixtures of the two. Some of these methods will be described in more detail later in this chapter. To clarify the connection between microscopic and macroscopic electric properties, we will take here the view of the liquid as composed of discrete, polarizable molecules, interacting via electrostatic multipole moments. This is essentially the picture applied in the rigorous local field (RLF) method (Janssen et al. 1999). In a typical RLF computation, the liquid is modeled by a molecular simulation method, e.g., a Monte Carlo or molecular dynamics calculation, which yields a series of different configurations. In a second step, the susceptibilities are computed for (usually) a subset of these configurations, and the simulated macroscopic responses are finally obtained by averaging over the individual responses.

In order to connect the macroscopic polarization with microscopic properties of *isolated molecules*, it is essential to realize that the microscopically effective fields in Eq. 2 are *local fields*, which differ from the macroscopic fields \underline{E} in Eq. 1. In a liquid subject to externally applied fields, the total local field on molecule k consists of two contributions, i.e., $\underline{F}_k^{\text{tot}} = \underline{F}_k^{(0)} + \underline{F}_k^{\text{ext}}$, where the first contribution $\underline{F}_k^{(0)}$ is due to electric fields arising from all the surrounding molecules in the liquid without any externally applied field, which, in turn, is considered by the second term and is described below. The *permanent local field* $\underline{F}_k^{(0)}$ is essentially a static field and may be computed, for example, by summing over the field contributions of the surrounding molecules:

$$F_{\alpha,k}^{(0)} = \sum_{l \neq k} \left[T_{\alpha,k;l}^{10} q_l + T_{\alpha,k;\beta,l}^{11} \mu_{\beta,l}^{\text{sol}} + \dots \right] \quad (14)$$

where $q, \mu_{\beta,l}^{\text{sol}}$ are (components of) the charge (if nonzero) and dipole of molecule l , respectively, and $T_{\alpha,k;l}^{10}, T_{\alpha,k;\beta,l}^{11}$ are components of the corresponding dipole–charge and dipole–dipole propagator tensors. In general, a propagator tensor $T_{\alpha_1 \dots \alpha_n, k; \beta_1 \dots \beta_m, l}^{nm}$ relates the negative of the n -th order derivative of the Coulomb potential $\Phi(\underline{r}_k)$ at molecule k to the m -th order multipole of molecule l . The dipole and higher multipole moments are the total moments, i.e., they depend again on the local field $\underline{F}_k^{(0)}$, e.g.,

$$\mu_{\alpha,k}^{\text{sol}} = \mu_{\alpha,k} + \alpha_{\alpha\beta;k} F_{\beta,k}^{(0)} + \dots \quad (15)$$

where $\mu_{\alpha,k}$ and $\alpha_{\alpha\beta,k}$ are components of the permanent dipole and (dipole–dipole) polarizability, respectively, of the *isolated* molecule.

The permanent local field can be quite large for dipolar solutes and/or dipolar or multipolar solvents, and may also be inhomogeneous over the molecule, especially for larger molecules, thus a converged description in terms of the one-point multipole description used above may require the consideration of multipoles higher than dipole and of field gradients of first or higher order, in addition to the homogeneous field. One way to alleviate this problem is to use distributed multipole moments and polarizabilities instead of the one-point properties. Some approaches will be discussed in section “Explicit Molecular Models.” A potentially more accurate procedure is to compute quantum–mechanically the properties of the solute embedded in the field due to surrounding molecules, as in the discrete reaction field (DRF), the polarizable embedding (PE), as well as the frozen-density embedding (FDE) approaches described later.

The properties of the molecules under the influence of the permanent local field have been called *solute* properties (Wortmann and Bishop 1998). The application of an external field gives rise then to the second contribution to the local field $\underline{F}_k^{\text{ext}}(\omega)$. It can be given in terms either of the applied field $\underline{E}^{(0)}(\omega)$ or of the macroscopic field $\underline{E}(\omega)$ and the thereby induced dipole moments $\underline{\mu}^{\text{ind}}(\omega)$ by

$$\underline{F}_k^{\text{ext}}(\omega) = \underline{E}^{(0)}(\omega) + \sum_{l \neq k} \underline{T}_{kl}^{11} \cdot \underline{\mu}_l^{\text{ind}}(\omega) \quad (16)$$

$$= \underline{E}(\omega) + \sum_{l \neq k} \underline{L}_{kl}^{11} \cdot \underline{\mu}_l^{\text{ind}}(\omega), \quad (17)$$

where \underline{T}_{kl}^{11} is the dipole–dipole field propagator tensor, which contains a term which is only *conditionally convergent* in the long-wavelength limit, while \underline{L}_{kl}^{11} is the (dipole–dipole) Lorentz factor tensor containing only the absolutely convergent terms, and the conditionally convergent term has been combined with $\underline{E}^{(0)}$ to yield the macroscopic field \underline{E} . For more details, see, e.g., Boettcher and Bordewijk (1978) and Munn (1988).

Again, the dipole moments $\underline{\mu}_k^{\text{ind}}(\omega)$ depend on $\underline{F}_k(\omega)$:

$$\begin{aligned} \underline{\mu}_{\alpha,k}^{\text{ind}}(\omega) = & \alpha_{\alpha\beta,k}^{\text{sol}}(\omega) F_{\beta,k}^{\text{ext}}(\omega) + K_{12}^{(2)} \frac{1}{2} \beta_{\alpha\beta\gamma,k}^{\text{sol}}(-\omega; \omega_1, \omega_2) F_{\beta,k}^{\text{ext}}(\omega_1) F_{\gamma,k}^{\text{ext}}(\omega_2) + \\ & K_{123}^{(3)} \frac{1}{6} \gamma_{\alpha\beta\gamma\delta,k}^{\text{sol}}(-\omega; \omega_1, \omega_2, \omega_3) F_{\beta,k}^{\text{ext}}(\omega_1) F_{\gamma,k}^{\text{ext}}(\omega_2) F_{\delta,k}^{\text{ext}}(\omega_3) \dots \end{aligned} \quad (18)$$

where the numerical factors $K_{12\dots n}^{(n)} = K^{(n)}(-\omega; \omega_1, \dots, \omega_n)$ depend on the number of equal and/or zero frequencies among the set of frequencies $\{\omega, \omega_1, \dots, \omega_n\}$. Here, it is assumed that $\underline{E}(\omega)$ is the field of light at optical wavelengths; thus, no dipole moment appears on the right-hand side of the equation. If a static external field is applied, it may cause a change of the liquid *structure*. In the consecutive two-step approach considered here, such a structure changing effect should be taken into account already in the molecular simulation. A computationally less expensive method is to assume that the orientational effect of the static field is well described by the Boltzmann distribution $\sim \exp^{-\underline{\mu} \cdot \underline{F}^{\text{ext}}(0)/kT}$. Assuming in addition that $\underline{\mu} \cdot \underline{F}^{\text{ext}}(0)/kT \ll 1$, the Boltzmann factor can be expanded and only the first nonzero terms retained. This leads, e.g., to the standard expression for the EFISH process given in Eq. 65, which can then be applied in conjunction with a field-free molecular simulation.

The *solute (hyper)polarizabilities* can again be expressed by the properties of the isolated molecule and the permanent local field, i.e.,

$$\alpha_{\alpha\beta,k}^{\text{sol}}(\omega) = \alpha_{\alpha\beta,k}(\omega) + \beta_{\alpha\beta\gamma}(-\omega; \omega, 0) F_{\gamma,k}^{(0)} + \dots \quad (19)$$

$$\beta_{\alpha\beta\gamma,k}^{\text{sol}}(-\omega; \omega_1, \omega_2) = \beta_{\alpha\beta\gamma,k}(-\omega; \omega_1, \omega_2) + \gamma_{\alpha\beta\gamma\delta,k}(-\omega; \omega_1, \omega_2, 0) F_{\delta,k}^{(0)} + \dots \quad (20)$$

$$\begin{aligned} \gamma_{\alpha\beta\gamma\delta,k}^{\text{sol}}(-\omega; \omega_1, \omega_2, \omega_3) = & \gamma_{\alpha\beta\gamma\delta,k}(-\omega; \omega_1, \omega_2, \omega_3) \\ & + \delta_{\alpha\beta\gamma\delta\epsilon,k}(-\omega; \omega_1, \omega_2, \omega_3, 0) F_{\epsilon,k}^{(0)} + \dots \end{aligned} \quad (21)$$

The set of Eqs. 13, 17, and 18 can be solved for the susceptibilities. The result is a set of temperature-independent expressions, which in general constitute the most important contributions, as well as some temperature-dependent contributions (Kasprowicz–Kielich and Kielich 1975; Janssen et al. 1999). The temperature-independent expressions for the diagonal components can be written as

$$\chi_{\alpha\alpha}^{(1)}(\omega) = \frac{1}{\epsilon_0 v} \left\langle \sum_k \alpha_{\alpha\beta,k}^{\text{sol}}(\omega) d_{\beta k,\alpha}(\omega) \right\rangle \quad (22)$$

$$\chi_{\alpha\alpha\alpha}^{(2)}(-\omega; \omega_1, \omega_2) = \frac{1}{2\epsilon_0 v} \left\langle \sum_k d_{\beta k,\alpha}(\omega) \beta_{\beta\gamma\delta,k}^{\text{sol}}(-\omega; \omega_1, \omega_2) d_{\gamma k,\alpha}(\omega_1) d_{\delta k,\alpha}(\omega_2) \right\rangle \quad (23)$$

$$\begin{aligned} & \chi_{\alpha\alpha\alpha\alpha}^{(3)}(-\omega; \omega_1, \omega_2, \omega_3) \\ &= \frac{1}{6\epsilon_0 v} \left\langle \sum_k d_{\beta k,\alpha}(\omega) \gamma_{\beta\gamma\delta\epsilon,k}^{\text{sol}}(-\omega; \omega_1, \omega_2, \omega_3) d_{\gamma k,\alpha}(\omega_1) d_{\delta k,\alpha}(\omega_2) d_{\epsilon k,\alpha}(\omega_3) \right\rangle \end{aligned} \quad (24)$$

where k labels the molecules in the simulation box with volume v . The *local field tensors* $d_{\alpha k,\beta}(\omega)$, which correspond to the *cavity* and *reaction* field factors in the continuum model, are given by

$$d_{\alpha k,\beta}(\omega) = \sum_{k'} [\underline{\mathbb{I}} - \underline{\underline{L}} \cdot \underline{\alpha}^{\text{sol}}(\omega) / (\epsilon_0 v)]_{\alpha k,\beta k'}^{-1}, \quad (25)$$

where $I_{\alpha k,\beta k'} = \delta_{kk'} \delta_{\alpha\beta}$ and $\alpha_{\alpha k,\beta k'}^{\text{sol}}(\omega) = \alpha_{\alpha\beta,k}^{\text{sol}} \delta_{kk'}$ and $L_{\alpha k,\beta k'}$ is an element of the Lorentz factor tensor. In the two-step approach for the calculation of susceptibilities mentioned above, for each (or each n th) configuration of the simulation, the expressions in the brackets are evaluated, and finally an average over all snapshots is performed. Apart from the direct contribution shown in Eq. 24, there is also a so-called cascading contribution to $\chi^{(3)}$, which, however, is often much smaller than the direct part and requires that the molecules have a nonvanishing first hyperpolarizability (Munn 1988; Reis et al. 2006).

The solute properties, defined in Eqs. 19, 20, and 21, are not, in general, experimentally accessible, being defined as electric properties in the absence of an external electric field. Experimentally relevant molecular properties may be defined as derivatives of the total molecular dipole moment with respect to the *macroscopic field* \underline{E} , i.e., as in Eq. 2 with $\underline{F} \equiv \underline{E}$. These have been introduced in the framework of the semiclassical continuum model of Onsager and Lorentz by Wortmann and Bishop (1998) and were called *effective properties*. In the semiclassical Onsager model, the connection between solute properties and effective properties is given by cavity and reaction field factors, e.g., for the polarizability:

$$\alpha_{\beta\beta}^{\text{eff}}(\omega) = f_{\beta\beta}^C \omega F_{\beta\beta}^{R\omega} \alpha_{\beta\beta}^{\text{sol}}(\omega) \quad (26)$$

where, in the *spherical cavity* approximation and with a cavity of volume v ,

$$f_{\beta\beta}^{C\omega} = \frac{3\epsilon(\omega)}{2\epsilon(\omega) + 1} \quad (27)$$

$$F_{\beta\beta}^{R\omega} = \frac{1}{1 - f_{\beta\beta}^{R\omega} \alpha_{\beta\beta}^{\text{sol}}(\omega)} \quad (28)$$

$$f_{\beta\beta}^{R\omega} = \frac{2(\epsilon(\omega) - 1)}{v(2\epsilon(\omega) + 1)} \quad (29)$$

This model can be extended to ellipsoidal cavities, with sometimes greatly improved results (Wortmann and Bishop 1998). For more details about the cavity and reaction field factors, see Boettcher and Bordewijk (1978).

From Eqs. 1 and 13 one may define effective properties in the RLF model as the coefficient of the corresponding term in the field expansion of the averaged dipole moment $\langle \mu_{\alpha}^I(\omega) \rangle$. Thus, they can be computed from Eqs. 22, 23, and 24 by removing the prefactors $1/(n!\epsilon_0 v)$ and restricting the sums over all molecules k to summations over all molecules of kind I , k_I .

To conclude this section, we remark that:

1. In more sophisticated continuum models, such as PCM, the connection between solute and effective properties is not linear any more (see section “Polarizable Continuum Model (PCM) Approaches”).
2. The definition of *effective* properties is not unique; see, e.g., the discrete reaction field model, described in section “Discrete Reaction Field (DRF) Method”.
3. The corresponding relationships of Eq. 26 between the effective and solute *hyperpolarizabilities* given in Wortmann and Bishop (1998) have been criticized and corrected in Munn et al. (2005).

Solute–Solvent Interactions

In this section, we discuss some aspects of intermolecular interactions on electric and optical properties, which can be relevant for the calculations of liquids. The emphasis is put here on effects which are considered only very approximately or not at all in models of liquid presented in later sections. This may help to keep the possible limitations of these approaches in perspective. The picture presented in the previous section rests essentially on the classical model of mutually polarizing charge densities, with or without an external applied electric field. No account is made of the quantum-mechanical effects of dispersion and exchange interactions. Although some of the models described below take these effects into account in a more or less empirical way, e.g., by using Lennard–Jones potentials, a more quantitative knowledge of these effects is desirable. The classical approximation of electrostatic interaction with polarization appears to work quite well in many

circumstances, but it has been shown in some cases that these effects may be strongly changed or even overwhelmed by short-range interaction and/or dispersion effects. In this connection one should also mention the *confinement* effect of charges on electric properties, which are especially pronounced in anions and which have been investigated a long time ago by Fowler, Madden, and coworkers on ionic crystals (see, e.g., Fowler and Madden 1984; Jemmer et al. 1998).

Interaction-Induced Properties

In order to study the effect of intermolecular interactions on electric properties, it is useful to introduce the concept of interaction-induced properties. We consider here only liquids or more generally clusters in which the molecules (or ions) retain essentially their identity and interact via weak intermolecular forces which are much smaller than the intramolecular forces. Then the interaction energy can be defined as the difference between the energy of the whole system and that of the isolated parts. As the electric properties are defined as electric field derivatives of the energy, an interaction-induced electric property P_{int} can naturally be defined as

$$P_{\text{int}} = P^{\text{tot}} - \sum_i P^i \quad (30)$$

where P^{tot} is the property of the total “supersystem” and P^i are the properties of the isolated subsystems. This equation, however, does not allow to determine which part of P_{int} “belongs” to which molecule. This is indeed not possible without further analysis, because many intermolecular interactions are not additive and/or may involve many-body effects. Thus, in order to be able to analyze the solvent effect on property P of solute A , it is necessary to develop a distributing or *splitting* scheme for P_{int} .

There are essentially two different approaches used for the determination of interaction energies and properties, based either on supermolecular calculations or on perturbation theory. The supermolecular (SM) approach relies on computation of the energies and/or properties of the whole system and of the isolated molecules, which yields P_{int} according to Eq. 30. If any approximate representation of the wave function relying on finite basis sets is used for these calculations, the well-known problem of basis set superposition error (BSSE) due to incomplete basis sets has to be taken care of. The BSSE can be quite large for E_{int} if too small basis sets are employed. This may be different for properties, and it was indeed shown in several works (Baranowska et al. 2011; Medveđ et al. 2015) that the BSSE for interaction-induced dipole moment and (hyper)polarizabilities of weakly bound (including hydrogen-bonded) systems is rather small, although it is quite large for the interaction energies. It thus seems that the BSSE has no serious effect in electric property computations provided that reasonable basis sets including diffuse functions are used, although more data may be required to draw a definite conclusion.

An advantage of the SM approach is that it is independent of the strength of the interactions; however, it yields only the total interaction energy or property. A deeper insight into the nature of interaction-induced properties in terms of the type of interaction can be obtained using perturbation theory, e.g., in the *variational-perturbational scheme* of Sokalski et al. (1988). Another popular approach is SAPT, which stands for *symmetry-adapted perturbation theory*, although this is also the generic name for a whole class of short-range perturbation theories (see, e.g., Stone 2013, pp. 110). For reviews of SAPT see Szalewicz (2012) (see also Misquitta 2015 in this handbook). In SAPT, the interaction energy of a dimer AB is evaluated as a double-perturbative expansion through the Møller–Plesset fluctuation potential operators W_A and W_B of the subsystems A and B, respectively, and the interaction potential V . In this manner, the interaction energy is determined *without* computing the total energy of the supersystem and subsystems, it is thus free of the BSSE, and, moreover, a decomposition of the interaction energy into physically meaningful components (i.e., electrostatic, exchange, induction, and dispersion terms) can be performed, e.g., in the simplest truncation of SAPT denoted as SAPT0:

$$E_{\text{int}}^{\text{SAPT0}} = E_{\text{elst}}^{(10)} + E_{\text{exch}}^{(10)} + E_{\text{ind}}^{(20)} + E_{\text{exch-ind}}^{(20)} + E_{\text{disp}}^{(20)} + E_{\text{exch-disp}}^{(20)} \quad (31)$$

where the perturbation term $E^{(nm)}$ is n -th order in V and m -th order in $W_A + W_B$. Thus, electrostatic and exchange interactions are already included in first order in the interaction V , while induction and dispersion first appear through second order. The exchange–induction energy $E_{\text{exch-ind}}^{(20)}$ and the exchange–dispersion energy $E_{\text{exch-disp}}^{(20)}$ terms represent the effect of the antisymmetrization of the first-order induction and dispersion wave functions.

Using the definition of electric moments and (hyper)polarizabilities as field derivatives of the energy, it is straightforward, e.g., by applying *finite field* techniques, to compute interaction-induced electric properties of the individual molecules of the cluster, as well as their decomposition into the different interaction types. For a property P , we thus have in the SAPT0 approximation

$$P_{\text{int}} = P_{\text{elst}}^{(10)} + P_{\text{exch}}^{(10)} + P_{\text{ind}}^{(20)} + P_{\text{exch-ind}}^{(20)} + P_{\text{disp}}^{(20)} + P_{\text{exch-disp}}^{(20)} \quad (32)$$

In Table 1 we show the effect of the type of interaction on electric properties for a few selected dimers. It can be seen that the total induced dipole moment can be well reproduced by considering only electrostatic effects. In the case of polarizability, the differences between the total and electrostatic contributions are more significant. It can also be observed that the latter usually overestimates the former mainly due to the important role of the exchange repulsion effects, particularly in the case of hydrogen-bonded systems. For the first hyperpolarizability, it is difficult to neglect any contribution without further analysis. Even the dispersion contribution, which is in most cases negligible, may sometimes become unusually large; it contributes, e.g., more than 15 % to β_{int} of the pABA-z...benzene complex.

Table 1 The decomposition of the dominant component of interaction-induced properties for several molecular dimers. The total P_{int} value includes all terms of Eq. 32. TCNE = tetracyanoethylene, pABA-c(z) = canonical (zwitterionic) form of *p*-aminobenzoic acid, Bz = benzene. DNA pairs correspond to the B-form. All values are in a.u.

Distance Dependence

If the distance between the entities *A* and *B* in a dimer *AB* is sufficiently large, the interaction Hamiltonian *V* in the SAPT perturbation expression may be represented by its multipole expansion as a sum of terms proportional to inverse powers of the intermolecular distance *R*. This allows to express the individual interactions mentioned in the previous subsection in terms of molecular properties and to study their distance dependence. It turns out that the first-order term $\mu_{\text{elst}}^{(10)}$ is due to the polarization of molecule *A* by the electric field created by the permanent multipole moments on molecules *B* and *vice versa*. The second-order term $\mu_{\text{ind}}^{(20)}$ is caused by two mechanisms. Firstly, an induced moment on *A* leads to first-order polarization of *B*, which in turn induces a dipole on *A*. Secondly, permanent moments of *B* interact with the hyperpolarizability of *A* and *vice versa*. This nonlinear effect requires a nonvanishing first hyperpolarizability on *A* and/or *B*.

Finally, the second-order $\mu_{\text{disp}}^{(20)}$ can be described as coming from the interaction of the polarizability of A with first hyperpolarizability of B and *vice versa*. The term $\mu_{\text{exch}}^{(20)}$ does not appear in the multipole expansion. Indeed it decays very fast with the intersystem distance since it is related to the overlap of the wave functions of A and B.

The influence of the distance dependence on interaction-induced properties can be demonstrated by considering two interacting HF molecules (Skwara et al. 2008) (Fig. 1a). Starting from the intermolecular distance, defined as the distance between the two hydrogen-bonded atoms $R = 2.3\text{--}2.5 \text{ \AA}$ (i.e., $R \approx R_{\text{eq}} + 0.5 \text{ \AA}$), the interaction energy is dominated essentially by E_{elst} , because the other terms cancel each other in this region, although they are individually quite large, about 10–15% of E_{elst} . In the region of $R > R_{\text{eq}} + 1.0 \text{ \AA}$, all terms except E_{elst} can be neglected. As shown in Fig. 1b, c, this holds also for μ_{int} and α_{int} . In both cases, the first-order electrostatic contribution fairly well describes the total interaction-induced values. For the interaction-induced first hyperpolarizability, the case is more complicated, since now $\beta_{\text{elst}}^{(10)}$ has the opposite sign compared to the total MP2 β value for $R > 1.5 \text{ \AA}$. This is caused by a much faster decay of $\beta_{\text{elst}}^{(10)}$ combined with relatively large β_{exch} and $\beta_{\text{exch-ind}}$ contributions.

Many-Body Effects

As already mentioned, some interactions (e.g., electrostatic and second-order dispersion forces) depend only on two interacting partners, which means that they are pairwise additive. However, some effects such as the induction, exchange, and third-order dispersion interactions have *many-body* character, i.e., they are not pairwise additive. Generally, the total property P^{tot} can be expressed as

$$P^{\text{tot}} = \sum_i P^i + \sum_{i < j} \Delta^{ij} P^{(2)} + \sum_{i < j < k} \Delta^{ijk} P^{(3)} + \sum_{i < j < k < l} \Delta^{ijkl} P^{(4)} + \dots \quad (33)$$

where P^i is the property of an isolated molecule i and $\Delta^{ij} P^{(2)}$, $\Delta^{ijk} P^{(3)}$, and $\Delta^{ijkl} P^{(4)}$ are two-, three-, and four-body contributions to the interaction-induced property arising from interaction between molecules i , j , k , and l , respectively. From many-body effects, the three-body interactions are usually most relevant; it has been shown that three-body effects may contribute from a few to several tens of percents of the two-body contributions to the interaction energy (Bukowski and Szalewicz 2001). The role of many-body effects on interaction-induced properties has been investigated, for example, by Skwara et al. (2007), Góra et al. (2011), and Baranowska et al. (2010). For hydrogen-bonded systems, the ratio of the three-body and the sum of two-body contributions ($\Delta^{123} P^{(3)} / \sum \Delta^{ij} P^{(2)}$) to the interaction-induced dipole moment was found to be small, about 5%, because the main contribution to $\Delta\mu$ comes from electrostatic forces, which are pairwise additive. For the dipole polarizability, $\Delta^{123} \alpha^{(3)} / \sum \Delta^{ij} \alpha^{(2)}$ is typically about 10–

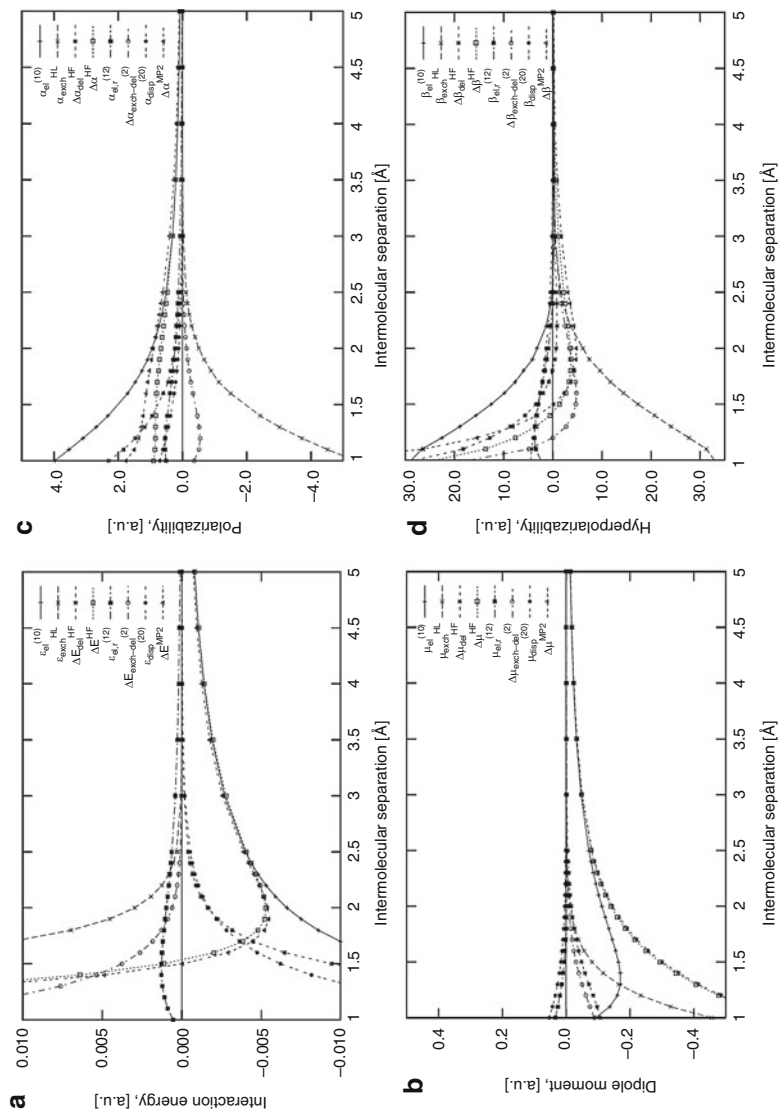

Fig. 1 Several contributions to the interaction energy (a) and interaction-induced properties (b–d) as a function of the intersystem distance for the HF dimer calculated at the MP2/aug-cc-pVTZ level of theory (Adapted from Skwara et al. 2008)

15 %, but for some cases, such as the diformamide trimer, it goes up to several tens of percents, and the many-body contributions may even be larger than the two-body contribution. The dominant component of the first hyperpolarizability was found to be even more sensitive to many-body effects than the polarizability. In this case, $\Delta^{123}\beta^{(3)}/\Sigma\Delta^{ij}\beta^{(2)}$ values typically span from 10 to 20 %. If the number of molecules in the cluster increases, the many-body effects become dominant (e.g., in HCHO... $(\text{HF})_n$) over the two-body effects (Baranowska et al. 2010). The decomposition of the three-body contribution to interaction-induced (hyper)polarizabilities shows that the nonadditivity arises mainly from the induction and exchange–induction interactions as well as higher-order electron correlation effects (Góra et al. 2011). To conclude, considering only two-body contributions may not be sufficient for a reliable description of the total interaction-induced (hyper)polarizabilities. In addition, it is not straightforward to predict whether nonadditive interactions will lead to an enhancement or a reduction of the two-body contribution.

Splitting Schemes

The previous sections have shown the usefulness of interaction-induced properties derived from approaches based on perturbation theory. As mentioned above, in order to assign molecular contributions to the properties or energies obtained from cluster (or supermolecular) calculations, some kind of splitting scheme has to be applied. The first schemes have been proposed for partitioning the total polarizability (Mikkelsen et al. 1995; Morita and Kato 1999; Jensen et al. 2002). In case of a system composed of N identical particles, the simplest way is to calculate the average polarizability per molecule (PPM), i.e., α/N (see, e.g., Hammond et al. 2009). Another scheme, which is also applicable to many component systems, is the differential shell approach (DSA) (Mikkelsen et al. 1995; Morita and Kato 1999), in which the solute polarizability is defined as the difference between the total supermolecular polarizability and the polarizability of the cluster without the solute molecule. The solute polarizability can thus be obtained in two calculations of the supersystem with and without the solute molecule. This scheme can also be applied for higher-order properties and provides a reasonable procedure to estimate the solute hyperpolarizability.

A more sophisticated treatment applicable for pure as well as many-component liquids is based on the expansion of the total polarizability, α^{tot} , through a cluster sum (Moraldi et al. 1989):

$$\alpha^{\text{tot}} = \sum_i \alpha^i + \sum_{i<j} \Delta^{ij} \alpha^{(2)} + \sum_{i<j<k} \Delta^{ijk} \alpha^{(3)} + \dots \quad (34)$$

where α^i is the polarizability of an isolated molecule i and $\Delta^{ij}\alpha^{(2)}$, $\Delta^{ijk}\alpha^{(3)}$, ... are two-body, three-body, ... contributions to the interaction-induced polarizability,

respectively. The total cluster polarizability can alternatively be expressed as the sum of many-body corrected molecular polarizabilities (MBP):

$$\alpha^{\text{tot}} = \sum_i \alpha_{\text{MB}}^i \quad (35)$$

which are defined in such a way that the two expansions of the total polarizability lead to the same result, i.e.,

$$\alpha_{\text{MB}}^i = \alpha^i + \sum_j W_{ij}^{(2)} \Delta^{ij} \alpha^{(2)} + \sum_{j,k} W_{ijk}^{(3)} \Delta^{ijk} \alpha^{(3)} + \dots \quad (36)$$

where $W_{ij}^{(2)}$, $W_{ijk}^{(3)}$, ... are weighting factors that divide the two-, three-, ... body contributions among the molecules according to a chosen scheme, which can be based, e.g., on the polarizabilities of the isolated molecules (Jensen et al. 2002)

$$W_{ij,\alpha\beta}^{(2)} = \frac{|\alpha_{\alpha\beta}^i|}{|\alpha_{\alpha\beta}^i| + |\alpha_{\alpha\beta}^j|} \quad (37)$$

and analogously for the higher-order weighting factors. The MBP scheme is in principle also applicable to hyperpolarizabilities. Its major disadvantage is that it is necessary to evaluate many-body contributions to the interaction-induced properties, which can be computationally demanding. Jensen et al. (2002) proposed an efficient scheme for partitioning the cluster polarizability called a localized dipole interaction model (LIM), which is based on the dipole interaction model of Applequist et al. (1972) and relies on decomposition of a so-called relay matrix into individual molecular contributions using the weighting factors as in the MBP approach. An *intramolecular* variant of this model has been used to define distributed polarizabilities and is described in section “Discrete Reaction Field (DRF) Method.” It was shown that for small water clusters the LIM scheme provides results comparable with the more demanding MBP approach. While the DSA scheme was in qualitative agreement with LIM and MBP, the PPM approach was not able to reproduce the anisotropic character of the molecular polarizability.

The appropriateness of the DSA scheme for the splitting of cluster polarizabilities into molecular contributions was also addressed by Morita and Kato (1999). The main drawback of DSA is that the difference of the property values for the supersystem with and without the solute molecule involves dielectric interference effects between the solute and solvent polarization, such as *electrostatic shielding* or *reaction field* coming from the medium polarization. In order to estimate these effects and thus to obtain the *net (intrinsic) solute polarizability* of a molecule in solution, Morita and Kato combined the multilayer dielectric continuum model with the supermolecular approach based on Monte Carlo simulations. In their three-layer model shown in Fig. 2, the solute molecule occupies the central part I, i.e., the cavity,

Fig. 2 Schematic picture of the three-layer model used by Morita and Kato (1999) to derive dielectric characteristics of the solvent enabling to determine the net (intrinsic) solute polarizability of a molecule in solution

whose radius l_1 was estimated from the van der Waals atomic radii of the solute and solvent molecules, similarly as in continuum models. Part II ($l_1 < r < l_2$) corresponds to the solvent with the static and optical dielectric constants ϵ_0^{II} and $\epsilon_\infty^{\text{II}}$, respectively, which may be different from their bulk values. Due to the statistical sampling, ϵ_0^{II} and $\epsilon_\infty^{\text{II}}$ are supposed to be isotropic. The size of the region II should be converged with respect to the target values (typically ca. 6–7 Å). Part III ($r > l_2$) is the external region, i.e., vacuum. From the boundary conditions for the electrostatic potential that must hold for the system in an external electric field E_∞ , Morita and Kato derived a pair of equations for spherical solutes, in which (i) the polarizability of the solvent α^{solv} can be expressed as a function of ϵ_∞ , l_1 , and l_2 and (ii) the difference $\Delta\alpha$ between the polarizability of the supersystem α^{tot} and that of the solvent is an explicit function of ϵ_∞ , l_1 , l_2 , and α , which is the intrinsic polarizability of the solute. Since α^{solv} and α^{tot} can be obtained from the QM/MC calculations, the optical dielectric constant ϵ_∞ can be determined from the first equation, and afterward the second equation can be utilized to obtain the intrinsic solute polarizability.

In Table 2 we show calculated isotropic polarizabilities for several solutes in water and liquid argon. The main conclusions that can be drawn are:

1. The intrinsic polarizability values α of the studied solutes are close to the difference $\Delta\alpha$, which means that the dielectric shielding or reaction field effects do not have large impact on the present systems.
2. A decrease of the molecular polarizabilities is observed when going from the gas phase to the solvent. Typically, the polarizabilities decrease by about 15 % for neutral systems; however, for the Cl^- anion it is more than 35 %.

Although the validity of the first conclusion requires justification for a wider spectrum of solvents, the good performance of the differential shell approach (DSA) is encouraging. The second conclusion is in contrast with the PCM findings, since the continuum models usually predict significant *enhancement* of the molecular

Table 2 Comparison of the gas phase, DSA, and net polarizabilities (in a.u.) of Ne, Ar, CH₄, Cl⁻, and H₂O in water and liquid argon (Taken from Morita and Kato 1999)

	α^{gas}	$\Delta\alpha^{\text{DSA}}$	α^{net}	$\alpha^{\text{net}}/\alpha^{\text{gas}}$	α^{gas}	$\Delta\alpha^{\text{DSA}}$	α^{net}	$\alpha^{\text{net}}/\alpha^{\text{gas}}$
Ne	2.358	1.923	1.945	0.825	2.357	2.160	2.160	0.917
Ar	10.586	9.188	9.227	0.872	10.582	10.368	10.334	0.977
CH ₄	16.002	13.947	14.003	0.875	16.000	15.904	115.839	0.990
Cl ⁻	31.036	19.563	19.677	0.634	30.940	25.510	25.406	0.821
H ₂ O	8.530	7.177	7.214	0.846	8.529	7.801	7.778	0.912

polarizability in solution (see previous subchapter). This qualitative disagreement has its roots in the fact that the PCM treatment leads to overpolarization, since it is not compensated (among other effects) for the exchange valence repulsion effects. The supermolecular approach of Morita and Kato, on the other hand, takes into account all interactions, as described by the level of theory applied. Analysis of the α^{tot} values (based on evaluation of a hypothetical polarizability α_{exch} of the solute molecule where only the solute–solvent exchange interaction is involved) suggests that the exchange interactions play indeed an important role in reducing the solute polarizability. For instance, the reduction of α^{gas} for Ne and H₂O in liquid water due to the exchange interactions was estimated to be about 47 % and 63 %, respectively, of the total reduction ($\alpha^{\text{gas}} - \alpha$). The remainder is attributed to other contributions such as the induction, dispersion, and charge transfer interactions. Nevertheless, the exchange interaction appears to be a dominant mechanism of the reduction as was shown also in Mennucci et al. (1998); Serr and Netz (2006).

Implicit Solvent Methods

Although there are several approaches which treat the molecules in a liquid explicitly, they scale very unfavorably with the size of the system. Consider a small dipolar organic molecule such as benzoic acid in aqueous solution. This system may require a cutoff radius of about 12 Å for a reasonably accurate description of

the long-range electrostatic dipole–dipole interactions. A sphere of this size contains about 300 molecules, which would be a sizable computationally demanding task. In addition, the calculation would have to be repeated for many different configurations which may occur in the liquid for a realistic description. It turns out that such a detailed description may not be necessary; in many cases the *average* influence of the solvent on the properties of a solute may be well described by just a few macroscopic parameters. This is the underlying principle of the continuum (or implicit solvent) models. Here the solvent is treated as a uniform, polarizable continuum, described by the dielectric constant ϵ and refractive index $n(\omega)$, while the solute surrounded by the continuum is treated on a molecular level.

The creation of a cavity in the medium for the solute requires work related to the destabilization of the system. This effect is counteracted by favorable electrostatic interactions between the molecular charge density and the polarizable continuum, which in turn acts back on the (polarizable) molecular charge density. Additional contributions to the interaction energy are due to dispersion and repulsion terms, which would need to be considered for a full description. The solvation free energy of the solute–solvent system may thus be written as a sum of three components:

$$\Delta G_{\text{solv}} = \Delta G_{\text{cav}} + \Delta G_{\text{elst}} + \Delta G_{\text{disp-rep}} \quad (38)$$

Not all terms are considered in each model; in most of the current implicit solvation models, only the electrostatic term is explicitly considered. The cavitation and dispersion–repulsion terms may be computed separately, using empirical parameters and/or simplifying assumptions (Amovilli and Mennucci 1997); such an approximate approach still needs to be validated by comparison with the fully quantum-mechanical studies at a molecular level.

As mentioned above, the polarization interaction between continuum and solute is not linear; thus, the energy has to be calculated iteratively, leading to the so-called self-consistent reaction field (SCRF) models. Many different SCRF models have been implemented in publicly available program packages, differing, for example, in the description of the cavity, the treatment of the electrostatic solute–continuum interactions, etc. Popular models include the polarizable continuum model (PCM) (Tomasi et al. 2005); the conductor-like screening model for real solvents (COSMO-RS) (Klamt 2011); the solvation models (SM x), where x provides information about the model (e.g., $x = 5.2$ denotes a fifth-generation model using Mulliken charges) (Marenich et al. 2007); and the multipole expansion method (MPE) (Rinaldi and Rivail 1973; Mikkelsen et al. 1994a). They generally perform very well in calculations of the solvation free energies of neutral molecules, with absolute mean errors lower than 1 kcal/mol (Klamt et al. 2009). This is a nice performance for such computationally quite cheap approaches leading to the spread of continuum models into many other branches of computational chemistry. Another attractive advantage of continuum models is that they have been implemented in conjunction with virtually all levels of computational chemistry.

Many computations of electric, linear, and nonlinear optical properties employing continuum models used either the PCM or the MPE model; thus, we will only describe these two models in more detail below.

Polarizable Continuum Model (PCM) Approaches

The simplest shape of the cavity for solute is a sphere. This form has the advantage that the electrostatic interaction between solute and the dielectric medium can be calculated analytically, and has been used in some of the very first dielectric continuum theories which were developed to account for solvent effects, such as the dielectric polarization theories of Onsager and Kirkwood (see Boettcher and Bordewijk (1978) for an extensive discussion of these theories). Although a generalization of the analytical solution to ellipsoidal shapes is possible, these are still rather unnatural cavity shapes for many molecules. The PCM tries to employ molecular-shaped cavities, generated by interlocking spheres centered on each nucleus. The radii of these spheres are usually taken to be the van der Waals radii, scaled by a constant (typically 1.1, but see discussion below). As no analytical solution is possible for such shapes, the resulting surface of this cavity is then partitioned into small pieces k , called *tesserae*, each being assigned then a point charge q_k . In this way the total potential due to the polarization of the dielectric medium can be written as a discrete sum over the tesserae k :

$$V(\underline{r}) = \sum_{k=1}^N \frac{q_k}{|\underline{r} - \underline{r}_k|} \quad (39)$$

where \underline{r}_k is a vector to a point of tessera k . The local value of the potential necessary to define q_k depends on all point charges $\underline{q} = (q_1, \dots, q_N)^T$, which may be determined from a matrix equation:

$$\underline{q} = -\underline{K}(\epsilon) \cdot \underline{V}(\underline{r}_k) \quad (40)$$

where $\underline{V}(\underline{r}_k)$ collects the electrostatic potential at the tesserae due to the remaining tesserae. The matrix \underline{K} depends on the cavity geometrical parameters and the dielectric constant of the solvent.

The solvent–solute coupling is then introduced into the Hamiltonian describing the solute by adding to the Hamiltonian of the isolated molecule (\hat{H}_0) the electrostatic potential defined by Eq. 39. The wave function and the free energy of the solute can be finally obtained by minimizing the following functional:

$$G(\Psi) = \langle \Psi | \hat{H}_0 + 1/2\hat{V} | \Psi \rangle \quad (41)$$

Following the definition of electric properties, the electric dipole moment, (hyper)polarizabilities, etc., may be obtained by differentiation of the total energy of the solvated molecule with respect to a static or dynamic external field. According to Eq. 38, each field derivative may consist of different contributions, although generally only the electrostatic term is taken into account self-consistently. Mennucci et al. (1998) investigated the different contributions to the electric properties of several small molecules. They found a reduction of components of polarizability and second hyperpolarizability tensors up to 2 % with respect to the gas-phase values due to the Pauli repulsion term. This can be understood as an effect of constraining solute electron density. As expected, the electrostatic contribution yields much larger effects on the properties mentioned above (up to +16 % for components of α and up to +26 % for components of γ). The overall effect of dispersion was positive, but small (+1–2 %). The contributions of Pauli repulsion and dispersion to β were positive or negative, depending on the component, but the absolute changes were generally larger than for α and γ .

The calculations reported above used water as a solvent, which is very polar. While the electrostatic component is clearly very sensitive to solvent polarity, the effect of the solvent polarity on the remaining terms is not clear a priori. In another study, the contributions of electrostatic, dispersion, and Pauli repulsion on the push–pull molecule *p*-nitroaniline in nonpolar cyclohexane, dichloromethane, as well as water were studied (Budzák, unpublished). It was found that the dispersion and repulsion effects were negligible in comparison to the electrostatic effect of the polar molecule. We reiterate that Pauli repulsion, dispersion, and cavitation energies are usually not computed by default in PCM calculations in many quantum chemistry codes. When dealing with less polar solutes in nonpolar solvents, it may be worthwhile to check the individual importance of those terms on electric properties.

As mentioned above, the cavity surface is usually constructed using van der Waals radii, which are scaled by an empirically determined factor 1.1. This scaling factor is probably appropriate for neutral molecules in the ground state, but may be questionable if it is suitable for solutes with a very diffuse electron density such as anions; see, e.g., Serr and Netz (2006). Similarly, for molecules in electronically excited states, the effect of cavity size should be checked carefully, as the van der Waals radii determined for the electronic ground state may not be appropriate for excited states. As it may be anticipated, electric properties like the polarizability tend to the gas-phase values with increasing cavity size and, in general, increase with decreasing cavity size. For cavities, which are too small, a substantial part of the wave function is not confined anymore by the cavity, and electron charge density escapes the cavity; this is the so-called charge penetration effect.

In section “Definition of Macroscopic and Microscopic Quantities” the concept of *solute* and *effective* properties was described, following the definition of Wortmann and Bishop (1998). Only the latter are the properties actually related to experimentally determined values, while the former are in a way fictive properties as they cannot be determined directly. The distinction carries over to the SCRf models: in a standard PCM computation the *solute* properties are calculated. These may be

multiplied by Onsager–Lorentz cavity factors for the conversion to the effective properties. A more consistent way would be to use the implementation of Cammi et al. (1998), which allows the computation of *effective* (hyper)polarizabilities in the framework of the PCM directly. In their formulation the interaction of an effective dipole moment (μ^{eff}) with the Maxwell electric field \underline{E} is introduced by adding the following term to the total Hamiltonian:

$$\hat{H}' = \hat{\underline{\mu}} \cdot \underline{E} + \sum_{k=1}^N V_k \frac{\partial q_k^{\text{ex}}}{\partial \underline{E}} \cdot \underline{E} \quad (42)$$

where $\hat{\underline{\mu}}$ and V_k are the electronic dipole moment operator of the solute and the electronic electrostatic potential at the cavity surface, respectively. The charges q_k^{ex} describe that part of the solvent polarization which is induced by the external field and are computed using the (static or frequency-dependent) dielectric constant $\epsilon(\omega)$. This term describes the cavity field effect including the response of the solvent to the external field after the creation of the cavity in the solvent and allows the direct calculation of the effective (hyper)polarizabilities of the solvated molecule.

A rigorous treatment of cavity field effects within the PCM has been presented recently by Pipolo et al. (2014), bypassing the use of Onsager–Lorentz factors. The cavity field interactions within the PCM are described by factors reflecting the different cavities created by different molecules. Ferrighi et al. (2006) observed in their study of push–pull phenylpolyenes that PCM cavity field factors are smaller than the Onsager–Lorentz factors; moreover, their values decrease with increasing chain length. Such effects may even substantially change trends obtained in series of homologues, e.g., polyenes with increasing chain lengths.

Multipole Expansion (MPE) Method

The multipole expansion method (Mikkelsen et al. 1994a) is another SCRF method and has been frequently applied for the prediction of solute (hyper)polarizabilities. Its implementation in Dalton (2015) allows the analytical calculation of electric properties using linear, quadratic, and cubic response theory for singlets at HF, DFT, and multiconfigurational SCF (MCSCF) levels of theory, where it is possible to employ both equilibrium and nonequilibrium solvation. In the latter case, the charge distribution of the solvent is not in equilibrium with the charge distribution of the solute, which is relevant if optical external fields are applied, e.g., in the form of light. For (quasi)-static electric fields, on the other hand, equilibrium solvation would be used.

The MPE method is based on the polarization theory of Onsager, as extended by Kirkwood. The cavity in this model is a sphere, and the interaction of the solute with the continuum is described by a multipole expansion of the charge density of the solute (not just the dipole as in the Onsager theory). Thus, the polarization free

energy can be written as

$$\Delta G_{\text{solv}} = \sum_{m,l} g_l(R, \epsilon) |\langle \Psi | \hat{T}_{lm} | \Psi \rangle|^2 \quad (43)$$

where \hat{T}_{lm} are the spherical multipole operators and $g_l(R, \epsilon)$ are functions of the (frequency-dependent) dielectric constant $\epsilon(\omega)$, the cavity radius R , and the rank of the multipole l :

$$g_l(R, \epsilon) = -\frac{1}{2} R^{-(2l+1)} \frac{(l+1)(\epsilon-1)}{l+(l+1)\epsilon} \quad (44)$$

The maximum order l_{max} used in the expansion of Eq. 43 is in principle unlimited, but in many cases, results are converged with $l_{\text{max}} = 6$. Nevertheless, this should be checked in any specific application of the method.

In the quantum-mechanical formulation, the total Hamiltonian for the solute becomes

$$\hat{H} = \hat{H}^{\text{vac}} + \hat{W}(\Psi) \quad (45)$$

$$\hat{W}(\Psi) = 2 \sum_{ml} g_l(\epsilon) \langle \Psi | \hat{T}_{ml} | \Psi \rangle \hat{T}_{ml} \quad (46)$$

As the solvation part depends on the wave function, the corresponding equations to determine energy and wave functions have to be solved iteratively.

Using a spherical cavity, the cavity radius is an even more decisive factor in MPE than in PCM with its molecular-shaped cavity. A nonempirical way to uniquely determine this radius for pure liquids by comparing the results based on the Clausius–Mossotti equation with the SCRF predictions has been suggested in Luo et al. (1997). It turns out that the radius is quite dependent on the quantum-mechanical method applied as well as on the basis set.

A comparison of the performance of the MPE and PCM approaches with explicit models for electric properties is presented in section “Two Case Studies: Liquid Water and *p*-Nitroaniline in 1,4-Dioxane.”

Explicit Molecular Models

In explicit molecular models, the description of a solution as “a molecule embedded in a dielectric continuum” in implicit models is abandoned, and the molecules composing the liquid are treated explicitly, usually at different levels of theory. Even with the most approximate methods, this is clearly not possible for all the molecules composing the liquid, so further approximations are still required to render the

computation feasible. The models we will present below use one of the following strategies:

1. The molecules treated explicitly are contained in a box (or a sphere), which is surrounded by a dielectric continuum (discrete reaction field (DRF), Langevin dipoles (QM/LD/MC)).
2. Periodic boundary conditions are applied, which means that the box filled with molecules is replicated in space (rigorous local field RLF)).
3. A sufficiently large cluster of molecules is taken as a representation of the liquid (supermolecular (SM) approach, polarizable embedding (PE), frozen-density embedding (FDE)).

In addition to the treatment of inter- and intramolecular interactions, explicit models usually also take into account the pronounced *dynamic* nature of a liquid at the molecular level, both by considering the change of the geometric structure of individual molecules and by describing the macroscopic structure as an average over a large number of different individual arrangements of the molecules satisfying certain thermodynamic conditions (usually NVT, NVE, or NPT ensembles). The usual way to treat this problem of statistical mechanics is to apply the methods of molecular simulation, e.g., by Monte Carlo or molecular dynamics calculations, which yield a number of snapshots to be analyzed individually and averaged. This is clearly computationally much more demanding than a continuum model calculation, but is probably also more physically appropriate. Advantages of explicit models over continuum models are, for example, that they are able to describe specific interactions such as hydrogen bonding. In addition, they do not depend on the definition of cavity, which is in some way an artificial construct.

Fully quantum-mechanical simulations are possible, generally at the DFT level; e.g., Car–Parrinello molecular dynamics (CPMD) simulations have been used to model condensed phases including the determination of molecular electric properties (Dyer and Cummings 2006). Those methods are, however, still computationally rather demanding, and therefore a more common and less expensive approach is to combine a fully QM method with force field-based molecular mechanics (MM) methods. In such a hybrid QM/MM method, the central region (usually a solute molecule) is modeled at the QM level, while the environmental effects of the surrounding solvents are computed using MM force fields. The interactions between QM and MM regions are taken into account by including electrostatic and polarization effects as well as short-range repulsion and dispersion interactions. Thus, an effective hybrid QM/MM Hamiltonian is constructed in the following form:

$$\hat{H}_{\text{ef}} = \hat{H}^0 + \hat{H}_{\text{QM/MM}} + \hat{H}_{\text{MM}}, \quad (47)$$

where \hat{H}^0 is the many-body quantum-mechanical Hamiltonian, $\hat{H}_{\text{QM/MM}}$ is Hamiltonian describing the interactions between QM and MM regions (atoms), and \hat{H}_{MM} is defined by classical force fields.

In general, a successful application of explicit QM/MM methods is significantly more involved than a continuum model calculation. This is due to a variety of parameters and variables which need to be decided upon, such as (a) the choice of the MM force field, (b) the type of simulations (molecular dynamics or Monte Carlo simulations), (c) technical details regarding simulations (time step of simulations, number of solute and solvent molecules, number of configurations required for statistical averaging, etc.), and (d) choice of level of QM theory, basis set, and technique for the determination of electrical properties. Hence, the construction of a reliable, but efficient, QM/MM technique for the investigation of the nonlinear optical response of molecular systems in condensed phases requires extended development as well as numerical testing (e.g., calibration of the QM/MM potential).

Usually, the determination of the liquid structure occurs separately from the computation of the electric properties, leading to sequential Monte Carlo (or molecular dynamics)/quantum mechanics (S-MC/QM or S-MD/QM) techniques (Canuto et al. 2005; Mata et al. 2009). The S-MC(MD)/QM methodology was successfully used in theoretical studies of the dynamic polarizability of liquid water as well as the polarizability of the fluoride anion (F^-) in water, where it was found that the polarizability of the F^- anion is significantly reduced compared to that of the free anion, as has been found previously for F^- in the crystal (Fowler and Madden 1984).

For a reliable structure determination of the liquid, the simulation box should be large enough to properly account, for example, for long-range electrostatic interactions. This is true even if periodic boundary conditions are applied; if the simulation box is too small, these may lead to artificial periodicity effects. In addition, the solute properties may significantly depend on the local geometry of solvent molecules in the vicinity of the solute. Consequently, particular attention should be paid to an accurate description of possible structural configurations of the first solvent shell. An alternative to the dynamic models may be to generate relevant configurations of the local environment of the solute ("microsolvation"). Marchal et al. 2009 proposed a method called the *global search algorithm of minima* (GSAM). While in dynamic models mean values of properties are obtained by averaging over the simulated configurations, in GSAM one relies on Boltzmann distribution factors. The GSAM method was successfully applied, e.g., in studies of the structure and properties of microhydrated nucleic acids.

A considerable number of papers using explicit models for the computation of macroscopic susceptibilities of liquids have been published. We present below various models which have been quite extensively employed, and/or are in active development. They differ in several aspects, for example, in the treatment of molecular electrostatic and polarization effects, which is clearly an important aspect for the computation of electric susceptibilities and will thus be treated in more details. Another relevant point is whether the method under consideration only allows the simulation of the solvent effect or it also takes the effect of the macroscopic field consistently into account. In the nomenclature of Wortmann

and Bishop (1998) mentioned above, we distinguish methods that stop after the computation of the solute properties, while others go all the way up to the effective properties. Solute properties in the first case may still be converted into susceptibilities using local field factors, which, however, would not be predicted by the theory in question.

Supermolecular (SM) Calculations

A relatively straightforward strategy to compute the NLO properties of aggregates of molecular systems is the supermolecular (SM) approach (Kanis et al. 1994). In this approach, the macroscopic system is approximated by a reasonably large cluster (the supermolecule) of a finite number of molecules, which are usually all described at the same quantum chemical level (the choice of the QM method is only restricted by the size of the cluster). There are no general rules for the structure of the clusters to be used in a SM calculation nor for the number of molecules to be included in the cluster. In the case of crystals, the information from experimental structure determinations (neutron diffraction or X-ray experiments) may be employed, but for liquids it is more customary either to rely on configurations generated by molecular simulations, which are then in some way averaged in order to create a single representative supermolecule, or to optimize chemically reasonable structures generated either by efficient search algorithms (e.g., in the global search algorithm of minima (GSAM) (Marchal et al. 2009)) or simply by using chemical intuition.

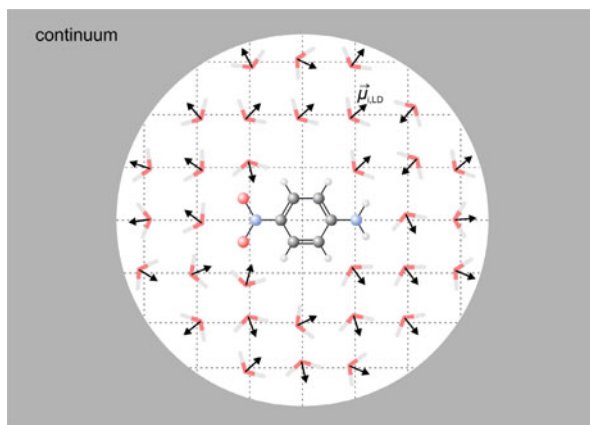

The size of the cluster should in principle be converged with respect to the property of interest. This can be a challenge in the case of NLO properties due to their strong dependence on long-range (e.g., dipole–dipole) electrostatic interactions, which may require the consideration of hundreds of molecules for a converged description. As this is usually computationally too expensive for standard correlated *ab initio* QM methods, one possibility to circumvent this problem is to use a multilayered approach, i.e., to apply different levels of theory for parts of the cluster (e.g., a high-level method for the solute, medium level for the first solvent shell, and a low level for more distant regions). Another possibility is to use a reasonable QM method for a smaller cluster and to combine this calculation with a continuum model. These multilayer approaches finally lead to the QM/MM models described later in this chapter. As for the SM method, it remains to note that the potentially high accuracy of this approach is often counterbalanced by the limited system size which can be treated. In addition one should mention the incapability of the SM method to account for dynamic structural effects.

The SM approach also suffers from the problem of distributing the computed response of the total cluster over the molecules which constitute the SM. See section “Splitting Schemes” for possible solutions based on the concept of interaction-induced properties.

The SM approach allows to study the dependence of the structure and the properties of specific molecular clusters (e.g., clusters with hydrogen or halogen bonds, π – π stacking, etc.), on specific structural parameters, e.g., mutual orientation, distances, etc. In a recent example, Suponitsky and Masunov (2013) considered several modes of stacking between donor–acceptor-substituted benzene and stilbene molecules, with different overlap of the corresponding molecular π systems. Several aspects connected with the type of intermolecular interactions due to the stacking were studied and their effect on the first hyperpolarizability of the aggregate analyzed. In another study using the SM method, a significant enhancement of the first hyperpolarizability of buckybowls in ordered aggregates was demonstrated (Li et al. 2013). Thus, the SM approach can lead to valuable insights in the effect of intermolecular interactions on NLO properties, which may also be very useful in the analysis of the NLO response of liquids.

As described in section “Implicit Solvent Methods,” most continuum models are not able to describe the effect of specific solute/solvent interactions, for example, hydrogen bonds. In particular, they often predict solvatochromic shifts as well as (hyper)polarizabilities of solute molecules dissolved in protic solvents incorrectly. An improved description is often achieved by including a small number of solvent molecules around the solute (e.g., the first solvent shell) in the explicit calculation while describing the rest of the solvent by the continuum model. Using this method, Wang et al. (2003) showed that H bonding has a large effect on the electronic structure and first hyperpolarizability of *p*-nitroaniline (pNA) in protic solvents. For a discussion of the application of this approach to liquid water, see section “Water.”

QM/Langevin Dipole/Monte Carlo (QM/LD/MC) Method

One of the first QM/MM implementations was described in Warshel and Levitt (1976). The authors used the semiempirical MNDO/2 Hamiltonian to describe the QM region. The MM part was represented by a polarizable force field and by Langevin dipoles (LDs) for the solvent molecules. In 1997, a modified and extended quantum-mechanical Langevin dipole/Monte Carlo (QM/LD/MC) technique was presented and applied to calculations of the solvent effect on molecular properties in electronic ground and excited states (Lipiński and Bartkowiak 1997). The new concepts in the classical LD/MC model and their QM/LD/MC extension included (i) the representation of a solute molecule by atomic charges, dipoles, and quadrupoles, (ii) the MC sampling technique for determination of the optimal position and orientation of the solute molecule, (iii) the use of the full Langevin formula for the orientational polarization in the self-consistent calculations, (iv) mutual polarization of the solute and solvent molecule.

In the QM/LD/MC model, the solvent molecules are represented by an ensemble of polarizable Langevin dipoles (LDs), which are distributed among the nodes of a regular cubic lattice with the center of mass of the solute in its center, extending up to a radius R , typically 12–18 Å, with a distance between two neighboring nodes (Δ) of ca. 3 Å. This sphere is then surrounded by a bulk solvent treated as a dielectric continuum with a bulk dielectric constant (ϵ) corresponding to the simulated solvent. The local field on the i -th node results from the charge density distribution of the solute molecule as well as from the electrostatic field generated by all other dipoles:

$$\underline{E}_i^{(n)} = \underline{E}_{i,0} + \underline{E}_{i,LD}^{(n)} \quad (48)$$

where $\underline{E}_{i,0}$ is the field generated by the solute molecule, $\underline{E}_{i,LD}^{(n)}$ is the field produced by other solvent molecules, and the upper index n refers to the n -th iterative step, since the fields are determined in a self-consistent manner reflecting the

mutual orientational as well as electronic polarization. In the LD model, the solvent polarization (expressed by the dipole moment of an i -th solvent molecule) is approximated by the Langevin-type function:

$$\underline{\mu}_{i,LD}^{(n+1)} = \underline{e}_i^{(n)} |\mu_p| [\coth(z_i^{(n)}) - (z_i^{(n)})^{-1}] \quad (49)$$

where $\underline{e}_i^{(n)}$ is the unit vector in the direction of $\underline{E}_i^{(n)}$, μ_p is the permanent dipole moment of the solvent molecule, and

$$z_i^{(n)} = \frac{|\mu_p| |E_i^{(n)}|}{kT} \quad (50)$$

where k is the Boltzmann constant and T denotes absolute temperature. In addition to the permanent dipole moment contribution defined by Eq. 50, the total solvent dipoles involve the electronically induced contribution evaluated as

$$\underline{\mu}_{i,LD,ind}^{(n+1)} = \underline{\alpha}_{LD} \cdot \underline{E}_i^{(n)} \quad (51)$$

where $\underline{\alpha}_{LD}$ is the polarizability of the solvent molecule.

The electrostatic potential generated by the solute on each solvent molecule represented by a LD is calculated using the cumulative atomic multipole moments (CAMP) scheme (Sokalski and Poirier 1983). In this formalism, each atom k of the solute molecule is represented by a scalar net atomic charge (q_k), a vector of atomic dipole ($\underline{\mu}_k$), as well as a tensor of atomic quadrupole (\underline{Q}_k). In addition, the polarization of the solute is modeled by atomic dipole polarizabilities. In the classical calculations, the optimum position and orientation of the solute molecule (treated as a rigid body), placed in a cubic grid of polarizable solvent molecules, is determined using the MC method. In each MC step, permanent and induced dipole moments of each solvent molecules and the electric potential produced by all solvent molecules on each atom of the solute are iteratively calculated.

We note that the QM/LD/MC technique is less expensive than a standard classical molecular simulation. However, the QM/LD/MC model was only formulated for two polar solvents: water and chloroform. Hence, this technique is restricted to the description of a polar solute in either one of these two polar solvents. The QM/LD/MC model belongs to the sequential simulation techniques (S-QM/LD/MC). The permanent and induced dipole moments of the solvent molecules obtained in the MC run generate the electrostatic potential over the solute molecule. This potential is then averaged over the MC snapshots. Hence, the total potential V_R is a sum of averaged potentials due to the permanent and induced dipole moments of solvent molecules ($V_R = V_{perm} + V_{ind}$). The effect of the reaction field is as usually introduced into the solute Hamiltonian by means of perturbation operator \hat{V}_R according to the equation

$$\hat{H}_{ef} = \hat{H}^0 + \hat{V}_R \quad (52)$$

where \hat{H}^0 is the unperturbed Hamiltonian of an isolated solute molecule. After the QM calculations, new values of CAMM are obtained, which generate new electrostatic potential ($V_R = V_{\text{perm}} + V_{\text{ind}}$), which is then incorporated into Eq. 52 to give new CAMM. This process is repeated, until self-consistency is reached. In the context of *solute* versus *effective* properties, it should be noted that both of them can in principle be determined by the QM/LD/MC approach (applying the numerical derivative using finite fields (ND-FF) method). While the former refer directly to the properties computed from the solute density corresponding the effective Hamiltonian given by Eq. 52, the latter can be obtained in the same manner as in other combined D/C approaches by multiplying the solute properties with cavity field factors.

The QM calculations based on the QM/LD/MC technique were performed using the semiempirical GRINDOL program which uses an approach based on the neglect of differential overlap (NDO) method (Lipiński 1988). The majority of the investigations using this method were devoted to linear and nonlinear electrical properties of large organic molecules in solutions (Zaleśny et al. 2002).

Rigorous Local Field (RLF) Method

In the rigorous local field (RLF) method, a liquid is considered as an infinitely replicated simulation box, using Born–von Karman periodic boundary conditions to account for long-range electrostatic and polarization effects, very similar in spirit to the treatment of a crystal in solid-state physics. The theoretical basis of the RLF method applied to liquids has been developed by Janssen et al. (1999).

The molecular properties entering the electrostatic calculations are computed by QM methods. The liquid structure is usually obtained beforehand by a classical molecular simulation computation; thus, this method would be accurately described as a sequential MM/QM/ES (electrostatic) method. As long as the simulation box is large enough to avoid artificial periodic artifacts, the electrostatic treatment is probably more accurate, but at the same time computationally more demanding

than the supermolecular method or the continuum model, which considers the liquid either as a simulation box or even just the solute molecule surrounded by a dielectric continuum.

Once the liquid structure is available, it can be used to determine the permanent local field or reaction field according to Eq. 14, which determines the *solute* properties. Using electric properties of the isolated molecules (solute and solvent), computed by ab initio methods, Eqs. 14 and 15 are solved. If the field expansion of the dipole moments (and higher multipole moments) is truncated after the polarizability terms, an analytical solution is possible (Reis et al. 2006). In the few cases where it has been checked, this was found to be a valid approximation, i.e., the contribution of the hyperpolarizabilities to the reaction field was small. The magnitude of the permanent local field depends clearly on the electric properties of the solute and solvent. In the case of pure benzene, for example, the field was considered to be small enough to be neglected completely (Janssen et al. 1999). On the other hand, the contribution of *quadrupole* moments may be substantial, for example, in solutions of *p*-nitroaniline in nonpolar to medium polar solvents (Reis et al. 2006) or for pure acetonitrile (Avramopoulos et al. 2007).

With the solute properties determined, the susceptibilities can finally be computed using Eqs. 22, 23, and 24, possibly supplemented by the temperature-dependent terms mentioned after Eq. 21, as has been done in the simulation of the third-harmonic generation (THG) of signal $\chi(-3\omega; \omega, \omega, \omega)$ of pure benzene in Janssen et al. (1999). We note, however, that according to Kasproicz-Kielich and Kielich (1975), a T -dependent term should only occur for the optical Kerr effect (or intensity-dependent refractive index IDRI) $\chi(-\omega; \omega, \omega, -\omega)$, but not in the case of THG. On the other hand, checks performed in Reis et al. (2001) showed that the effect of these terms is small anyway for liquid benzene.

The theory developed by Janssen et al. (1999) is applicable for the special case of a liquid in an *optical* macroscopic field $\underline{E}(\omega)$. For such a field one may assume that the liquid structure is not affected by the field, which means that the field can be neglected in the molecular simulation step, i.e., the determination of the liquid structure. If all applied fields are optical, the liquid is isotropic, so $\chi^{(2)}$ should be zero, which yields a condition which may be used to check the correctness of the details of the simulation, for example, simulation time or number of configurations.

We note that the formulation of the local field problem in terms of the *macroscopic field* E and Lorentz factor tensors \underline{L} in Eq. 17, instead of the external field E^0 and the dipole-dipole propagator tensors \underline{T}^{11} , takes care automatically of the *cavity field factors*, which need to be considered separately for the calculation of susceptibilities by methods which contain a dielectric continuum as part of the description of the liquid system.

In several applications of RLF, e.g., for acetonitrile (Avramopoulos et al. 2007), water, and benzene (Reis et al. 2001), the molecules considered and their properties were small enough so that the one-point expansion of the electric properties was an accurate approximation. For larger molecules such as *p*-nitroaniline, however, this was not the case. Here, a very simple distributed model called the *submolecule*

approach was applied. In this model, the molecule was partitioned into n smaller units, and of each electric property P , a part P/n was assigned to each subunit. Thus, for example, if μ is the permanent dipole moment of the molecule, each submolecule carries a dipole moment μ/n . Although quite simple and crude, this distribution scheme was found to be surprisingly successful.

As mentioned above, only for all-optical external fields one may assume that the liquid structure is undisturbed, and a field-free molecular simulation is sufficient to obtain this structure. If an applied field component is *static*, as in an electric field-induced second harmonic generation (EFISH) experiment, the isotropy of the liquid will in general be destroyed. Thus, a static field will influence the liquid structure and needs to be included already in the simulation step. In that case a nonzero $\chi^{(2)}$ should be obtained from Eq. 23. This approach has been used to compute the EFISH susceptibility of liquid acetonitrile in Avramopoulos et al. (2007). The total EFISH signal $\chi_{iiii}^{(3)}(-2\omega; \omega, \omega, 0)$ was computed by summing the contribution due to the orientational effect of the static field via the permanent dipole moments and the “intrinsic” third-order effect due to the second hyperpolarizability γ :

$$\chi_{zzzz}^{(3)}(-2\omega; \omega, \omega, 0) = \frac{\chi_{zzz}^{(2)}(-2\omega; \omega, \omega; E_z)}{3E_z} + \chi_{zzzz}^{(3\gamma)}(-2\omega; \omega, \omega, 0) \quad (53)$$

An alternative to a field-dependent molecular simulation for the description of static field effects is the assumption of a Boltzmann distribution in the field; see Eq. 65 in section “Discrete Reaction Field (DRF) Method.”

Discrete Reaction Field (DRF) Method

The discrete reaction field (DRF) method (Jensen et al. 2003) is based on the model devised by Lorentz to derive the local field in an isotropic liquid. In this model, the liquid is partitioned into two parts. The first part is a sphere around the molecule of interest, which is microscopically large but macroscopically small and in which the

molecules are considered as discrete entities. The second part is the rest of the liquid, which is described as a dielectric continuum with a relative permittivity $\epsilon(\omega)$. If an external electric field is applied to the liquid, the local field acting on the molecule in the center of the sphere (the solute) can be expressed as

$$\underline{F}^{\text{loc}} = \underline{E}^{\text{mac}} + \frac{4\pi}{3} \underline{P} + \underline{F}^{\text{disc}} \quad (54)$$

where the first two terms comprise the macroscopic contribution due to the macroscopic field and the polarization of the sphere and the third term is the discrete contribution from the molecules inside the sphere. Lorentz showed that for randomly distributed nonpolar molecules, this third term is zero. This assumption is certainly not valid any more for polar molecules and has been amended, e.g., by Onsager through the introduction of a reaction field (comp. Eq. 26). The DRF method tries to compute the field more accurately, firstly by performing a molecular simulation of the molecules in the sphere and subsequently by computing the electric properties of the solute in the presence of the total field by a quantum-mechanical DFT computation. In the simulation step, a classical molecular dynamics simulation of the molecules in the sphere is performed, using the discrete reaction field polarizable force field and a soft wall force potential to prevent the molecules from leaving the sphere. A subset of the configurations is kept and subjected to a QM/MM calculation, where the solute is treated quantum-mechanically, with the remaining solvent molecules contributing an electrostatic term to the solute Hamiltonian via partial charges and a polarization term via distributed polarizabilities.

The force field applied in DRF consists of a standard 6-12 Lennard–Jones potential for the repulsion–dispersion interactions, partial charges for the electrostatic component, and distributed polarizabilities for the polarization interaction, taken from the Applequist model with Thole damping. The Applequist model considers the total molecular polarizabilities as emerging from a set of *interacting* atomic polarizabilities. The atomic multipoles create internal fields, which induce multipoles on all other atoms (*atomic self-polarization* is excluded). This model has been developed by Applequist et al. (1972), first for fields and dipole polarizabilities and later for higher-rank fields and polarizabilities. The DRF method uses partial charges and isotropic atomic dipole polarizabilities, although the model can be easily generalized to anisotropic polarizabilities. This model, called the dipole-interaction model (DIM), has also been extended to second hyperpolarizabilities by Jensen et al. (2003). In the DIM, the induced dipole of site k of a molecule subject to an (possibly inhomogeneous) electric field \underline{E} is a sum of two contributions:

$$\mu_{k,\alpha} = \alpha_k \left[E_{k,\alpha} + \sum_{k' \neq k} T_{\alpha k, \beta k'} \mu_{k',\beta} \right], \quad (55)$$

where the first term takes the external electric field into account and the second term considers the effect of the fields arising from induced dipoles from the other sites in

the molecule. Together with the equation $\mu_\alpha^{\text{mol}} = \sum_k \mu_{k,\alpha}$ and the definition of the molecular polarizability $\mu_\alpha^{\text{mol}} = \alpha_{\alpha\beta}^{\text{mol}} E_\beta$, a condition for the α_i can be deduced:

$$\alpha_{\alpha\beta}^{\text{mol}} = \sum_{ij} [\alpha_i^{-1} + T_{ij}]^{-1} \quad (56)$$

In combination with the assumption that the atomic polarizabilities are *transferable* between molecules, the condition of Eq. 56 is sufficient to derive atomic polarizabilities by fitting them to a set of known molecular polarizabilities, either taken from experiment or from high-level ab initio computations. A problem which remains in this description of interacting *polarizable points* is that the electrostatic interaction may grow without bounds with decreasing distance between the points. To circumvent this so-called *polarization catastrophe*, Thole (1981) proposed to replace the interaction between point charges by the interaction of spherically smeared-out charge densities.

One advantage of this interaction model is that it is able to describe the electrostatic interaction of flexible molecules, without a need to reparametrize the atomic polarizabilities. The distributed polarizability model of section “Distributed Multipole and Polarizability Analysis,” on the other hand, would require a new calculation of the distributed properties for each different geometry.

The partial charges and distributed polarizabilities are also used in the QM/MM calculations. The coupling Hamiltonian $\hat{H}_{QM/MM}$ of Eq. 47 is given by

$$\hat{H}_{QM/MM}(r) = \sum_s \left[\frac{q_s}{|r - \underline{R}_s|} + \mu_{s,\alpha}^{\text{ind}} \frac{(r_\alpha - R_{s,\alpha})}{|r - \underline{R}_s|^3} \right], \quad (57)$$

where the summation is over all atoms s of the surrounding solvent molecules. The induced dipoles μ_s^{ind} have to be computed self-consistently via an equation similar to Eq. 55, where the external field \underline{E}_k is replaced in the first step of the self-consistent procedure by the initial field $\underline{F}_s^{\text{init}}$:

$$\underline{F}_s^{\text{init}}(\omega) = \underline{F}_s^{\text{QM}}(\omega) + \delta_{0\omega} \underline{F}_s^{\text{MM}} + \underline{F}_s^{\text{mac}}(\omega) \quad (58)$$

where the first two terms are the fields due to the charge density of the solute and the solvent molecules, respectively, and the last term is the macroscopic field. Due to partial charges and the nonzero charge density of the solute, there will be a nonzero field even in the absence of the macroscopic field term, and in effect, in this case the *solute* properties as defined, e.g., in Eq. 15 will be obtained. If the macroscopic field is included, the DRF implementations will compute instead the *effective* properties of the solute. These are defined in the DRF model via an effective (optical) macroscopic field $\underline{F}^{\text{eff}} = \underline{F}^{\text{mac}} + \frac{4\pi}{3} \underline{P}$, i.e.,

$$\begin{aligned} \mu_\alpha^{\text{ind}}(\omega) &= \alpha_{\alpha\beta}^{\text{eff}}(\omega) F_{\beta,k}^{\text{eff}}(\omega) + K_{12}^{(2)} \frac{1}{2} \beta_{\alpha\beta\gamma}^{\text{eff}}(-\omega; \omega_1, \omega_2) F_\beta^{\text{eff}}(\omega_1) F_\gamma^{\text{eff}}(\omega_2) + \\ &K_{123}^{(3)} \frac{1}{6} \gamma_{\alpha\beta\gamma\delta}^{\text{eff}}(-\omega; \omega_1, \omega_2, \omega_3) F_\beta^{\text{eff}}(\omega_1) F_\gamma^{\text{eff}}(\omega_2) F_\delta^{\text{eff}}(\omega_3) \dots \end{aligned} \quad (59)$$

The macroscopic susceptibilities in the DRF method are finally obtained by multiplication of the effective properties with the cavity-field factors $L(\omega)$ for optical frequencies ω , e.g., for the linear and THG effects by

$$\chi_{ZZ}^{(1)}(\omega) = NL(\omega) \langle \alpha_{\alpha\beta}^{\text{eff}}(\omega) \rangle_{ZZ} \quad (60)$$

$$= N \frac{\langle \alpha_{\alpha\beta}^{\text{eff}}(\omega) \rangle_{ZZ}}{1 - \frac{4\pi}{3} \langle \alpha_{\alpha\beta}^{\text{eff}}(\omega) \rangle_{ZZ}} = N \frac{\bar{\alpha}^{\text{eff}}(\omega)}{1 - \frac{4\pi}{3} \bar{\alpha}^{\text{eff}}(\omega)} \quad (61)$$

$$\chi_{ZZZZ}^{(3)}(-3\omega; \omega, \omega, \omega) = \frac{N}{6} L(3\omega) L^3(\omega) \langle \gamma_{\alpha\beta\gamma\delta}^{\text{eff}}(-3\omega; \omega, \omega, \omega) \rangle_{ZZZZ} \quad (62)$$

$$= \frac{N}{6} L(3\omega) L^3(\omega) \bar{\gamma}_{||}^{\text{eff}}(-3\omega; \omega, \omega, \omega) \quad (63)$$

where $\bar{\alpha}^{\text{eff}} = \sum_{\alpha} \alpha_{\alpha\alpha}^{\text{eff}}$ and $\bar{\gamma}_{||}^{\text{eff}} = \frac{1}{15} \sum_{\alpha\beta} (\gamma_{\alpha\alpha\beta\beta}^{\text{eff}} + \gamma_{\alpha\beta\alpha\beta}^{\text{eff}} + \gamma_{\beta\beta\alpha\alpha}^{\text{eff}})$ are the orientationally averaged effective polarizability and second hyperpolarizability, respectively. Equation 60 defines the cavity field factor $L(\omega)$ in the model and shows how it may be computed in DRF. In the case of a *static* field component, however, the cavity field factors are computed via the Onsager equation:

$$L(0) = \frac{\epsilon(0)(2 + n^2(0))}{2\epsilon(0) + n^2(0)}, \quad (64)$$

where $\epsilon(0)$ and $n(0)$ are the linear dielectric constant and the refractive index, respectively, at zero frequency. The computation of $\epsilon(0)$ by simulation methods is quite cumbersome and is thus usually taken from experiment in the DRF model. On the other hand, $n(0)$ can be obtained via $n(0) = \sqrt{1 + 4\pi\chi_{ZZ}^{(1)}(\omega)}$.

In the same spirit, the EFISH effect $\chi_{ZZZZ}^{(3)}(-2\omega; \omega, \omega, 0)$, which contains a static field component, is not computed via a molecular simulation with applied fields. As mentioned above, an alternative is the assumption of a Boltzmann distribution in the field and an expansion of the exponential terms, assuming that the field effect is small compared to kT (Reis et al. 2006). Then,

$$\chi_{ZZZZ}^{(3)}(-2\omega; \omega, \omega, 0) = \frac{N}{6} L(2\omega) L^2(\omega) L(0) \langle \gamma^{\text{eff}}(-2\omega; \omega, \omega, 0) \rangle_{ZZZZ} \quad (65)$$

$$= \frac{N}{6} L(2\omega) L^2(\omega) L(0) \left(\bar{\gamma}_{||}^{\text{eff}}(-2\omega; \omega, \omega, 0) + \frac{\underline{\mu}^{\text{sol}} \cdot \underline{\beta}^{\text{eff}}(-2\omega; \omega, \omega)}{3kT} \right) \quad (66)$$

where $\underline{\beta}^{\text{eff}}$ is the *vectorial part* of the averaged effective first hyperpolarizability, with components $\beta_i = \frac{1}{3} \sum_{j=1}^3 \beta_{ijj} + \beta_{jij} + \beta_{jji}$. Instead of $\underline{\beta}$ one often encounters the quantity $\beta_{||} = \frac{3}{5} \underline{\beta}$.

As mentioned in section “Definition of Macroscopic and Microscopic Quantities,” other authors define effective properties via the macroscopic field $\underline{F}^{\text{mac}}$, e.g., Wortmann and Bishop (1998) and Cammi et al. (2000), instead of the effective macroscopic field (which, incidentally, is just the local field of the Lorentz model).

Polarizable Embedding (PE)

The polarizable embedding (PE) (Olsen and Kongsted 2011) is a quite general method for the calculation of molecular properties in liquids. It is a QM/MM method with a separate simulation step, which creates a set of configurations. Molecular dynamics with classical, polarizable, or nonpolarizable force fields are usually applied for this step. Selected configurations are then subjected to the QM/MM calculation, using response theory to compute the property of interest of the solute molecule at the QM level self-consistently in the polarization field of the surrounding solvent molecules, described by MM. A unique feature of PE is that it allows to employ different levels of theory at the QM step, including Hartree–Fock (HF) and DFT (Olsen et al. 2010), MP2 and the second-order polarization propagator approximation (SOPPA) (Eriksen et al. 2012), multiconfigurational SCF (MCSCF) (Hedegård et al. 2013), and several coupled-cluster levels (Sneskov et al. 2011), although not all levels were already implemented for each property

at the time of writing. It also allows a large variety of molecular properties to be computed, e.g., nonlinear optical properties, one- and two-photon absorption spectra, NMR properties, etc. PE is implemented in the program packages Dalton (2015) and TURBOMOLE (<http://www.turbomole.com>). The description below is mainly based on the implementation of PE in Dalton (2015). The implementation in TURBOMOLE differs mainly by the possibility to use the resolution of identity (RI) in conjunction with the CC2 method for the description of ground and excited electric-state properties (PERI-CC2), unfortunately, however, not for (hyper)polarizabilities. In Dalton, singlet linear response is implemented for HF, DFT, SOPPA, MCSCF, CC2, and CCSD for closed-shell systems and for HF and DFT for open-shell systems. Singlet quadratic response is implemented for HF and DFT for closed-shell systems. Using finite field techniques, partially static (hyper)polarizabilities are also available.

As the molecular simulation and the QM/MM calculation are separated, any kind of simulations may be used, and we will only remark here on some points connected with the QM/MM step as implemented in the Dalton program package.

The total Hamiltonian is partitioned according to Eq. 47, with the interaction term $\hat{H}_{QM/MM}$ defined as

$$\hat{H}_{QM/MM} = \hat{H}^{\text{es}} + \hat{H}^{\text{pol}} + \hat{H}^{\text{vdW}} \quad (67)$$

where \hat{H}^{es} is the electrostatic interaction between the solute (treated by QM) and the multipole moments of the solvent molecules (the MM part). The latter may be, e.g., just point charges or permanent multipole moments, either molecular or distributed. The induction term \hat{H}^{pol} may be written as

$$\hat{H}^{\text{pol}} = -\frac{1}{2} \sum_a \underline{\mu}_a^{\text{ind}} \cdot \underline{F}^{QM}(\underline{r}_a) \quad (68)$$

where the summation runs over all MM molecules, $F^{QM}(\underline{r}_a)$ is the electric field at a MM molecule due to the solute molecule (electrons and nuclei), and $\underline{\mu}_a^{\text{ind}}$ is the induced dipole moment of the MM molecule a , given in linear approximation by

$$\underline{\mu}_a^{\text{ind}} = \underline{\alpha}_a \cdot \underline{E}_a^{\text{total}} \quad (69)$$

where $\underline{\alpha}_a$ is the dipole–dipole polarizability of the MM molecule a and $\underline{E}_a^{\text{total}}$ is the total electric field on a , due to the solute and the permanent and induced moments of the MM molecules. Thus, this field, as well as the field $\underline{F}^{QM}(\underline{r}_a)$ in Eq. 68, depends in turn on $\underline{\mu}_a^{\text{ind}}$. The set of coupled equations require thus either an iterative solution or an analytical inversion of the full matrix equation. This has to be repeated for each step of the wave function optimization.

Although only dipole–dipole polarizabilities are taken into account, they may be distributed over the molecules in the form of *localized* polarizabilities (i.e., without intermolecular polarizabilities (Misquitta 2015)).

Finally, the term \hat{H}^{vdW} takes into account dispersion and short-range repulsion using a 6-12 Lennard–Jones potential, which depends only on the position of nuclei.

By combining Eqs. 47 and 67, 68, and 69, the equations to solve for the quantum-mechanical method considered, i.e., CC, DFT, etc., can be finally set up. It turns out that the equations are quite similar to the vacuum case, extended by some additional terms considering the new QM/MM interactions. A point to note is that the whole system of equations is solved to self-consistency. With the optimized wave function thus obtained, first-order properties of the solute molecule can then be computed. For higher-order properties, response theory is applied in conjunction with the QM method considered. This leads again to certain modifications of the corresponding vacuum equations. For details we refer to the literature in Nielsen et al. (2007), Osted et al. (2006), and references therein.

We note that the QM/MM step is usually performed on a cluster of the solute embedded in solvent molecules, which is extracted from the larger simulation box of the classical molecular dynamics or Monte Carlo calculation. The size of the cluster is varied until the properties of interest are converged with respect to cluster size, which may require different sizes depending on the property considered. With the converged cluster size determined, clusters of similar size are then extracted from a sufficiently large number of snapshots from the simulation trajectory and their properties computed with the QM/MM method and averaged to yield the final simulated value for the solution. The properties extracted in this way are therefore *solute* properties in the definition of Wortmann and Bishop (1998). Effective properties and thus also susceptibilities are computed by multiplying the solute properties with the corresponding cavity field factors obtained in the Lorentz model, usually computed using the polarizabilities computed within the PE model, thus only assuming that the form of the cavity field factors is appropriate.

Frozen-Density Embedding (FDE)

A weak point of the QM/MM models described so far is that the MM description of the solvent environment and solute–solvent interactions relies in a large extent on the predominantly electrostatic nature of these interactions. Although this assumption is valid in many cases, it can be expected that QM effects such as the exchange repulsion and dispersion interactions can play an important role especially in the inner solvent shell and these effects are either neglected or modeled only indirectly in an empirical way in the QM/MM approach. A careful parameterization of the force field (FF) used in the MM part can in some cases yield more accurate results than large-scale DFT calculations, but it is unclear if the given FF parameterization is generally applicable. Moreover, the role of particular interaction contributions in the description of the interaction energy and interaction-induced properties is not the same (see section “Interaction-Induced Properties”), and thus the good performance of a selected FF does not automatically guarantee its applicability to molecular property calculations.

As a compromise between the full QM treatment based on supermolecular calculations and combined QM/MM models, Wesolowski and Warshel (1993) proposed an alternative scheme within the DFT framework, in which the frozen electron density of the solvent is used to construct an embedding potential that enters the Hamiltonian in the calculation of the solute properties. In this so-called *frozen-density embedding* (FDE) scheme, both subsystems (solute and solvent) are treated at a QM level (not necessarily the same), but the electron density of the subsystems are determined separately, so the full calculation for the supersystem is avoided. This makes the QM calculations feasible for a solute molecule surrounded by physically reasonable number of solvent molecules.

The FDE variants can be classified according to (i) the degree of allowed relaxation of subsystem electron densities, (ii) the QM levels used to describe the solute and the solvent, and (iii) the approximation of nonadditive kinetic energy functional (see further). In the simplest model, the solvent electron density is kept frozen in the molecular (response) property calculation within a limited orbital space of the solute. The solvent embedding potential can be calculated at a low QM level or even constructed from the sum of the electron densities of isolated solvent molecules by using the sum-of-molecular-fragments approach (Neugebauer et al. 2005). This approximated electron density of the environment can be improved by including the relaxation effects through so-called *freeze-and-thaw* cycles (Wesolowski and Weber 1993), in which the roles of the frozen and nonfrozen systems are interchanged. Depending on the size and character of the system (e.g., the presence of the hydrogen bonds), one can decide for a full (i.e., reaching the self-consistency) or partial relaxation schemes. In the latter case, a typical choice is to update the solvent electron density in two freeze-and-thaw cycles. Obviously, the described approximations can be combined to achieve a reasonable compromise between the accuracy and computational demands. For example, it can appear useful to split the solvent environment into inner and outer

shells and to treat the former by the freeze-and-thaw strategy while for the latter one can use the sum-of-molecular-fragments density (Jacob et al. 2006). In addition, different DFT levels can be used for the solute molecule and inner and outer solvent shells, respectively. In the following we briefly summarize basic features of the FDE approach, and we put them in the context of molecular property calculations.

As already mentioned, in the FDE formalism, the total electron density (ρ_{tot}) of the cluster is split into two (or more) parts – the electron density of the solute (ρ_A) and that of the solvent (ρ_B):

$$\rho_{\text{tot}}(\underline{r}) = \rho_A(\underline{r}) + \rho_B(\underline{r}) \quad (70)$$

Under the assumption that the electron density ρ_B of the solvent is known and kept frozen, ρ_A can be obtained by minimizing the energy of the total system $E[\rho_{\text{tot}}]$. Following the idea of the Kohn–Sham (KS) method, ρ_A can be expressed in terms of KS orbitals (for a closed-shell solute molecule containing N_A electrons):

$$\rho_A(\underline{r}) = 2 \sum_{i=1}^{N_A/2} \phi_i^*(\underline{r})\phi_i(\underline{r}) \quad (71)$$

which can be determined through KS-like equations in which the effect of the frozen solvent electron density is included by an embedding term in the effective potential for ρ_A (in a.u.):

$$\left[-\frac{\nabla^2}{2} + V_{\text{eff}}^{\text{KS}}[\rho_A](\underline{r}) + V_{\text{eff}}^{\text{emb}}[\rho_A, \rho_B](\underline{r}) \right] \phi_i(\underline{r}) = \epsilon_i \phi_i(\underline{r}) \quad i = 1, 2, \dots, N_A/2 \quad (72)$$

where $V_{\text{eff}}^{\text{KS}}$ is the effective KS potential of the isolated solute. The embedding potential $V_{\text{eff}}^{\text{emb}}[\rho_A, \rho_B]$ can be written as

$$\begin{aligned} V_{\text{eff}}^{\text{emb}}[\rho_A, \rho_B](\underline{r}) &= v_B(\underline{r}) + \int \frac{\rho_B(\underline{r}')}{|\underline{r} - \underline{r}'|} d\underline{r}' + V_{\text{XC}}[\rho_A + \rho_B](\underline{r}) \\ &\quad - V_{\text{XC}}[\rho_A](\underline{r}) + \frac{\partial T_s^{\text{nadd}}[\rho_A, \rho_B]}{\partial \rho_A(\underline{r})} \end{aligned} \quad (73)$$

with $v_B(\underline{r})$ being the field of clamped nuclei in the subsystem B (solvent) and V_{xc} is the exchange-correlation potential. The last term in Eq. 73 is the functional derivative of the nonadditive kinetic energy functional, which is defined by the following decomposition of the total kinetic energy:

$$T_s^{\text{nadd}}[\rho_A, \rho_B] = T_s[\rho_A, \rho_B] - T_s[\rho_A] - T_s[\rho_B] \quad (74)$$

Although this scheme is exact in the exact functional limit, in practical calculations, an approximate density-dependent functional is used for the nonadditive kinetic energy functional and its functional derivative. It was shown by Casida and

Wesołowski (2004) that the FDE strategy can be combined with the time-dependent response theory, and thus it can also be applied in molecular property calculations within the TDDFT framework. If we assume that the response to an external electromagnetic field is localized to the embedded system (solute), i.e., that the response of the frozen environment (solvent) can be neglected, one can obtain solute (hyper)polarizabilities by solving the conventional TDDFT response equations with the kernel modified by adding an effective embedding contribution, which is evaluated for the ground-state density of the solvent. In consistency with conventional TDDFT, in which the adiabatic local density approximation (ALDA) is applied for the kernel, the embedding contribution containing the nonadditive kinetic energy functional derivative is also approximated by using the Thomas–Fermi density-dependent functional. Let us note that using the ALDA approximation in linear response property calculations can lead to slight discrepancies when compared to finite field property calculations.

Using the described TDDFT/FDE approach, Jacob et al. (2006) evaluated the mean polarizability and its anisotropy for a water molecule surrounded by 127 water molecules. They have shown that FDE predicts a decrease of $\bar{\alpha}$ in solution by about 7% compared to the isolated molecule, which was in contradiction with the DRF approach predicting even a slight increase of this quantity. This qualitative disagreement was explained in terms of different consideration of the short-range (mainly exchange repulsion) and polarization effects in the two approaches. In DRF, the direct solvent effect on the HOMO–LUMO gap (leading to the decrease of $\bar{\alpha}$) is overcompensated by the response of the solvent to the polarization of the solvated molecule. This response stabilizes the polarized molecule and therefore causes an increase in the solute polarizability. On the other hand, in the TDDFT/FDE calculations, the polarization of the solvent is neglected, while the hydrogen bonding and Pauli repulsion are accounted for, which naturally results in the decrease of $\bar{\alpha}$. In order to include the solvent polarization effects in the FDE calculations, Jacob et al. (2006) proposed to calculate the static polarizabilities by the ND-FF method from the change of the dipole moment due to an external electric field. Since the electron density is split in FDE, the ND-FF/FDE approach enables to control whether the external field directly affects only the solute molecule (solvent molecules are then affected only indirectly through their response to the polarization of the solute) or the field is imposed on the whole cluster. While the former method leads to the solute properties, the latter enables to determine effective properties.

Distributed Multipole Moments and (Hyper)polarizabilities

As mentioned in section “Definition of Macroscopic and Microscopic Quantities,” a converged description of the reaction field acting on a solute may require high-order multipoles as well as reaction field gradients in the one-point multipole description. This is especially problematic for large or nonspherical solutes as discussed by Misquitta (2015) in this handbook. A solution for this problem is to use several points for the multipole expansions, i.e., to distribute the multipole moments and

(hyper)polarizabilities in some way over the molecules. There have been several distribution schemes developed, all with their own advantages and disadvantages (see, e.g., Stone 2013, Chs. 7 and 9). Some of them have already been mentioned in previous subsections. Below we describe two approaches, which have been previously employed for the calculation of macroscopic susceptibilities, although not yet for liquids, and/or which are implemented in generally available program packages.

Distributed Multipole and Polarizability Analysis

The distributed multipole analysis (DMA) by Stone is available in several program packages, such as GDMA (<http://www-stone.ch.cam.ac.uk/pub/gdma/index.php>), and others. A fully distributed polarizability approach has been developed by Stone and Misquitta, and it is implemented in the program package CamCASP (Misquitta and Stone 2007). Both approaches are also described in Misquitta (2015). Unfortunately, this approach has not been extended to hyperpolarizabilities. Fully distributed (first) hyperpolarizabilities have been implemented using the Atoms-in-Molecules (AIM) approach by Bader (Reis et al. 2000), but this approach is not implemented in any publicly available program package. Distributed polarizabilities using the AIM approach have been computed and employed in interaction studies of dimers, but again no generally available implementation is known to us. For details of computations of distributed electric properties, see Stone (2013); here, we only point out the consequences of using a distributed scheme for the calculation of macroscopic susceptibilities.

In a fully distributed model, the charge density of a molecule is partitioned according to some scheme over several sites, which may be atoms, small groups of bonded atoms, or some other sites not coinciding with any nucleus, e.g., the middle of a bond or a nonnuclear attractor. This scheme may be based on real-space partitioning, as in the case of AIM, or based on properties of Gaussian functions used to describe the wave function in the case of DMA. The partitioning will assign to each site t a charge q_t , a dipole μ_t , and higher multipoles. In an external field, each site t of the molecule will develop on-site polarizabilities α_{tt}^{ab} , i.e., charge–charge ($a = b = 0$), charge–dipole ($a = 0, b = 1$ or $a = 1, b = 0$), and dipole–dipole ($a = b = 1$) polarizabilities, if we restrict ourselves to the dipole approximation. In addition there will be site–site polarizabilities α_{tu}^{ab} , which describe the change of multipole a at site t due to the b -th derivative of the potential at site u (or vice versa). As the potentials on each site do not need to be equal among the sites, this description allows the treatment of inhomogeneous fields in a natural way, even for extended molecules.

In order to describe the permanent local field in terms of distributed properties, we need to introduce the potential $\Phi_{tk}^{(0)}$ and the local field $F_{tk}^{(0)} = -\nabla\Phi_{tk}^{(0)}$ at a point in site t of a molecule k . Then, the set of equations determining the permanent local field in the distributed treatment which correspond to Eqs. 14 and 15 in the one-point expansion can be written as

$$-\Phi_{tk}^{(0)} = \sum_{l \neq k} \sum_{u \in l} \left[T_{tk;ul}^{00} q_{ul} + T_{tk;\beta ul}^{01} \mu_{\beta u,l} + \dots \right] \quad (75)$$

$$F_{\alpha tk}^{(0)} = \sum_{l \neq k} \sum_{u \in l} \left[T_{\alpha tk;ul}^{10} q_{ul} + T_{\alpha tk;\beta ul}^{11} \mu_{\beta u,l} + \dots \right] \quad (76)$$

and

$$q_{tk} = q_{tk}^{(0)} + \sum_{u \in k} \left[-\alpha_{tu,k}^{00} \Phi_{uk}^{(0)} + \alpha_{t\alpha u,k}^{01} F_{\alpha u,k}^{(0)} + \dots \right] \quad (77)$$

$$\mu_{\alpha t,k} = \mu_{\alpha t,k}^{(0)} + \sum_{u \in k} \left[-\alpha_{\alpha tu,k}^{10} \Phi_{uk}^{(0)} + \alpha_{\alpha t\beta u,k}^{11} F_{\beta u,k}^{(0)} + \dots \right] \quad (78)$$

The distribution model can be extended beyond polarizabilities, which leads first to distributed first hyperpolarizabilities β_{tuv}^{abc} , describing the change of multipole a at site t due to the simultaneous application of the b -th order derivative of the potential at site u and the c -th order derivative of the potential at site v . Up to $a = b = c = 1$, there are already eight tensors, although not all of them are different, because it is, e.g., $\beta_{tuv}^{100} = \beta_{utv}^{010} = \beta_{vut}^{001}$. A similar symmetry relation holds for α_{uv}^{ab} . Nevertheless, the number of nonzero values of fully distributed (hyper)polarizabilities can be quite large, and several localization methods have been devised to reduce the number of values, e.g., for interpretational purposes. For the computation of susceptibilities, such a localization does not seem to be necessary.

The molecular (hyper)polarizabilities can be reconstructed from the corresponding distributed properties, e.g., for the (dipole–dipole) polarizability α and (dipole–dipole–dipole) hyperpolarizability β :

$$\alpha_{\alpha\beta} = \sum_{tu} \left[r_{\alpha t} r_{\beta u} \alpha_{tu}^{00} + r_{\alpha t} \alpha_{t\beta u}^{01} + r_{\beta u} \alpha_{\alpha t u}^{10} + \alpha_{\alpha t \beta u}^{11} \right] \quad (79)$$

$$\beta_{\alpha\beta\gamma} = \sum_{tuv} \left[r_{\alpha t} r_{\beta u} r_{\gamma v} \beta_{tuv}^{000} + r_{\alpha t} r_{\beta u} \beta_{tu\gamma v}^{001} + r_{\alpha t} r_{\gamma v} \beta_{t\beta uv}^{010} + r_{\beta u} r_{\gamma v} \beta_{\alpha t uv}^{100} \right. \\ \left. + r_{\alpha t} \beta_{t\beta u\gamma v}^{011} + r_{\gamma v} \beta_{\alpha t \beta uv}^{110} + r_{\beta u} \beta_{\alpha t u\gamma v}^{101} + \beta_{\alpha t \gamma u\gamma v}^{111} \right] \quad (80)$$

where $r_{\alpha t}$ is the α component of the vector from the molecular origin to the atom t .

Distributed (hyper)polarizabilities have been used to compute the linear and first nonlinear susceptibility of the urea crystal (Reis et al. 2000), but not yet of liquids. For the use of distributed electric properties in dimers and other small clusters see, e.g., Misquitta (2015).

The Local Properties (LoProp) Approach

The LoProp approach was designed to yield a computationally simple method for the partitioning of multipolar moments and polarizabilities while still avoiding the problem of basis set sensitivity which plagues cheaper methods such as Mulliken

or Löwdin partitioning schemes (Gagliardi et al. 2004). It works essentially by first separating the atomic orbitals (the basis set) into subsets of occupied and unoccupied orbitals. This means that core and valence orbitals of the atoms in the system should be well described by the basis set applied, which is usually the case, if, e.g., atomic natural orbital basis sets (ANOs) are used. Other basis sets may need reconstructions to meet this requirement; see Gagliardi et al. (2004) for more details.

In the second step, the overlap matrix is diagonalized in a series of four transformations, while still maintaining the division into occupied and unoccupied subspaces. With the total transformation matrix determined, it is then possible to *localize* multipole moments to atomic centers and bonds between two centers. The molecular dipole moment $\underline{\mu}$ with respect to the point \underline{r}_0 can be expressed by

$$\underline{\mu}_{\underline{r}_0} = \sum_{ij} \underline{\mu}^{(ij)} + \sum_i q^{(i)}(\underline{r}^{(i)} - \underline{r}_0) \quad (81)$$

where i, j are the atomic centers localized at $\underline{r}_i, \underline{r}_j$, $q^{(i)}$ are the localized charges, and $\underline{\mu}^{(ii)}$ and $\underline{\mu}^{(ij)}$ are localized one-center and bond dipole moments, respectively. Due to construction, no bond charges $q^{(ij)}$ occur.

The computation of localized polarizabilities proceeds via the definition of the polarizability as change of the dipole moment in an applied field:

$$\alpha_{\alpha\beta} = \frac{\partial \mu_\alpha}{\partial F_\beta} = \frac{\partial \mu_\beta}{\partial F_\alpha} \quad (82)$$

In addition, *charge transfer* quantities Q^{ij} between two centers due to the applied field are introduced. The definition of Q^{ij} is not unique, and to determine them, they are *required* to be as small as possible as well as short ranged. Using a penalty function to satisfy these requirements, a Lagrangian is set up, which can easily be solved to yield the $Q^{(ij)}$. Finally, the localized polarizabilities are computed from a numerical finite field difference equation:

$$\alpha_{\alpha\beta}^{(ij)} = \frac{\mu_\alpha^{(ij)}(F_\beta) - \mu_\alpha^{(ij)}(-F_\beta)}{F_\beta} + \frac{[Q^{(ij)}(F_\beta) - Q^{(ij)}(-F_\beta)][r_\alpha^{(i)} - r_\alpha^{(j)}]}{2F_\beta} \quad (83)$$

where \underline{F} is the applied field and $P(\pm F_\alpha)$ is the property P in the field $\pm F_\alpha$. These localized polarizabilities are origin independent.

The LoProp scheme has been implemented in the MOLCAS 6.0 software (Molcas 6.0 2003). Unfortunately, it has not been extended to hyperpolarizabilities yet. Finally it is worth noting that LoProp polarizabilities are *localized* properties, not fully *distributed* ones in the sense used in section Distributed Multipole and Polarizability Analysis. One should also mention that LoProp polarizabilities have been shown to be transferable in a couple of series of homologues (Gagliardi et al.

2004), although more extensive tests are required to establish the validity and limits of this property more accurately.

Two Case Studies: Liquid Water and *p*-Nitroaniline in 1,4-Dioxane

In this final section we compare the results of several of the described methods for the linear and nonlinear susceptibilities of two specific systems, namely, liquid water (i.e., a “solution” of water in water) and *p*-nitroaniline in 1,4-dioxane. Especially the latter case is a warning example for many points which one needs to consider when theoretical NLO results are compared with experimental values. Both are systems with strong and specific intermolecular interactions, which are a challenge for a reliable treatment and can thus serve as a probe for the strengths and weaknesses of the specific method used. We emphasize, however, that the results collected here have not been computed under strictly comparable conditions, i.e., using the same basis sets, level of calculation, box sizes, etc. This will certainly lead to some differences for the results and should be kept in mind in the comparisons below.

Water

Liquid water is a difficult system for computational modeling in general and for the prediction of electric properties in particular. The presence of an extended and dynamic network of strong hydrogen bonds represents a serious difficulty for dielectric continuum models as well as for explicit models using molecular mechanics force fields for structure predictions. In particular, the reliable prediction of the molecular first hyperpolarizability in liquid water is a challenge for any model. Experimentally, it was found that $\beta(-2\omega, \omega, \omega)$ undergoes a change of $\sim 200\%$ from the gas phase to the liquid, involving a change of sign (Levine and Bethea 1976; Kaatz et al. 1998). Consequently, nearly all models tried their hand on this interesting system: the multipole expansion (MPE) method (Mikkelsen et al. 1995), DRF (Jensen et al. 2005), PE-CCSD (Osted et al. 2006), PE-DFT (Nielsen et al. 2007), and RLF (Reis et al. 2001). A selection of predicted values for some electric properties of isolated and solvated water is shown in Table 3, where we also include static values obtained with PCM using the CCSD/d-aug-cc-pVTZ level computed for this work.

Mikkelsen et al. (1995) compared results for $\beta(-\omega, \omega, 0)$ of the isolated molecule with those obtained for a cluster with five molecules (SM), the MPE model, and the combined SM+MPE model. They found that at the RHF level the MPE model does not reproduce the change of sign, the SM approach qualitatively reveals this change, and finally their combination yields a value at an order of magnitude comparable with experiment. Although the computed property $\beta(-\omega, \omega, 0)$ corresponds to the dc-Pockels effect, Ågren et al. (2004) subsequently confirmed their conclusions also for $\beta(-2\omega, \omega, \omega)$. Later work, using larger basis sets, more

^aEffective property

advanced methods, and refined solvation approaches, e.g., using nonequilibrium solvation, did not change the main finding that the single-molecule continuum approach does not yield a change of sign for β in liquid water. However, Kongsted et al. (2003) showed that the MPE model, using CC2 and CCSD in combination with large diffuse basis sets, is able to predict the sign change for water, which they rationalize in terms of large charge penetration effects. In contrast, our values show that PCM is not able to reproduce the large changes of β upon solvation, even at the CCSD/d-aug-cc-pVTZ level.

Kongsted et al. (2003) also applied a QM/MM method, using an averaging procedure over the simulated trajectory to produce a mean configuration on which the QM calculation was performed. In this way, they were also able to predict the sign change. In addition, they showed that a qualitatively correct result can only be obtained if the MM part is *polarizable*. In a continuation of this work, Osted et al. (2006) applied the PE model at the CCSD/MM level and analyzed the results statistically. Although great effort was expended to obtain converged procedures, the agreement for the EFISH value with experiment was again only qualitative. Later work using the PE method with DFT instead of CCSD were in good agreement with the PE/CCSD/MM values (Nielsen et al. 2007). An application of the explicit DRF model to liquid water was reported in Jensen et al. (2005), where the sign change could also be predicted, although the final value was again only in qualitative agreement with experiment. Similarly, the RLF model is able to reproduce the large changes of β upon solvation, without, however, better agreement with experiment (Reis et al. 2001).

To summarize, although in general the explicit models yield better predictions compared with experiment than the continuum models, none of the methods is able to predict the experimental EFISH value quantitatively. One possible explanation is that all methods used the equation obtained by thermal averaging over the dipole orientations, i.e., Eq. 65, instead of modeling the orientational effect directly (Jensen

et al. 2005). Another possible explanation, of course, is that the single experimental value available may not be accurate.

It should be mentioned finally that nearly all methods are able to predict the linear optical effects, i.e., the refractive index $n(\omega)$ in good agreement with experiment.

EFISH of *p*-Nitroaniline in 1,4-Dioxane

Para-nitroaniline is a typical donor–acceptor compound with a quite large first hyperpolarizability and has been studied extensively both experimentally and theoretically. Many experimental studies were performed in the solvent 1,4-dioxane, which has long been known to show unusual dielectric properties: although the relative permittivity is with $\epsilon = 2.209$ that of a typical nonpolar solvent, it behaves like a medium polar solvent, e.g., in solvatochromic shift measurements. Several studies have shown that this is probably due to a large quadrupolar moment of the molecule (Geerlings et al. 2000; Cinacchi et al. 2006; Reis et al. 2006). Thus, this solvent could be a challenge for continuum models, which rely only on dipolar properties of the solvent, i.e., the relative permittivity ϵ and/or the refractive indices $n(\omega)$. Nevertheless, in several applications of continuum models on the EFISH signal of pNA in 1,4-dioxane, it was claimed that good agreement with experimental values has been found. As shown in Reis (2006), this is probably erroneous in most cases due to a mixture of several factors, among which we mention:

1. The correct conversion factor for many of the experimental values of β to the convention used here is 4. In a landmark paper (Willets et al. 1992), which was often used for the conversion of experimental to theoretical values, this factor was incorrectly given as 6. Several authors considered this factor correctly as too large and applied instead the (incorrect) factor of two (Jensen and van Duijnen 2005).
2. The experimental calibration factor for EFISH is based on the SHG value of quartz and has changed considerably over the years. The currently accepted value is about 60 % of the previously used value. Accordingly, this leads to some confusion in the choice of values with which to compare the theoretical results (Mikkelsen et al. 1994).
3. An experimental calibration factor independent of quartz was determined by Shelton, using the Hyper-Rayleigh scattering (HRS) signal of liquid CCl_4 . However, this calibration factor was later revised to a value which is a factor of 1.88 larger (Pyatt and Shelton 2001). The first factor applied to the experimental HRS signal of pNA/1,4-dioxane yields a value close to that of the EFISH-signal, if for the latter the (incorrect) conversion factor of 2 is applied (Jensen and van Duijnen 2005). The revised factor brings the HRS signal in good agreement with the EFISH values, using the correct factor of 4 (Reis 2006).

In Table 4, we compare some theoretical values reported in the literature with updated experimental values from different sources. As expected, the continuum

models in general yield values which are too low. Nevertheless, the depolarization ratio of certain components of β , which can be obtained from Hyper-Rayleigh scattering experiments and are independent of the absolute values, could be predicted quite well by the MPE approach (Norman et al. 1997). In addition, DFT does not appear to be a good choice for pNA at all, even if long-range corrected functionals like CAM-B3LYP are used, as not even the gas phase is predicted reasonable well (Benassi et al. 2015). A similar failure of CAM-B3LYP has also been found in a related study using the PE approach on the excited states of pNA dissolved in water (Eriksen et al. 2013).

The two explicit models DRF and RLF use instead a molecular charge distribution for 1,4-dioxane, either using point charges (DRF) or quadrupole and higher multipole moments (RLF). As a consequence, they are in much better agreement with experiment (note that for DRF, the effective hyperpolarizability should be compared with the experimental β_z^{sol}). Nevertheless, the gas-phase value for β_z used for DRF is much too high, which probably again is a DFT/TDDFT issue, and may throw some doubt on the good value obtained for the solution. The RLF approach yields values for β_z , which are in reasonable agreement both for the gas and solvated phases, although the quantum-mechanical approach used in that work (MP2 scaled with RPA or CC2 dispersion) is already a bit outdated. Unfortunately, no values using any of the more modern approaches PE or FDE are available.

Abstract

The working equations of auxiliary density functional theory (ADFT) and auxiliary density perturbation theory (ADPT) are derived in the framework of the linear combination of Gaussian-type orbital expansion. The inclusion of hybrid functionals into ADFT is presented. Its extension for the calculation of magnetic properties is outlined. The ADFT and ADPT implementations in the density functional theory program deMon2k are discussed. Special attention is given to the efficient calculation of electron repulsion integrals in nanostructures. The use of ADFT and ADPT in first-principles Born-Oppenheimer molecular dynamics at the pico- to nanosecond time scale is reviewed. In particular, the long-standing mystery of the discrepancy between experiments and computations for the polarizability of small sodium clusters is resolved. Applications of the parallel deMon2k ADFT implementation to systems on the nanometer scale are reviewed. This includes Al-zeolites and giant fullerenes. It is shown that structures as large as C₅₄₀ can be fully optimized within a few days without any symmetry constraints in the ADFT framework employing all-electron basis sets. The successful application of a hierarchical transition state finder for the study of selected sodium cluster rearrangements is presented, too.

Introduction

Within the broad spectrum of computational methods included in this Handbook of Computational Chemistry, the present chapter will focus on auxiliary density functional theory (ADFT) (Köster et al. 2004b) as implemented in the software package deMon, the most recent version of which is known as deMon2k (Köster et al. 2011a; Geudtner et al. 2011).

Density functional theory (DFT) has shown solid progress since its formal beginnings in the theorems of Hohenberg and Kohn (1964) and Kohn and Sham (1965) and its even older roots dating back to the early work of Thomas and Fermi (Thomas 1927; Fermi 1927, 1928a,b), Slater (1951), and others (Gaspar 1954; Schwarz 1972). Our deMon program, too, has a significant track record of steady improvement over the years.

Looking back to the 1960s and early seventies, the most popular DFT method was the X α -scattered wave (SW) method of Slater and Johnson (Johnson 1966; Johnson and Smith 1970). This method, with its unsightly muffin-tin potential, was the trailblazer for DFT in molecular applications. It had good success for the

spectroscopy of inorganic complexes, including those containing transition metals (Johnson and Smith 1971, 1972; Johnson and Messmer 1974; Messmer et al. 1975, 1978; Weber et al. 1977; Salahub 1978). But the lack of a full potential prevented the SW technique from performing even such simple tasks as geometry optimizations which, at the time, were coming under control by the usual wavefunction-based methods of quantum chemistry, at least for simple molecules. Hence $X\alpha$ -SW remained a rather specialized fringe methodology, which was either ignored or scorned by mainstream quantum chemists.

The seventies and early eighties saw work that changed all of that. A few “ab initio quantum chemists” got interested in DFT and slowly but surely brought over some of the methodology and techniques that would allow a broader and broader base of functionality for DFT codes. This was the case for the earliest versions of deMon (St-Amant and Salahub 1990; Casida et al. 1996) as well as for several other codes, such as LCGTO- $X\alpha$ (Dunlap and Rösch 1990), DGAUSS (Andzelm and Wimmer 1992), ADF (Velde et al. 2001), and DMOL (Delley 1990). The deMon program, for example, was based on Gaussian functions, and much of the machinery comes over to the DFT world straightforwardly, although some aspects like numerical integration (Becke 1987) remain special. Now geometry optimizations held no mystery for the DFT codes, and one could start to think about real chemical applications. Then, in the late eighties, the holy grail of chemical accuracy was reached, at least for organic thermochemistry, with the development of hybrid functionals (Becke 1993a, b). This really got the chemists interested in DFT and that interest has persisted until today.

In parallel, a broad range of physical and chemical properties and processes came into range. The nineties saw the development of powerful methodology that included NMR chemical shifts and coupling constants (Malkin et al. 1993a, b, 1994; Valerio et al. 1998), core-electron spectroscopies (Triguero and Pettersson 1998; Triguero et al. 1998), optical properties through the time-dependent-DFT (TD-DFT) (Casida 1995; Jamorski et al. 1996) approach, photoelectron spectroscopy including the ZEKE (zero-electron kinetic energy) technique (Yang et al. 1996; Calaminici et al. 2001, 2003) molecular polarizabilities and hyperpolarizabilities (Sim et al. 1992; Guan et al. 1995; Calaminici et al. 1998, 1999, 2000), and many others. DFT and programs like deMon were now established as components of the quantum chemical tool kit. The first decade of the twenty-first century, like its predecessors, continued to show steady progress. Born-Oppenheimer molecular dynamics (BOMD) (Wei and Salahub 1994, 1997; Wei et al. 2000; Krishnamurty et al. 2003; Calaminici et al. 2007b; Gamboa et al. 2008; Krishnamurty et al. 2008a, b; Vásquez et al. 2009) have now become “routine” (though sometimes costly) for systems with a hundred or so atoms for simulation times of hundreds of picoseconds or even nanoseconds (Goursot et al. 2013). The recent calculations of melting temperatures and latent heats of free metal clusters have probed the quantitative predictive power of all-electron ADFT-BOMD simulations. The excellent agreement with experimental results (Vásquez et al. 2013, 2015) has further strengthened the confidence in these ab initio molecular dynamics simulations. As a result, ADFT-BOMD has also gained increasing popularity in

global optimizations (Köster et al. 2011b; Geudtner et al. 2013; Medel et al. 2014). Geometry optimizations and transition state searches (Campo and Köster 2008) can now be performed for systems containing several hundred atoms (Dominguez-Soria et al. 2007, 2008; Calaminici et al. 2009) as well as transition metal clusters (Cruz-Olvera et al. 2015); the thousand-atom barrier has been broken (Salahub et al. 2005; Dominguez-Soria et al. 2009), thanks mainly to the development of ADFT (auxiliary density functional theory) (Köster et al. 2004b). More recently, ADFT has also been extended to constrained density functional theory (de la Lande et al. 2013). Hybrid, QM/MM, and QM/QM' methodologies (Lev et al. 2010; Bertran et al. 2010) are now being applied with considerable confidence to systems with a level of complexity that would not have been contemplated just a few years ago. The implementation of force fields into deMon2k now permits multi-scale calculations within deMon2k itself (Salahub et al. 2015). These modules have been further extended by the implementation of asymptotic expansions for electrostatic interaction integrals (Alvarez-Ibarra et al. 2012; Alvarez-Ibarra and Köster 2013) and the efficient variational fitting of exact exchange (Mejia-Rodriguez and Köster 2014). So, at the present time, deMon2k is one of the most powerful LCGTO-DFT codes available. In particular, it includes hybrid functionals without the need for four-center electron repulsion integrals (Mejia-Rodriguez et al. 2015a).

In the next section, we will present the underlying theory, including a description of ADFT and auxiliary density perturbation theory (ADPT), a rather new non-iterative alternative to the coupled perturbed Kohn-Sham (CPKS) methodology. These general theory sections are followed by three more specific methodological sections addressing the computationally demanding three-center electron repulsion integral (ERI) calculations in ADFT, the variational fitting of exact exchange in ADFT, and the ADFT-GIAO (GIAO: Gauge Including Atomic Orbitals) method for the calculation of magnetic properties. Then, in the Applications section, we will describe four recent studies that represent the state of the art in “pure DFT” on large and/or difficult molecular and cluster problems, the largest of which are well into the nano- regime. We solve a long-standing mystery of the discrepancy between experiments and computations for the polarizabilities of sodium clusters (up to the nonamer) – finite temperature effects are the key. In the second application, large models for Na^+ and protonated Al-zeolites are constructed, and the acidic sites are analyzed, including important vibrational effects. The structures of giant fullerenes up to C_{540} have been optimized using all-electron basis sets. The results confirm that for all of the large fullerenes, a faceted shape is preferred over a spherical shape. The calculated binding energies are in the diamond range but considerably below the value for graphene. Finally, a hierarchical transition state algorithm is applied to locate transition states for small sodium cluster rearrangements with six to ten atoms. The minimum structures needed as input were obtained from Born-Oppenheimer molecular dynamics simulations. To connect the found transition states with the corresponding minimum structures, the intrinsic reaction coordinates were calculated. This work demonstrates how rearrangement mechanisms that are not intuitive can be studied in metal clusters.

Theory

Kohn-Sham Density Functional Theory

Density functional theory (DFT) is based on the Hohenberg-Kohn theorem (Hohenberg and Kohn 1964). According to this theorem, the ground-state energy, E , of a many-electron system with the external potential $v(\mathbf{r})$ can be expressed by the following density functional (Parr and Yang 1989; Dreizler and Gross 1990):

$$E[\rho] = T[\rho] + \int \rho(\mathbf{r}) v(\mathbf{r}) d\mathbf{r} + V_{ee}[\rho]. \quad (1)$$

Here $\rho(\mathbf{r})$ is the electron density, $T[\rho]$ is the kinetic energy, and $V_{ee}[\rho]$ collects all electron-electron interaction energies. A major technical problem is the accurate description of the kinetic energy functional $T[\rho]$. In the Kohn-Sham approximation, this problem is avoided by introducing orbitals of a noninteracting reference system. Levy and Perdew (Levy 1979; Levy and Perdew 1985) have shown that these orbitals are delivered by the following minimization procedure:

$$T_{KS}[\rho] = \min_{\Psi \rightarrow \rho} \langle \Psi | \hat{\mathbf{T}} | \Psi \rangle. \quad (2)$$

Here Ψ is a Slater determinant composed of the orthonormal Kohn-Sham orbitals $\psi_i(\mathbf{r})$, and $T_{KS}[\rho]$ is the corresponding Kohn-Sham kinetic energy. This energy can be calculated from the occupied orbitals of the noninteracting system,

$$T_{KS}[\rho] = -\frac{1}{2} \sum_i^{\text{occ}} \langle \psi_i[\rho] | \nabla^2 | \psi_i[\rho] \rangle. \quad (3)$$

These Kohn-Sham orbitals are functionals of the density and can be derived from it as shown by Parr and coworkers (Zhao and Parr 1992, 1993; Zhao et al. 1994). Imposing the constraint that occupied orbitals of the noninteracting system reproduce the true ground-state density,

$$\rho(\mathbf{r}) = \sum_i^{\text{occ}} |\psi_i(\mathbf{r})|^2, \quad (4)$$

to the variation in Eq. (2) by using a local Lagrange multiplier $v_{KS}(\mathbf{r})$, the following set of equations is obtained:

$$\left(-\frac{1}{2} \nabla^2 + v_{KS}(\mathbf{r}) \right) \psi_i(\mathbf{r}) = \epsilon_i \psi_i(\mathbf{r}). \quad (5)$$

These are the Kohn-Sham equations and $v_{KS}(\mathbf{r})$ determines (within a trivial constant) the external potential of the Kohn-Sham reference system.

In order to find a more explicit representation of $v_{KS}(\mathbf{r})$, we now rewrite the energy functional Eq. (1) using the Kohn-Sham kinetic energy term Eq. (3) and the explicit expression for the classic electronic (Coulomb) interaction energy,

$$J[\rho] = \frac{1}{2} \iint \frac{\rho(\mathbf{r}) \rho(\mathbf{r}')}{|\mathbf{r} - \mathbf{r}'|} d\mathbf{r} d\mathbf{r}', \quad (6)$$

and it then follows

$$E[\rho] = T_{KS}[\rho] + \int \rho(\mathbf{r}) v(\mathbf{r}) d\mathbf{r} + J[\rho] + E_{xc}[\rho]. \quad (7)$$

Here the newly introduced exchange-correlation energy functional is defined as

$$E_{xc}[\rho] \equiv T[\rho] - T_{KS}[\rho] + V_{ee}[\rho] - J[\rho]. \quad (8)$$

This quantity collects all nonclassical interactions between the electrons and the difference of the kinetic energies of the interacting and noninteracting system. The accuracy of the Kohn-Sham method is mainly determined by the quality of the approximation used for the calculation of $E_{xc}[\rho]$. The kinetic energy difference appearing in $E_{xc}[\rho]$ is on the order of magnitude of the correlation energy (Almbladh and Pedrosa 1984).

Based on the Hohenberg-Kohn theorem, the ground-state density minimizes the energy functional Eq. (7) and hence satisfies the Euler equation:

$$\mu = \frac{\delta E[\rho]}{\delta \rho(\mathbf{r})}, \quad (9)$$

where μ is the Lagrange multiplier associated with the normalization of the electronic density to the number of electrons n in the system:

$$\int \rho(\mathbf{r}) d\mathbf{r} = n. \quad (10)$$

The functional derivative of the energy functional Eq. (7) yields

$$\begin{aligned} \frac{\delta E[\rho]}{\delta \rho(\mathbf{r})} &= \frac{\delta T_{KS}[\rho]}{\delta \rho(\mathbf{r})} + v(\mathbf{r}) + \int \frac{\rho(\mathbf{r}')}{|\mathbf{r} - \mathbf{r}'|} d\mathbf{r}' + \frac{\delta E_{xc}[\rho]}{\delta \rho(\mathbf{r})} \\ &= \frac{\delta T_{KS}[\rho]}{\delta \rho(\mathbf{r})} + v_{KS}(\mathbf{r}). \end{aligned} \quad (11)$$

Thus, the Kohn-Sham potential has the following explicit form:

$$v_{KS}(\mathbf{r}) = v(\mathbf{r}) + \int \frac{\rho(\mathbf{r}')}{|\mathbf{r} - \mathbf{r}'|} d\mathbf{r}' + v_{xc}[\rho; \mathbf{r}], \quad (12)$$

where the exchange-correlation potential is defined as

$$v_{xc}[\rho; \mathbf{r}] \equiv \frac{\delta E_{xc}[\rho]}{\delta \rho(\mathbf{r})}. \quad (13)$$

Inserting Eq. (12) in Eq. (5) yields the canonical Kohn-Sham orbital equations:

$$\left(-\frac{1}{2}\nabla^2 + v(\mathbf{r}) + \int \frac{\rho(\mathbf{r}')}{|\mathbf{r} - \mathbf{r}'|} d\mathbf{r}' + v_{xc}[\rho; \mathbf{r}] \right) \psi_i(\mathbf{r}) = \epsilon_i \psi_i(\mathbf{r}). \quad (14)$$

These equations have to be solved iteratively to reach self-consistency. They can be cast in matrix form yielding Roothaan-Hall-like equations (Roothaan 1951; Hall 1951).

The LCGTO Kohn-Sham Method

In the linear combination of Gaussian-type orbital (LCGTO) ansatz, the Kohn-Sham orbitals are expanded in atomic orbitals:

$$\psi_i(\mathbf{r}) = \sum_{\mu} c_{\mu i} \mu(\mathbf{r}). \quad (15)$$

In our notation, $\mu(\mathbf{r})$ represents an atomic orbital and $c_{\mu i}$ the corresponding molecular orbital coefficient. To avoid unnecessary complications in the presentation, we restrict ourselves to the closed-shell case. The extension to the open-shell formalism (Pople and Nesbet 1954; Roothaan 1960; Binkley et al. 1974) is straightforward. With the LCGTO expansion, we find for the electron density Eq. (4):

$$\rho(\mathbf{r}) = \sum_{\mu, \nu} P_{\mu\nu} \mu(\mathbf{r}) \nu(\mathbf{r}). \quad (16)$$

$P_{\mu\nu}$ represents an element of the closed-shell density matrix defined as

$$P_{\mu\nu} \equiv 2 \sum_i^{\text{occ}} c_{\mu i} c_{\nu i}. \quad (17)$$

Using the above expansions for the Kohn-Sham orbitals Eq. (15) and the density Eq. (16), the Kohn-Sham energy expression Eq. (7) can be rewritten in terms of atomic orbitals,

$$E = \sum_{\mu, \nu} P_{\mu\nu} H_{\mu\nu} + \frac{1}{2} \sum_{\mu, \nu} \sum_{\sigma, \tau} P_{\mu\nu} P_{\sigma\tau} \langle \mu\nu || \sigma\tau \rangle + E_{xc}[\rho], \quad (18)$$

with

$$H_{\mu\nu} = \langle \mu | -\frac{1}{2}\nabla^2 | \nu \rangle - \sum_C^{\text{Atoms}} \langle \mu | \frac{Z_C}{|\mathbf{r} - \mathbf{C}|} | \nu \rangle \quad (19)$$

and

$$\langle \mu\nu \| \sigma\tau \rangle \equiv \iint \frac{\mu(\mathbf{r})\nu(\mathbf{r})\sigma(\mathbf{r}')\tau(\mathbf{r}')}{|\mathbf{r} - \mathbf{r}'|} d\mathbf{r} d\mathbf{r}'. \quad (20)$$

The SCF convergence is based on this energy expression. The $H_{\mu\nu}$ in Eq. (19) denotes an element of the one-electron Hamiltonian matrix. They are built from the kinetic and nuclear-attraction energy of the electrons and describe the distribution of an electron in the nuclear framework. The computation of this matrix has a formal quadratic scaling with the number of basis functions N of the system. The second term in Eq. (18) represents the Coulomb repulsion energy of the electrons. In contrast to Hartree-Fock theory, the calculations of the Coulomb and exchange energies are separated in DFT. The Coulomb term introduces a formal N^4 scaling. The exchange-correlation energy can be obtained by means of an integral of the following type:

$$E_{xc}[\rho] = \int \rho(\mathbf{r}) \epsilon_{xc}[\rho] d\mathbf{r}. \quad (21)$$

In general, the explicit form of the exchange-correlation energy density, $\epsilon_{xc}[\rho]$, will not permit an analytic solution of this integral. Therefore, a three-dimensional numerical integration has to be performed. It scales formally as $N^2 \times G$, where G denotes the number of grid points in the numerical integration.

From the above discussion, it follows that the calculation of the Coulomb repulsion energy represents the most demanding computational task in Eq. (18). The introduction of the variational approximation of the Coulomb potential (Dunlap et al. 1979; Mintmire and Dunlap 1982; Mintmire et al. 1982) reduces the formal scaling of this term to $N^2 \times M$, where M is the number of auxiliary functions which is usually three to five times N . This technique is nowadays used in most LCGTO-DFT programs. It is identical to the so-called resolution of the identity (RI) (Vahtras et al. 1993; Hamel et al. 2001; Flores-Moreno and Ortiz 2009) that cropped up in wave-function methods, too. The variational approximation of the Coulomb potential, as implemented in deMon2k, is based on the minimization of the following self-interaction term:

$$\mathcal{E}_2 = \frac{1}{2} \iint \frac{[\rho(\mathbf{r}) - \tilde{\rho}(\mathbf{r})][\rho(\mathbf{r}') - \tilde{\rho}(\mathbf{r}')]}{|\mathbf{r} - \mathbf{r}'|} d\mathbf{r} d\mathbf{r}'. \quad (22)$$

The approximate density $\tilde{\rho}(\mathbf{r})$ is expanded in primitive Hermite Gaussians (Köster 2003) which are centered at the atoms:

$$\tilde{\rho}(\mathbf{r}) = \sum_{\bar{k}} x_{\bar{k}} \bar{k}(\mathbf{r}). \quad (23)$$

The primitive Hermite Gaussian auxiliary functions are indicated by a bar. An (unnormalized) auxiliary function $\bar{k}(\mathbf{r})$ centered at atom C with exponent ζ_k has the form

$$\bar{k}(\mathbf{r}) = \left(\frac{\partial}{\partial C_x} \right)^{\bar{k}_x} \left(\frac{\partial}{\partial C_y} \right)^{\bar{k}_y} \left(\frac{\partial}{\partial C_z} \right)^{\bar{k}_z} e^{-\zeta_k(\mathbf{r}-\mathbf{C})^2}. \quad (24)$$

In deMon2k, these auxiliary functions are normalized with respect to the Coulomb norm and grouped into *s*, *spd*, and *spdfg* sets. The exponents are shared within each of these sets (Andzelm et al. 1985, 1987). Based on the exponent range of the primary atomic basis set, an automatic generation of auxiliary function sets, indicated by the abbreviation GEN, is available in deMon2k. A detailed description is given in Calaminici et al. (2007a) for all-electron calculations and in Calaminici et al. (2005) for effective and model core potential calculations.

With the LCGTO expansion for $\rho(\mathbf{r})$ and $\tilde{\rho}(\mathbf{r})$, we obtain the following representation for \mathcal{E}_2 :

$$\begin{aligned} \mathcal{E}_2 = & \frac{1}{2} \sum_{\mu, \nu} \sum_{\sigma, \tau} P_{\mu\nu} P_{\sigma\tau} \langle \mu\nu \| \sigma\tau \rangle \\ & - \sum_{\mu, \nu} \sum_{\bar{k}} P_{\mu\nu} \langle \mu\nu \| \bar{k} \rangle x_{\bar{k}} + \frac{1}{2} \sum_{\bar{k}, \bar{l}} x_{\bar{k}} x_{\bar{l}} \langle \bar{k} \| \bar{l} \rangle. \end{aligned} \quad (25)$$

The two- and three-center electron repulsion integrals are defined as

$$\langle \bar{k} \| \bar{l} \rangle \equiv \iint \frac{\bar{k}(\mathbf{r}) \bar{l}(\mathbf{r}')}{|\mathbf{r} - \mathbf{r}'|} d\mathbf{r} d\mathbf{r}', \quad (26)$$

$$\langle \mu\nu \| \bar{k} \rangle \equiv \iint \frac{\mu(\mathbf{r}) \nu(\mathbf{r}) \bar{k}(\mathbf{r}')}{|\mathbf{r} - \mathbf{r}'|} d\mathbf{r} d\mathbf{r}'. \quad (27)$$

In deMon2k, optimized integral recurrence relations for the calculation of the three-center electron repulsion integrals (ERIs) in Eq. (27) are implemented (Köster 1996). The expansion coefficients $x_{\bar{k}}$ of the approximate density are determined by the minimization of \mathcal{E}_2 :

$$\frac{\partial \mathcal{E}_2}{\partial x_{\bar{m}}} = - \sum_{\mu, \nu} P_{\mu\nu} \langle \mu\nu \| \bar{m} \rangle + \sum_{\bar{k}} x_{\bar{k}} \langle \bar{k} \| \bar{m} \rangle = 0 \quad \forall \bar{m}. \quad (28)$$

At this point, it is useful to introduce the Coulomb matrix,

$$\mathbf{G} = \begin{pmatrix} \langle \bar{1} \| \bar{1} \rangle & \langle \bar{1} \| \bar{2} \rangle & \dots & \langle \bar{1} \| \bar{m} \rangle \\ \langle \bar{2} \| \bar{1} \rangle & \langle \bar{2} \| \bar{2} \rangle & \dots & \langle \bar{2} \| \bar{m} \rangle \\ \vdots & \vdots & \ddots & \vdots \\ \langle \bar{m} \| \bar{1} \rangle & \langle \bar{m} \| \bar{2} \rangle & \dots & \langle \bar{m} \| \bar{m} \rangle \end{pmatrix}, \quad (29)$$

and the Coulomb vector,

$$\mathbf{J} = \begin{pmatrix} \sum_{\mu,\nu} P_{\mu\nu} \langle \mu\nu \| \bar{1} \rangle \\ \sum_{\mu,\nu} P_{\mu\nu} \langle \mu\nu \| \bar{2} \rangle \\ \vdots \\ \sum_{\mu,\nu} P_{\mu\nu} \langle \mu\nu \| \bar{m} \rangle \end{pmatrix}. \quad (30)$$

With \mathbf{G} and \mathbf{J} , the following system of inhomogeneous equations for the determination of the fitting coefficients, collected in \mathbf{x} , can be formulated:

$$\mathbf{G} \mathbf{x} = \mathbf{J}. \quad (31)$$

A straightforward solution is obtained by the inversion of the Coulomb matrix \mathbf{G} :

$$\mathbf{x} = \mathbf{G}^{-1} \mathbf{J}. \quad (32)$$

Because \mathbf{G} is symmetric and positive definite, in principle, its inversion can be very efficiently performed via Cholesky decomposition (Press et al. 1992). However, if very large auxiliary function sets are used, the Coulomb matrix tends to become ill conditioned. As a consequence, the Cholesky decomposition might fail. For this reason, in deMon2k, we perform by default a singular value decomposition (SVD) of \mathbf{G} at the initial SCF and use in the following energy calculations (e.g., in a geometry optimization or molecular dynamic run) a numerical solver (Dominguez-Soria et al. 2009) that acts only on the nonredundant space of the SVD. This has proven to be a good compromise between accuracy and efficiency. The approach is suitable for systems with thousands of atoms and tight SCF convergence criteria (10^{-9} a.u.). The SVD threshold can be altered by the keyword MATINV (Köster et al. 2011c). Its default value is 10^{-6} .

After the description of the calculation of the fitting coefficients, we now turn to the energy and SCF calculation. Because \mathcal{E}_2 is positive definite, the following inequality holds:

$$\frac{1}{2} \sum_{\mu,\nu} \sum_{\sigma,\tau} P_{\mu\nu} P_{\sigma\tau} \langle \mu\nu \| \sigma\tau \rangle \geq \sum_{\bar{k}} \sum_{\mu,\nu} P_{\mu\nu} \langle \mu\nu \| \bar{k} \rangle x_{\bar{k}} - \frac{1}{2} \sum_{\bar{k},\bar{l}} x_{\bar{k}} x_{\bar{l}} \langle \bar{k} \| \bar{l} \rangle.$$

With this inequality, an approximate SCF energy, which is based on Eq. (18), can be derived:

$$E = \sum_{\mu,\nu} P_{\mu\nu} H_{\mu\nu} + \sum_{\bar{k}} \sum_{\mu,\nu} P_{\mu\nu} \langle \mu\nu \| \bar{k} \rangle x_{\bar{k}} - \frac{1}{2} \sum_{\bar{k},\bar{l}} x_{\bar{k}} x_{\bar{l}} \langle \bar{k} \| \bar{l} \rangle + E_{xc}[\rho]. \quad (33)$$

The variation of this energy expression with respect to the molecular orbital coefficients, constraining the Kohn-Sham orbitals to be orthonormal,

$$\sum_{\mu, \nu} c_{\mu i} S_{\mu \nu} c_{\nu j} = \delta_{ij} \quad \forall i, j, \quad (34)$$

yields

$$\begin{aligned} \frac{\partial E}{\partial c_{\mu i}} = & 4 \sum_{\nu} \left(H_{\mu \nu} + \sum_{\bar{k}} \langle \mu \nu \parallel \bar{k} \rangle x_{\bar{k}} + \langle \mu \mid v_{xc}[\rho] \mid \nu \rangle \right) c_{\nu i} \\ & - 4 \sum_{\nu} \sum_j S_{\mu \nu} c_{\nu j} \epsilon_{ji} \quad \forall \mu, i. \end{aligned} \quad (35)$$

Here, the derivative of the exchange-correlation energy, restricting ourselves to local functionals for clarity, was developed as (Gel'fand and Fomin 1963):

$$\frac{\partial E_{xc}[\rho]}{\partial c_{\mu i}} = \int \frac{\delta E_{xc}[\rho]}{\delta \rho(\mathbf{r})} \frac{\partial \rho(\mathbf{r})}{\partial c_{\mu i}} d\mathbf{r} = 4 \sum_{\nu} \langle \mu \mid v_{xc}[\rho] \mid \nu \rangle c_{\nu i}. \quad (36)$$

The ϵ_{ji} in Eq.(35) are the undetermined Lagrange multipliers. Because the electronic density is invariant to unitary transformations of the occupied molecular orbitals (MOs), it is possible (and convenient) to choose a set of MOs for which the off-diagonal multipliers are zero. These MOs are called canonical and are the solutions of the canonical Kohn-Sham equations,

$$\mathbf{K} \mathbf{c} = \mathbf{S} \mathbf{c} \boldsymbol{\epsilon}, \quad (37)$$

with the elements of the Kohn-Sham matrix \mathbf{K} defined as

$$K_{\mu \nu} \equiv H_{\mu \nu} + \sum_{\bar{k}} \langle \mu \nu \parallel \bar{k} \rangle x_{\bar{k}} + \langle \mu \mid v_{xc}[\rho] \mid \nu \rangle. \quad (38)$$

In Eq. (37), \mathbf{S} represents the overlap matrix, \mathbf{c} the molecular orbital coefficient matrix, and $\boldsymbol{\epsilon}$ the diagonal matrix of the Lagrange multipliers, i.e., the Kohn-Sham orbital energies.

As can be seen from Eq. (38), the Kohn-Sham matrix elements depend on the fitting coefficients $x_{\bar{k}}$ and the molecular orbital coefficients $c_{\mu i}$ via the dependence of the exchange-correlation potential on the orbital density $\rho(\mathbf{r})$. In deMon2k, this theoretical model is selected by the keyword specification VXCTYPE BASIS (Köster et al. 2011c) and is often referred to as the BASIS approach. It should be noted that the SCF convergence can be guided either by the molecular orbital coefficients or by the fitting coefficients that arise from the variational fitting of the Coulomb potential. In any case, the variational fitting of the Coulomb potential turns the original energy minimization into a MinMax variation (Köster et al. 2002). In deMon2k, the SCF convergence is guided by the fitting coefficients because they form a vector rather than a matrix. As a result, memory-efficient SCF convergence

acceleration methods suitable for very large systems are available (Köster et al. 2009).

Due to the use of efficient three-center electron repulsion integral algorithms (Köster 1996, 2003; Alvarez-Ibarra and Köster 2013), the numerical integration of the exchange-correlation energy and potential is the computationally most demanding task in this approach. Therefore, a more efficient approach for the calculation of the exchange-correlation energy and potential is desirable. In fact, the use of auxiliary functions for the calculation of the exchange-correlation energy and potential has a long history in DFT methods (Baerends et al. 1973; Sambe and Felton 1975). In programs like deMon-KS (Casida et al. 1996), DGAUSS (Andzelm and Wimmer 1992) or GTOFF (Trickey et al. 2004), the exchange-correlation potential is expanded in auxiliary functions as proposed by Sambe and Felton (1975). The expansion coefficients are obtained by a least squares fit on a grid. Because this fit and the corresponding energy expression are not variational, only approximate gradients and higher-energy derivatives are available (Verluis and Ziegler 1988; Gusarov et al. 2006).

Auxiliary Density Functional Theory

As an alternative to the fitting of the exchange-correlation potential by auxiliary functions, the direct use of the auxiliary function density from the variational fitting of the Coulomb potential for the calculation of the exchange-correlation potential has been investigated over the last years (Laikov 1997; Köster 1998; Köster et al. 2004b; Birkenheuer et al. 2005; Belpassi et al. 2006; Janetzko et al. 2008). The resulting energy expression, from now on named the auxiliary density functional theory (ADFT) energy, is variational and has the form (Köster et al. 2004b)

$$E = \sum_{\mu,\nu} P_{\mu\nu} H_{\mu\nu} + \sum_{\bar{k}} \sum_{\mu,\nu} P_{\mu\nu} \langle \mu\nu \| \bar{k} \rangle x_{\bar{k}} - \frac{1}{2} \sum_{\bar{k},\bar{l}} x_{\bar{k}} x_{\bar{l}} \langle \bar{k} \| \bar{l} \rangle + E_{xc}[\bar{\rho}]. \quad (39)$$

In deMon2k, this theoretical model is selected by the keyword specification VXCTYPE AUXIS (Köster et al. 2011c); that is the default setting and often referred to as the AUXIS approach. Because the approximate density is a linear combination of auxiliary functions, the density calculation at each grid point scales linearly. In contrast, with the orbital density, products of basis functions have to be evaluated. Obviously, this represents a considerable simplification of the grid work. In particular, using auxiliary function sets that share the same exponents reduces significantly the number of expensive exponential function evaluations at each grid point. Moreover, by using Hermite Gaussian auxiliary functions, the Hermite polynomial recurrence relations (Saunders 1983) can be used for the function calculations on the grid. For the numerical integration of the exchange-correlation energy and potential adaptive and fixed grids (Krack and Köster 1998; Köster et al.

2004a) of various qualities are available in deMon2k. The default setting guarantees energy accuracies in the range of 10^{-5} a.u. for most systems. Higher accuracies can be selected with the GRID keyword (Köster et al. 2011c).

The variation of the ADFT energy expression Eq. (39) with respect to the molecular orbital coefficients, again constraining the Kohn-Sham orbitals to orthonormality Eq. (34), yields

$$\begin{aligned} \frac{\partial E}{\partial c_{\mu i}} &= 4 \sum_v \left(H_{\mu v} + \sum_{\bar{k}} \langle \mu v \parallel \bar{k} \rangle (x_{\bar{k}} + z_{\bar{k}}) \right) c_{vi} \\ &- 4 \sum_v \sum_j S_{\mu v} c_{vj} \epsilon_{ji} \quad \forall \mu, i. \end{aligned} \quad (40)$$

The derivative of the exchange-correlation energy, again restricting ourselves to local functionals, now contains the fitted density:

$$\frac{\partial E_{xc}[\tilde{\rho}]}{\partial c_{\mu i}} = \int \frac{\delta E_{xc}[\tilde{\rho}]}{\delta \tilde{\rho}(\mathbf{r})} \frac{\partial \tilde{\rho}(\mathbf{r})}{\partial c_{\mu i}} d\mathbf{r}. \quad (41)$$

The resulting functional derivative defines the exchange-correlation potential calculated with the fitted density:

$$v_{xc}[\tilde{\rho}; \mathbf{r}] \equiv \frac{\delta E_{xc}[\tilde{\rho}]}{\delta \tilde{\rho}(\mathbf{r})}. \quad (42)$$

The derivative of the fitted density with respect to molecular orbital coefficients is given by

$$\frac{\partial \tilde{\rho}(\mathbf{r})}{\partial c_{\mu i}} = \sum_{\bar{l}} \frac{\partial x_{\bar{l}}}{\partial c_{\mu i}} \bar{l}(\mathbf{r}). \quad (43)$$

After differentiation of Eq. (32), it follows for the derivative of the fitted density:

$$\frac{\partial \tilde{\rho}(\mathbf{r})}{\partial c_{\mu i}} = 4 \sum_{\bar{k}, \bar{l}} \sum_v c_{vi} \langle \mu v \parallel \bar{k} \rangle G_{\bar{k}\bar{l}}^{-1} \bar{l}(\mathbf{r}). \quad (44)$$

Substituting this expression and the definition of the approximate exchange-correlation potential Eq. (42) into Eq. (41) yields

$$\frac{\partial E_{xc}[\tilde{\rho}]}{\partial c_{\mu i}} = 4 \sum_{\bar{k}} \sum_v c_{vi} \langle \mu v \parallel \bar{k} \rangle z_{\bar{k}}, \quad (45)$$

with

$$z_{\bar{k}} = \sum_{\bar{l}} G_{\bar{k}\bar{l}}^{-1} \langle \bar{l} | v_{xc}[\tilde{\rho}] \rangle. \quad (46)$$

In order to distinguish the $x_{\bar{k}}$ and $z_{\bar{k}}$ coefficients, we name them Coulomb and exchange-correlation coefficients, respectively. The corresponding Kohn-Sham matrix elements are defined as

$$K_{\mu\nu} = H_{\mu\nu} + \sum_{\bar{k}} \langle \mu\nu \| \bar{k} \rangle (x_{\bar{k}} + z_{\bar{k}}). \quad (47)$$

These matrix elements depend only on the fitting coefficients. In contrast to the traditional fitting of the exchange-correlation potential, ADFT employs the fitted density for the exchange-correlation potential calculation, and hence the numerical integration of v_{xc} is not avoided. However, the work on the grid is considerably reduced because only one-center terms are involved in the integrals in Eq. (46). Despite the fact that these terms are evaluated numerically, the calculation of the Kohn-Sham elements Eq. (47) scales linearly (Köster et al. 2003). Because the ADFT energy is variational, analytic gradients (Köster et al. 2004b) and higher-energy derivatives can be formulated.

Auxiliary Density Perturbation Theory

For second energy derivatives that appear in the calculation of polarizabilities, chemical hardness, van der Waals coefficients, vibrational frequencies, and other second-order properties, the perturbed density matrix is required. McWeeny's self-consistent perturbation (SCP) theory (McWeeny 1962, 2001; Diercksen and McWeeny 1966; McWeeny and Diercksen 1968; Dodds et al. 1977; Raynes et al. 1977; McWeeny et al. 1977) represents a direct approach for the calculation of this matrix. For clarity of presentation, we assume perturbation-independent basis and auxiliary functions and restrict ourselves to closed-shell systems. Under these conditions, the elements of the perturbed density matrix are given by the SCP formalism as (McWeeny et al. 1977)

$$P_{\mu\nu}^{(\lambda)} \equiv \frac{\partial P_{\mu\nu}}{\partial \lambda} = 2 \sum_i^{\text{occ}} \sum_a^{\text{uno}} \frac{\mathcal{K}_{ia}^{(\lambda)}}{\varepsilon_i - \varepsilon_a} (c_{\mu i} c_{\nu a} + c_{\mu a} c_{\nu i}). \quad (48)$$

Extension to the case of perturbation-dependent basis and auxiliary functions is straightforward but can lead to tedious expressions. Therefore, we will discuss here only Eq. (48). In this equation, λ denotes the perturbation parameter, e.g., an electric field component in the calculation of polarizabilities, ε_i and ε_a orbital energies of the i th occupied and a th unoccupied orbital, and $\mathcal{K}_{ia}^{(\lambda)}$ the perturbed Kohn-Sham matrix in the molecular orbital representation:

$$\mathcal{K}_{ia}^{(\lambda)} = \sum_{\mu,\nu} c_{\mu i} c_{\nu a} K_{\mu\nu}^{(\lambda)}, \quad (49)$$

with

$$K_{\mu\nu}^{(\lambda)} = H_{\mu\nu}^{(\lambda)} + \sum_{\bar{k}} \langle \mu\nu \| \bar{k} \rangle (x_{\bar{k}}^{(\lambda)} + z_{\bar{k}}^{(\lambda)}). \quad (50)$$

The perturbation of the exchange-correlation coefficients is given by

$$z_{\bar{k}}^{(\lambda)} = \sum_{\bar{l}} G_{\bar{k}\bar{l}}^{-1} \langle \bar{l} | v_{xc}^{(\lambda)}[\bar{\rho}] \rangle. \quad (51)$$

Since $v_{xc}[\bar{\rho}; \mathbf{r}]$ itself is a (local) functional of the density, it follows

$$\begin{aligned} \langle \bar{l} | v_{xc}^{(\lambda)}[\bar{\rho}] \rangle &= \iint \bar{l}(\mathbf{r}) \frac{\delta v_{xc}[\bar{\rho}; \mathbf{r}]}{\delta \bar{\rho}(\mathbf{r}')} \frac{\partial \bar{\rho}(\mathbf{r}')}{\partial \lambda} d\mathbf{r} d\mathbf{r}' \\ &= \sum_{\bar{m}} \langle \bar{l} | f_{xc}[\bar{\rho}] | \bar{m} \rangle x_{\bar{m}}^{(\lambda)}, \end{aligned} \quad (52)$$

with the exchange-correlation kernel defined as

$$f_{xc}(\mathbf{r}, \mathbf{r}') = \frac{\delta^2 E_{xc}[\bar{\rho}]}{\delta \bar{\rho}(\mathbf{r}') \delta \bar{\rho}(\mathbf{r})} = \frac{\delta v_{xc}[\bar{\rho}; \mathbf{r}]}{\delta \bar{\rho}(\mathbf{r}')}. \quad (53)$$

Compared to the standard LCGTO kernel $\langle \mu\nu | f_{xc} | \sigma\tau \rangle$, the scaling of the kernel calculation is reduced by almost two orders of magnitude in the ADPT approach. With this result, we now rewrite the perturbed Kohn-Sham matrix elements in molecular orbital representation as

$$\mathcal{K}_{ia}^{(\lambda)} = \mathcal{H}_{ia}^{(\lambda)} + \sum_{\bar{k}, \bar{l}} \langle ia | \bar{k} \rangle M_{\bar{k}\bar{l}} x_{\bar{l}}^{(\lambda)}, \quad (54)$$

with

$$M_{\bar{k}\bar{l}} = \delta_{\bar{k}\bar{l}} + \sum_{\bar{m}} G_{\bar{k}\bar{m}}^{-1} \langle \bar{m} | f_{xc}[\bar{\rho}] | \bar{l} \rangle. \quad (55)$$

On the other hand, we find as the derivative of the fitting equation system Eq. (31):

$$\sum_{\bar{k}} G_{\bar{m}\bar{k}} x_{\bar{k}}^{(\lambda)} = \sum_{\mu, \nu} P_{\mu\nu}^{(\lambda)} \langle \mu\nu | \bar{m} \rangle. \quad (56)$$

Substituting Eq. (54) and Eq. (56) into Eq. (48) yields

$$\begin{aligned} \sum_{\mu, \nu} P_{\mu\nu}^{(\lambda)} \langle \mu\nu | \bar{m} \rangle &= 4 \sum_i^{\text{occ}} \sum_a^{\text{uno}} \frac{\langle \bar{m} | ia \rangle \mathcal{H}_{ia}^{(\lambda)}}{\varepsilon_i - \varepsilon_a} \\ &\quad + 4 \sum_i^{\text{occ}} \sum_a^{\text{uno}} \sum_{\bar{k}, \bar{l}} \frac{\langle \bar{m} | ia \rangle \langle ia | \bar{k} \rangle}{\varepsilon_i - \varepsilon_a} M_{\bar{k}\bar{l}} x_{\bar{l}}^{(\lambda)} \\ &= \sum_{\bar{k}} G_{\bar{m}\bar{k}} x_{\bar{k}}^{(\lambda)}. \end{aligned} \quad (57)$$

We now define the elements of the Coulomb coupling matrix as

$$A_{\bar{k}\bar{l}} = \sum_i^{\text{occ}} \sum_a^{\text{uno}} \frac{\langle \bar{k} \| ia \rangle \langle ia \| \bar{l} \rangle}{\varepsilon_i - \varepsilon_a}. \quad (58)$$

Similarly, the elements of the perturbation vector are given by

$$b_{\bar{k}}^{(\lambda)} = \sum_i^{\text{occ}} \sum_a^{\text{uno}} \frac{\langle \bar{k} \| ia \rangle \mathcal{H}_{ia}^{(\lambda)}}{\varepsilon_i - \varepsilon_a}. \quad (59)$$

With these matrices and vectors, Eq. (57) can now be recast into

$$(\mathbf{G} - 4\mathbf{A}\mathbf{M}) \mathbf{x}^{(\lambda)} = 4\mathbf{b}^{(\lambda)} \iff \mathbf{x}^{(\lambda)} = \left(\frac{1}{4} \mathbf{G} - \mathbf{A}\mathbf{M} \right)^{-1} \mathbf{b}^{(\lambda)}. \quad (60)$$

In the case of perturbation-dependent basis and auxiliary functions, only $\mathbf{b}^{(\lambda)}$ has to be modified. The matrix that needs to be inverted is exactly the same as in Eq. (60). Thus, the calculation of the perturbed fitting coefficients is reduced to the solution of the above inhomogeneous equation system. In contrast to the traditional coupled-perturbed Kohn-Sham equation system (Fournier 1990; Komornicki and Fitzgerald 1993), the dimension of Eq. (60) is M^2 , and, therefore, the memory requirement for the solution of this equation system is similar to that of the fitting equation system Eq. (31) in the corresponding SCF calculation. With the perturbed fitting coefficients, the perturbed Kohn-Sham matrix can be constructed via Eq. (54), and the perturbed density matrix can then be calculated by Eq. (48).

So far Eq. (60) has been applied successfully for the calculation of static and dynamic molecular dipole-dipole and dipole-quadrupole polarizabilities (Flores-Moreno and Köster 2008; Shedge et al. 2010, 2012, 2011; Carmona-Espíndola et al. 2010; Calaminici et al. 2012; Mejia-Rodriguez et al. 2015b) and static and dynamic molecular hyperpolarizabilities (Carmona-Espíndola et al. 2012; Karne et al. 2015) as well as for the calculation of Fukui functions (Flores-Moreno et al. 2008; Flores-Moreno 2010). Also a time-dependent ADFT variant was developed (Ipatov et al. 2006; Carmona and Köster 2013). Calculation of second derivatives with respect to nuclear displacements is currently under development.

ERI Expansion in ADFT

Due to the efficient calculation of the exchange-correlation potential in ADFT, the calculation of three-center ERIs, Eq. (27), arises as a potential bottleneck in the ADFT SCF procedure. The reason is twofold. First, the number of ERIs increases formally as $N^2 \times M$ (N basis functions and M auxiliary functions) with system size. Second, the increasing popularity of BOMD simulations raises demand for fast SCF solutions for small- to medium-sized systems. Two major developments have been

recently implemented in deMon2k to improve the computational performance of the ERI calculation. These are the double asymptotic expansion of ERIs (Alvarez-Ibarra and Köster 2013) and the mixed SCF scheme (Alvarez-Ibarra and Köster 2015). A brief discussion of these implementations is presented in the following subsections.

Double Asymptotic Expansion of ERIs

In large molecular systems, a large portion of ERIs involves atoms that are far apart from each other. Due to the form of the Coulomb operator, ERIs cannot be discarded loosely. However, the calculation of so-called far-field ERIs (because they occur in the far field of the electron density of the involved atoms) can be reduced by performing multipole expansions of the Coulomb operator. Multipole expansions are only feasible if the electron density centers are widely separated from each other, limiting their use to large molecular systems. The fast multipole method (FMM), originally developed by Greengard and Rokhlin (1987), has been adapted to electronic structure methods by several researchers (White and Head-Gordon 1994; Petersen et al. 1994; Kudin and Scuseria 1998; White et al. 1995; Strain et al. 1996). However, the double asymptotic ERI expansion used in deMon2k differs from the FMM in two ways (Alvarez-Ibarra and Köster 2013). First, the asymptotic expansion is performed in the final form of the ERI thus allowing the expansion to be applied independently from other integrals (e.g., nuclear-attraction integrals and other ERIs). Second, the space division procedure is avoided in exchange for an ERI classification based on the distance between the atomic centers and the extension of the orbitals and the Coulomb potential generated by the auxiliary function (information that is known from the input definition). The double asymptotic expansion of far-field ERIs has the following form:

$$\langle \mu v || \bar{k} \rangle^A \sim \left(\frac{\pi}{\zeta_{\bar{k}}} \right)^{3/2} \sum_{m_x, m_y, m_z} \frac{(-1)^M}{m_x! m_y! m_z!} \left(\frac{\pi}{\zeta_{\bar{k}}} \right)^{3/2} T_{AC}(m + \bar{k}) S_{\mu v}^A(m), \quad (61)$$

where

$$T_{AC}(m + \bar{k}) = \left(\frac{\partial}{\partial C_x} \right)^{m_x + \bar{k}_x} \left(\frac{\partial}{\partial C_y} \right)^{m_y + \bar{k}_y} \left(\frac{\partial}{\partial C_z} \right)^{m_z + \bar{k}_z} \frac{1}{|\vec{A} - \vec{C}|}, \quad (62)$$

$$S_{\mu v}^A(m) = \langle \mu + m | v \rangle, \quad (63)$$

and m_x , m_y and m_z are the expansion indices that sum up to M , i.e., $M = m_x + m_y + m_z$. Orbital μ is centered on A , whereas the Coulomb potential generated by the auxiliary function \bar{k} is centered on C . The superscript in the expanded integral Eq. (61) indicates the expansion center. There is an equivalent expansion for orbital v (Alvarez-Ibarra and Köster 2013). The double asymptotic expansion transforms the two-electron three-center integral, Eq. (27), into a series of modified

Fig. 1 Calculation time per SCF cycle of ERIs for selected n-alkane systems. *Black bars* indicate times using the direct SCF (for all integrals). *Red and yellow bars* indicate near- and far-field ERI times, respectively. *Red and yellow bars* add to the total time using the near- and far-field separation as described in the text

two-center overlap integrals with prefactors that depend only on atomic coordinates. When the number of far-field ERIs dominates significantly over the number of near-field ERIs (ERIs for which the asymptotic expansion is not applicable), the factorization of auxiliary function information to the atomic level, Eq. (62), and the efficient algorithms for the calculation of overlap integrals (Obara and Saika 1986) reduce enormously the calculation time required for the two-electron ERIs.

Figure 1 shows the calculation time for ERIs per SCF cycle in a number of selected n-alkanes using sixty 2.53 GHz Xeon E5649 processors with 2 GB RAM per CPU. The DZVP basis set and the GEN-A2 auxiliary function set were used for the calculation, along with the VWN functional for the exchange-correlation potential. Black bars indicate the time for ERI calculations with the optimized recurrence relations, i.e., treating all ERIs as if they were in the near field, whereas red and yellow bars indicate the time used calculating near-field ERIs via recurrence relations and far-field ERIs via the double asymptotic expansion, respectively. Since near-field ERIs are calculated using the same formulas as in the direct SCF, the difference between bars corresponds to the time savings obtained by the double asymptotic expansion of far-field ERIs. For the smallest n-alkane system ($C_{100}H_{202}$), the ERI calculation time is already reduced by half employing the double asymptotic expansion. Note that this plot shows a linear scaling for the new ERI calculation scheme with respect to system size. This is due to the large number of far-field

ERIs in the alkane chains with respect to the number of near-field ERIs. Note also that for systems with few or non-existing far-field ERIs, the new method will not significantly impact CPU timings. In order to address this situation, a new SCF scheme is proposed, which is presented in the following subsection.

The Mixed SCF Scheme

Regardless of the molecular system size, the ERI calculation may become a bottleneck in the direct SCF procedure if many iteration cycles are required for convergence. This is particularly true if the variational fitting of the Coulomb potential is used since ERIs are needed twice per SCF cycle, namely, for the calculation of the Coulomb vector, Eq. (30), and the calculation of the Kohn-Sham matrix, Eq. (38). In this situation, even the calculation of near-field ERIs alone can become a bottleneck since, according to Fig. 1, these calculations dominate the total ERI calculation time. Since multipole or asymptotic expansions are not applicable to these ERIs, the solution implemented in deMon2k is the so-called mixed SCF scheme (Alvarez-Ibarra and Köster 2015), named after the combination of the conventional (Clementi 1963) and direct (Almlöf 1982) SCF schemes. In the mixed SCF, the near-field ERIs are calculated once and stored in memory (as in the conventional SCF), whereas the far-field ERIs are calculated in a recurrent fashion (as in the direct SCF) using the efficient double asymptotic expansion. The difference between the mixed SCF and other modified SCF schemes is that the determination of the ERIs to be stored is based on the near- and far-field ERI separation, which is readily available from input information. In order to avoid I/O operations, the mixed SCF scheme stores near-field ERIs only in RAM, never on hard disk. If no far-field ERIs are in the system, the mixed SCF reduces to a conventional SCF that uses only RAM for ERI storage.

Initially the mixed SCF algorithm determines the amount of RAM necessary for the allocation of the working fields for the SCF procedure. Then, the amount of free RAM is used to store near-field ERIs. When the SCF procedure is about to start, near-field ERIs are calculated and stored in RAM. Then, in the SCF cycles, they are used in the two corresponding modules, Coulomb vector and Kohn-Sham matrix calculation. In the parallel version of the mixed SCF, only RAM from the slave processors is used to store ERIs, leaving the RAM of the master processor free to store SCF fields. Far-field ERIs are calculated on every processor since their memory demands are much smaller. This algorithm produces an outstanding performance, which allows the reduction of the ERI calculation time to a practically insignificant fraction of the total electronic structure calculation time. Since the mixed SCF scheme uses all the free RAM available in the computational architecture, calculation of larger systems is possible simply by requesting more processors for the job with no significant overhead due to the ERI calculation.

Figure 2 depicts the calculation time for ERIs per SCF cycle in the same *n*-alkanes from Fig. 1. Also the computational details are the same as for Fig. 1. In this case, the comparison is between the direct SCF with the double asymptotic expansion algorithm for the far-field ERIs and the mixed SCF scheme. Red and

Fig. 2 Calculation time per SCF cycle of ERIs for selected n-alkane systems. *Red* and *yellow bars* indicate direct SCF near- and double asymptotically expanded far-field ERI times, respectively. *Blue* and *green bars* indicate mixed SCF near- and double asymptotically expanded far-field ERI times

yellow bars show the calculation time for near-field and far-field ERIs in the direct SCF, whereas blue and green bars indicate the calculation time for near-field and far-field ERIs in the mixed SCF. Note that far-field ERI times are the same for both SCF schemes, since they are calculated in the same way. For the near-field ERIs, in-RAM storage achieves speedups that range from three and a half to six in this example. If we compare times from the original direct SCF scheme, i.e., without the double asymptotic ERI expansion, the ERI calculation time per SCF cycle for $C_{100}H_{202}$ is reduced from 4s to 0.5s, and for $C_{300}H_{602}$, it is reduced from 32s to less than 2s. As a conclusion, it is reasonable to state that the mixed SCF scheme eliminates the ERI computational bottleneck in ADFT when a computational architecture with enough RAM is used for the calculation.

Variational Fitting of Exact Exchange in ADFT

Hybrid functionals, where a certain portion of exact exchange is admixed with an exchange-correlation functional, are now a standard tool in quantum chemical calculations (Becke 2014). The functional form of exact exchange in DFT is equivalent to the Fock exchange in Hartree-Fock theory. Therefore, computing contributions from exact exchange in Kohn-Sham methods leads to a formal N^4 scaling. In order to avoid this unfavorable scaling, we implemented a variational fitting exact exchange approach in deMon2k which allows the computation of hybrid functionals with both the AUXIS and BASIS approaches.

In closed-shell systems, exact exchange is given by

$$E_{\text{EXX}} = -\frac{1}{4} \sum_{\mu, \nu} \sum_{\sigma, \tau} P_{\mu\sigma} P_{\nu\tau} \langle \mu\nu \| \sigma\tau \rangle \quad (64)$$

$$= -\sum_{i,j}^{\text{occ}} \langle ij \| ij \rangle, \quad (65)$$

where we used Eq. (17) for transforming Eq. (64) into Eq. (65). In the variational fitting exact exchange approach, the orbital products

$$\rho_{ij}(\mathbf{r}) \equiv \psi_i(\mathbf{r})\psi_j(\mathbf{r}) \quad (66)$$

are expanded in linear combinations of the same atom-centered primitive Hermite Gaussian auxiliary functions used to approximate the density:

$$\tilde{\rho}_{ij}(\mathbf{r}) = \sum_{\bar{k}} x_{\bar{k}ij} \bar{k}(\mathbf{r}). \quad (67)$$

For the variational fitting, the self-interaction term,

$$\varepsilon_2^{\text{EXX}} = -\sum_{i,j}^{\text{occ}} \iint \frac{[\rho_{ij}(\mathbf{r}) - \tilde{\rho}_{ij}(\mathbf{r})][\rho_{ij}(\mathbf{r}') - \tilde{\rho}_{ij}(\mathbf{r}')]}{|\mathbf{r} - \mathbf{r}'|} d\mathbf{r} d\mathbf{r}', \quad (68)$$

which is negative definite, must be maximized. Thus, the variations of $\varepsilon_2^{\text{EXX}}$ with respect to each fitting coefficient $x_{\bar{k}ij}$ must vanish:

$$\frac{\partial \varepsilon_2^{\text{EXX}}}{\partial x_{\bar{k}ij}} = \sum_{i,j}^{\text{occ}} \langle ij \| \bar{k} \rangle - \sum_{i,j}^{\text{occ}} \sum_{\bar{l}} \langle \bar{k} \| \bar{l} \rangle x_{\bar{l}ij} \equiv 0 \quad \forall \bar{k}, i, j. \quad (69)$$

Similar to the variational Coulomb fitting, one can cast a set of inhomogeneous equation systems, one for each orbital product

$$\mathbf{G}\mathbf{x}_{ij} = \mathbf{J}_{ij} \quad \forall i, j, \quad (70)$$

where \mathbf{x}_{ij} collects the fitting coefficients for each orbital product and \mathbf{J}_{ij} is defined as

$$\mathbf{J}_{ij} = \begin{pmatrix} \langle ij \| \bar{1} \rangle \\ \langle ij \| \bar{2} \rangle \\ \vdots \\ \langle ij \| \bar{m} \rangle \end{pmatrix}. \quad (71)$$

It is important to note that $\langle ij || \bar{k} \rangle = \langle ji || \bar{k} \rangle$ by the permutational symmetry properties of the three-center electron repulsion integrals. Therefore, only $N_{\text{occ}} \times (N_{\text{occ}} + 1)/2$ inhomogeneous equation systems are needed. After the set of equation systems, defined in Eq. (70), has been solved, the fitted exact exchange energy can be computed as

$$\tilde{E}_{\text{EXX}} = - \sum_{i,j}^{\text{occ}} \sum_{\bar{k}, \bar{l}} x_{\bar{k}ij} \langle \bar{k} || \bar{l} \rangle x_{\bar{l}ij} \quad (72)$$

$$= - \sum_{i,j}^{\text{occ}} \sum_{\bar{k}, \bar{l}} \langle ij || \bar{k} \rangle G_{\bar{k}\bar{l}}^{-1} \langle \bar{l} || ij \rangle. \quad (73)$$

The total hybrid ADFT energy thus becomes

$$E = \sum_{\mu,\nu} P_{\mu\nu} H_{\mu\nu} + \sum_{\bar{k}} \sum_{\mu,\nu} P_{\mu\nu} \langle \mu\nu || \bar{k} \rangle x_{\bar{k}} - \frac{1}{2} \sum_{\bar{k}, \bar{l}} x_{\bar{k}} x_{\bar{l}} \langle \bar{k} || \bar{l} \rangle + E_c[\tilde{\rho}] + (1 - \alpha) E_x[\tilde{\rho}] - \alpha \sum_{i,j}^{\text{occ}} \sum_{\bar{k}, \bar{l}} \langle ij || \bar{k} \rangle G_{\bar{k}\bar{l}}^{-1} \langle \bar{l} || ij \rangle, \quad (74)$$

where the exchange-correlation energy has been explicitly separated. Eq. (74) is only an illustrative case of how to build a hybrid functional, and, in practice, more than one mixing parameter can be found in a hybrid definition. Variation of Eq. (74) with respect to the molecular orbital coefficients under the orthonormality constraint, Eq. (34), yields

$$\begin{aligned} \frac{\partial E}{\partial c_{\mu i}} &= 4 \sum_{\nu} \left(H_{\mu\nu} + \sum_{\bar{k}} \langle \mu\nu || \bar{k} \rangle (x_{\bar{k}} + z_{\bar{k}}) - \alpha \sum_j^{\text{occ}} \sum_{\bar{k}, \bar{l}} \langle \mu j || \bar{k} \rangle G_{\bar{k}\bar{l}}^{-1} \langle \bar{l} || \nu j \rangle \right) c_{\nu i} \\ &\quad - 4 \sum_{\nu} \sum_j S_{\mu\nu} c_{\nu j} \epsilon_{ji} \end{aligned} \quad (75)$$

with

$$z_{\bar{k}} = \sum_{\bar{l}} G_{\bar{k}\bar{l}}^{-1} \langle \bar{l} || (1 - \alpha) v_x[\tilde{\rho}] + v_c[\tilde{\rho}] \rangle. \quad (76)$$

The corresponding Kohn-Sham matrix elements are defined as

$$K_{\mu\nu} = H_{\mu\nu} + \sum_{\bar{k}} \langle \mu\nu || \bar{k} \rangle (x_{\bar{k}} + z_{\bar{k}}) - \alpha \sum_j^{\text{occ}} \sum_{\bar{k}, \bar{l}} \langle \mu j || \bar{k} \rangle G_{\bar{k}\bar{l}}^{-1} \langle \bar{l} || \nu j \rangle. \quad (77)$$

Straightforward implementation of Eqs. (73) and (77) leads to an algorithm that scales as $N_{\text{occ}} \times N \times M^2$. It has been noted that this quartic scaling algorithm is only

advantageous to its four-center counterpart, Eq. (65), when $N_{\text{occ}} \ll N$, i.e., using basis sets of at least triple-zeta quality.

Many groups have proposed modifications to the variational exact exchange fitting method giving rise to algorithms like the atomic resolution of the identity (Sodt and Head-Gordon 2008), local density fitting (LDF) (Polly et al. 2004; Mejia-Rodriguez and Köster 2014), concentric atomic density fitting (Hollman et al. 2014), pair atomic resolution of the identity (Watson et al. 2003; Merlot et al. 2013; Manzer et al. 2015), as well as atom-centered Cholesky decomposition approaches (Aquilante et al. 2007). We have recently developed an LDF approach to exact exchange (LDF-EXX) which has proven to be robust and efficient (Mejia-Rodriguez and Köster 2014). LDF-EXX is based on the fact that the exact exchange contribution to the Kohn-Sham matrix,

$$-\alpha \sum_j^{\text{occ}} \sum_{\bar{k}, \bar{l}} \langle \mu_j \| \bar{k} \rangle G_{\bar{k}\bar{l}}^{-1} \langle \bar{l} \| \nu_j \rangle, \quad (78)$$

is invariant under unitary transformations of the molecular orbitals. Thus, any set of molecular orbitals generated through a standard localization procedure, like Edmiston-Ruedenberg (Edmiston and Ruedenberg 1963), Foster-Boys (Boys 1960; Foster and Boys 1960), or Pipek-Mezey (Pipek and Mezey 1989), can be used to calculate the exact exchange contribution. By using localized molecular orbitals, the three-center ERIs appearing in Eq. 78 have non-negligible values only when atomic orbitals $\mu(\mathbf{r})$ and $\nu(\mathbf{r})$ are close in space to the localized molecular orbital $\psi_j(\mathbf{r})$. This allows the definition of local sets of basis functions around each localized molecular orbital and the screening of a large number of integrals. Furthermore, since all orbital products $\psi_j(\mathbf{r})\mu(\mathbf{r})$ are also localized in space, the auxiliary functions needed to accurately fit these products can also be restricted to a region close to $\psi_j(\mathbf{r})$. In this way, local auxiliary function sets can also be defined for each localized molecular orbital. For sufficiently large systems, the sizes of the local sets remain constant, reducing the scaling to N_{occ} with an $N_{\text{local}} \times M_{\text{local}}^2$ constant prefactor.

A very important ingredient to ensure that N_{local} and M_{local} are kept at their smallest possible size is the localization procedure. Unfortunately, orbital localization algorithms based on Jacobi sweeps scale as N^3 and can become very unstable when large basis sets are employed. In order to partially overcome this situation, a combination of the pivoted Cholesky decomposition of the density matrix (Aquilante et al. 2006) followed by the Foster-Boys algorithm is employed in our LDF-EXX. This combination yields tightly localized molecular orbitals without jeopardizing the potential linear scaling of the LDF-EXX algorithm for systems composed of a few hundred atoms (Mejia-Rodriguez and Köster 2014), despite the fact that both steps (Cholesky decomposition and Foster-Boys localization) scale cubically. Thus, the LDF-EXX algorithm can be summarized as follows:

1. Pivoted Cholesky decomposition of $\mathbf{P} \mapsto \mathbf{C}$.
2. Foster-Boys localization of the resulting \mathbf{C} matrix.

3. Selection of the local basis and auxiliary function sets for each MO.
4. Calculation of the ERI matrix, with elements $E_{\bar{k}\mu,i} = \langle \bar{k} || \mu i \rangle$, for each MO.
5. Calculation, Cholesky decomposition, and inversion of $\mathbf{G}_i = \mathbf{L}_i \mathbf{L}_i^T$ for each MO.
6. Compute exact exchange contribution to the Kohn-Sham matrix: $-\alpha \sum_i^{\text{occ}} \mathbf{E}_i^T \mathbf{G}_i^{-1} \mathbf{E}_i$.

The computational efficiency of the LDF-EXX algorithm depends crucially on the selection of the local sets in Step 3. Our selection is based on atomic Löwdin populations for each MO. All auxiliary and basis functions centered on atoms with significant Löwdin populations for a given MO will form the local auxiliary and basis sets, respectively, of that particular localized orbital. In addition, the local basis set is extended with basis functions centered on atoms with non-negligible overlaps to any function in the previously selected local basis set. In deMon2k, significant atomic Löwdin populations are defined as the n largest atomic populations whose sum does not exceed a predefined threshold set by default to 0.99. Also in this context, non-negligible overlaps are those whose absolute values are greater than 10^{-6} a.u. (Mejia-Rodriguez and Köster 2014).

The extension of the preceding hybrid ADFT energy expression, Eq. (74), to the BASIS approach is trivial and has also been implemented in deMon2k. While using the GEN-A2* auxiliary function set, the above algorithm yields standard enthalpies of formation within 0.5 kcal/mol with respect to a four-center reference for the entire G3/99 molecular test set (Curtiss et al. 1997, 1998, 2001) and the PBE0 (Perdew et al. 1996b; Adamo and Barone 1999), B3LYP (Stephens et al. 1994) or M06-2X (Zhao and Truhlar 2006) hybrid functionals (Mejia-Rodriguez et al. 2015a). It is important to note that the meta-GGA is only available through the BASIS approach.

DNA Double Strands

In order to demonstrate the advantages of the LDF-EXX algorithm implemented in deMon2k, we show Hartree-Fock calculations on DNA double strands containing up to 8 adenine-thymine pairs. The structures were generated with the Accelrys Discovery Studio Client in the DNA B-strand conformation with both ends capped with hydroxyl groups. The phosphate groups were protonated in order to obtain neutral systems.

The largest DNA strand, depicted in Fig. 3, has the molecular formula $\text{C}_{160}\text{H}_{202}\text{O}_{92}\text{N}_{56}\text{P}_{14}$ with a total of 524 atoms. All computations were performed using the 6-31G** basis set (Hehre et al. 1972; Francl et al. 1982) and the GEN-A2/GEN-A2* approach described in Mejia-Rodriguez and Köster (2014). The largest system contains about 6,000 basis functions and more than 15,000 auxiliary functions.

Figure 4 shows the time needed for single point Hartree-Fock calculations using the LDF-EXX algorithm in an Intel Xeon X5675 @ 3.07 GHz with 4 GB of RAM memory. Convergence was achieved after 10 SCF iterations in all cases. Figure 4 also shows the scaling between two consecutive points. It can be seen that the

Fig. 3 Ball and stick representation of the DNA double strand in the B-strand conformation with 8 adenine-thymine base pairs

Fig. 4 Wall clock times, in minutes, for serial Hartree-Fock calculations of DNA double strands. All calculations were performed employing the LDF-EXX algorithm. The number above each point shows the scaling calculated with respect to the immediately anterior point

calculated scaling is diminishing and becomes subquadratic for the DNA₄ to DNA₈ step, showing the potential linear scaling that can be achieved by the algorithm.

It is important to note that the N^3 molecular orbital localization took less than 5% of the total time in all cases. Furthermore, since well-localized molecular orbitals were obtained, all \mathbf{E}_i matrices could be calculated in one batch up to DNA₄ and two batches for DNA₈. Despite the difference in the number of batches, the drop in the scaling remained constant for the steps DNA₂ to DNA₄ and DNA₄ to DNA₈.

Summary

In this section, a novel implementation of exact exchange has been reviewed. The algorithm has a potential linear scaling behavior for sufficiently large (extended) systems. The algorithm has been called local density-fitting exact exchange (LDF-EXX).

Furthermore, test calculations on DNA double strands containing more than 500 atoms and described with a double-zeta plus polarization basis set are shown. These results demonstrate the low-scaling behavior of the algorithm.

With the new LDF-EXX implementation, hybrid functional calculations within the ADFT framework are now possible in deMon2k. Further improvements are directed toward an efficient parallelization of the LDF-EXX algorithm so it can be employed in large-scale computations including BOMD simulations.

The ADFT-GIAO Methodology

The computation of magnetic properties from first principles demands a reformulation of the corresponding Hamilton operator. In order to include the magnetic field in the nonrelativistic Hamiltonian, the momentum operator \hat{p} is replaced by the conjugate momentum operator $\hat{\pi}$:

$$\hat{p} \longrightarrow \hat{\pi} = -i\vec{\nabla} + \vec{A}(\vec{r}). \quad (79)$$

The quantity $\vec{A}(\vec{r})$ denotes the vector potential of the total magnetic field, which is composed of two contributions. The first contribution, $\vec{A}^{\text{loc}}(\vec{r})$, originates from the intrinsic magnetic moment, $\vec{\mu}_C$, located at the position \vec{C} , of all the nuclei,

$$\vec{A}^{\text{loc}}(\vec{r}) = \frac{1}{c^2} \sum_C^{\text{Atoms}} \vec{\mu}_C \times \frac{\vec{r} - \vec{C}}{|\vec{r} - \vec{C}|^3}, \quad (80)$$

while the applied external magnetic field, \vec{B} , is responsible for the second one, $\vec{A}^{\text{ext}}(\vec{r})$,

$$\vec{A}^{\text{ext}}(\vec{r}) = \frac{1}{2} \vec{B} \times (\vec{r} - \vec{G}). \quad (81)$$

Here \vec{G} denotes the arbitrary origin of the vector potential, i.e., the gauge. The basic physical laws require that the observables are invariant with respect to the

chosen gauge origin. However, this gauge invariance is not necessarily ensured for approximate solutions of the Schrödinger equation. The origin of the problem has been traced back to the finite-basis set representation used for the molecular orbital expansion. Therefore, the enlargement of the basis set can resolve the problem, but this approach is only feasible for very small systems. A more practical solution is provided by so-called local or distributed gauge origin methods. The idea is to consider a different gauge origin for each atomic or molecular orbital. The developed schemes following this idea permit the computation of gauge-invariant results independently of the size of the basis set. Nowadays, the gauge-including atomic orbital (GIAO) (Ditchfield 1972) scheme has been established as a standard for magnetic property calculations. In GIAO, the atomic orbitals depend on the electronic coordinates and on the perturbation, i.e., the applied magnetic field, \vec{B} . The perturbation-dependent atomic orbitals are built by attaching an exponential factor, known as London factor (London 1937), to the unperturbed atomic orbital,

$$\phi_{\mu}(\vec{r}, \vec{B}) = \mu(\vec{r}) e^{-\frac{i}{2} \vec{B} \cdot (\vec{A} - \vec{G}) \times \vec{r}}. \quad (82)$$

As a consequence, the ADFT energy, Eq. (39), is now expressed in terms of these GIAOs. This combination is named the ADFT-GIAO methodology. Further, the elements of the one-electron Hamiltonian matrix, $H_{\mu\nu}$, also change due to the introduction of the conjugated momentum operator, given in Eq. (79), for the evaluation of the kinetic energy. Introducing Eqs. (79) and (82) into Eq. (19), we find, after some lengthy algebra,

$$H_{\mu\nu} = \left\langle \phi_{\mu} \left| \hat{H} \right| \phi_{\nu} \right\rangle = \left\langle \mu \left| \mathcal{L}_{AB} \hat{H}_g \right| \nu \right\rangle \quad (83)$$

with

$$\mathcal{L}_{AB} = e^{\frac{i}{2} \vec{B} \cdot (\vec{A} - \vec{B}) \times \vec{r}}, \quad (84)$$

being the product of the GIAO pair London factors where the vector \vec{B} denotes the center of the basis function $\nu(\vec{r})$ in Eq. (83). The corresponding gauge-invariant one-electron Hamilton operator has the form

$$\hat{H}_g = \hat{H}_0 + \vec{B} \cdot \hat{\xi}_g^p + \sum_C^{\text{Atoms}} \vec{\mu}_C \cdot \hat{\sigma}_g^p(\vec{C}) + \vec{B} \cdot \hat{\xi}_g^d \cdot \vec{B} + \sum_C^{\text{Atoms}} \vec{B} \cdot \hat{\sigma}_g^d(\vec{C}) \cdot \vec{\mu}_C. \quad (85)$$

Here \hat{H}_0 is the sum of the usual kinetic and nuclear-attraction operators of the electrons, as given in Eq. (19). The second and third terms correspond to the gauge-invariant paramagnetic vector operators for the magnetizability,

$$\hat{\xi}_g^p(\vec{B}) = -\frac{i}{2} (\vec{r} - \vec{B}) \times \vec{\nabla}, \quad (86)$$

and for the magnetic shielding,

$$\hat{\sigma}_g^p(\vec{C}) = -\frac{i}{c^2} \frac{\vec{r} - \vec{C}}{|\vec{r} - \vec{C}|^3} \times \vec{\nabla}. \quad (87)$$

The fourth and fifth terms are the gauge-invariant diamagnetic tensor operators for the magnetizability,

$$\hat{\xi}_g^d(\vec{B}) = \frac{1}{8} \left[|\vec{r} - \vec{B}|^2 \mathbf{E} - (\vec{r} - \vec{B}) \otimes (\vec{r} - \vec{B}) \right] \quad (88)$$

and the magnetic shielding,

$$\hat{\sigma}_g^d(\vec{C}) = \frac{1}{2c^2} \left[\frac{(\vec{r} - \vec{B}) \cdot (\vec{r} - \vec{C})}{|\vec{r} - \vec{C}|^3} \mathbf{E} - \frac{(\vec{r} - \vec{C}) \otimes (\vec{r} - \vec{B})}{|\vec{r} - \vec{C}|^3} \right]. \quad (89)$$

As the applied magnetic field and the intrinsic magnetic moments are treated as perturbations, the corresponding properties are computed as second-order energy derivatives. An element of the magnetic shielding tensor (Zuniga-Gutierrez et al. 2011) is given by the second-order energy derivative with respect to a Cartesian component of the external magnetic field and of the intrinsic magnetic moment of the nucleus C , i.e.,

$$\sigma_{\eta\lambda}(\vec{C}) = \lim_{\substack{\vec{B} \rightarrow 0 \\ \mu_C \rightarrow 0}} \frac{\partial^2 E}{\partial \mathcal{B}_\lambda \partial \mu_{C,\eta}} = \sum_{\mu,\nu} P_{\mu\nu}^{(\lambda)} H_{\mu\nu}^{(\eta)}(\vec{C}) + \sum_{\mu,\nu} P_{\mu\nu} H_{\mu\nu}^{(\lambda\eta)}(\vec{C}). \quad (90)$$

Here λ and η denote Cartesian components (x , y or z). As enclosed superscripts, (λ) and (η) , of perturbed matrix elements, they denote differentiation with respect to \mathcal{B}_λ and $\mu_{C,\eta}$, respectively. Thus, the expression for the derivatives of $H_{\mu\nu}$ appearing in Eq. (90) are

$$H_{\mu\nu}^{(\eta)}(\vec{C}) = \left\langle \mu \left| \hat{\sigma}_{g,\eta}^p \right| \nu \right\rangle \quad (91)$$

and

$$H_{\mu\nu}^{(\eta\lambda)}(\vec{C}) = \left\langle \mu \left| \mathcal{L}_{AB}^{(\lambda)} \hat{\sigma}_{g,\eta}^p + \hat{\sigma}_{g,\lambda\eta}^d \right| \nu \right\rangle \quad (92)$$

with

$$\mathcal{L}_{AB}^{(\lambda)} = \frac{i}{2} \left[(\vec{A} - \vec{B}) \times \vec{r} \right]_\lambda. \quad (93)$$

Because of the use of GIAOs, the basis functions are perturbation dependent. Thus the perturbed density matrix is given by (McWeeny 2001)

$$P_{\mu\nu}^{(\lambda)} = 2 \sum_i^{\text{occ}} \sum_a^{\text{uno}} \frac{K_{ia}^{(\lambda)} - \varepsilon_i S_{ia}^{(\lambda)}}{\varepsilon_i - \varepsilon_a} (c_{\mu i} c_{\nu a} - c_{\mu a} c_{\nu i}) - \frac{1}{2} \sum_{\sigma, \kappa} P_{\mu\sigma} S_{\sigma\kappa}^{(\lambda)} P_{\kappa\nu}. \quad (94)$$

Here $S_{\mu\nu}^{(\lambda)}$ is the first derivative of an element of the overlap matrix,

$$S_{\mu\nu}^{(\lambda)} = \left\langle \mu \left| \mathcal{L}_{AB}^{(\lambda)} \right| \nu \right\rangle, \quad (95)$$

and its form is independent of the employed methodology, BASIS or AUXIS. Note that for perturbation-independent basis functions, the terms including derivatives of elements of the overlap matrix vanish and, consequently, Eq. (94) reduces to Eq. (48), except for the sign in the parentheses. This difference originates from the pure imaginary paramagnetic shielding operator, Eq. (87), that causes the response of the electron density. A closer examination of Eq. (94) reveals that the response of the molecular orbitals must also be purely imaginary. According to the definition of the electron density in terms of molecular orbitals, we find for the response of the electron density:

$$\begin{aligned} \rho^{(\lambda)}(\vec{r}, \vec{\mathcal{B}}) &= \lim_{\vec{\mathcal{B}} \rightarrow 0} \frac{\partial}{\partial \mathcal{B}_\lambda} \sum_i^{\text{occ}} [\psi_i(\vec{r})]^* \psi_i(\vec{r}) \\ &= \sum_i^{\text{occ}} [\psi_i^{(\lambda)}(\vec{r})]^* \psi_i(\vec{r}) + [\psi_i(\vec{r})]^* \psi_i^{(\lambda)}(\vec{r}) \\ &= 0. \end{aligned} \quad (96)$$

This result must be emulated by the auxiliary density in order to compute magnetic properties within the ADFT framework. To do so, we have chosen the simplest ansatz by using perturbation-independent auxiliary functions (Zuniga-Gutierrez et al. 2011). With this choice, the linear response for a magnetic perturbation of the auxiliary density vanishes:

$$\tilde{\rho}^{(\lambda)}(\vec{r}) = \frac{\partial \tilde{\rho}(\vec{r})}{\partial \mathcal{B}_\lambda} = 0. \quad (97)$$

In Eq. (94), $K_{\mu\nu}^{(\lambda)}$ is the magnetic perturbed Kohn-Sham matrix whose form depends on whether the Kohn-Sham (BASIS) or the auxiliary density (AUXIS) is used for the evaluation of the exchange-correlation contributions. For the first choice, (conventional DFT) $K_{\mu\nu}^{(\lambda)}$ is found to be

$$K_{\mu\nu}^{(\lambda)} = H_{\mu\nu}^{(\lambda)} + \sum_{\vec{k}} \left\langle \mathcal{L}_{AB}^{(\lambda)} \mu\nu \middle| \vec{k} \right\rangle x_{\vec{k}} + \lim_{\vec{\mathcal{B}} \rightarrow 0} \frac{\partial^2 E_{xc}[\rho]}{\partial \mathcal{B}_\lambda \partial P_{\mu\nu}} \quad (98)$$

while for the latter (ADFT) $K_{\mu\nu}^{(\lambda)}$ is

$$K_{\mu\nu}^{(\lambda)} = H_{\mu\nu}^{(\lambda)} + \sum_{\bar{k}} \left\langle \mathcal{L}_{AB}^{(\lambda)} \mu\nu \middle| \bar{k} \right\rangle (x_{\bar{k}} + z_{\bar{k}}). \quad (99)$$

Here $H_{\mu\nu}^{(\lambda)}$ denotes the first derivative of the one-electron Hamiltonian contributions, Eq. (83), whose form is

$$H_{\mu\nu}^{(\lambda)} = \left\langle \mu \middle| \mathcal{L}_{AB}^{(\lambda)} \hat{H}_0 \middle| \nu \right\rangle + \left\langle \mu \middle| \hat{\xi}_{g,\lambda}^p \middle| \nu \right\rangle. \quad (100)$$

The second term in Eq. (100) corresponds to the molecular integral of the λ -Cartesian component of the paramagnetic magnetizability vector operator, Eq. (86). The $H_{\mu\nu}^{(\lambda)}$ and electronic Coulomb repulsion energy, second term in Eqs. (98) and (99), have the same form for both methodologies. The difference between Eqs. (98) and (99) lies in the exchange-correlation contributions. Within the conventional DFT framework, this contribution is evaluated with the magnetic field-dependent electron density that generates new expressions which have to be evaluated by numerical integration. This is an expensive computational task. The number of additional integrals depends on the approximation of the exchange-correlation functional: Three additional integrals for LDA and six for GGA. On the other hand, the exchange-correlation contributions are uniquely accounted for by the exchange-correlation coefficients $\{z_{\bar{k}}\}$, Eq. (46), in the ADFT expression of $K_{\mu\nu}^{(\lambda)}$, Eq. (99). Note that these coefficients have already been evaluated in the preceding SCF calculation. Therefore, they are read from memory. As a result, no extra numerical integration is required within ADFT-GIAO.

The ADFT-GIAO methodology has also been used for the computation of the magnetizability tensor (Zuniga-Gutierrez et al. 2012). It is computed as the second energy derivative with respect to Cartesian components of the applied magnetic field,

$$\begin{aligned} \xi_{\tau\lambda} = \lim_{\vec{B} \rightarrow 0} \frac{\partial^2 E}{\partial B_\tau \partial B_\lambda} &= \sum_{\mu,\nu} P_{\mu\nu}^{(\lambda)} K_{\mu\nu}^{(\tau)} + \sum_{\mu,\nu} P_{\mu\nu} \left[H_{\mu\nu}^{(\tau\lambda)} + \left\langle \mathcal{L}_{AB}^{(\tau\lambda)} \mu\nu \middle| \bar{k} \right\rangle (x_{\bar{k}} + z_{\bar{k}}) \right] \\ &\quad - \sum_{\mu,\nu} S_{\mu\nu}^{(\tau\lambda)} W_{\mu\nu} - \sum_{\mu,\nu} S_{\mu\nu}^{(\lambda)} W_{\mu\nu}^{(\tau)}. \end{aligned} \quad (101)$$

Here $W_{\mu\nu}$ and $W_{\mu\nu}^{(\tau)}$ denote elements of the weighted density matrix and its corresponding derivative. Moreover, second derivatives of elements of the one-electron Hamiltonian matrix,

$$\begin{aligned} H_{\mu\nu}^{(\tau\lambda)} &= \left\langle \mu \middle| \mathcal{L}_{AB}^{(\tau)} \mathcal{L}_{AB}^{(\lambda)} \hat{H}_0 \middle| \nu \right\rangle + \left\langle \mu \middle| \mathcal{L}_{AB}^{(\lambda)} \hat{\xi}_{g,\tau}^p \middle| \nu \right\rangle \\ &\quad + \left\langle \mu \middle| \mathcal{L}_{AB}^{(\tau)} \hat{\xi}_{g,\lambda}^p \middle| \nu \right\rangle + \left\langle \mu \middle| \hat{\xi}_{g,\lambda\tau}^d \middle| \nu \right\rangle, \end{aligned} \quad (102)$$

and of the overlap matrix,

$$S_{\mu\nu}^{(\tau\lambda)} = \left\langle \mu \left| \mathcal{L}_{AB}^{(\tau\lambda)} \right| \nu \right\rangle, \quad (103)$$

with

$$\mathcal{L}_{AB}^{(\tau\lambda)} = -\frac{1}{4} \left[\left(\vec{A} - \vec{B} \right) \times \vec{r} \right]_{\tau} \left[\left(\vec{A} - \vec{B} \right) \times \vec{r} \right]_{\lambda}, \quad (104)$$

are needed for the calculation of magnetizability tensor elements. These matrix elements can be straightforwardly calculated by extending molecular integral recurrence relations.

Magnetic properties related to the nuclear motion have also been computed with the ADFT-GIAO methodology, i.e., the rotational g-tensor (Zuniga-Gutierrez et al. 2015) and the nuclear spin-rotation constants (NSRC) (Zuniga-Gutierrez et al. 2015), that are experimentally accessible by molecular beam or microwave spectroscopy, respectively. Theoretically, these spectroscopic parameters are calculated as second energy derivatives with respect to a Cartesian element of the rotational angular momentum, \vec{J} , and either an element of the applied magnetic field for the rotational g-tensor or an element of the nuclear intrinsic magnetic moment for the NSRC. It is worth to mention that the rotational g-tensors and the NSRC can also be expressed in terms of the magnetizability and magnetic shielding tensors (Sauer 2011). They represent the most complex quantities to solve for the corresponding equations. Furthermore, due to the inherent efficiency of the ADFT-GIAO methodology, the 3D plotting of the induced magnetic field has become feasible for large systems, like doped fullerenes. Temperature and dynamic effects can also be studied with ADFT-GIAO by analyzing the average or instantaneous values of any of the magnetic properties along a molecular dynamics (MD) trajectory (Goursot et al. 2013; Zuniga-Gutierrez et al. 2015). For these kinds of calculations, the magnetic property is sometimes calculated for hundreds of thousands of different structures. All these types of calculations are available in the deMon2k code.

For all magnetic properties studied so far, i.e., magnetic shielding tensors, magnetizability tensors, rotational g-tensors, and nuclear spin-rotation tensors, the ADFT-GIAO methodology was thoroughly validated against conventional DFT-GIAO approaches. In all cases, ADFT-GIAO yields practically indistinguishable results, with much less computational effort. As a benchmark example, the magnetic shielding tensors for all atoms in triphenylene ($C_{18}H_{12}$) and the corresponding magnetizability were calculated employing the PW91 exchange-correlation functional in combination with the aug-cc-pVXZ (X=D,T,Q) basis sets and the GEN-A2 auxiliary function set. Figure 5 shows the timings for the calculations performed with the conventional DFT-GIAO (black bars) and with the ADFT-GIAO (gray bars) methodologies. Clearly, the ADFT-GIAO methodology outperforms the conventional DFT-GIAO method. Note that the difference in computational performance increases rapidly with the number of basis functions. For the largest

Fig. 5 Comparison of CPU timings between conventional DFT- and ADFT-GIAO methodologies for the calculation of the magnetic shielding (*left*) and magnetizability (*right*) tensors of the triphenylene

basis set, with 3108 basis functions, the ADFT-GIAO magnetic shielding and magnetizability calculations were 6 and 15 times faster than the corresponding DFT-GIAO calculations. Therefore, magnetic property calculations of nanosystems with hundreds or even thousands of atoms become feasible with the ADFT-GIAO methodology.

Figure 6 shows computational timings for magnetic properties in large systems: All magnetic shielding tensors for models of ZSM5 zeolites (Zuniga-Gutierrez et al. 2011) with one ($\text{Si}_{96}\text{O}_{200}\text{H}_{80}$), two ($\text{Si}_{192}\text{O}_{400}\text{H}_{128}$), and three ($\text{Si}_{288}\text{O}_{600}\text{H}_{176}$) cell units and the magnetizability tensor for models of a single-walled carbon nanotube ($\text{C}_{600}\text{H}_{40}$), a peapod ($\text{C}_{780}\text{H}_{40}$), and a double-walled carbon nanotube ($\text{C}_{952}\text{H}_{72}$) (Zuniga-Gutierrez et al. 2012). The calculations were performed with the LDA and PBE exchange-correlation functionals for magnetic shielding and magnetizability, respectively. In both cases, the DZVP basis set combined with the GEN-A2 auxiliary functions were used. The timings in Fig. 6 refer to parallel calculations with 8 Intel XeonTM cores with 2.4 GHz. The total time for the calculation of all magnetic shielding tensors in the largest ZSM5 model takes approximately 6 days. Note that the property calculation (gray bars) is computationally much less demanding than the SCF procedure (black bars).

Applications

Dynamics of Sodium Clusters

In this section, we review the results obtained from a systematic study of the temperature dependency of the polarizabilities of small sodium clusters at a reliable first-principles all-electron level of theory (Calaminici et al. 2007b; Gamboa et al. 2008).

Static polarizability measurements have been used for a long time to gain insight into the electronic structure of small clusters (Bonin and Kresin 1997; Knickelbein 2001, 2003, 2004; Bowlan et al. 2011). Because the polarizability is very sensitive to the distribution of the valence electron density, it can also be used as an indicator for chemical reactivity (Pearson 1973; Politzer 1987). Therefore, the study of the size dependency of the polarizability of simple clusters yields results of fundamental importance to chemistry and physics. A particular example resides in the polarizability studies on sodium clusters which were of paramount importance for the derivation of the jellium model (Knight et al. 1984). Today, this model is used with great success in cluster science (Bergeron et al. 2004, 2005). Several series of experimental data on sodium cluster polarizabilities are available in the literature (Molof et al. 1974a, b; Knight et al. 1985; Rayane et al. 1999; Tikhonov et al. 2001; Bowlan et al. 2011). In the pioneering work of Knight et al. (1984), the static polarizabilities of sodium clusters in a size range from 2 to 40 sodium atoms were studied. Later on, Rayane et al. (1999) repeated these measurements for a smaller size range from 2 to 22 sodium atoms. More recently, Tikhonov et al. (2001) measured the polarizability of selected sodium clusters up to 93 atoms. Just a few years ago, Bowlan et al. performed high precision measurements of

Fig. 6 Computational times for the calculation of magnetic shieldings (*left plot*) for ZSM5 models and the magnetizabilities (*right plot*) for models of carbon nanotubes. See text for details

cluster polarizabilities and dipole moments for sodium clusters containing less than 200 atoms. The overall agreement between these different experiments is quite satisfying. Nevertheless, discrepancies exist.

In Fig. 7, the experimental data for a series of sodium cluster polarizabilities are plotted together with our theoretical values. In particular, the pronounced oscillating behavior observed by Knight et al. up to the hexamer (Fig. 7a, dots) was not confirmed by the more recent study of Rayane and coworkers (Fig. 7a, squares). To emphasize the spread between these two experimental data sets, we have connected the data points in Fig. 7 by vertical lines. This figure also shows that for the larger sodium clusters with 7, 8, and 9 atoms excellent agreement between the reported data sets exist. The heptamer and octamer polarizabilities were also measured by Tikhonov et al. (2001) and are in good agreement with the depicted experimental data in Fig. 7, too.

In order to resolve the discrepancy in the measured polarizabilities of the smaller sodium clusters, many theoretical studies have been performed over the last two decades (see, e.g., Politzer 1987; Chandrakumar et al. 2004; Kümmel et al. 2000; Blundell et al. 2000; Kronik et al. 2000 and references therein). Most calculations employed density functional theory (Hohenberg and Kohn 1964; Kohn and Sham 1965), but wave-function-based studies are also available (Chandrakumar et al. 2004). A comparison of these theoretical studies reveals that the static polarizabilities of sodium clusters are severely underestimated at all reliable levels of theory. Over the last two decades, different corrections have been proposed to resolve this long-standing discrepancy between theory and experiment. More recently, it has been speculated that the mismatch between calculated and measured sodium cluster polarizabilities is due to finite temperature effects (Kümmel et al. 2000; Blundell et al. 2000; Kronik et al. 2000). In fact, this idea was already mentioned in the original experimental work (Knight et al. 1985). However, a systematic study of the temperature dependence of sodium cluster polarizabilities at a reliable first-principles all-electron level of theory was still absent until very recently. We have finally closed this gap by performing a temperature-dependent polarizability study of small sodium clusters by employing Born-Oppenheimer molecular dynamics (BOMD) simulations (Calaminici et al. 2007b; Gamboa et al. 2008).

The calculations were performed with the linear combination of Gaussian-type orbital density functional theory (LCGTO-DFT) deMon2k (Köster et al. 2011a) code. In Fig. 7, the crosses refer to all-electron polarizabilities calculated with the local density approximation (LDA) employing the exchange functional from Dirac (1930) in combination with the correlation functional proposed by Vosko, Wilk, and Nusair (VWN) (Vosko et al. 1980). The asterisks denote polarizabilities obtained with the gradient-corrected exchange-correlation functional proposed by Perdew, Burke, and Ernzerhof (PBE) (Perdew et al. 1996a).

The cluster structures were optimized at the corresponding level of theory employing a double-zeta valence polarization (DZVP) basis set (Godbout et al. 1992). For the polarizability calculations, a triple-zeta valence polarization (TZVP) basis set augmented with field-induced polarization (FIP) function was used (Calaminici et al. 1999). All calculations were performed in the framework of

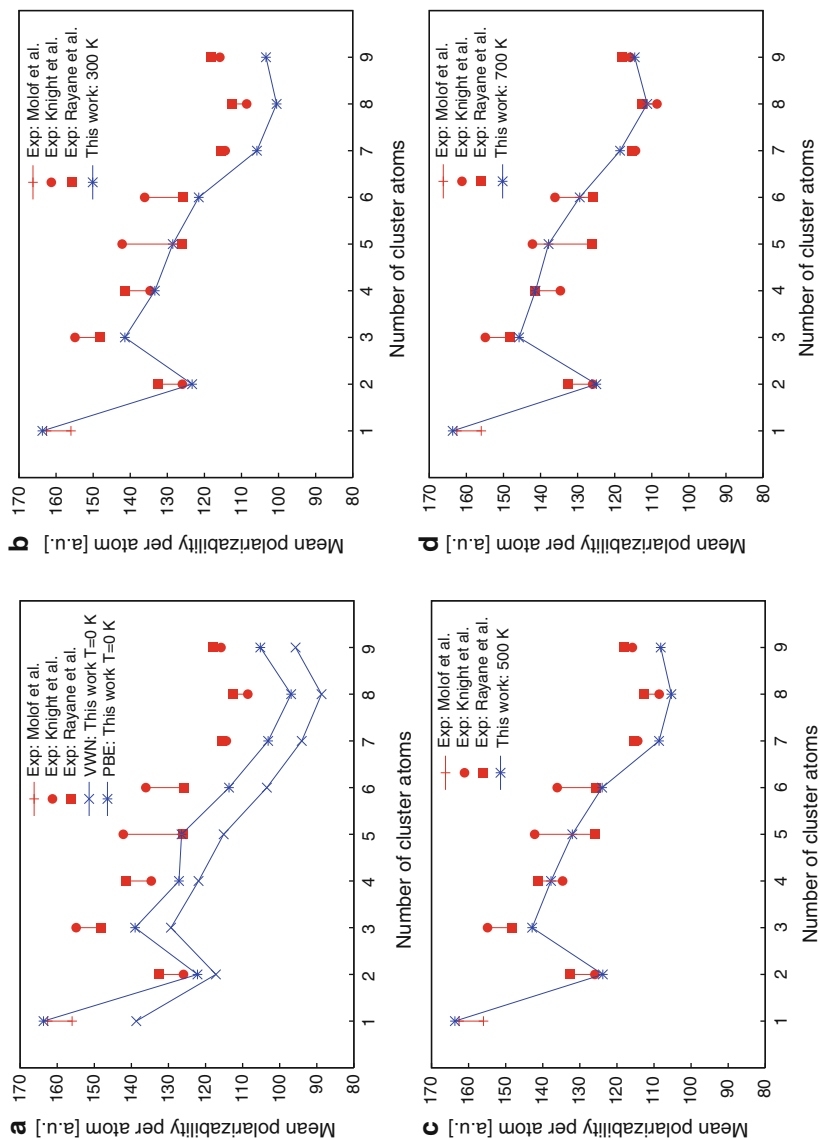

Fig. 7 Experimental and theoretical mean polarizabilities per atom [a.u.] of Na_n ($n=2-9$) clusters. The theoretical values are calculated at the VWN/TZVP-FIP/GEN-A2^{8*} (crosses) and PBE/TZVP-FIP/GEN-A2^{8*} (asterisks) level of theory. These values are connected in order to guide the eye. The individual graphs display calculated polarizabilities at 0 (a), 300 K (b), 500 K (c), and 700 K (d)

auxiliary density functional theory (ADFT) (Köster et al. 2004b) with A2 or GEN-A2* auxiliary function sets (Calaminici et al. 2007a). The latter was used in the analytical calculation of the cluster polarizabilities (Flores-Moreno and Köster 2008).

It is well established in the literature that calculated DFT polarizabilities at this level of theory differ by no more than 5 % from experiment (Calaminici et al. 1998). Figure 7a, however, shows that the calculated polarizabilities of the sodium clusters are not only considerably too low, but even at the level of the gradient-corrected PBE functional, differences of more than 10 % relative to the experimental values can occur. By and large, these results are confirmed by many other theoretical calculations.

In order to study the dynamics of small sodium clusters at finite temperatures, Born-Oppenheimer molecular dynamics (BOMD) calculations were performed at the above described PBE/DZVP/A2 level of theory. For each cluster, from the dimer to the nonamer, 18 trajectories were recorded in a temperature range from 50 to 900 K with intervals of 50 K. Each trajectory has a length of 220 ps and was recorded with a time step of 2 fs. Similar statistics have already been successfully applied to determine the melting temperatures of sodium clusters with LDA pseudo-potential DFT molecular dynamics (Chacko et al. 2005).

The temperature in the canonical BOMD simulation was controlled by a Nosé-Hoover chain thermostat (Nosé 1984; Hoover 1985; Martyna et al. 1992). In order to study the temperature dependency of the sodium cluster polarizabilities, the polarizability tensor α was calculated along the recorded trajectories. For this purpose, the first 20 ps of each trajectory were discarded, and α was then calculated in 100 fs time steps along the remaining 200 ps. Due to the computational demand of the analytical polarizability calculation along the BOMD trajectories, we employed the LDA kernel. Thus, the computational level for the calculation of the temperature-dependent part of the cluster polarizabilities was VWN/TZVP-FIP/GEN-A2*. The temperature-dependent mean sodium cluster polarizability was then calculated as

$$\bar{\alpha}(T) = \bar{\alpha}^{PBE}(0) + \delta\bar{\alpha}^{VWN}(T) \quad (105)$$

with

$$\bar{\alpha}(T) = \frac{1}{3} [\bar{\alpha}_{xx}(T) + \bar{\alpha}_{yy}(T) + \bar{\alpha}_{zz}(T)]. \quad (106)$$

This approximation assumes that the temperature dependency of $\bar{\alpha}(T)$, namely, $\delta\bar{\alpha}(T)$, is the same at PBE and VWN levels of theory. It should be remembered that the geometries are of course always determined from PBE BOMD calculations.

In Fig. 7, the calculated cluster polarizabilities at 0 (a), 300 (b), 500 (c), and 700 K (d) are depicted. As this figure shows, the individual cluster polarizabilities increase with temperature. Somewhere between 500 and 700 K, the calculated $\bar{\alpha}(T)$ per atom matches into the experimental data sets. In particular, the comparison of the calculated and experimental $\bar{\alpha}(T)$ per atom at 700 K for Na₇, Na₈, and Na₉, for which excellent agreement between the different experimental data sets exist,

is very satisfying. Moreover, it is interesting to note that the oscillating behavior of the $\bar{\alpha}$ per atom for the smaller clusters, which was observed in the original measurement (Knight et al. 1985) and also appears, less pronounced, in the $T=0$ K PBE calculations (Fig. 7a, asterisks), disappears at higher temperatures. Instead, the $\bar{\alpha}$ per atom decreases monotonically from Na_3 to Na_8 . Therefore, we can conclude that the finite temperature polarizabilities of small sodium clusters do not reflect individual molecular structures. Instead, they only reflect the shell closing at the dimer and octamer consistent with the jellium model. Our BOMD calculations also show that cluster fragmentations are not important for the cluster polarizabilities. Such fragmentations occur in our simulations above 800 K.

The change in the trend of the $\bar{\alpha}$ per atom for the small sodium clusters with increasing temperature is due to the different temperature dependencies of the individual cluster polarizabilities. In Fig. 8, the temperature dependencies of the individual cluster polarizabilities are presented. As this figure shows, for the smaller clusters up to the pentamer (Fig. 8a), the behavior of Na_4 is particular. Over a large temperature range up to 600 K the $\delta\bar{\alpha}(T)$ value for this cluster changes almost ideally linearly with the temperature. A closer analysis reveals that in this temperature range the D_{2h} rhombic structure of Na_4 rearranges only in the molecular plane. At 600 K and above, three-dimensional rearrangements occur. In this case, the temperature dependency of the polarizability reflects directly the dynamics of the cluster rearrangement. Figure 8a also shows that $\delta\bar{\alpha}(T)$ increases considerably faster with temperature for Na_4 than for Na_5 . As a result, the bump in the static $T=0$ K PBE polarizabilities at the pentamer (Fig. 7a) disappears in the finite temperature polarizabilities. For the larger clusters, we found very similar temperature dependencies of $\delta\bar{\alpha}(T)$ for Na_8 and Na_9 (Fig. 8b). The shape of our Na_8 temperature-dependent polarizability resembles previous studies with the extended Thomas-Fermi approximation (Blundell et al. 2000). The enlarged sodium hexamer polarizabilities in the temperature range between 200 and 600 K are due to the coexistence of two isomers, planar and pentagonal-pyramidal, as was already previously speculated in (Calaminici et al. 1999).

Summary

In this section, the results obtained by the first systematic study of the temperature dependency of the sodium cluster polarizabilities at a reliable first-principles all-electron level of theory were reviewed. The main results of this study are summarized as follows:

1. The calculated $\bar{\alpha}(T)$ per atom matches well the available experimental data sets at around 700 K;
2. The long-standing discrepancy between theory and experiment is resolved by inclusion of finite temperature effects in the electronic structure calculation;
3. The calculated finite temperature sodium cluster polarizabilities show characteristic minima at the dimer and octamer as expected from the jellium model;
4. Individual molecular structures besides these two are not resolved in the calculated finite temperature sodium cluster polarizabilities.

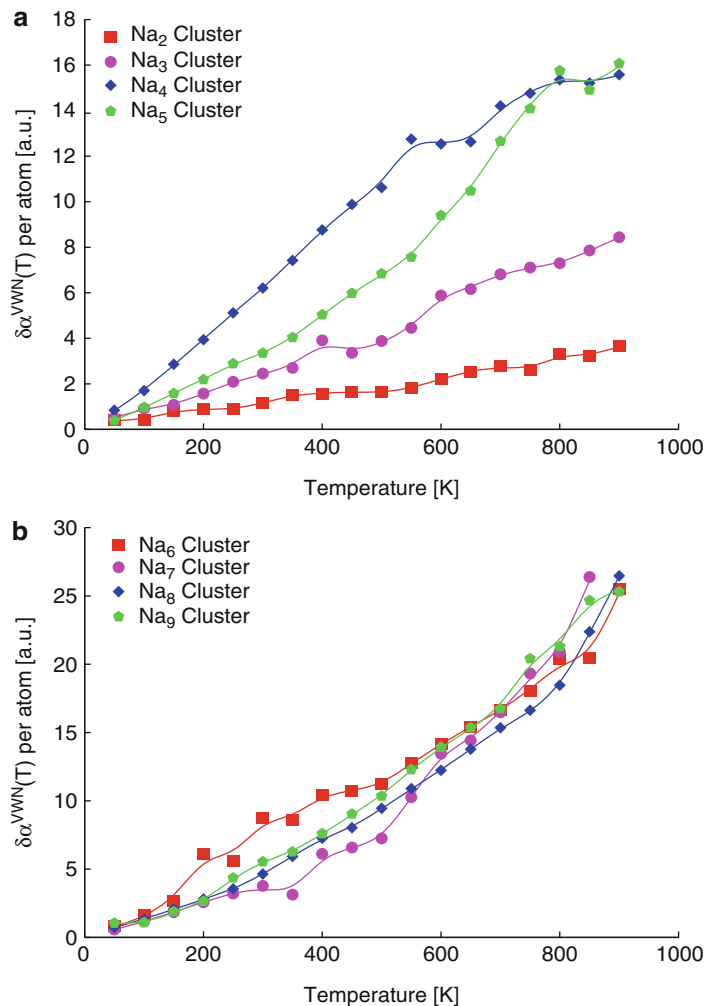

Fig. 8 Change of the mean polarizability per atom with temperature for Na_n clusters with $n = 2-5$ (a) and $n = 6-9$ (b). The calculations were performed at the VWN/TZVP-FIP/GEN-A2* level of theory

Structure of Zeolites

In this section, the calculated structural parameters and energetic properties of Na- and H-mordenites (MOR), using cluster models with more than 400 atoms, will be reviewed. These calculations (Dominguez-Soria et al. 2007, 2008) were performed in the framework of ADFT, using both the local (LDA) and the generalized gradient approximation (GGA), employing all-electron basis sets. For this study, the most populated T3, T4, and T1 Al sites have been investigated, using two different MOR

models, each containing two isolated Al sites. A detailed analysis of the structures, 3D contours of the molecular electrostatic potential (MEP), binding energies of Na cations and protons, and Brønsted O-H harmonic frequencies is discussed. If possible, comparison with available experimental results is made. The structural changes among Si/Al substitution as well as Na/H exchange are discussed as well.

Diffusion, adsorption, and reactivity of molecules within micro- or mesoporous materials are specifically related with the physicochemical properties of the material structures. It was originally underlined by Derouane et al. (1988) that the interactions of the host molecules with the material surfaces depend on the volume, shape, and topology of the cavities, which generate particular organizations of these molecules. The interrelationship between the porous materials and the host molecules has been referred to as “confinement” and attributed a large role in the selectivity and catalytic activity of zeolite materials, in particular, in acid-catalyzed reactions (Thibault et al. 1998; Anquetil et al. 1999; Smirnov et al. 1999).

Computer modeling based on ab initio techniques have been used in recent years to provide a better understanding of the physicochemical processes involved in the protonation of reactants. They lead to somewhat different conclusions, according to the methods applied and the reactions studied:

- (i) A confinement effect should originate from van der Waals interactions between the reactants and the zeolite framework (Rungsisirakun et al. 2005);
- (ii) Protonated products are stabilized by the long-range electrostatic effects of the framework (Vos et al. 2001; Demuth et al. 2001; Rozanska et al. 2003, 2005);
- (iii) Confinement acts through the stabilizing interaction of the framework oxygens on protonated transition states, which are also favored when matched with the zeolite cavities, van der Waals interactions being dominant when neutral species are considered (Vos et al. 2001; Demuth et al. 2001; Rozanska et al. 2003, 2005).

These results obtained with modern computational methods demonstrate that the concept of confinement is now widely invoked but not yet clearly quantified, differing with the level of accuracy and approximation. The relative influence of the local structure on the Brønsted acid strengths (large versus small cavities), of the solid-reactant dispersion interactions, and of electrostatic polarization effects on the reactants has not really been quantified yet. We believe that such a study necessitates first to set up an accurate and also efficient methodology in order to answer the following fundamental questions:

- (i) Is the Brønsted acid strength different in small and large cavities and what is the role of the local site geometry on this property?
- (ii) How dependent on the cavity size is the stabilization of the guest molecule through long-range dispersion and electrostatic polarization due to the solid framework?

We have focused our attention on the first question (Dominguez-Soria et al. 2007, 2008), studying the structure and the intrinsic properties of mordenite (MOR)

cationic sites, in particular sodium binding energies and acid strengths. For these studies, we proposed a new methodological approach based on very large model clusters, which can eventually be embedded in a classical environment, which we believe is a promising alternative to the idealized periodic representation of a zeolitic solid. This is particularly important for zeolites where the experimental Si/Al ratio is not very large, i.e., when the solid contains an Al distribution which can hardly be represented as periodic. In the next sections, we will compare our results with those reported experimentally for natural and synthetic zeolites. In section “Models and Methodology,” we discuss the zeolite models that we have chosen and the applied methodology. In section “Calculated Geometries and Properties,” we report the calculated geometries and properties and discuss them with respect to experiment and other theoretical results. The results obtained so far are summarized in section “Summary.”

Models and Methodology

Mordenites are natural and synthetic zeolites with Si/Al ratios of 4.3 to 6.0 in the former case and 5.0 to 12.0 in the latter (Passaglia 1975; Jacobs and Martens 1987). Synthetic mordenites are used for acidic catalysis. MOR catalysts are synthesized in the Na form followed by a mild treatment with NH_4Cl which leads to H-exchanged forms. The MOR structure can be described as composed of edge-sharing five-membered (5-m) rings of tetrahedra forming chains along the *c* crystallographic axis (Meier 1961). Their architectures comprise large mono-directional accessible 12-m ring channels of TO_4 tetrahedra where T stands for either Si or Al and small 8-m ring channels, which are interconnected through 8-m ring tubes. The topological symmetry of MORs is orthorhombic with space group *Cmcm* having in the unit cell four symmetrically independent tetrahedral sites, usually called T1, T2, T3, and T4. T1 and T2 sites connect four different rings while the T3 and T4 sites constitute the 4-m rings of the zeolite framework (Meier 1961). Since the first structural study of natural mordenite by Meier (1961), much work has been performed to solve several problems about the real symmetry of the solid due to the presence of Al tetrahedra and extra-framework cations, framework defects, and other structural distortions (Alberti et al. 1986; Alberti 1997). Having different Si/Al ratios, natural and synthetic zeolites also have different Al distribution patterns and slightly different T-O bond lengths (Schlenker et al. 1979).

Our strategy in this study for the determination of the structure and intrinsic properties of the catalyst has been to use clusters containing 120 tetrahedra, sufficiently large to enclose the main 12m-rings and the side pocket 8m-rings. These models include 2 unit cells along *a* and *b*, whereas the *2c* dimension has been cut at the middle of the second 12m-ring channel (see Fig. 9). The substitution of Si by Al has previously been studied extensively for natural and synthetic mordenites (Alberti et al. 1986; Alberti 1997; Schlenker et al. 1979; Ito and Saioto 1985; Simoncic and Armbruster 2004). Following these results based on crystal structure refinement (Alberti et al. 1986; Alberti 1997) and IR intensities of the OH stretching bands (Yang et al. 2001), it has been proposed that the Brønsted sites of MOR are related to an Al substitution with the probability $\text{T3} > \text{T4} > \text{T1} > \text{T2}$, associated with

Fig. 9 Structures, T and O atoms legend of the studied mordenite models. The orientation of the three crystallographic axis a , b , and c is also given

a relative population of the OH sites which is probably larger in the 12-ring channel for natural zeolites (Alberti et al. 1986). The T4 site has also been proposed as the most probable candidate for Al substitution by Demuth et al. based on the relative stability of Al embedded clusters with Al substituted in turn at the 4 possible sites (Demuth et al. 2001). Due to the low probability of Al in T2 and the high probability of more Al sites in the main channel (Alberti 1997), we have selected two models with the distributions T4, T3 and T4, T1, associated with both Na cations (Na-MOR1, Na-MOR2) and protons (H-MOR1 and H-MOR2). The original models have been cut from a solid with the appropriate Al distribution, generated using the Cerius2 program (Cerius 2005) and terminated with hydrogens. In order to constrain the structure of the cluster to that of the solid, the coordinates of the terminal hydrogen atoms, positioned along the Si-O bonds, have been fixed during the subsequent optimizations, all other atomic coordinates being relaxed. Figure 9 illustrates the two models Na-MOR1 and Na-MOR2. In order to test the influence of the Al content on the mordenite geometrical parameters, we have also studied the same model without Al atoms, as will be discussed later.

For these studies, we have used an ADFT-based approach, using a linear combination of atomic orbitals, as implemented in the deMon2k program (Köster et al. 2011a). Geometry optimizations and molecular electrostatic potential (MEP)

calculations were performed at the local level using the correlation functional proposed by Vosko et al. (1980), whereas energetic properties (binding energies and proton affinities) have also been evaluated using the exchange-correlation functional of Perdew, Burke, and Ernzerhof (Perdew et al. 1996a). DFT-optimized double-zeta plus valence polarization (DZVP) basis sets were employed for all atoms (Godbout et al. 1992). For the fitting of the density, the A2 auxiliary function set was used (Godbout et al. 1992). The exchange-correlation potential was numerically integrated on an adaptive grid (Köster et al. 2004a). The grid accuracy was set to 10^{-5} a.u. in all calculations. The Coulomb energy was calculated by the variational fitting procedure proposed by Dunlap, Connolly, and Sabin (Dunlap et al. 1979; Mintmire and Dunlap 1982). A quasi-Newton method in internal redundant coordinates with analytical energy gradients was used for the structure optimization (Reveles and Köster 2004). The convergence was based on the Cartesian gradient and displacement vectors with a threshold of 10^{-4} and 10^{-3} a.u., respectively. For the geometry optimization of the mordenite structures, the parallel version of deMon2k (Calaminici et al. 2006; Geudtner et al. 2006) was used. Each mordenite model possesses more than 400 atoms with around 6000 orbital basis functions and 11,000 auxiliary functions. The calculations were performed on 6 or 8 2.4 GHz Intel Xeon CPUs. These nodes were connected with a Myrinet switch. The geometry optimization of such models takes about 13 days on 8 CPUs. In this time, roughly 25 optimization steps are performed. The cation binding energies (BE) to the framework have been calculated using the formula: $BE = E(\text{neutral model}) - E(\text{cation}) - E(\text{anionic model})$. The O-H stretching frequencies of the H-MOR1 model have been calculated within the harmonic approximation. This normal mode being uncoupled with all the other vibrational modes of the model, its frequency has been calculated using a partial Hessian analysis, as proposed by Li and Jensen (2002).

Calculated Geometries and Properties

General Structural Parameters of the Mordenite Models

Our purpose here was to simulate averaged bond length and bond angle data that can be compared with those provided by X-ray experiments performed on natural and synthetic mordenites with various Si/Al ratios. Comparison with available theoretical data was also presented (Dominguez-Soria et al. 2007). The main geometrical parameters (T-O bonds and T-O-T bond angles) of the fully siliceous and sodium mordenite models have been compared in Table 1 of Dominguez-Soria et al. (2007) with experimental data. The calculated values have been averaged over Na-MOR1 and Na-MOR2, namely, considering different Al distributions. This procedure mimics the experimental averaging over the non-distinguishable Si and Al positions. Among several experimental structures of natural mordenites (Alberti et al. 1986; Alberti 1997; Schlenker et al. 1979; Ito and Saioto 1985; Simoncic and Armbruster 2004), the structure obtained by Alberti et al. (1986) has been chosen for comparison together with the experimental structure of a natural and a synthetic Na-mordenite (Simoncic and Armbruster 2004).

As we have shown in Table 1 of Dominguez-Soria et al. (2007), the calculated bond lengths are very comparable with the experimental results, within 0.02 Å. We have noticed that this uncertainty is of the same order of magnitude as that obtained in previous theoretical work using the LDA level of theory and periodic boundary conditions (Demuth et al. 2001). The systematic lengthening of the T-O bonds in our calculations with respect to standard experimental bond distances could be interpreted in terms of a correction for thermal motions as given in Simoncic and Armbruster (2004). The average values of the T-O-T bond angles, presented in Table 2 of Dominguez-Soria et al. (2007), are in good agreement with experiment, within 4 degrees, which is also the average difference of our calculated bond angles with respect to those reported previously by Demuth et al. (2001). It is worth noting that the isotropic temperature factors provided by X-ray refinements for the zeolite oxygens are all very large (2.4 to 4.6 Å²) (Alberti et al. 1986; Simoncic and Armbruster 2004), leading to a substantial uncertainty on the oxygen positions. It was also shown that the averaged bond length and bond angle are rather insensitive to the Al content of the model. This allowed us to compare our models containing two Al sites with experimental mordenites which contain about 4 to 6 Al per unit cell.

Al sites of Na-MOR

Previous Data for Extra-Framework Cations

Experimentally, the positions of the extra-framework cations are not easily determined. Moreover, there is a clear difference between natural and synthetic mordenites, due to the different natures of their extra-framework cations, as it was demonstrated in the literature (Simoncic and Armbruster 2004). Whereas Ca and K cations predominate in natural mordenites, synthetic zeolites are grown using Na cations, leading, presumably, to different locations of the (Al, cation) pairs; although T3 remains slightly more populated than the other sites, the distribution of Al among the possible T sites is much more balanced according to the pattern reported by Simoncic and Armbruster (2004) (for an Al content of 6, one can expect 1.3 Al at T1 and T4, 0.8 at T2 and 2 at T3). Consequently, the Na cations compensating the Al charges are found distributed within two regions, i.e., the side pocket and the main channel. Due to the presence of water, about 60 % of the cations cannot be precisely determined, presumably being located mainly in the main channel (Simoncic and Armbruster 2004). The remaining cations are found either bonded to three oxygens around T3 in the side pocket or pushed downward into the 8m-ring tube.

Since our study concerns Na-MOR models, we focus on comparing our results with the experimental data provided for synthetic Na-mordenites. Previous theoretical work on Na-mordenite used periodic models involving 8 (Al, Na) pairs per unit cell, and results were compared with the natural zeolite data available (Demuth et al. 2001). The choice of occupying only T3 and T4 sites with equal populations was made, leading then to a strong concentration of cations in each cavity, related to the high symmetry of the solid. Therefore, it is hardly possible to make a direct comparison with this study, concerning the Na positions with respect to the framework oxygens.

Analysis of the Properties of the Cationic Sites in Na-MOR1 and Na-MOR2

The substitution of one Si by Al in the framework generates one negative charge, which has to be compensated by the presence of a counterion. The framework negative charge is distributed among the framework oxygens, more particularly to the four oxygens adjacent to Al. The location of the cation thus depends on the local geometry around the T site for large Si/Al ratios, i.e., when the Al sites can be considered isolated. In these conditions, it is well established that smaller Al-O-Si angles are generally associated with larger electrostatic potentials, i.e., larger attractive interactions with an incoming positive charge (Goursot et al. 1998). In order to locate the most probable positions of the counterions, we have used the well-known strategy of approximating the cation position by searching the largest electrostatic interaction of the system density with a positive point charge. To do so, the molecular electrostatic potential (MEP) was calculated around the three AlO_4 T4, T3, and T1 tetrahedra. The contour plots of these MEPs are illustrated in Figure 2a, 2b, and 2c of Dominguez-Soria et al. (2007), respectively. These MEP values have been calculated for the optimized structures of the corresponding T anions, at the T4 and T3 sites in Na-MOR1 and at the T4 and T1 sites in Na-MOR2, respectively. As expected, the MEP wells in Na-MOR1 surround the two O2 and O10 in the main channel at T4 and the two O1 and O9 at T3 in the side pocket. The lowest MEP minimum at T4 is located between the two O2 and O10 (-4.13 eV). The lowest minimum at T3 is located close to O9 (-4.22 eV). In Na-MOR2, the MEPs at T4 are identical to the ones calculated for T4 in Na-MOR1, showing that the two Al sites are independent. Interestingly, the T1 site of Na-MOR2 belongs to both the main channel and the side pocket. The O1 and O6 adjacent oxygens are in the side pocket, whereas O3 and O7 are located in the main channel (Fig. 9). The MEP well at T1 is essentially located within the side pocket, with the lowest minimum close to O6 (-3.94 eV). It is worthwhile to underline that the MEP values at O7 and O3, i.e., in the main channel, are equal to -3.60 and -3.10 eV, respectively, showing that a compensating Na^+ or H^+ at those oxygens is unfavored with respect to O6. This result indicates that the counterion at T1 will be more stable within the side pocket than in the main channel, at least after dehydration. This conclusion is also valid for protons (Dominguez-Soria et al. 2007).

Si substitution by Al leads, as expected, to lengthening the T-O bonds and decreasing the T-O-Si angles. The average elongation of the T-O bonds reaches 0.115 for T1, 0.124 for T3, and 0.123 Å for T4. The corresponding T-O-Si averaged decrease is found to be 3.3 degrees, 7.2 degrees, and 8.3 degrees for T1, T3, and T4, respectively. These changes are in a reasonable range, with a lower variation for the T1 site, due to its more rigid environment. The optimized structures of the Na^+ sites were reported in Table 3 of Dominguez-Soria et al. (2007), as well as the Na binding energies to the framework. From the reported Na-O distances, the cation can be considered as bi-coordinated at T4 and T1 and mono-coordinated at T3. This result correlates with the calculated positions of the MEP minima, as shown in Figure 2 of Dominguez-Soria et al. (2007). Interestingly we noticed that the shortest NaO distances correspond to the smallest Al-O-Si angles (smaller Al-O-Si angles correlate with more electron density available for cations in the O lone pair due to better hybridization conditions) (Goursot et al. 1998). This result can

be considered as the physical reason why the cation at T1 is located inside the side pocket. Moreover, this finding allows us to anticipate the preferred oxygen for protonation, i.e., O10 at T4, O9 at T3, and O6 at T1.

The calculated Na binding energies follow the ordering $T3 > T4 \approx T1$, which is very comparable with that indicated by the MEPs. This result indicates that electrostatics governs the cation – framework binding. Moreover, we noticed that the use of the PBE GGA exchange-correlation functionals does not modify the trend established on the basis of LDA calculations. For sites T1, T3, and T4, it can be pointed out that the ordering of the Na binding energies reproduces the (Na, Al) population pattern, reported for synthetic Na-MOR. This result supports the suggestion of Simoncic et al. that there is a synergistic effect between cations and (Al, Si) order during the growth of the solid (Simoncic and Armbruster 2004). Finally, we remark that the binding properties found at T1 and T3 are different although both sites belong to the side pocket. This is related to a sum of different effects, the predominant one being most probably the global electrostatic potential felt by the cation. For the same reason, T1 and T4 present comparable binding properties, despite their different locations in the zeolite framework. It is important here to stress that these conclusions are made on the basis of the existence of two independent Al sites. If several (Al, Na) pairs are present within the side pockets, the distribution of the cations would most probably be governed by their mutual repulsion (Campana et al. 1997).

For isolated sites, we have found that both T1 and T3 compensating cations are located in the side pocket area. In synthetic mordenites, at least two sites in side pockets are substituted by Al (≈ 2.5). Since the binding of Na^+ at T3 is favored with respect to that at T1, the three short Na-O bonds indicated by experiment (to O1, O1' and O9) can then be related to our calculated values at T3. In the presence of a second Na^+ to compensate Al in T1, one can expect that the mutual repulsion of the two cations will modify their position. Taking into account their relative stability, the experimental evidence that the other cation is pushed downward to the main cavity (Simoncic and Armbruster 2004) is supported by our results. Moreover we could argue further about Na-MOR with 6 Al per unit cell: this Al content would imply the presence of three (Na, Al) pairs in the side pockets (presumably two at T3 and one at T1). In this situation, one may expect that only two cations will remain inside the pocket, whereas the third one will be pushed outside due to cation-cation repulsion (this argument is verified by classical molecular mechanics simulations using Cerius2 associated with the cvff-aug-ionic force field (Demuth et al. 2001)).

Al Sites of H-MOR

As for the Na-MOR models, the protonated structures have been optimized, the original proton positions being those of the respective lowest MEP minima. At T4, the MEP well is situated at equivalent distances from the two O2 and O10. Whereas the Na^+ cation at T4 was found at equal distances from O10 and O2, the optimized position of the proton corresponds to a bonding to O2. In a previous theoretical study of the relative energies of various H-MOR models, the O2 protonation was also found to be more favorable than the O10 protonation (Li and Jensen 2002).

Consistency with the mentioned relationship between Al-O-Si bond angle values and cation binding energies would lead one to expect comparable proton affinities at O2 and O10. At T1 and T3, the proton attaches to O6 and O9, respectively. Moreover, the O2-H and O6-H bonds are pointing toward the center of the 8m-ring which contains the T4 and T1 site, respectively, these bonds lying in the 8m-ring planes. The proton at T4 can thus be reached by a molecule being in the main channel as well as coming from the side pocket. In contrast, the O9-H bond at T3 is pointing toward the center of the side pocket.

We could see that the Al-O bonds which do not connect to a proton are only little changed with respect to those of the Na-MOR models, with a maximum elongation of about 0.05 Å. As expected, the Al-O(H) bonds are elongated by about 0.12–0.16 Å with respect to the same bonds in the Na-MOR models. This effect is due to the covalent character of the OH bond, which induces the weakening of the Al-O bonds, whereas the Na⁺ – oxygen interactions are weaker and essentially electrostatic. The presence of the sodium cation, bonded to two O (T4, T1) or one O (T3), had thus much less impact on the Si-O-Al framework than that of the proton.

In contrast with the Na binding energies, we found that the proton affinity values are more sensitive to the inclusion of the GGA correction, leading to increased values with respect to LDA and to nonsignificant differences among the three acid sites (less than 0.08 eV) if one takes into account all methodological errors. From these values, we conclude that the sites belonging to the main channel and to the side pocket display similar proton affinities, showing thus that the strength of the OH bond is not dependent on the local structure of the studied sites. It is worth noting that proton affinities are not related to relative energies of models with different H sites, which are reported in previous theoretical work (Demuth et al. 2001), relative total energies being essentially related with relative Al site stabilities.

In order to complete the description of the OH bond strength, the vibrational harmonic frequencies of O2-H and O9-H in the H-MOR1 model have been calculated. The values are 3667 cm⁻¹ for O9-H at T3 and 3659 cm⁻¹ for O2-H at T4, with IR intensities of 174 and 182 km/mol, respectively. These frequencies, not corrected by any scaling factor, can be considered similar within the theoretical error bar. This result is consistent with the corresponding proton affinity found for the proton at O9 (T3) with respect to O2 (T4). They are shifted toward higher energies by about 50 cm⁻¹ with respect to the reported infrared (IR) experimental asymmetric band at about 3610 cm⁻¹. The comparison of our results with X-ray and IR experimental data allows us to suggest that the O9H stretching vibration (T3 site) is not responsible for the observed low-energy component at 3585 cm⁻¹.

Due to the similarity of the model and method used for both vibrations, it is most probable that the lower energy vibration is related to another Brønsted hydroxyl originating from:

- (i) Proton migration, after dehydration, to another oxygen, especially if both T1 and T3 sites are aluminated, leading to different local interactions;

- (ii) The presence of two T3 and one T1 aluminated sites in the side pocket (Simoncic and Armbruster 2004) will induce different MEP surfaces and different electrostatics;
- (iii) The presence of a (100) defect layer (Simoncic and Armbruster 2004) that induces geometry changes in the side pockets which are not reproduced in our models.

We can thus argue that our models with isolated Al sites ($\text{Si}/\text{Al}=23$) show that main channel and side pocket hydroxyls are energetically not different because of their framework environment. Their different energetical behaviors are most probably generated by the different content of framework Al at the 12-membered ring channels and in the side pockets obtained after crystallization.

Summary

In this work, Na and protonated models of a mordenite zeolite, including Al in T1, T3, and T4 crystallographic sites, were studied using all-electron DFT calculations. From the analysis of the obtained results, the following conclusions can be drawn:

- (i) A good agreement with experimental bond length and bond angle data reported for synthetic Na-mordenites has been obtained;
- (ii) The binding energies of the Na cation follow the same ordering as the populations of Al T sites, as derived from X-ray measurements on synthetic Na-mordenites; this result shows the existence of a synergistic effect between cations and (Al, Si) order during the growth of the solid, as suggested experimentally;
- (iii) The compensating cation at the T1 site is found to be more stable in the side pocket than in the main channel, which questions the assignments of the T1-associated proton to a main channel location;
- (iv) The calculated proton affinities at T1, T3, and T4 sites are equivalent, indicating that these Brønsted sites have similar acid strengths. One can thus infer that the different acidic behaviors at the different sites (Marie et al. 2000, 2004) do not originate from different acid strengths of these OH sites. This leads to the suggestion that the MOR acidic properties are more related to the electronic structure of the base than to effects of the solid framework.

Thus, for the evaluation of differences in local acidity, the presence of the associated base (CO, CH₃CN, NH₃, etc. . .) has to be taken into account. Further studies in this direction have been published by our laboratories (Dominguez-Soria et al. 2008, 2011).

Stability of Giant Fullerenes

Fullerenes are carbon nanostructures formed by the closing of a graphitic sheet with the needed curvature supplied by intersecting, among a given number of

graphitic hexagons, of 12 pentagons (Kadish and Ruoff 2007; Andreoni 2007). These carbon aggregates have been experimentally known for more than 20 years (Kroto et al. 1985) and, consequently, a large number of works, experimental as well as theoretical, focused on this subject (see, e.g., Seifert et al. 1996; Cioslowski 1995; Boltalina et al. 2000; Bühl and Hirsch 2001 and references therein).

One main reason for the great interest in the study of fullerenes is certainly to be found in their particularly appealing geometrical form. The best-known fullerene is the so-called buckminsterfullerene that contains 60 carbon atoms (C_{60}) and is composed of 12 pentagonal carbon rings located around the vertexes of an icosahedron and 20 hexagonal carbon rings at the centers of icosahedral faces (Kroto et al. 1985).

Larger fullerenes that have an icosahedral symmetry can be constructed (Kroto and McKay 1988; Itoh et al. 1996) as well. These clusters, known as *giant fullerenes*, can be thought of as cutout pieces of graphene that are folded into their final shapes (icosahedrons). This kind of procedure generates 12 pentagonal carbon rings situated around vertices of an icosahedron, while all other carbon rings are hexagonal. Giant or large fullerenes have been the subject of different theoretical studies in the last years. We direct the interested reader to Dunlap et al. (1991), York et al. (1994), Bakowies et al. (1995), Scuseria (1995), Xu and Scuseria (1996), Scuseria (1996), Haddon et al. (1997), Bates and Scuseria (1998), Heggie et al. (1998), Geudtner et al. (2006), Dunlap and Zope (2006), Shao et al. (2006, 2007), Zope et al. (2008) and references therein.

Most of these studies were focused either on understanding if the shape of these clusters is spherical or faceted (York et al. 1994; Bakowies et al. 1995; Scuseria 1995; Xu and Scuseria 1996; Scuseria 1996; Bates and Scuseria 1998; Geudtner et al. 2006), on calculating their response properties (Zope et al. 2008) or testing new algorithms developed for the investigation of large systems (Dunlap and Zope 2006; Geudtner et al. 2006). Most previous first-principles theoretical studies of large fullerenes have been performed either at the Hartree-Fock level of theory using symmetry restrictions and relatively small basis sets or employing analytic density functional theory (York et al. 1994; Bakowies et al. 1995; Scuseria 1995; Xu and Scuseria 1996; Scuseria 1996; Haddon et al. 1997; Bates and Scuseria 1998; Heggie et al. 1998; Dunlap and Zope 2006; Shao et al. 2006, 2007; Zope et al. 2008).

In a recent study, we have performed state-of-the-art calculations on the large C_{180} , C_{240} , C_{320} and C_{540} fullerenes by employing the linear combination of Gaussian-type orbital density functional theory (LCGTO-DFT) approach (Calaminici et al. 2009). The structures of these clusters were fully optimized without any symmetry constraints. This work represents the first systematic study on large fullerenes based on non-symmetry adapted first-principles calculations, and it demonstrates the capability of ADFT for energy calculations and structure optimizations of large-scale structures without any symmetry constraint.

In the next two sections, the computational details will be presented, and the most important results we have obtained in terms of structural changes, of the evolution of the bond lengths, and of the calculated binding energies will be reviewed.

Computational Details

All calculations were performed using the DFT program deMon2k (Köster et al. 2011a). The exchange-correlation potential was numerically integrated on an adaptive grid (Köster et al. 2004a). The grid accuracy was set to 10^{-5} a.u. in all calculations. The Coulomb energy was calculated by the variational fitting procedure proposed by Dunlap, Connolly, and Sabin (Dunlap et al. 1979; Mintmire and Dunlap 1982). The calculation of the exchange-correlation energy was performed with the auxiliary function density (Köster et al. 2004b), i.e., auxiliary density functional theory was used. The structure optimizations were performed with the local density approximation (LDA) employing the Dirac exchange functional (Dirac 1930) in combination with the correlation functional from Vosko, Wilk, and Nusair (VWN) (Vosko et al. 1980). DFT-optimized double-zeta plus valence polarization (DZVP) all-electron basis sets optimized for local functionals (Godbout et al. 1992) were employed. For the structure optimization, a quasi-Newton method in internal redundant coordinates with analytic energy gradients was used (Reveles and Köster 2004). The geometry optimizations were performed using the parallel version of the deMon2k code (Calaminici et al. 2006; Geudtner et al. 2006). The convergence was based on the Cartesian gradient and displacement vectors with a threshold of 10^{-4} and 10^{-3} a.u., respectively.

The diamond and graphene calculations were performed in the same theoretical framework using the cyclic cluster model (CCM) (Janetzko et al. 2008). The obtained energies using the CCM are in the range of other calculated cohesive energies for graphene (Trickey et al. 1992; Dunlap and Boettger 1996). Because the fullerene and graphene calculations are performed within the same theoretical framework, the relative energy differences found here are reliable.

Results and Discussion

The DFT-optimized singlet structures of C_{180} , C_{240} , C_{320} , and C_{540} are depicted in Fig. 10. These structures have been fully optimized at the all-electron level using DZVP basis sets in combination with the VWN functional. A long-standing discussion in the literature addresses the question of whether giant fullerenes prefer a faceted or a spherical shape. This question was raised considering pictures obtained by transmission electron microscopy (TEM) that have shown evidence of possible spheroidal structures in concentric carbon particles (Iijima 1980; Ugarte 1992, 1995). Using a divide-and-conquer method for density functional calculations, the structure and stability of C_{240} were studied, and the most stable structure was claimed to be highly spherical (York et al. 1994). However, this result was not confirmed by any successive theoretical work that have clearly shown evidence of a faceted shape for this fullerene (Dunlap et al. 1991; Bakowies et al. 1995; Scuseria 1995, 1996; Xu and Scuseria 1996; Haddon et al. 1997; Bates and Scuseria 1998). Depending on the viewing axis, simulated TEM of icosahedral fullerenes can provide either images with spherical or with faceted shapes (Scuseria 1995). In addition, an explanation of why experimental results showed rounder shapes for large fullerenes was also given (Scuseria 1995).

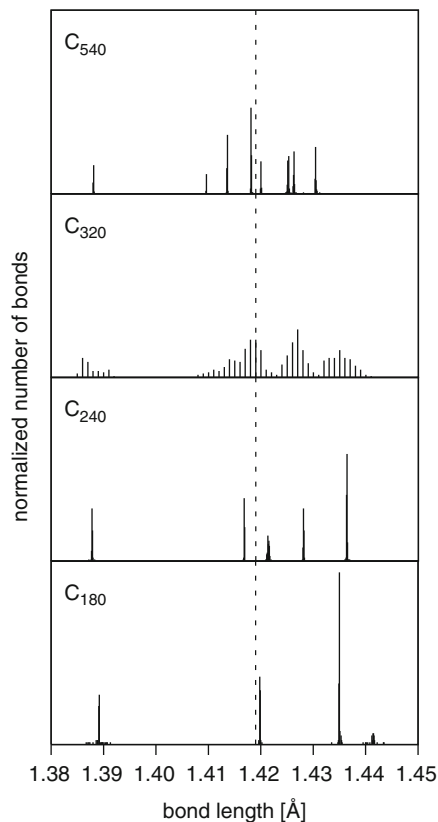

Fig. 10 Optimized structure of C_{180} , C_{240} , C_{320} , and C_{540} fullerenes. The calculations have been performed with the VWN functional in combination with DZVP basis sets

As Fig. 10 shows, our first-principles-based structure optimizations predict that larger fullerenes, C_{240} , C_{320} , and C_{540} , prefer a faceted shape. Moreover, even for the smallest fullerene here studied, C_{180} , there is clear evidence that the faceted shape is preferred over a spherical shape if first-principles all-electron optimizations without any symmetry restriction are performed (see Fig. 10). Details about the timing of these calculations are reported in Geudtner et al. (2006) where it is shown that the optimization of such large fullerenes is feasible within a few days on a parallel architecture with 32 to 64 cores.

We noticed that the obtained results are in agreement with most of the previous reported theoretical studies (Dunlap et al. 1991; Bakowies et al. 1995; Scuseria 1995, 1996; Xu and Scuseria 1996; Haddon et al. 1997; Bates and Scuseria 1998).

In order to gain more insight into the structural changes of these systems as the number of carbon atoms increases, a detailed analysis of the bond length evolution was performed. In Fig. 11, the normalized number of bonds for C_{180} , C_{240} , C_{320} , and C_{540} are plotted versus the bond length. The dashed line at 1.419 Å represents the graphene bond length obtained from the periodic (CCM) deMon2k calculation. Most obvious from this figure is the difference of C_{320} to all other fullerenes. In fact, whereas usually a discrete distribution of bond lengths is found, in C_{320} , a wide, in some ranges almost continuous, bond length distribution is observed. This clearly indicates a break in the expected high symmetry of the system. Our studies

Fig. 11 Normalized number of bonds for C_{180} , C_{240} , C_{320} , and C_{540} versus the bond lengths (in Å)

show that the C_{320} fullerene possesses a ground-state potential energy surface (PES) of higher multiplicity, most likely either triplet or quintet. Further test calculations indicated that for this fullerene also in the cases of triplet and quintet PESs the continuous bond length distribution observed for the singlet PES persists. Of course, only non-symmetry adapted optimizations can lead to such a result. To the best of our knowledge, this symmetry breaking in larger fullerenes due to their electronic structure has never been observed in previous calculations. As Fig. 10 shows, the observed symmetry breaking does not alter the global shape of the giant fullerene.

For the other systems, C_{180} , C_{240} , and C_{540} , the expected discrete bond length distribution is obtained, indicating that the symmetry of the electronic structures matches with the expected geometrical symmetry. In these systems, the number of different bond lengths increases with system size, and an accumulation of bond lengths around the graphene bond length is observed (Fig. 11).

More surprising is the trend that the longest bond length in the cluster shortens with increasing cluster size. This indicates that delocalization increases with cluster size despite the global building pattern, i.e., the appearance of 12 pentagons.

With the aim of guiding future desirable experiments on large fullerenes and to gain more information about their stability, we have also explored the behavior of the binding energy of the studied fullerenes with increasing fullerene size. The results of the uncorrected binding energy (in eV) per carbon atom obtained with the VWN functional have been illustrated in Figure 3 of Calaminici et al. (2009) showing that the binding energy increases monotonically with the increase in the number of carbon atoms. This indicates that the large fullerenes become more and more stable with increasing size. However, the increase turned out to be very moderate. We have also included the basis set superposition error (BSSE) in the calculation of the binding energies. The inclusion of the BSSE decreases the calculated binding energies of each studied fullerene by 0.02 eV but without altering the trend (Calaminici et al. 2009).

From the comparison of the CCM calculations, we found that the calculated binding energy of C_{540} of 8.75 eV is very close to the cohesive energy of diamond (8.78 eV). This result indicates that C_{540} has a similar binding energy to diamond which fuels the hope that such giant fullerenes could indeed be prepared. However, the binding energy of even the largest studied fullerene, C_{540} , is still far away from the corresponding value in graphene which was calculated to be 8.91 eV (Janetzko et al. 2008).

Summary

In this section, the results obtained from state-of-the-art density functional theory calculations performed on large fullerenes, such as C_{180} , C_{240} , C_{320} , and C_{540} , have been reviewed. The study was carried out with all- electron basis sets, and all structures were fully optimized without any symmetry restriction. The results obtained can be summarized as follows:

- (i) This work confirms that for all large fullerenes studied here, a faceted shape is preferred over the spherical shape;
- (ii) The analysis of the bond length evolution reveals for C_{320} a qualitatively different pattern than for the other fullerenes. The most likely explanation for this difference is a symmetry breaking in the electronic structure of this large fullerene;
- (iii) The shortening of the longest bond length with increasing cluster size indicates that delocalization increases with cluster size;
- (iv) The calculated binding energies are in the range of diamond but considerably below the graphene value. Thus, even giant fullerenes as those reviewed in this section are only metastable.

Transition State Search in Metal Clusters

Generally, in cluster studies, the properties of interest are investigated considering the lowest minimum structure. However, the study of the full potential energy surface (PES) landscape is very important if one aims to understand how for a given

finite system a chemical reaction may occur. A chemical reaction can be described in terms of an energy profile picture with which aspects of the mechanisms, structures, and energies of the reaction are explained. A way to characterize a PES is by the location of its relevant critical points (CPs). In general, stationary points of a function that depends on N variables are reached when the gradient of the given function vanishes. For a multidimensional function such as the PES, several different kinds of stationary points usually exist. These are minima, maxima, and saddle stationary points. These CPs are characterized by the eigenvalue spectrum of the corresponding Hessian matrix. A minimum CP possesses only positive eigenvalues that correspond to positive curvatures, in all principal directions. A maximum possesses only negative eigenvalues that correspond to negative curvatures in all principal directions. Saddle points of different order can be present on a PES, too. A transition state is a saddle point of first order, i.e., it possesses a negative curvature in one principle direction and positive curvatures in all other directions. From a chemical point of view, only minima and first-order saddle points are CPs of interest on a PES because they correspond to stable isomers and to transition states, respectively.

For a molecular system, the reaction coordinate is defined by the minimum energy path on the PES that connects the energy minimum of the reactant with that of the product. For an elementary reaction step, this path has only one maximum which is a first-order saddle point and named the transition state. For metal clusters, the PES of even very simple system consisting of only a small number of atoms can possess a large number of local minimum structures. As a result, a complex network of rearrangement reactions exists in these systems. To unravel such networks, the systematic location of transition states is mandatory. We applied the hierarchical transition state search algorithm (Campo and Köster 2008) for the first time to rearrangement reactions of pure metal clusters, in particular selected sodium clusters. These systems are very challenging because neither the transition states nor the reaction coordinates are chemically intuitive. Therefore, it is usually not guaranteed that the two initial minima structures are indeed connected by an elementary rearrangement step free of intermediates. To this end, we performed intrinsic reaction coordinate (IRC) calculations starting from the located transition states. By the combination of the hierarchical transition state search algorithm with the IRC calculations, reaction intermediates can be found. In this way, complex rearrangement networks can be completely unraveled.

Computational Details

All calculations were performed using the linear combination of Gaussian-type orbital density functional theory (LCGTO-DFT) deMon2k program (Köster et al. 2011a; Geudtner et al. 2011). The Coulomb energy was calculated by the variational fitting procedure proposed by Dunlap, Connolly, and Sabin (Dunlap et al. 1979; Mintmire and Dunlap 1982). The auxiliary density was expanded in primitive Hermite Gaussian functions using the GEN-A2 auxiliary function set (Calaminici et al. 2007a). The exchange-correlation functional was evaluated with this auxiliary density, i.e., the auxiliary density functional theory (ADFT) method was

used (Köster et al. 2004b). The exchange-correlation energy and potential were numerically integrated on an adaptive grid (Krack and Köster 1998; Köster et al. 2004a). The grid accuracy was set to 10^{-5} a.u. in all calculations. The structure optimization and the frequency analysis of the clusters were performed employing the gradient corrected exchange-correlation functional proposed by Perdew, Burke, and Ernzerhof (PBE) (Perdew et al. 1996a) in combination with DFT-optimized double-zeta valence plus polarization (DZVP) basis sets (Godbout et al. 1992).

In order to determine the geometry of the ground state and of corresponding low-lying states of the studied clusters, a very extensive search was performed and several dozens of initial configurations were studied. In this search, structures previously reported by other authors were included as well as many other initial structures which were extracted from BOMD trajectories recorded at a temperature of 250 K. The BOMD trajectories were generated in the canonical ensemble employing a Nosé-Hoover chain thermostat (Nosé 1984; Hoover 1985; Martyna et al. 1992; Gamboa et al. 2010) with seven thermostats in the chain and a coupling frequency of 200 cm^{-1} . For all structures, a full geometry optimization without any symmetry restriction was performed using a quasi-Newton optimization method in delocalized internal coordinates (Reveles and Köster 2004). The convergence was based on the Cartesian gradient and displacement vectors with a threshold of 10^{-4} and 10^{-3} a.u., respectively.

The obtained minima were characterized by frequency analysis. The second derivatives were calculated by numerical differentiation (two-point finite difference) of the analytic energy gradients using a displacement of 0.001 a.u. from the optimized geometry for all $3N$ coordinates. The harmonic frequencies were obtained by diagonalizing the mass-weighted Cartesian force constant matrix.

As already discussed, the transition states were located with the hierarchical transition state finder as implemented in the deMon2k code (Campo and Köster 2008; Geudtner et al. 2011). The only input information consisted of the minimum structures of the sodium clusters involved in the rearrangement. Starting from the obtained transition states, the IRC was calculated, using the approach from Gonzalez and Schlegel (Gonzalez and Schlegel 1989), either to find potential intermediates or to calculate the minimum energy path that connects the two starting minimum structures. Both the IRC and the uphill trust region optimization in the hierarchical transition state search were initialized by Hessian calculations in order to provide the correct eigenvalue spectrum.

Showcase Results

In this section, the results of selected transition state searches in Na_8 and Na_{10} clusters are discussed. The two lowest minimum structures of Na_8 are depicted in Fig. 12 (top), as well as the lowest energy structure and a planar high-energy stable isomer for the Na_{10} cluster (bottom). All minimum structures are in their lowest multiplicity. The relative energies of these structures with respect to the ground-state structure are given in kcal/mol in this figure. The Na_8 ground-state structure is a slightly distorted snub disphenoid formed by a square bipyramidal fragment with two extra Na atoms capping two triangular faces. The first low-lying

Fig. 12 Lowest minima structures of the Na_8 clusters (*top*) and lowest minimum structure with a planar high-energy structure of Na_{10} (*bottom*). The energy differences between the found ground-state structures (*left*) and the other structure (*right*) are in kcal/mol

minimum structure is formed by five slightly distorted tetrahedral fragments and lies 2.3 kcal/mol above the ground-state structure. The hierarchical transition state finder was applied with these two minimum structures as input. As result, a transition state characterized by an imaginary frequency of $\omega = 24i \text{cm}^{-1}$ was found.

Figure 13a illustrates some snapshots along the IRC for this cluster rearrangement reaction. The second structure in Fig. 13a is the transition state structure. The very small energy difference of only 0.2 kcal/mol between the high-energy isomer and the transition state challenges the transition state search algorithm. The hierarchical transition state finder worked flawlessly in the Na_8 rearrangement investigated here. The above discussed rearrangement is, however, not the most common rearrangement in low-temperature Na_8 molecular dynamics. Instead, rearrangements that transfer the minimum structure of Na_8 into a mirror image are typical for the low-temperature dynamics of this cluster. Also this kind of rearrangement can be studied with the hierarchical transition state finder if the atoms of the reactant and product structures are correctly labeled (otherwise the initial alignment algorithm will superimpose the two identical structures). The corresponding IRC is depicted in Fig. 13b. At the starting point (first snapshot of Fig. 13b), the square bipyramidal fragment of the ground-state structure is at the right side of the structure. Following the black point on the energy path, we can see how the structure deforms going uphill to the transition state (second snapshot of Fig. 13). This transition state is characterized by an imaginary frequency of $\omega = 22i \text{cm}^{-1}$. The energy difference between this transition state and the ground-state structure is 0.9 kcal/mol. Once the transition state is formed, the structure deforms then downhill to reach again the ground-state structure configuration at the end point of the energy path (last snapshot of Fig. 13b). At this last point, the square bipyramidal fragment, characteristic of the ground-state structure, is now on the left side of the structure.

The lowest minimum structure we found for the Na_{10} cluster is depicted at the bottom of Fig. 12 (left). We notice that as the cluster size increases, it becomes more complicated to locate the ground-state structure due to the increasing

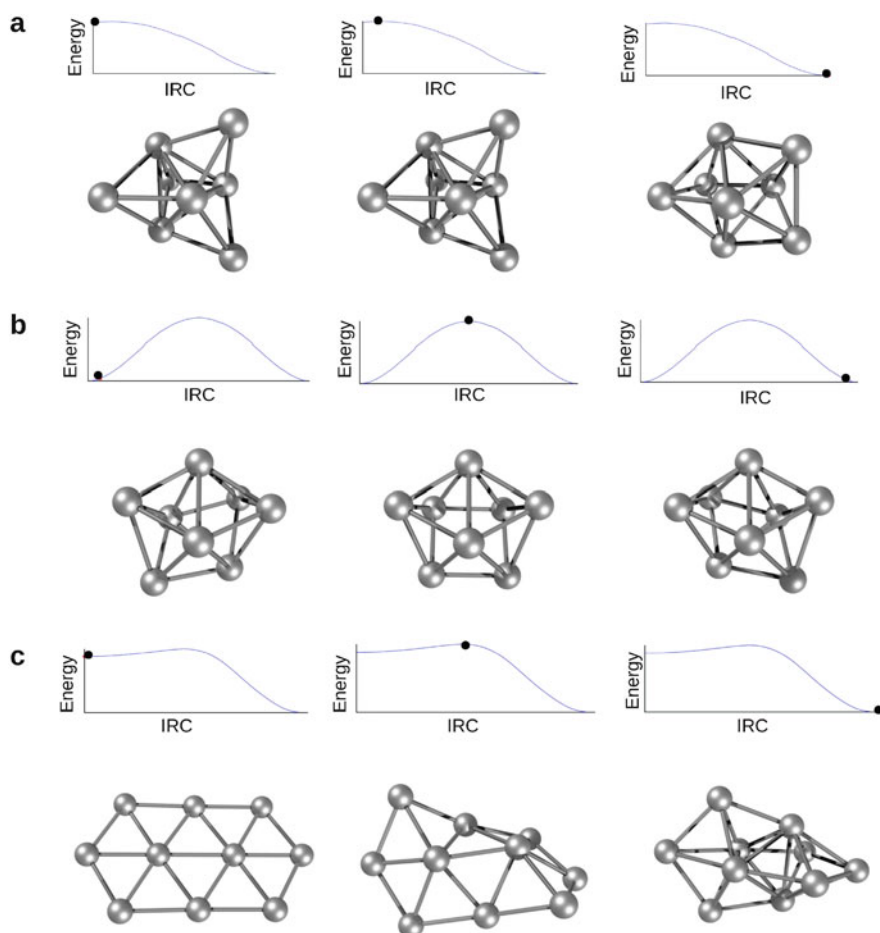

Fig. 13 Snapshots along the IRC for the Na₈ rearrangement between the two lowest minimum structures of this cluster (a), between two mirrored images (b), and rearrangement between the lowest minimum and a planar structure for Na₁₀ (c). The energy is plotted versus the IRC. The structure position is indicated by the *black point* on the energy path

number of low-lying minima. The ground-state structure is built by two pentagonal bipyramidal moieties which are perpendicular to each other. Lying at 11.42 kcal/mol above the ground state, we found a completely planar minimum structure. The hierarchical transition state finder was applied considering this structure and the ground-state structure as input (see Fig. 12 bottom). Due to the shape of the two structures involved as reactant and product, this reaction mechanism is not chemically intuitive. Our result shows that also this rearrangement is free of intermediates. Snapshots along the corresponding IRC are illustrated in Fig. 13c. The activation energy is 1.5 kcal/mol and an imaginary frequency of $\omega = 26i \text{ cm}^{-1}$ characterizes the transition state.

Summary

In this work, a hierarchical transition state algorithm which combines the so-called double-ended interpolation method with the uphill trust region method was applied to search for transition states of selected sodium clusters. These systems are prototypes of finite systems for which transition states are not chemically intuitive. Sodium clusters Na_8 and Na_{10} have been investigated, and selected transition states have been analyzed. All found transition states have been confirmed by the intrinsic reaction coordinate calculations to connect the reactant and product of the corresponding isomerization reaction. The successful application of the hierarchical transition state finder to highly unsymmetrical reaction paths with small activation barriers underlines the robustness of this approach. A particular example is the Na_8 cluster rearrangement. Again it is important to note that no other information than the minimum structures of reactants and products are used in these transition state optimizations. We also showed for Na_8 that with the hierarchical transition state finder transition states between symmetry-equivalent minima can be found if reactant and product structures are correctly labeled. Similar studies for other metal clusters are currently underway in our laboratories.

Conclusion

This review highlights recent developments in auxiliary density functional theory (ADFT) and their implementation in deMon2k. The simplifications associated with ADFT permit an efficient parallel code structure that is suitable for research applications in the nano-regime with chemical accuracy. The presented Born-Oppenheimer molecular dynamics simulation shows that simulation times on the nanosecond time scale can be reached with ADFT. As the applications presented here show, this opens new and exciting perspectives for computational chemistry and material simulations with first-principles methods.

The development of ADFT in deMon2k is also a very educational example for the interplay of theoretical chemistry and computer science. The simplifications of the Kohn-Sham method by employing an atom-centered auxiliary density for the calculation of the Kohn-Sham potential yield simple and very efficient parallel algorithms. A typical example is the SCF acceleration by the MinMax procedure. Because only fitting vectors are involved, it can be applied to systems with hundreds of atoms like the zeolites and fullerenes discussed here. Another example is the formulation of the non-iterative auxiliary density perturbation theory (ADPT) that substitutes the computationally cumbersome CPKS method in ADFT. Similarly, the ADFT-GIAO methodology delivers magnetic properties that are indistinguishable from conventional DFT approaches but with a fraction of the computational cost. With the new variational fitting of exact exchange, almost all chemically relevant exchange-correlation functionals can now be used within the ADFT framework.

The increased use of ADFT in the quantum chemical community over the last years has considerably enhanced our understanding of this fitting approach. While the present authors are responsible for errors or omissions in this small review, the

credit for the advances in ADFT and ADPT is shared with a much wider group cited in the references here and elsewhere.

Abstract

This chapter reviews most of the widely used nonrelativistic quantum chemistry program packages. Considering that information about availability and capabilities of the free quantum chemistry programs is more limited than that of the commercial ones, the authors concentrated on the free programs. More specifically, the reviewed programs are free for the academic community. Features of these programs are described in detail. The capabilities of each free program can generally be categorized into five fields: independent electron model; electron correlation treatment; excited state calculation; nuclear dynamics including gradient and hessian; and parallel computation. Examples of input files for the Møller–Plesset calculation of formaldehyde are presented for most of the free programs to illustrate how to create the input files. The main contributors of each free program and their institutions are also introduced, with a brief history of program development if available. All the key references of the cited algorithms and the hyperlinks of the home page of each program (both free and commercial) are given in this review for the interested readers. As the most important information of every cited free program's documentation has been extracted here, it is appropriate to consider this chapter to be the manual of manuals.

Introduction

Computational quantum chemistry has been experiencing recently a period of tremendous growth. As the capabilities of computer hardware increased, so did the appetites of researchers for modeling tools. Many computer packages became available, both commercially and as free programs, the latter usually requiring a simple registration procedure to obtain and use the code. The free access is usually restricted to researchers from academic institutions and the programs are sometimes unsupported; however, an associated users' discussion forum often accompanies the program. In this chapter, we will review the software that is currently available, focusing on packages that are familiar to the reviewers. In addition to outlining the unique capabilities of each program, we added the URL links to the home pages to allow the readers to follow the latest developments of each code.

The programs that use only the density functional theory and the programs for relativistic calculations at the level of Dirac theory and beyond are reviewed in other chapters.

All the reviewed programs carry out fundamental tasks of a computational chemist or a computational molecular physicist: calculation of energy for various Hamiltonians; evaluation of gradients of energy (needed to locate stationary points on the potential energy surface); evaluation of the energy hessian (required to analyze the character of the located stationary point, identify local minima and saddle points, and perform vibrational frequency calculation); and evaluation of basic properties (population analysis, dipole moments). The components of the programs include basis set libraries and pseudopotentials.

At the Hartree-Fock level (Hartree 1928; Fock 1930), the energies for closed-shell systems are evaluated using the restricted Hartree-Fock (RHF) method (Hall and Lennard-Jones 1951; Roothaan 1951). For the open-shell molecules, there are several methods that are available in most programs: the unrestricted Hartree-Fock (UHF) method (Pople and Nesbet 1954), several variants of the restricted open-shell Hartree-Fock (ROHF) method (Hsu et al. 1976; McWeeny and Dierksen 1968), and the generalized valence bond (GVB) method (Bobrowicz and Schaefer 1977).

The wavefunction based on a single-configuration Hartree-Fock method is often inadequate to describe bonding in a molecule, and in such a case several multi-configuration methods are used; the approach is usually called multiconfiguration self-consistent field (MCSCF) (Olsen et al. 1983; Roos 1983, 1994; Schmidt and Gordon 1998; Shepard 1987; Werner 1987), and its practical implementations are the full orbital reaction space (FORS) (Ruedenberg et al. 1982a, b, c) and complete active space (CAS) (Roos 1987).

Beyond Hartree-Fock, the energies (and wavefunctions) may be improved at several levels: various orders of the perturbation method at the Møller–Plesset level (1934) (MP2, MP3, MP4); for open-shell systems we could use either unrestricted MP2 (Pople et al. 1976) or one of several variants of the perturbation method based on the ROHF wavefunction: the Z-averaged perturbation theory (ZAPT) (Lee and Jayatilaka 1993; Lee et al. 1994) and RMP (Knowles et al. 1980; Lauderdale et al. 1991); configuration interaction (CI) method (Brooks and Schaefer 1979; Ivanic and Ruedenberg 2001).

Very accurate energies may be obtained using the coupled-cluster theory (CC) (Paldus 2005; Shavitt and Bartlett 2009).

Excited states may be studied using the general post-Hartree-Fock methods listed above, or some specialized techniques, such as configuration interaction with single substitutions (CIS) (Foresman et al. 1992), time-dependent density functional theory (TDDFT) (Dreuw and Head-Gordon 2005; Elliott et al. 2009), and equations-of-motion coupled cluster (EOM-CC) (Kowalski and Piecuch 2004; Włoch et al. 2005).

Solvent effects may be treated using several models: self-consistent reaction field (SCRF) (Karelson et al. 1986, 1993; Kirkwood 1934; Tapia and Goscinski 1975), polarizable continuum model (PCM) (Cammi and Tomasi 1995; Miertuš et al. 1981; Tomasi and Persico 1994; Tomasi et al. 2005), surface and simulation of volume polarization for electrostatics (SS(V)PE) (Chipman 1997, 2000, 2002), and conductor-like screening model (COSMO) (Baldrige and Klamt 1997; Klamt 1995; Klamt and Schüürmann 1993).

Even though the programs described in this chapter are referred to as “non-relativistic” (i.e., using single-component wavefunction), for molecules containing heavy atoms it is necessary to include at least scalar relativistic effects. A popular method of adding relativistic corrections is based on the formalism developed by Douglas and Kroll (1974) and by Hess (1986, 1989), and is usually referred to as DKH n (where n denotes the order of the method).

Some scalar relativistic effects are included implicitly in calculations if pseudopotentials for heavy atoms are used to mimic the presence of core electrons; there are several families of pseudopotentials available: the effective core potentials

(ECP) (Cundari and Stevens 1993; Hay and Wadt 1985; Kahn et al. 1976; Stevens et al. 1984), energy-adjusted pseudopotentials (Cao and Dolg 2006; Dolg 2000; Peterson 2003; Peterson et al. 2003), averaged relativistic effective potentials (AREP) (Hurley et al. 1986; LaJohn et al. 1987; Ross et al. 1990), model core potentials (MCP) (Klobukowski et al. 1999), and ab initio model potentials (AIMP) (Huzinaga et al. 1987).

For very large molecular systems several programs offer semiempirical Hamiltonians (Stewart 1990), including Modified Neglect of Differential Overlap (MNDO) (Dewar and Thiel 1977), Semi-Ab initio Model 1 (SAM1) (Dewar et al. 1993), Austin Model 1 (AM1) (Dewar et al. 1985), Parametric Method 3 (PM3) (Stewart 1989), and Parametric Method 6 (PM6) (Stewart 2007) (the PM3 parameterization is available in the MOPAC2009 program which is freely available to academics, see <http://openmopac.net/downloads.html>). Zerner's modification of the Intermediate Neglect of Differential Overlap approach (ZINDO) (Ridley and Zerner 1973) (see also Zerner 1991) is available in the ArgusLab program <http://www.arguslab.com/index.htm>.

The present Guide will focus on those programs that are freely available to academic community. In describing the capabilities of the programs we heavily borrowed from the available documentation. Commercial programs for ab initio computational chemistry (including several that employ semiempirical methods) will be mentioned only very briefly, guiding the reader to relevant home pages on the Internet.

Several collections of references to quantum chemistry software may be found on the Internet http://en.wikipedia.org/wiki/Quantum_chemistry_computer_programs.

Free Software

Free access to computer programs discussed in the present section is sometimes restricted to academic researchers. Please consult the Internet links for each program for specific restrictions.

GAMESS-US

GAMESS-US (GAMESS = General Atomic and Molecular Electronic Structure System) is one of the early programs for the large-scale ab initio calculations in the public domain (Gordon and Schmidt 2005; Schmidt et al. 1993). The origins of GAMESS-US go back to the National Resources for Computations in Chemistry (NRCC), where the original GAMESS was assembled before 1981 (Dupuis et al. 1980). Since 1982 the development of GAMESS-US was carried out in the research group of Mark Gordon, first at North Dakota State and then at Iowa State University, with several research groups across the world making their contributions. The code is a good illustration of the care and effort that go into the development of any modern ab initio code: the October 2010 (Release 2) version has 769,161 lines of code and 221,147 lines of comments.

The capabilities of GAMESS-US are listed below:

Analytic gradients and Hessians for RHF, ROHF, UHF, GVB, and MCSCF wavefunctions that are used to locate stationary points on the potential energy surface and identify their character (local minimum or transition state).

MP2 energy and gradients for RHF, ROHF, and UHF wavefunctions.

CI energy for very general CI excitation schemes (Ivanic 2003a, b; Ivanic and Ruedenberg 2001).

Several methods of evaluating the CC energy, such as CC with single and double excitations (CCSD), with perturbative triple excitations (CCSD(T)), and including the latest completely renormalized (CR) CR-CC(2,3) method (Piecuch and Włoch 2005; Piecuch et al. 2002); numerical gradients for the CC methods are available.

Excited states may be treated using the CIS, TDDFT, multiconfigurational quasidgenerate perturbation theory (MCQDPT) (Nakano 1993a, b), and equation-of-motion coupled-cluster (EOM-CC) methodologies.

There are many ubiquitous density functionals available.

Extensive basis set libraries.

Pseudopotentials: both effective core potentials and model core potentials are available.

The intrinsic reaction coordinate method allows for checking whether the path from a transition state connects the two minima that correspond to the required reactant and product.

Anharmonic vibrational analysis via the vibrational self-consistent field (VSCF) method (Chaban et al. 1999).

Many molecular properties may be calculated (static polarizability and hyperpolarizability; frequency-dependent polarizability; electric moments; electric field, and electric field gradient).

Solvent effects may be studied via continuum solvation methods using effective fragment potentials (EFP) (Adamovic et al. 2003; Day et al. 1996; Gordon et al. 2007; Jensen et al. 1984), polarizable continuum model (PCM), surface and simulation of volume polarization for electrostatics (SS(V)PE), conductor-like screening model (COSMO), and self-consistent reaction field (SCRF).

A unique feature of the program is its ability to carry out all-electron calculations based on the Fragment Molecular Orbital (FMO) method (Fedorov and Kitaura 2007, 2009).

Several possibilities for carrying out multireference perturbation calculations; spin-orbit coupling may be treated as a perturbation.

For spin-orbit coupling CI wave functions, two-component natural orbitals (natural spinors) may be formed and analyzed (Zeng et al. 2011a, b)

Scalar relativistic effects may be included at the levels of DKH2, DKH3, normalized elimination of small components (NESC) (Dyall 2002), and relativistic elimination of small components (RESC) (Nakajima and Hirao 1999) methods.

Semiempirical Hamiltonians (AM1, PM3, and MNDO) are available.

The input style is illustrated below for the MP2 energy calculation for formaldehyde H_2CO at the experimental geometry $r(\text{CH}) = 1.116 \text{ \AA}$, $r(\text{CO}) = 1.208 \text{ \AA}$. The

basis set is the correlation consistent cc-pVDZ basis (Dunning 1989), used in the form of spherical Gaussian functions. C_{2v} point group symmetry is used. In this example, the geometric structure of formaldehyde is defined in terms of internal coordinates (bond lengths, bond angles, and dihedral angles) in the representation known as Z-matrix. For H_2CO , the first line in the Z-matrix definition specifies the starting atom, in this case oxygen O. The second line, C 1 1.208, defines the second atom, carbon, which is connected to the first atom, and the CO bond length equals 1.208 Å. The first hydrogen atom is defined on the third line, H 2 1.116 1 121.75; this H atom is connected to the second atom (carbon), the CH bond length equals 1.116 Å, and the bond angle H–C(2)–O(1) equals 121.75°. Finally, the fourth line, H 2 1.116 1 121.75 3 180.0, defines the second hydrogen atom, which is connected to the second atom (C) with the CH bond length of 1.116 Å, the bond angle H–C(2)–O(1) of 121.75°, and the dihedral angle H(4)–C(2)–O(1)–H(3) of 180.0°.

Firefly

Formerly known as PC-GAMESS, the Firefly was developed on the basis of GAMESS-US, ending with the 1999 version. The program has been extensively modified, with large sections written to increase the efficiency of the program. The program is available as binaries for Windows-based computers as well as the Macintosh computers. The development of the code took place at the lab of A. A. Granovsky (Moscow State University). Some interesting features of the program are

The Møller–Plesset energy corrections may be calculated up to the fourth order (MP2, MP3, and MP4).

Compression of files allows for very large calculations to be carried out; the compression is accomplished via packing of integrals, matrix elements, and their indices reduce file size and input/output (I/O) time.

Faster MCQDPT algorithm and availability of XMCQDPT implementation.

Integral code allows for fast evaluation of generally contracted basis sets (Raffenetti 1973), such as atomic natural orbitals (ANO) (Almlöf 1987).

Sample input file is illustrated below for the same MP2 energy calculation. At present, the program's internal library does not have the cc-pVDZ basis set; in order to avoid the explicit (and thus rather lengthy) definition of this basis, the double-zeta basis set of Dunning and Hay (1977) is used instead. This input file also illustrates an alternative definition of the geometric structure of a molecule: in terms of Cartesian coordinates (according to Firefly's defaults, in Ångströms), with only the symmetry-nonequivalent atoms defined. Each line defining atomic Cartesian coordinates specifies also the atom name and its nuclear charge.

GAMESS-UK

This code also originated from the NRCC code (Dupuis et al. 1980) and has been extensively modified by the Daresbury Laboratory (UK) group that included M. F. Guest, J. H. van Lenthe, J. Kendrick, K. Schöffel, P. Sherwood, and R. J. Harrison. A good summary of the code's features has been published (Guest et al. 2005). A summary of the program's capabilities is given below:

Gradients and Hessians for many energies (RHF, ROHF, UHF, MCSCF, CASSCF). Energies of the excited states and corresponding transition moments may be calculated using the multireference CI method (MR-DCI). For the studies of electronically excited states, direct random-phase approximation (RPA) and multiconfigurational linear response (MCLR) (Fuchs et al. 1993) excitation energies and oscillator strengths are also available.

Ionization potentials may be calculated using the Green's function methodology (Cederbaum and Domcke 1977) and the two-particle-hole Tamm-Dancoff method (Schirmer and Cederbaum 1978).

MP2 (energies and gradients) and MP3 (energies).

Multireference second-order perturbation method (CASPT2 method); multireference MP3 method (MR-MP3) is also available.

CCSD and CCSD(T) energies.

Many density functionals for the density functional theory calculations.

Many properties may be evaluated, among them atomic charges (derived from Mulliken and Löwdin population analysis, natural population analysis (Read and Weinhold 1983; Read et al. 1985), and electrostatic potentials), polarizabilities, hyperpolarizabilities, and magnetizabilities.

Semiempirical Hamiltonians (MNDO, MINDO/3, AM1, PM3, PM5, and MNDO-d) are available.

Pseudopotentials (Hay and Wadt 1985; Roy et al. 2008) may be employed, with many pseudopotentials included in the library.

The effects of the solvent may be modeled using the direct reaction field (DRF) method (de Vries et al. 1995; Duijnen and de Vries 1996).

Relativistic effects may be treated using the zeroth-order regular approximation (ZORA) (Faas et al. 1995).

Sample input file for the H₂CO calculation at the MP2/cc-pVDZ level of theory is shown below; notice that the symmetry of the molecule is determined by the program.

Dalton

To quote from the authors of the program, “the Dalton program system is designed to allow convenient, automated determination of a large number of molecular properties based on an HF, density functional theory (DFT), MP2, coupled cluster, or MCSCF reference wave function.” Given the great flexibility of Dalton’s computational capabilities, the authors describe it as directed at experts in ab initio calculations. The program has been developed at the University of Oslo.

A very short list of Dalton’s capabilities is shown below; for those interested in the evaluation of molecular properties we suggest that Dalton’s manual be consulted (<http://www.kjemi.uio.no/software/dalton/dalton.html>).

Complete Active Space (CAS) or Restricted Active Space (RAS) wave functions.
 Calculation of excited states and core hole states.
 Several coupled-cluster (CC) wave functions.
 MP2 and explicitly correlated R12-MP2 triples models.
 Dalton can calculate a large variety of molecular properties at many levels of theory:
 linear, quadratic, and cubic frequency-dependent response properties.
 Linear second-order polarization propagator approach (SOPPA) (Nielsen et al. 1980).
 NMR properties (magnetizabilities, nuclear shieldings, and all contributions to nuclear spin-spin coupling constants).
 EPR properties (electronic g -tensor, hyperfine coupling tensor, and zero-field splitting tensor).
 Circular dichroism properties (electronic circular dichroism, vibrational circular dichroism, and Raman optical activity).
 Gauge-origin independent magnetic properties.
 Solvent effects may be modeled via the self-consistent reaction field (SCRf) to arbitrary order in the multipole expansion.
 First-order properties for ground states: dipole and quadrupole moments, second moments of the electronic charge distribution and electric field gradients at the nuclei, as well as scalar-relativistic one-electron corrections (Darwin and mass velocity).
 Relativistic two-electron Darwin correction to the ground state.
 Excitation energies may be calculated for several levels of the coupled-cluster wavefunctions.
 Density functional theory.
 Effective core potentials.

Input file for the calculation of the MP2/cc-pVDZ energy of H₂CO is shown below; the symmetry of the molecule is determined by the program.

NWChem

The program has been developed in the Molecular Sciences Software Group at the Pacific Northwest National Laboratory (Richland, WA, USA). The authors of the program state that “NWChem is a computational chemistry package designed to run on high-performance parallel supercomputers. Code capabilities include the calculation of molecular electronic energies and analytic gradients using Hartree-Fock self-consistent field (SCF) theory, Gaussian density function theory (DFT), and second-order perturbation theory. For all methods, geometry optimization is available to determine energy minima and transition states.” Furthermore, they add that “Classical molecular dynamics capabilities provide for the simulation of macromolecules and solutions, including the computation of free energies using a variety of force fields.” Details of the NWChem program system were described (Kendall et al. 2000).

Features of the program include

Spin-orbit density functional theory.

Electron correlation energies may be calculated using many methods, including linearized coupled-cluster doubles (LCCD), coupled-cluster doubles (CCD), linearized coupled-cluster singles and doubles (LCCSD), coupled-cluster singles and doubles (CCSD), coupled-cluster singles, doubles, and triples (CCSDT), coupled-cluster singles, doubles, and active triples (CCSDTA), coupled-cluster singles, doubles, triples, and quadruples (CCSDTQ), CCSD and perturbative connected triples (CCSD(T)), CCSD and perturbative connected triples (CCSD[T]), completely renormalized CCSD[T] method (CR-CCSD[T]), completely renormalized CCSD(T) method (CR-CCSD(T)), CCSD and perturbative locally renormalized CCSD(T) correction (LR-CCSD(T)), quadratic configuration interaction singles and doubles (QCISD), configuration interaction singles and doubles (CISD), configuration interaction singles, doubles, and triples (CISDT), configuration interaction singles, doubles, triples, and quadruples (CISDTQ), second-, third-, and fourth-order Møller–Plesset perturbation theory (MP2, MP3, and MP4).

Multiconfiguration SCF wavefunctions.

Selected configuration interaction with perturbation correction.

Effective core potentials that allow to include both the scalar relativistic effects and spin-orbit effects (Pacios and Christiansen 1985).

Relativistic corrections may be added at the levels of DKH2 and ZORA.

Solvent effects may be described using COSMO (Baldrige and Klamt 1997; Klamt 1995; Klamt and Schüürmann 1993).

For the studies of excited states, the CIS, time-dependent Hartree-Fock (TDHF), and TDDFT methods are available.

Anharmonic vibrational analysis may be carried out using the VSCF method (Chaban et al. 1999).

Sample input file for the H₂CO calculation at the MP2/cc-pVDZ level of theory is shown below; the symmetry of the molecule is determined by the program. The Cartesian coordinates of all atoms must be defined, and the atomic symbol must be used as atom name, eliminating the need to define nuclear charges.

ORCA

The principal developer of the code has been Frank Neese, first at the Max Planck Institute for Bioinorganic Chemistry in Mülheim and then at the University of Bonn. In the words of the program's author, "ORCA is a flexible, efficient and easy-to-use general purpose tool for quantum chemistry with specific emphasis on spectroscopic properties of open-shell molecules. It features a wide variety of standard quantum chemical methods ranging from semiempirical methods to DFT to single- and multireference correlated ab initio methods. It can also treat environmental and relativistic effects." An abbreviated list of program's features includes

Calculation of MP2 and RI-MP2 energies and gradients.

Coupled cluster methods.

CASSCF wavefunction.

Scalar relativistic corrections at the levels of Douglas-Kroll, ZORA, and the infinite-order relativistic approximation (IORA) (Dyall and van Lenthe 1999).

Excited states energies may be calculated using the CIS, CIS(D), and TDDFT methods.

Multireference CI and perturbation theory.

Many properties may be calculated, including spin-orbit coupling, hyperfine and quadrupole couplings, the EPR g -tensor, and zero-field splitting.

Sample input file for calculation of the MP2/cc-pVDZ energy of H₂CO is shown below (the symmetry of the molecule is determined by the program).

PSI3

In the description of the designers of the code, C.D. Sherrill, T.D. Crawford, and E.F. Valeev (from Georgia Institute of Technology and Virginia Tech), “the PSI3 suite of quantum chemical programs is designed for efficient, high-accuracy calculations of properties of small to medium-sized molecules. The package’s current capabilities include a variety of Hartree-Fock, coupled cluster, complete-active-space self-consistent-field, and multi-reference configuration interaction models.” PSI3, written in the programming languages C and C++ (rather than in the Fortran language, which has been traditionally used in computational quantum chemistry), was recently reviewed (Crawford et al. 2007).

Some interesting features of the program are

Arbitrarily high angular momentum levels in integrals and derivative integrals (up to m -type functions have been tested).

Coupled cluster methods including CC2, CCSD, CCSD(T), and CC3 with RHF, ROHF, UHF, and Brueckner orbitals.

Determinant-based CI including CASSCF, RAS-CI, and full CI.

MP2 and MP2-R12 methods.

Methods for excited state: CIS, CIS(D), random phase approximation (RPA), EOM-CCSD, and CC3.

Analytic energy gradients for CCSD based on RHF, ROHF, and UHF orbitals.

Coupled cluster linear response methods for static and dynamic polarizabilities and optical rotation.

Diagonal Born–Oppenheimer correction (DBOC) for RHF, ROHF, UHF, and CI wave functions.

Sample input file for the H₂CO calculation at the MP2/cc-pVDZ level of theory is shown below (symmetry of the molecule is determined by the program).

ACES II

The program ACES II (Advanced Concepts in Electronic Structure) was developed in the research group of R.J Bartlett at the Quantum Theory Project (QTP) of the University of Florida in Gainesville. The program's backbone was written in the early 1990s and has undergone extensive developments since that time. ACES II focused on the coupled-cluster theory (Paldus 2005) and its applications (Bartlett 2005; Bartlett and Musiał 2007).

Single point energy calculations may be carried out for the following cases:

Independent particle models RHF, UHF, and ROHF.

Correlation methods utilizing RHF and UHF reference determinants, including MBPT(2), MBPT(3), SDQ-MBPT(4), MBPT(4), CCD, CCSD, CCSD(T), CCSD + TQ*(CCSD), CCSD(TQ), CCSDT-1, CCSDT-2, CCSDT-3, QCISD, QCISD(T), QCISD(TQ), UCCS(4), UCCSD(4), CID, and CISD.

Correlation methods that can use ROHF reference determinants include MBPT(2), CCSD, CCSDT, CCSD(T), CCSDT-1, CCSDT-2, and CCSDT-3.

Correlation methods that can use quasi-restricted Hartree-Fock (QRHF) or Brueckner orbital reference determinants include CCSD, CCSDT, CCSD(T), CCSDT-1, CCSDT-2, and CCSDT-3.

Two-determinant CCSD calculations for open-shell singlet state.

Equation-of-motion CCSD calculation of dynamic polarizabilities and of NMR spin-spin coupling constants.

Equation-of-motion CCSD calculations of excitation energies.

Kohn-Sham DFT density functional methods combined with a wide selection of density functionals.

Analytical gradients may be calculated for

Independent particle models RHF, UHF, and ROHF.

Correlation methods utilizing RHF and UHF reference determinants, including MBPT(2), MBPT(3), SDQ-MBPT(4), MBPT(4), CCD, CCSD, CCSD + T(CCSD), CCSD(T), CCSDT-1, CCSDT-2, CCSDT-3, QCISD, QCISD(T), UCC(4), UCCSD(4), CID, and CISD.

Correlation methods that can utilize ROHF reference determinants, including MBPT(2), CCSD, and CCSD(T).

Correlation methods that can utilize QRHF reference determinants, including CCSD.

Two-determinant CCSD calculations for open-shell singlet state based on QRHF orbitals.

EOM-CCSD for excited states.

TD-CCSD analytical derivatives.

Analytical Hessians may be carried out for the independent particle models RHF, UHF, and ROHF.

ACES III

The program represents a significant advance in parallel processing and resulted from completely rewriting ACES II for efficiency in parallel calculations. The parallel technology based on the super instruction assembly language (SIAL) that marked the progress from ACES II to ACES III was discussed by Bartlett and coworkers (Lotrich et al. 2008).

Home page <http://www.qtp.ufl.edu/ACES/>.

CFOUR

The four Cs in the name of the program stand for Coupled-Cluster techniques for Computational Chemistry. The predecessor of this program was known as the Mainz-Austin-Budapest version of ACES II which was replaced by CFOUR in April 2009 (see <http://www.aces2.de/>). At present, the development of the program is continued at the University of Mainz (J. Gauss), at the University of Texas at Austin (J.F. Stanton and M.E. Harding), and at Eötvös Loránd University (P.G. Szalay).

Some of the features of the program are

NMR chemical shifts.

Many properties, including nuclear spin-rotation constants, magnetizabilities, rotational g -tensors, indirect spin-spin coupling constants.

Electronically excited states may be calculated via CIC, CIS(D), and several EOM-CC methods; the ionized and electron-attached states may be described via EOM-CC methods.

Anharmonic force-field calculations may be carried out.

Vibrationally averaged properties.

Relativistic corrections.

Diagonal Born–Oppenheimer corrections.

Automated additivity and basis-set extrapolation schemes.

Basis sets up to *i*-type Gaussian functions.

Effective core potentials.

Home page <http://www.cfour.de/>.

COLUMBUS

COLUMBUS originated in 1980 at the Ohio State University and was developed by I. Shavitt, H. Lischka (University of Vienna), and R. Shepard (Battelle Columbus Laboratories). The program was designed to carry out a variety of multireference calculations on ground and excited states of molecules (Lischka et al. 2006). Specific features include

Geometry optimization to find minima and saddle points.

Searches for minima on the crossing seam (conical intersections).

General MCSCF with quadratic convergence including state averaging.

Direct MR-CISD (single and double excitations), using an arbitrary set of reference configurations.

Multireference averaged coupled-pair-functional (MR-ACPF) and multi-reference average quadratic coupled-cluster (MR-AQCC) with size-extensivity corrections.

Spin-orbit CI (based on graphical unitary group approach) (Yabushita et al. 1999).

Search for conical intersections may be done at the MRCI level.

For excited states, MCSCF, MR-CISD, and MR-AQCC-LRT transition moments may be calculated.

Finite field method for second-order properties (polarizabilities).

Home page <http://www.univie.ac.at/columbus/>.

MPQC

The Massively Parallel Quantum Chemistry (MPQC) program is an object-oriented code that was written in C++. The work on the code has been initiated by C.L. Janssen at the Sandia National Laboratories (USA).

The capabilities of MPQC include

Energies and gradients are available for closed shell, unrestricted and general restricted open shell Hartree-Fock and density functional methods.

Energies may be calculated for the second-order open-shell perturbation theory.

Energies and gradients may be evaluated for the second-order closed-shell Møller–Plesset perturbation theory (MP2).

MP2 energies of closed-shell systems, including an R12 correlation factor and using an auxiliary basis set, are supported.

Commercial Software

For the details of commercial software the reader is referred to the links listed below for the most up-to-date information about each program. For completeness, both ab initio and semiempirical programs are included.

Gaussian

One of the first programs for large-scale calculations in the commercial domain, dating its origins to 1970, is currently in its 2009 edition.¹

Please see home page <http://www.gaussian.com/>.

Molcas

Please see home page <http://www.teokem.lu.se/molcas/introduction.html>

Q-Chem

Please see home page <http://www.q-chem.com/>

¹The original 13,370 lines of Gaussian 70 code were released to general public via the now defunct Quantum Chemistry Program Exchange (QCPE). Historic information about QCPE may be found on http://www.ccl.net/ccl/qcpe/QCPE_removed/. QCPE offered as the first ab initio program Polyatom (Version I with 3,275 lines of code) was made available by Csizmadia et al. in 1964. It is worth mentioning in passing that the fees that QCPE charged for the programs were very modest by today's standards: \$175 for codes greater than 10,000 lines plus \$35 for media and handling. The programs grew as new capabilities were added: in 1974 Polyatom (Version II for IBM 360) grew to 20,000 lines, while the 1980 release of Gaussian (IBM Version II) contained about 60,000 lines of code. The current status of QCPE was explained in a brief note saved in Computational Chemistry List <http://ccl.net/chemistry/resources/messages/2009/06/04.001-dir/index.html>.

Abstract

In this chapter, we briefly discuss the theoretical foundations of relativistic two-component methods used in quantum chemistry calculations. Specifically, we focus on two groups of methods. These are (i) methods based on the elimination of the small component, such as the zeroth-order regular approximation (ZORA),

the first-order regular approximation (FORA), and the normalized elimination of small component (NESC) formalisms, and (ii) approaches that use a unitary transformation to decouple the electronic and positronic states such as the Douglas–Kroll–Hess (DKH) and the infinite-order two-component (IOTC) Hamiltonians. Furthermore, we describe the algebraic approach to IOTC and scrutinize pure algebraic schemes that paved the way to the eXact 2-Component (X2C) Hamiltonians taking advantage of the nonsymmetric algebraic Riccati equation (nARE). Finally, we assess the accuracy of the aforementioned methods in calculating core and valence properties of heavy-element compounds and discuss some challenging examples of computational actinide chemistry.

Origin of Relativistic Effects and Their Importance in Chemistry

Computational chemistry aims at modeling the electronic structure of atoms and molecules and at predicting their properties. This task is usually accomplished by solving the electronic Schrödinger equation:

$$\hat{H}_S|\Psi\rangle = E|\Psi\rangle, \quad (1)$$

which describes the nonrelativistic movement of electrons in the field of the nuclei. Solving the above equation gives us the electronic wavefunction $|\Psi\rangle$ of the investigated atom or molecule and the electronic energy E as the target quantity, which is the eigenvalue of the Hamiltonian \hat{H}_S (Kędziera and Kaczmarek-Kędziera 2012) for the eigenvector $|\Psi\rangle$. The (electronic) Hamiltonian \hat{H}_S can be generally partitioned into one- and two-electron terms:

$$\hat{H}_S = \hat{H}_{S,1} + \hat{H}_{S,2}. \quad (2)$$

This common partitioning will be particularly useful when we will “design” relativistic approximations or analyze relativistic effects in the following sections. In Eq. (2), the one-electron part for a molecule comprising M nuclei and N electrons can be further partitioned in two contributions:

$$\hat{H}_{S,1} = - \sum_A^M \sum_i^N \frac{Z_A}{|\hat{\mathbf{r}}_i - \hat{\mathbf{R}}_A|} - \frac{1}{2} \sum_i^N \hat{\nabla}_i^2, \quad (3)$$

where the first term contains the electron–nuclear attraction for nuclei A with charge Z_A and electron–nucleus distance $|\hat{\mathbf{r}}_i - \hat{\mathbf{R}}_A|$ and the second term accounts for the kinetic energy of the electrons. Throughout this chapter, we will use the conventional notation of quantum chemistry, where capital letters indicate nuclei, while small letters are used to index electrons. The two-electron part of Eq. (2) comprises the electron–electron repulsion (Coulomb interaction):

$$\hat{H}_{S,2} = \sum_{i < j}^N \frac{1}{|\hat{\mathbf{r}}_i - \hat{\mathbf{r}}_j|}, \quad (4)$$

where $|\hat{\mathbf{r}}_i - \hat{\mathbf{r}}_j|$ is the electron–electron distance, sometimes abbreviated as $|\hat{r}_{ij}|$ or \hat{r}_{ij} . Both the one- and two-electron Hamiltonian in Eqs. (3) and (4) are written in (Hartree) atomic units (a.u.). This convention will be used through the whole chapter, unless specified otherwise.

Although the nonrelativistic electronic Schrödinger equation (*cf.* Eq. (1)) is a reliable model to theoretically describe the properties of light atoms and molecules, it is an inappropriate model when we move down in the periodic table, toward heavy elements. Well-known examples where the Schrödinger model is insufficient and fails in elucidating the properties of atoms and molecules are the goldish color of gold (unlike most other metals that are silver) and the bond-length shortening in the Au–H molecule, which cannot be explained using nonrelativistic theories (Pyykkö 1988; Autschbach 2012). Some basic ideas on which type of relativistic effects need to be incorporated into nonrelativistic models can be deduced from the Bohr model of hydrogen-like atoms. For that purpose, let us consider Bohr’s formula for the average speed of an electron v_n in hydrogen-like atoms

$$v_n = \frac{Z}{n} \quad (5)$$

and for the average distance of an electron from the nucleus r_n in hydrogen-like atoms

$$r_n = \frac{n^2}{mZ}, \quad (6)$$

where n denotes the main quantum number and Z and m are the charge of the nucleus and the mass of the electron, respectively. When we move toward heavier nuclei, i.e., with increasing charge Z , we increase the average speed of the electron (the numerator increases faster than the denominator in Eq. (5)). For some atomic charge onward, v_n becomes a significant fraction of the speed of light c , which takes on an approximate value of $c \approx 137$ a.u. This is the maximum speed at which all massless particles, light, and gravitational waves travel in vacuum. The considerable increase in the average velocity of the electron in heavy elements is illustrated in the following example.

Example 1. For the hydrogen atom ($Z_A = 1$ and $n = 1$), the average speed of the electron is $v_n = 1$ a.u.¹ For the 1s electron in the C^{5+} cation ($Z_A = 6$ and $n = 1$), we have $v_n = 6$ a.u., which is approximately 4% of the speed of light c , while for

¹The atomic unit of speed is defined as $\frac{a_0 E_h}{\hbar} = \alpha c$, which corresponds to $2.18769126277 \times 10^6 \frac{\text{m}}{\text{s}}$.

the U^{91+} cation, the average speed of the 1 s electron increases to $v_n \approx 92$ a.u. and reaches approximately 67 % of c .

The increasing average speed of the electron requires modification of the electron mass in accordance with the theory of relativity (Dyall and Faegri 2007; Reiher and Wolf 2014):

$$m = \frac{m_0}{\sqrt{1 - \frac{v_n^2}{c^2}}}, \quad (7)$$

where m_0 is the rest mass, i.e., the mass of the particle at rest. The modified value for the electron mass will change the average distance of the electron from the nucleus as given in Eq. (6). Substituting the above equation for the electron mass into Eq. (6) and inserting Eq. (5) for the average speed of an electron lead to the following relativistic equation for r_n :

$$r_n^{\text{rel}} = \frac{n^2 \sqrt{1 - \frac{Z^2}{n^2 c^2}}}{m_0 Z}. \quad (8)$$

In nonrelativistic quantum mechanics, the electron mass equals the rest mass ($m = m_0$) and Eq. (6) remains valid. Since $v_n < c$, the denominator in Eq. (7) will always be less than or equal to 1. Thus, the electron mass is always greater or equal to the rest mass and increases with increasing v_n . Therefore, we obtain the following inequality:

$$r_n > r_n^{\text{rel}}, \quad (9)$$

which explains the origin of the shortening (contraction) of bond lengths in heavy-element-containing molecules.

In nonrelativistic theory, the average speed of a 1 s electron is proportional to the atomic charge Z (see Eq. (5)). If we want to anticipate the importance of relativistic effects in heavy elements, we can simply calculate the ratio $\frac{v_n}{c}$ for the 1 s-shell.

Example 2. The average speed of the 1 s electron in the uranium atom ($Z = 92$) equals 67 % of c ($\frac{92}{137} = 0.67$). Using Eq. (7), the mass of the (moving) 1 s electron thus becomes $\approx 1.35m_0$. This corresponds to a radial shrinkage of 25 % (compare Eqs. (6) and (8)).

These simple examples illustrate that nonrelativistic quantum mechanics based on the Schrödinger equation is inadequate for heavy elements like the uranium atom. Applications of relativistic quantum chemistry explained many phenomena observed in heavy-element chemistry that could not be understood using nonrelativistic quantum mechanics. These are the contraction of s and p orbitals, the expansion of d and f orbitals, and singlet-triplet excitations with

nonzero intensities (due to spin–orbit coupling). There are thus numerous examples that demonstrate that heavy elements have to be described using relativistic quantum mechanics, i.e., using the Dirac equation (Dirac 1928a, b) instead of the Schrödinger picture.

Relativistic Quantum Chemistry Made Simpler: Two-Component Hamiltonians

Including relativistic corrections in the theoretical model improves a quantum-mechanical description of heavy elements compared to nonrelativistic methods. Unfortunately, a reliable relativistic description of quantum systems is not a straightforward task and remains a remarkable challenge. The technical and mathematical difficulties that come along with a fully relativistic treatment of the movement of electrons will be addressed in the following sections.

By analogy to nonrelativistic theory, the relativistic Hamiltonian \hat{H}_R can be written as a sum of one- and two-electron parts:

$$\hat{H}_R = \hat{H}_{R,1} + \hat{H}_{R,2}. \quad (10)$$

The one-electron part $\hat{H}_{R,1}$ is simply a sum of the one-electron Dirac Hamiltonian \hat{H}_D for all electrons in the atom or molecule. For one electron, the Dirac Hamiltonian \hat{H}_D can be written in closed form. For the H atom, we have

$$\hat{H}_D = \hat{\beta}c^2 + \hat{V} + c\hat{\alpha} \cdot \hat{p}, \quad (11)$$

where c indicates the velocity of light, $\hat{p} = (\hat{p}_x, \hat{p}_y, \hat{p}_z)$ is the momentum operator, and \hat{V} is the Coulomb potential (electron–nuclear interaction). In addition, we also have a vector $\hat{\alpha}$ with elements $(\hat{\alpha}_x, \hat{\alpha}_y, \hat{\alpha}_z)$ as well as $\hat{\beta}$, all being 4×4 matrices. It is important to stress that according to Dirac’s theory (Dyall and Faegri 2007; Reiher and Wolf 2014), the matrices $\hat{\alpha}_i$ and $\hat{\beta}$ have to fulfill the following conditions:

$$\hat{\alpha}_i^2 = \hat{\beta}^2 = \hat{I}_4 \quad (12)$$

and

$$\hat{\alpha}_i\hat{\alpha}_j + \hat{\alpha}_j\hat{\alpha}_i = \hat{\alpha}_i\hat{\beta} + \hat{\beta}\hat{\alpha}_i = \hat{0}_4, \quad \text{for } i \neq j, \quad (13)$$

where \hat{I}_4 and $\hat{0}_4$ are the 4×4 identity and zero matrices, respectively.

Among possible choices of $\hat{\alpha}_i$ and $\hat{\beta}$, the most common ones are

$$\hat{\alpha}_i = \begin{pmatrix} 0 & \hat{\sigma}_i \\ \hat{\sigma}_i & 0 \end{pmatrix}, \quad \hat{\beta} = \begin{pmatrix} \hat{I}_2 & 0 \\ 0 & -\hat{I}_2 \end{pmatrix}, \quad (14)$$

where σ_i are the (two-dimensional) Pauli spin matrices

$$\hat{\sigma}_x = \begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix}, \quad \hat{\sigma}_y = \begin{pmatrix} 0 & -i \\ i & 0 \end{pmatrix}, \quad \hat{\sigma}_z = \begin{pmatrix} 1 & 0 \\ 0 & -1 \end{pmatrix}. \quad (15)$$

It is convenient to use the abovementioned structures of $\hat{\alpha}_i$ and $\hat{\beta}$ and rewrite the Dirac Hamiltonian \hat{H}_D as

$$\hat{H}_D = \begin{pmatrix} (\hat{V} + c^2)\hat{I}_2 & c\hat{\sigma} \cdot \hat{\mathbf{p}} \\ c\hat{\sigma} \cdot \hat{\mathbf{p}} & (\hat{V} - c^2)\hat{I}_2 \end{pmatrix}, \quad (16)$$

with \hat{I}_2 being the 2×2 identity matrix. This leads to the following eigenvalue problem:

$$\begin{pmatrix} \hat{V}\hat{I}_2 & c\hat{\sigma} \cdot \hat{\mathbf{p}} \\ c\hat{\sigma} \cdot \hat{\mathbf{p}} & (\hat{V} - 2c^2)\hat{I}_2 \end{pmatrix} \begin{pmatrix} \psi^L(\mathbf{r}) \\ \psi^S(\mathbf{r}) \end{pmatrix} = \epsilon \begin{pmatrix} \psi^L(\mathbf{r}) \\ \psi^S(\mathbf{r}) \end{pmatrix}, \quad (17)$$

known as the four-component form of the *Dirac equation*, where

$$\epsilon = E - c^2 \quad (18)$$

denotes the adjusted (scaled) Dirac energy. The wavefunction resulting from Eq. (17),

$$\psi(\mathbf{r}) = \begin{pmatrix} \psi^L(\mathbf{r}) \\ \psi^S(\mathbf{r}) \end{pmatrix}, \quad (19)$$

after taking the normalization condition,

$$\langle \psi(\mathbf{r}) | \psi(\mathbf{r}) \rangle = \langle \psi^L(\mathbf{r}) | \psi^L(\mathbf{r}) \rangle + \langle \psi^S(\mathbf{r}) | \psi^S(\mathbf{r}) \rangle = 1, \quad (20)$$

has a four-component structure and differs therefore from the nonrelativistic wavefunction.

The two-component elements in Eq. (19) are called the large $\psi^L(\mathbf{r})$ and small $\psi^S(\mathbf{r})$ component, respectively. This naming convention originates from the fact that, for the electronic solutions, the large component has a larger norm than the small component. We refer the interested reader to relativistic quantum chemistry textbooks for more details (see, e.g., Schwerdtfeger (2002), Dyall and Faegri (2007), and Reiher and Wolf (2014)). Here, we mention only two key features of the Dirac equation. First, the Dirac equation describes the behavior of both electrons and positrons (the counterpart of the electron with an opposite charge). Second, with the $\hat{\sigma}$ matrices embedded into the Dirac equation, the electron spin emerges naturally, while in nonrelativistic quantum mechanics, the existence of the electron spin is

postulated and included a posteriori into the model. In the following, we will drop the “ $\hat{}$ ” sign above all operators for simplicity. The notation will be evident from the context.

Let us have a closer look at Eq. (17). We can rewrite Eq. (17) as a set of two coupled equations:

$$V\psi^L(\mathbf{r}) + c(\boldsymbol{\sigma} \cdot \mathbf{p})\psi^S(\mathbf{r}) = \epsilon\psi^L(\mathbf{r}) \quad (21)$$

$$c(\boldsymbol{\sigma} \cdot \mathbf{p})\psi^L(\mathbf{r}) + (V - 2c^2)\psi^S(\mathbf{r}) = \epsilon\psi^S(\mathbf{r}) \quad (22)$$

Now, only consider Eq. (22), which can be written as (using matrix–vector multiplication and neglecting all magnetic fields),

$$c(\boldsymbol{\sigma} \cdot \mathbf{p})\psi^L(\mathbf{r}) - 2c^2\psi^S(\mathbf{r}) + V\psi^S(\mathbf{r}) = \epsilon\psi^S(\mathbf{r}). \quad (23)$$

Bringing all terms containing the small component on one side and the remaining terms on the other side yields

$$(2c^2 + \epsilon - V)\psi^S(\mathbf{r}) = c(\boldsymbol{\sigma} \cdot \mathbf{p})\psi^L(\mathbf{r}). \quad (24)$$

From the above equation, we can deduce a relation between the large and small component. After multiplying both sides by $\frac{1}{2c^2}$ and dividing by the prefactor of $\psi^S(\mathbf{r})$, we get a mathematical relation between the small and large component function, the so-called *atomic balance*,

$$\psi^S(\mathbf{r}) = \frac{1}{2c} \frac{1}{1 - \frac{V-\epsilon}{2c^2}} (\boldsymbol{\sigma} \cdot \mathbf{p})\psi^L(\mathbf{r}). \quad (25)$$

Unfortunately, we are dealing with finite-size basis sets in quantum chemistry and this relation cannot be strictly fulfilled. As a consequence, difficulties with the representation of the operator $\boldsymbol{\sigma} \cdot \mathbf{p}$ may occur, which can further lead to unphysical energies lying below the Dirac energy levels. To illustrate this issue, it is worth to analyze the formula resulting from substituting Eq. (25) into Eq. (21),

$$\left(V + \frac{1}{2}(\boldsymbol{\sigma} \cdot \mathbf{p}) \frac{1}{1 - \frac{V-\epsilon}{2c^2}} (\boldsymbol{\sigma} \cdot \mathbf{p}) \right) \psi^L(\mathbf{r}) = \epsilon\psi^L(\mathbf{r}). \quad (26)$$

Equation (26) is a pseudo-eigenvalue equation with a structure similar to the Schrödinger equation written in a basis of Pauli spinors,

$$(V + \frac{1}{2}(\boldsymbol{\sigma} \cdot \mathbf{p})(\boldsymbol{\sigma} \cdot \mathbf{p}))\psi_{\text{nr}}(\mathbf{r}) = E_{\text{nr}}\psi_{\text{nr}}(\mathbf{r}), \quad (27)$$

where the subscript nr denotes the nonrelativistic (but two-component) form of the wavefunction. The similarity between the relativistic and the nonrelativistic

framework will become more evident after introducing the so-called Dirac's relation (Reiher and Wolf 2014):

$$\frac{(\boldsymbol{\sigma} \cdot \mathbf{p})(\boldsymbol{\sigma} \cdot \mathbf{p})}{2} = \frac{p^2}{2}. \tag{28}$$

Now, if we take the limit $c \rightarrow \infty$, we should obtain two identical equations, that is, Eq. (26) should be equal to Eq. (27). Unfortunately, this is not the case as we need to change the analytical derivation into its algebraic counterpart (algebraization of the problem) by introducing some (approximate) expansion for the expression between the $\boldsymbol{\sigma} \cdot \mathbf{p}$ operators in Eq. (26) (i.e., introducing a finite basis set). By using orthonormal basis functions approximating $\psi^L(\mathbf{r})$ and $\psi^S(\mathbf{r})$,

$$\psi^L(\mathbf{r}) \approx |\chi^L\rangle C^L, \tag{29}$$

$$\psi^S(\mathbf{r}) \approx |\chi^S\rangle C^S, \tag{30}$$

we obtain the algebraic representation of Eq. (26),

$$\langle \chi^L | \left(V + \frac{1}{2}(\boldsymbol{\sigma} \cdot \mathbf{p})|\chi^S\rangle\langle \chi^S| \frac{1}{1 - \frac{V-\epsilon}{2c^2}}|\chi^S\rangle\langle \chi^S|(\boldsymbol{\sigma} \cdot \mathbf{p}) \right) | \chi^L \rangle C^L = \langle \chi^L | \chi^L \rangle C^L \epsilon, \tag{31}$$

which after taking the limit $c \rightarrow \infty$ results in

$$\langle \chi^L | \left(V + \frac{1}{2}(\boldsymbol{\sigma} \cdot \mathbf{p})|\chi^S\rangle\langle \chi^S|(\boldsymbol{\sigma} \cdot \mathbf{p}) \right) | \chi^L \rangle C^L = \langle \chi^L | \chi^L \rangle C^L \epsilon. \tag{32}$$

The problem with the nonrelativistic limit can be thus resolved if $\langle \chi^L | p^2 | \chi^L \rangle$ will equal $\langle \chi^L | \boldsymbol{\sigma} \cdot \mathbf{p} | \chi^S \rangle \langle \chi^S | \boldsymbol{\sigma} \cdot \mathbf{p} | \chi^L \rangle$. This equality is true if the basis $|\chi^S\rangle$ spans the whole space of small component functions, which, however, is difficult to achieve in calculations. In most cases, the aforementioned equality is not true.

If we introduce the complement of the small component basis $|\chi^S\rangle$ denoted as $|\bar{\chi}^S\rangle$, we can recover the equality relation,

$$\langle \chi^L | p^2 | \chi^L \rangle = \langle \chi^L | \boldsymbol{\sigma} \cdot \mathbf{p} | \chi^S \rangle \langle \chi^S | \boldsymbol{\sigma} \cdot \mathbf{p} | \chi^L \rangle + \langle \chi^L | \boldsymbol{\sigma} \cdot \mathbf{p} | \bar{\chi}^S \rangle \langle \bar{\chi}^S | \boldsymbol{\sigma} \cdot \mathbf{p} | \chi^L \rangle. \tag{33}$$

Since the operator $\boldsymbol{\sigma} \cdot \mathbf{p}$ is Hermitian, the matrix $\langle \chi^L | \boldsymbol{\sigma} \cdot \mathbf{p} | \bar{\chi}^S \rangle \langle \bar{\chi}^S | \boldsymbol{\sigma} \cdot \mathbf{p} | \chi^L \rangle$ is positive semi-definite. The incompleteness of the $|\chi^S\rangle$ basis (i.e., the missing second terms on the right-hand side of Eq. (33)) leads to

$$\langle \chi^L | \boldsymbol{\sigma} \cdot \mathbf{p} | \chi^S \rangle \langle \chi^S | \boldsymbol{\sigma} \cdot \mathbf{p} | \chi^L \rangle \leq \langle \chi^L | p^2 | \chi^L \rangle. \tag{34}$$

And thus, even after taking the nonrelativistic limit, the resulting Dirac energies might be artificially lower than the energies obtained from the Schrödinger equation which can be attributed to lower (relativistic) kinetic energies.

Therefore, it is particularly important in relativistic quantum chemistry calculations to use basis sets that are suitable for the large component (which should lead to nonrelativistic functions in the nonrelativistic limit) but that also allow us to represent the small component in a well-balanced way. How can we ensure that the small component functions are well balanced in practical calculations? This is not an easy task, primarily because the small and large component functions have to be of different type. For instance, the large component s -type functions have to balance the small component p -type functions, while functions of p -type have to balance functions of s - and d -type, functions of d -type have to balance functions of p - and f -type, etc. Satisfying these conditions results in large basis set sizes, typically much larger than in nonrelativistic calculations, which makes calculations susceptible to linear dependencies in the basis set. These difficulties motivate us to eliminate the small component functions right from the start. In the following, we will describe different methods that aim at solving the Dirac equation using large component functions only. Before scrutinizing the so-called two-component methods, we will briefly discuss the two-electron part of the relativistic Hamiltonian.

The exact (Lorentz-invariant) form of the operator for the electron–electron interaction is unknown and we are forced to use inaccurate approximations. Two approximations are commonly used in relativistic quantum chemistry. These are (i) the standard nonrelativistic two-electron operator as defined in Eq. (4), which is added to the relativistic one-electron term and leads to the Dirac–Coulomb (DC) Hamiltonian, and (ii) the Coulomb term augmented by the Breit operator:

$$O(i, j)^{\text{Breit}} = -\frac{c\boldsymbol{\alpha}_i \cdot c\boldsymbol{\alpha}_j}{2c^2 r_{ij}} - \frac{(c\boldsymbol{\alpha}_i \mathbf{r}_{ij}) \cdot (c\boldsymbol{\alpha}_j \mathbf{r}_{ij})}{2c^2 r_{ij}^3}. \quad (35)$$

Including the Breit operator into the two-electron part of the Hamiltonian leads to the Dirac–Coulomb–Breit (DCB) Hamiltonian (Autschbach 2012),

$$H_{R,2}^{\text{DCB}} = \sum_{i < j}^N \left(\frac{1}{|\mathbf{r}_i - \mathbf{r}_j|} + O(i, j)^{\text{Breit}} \right), \quad (36)$$

which, in addition to the charge–charge interaction (through the Coulomb term), also accounts for the current–current interaction. Although the nonrelativistic Coulomb interaction is straightforward to evaluate compared to the DCB expression, the resulting DC Hamiltonian is not even close to being Lorentz invariant. Adding the Breit interaction results in a Hamiltonian that is *approximately* Lorentz invariant (Reiher and Wolf 2014). Yet, the approximate Lorentz invariance of the DCB Hamiltonian is usually sufficient for chemical applications.

In summary, solving the four-component Dirac equation is difficult, primarily because of the desire to have large and small component functions that are well balanced. Furthermore, the necessity to include both small and large component basis functions at the same time significantly increases the computational cost. On the other hand, when solving the Dirac equation, we obtain solutions for both

electrons and positrons. While the former are of interest in chemistry, the latter are irrelevant for chemical purposes. Furthermore, the Dirac equation (either written in its full four-component form or abbreviated by only two components) poses technical problems for conventional (usually nonrelativistic) quantum chemistry software packages, primarily because the Dirac Hamiltonian differs so much from the Schrödinger Hamiltonian that quantum chemistry codes require a fundamental rewrite to facilitate implementing the Dirac equation. Thus, the Dirac Hamiltonian is usually not supported in mainstream software packages, and relativistic effects are typically included as corrections to the Schrödinger Hamiltonian. Such corrections can be easily implemented in nonrelativistic software packages. In the following, we will discuss some popular approaches that aim at “simplifying” the Dirac Hamiltonian in a form that can be handled by nonrelativistic codes. All methods presented in this chapter transform the four-component Dirac equation into a Hamiltonian with at most two components (Mastalerz and Reiher 2008; Reiher 2012; Wolf et al. 2002; Kędziera and Barysz 2004; Reiher 2006; Liu 2010; Saue 2011).

Methods Based on Eliminating the Small Component

One family of methods tries to simplify the (four-component) Dirac equation by eliminating the small component (ESC) $\psi^S(\mathbf{r})$ from Eq. (17), thus resulting in an eigenvalue equation for the large component $\psi^L(\mathbf{r})$ only. To eliminate the small component from the Dirac equation, we start with the atomic balance relation between the small and large component functions (Eq. (25), but slightly rewritten):

$$\psi^S(\mathbf{r}) = \left(1 + \frac{\epsilon - V}{2c^2}\right)^{-1} \frac{\boldsymbol{\sigma} \cdot \mathbf{p}}{2c} \psi^L(\mathbf{r}), \quad (37)$$

which has the nonrelativistic limit, i.e., the limit for $c \rightarrow \infty$,

$$\lim_{c \rightarrow \infty} 2c \psi^S(\mathbf{r}) = (\boldsymbol{\sigma} \cdot \mathbf{p}) \psi^L(\mathbf{r}). \quad (38)$$

The first factor in Eq. (37) is a multiplicative operator that depends on the energy (the eigenvalue of the Dirac equation) and the position of the electron encoded in the potential V . It is convenient for us to introduce an abbreviation for this operator

$$K(\epsilon, \mathbf{r}) = \left(1 + \frac{\epsilon - V}{2c^2}\right)^{-1}. \quad (39)$$

The relation between the large and small component of Eq. (37) as well as the multiplicative operator $K(\epsilon, \mathbf{r})$ will serve as a starting point for approximations to the (four-component) Dirac equation. Specifically, Eq. (37) suggests that, given a solution for the large component $\psi^L(\mathbf{r})$, we can immediately determine a solution for the small component $\psi^S(\mathbf{r})$. Hence, we can *eliminate* the small component from

the Dirac equation and solve the resulting equations only for the large component. Substituting the relation for the small component $\psi^S(\mathbf{r})$ (Eq. (37)) into Eq. (21), we arrive at a *two-component* equation for the large component of the wavefunction $\psi^L(\mathbf{r})$,

$$\left(\frac{1}{2}(\boldsymbol{\sigma} \cdot \mathbf{p})K(\epsilon, \mathbf{r})(\boldsymbol{\sigma} \cdot \mathbf{p}) + V \right) \psi^L(\mathbf{r}) = \epsilon \psi^L(\mathbf{r}). \quad (40)$$

This will be our starting point for deriving approximate Hamiltonians that aim at eliminating the small component.

To solve Eq. (40) for the large component, we need to calculate the expression for the multiplicative operator $K(\epsilon, \mathbf{r})$, which is the inverse of a function containing the energy and some potential. In principle, this can be accomplished using a series expansion in the parameter $\frac{\epsilon - V}{2c^2}$. Specifically, K can be rewritten in terms of a geometric series,²

$$K(\epsilon, \mathbf{r}) = \left(1 + \frac{\epsilon - V}{2c^2} \right)^{-1} = \sum_{k=0}^{\infty} \left(\frac{V - \epsilon}{2c^2} \right)^k. \quad (41)$$

However, such a procedure will only work if the expansion parameter $\frac{\epsilon - V}{2c^2}$ is small. Since the denominator ($2c^2$) is a constant, the validity of the series expansion depends on the energy difference $\epsilon - V$ in the numerator. For valence electrons, the numerator will be much smaller than $2c^2$ and the expansion will be still valid. However, in the case of electrons that are close in position to the nuclei, V increases significantly in magnitude, the series expansion breaks down, and the resulting operator expression becomes invalid. This problem implicates singularities in the approximated K function (i.e., the series expansion) near the nuclei. To remedy the problem of singularities and to arrive at a variationally stable operator, we have to find a series expansion that is valid for the whole region of space, that is, for electrons in the valence shell as well as core electrons. One possible choice is the regular approximation (RA) introduced by Chang et al. (1986), which was later popularized by van Lenthe et al. (1994) within the framework of density functional theory. The basic idea of the regular approximation is to rewrite the expression for the K operator Eq. (39) as

$$K(\epsilon, \mathbf{r}) = \left(1 + \frac{\epsilon - V}{2c^2} \right)^{-1} = \left(1 - \frac{V}{2c^2} \right)^{-1} \left(1 + \frac{\epsilon}{2c^2 - V} \right)^{-1} \quad (42)$$

and to choose $\frac{\epsilon}{2c^2 - V}$ as the expansion parameter. Since the numerator ϵ is constant and always much smaller than the denominator ($2c^2 - V$),³ this parameter is small

²The geometric series is defined as $\frac{a}{1-x} = \sum_{k=0}^{\infty} ax^k$, for $|x| < 1$.

³Note that V is negative and hence the denominator is even larger than $2c^2$.

for all regions in space and the (geometric) series expansion is well defined (no singularities occur). Expanding the second factor of Eq. (42) using the geometric series, the K operator becomes

$$K(\epsilon, \mathbf{r}) = \left(1 - \frac{V}{2c^2}\right)^{-1} \sum_{k=0}^{\infty} \left(\frac{\epsilon}{V - 2c^2}\right)^k. \quad (43)$$

After inserting the above series expansion for the K operator into Eq. (40), we obtain a general expression for the regular approximation,

$$\left(\frac{1}{2}(\boldsymbol{\sigma} \cdot \mathbf{p}) \left[\left(1 - \frac{V}{2c^2}\right)^{-1} \sum_{k=0}^{\infty} \left(\frac{\epsilon}{V - 2c^2}\right)^k \right] (\boldsymbol{\sigma} \cdot \mathbf{p}) + V\right) \psi^L(\mathbf{r}) = \epsilon \psi^L(\mathbf{r}). \quad (44)$$

In practice, we cannot include all terms in the series expansion (there are infinitely many), and it is a common procedure to truncate the series expansion after a given order to approximate the relativistic Hamiltonian. This will result in different flavors of the regular approximation. The most popular approaches include only the first as well as the first and second term of the expansion in Eq. (41).

The most popular and also most simple flavor of the regular approximation includes only the first term of the series expansion (van Lenthe et al. 1996). Since the first term of the sum in Eq. (43) is for $k = 0$, this approximation is called the zeroth-order regular approximation, abbreviated as ZORA (Chang et al. 1986; van Lenthe et al. 1994). Keeping only the first term of Eq. (43), which is equal to 1, the K operator becomes

$$K(\epsilon, \mathbf{r}) = \left(1 - \frac{V}{2c^2}\right)^{-1}. \quad (45)$$

Inserting the above equation into Eq. (40), we obtain the so-called ZORA equation for the large component $\psi_{\text{ZORA}}^L(\mathbf{r})$,

$$\left(\frac{1}{2}(\boldsymbol{\sigma} \cdot \mathbf{p}) \left(1 - \frac{V}{2c^2}\right)^{-1} (\boldsymbol{\sigma} \cdot \mathbf{p}) + V\right) \psi_{\text{ZORA}}^L(\mathbf{r}) = \epsilon \psi_{\text{ZORA}}^L(\mathbf{r}), \quad (46)$$

where the expression in parentheses is the ZORA Hamiltonian. In practical calculations, one usually employs the *scalar relativistic* version of the ZORA equation, where the spin-orbit interaction is not taken into account, which reads

$$\left(\frac{1}{2}\mathbf{p} \left(1 - \frac{V}{2c^2}\right)^{-1} \mathbf{p} + V\right) \psi_{\text{ScZORA}}^L(\mathbf{r}) = \epsilon \psi_{\text{ScZORA}}^L(\mathbf{r}), \quad (47)$$

where we have used Dirac's relation Eq. (28).

The advantages of ZORA are the normalization of the ZORA wavefunction $\psi_{\text{ZORA}}^L(\mathbf{r})$ and the absence of the energy ϵ in the denominator of the approximate K operator. Although ZORA is the simplest form of the regular approximation, it can account for the most important relativistic effects in the region of the nucleus. Furthermore, it excellently reproduces valence shell properties compared to the fully relativistic Dirac equation.

The disadvantage of the ZORA Hamiltonian is the *gauge invariance* problem. If the potential V is changed by adding a constant shift, i.e., some constant background potential C , so that the new potential reads $V' = V + C$, it does not shift the energy uniformly by this constant C , as it, however, should. This gauge dependence crucially affects properties of core orbitals, for instance, X-ray spectroscopy, but also the optimization of molecular structures. There are, however, ways to remedy the gauge invariance problem (scaling procedures, introduction of model potentials, etc.), which make ZORA a very powerful and efficient relativistic approximation to optimize structures and predict properties of heavy-element compounds (van Lenthe et al. 1993, 1999).

The ZORA Hamiltonian can be improved by including higher-order terms in the series expansion of the K operator (van Lenthe et al. 1994, 1993; Dyall and van Lenthe 1999). If the expansion is truncated after the second term, i.e., $k = 1$, we obtain the so-called first-order regular approximation (FORA), which can be considered as a first-order correction to the ZORA Hamiltonian. Keeping only the first two terms in Eq. (43), the K operator of FORA reads

$$K(\epsilon, \mathbf{r}) = \left(1 - \frac{V}{2c^2}\right)^{-1} \left(1 + \frac{\epsilon}{V - 2c^2}\right), \quad (48)$$

while the FORA equation for the large component $\psi_{\text{FORA}}^L(\mathbf{r})$ takes on the form

$$\left(\frac{1}{2}(\boldsymbol{\sigma} \cdot \mathbf{p}) \left[\left(1 - \frac{V}{2c^2}\right)^{-1} \left(1 + \frac{\epsilon}{V - 2c^2}\right) \right] (\boldsymbol{\sigma} \cdot \mathbf{p}) + V\right) \psi_{\text{FORA}}^L(\mathbf{r}) = \epsilon \psi_{\text{FORA}}^L(\mathbf{r}). \quad (49)$$

In contrast to the ZORA Hamiltonian, which can be used variationally, the FORA Hamiltonian is unbounded from below and can thus only be applied in a perturbative manner. The FORA energy contains terms that are missing from the ZORA Hamiltonian and form a relativistic correction to the ZORA energy. Specifically, the first-order correction term of FORA results in an energy that is correct to $\mathcal{O}(c^{-2})$ and hence removes the $\mathcal{O}(c^{-2})$ error in the ZORA energy (Dyall and van Lenthe 1999; Visscher 2013).

Further improvements over the ZORA and FORA Hamiltonians can be achieved by the infinite-order regular approximation (IORA) (Dyall and van Lenthe 1999; Filatov 2002).

Going back to our starting point when deriving the regular approximation, Eq. (40) is known as the unnormalized elimination of the small component (UESC)

equation.⁴ Although being exact, UESC is not a practical approach, primarily because the energy ϵ appears on both sides of the equation making UESC not an eigenvalue problem (like the Dirac equation). This results from using the strict *atomic balance* relation that depends on the energy. We can remedy this problem by replacing the small component of the wavefunction with a *pseudo-large component* $\phi^L(\mathbf{r})$,

$$\psi^S(\mathbf{r}) = \frac{\boldsymbol{\sigma} \cdot \mathbf{p}}{2c} \phi^L(\mathbf{r}). \quad (50)$$

The above equation can be understood as a modification of Eq. (37). The non-relativistic limit of the pseudo-large component is the large component; note that Eq. (37) has the same limit as in the case of the pseudo-large component:

$$\lim_{c \rightarrow \infty} 2c \psi^S(\mathbf{r}) = (\boldsymbol{\sigma} \cdot \mathbf{p}) \phi^L(\mathbf{r}). \quad (51)$$

Inserting the relation for the pseudo-large component in the two-component form of the Dirac equation (Eq. (17)) and using Dirac's relation given in Eq. (28) will lead us to

$$(V - \epsilon) \psi^L(\mathbf{r}) + \frac{p^2}{2} \phi^L(\mathbf{r}) = 0 \quad (52)$$

$$\frac{p^2}{2} \psi^L(\mathbf{r}) + \left(\frac{1}{4m^2 c^2} (\boldsymbol{\sigma} \cdot \mathbf{p})(V - \epsilon)(\boldsymbol{\sigma} \cdot \mathbf{p}) - \frac{p^2}{2} \right) \phi^L(\mathbf{r}) = 0. \quad (53)$$

The above set of equations are known as the modified Dirac equation (Dyall 1994), a coupled second-order differential equation for the two components of the modified Dirac wavefunction ($\psi^L(\mathbf{r})$, $\phi^L(\mathbf{r})$). Note that Eq. (52) has a structure similar to the nonrelativistic Schrödinger equation. The advantage of the modified Dirac equation is that $\psi^L(\mathbf{r})$ and $\phi^L(\mathbf{r})$ have the same parity, so they can be expanded in the basis set of the same type. This is beneficial in practical calculations since only one basis set for both components is used. The modified Dirac equation (Dyall 1994) was a big step forward in the development of relativistic methods. Equations (52) and (53) form the starting point for eliminating the small (here, pseudo-large) component. An elimination recipe has been developed by Dyall (1997, 1998) and is known as the normalized elimination of the small component (NESC). Specifically, the NESC method gives energy eigenvalues that are correct to $\mathcal{O}(c^{-4})$ with respect to the Dirac eigenvalue, while UESC is correct to only $\mathcal{O}(c^{-2})$. Besides, NESC is free from singularities, which are a common problem for unnormalized methods

⁴The term unnormalized refers to the normalization property of the large component of the wavefunction, which does not fulfill the normalization condition $\int |\psi^L|^2 d\mathbf{r} \neq 1 = \int |\psi^L|^2 d\mathbf{r} + \int |\psi^S|^2 d\mathbf{r}$.

(Zou et al. 2011) (A detailed description of the UESC method can be found in the book of Dyall and Faegri (2007).).

Before we move on to other two-component methods, we should emphasize that Eqs. (52) and (53) are equivalent to the original Dirac Hamiltonian transformed by a matrix

$$U = \begin{pmatrix} 1 & 0 \\ 0 & \frac{\sigma \cdot \mathbf{p}}{2c} \end{pmatrix}. \quad (54)$$

In general, transformations of this kind can be used to derive equations with a more convenient structure. In the following, we will focus on other the two-component methods that are based on a unitary transformation and decompose the Dirac Hamiltonian into a block diagonal form. For better readability, we will omit the explicit dependence of the wavefunction ψ on \mathbf{r} and simply write ψ instead of $\psi(\mathbf{r})$.

Unitary Transformation of the Dirac Equation

When solving the four-component Dirac equation (*cf.* Eq.(17)), it would be advantageous to use as much as possible the standard techniques in nonrelativistic quantum chemistry. Unfortunately, the presence of the positronic states makes it impossible to blindly use the variational principle without any precautions. As positronic states are much lower in energy than electronic states and unbound, i.e., no energy minimum exists, minimizing the energy without any constraints would result in a *variational collapse* (Brown and Ravenhall 1951). Such a collapse would be avoided if we managed to fully *decouple* the electronic and positronic solutions, yielding a set of equations for the electronic states only. This is desirable in quantum chemistry, primarily because we are interested in electronic states only and wish to ignore the positronic states. A decoupling of electronic and positronic solutions can be accomplished by a *unitary transformation* \mathcal{U} of the Dirac Hamiltonian,

$$\tilde{H}_D = \mathcal{U}^\dagger H_D \mathcal{U} = \begin{pmatrix} h_+ & 0 \\ 0 & h_- \end{pmatrix}, \quad (55)$$

that makes the Dirac Hamiltonian H_D block diagonal with respect to the large and small component. In the above equation, we have denoted the unitary transformed Hamiltonian as \tilde{H}_D , while h_+ and h_- are two-component Hamiltonians that act only on electronic and positronic states, respectively. The unitary transformation also modifies the four-component Dirac wavefunction and transforms it into a wavefunction with only two components (for the electronic part only),

$$\mathcal{U}^\dagger \begin{pmatrix} \psi^L \\ \psi^S \end{pmatrix} = \begin{pmatrix} \phi_+ \\ 0 \end{pmatrix}, \quad (56)$$

where ϕ_+ is an eigenfunction of the two-component Hamiltonian h_+ . Thus the unitary transformation separates the large and small component of the untransformed Dirac wavefunction and converts the Dirac Hamiltonian into two separate eigenvalue problems, one for the electronic states (our *target* states) and the positronic states (the ones we wish to ignore). Combining Eqs. (55) and (56), the movement of the electrons is then described by the following equation

$$h_+ \phi_+ = E_+ \phi_+. \quad (57)$$

Note that h_+ is a two-dimensional matrix, while ϕ_+ is a two-dimensional vector. Thus, the above equation has two components. We should emphasize that all approaches mentioned above (methods based on elimination of the small component and methods based on a unitary transformation) aim at eliminating the small component from the electronic part of the Dirac equation. Furthermore, these two kinds of approaches are equivalent in the limit of infinite expansion used in ESC or RA.

Heully and coworkers (1986) proposed a particularly useful form for the transformation \mathcal{U} ,

$$\mathcal{U} = \begin{pmatrix} \Omega_+ & R^\dagger \Omega_- \\ R \Omega_+ & -\Omega_- \end{pmatrix}, \quad (58)$$

where

$$\Omega_+ = (1 + R^\dagger R)^{-1/2}, \quad \Omega_- = (1 + R R^\dagger)^{-1/2}. \quad (59)$$

The structure of Eq. (58) enforces operator R to be unitary, independent of its form, except that the condition

$$R^\dagger = -R \quad (60)$$

must be satisfied. The R operator is determined by requiring the off-diagonal elements of \bar{H}_D to be equal to zero, thus ensuring that the transformed Hamiltonian \bar{H}_D is block diagonal,

$$R(H_1)_{11} + R(H_1)_{12}R - (H_1)_{21} - (H_1)_{22}R = 0. \quad (61)$$

Unfortunately, neither the analytical solution of the above equation nor the form of the unitary transformation \mathcal{U} is known. Finding reliable approximations to R is one of the central problems in the relativistic quantum chemistry community. Even though we do not know the analytical form of R , we can analyze its physical meaning. Substituting Eq. (58) into Eq. (56), we obtain

$$\phi^L = \Omega_+(\psi^L + R^\dagger \psi^S), \quad 0 = \Omega_-(R\psi^L - \psi^S), \quad (62)$$

where the second equation is only satisfied if

$$\psi^S = R\psi^L. \quad (63)$$

Thus, R can be understood as an operator converting the large component of electronic solutions into its small component counterpart. Moreover, using Eq. (63), the normalized two-component electronic function ϕ^L simplifies to

$$\phi^L = \Omega_+^{-1}\psi^L. \quad (64)$$

The exact form of \mathcal{U} is only known for the *free-particle* Dirac Hamiltonian (a single freely moving particle, i.e., neglecting any scalar potentials ($V = 0$) and vector fields ($A = 0$), for instance, the nucleus–electron attraction) and called the *Foldy–Wouthuysen* transformation (Foldy and Wouthuysen 1950). The free-particle Foldy–Wouthuysen transformation (Foldy and Wouthuysen 1950) can be written as

$$\mathcal{U}_{\text{fpFW}} = \begin{pmatrix} A & \alpha AB \\ \alpha AB & -A \end{pmatrix}, \quad (65)$$

where

$$A = \sqrt{\frac{e_p + 1}{2e_p}}, \quad B = b(\boldsymbol{\sigma} \cdot \mathbf{p}), \quad b = \frac{1}{e_p + 1}, \quad e_p = \sqrt{1 + \alpha^2 p^2}, \quad \alpha = 1/c. \quad (66)$$

This transformation brings the free-particle Dirac Hamiltonian,

$$H_{\text{fpD}} = \begin{pmatrix} \mathbf{0}_2 & c(\boldsymbol{\sigma} \cdot \mathbf{p}) \\ c(\boldsymbol{\sigma} \cdot \mathbf{p}) & -2c^2 \mathbf{I}_2 \end{pmatrix}, \quad (67)$$

into block-diagonal form,

$$\mathcal{U}_{\text{fpFW}}^\dagger H_{\text{fpD}} \mathcal{U}_{\text{fpFW}} = \begin{pmatrix} T_p & \mathbf{0}_2 \\ \mathbf{0}_2 & -T_p - 2c^2 \mathbf{I}_2 \end{pmatrix}, \quad (68)$$

where

$$T_p = c^2(e_p - 1). \quad (69)$$

The free-particle Foldy–Wouthuysen transformation (Foldy and Wouthuysen 1950) thus involves square roots of the square root operator and the final block-diagonalized operator looks more complicated than the original Dirac Hamiltonian. Nonetheless, explicitly eliminating the small component results in a Hamiltonian for the positive-energy states (the electronic states) that may have a variationally lower bound, which removes the problem of variational collapse encountered in the

Dirac equation. However, the Foldy–Wouthuysen transformation discussed above is only exact for a constant potential. If we consider the Dirac Hamiltonian for an electron moving in the field of a nucleus like the hydrogen atom (i.e., with a nonconstant potential V), the decoupling operator is not exact, and the resulting transformed Hamiltonian still contains off-diagonal elements. Specifically, the free-particle Foldy–Wouthuysen transformation of the Dirac Hamiltonian, here indicated as H_1 , only reduces the mixing terms between the small and large component to the order of α^2 ,

$$H_1 = \begin{pmatrix} T_p + A(V + \alpha^2 BVB)A & \alpha A[V, B]A \\ \alpha A[B, V]A & -2\alpha^{-2} - T_p + A(V + \alpha^2 BVB)A \end{pmatrix}. \quad (70)$$

Similarly, the relation between the large and small component is modified. After the free-particle Foldy–Wouthuysen transformation, the small component is approximately proportional to the large component as

$$\psi_1^S \approx \alpha^3 \psi_1^L. \quad (71)$$

Because of the above relation, the transformed Hamiltonian H_1 (cf. Eq.(70)) represents a better starting point for subsequent two-component methods than the Dirac Hamiltonian itself.

One of the very first methods using the Foldy–Wouthuysen transformation as an initial transformation of the Dirac Hamiltonian has been introduced to chemistry by Bernard Hess under the name Douglas–Kroll transformation (Douglas and Kroll 1974). The Douglas–Kroll–Hess method (often denoted by DKH n , where n indicates the order of accuracy) is based on the transformation of the H_1 Hamiltonian, introduced by Douglas and Kroll, where the unitary transformation is given by (Douglas and Kroll 1974)

$$U_1 = \sqrt{1 + \mathscr{W}_1^2} + \mathscr{W}_1, \quad (72)$$

with \mathscr{W}_1 being some unknown anti-Hermitian operator that can be determined from Eq. (70) by eliminating off-diagonal terms to first order in the external potential V . The original implementation proposed by Hess (1985) was accurate up to the 2nd order in V . Further development of this method by Nakajima and coworkers (2000) in 2000 led to a relativistic Hamiltonian that is accurate up to the 3rd order in V . In 2002, Wolf and coworkers (2002) introduced a generalized form of the Douglas–Kroll–Hess transformation that facilitated the derivation of a Hamiltonian accurate up to the 5th order. Further improvements of this scheme by Reiher and Wolf (2004a, b) resulted in a transformed Hamiltonian that is accurate up to infinite order.

Below, we briefly describe the derivation and implementation of the DKH3 Hamiltonian. The derivation of higher-order terms can be done in a similar way, but is more tedious and time consuming. For transferability reasons to the original DKH work, we introduce some helpful notations

- \mathcal{E}_k : an even and Hermitian operator
- \mathcal{O}_k : an odd and Hermitian operator
- \mathcal{W}_k : an odd and anti-Hermitian operator

The subscript k indicates the order with respect to V . We should note that elements of the four-component Hamiltonian are written using calligraphic letters, while roman-type letters denote the corresponding two-component ones. Furthermore, a “'” will mark those terms that will be corrected in subsequent transformations. We will also apply this convention to the \mathcal{W}_k operator until its final representation has been found. Using this notation, the (transformed) Hamiltonian from Eq. (70) has the following form:

$$H_1 = \mathcal{E}_0 + \mathcal{E}_1 + \mathcal{O}'_1, \quad (73)$$

where

$$\mathcal{E}_0 = \begin{pmatrix} T_p & \mathbf{0}_2 \\ \mathbf{0}_2 & -2\alpha^{-2} - T_p \end{pmatrix}, \quad (74)$$

$$\mathcal{E}_1 = \begin{pmatrix} A(V + \alpha^2 BVB)A & \mathbf{0}_2 \\ \mathbf{0}_2 & A(V + \alpha^2 BVB)A \end{pmatrix}, \quad (75)$$

and

$$\mathcal{O}'_1 = \begin{pmatrix} \mathbf{0}_2 & \alpha A[V, B]A \\ \alpha A[B, V]A & \mathbf{0}_2 \end{pmatrix}. \quad (76)$$

The key idea of the DKH method is to apply a product of transformations as defined in Eq. (72) in order to gradually eliminate odd terms \mathcal{O}_k in the Hamiltonian. The DKH transformation can thus be understood as an order-by-order diagonalization. The transformed Hamiltonian of $(n + 1)$ th order has the general form

$$\begin{aligned} H_{n+1} &= U_n^\dagger U_{n-1}^\dagger \dots U_2^\dagger U_1^\dagger H_1 U_1 U_2 \dots U_{n-1} U_n \\ &= \sum_{i=0}^{2n+1} \mathcal{E}_i + \sum_{i=2n+2}^{\infty} \mathcal{E}'_i + \sum_{i=n+1}^{\infty} \mathcal{O}'_i. \end{aligned} \quad (77)$$

If we are interested in the DKH3 Hamiltonian, we have to include all \mathcal{E}_k operators for $k = 0, 1, 2, 3$. Thus, we have to transform the Hamiltonian H_1 only once to determine the DKH3 Hamiltonian (if $n = 1$, i runs over 0, 1, 2, 3 and we obtain a complete form of the operator \mathcal{E}_3). The most general (but not exclusive) ansatz to construct a unitary transformation is to use a power series expansion of an (anti-Hermitian) operator. In so doing, the U_1 transformation can be written as

$$U_1 = a_0 \mathbf{1}_4 + a_1 \mathcal{W}'_1 + a_2 \mathcal{W}'_1{}^2 + a_3 \mathcal{W}'_1{}^3 + \dots, \quad (78)$$

where the coefficients a_i correspond to the coefficients of a Taylor series expansion of Eq. (72). These coefficients are chosen in such a way that U_1 is as close to unitary as possible. This condition is particularly important when deriving higher-order DKH corrections and originates from the fact that the operators U_i can be represented in other ways than shown in Eq. (72). These different operator representations implicate some arbitrariness when choosing the expansion coefficients a_i .

The unitary condition for Eq. (78) reads

$$U_1^\dagger U_1 = \mathbf{1}_4 = a_0^2 \mathbf{1}_4 + (2a_0 a_2 - a_1^2) \mathscr{W}'_1{}^2 + (2a_0 a_4 - 2a_1 a_3 + a_2^2) \mathscr{W}'_1{}^4 + \dots \quad (79)$$

This condition is fulfilled if the parameter a_0 is equal to 1, while all remaining coefficients in front of the different powers of \mathscr{W}'_1 are equal to 0, that is,

$$a_0^2 = 1, \quad (80)$$

$$2a_0 a_2 - a_1^2 = 0, \quad (81)$$

$$2a_0 a_4 - 2a_1 a_3 + a_2^2 = 0, \quad (82)$$

etc. It is convenient to express the even coefficients (a_2, a_4 , etc.) using the odd coefficients (a_1, a_3 , etc.)

$$a_0^2 = 1, \quad (83)$$

$$a_2 = \frac{1}{2} \frac{a_1^2}{a_0}, \quad (84)$$

$$a_4 = a_0 a_1 a_3 - \frac{1}{8} a_0 a_1^4. \quad (85)$$

These relations will be particularly useful for simplifying higher-order corrections to DKH.

Our primary goal is to find the DKH3 Hamiltonian. To achieve this goal, we have to determine the operator \mathcal{E}_3 . This means that the transformation U_1 has to be accurate up to $\mathscr{W}'_1{}^2$. Therefore, the H_2 Hamiltonian can be obtained using the following approximate unitary transformation:

$$U_1 \approx a_0 \mathbf{1} + a_1 \mathscr{W}'_1 + a_2 \mathscr{W}'_1{}^2. \quad (86)$$

The transformed H_2 Hamiltonian, $H_2 = U_1^\dagger H_1 U_1$, can be expressed as

$$H_2 \approx \mathcal{E}_0 + \mathcal{E}_1 + \mathcal{E}_2 + \mathcal{E}_3 + \mathcal{E}_4 + \mathcal{E}_5 \dots + \mathcal{O}_1 + \mathcal{O}_2 + \mathcal{O}_3, \quad (87)$$

where

$$\mathcal{E}_2 = -a_0 a_1 [\mathscr{W}'_1, \mathcal{O}'_1] + \frac{1}{2} a_1^2 [\mathscr{W}'_1, [\mathscr{W}'_1, \mathcal{E}_0]] \quad (88)$$

$$\mathcal{E}_3 = \frac{1}{2}a_1^2[\mathcal{W}'_1, [\mathcal{W}'_1, \mathcal{E}_1]] \quad (89)$$

$$\mathcal{O}'_1 = \mathcal{O}'_1 - a_0a_1[\mathcal{W}'_1, \mathcal{E}_0]. \quad (90)$$

Note that the brackets $[\]$ are used to denote commutators, that is, $[A, B] = AB - BA$, while the brackets $\{ \}$ indicate anticommutators, that is, $\{A, B\} = AB + BA$. The remaining (prime) terms are not complete, that is, block diagonal, and will be modified in a subsequent DKH transformation step. Now, we have to eliminate the first odd term \mathcal{O}'_1 , that is, we have to ensure that $\mathcal{O}'_1 = 0$. This elimination procedure defines the \mathcal{W}'_1 operator,

$$[\mathcal{W}'_1, \mathcal{E}_0] = \frac{a_0}{a_1}\mathcal{O}'_1. \quad (91)$$

Substituting the above equation into Eq. (88) further simplifies the expression for \mathcal{E}_2 ,

$$\mathcal{E}_2 = -\frac{1}{2}a_0a_1[\mathcal{W}'_1, \mathcal{O}'_1]. \quad (92)$$

The dependence on the coefficients a_0 and a_1 in the above equation can be eliminated by substituting

$$\mathcal{W}_1 = a_0a_1\mathcal{W}'_1, \quad (93)$$

which according to Eq. (91) leads to

$$[\mathcal{W}_1, \mathcal{E}_0] = \mathcal{O}'_1. \quad (94)$$

Using this definition of the \mathcal{W}_1 operator, we can write for \mathcal{E}_2

$$\mathcal{E}_2 = -\frac{1}{2}[\mathcal{W}_1, \mathcal{O}'_1], \quad (95)$$

and for \mathcal{E}_3

$$\mathcal{E}_3 = \frac{1}{2}[\mathcal{W}_1, [\mathcal{W}_1, \mathcal{E}_1]]. \quad (96)$$

Consistent with our notation, the abovementioned operators \mathcal{E}_2 and \mathcal{E}_3 are 4×4 matrices. We can now derive corrections for the two-component operators acting on the electronic states, which will be denoted (now using roman-type letters) as E_i . We have

$$E_0 = T_p, \quad (97)$$

and

$$E_1 = A(V + \alpha^2 BVB)A. \quad (98)$$

Furthermore, the operators \mathcal{O}'_1 and \mathcal{W}_1 can be expressed using two-component operators

$$\mathcal{O}'_1 = \begin{pmatrix} \mathbf{0}_2 & O_1 \\ -O_1 & \mathbf{0}_2 \end{pmatrix}, \quad \mathcal{W}_1 = \begin{pmatrix} \mathbf{0}_2 & W_1 \\ W_1 & \mathbf{0}_2 \end{pmatrix}, \quad (99)$$

where

$$O_1 = \alpha A[V, B]A, \quad (100)$$

and the operator W_1 is given by

$$\{W_1, e_p\} = -\alpha^2 O_1. \quad (101)$$

Finally, we can bring the operators \mathcal{E}_i to a block diagonal form (which will give us the DKH3 Hamiltonian), where the operators acting on the electronic states (upper block) are separated from the operators acting on the positronic states:

$$\mathcal{E}_0 = \begin{pmatrix} E_0 & \mathbf{0}_2 \\ \mathbf{0}_2 & -E_0 - 2c^2 \mathbf{I}_2 \end{pmatrix}, \quad \mathcal{E}_1 = \begin{pmatrix} E_1 & \mathbf{0}_2 \\ \mathbf{0}_2 & E_1 \end{pmatrix}, \quad (102)$$

$$\mathcal{E}_2 = \begin{pmatrix} E_2 & \mathbf{0}_2 \\ \mathbf{0}_2 & -E_2 \end{pmatrix}, \quad \mathcal{E}_3 = \begin{pmatrix} E_3 & \mathbf{0}_2 \\ \mathbf{0}_2 & E_3 \end{pmatrix}, \quad (103)$$

with

$$E_2 = \frac{1}{2}\{W_1, O_1\} \quad (104)$$

and

$$E_3 = \frac{1}{2}[W_1, [W_1, E_1]]. \quad (105)$$

Higher orders of the DKH Hamiltonian can be constructed according to a snap-together modular building block system. Such an approach was developed by Reiher and Wolf and led to the development of the infinite-order DKH method (Reiher and Wolf 2004a, b). However, higher-order DKH Hamiltonians have a more complex structure due to additional parameters that have to be determined to ensure that the transformation matrices are unitary. In practical applications, corrections higher than the 14th order are not used because the time required to calculate these higher-order corrections (for the one-electron part of the Hamiltonian) becomes larger than

an actual four-component calculation, while the differences from the reference Dirac energies are negligible. Besides, no matter which DKH order we are considering, the problem will become algebraic at some point. Both the Foldy–Wouthuysen and DKH Hamiltonians are well defined in momentum space. The construction of the matrix representation of such Hamiltonians thus requires a Fourier transformation from \mathbf{r} to \mathbf{p} space. Most probably, one reason for the popularity of the DKH method is the scheme proposed by Hess (1985) that allows us to obtain matrix representations of the operator products in different spaces. We will elaborate on this issue by means of the matrix representation of the E_2 operator.

Let $|\chi\rangle$ denote some orthogonal basis with functions depending on \mathbf{r} . After introducing such a basis set, we can diagonalize the matrix representation of the operator p^2 ,

$$\mathbf{G}^\dagger \langle \chi | p^2 | \chi \rangle \mathbf{G} = \mathbf{p}^2, \quad (106)$$

where \mathbf{G} is an orthogonal and \mathbf{p}^2 a diagonal matrix, respectively. After diagonalization, we can introduce a new basis

$$|\mathbf{k}\rangle = |\chi\rangle \mathbf{G}, \quad (107)$$

that is an eigenvector of the operator p^2 represented in terms of functions dependent on \mathbf{r} . The important point now is that, within this new basis $|\mathbf{k}\rangle$ (which is \mathbf{r} dependent), we can represent operators that are functions of p^2 ,

$$\langle \mathbf{k} | f(p^2) | \mathbf{k} \rangle = f. \quad (108)$$

Furthermore, using the approximate resolution of identity,

$$|\mathbf{k}\rangle \langle \mathbf{k}| \approx 1 \quad (109)$$

we can derive the representations of the operator products defined in \mathbf{r} and \mathbf{p} space. Specifically, in the DKH method, we have to define the general matrix representation of two kinds of operators, namely:

$$X = f(p^2)g(r)h(p^2), \quad (110)$$

and

$$Y = (\boldsymbol{\sigma} \cdot \mathbf{p}) f(p^2)g(r)h(p^2)i(r)j(p^2)(\boldsymbol{\sigma} \cdot \mathbf{p}). \quad (111)$$

In the first case, we have to substitute Eq. (109) between the operators dependent on p^2 and r :

$$\langle \mathbf{k} | X | \mathbf{k} \rangle = \langle \mathbf{k} | f(p^2) | \mathbf{k} \rangle \langle \mathbf{k} | g(r) | \mathbf{k} \rangle \langle \mathbf{k} | h(p^2) | \mathbf{k} \rangle \quad (112)$$

$$= f \mathbf{G}^\dagger \langle \chi | g(r) | \chi \rangle \mathbf{G} h, \quad (113)$$

where in going from the first to the second equality, we have used Eqs.(108) and (106). We cannot, however, use the same procedure for the second case as the p^2 -dependent part will be linear in the operator product $(\boldsymbol{\sigma} \cdot \mathbf{p})$, that is, we will have odd terms. Instead, operator Y can be rearranged using

$$\frac{(\boldsymbol{\sigma} \cdot \mathbf{p})(\boldsymbol{\sigma} \cdot \mathbf{p})}{p^2} = 1, \quad (114)$$

to the following form

$$Y = f(p^2)(\boldsymbol{\sigma} \cdot \mathbf{p})g(r)(\boldsymbol{\sigma} \cdot \mathbf{p})h(p^2)\frac{1}{p^2}(\boldsymbol{\sigma} \cdot \mathbf{p})i(r)(\boldsymbol{\sigma} \cdot \mathbf{p})j(p^2), \quad (115)$$

which results in the following matrix representation

$$\langle \mathbf{k} | Y | \mathbf{k} \rangle = \mathbf{f} \mathbf{G}^\dagger \langle \boldsymbol{\chi} | (\boldsymbol{\sigma} \cdot \mathbf{p})g(r)(\boldsymbol{\sigma} \cdot \mathbf{p}) | \boldsymbol{\chi} \rangle \mathbf{G} \mathbf{h} \frac{1}{p^2} \mathbf{G}^\dagger \langle \boldsymbol{\chi} | (\boldsymbol{\sigma} \cdot \mathbf{p})i(r)(\boldsymbol{\sigma} \cdot \mathbf{p}) | \boldsymbol{\chi} \rangle \mathbf{G} \mathbf{j}. \quad (116)$$

Integrals of the type $\langle \boldsymbol{\chi} | (\boldsymbol{\sigma} \cdot \mathbf{p})g(r)(\boldsymbol{\sigma} \cdot \mathbf{p}) | \boldsymbol{\chi} \rangle$, which appear in the above equations, are computed using the Hermitian property of the operator $(\boldsymbol{\sigma} \cdot \mathbf{p})$,

$$\langle \boldsymbol{\chi} | (\boldsymbol{\sigma} \cdot \mathbf{p})g(r)(\boldsymbol{\sigma} \cdot \mathbf{p}) | \boldsymbol{\chi} \rangle = \langle (\boldsymbol{\sigma} \cdot \mathbf{p}) \boldsymbol{\chi} | g(r) | (\boldsymbol{\sigma} \cdot \mathbf{p}) \boldsymbol{\chi} \rangle. \quad (117)$$

Now, we are all set to derive a matrix representation of the operator E_2 in the basis $\boldsymbol{\chi}$. Recall that the E_2 operator has the following form

$$E_2 = \frac{1}{2}(W_1 O_1 + O_1 W_1). \quad (118)$$

From the property of the operators \mathscr{W}_1 (anti-Hermitian) and \mathscr{O}_1 (Hermitian), we can deduce that (cf. Eq. (99))

$$W_1^\dagger = -W_1 \quad \text{and} \quad O_1^\dagger = O_1. \quad (119)$$

Since $(W_1 O_1)^\dagger = O_1 W_1$, it is, thus, sufficient to derive only one of the two possible products of Eq.(118). First, let us introduce a temporary operator Y defined as follows:

$$Y = W_1 O_1, \quad (120)$$

for which Eq. (118) becomes

$$E_2 = \frac{1}{2}(Y + Y^\dagger). \quad (121)$$

As the W_1 and O_1 operators are odd, their matrix representations should be obtained with two basis sets of different parity. However, in two-component methods, we are interested in using only the large component. A remedy to this problem is obvious: we can insert Eq. (114) between the W_1 and O_1 operators and bring the operator Y to a new form,

$$Y = W_1(\boldsymbol{\sigma} \cdot \mathbf{p}) \frac{1}{p^2} (\boldsymbol{\sigma} \cdot \mathbf{p}) O_1. \quad (122)$$

As a result, we have to determine matrices of two even operators,

$$W = W_1(\boldsymbol{\sigma} \cdot \mathbf{p}) \quad \text{and} \quad O = (\boldsymbol{\sigma} \cdot \mathbf{p}) O_1. \quad (123)$$

The W operator, which defines the \mathcal{U}_1 transformation, can be determined from the following condition (*cf.* Eq. (101)):

$$W e_p + e_p W = -\alpha^2 O. \quad (124)$$

In practice, we have, thus, to derive the matrix representation of the operator O only,

$$O = \alpha A (V b p^2 - b(\boldsymbol{\sigma} \cdot \mathbf{p}) V (\boldsymbol{\sigma} \cdot \mathbf{p})) A. \quad (125)$$

Given the matrix representation of an arbitrary operator Γ in the basis \mathbf{k}

$$\Gamma = \langle \mathbf{k} | \Gamma | \mathbf{k} \rangle, \quad (126)$$

we can write for the matrix representation of O

$$O = \alpha A \left(G \langle \chi | V | \chi \rangle G^\dagger b p^2 - b G \langle (\boldsymbol{\sigma} \cdot \mathbf{p}) \chi | V | (\boldsymbol{\sigma} \cdot \mathbf{p}) \chi \rangle \right) A. \quad (127)$$

Now, Eq. (124) can be rewritten in the same basis

$$W e_p + e_p W = -\alpha^2 O. \quad (128)$$

Finding a solution to the above equation is straightforward as the matrix e_p is diagonal. Using matrix representation, we obtain

$$W_{(i,j)} e_{p(j,j)} + e_{p(i,i)} W_{(i,j)} = -(\alpha^2 O^\dagger)_{(i,j)}, \quad (129)$$

with matrix elements of W defined as

$$W_{(i,j)} = -\alpha^2 \frac{O_{(i,j)}}{e_{p(i,i)} + e_{p(j,j)}} \quad (130)$$

Finally, after we have determined the matrix representation of the operators W and O , we can derive the matrix representation of the Y operator,

$$Y = W \frac{1}{p^2} O, \quad (131)$$

which can be used to calculate the matrix representation of the operator E_2 in the basis $|\mathbf{k}\rangle$,

$$E_2 = \frac{1}{2}(Y + Y^\dagger). \quad (132)$$

Since we intended to obtain a matrix representation of E_2 in basis χ , we have to reverse the transformation defined in Eq. (107). This results in

$$\langle \chi | E_2 | \chi \rangle = \mathbf{G} E_2 \mathbf{G}^\dagger. \quad (133)$$

Matrix representations of other corrections and W_i operators can be determined in a similar way.

We should emphasize that the second-order DKH (DKH2) Hamiltonian is used in the majority of applications of the DKH method. Higher-order DKH Hamiltonians (DKH n with $n = 3, 4, \dots$) are supported in some quantum chemistry computer programs but are less frequently used (Nakajima and Hirao 2000; van Wüllen 2004; Reiher and Wolf 2004a, b). The reason for the prevalent use of the DKH2 Hamiltonian is that the accuracy of the second-order approximation is usually sufficient for chemical applications, resulting in negligible deviations from a four-component reference calculation (see section “Two-Component Hamiltonians in Practice” for a detailed discussion on the performance of two-component Hamiltonians). Furthermore, a higher-order transformation only reduces the error in the external potential V , but does not affect the error in the electron–electron interaction. The error in the electron–electron interaction is caused by the fact that in a conventional DKH transformation, only the one-electron part of the Hamiltonian has been replaced by the DKH transformed expressions, while the (nonrelativistic) two-electron part remains unchanged. However, transforming the nonrelativistic Coulomb interaction, or the even more complicated Breit interaction (Eq. (35)), results in a considerably complicated expression for the two-electron part of the Hamiltonian. Since this term is difficult to evaluate efficiently, the two-electron interaction is not altered in conventional applications of the DKH method. The different treatment of one- and two-electron terms is, however, inconsistent and gives rise to the so-called *picture change* (Dyall and Faegri 2007; Kello and Sadlej 1997).

A picture change error is always encountered when only some operators are transformed to the DKH picture, while others are left untouched. For instance, if the Hamiltonian is augmented by other operators (dipole moment operator, etc.), these additional operators need to be transformed first before molecular properties can be evaluated. Skipping this transformation and using the original form of the operator to evaluate its expectation value lead to non-negligible errors, the so-called

picture change errors (Kello and Sadlej 1997). Therefore, to achieve results that agree well with reference (four-component) Dirac calculations, the corresponding operators have to be transformed to the DKH picture to eliminate (or minimize) the picture change error.

A One-Step DKH Method

One may think that DKH n is the method we have been looking for: it describes only the electronic part of the spectrum and the electronic wavefunction can be optimized as in nonrelativistic calculations, that is, we don't have to modify our quantum chemistry code substantially. However, higher orders of the DKH n Hamiltonian are computationally demanding, primarily because we have to perform a series of product transformations \mathcal{U}_i that have to be expressed in higher powers of \mathcal{H}_i (longer expansions). Even though we can utilize algorithms to obtain higher-order corrections to DKH, the method is nonetheless computationally expensive. A solution to this problem is to replace the product of transformations by a one-step procedure. A particularly useful scheme was proposed by Heully and coworkers (1986) that uses a transformation \mathcal{U} as defined in Eq. (58) in terms of an anti-Hermitian, unitary operator R . The arbitrariness of the operator R , however, does not deteriorate the ansatz for \mathcal{U} but allows us to construct different two-component Hamiltonians starting with the same general expression. Yet, not every form of the operator R leads to a block-diagonal form of the Hamiltonian.

If \mathcal{U} is chosen as in Eq. (58), the transformed electronic Hamiltonian is given by

$$h_+ = \Omega_+ \left((H_1)_{11} + R^\dagger (H_1)_{21} + (H_1)_{12} R + R^\dagger (H_1)_{22} R \right) \Omega_+, \quad (134)$$

which can be rewritten using the matrix elements of H_1 (Eq. (70)) and the notation defined in Eqs. (97), (98), and (100)

$$h_+ = \Omega_+ \left(E_0 + E_1 + [R, O_1] - R(-E_0 + E_1 - 2\alpha^{-2})R \right) \Omega_+. \quad (135)$$

We can completely eliminate the off-diagonal blocks of the Hamiltonian H_1 if

$$O_1 + \alpha^{-2}(e_p R + R e_p) + R E_1 - E_1 R + R O_1 R = 0 \quad (136)$$

is satisfied. We now seek a method analogous to DKH n but with a unitary transformation as given by Eq. (58). First, we expand the operator R into a series (Kędziera 2005),

$$R = \sum_{i=1}^{\infty} R_i, \quad (137)$$

where the index i denotes the contribution of the i th order in the external potential V . The first and main advantage of this approach over the standard DKH

transformation is that we don't need to parameterize any coefficients in front of the R_i operators. Substituting Eq. (137) into Eq. (136) gives

$$O_1 + \alpha^{-2} \sum_{i=1}^{\infty} (e_p R_i + R_i e_p) + \sum_{i=1}^{\infty} (R_i E_1 - E_1 R_i) = 0 + \sum_{i=1}^{\infty} \sum_{j=1}^{\infty} R_i O_1 R_j. \quad (138)$$

After rearranging with respect to orders in V , we get

$$\begin{aligned} 0 = & O_1 + \alpha^{-2}(e_p R_1 + R_1 e_p) \\ & + \alpha^{-2}(e_p R_2 + R_2 e_p) + (R_1 E_1 - E_1 R_1) \\ & + \alpha^{-2}(e_p R_3 + R_3 e_p) + (R_2 E_1 - E_1 R_2) + R_1 O_1 R_1 \\ & + \alpha^{-2}(e_p R_4 + R_4 e_p) + (R_3 E_1 - E_1 R_3) + R_1 O_1 R_2 + R_2 O_1 R_1 \\ & + \alpha^{-2}(e_p R_5 + R_5 e_p) + (R_4 E_1 - E_1 R_4) + R_1 O_1 R_3 + R_2 O_1 R_2 \\ & + R_3 O_1 R_1 \\ & + \dots \end{aligned} \quad (139)$$

We can write the above equation in closed form

$$e_p R_1 + R_1 e_p = -\alpha^2 O_1 \quad (140)$$

for $i = 1$ and

$$e_p R_i + R_i e_p = -\alpha^2 \left(R_{i-1} E_1 - E_1 R_{i-1} + \sum_{k=1}^{i-2} R_k O_1 R_{i-1-k} \right) \quad (141)$$

for $i \geq 2$. The above equations can be solved up to arbitrary order in V , which guarantees accuracy of the electronic Hamiltonian. As in the case of the W_1 operator for DKH, the R operator must be multiplied by $\sigma \cdot p$ to make it even. For that purpose, we now introduce temporary operators Y_i ,

$$Y_i = (\sigma \cdot p) R_i. \quad (142)$$

We can determine the operators Y_i from

$$e_p Y_1 + Y_1 e_p = -\alpha^2 O \quad (143)$$

for $i = 1$ and

$$e_p Y_i + Y_i e_p = -\alpha^2 \left(Y_{i-1} E_1 - (\sigma \cdot p) E_1 (\sigma \cdot p) Y_{i-1} + \sum_{k=1}^{i-2} Y_k O p^{-2} Y_{i-1-k} \right) \quad (144)$$

for $i \geq 2$. These equations can be rewritten in a more elegant way by introducing some auxiliary operators Z_i , with

$$Z_1 = O \quad (145)$$

and

$$Z_i = Y_{i-1}E_1 - (\boldsymbol{\sigma} \cdot \mathbf{p})E_1(\boldsymbol{\sigma} \cdot \mathbf{p})Y_{i-1} + \sum_{k=1}^{i-2} Y_k O p^{-2} Y_{i-1-k} \quad (146)$$

for $i \geq 2$. Now, we can obtain the expressions for Y_i in closed form which is similar to Eq. (124),

$$e_p Y_i + Y_i e_p = -\alpha^2 Z_i \quad (147)$$

with the following matrix expansion

$$Y_{i,(k,l)} = -\alpha^2 \frac{Z_{i,(k,l)}}{e_{p(k,k)} + e_{p(l,l)}}. \quad (148)$$

If we are interested in numerical accuracy rather than its analytical form, we can use an iterative approach to Eq. (136) suggested by Sadlej and coworkers (2002). This method is known as the infinite-order two-component (IOTC) approach. In the IOTC method, Eq. (136) is rewritten in terms of the operator Y ,

$$O + \alpha^{-2}(e_p Y + Y e_p) + Y E_1 + (\boldsymbol{\sigma} \cdot \mathbf{p}) E_1 (\boldsymbol{\sigma} \cdot \mathbf{p}) p^{-2} Y + Y O p^{-2} Y = 0. \quad (149)$$

After some rearrangements, the above equation can be directly used in an iterative scheme

$$e_p Y_{k+1} + Y_{k+1} e_p = -\alpha^2 (O + Y E_1 + (\boldsymbol{\sigma} \cdot \mathbf{p}) E_1 (\boldsymbol{\sigma} \cdot \mathbf{p}) p^{-2} Y + Y O p^{-2} Y), \quad (150)$$

where we have the initial condition

$$e_p Y_0 + Y_0 e_p = -\alpha^2 O \quad (151)$$

to start the iteration.

In practice, finding the solutions to these equations is equivalent to finding the matrix representation of operator Y and, as a consequence, the electronic Hamiltonian. Such a procedure is rather ordinary in quantum chemistry as we often elaborate on mathematical formulas in favor of their algebraization. This is exactly what we do when we compute expectation values (like energies) in any quantum chemistry software package.

To conclude, the Foldy–Wouthuysen transformation yields an initial Hamiltonian that can be used to derive various electronic two-component Hamiltonians.

Specifically in this subsection, we have discussed only a couple of approaches that are based on an expansion with respect to the external potential V . There also exist two-component methods that are based on an expansion with respect to the parameter α , like the Barysz–Sadlej–Snijders (BSS) approach (Barysz et al. 1997). This family of methods is, however, not as effective as methods based on an expansion with respect to V due to slow convergence or presence of singularities, unless the complete expansion is used (Reiher and Wolf 2014). Nonetheless, the Foldy–Wouthuysen transformation is a key step in improving the accuracy of two-component methods. We should note that, in quantum chemistry calculations, we have to ensure the elimination of odd operators, linear in $(\boldsymbol{\sigma} \cdot \boldsymbol{p})$. So far, this has been realized at the two-component level. It is, however, also possible to eliminate odd operators at the Hamiltonian level, that is, using transformations that are similar to those used in NESCF.

Algebraic Alternatives: The X2C Family of Methods

If we are not interested in analytic formulas of operators, but rather in their matrix representation, we have to solve Eq. (61) in its corresponding matrix form:

$$\mathbf{R}(\mathbf{H})_{11} + \mathbf{R}(\mathbf{H})_{12}\mathbf{R} - (\mathbf{H})_{21} - (\mathbf{H})_{22}\mathbf{R} = 0, \quad (152)$$

where \mathbf{H}_{ij} is a block representation of the Hamiltonian matrix H in a given basis set. In mathematics, there is an identical quadratic equation known as the nonsymmetric algebraic Riccati equation (nARE) (Kędziera 2006; Kędziera and Barysz 2007)

$$-\mathbf{X}\mathbf{C}\mathbf{X} + \mathbf{A}\mathbf{X} + \mathbf{X}\mathbf{D} + \mathbf{B} = \mathbf{0}, \quad (153)$$

where \mathbf{X} is an unknown matrix and the coefficients \mathbf{A} , \mathbf{B} , \mathbf{C} , \mathbf{D} are matrices (the individual sizes of all elements must lead to an $n \times n$ matrix for $\mathbf{0}$). The solutions of Eq. (153) are connected to the eigenvectors of a matrix \mathbf{M} defined by

$$\mathbf{M} = \begin{bmatrix} \mathbf{D} & -\mathbf{C} \\ -\mathbf{B} & \mathbf{A} \end{bmatrix}. \quad (154)$$

When comparing Eqs. (152) and (153), we observe that the solutions of Eq. (152) depend on the eigenvectors of the Hamiltonian matrix \mathbf{H} , that is, the matrix representation of the Hamiltonian. Before we write down the form of the solutions of \mathbf{R} , let us examine the eigenproblem of \mathbf{H} ,

$$\mathbf{H}\mathbf{V} = \mathbf{V}\mathbf{E}, \quad (155)$$

where \mathbf{V} is the matrix of eigenvectors and \mathbf{E} is a diagonal matrix containing the eigenvalues. In our case, we can organize the eigenvalues in such a way that we

split them into two subsets, \mathbf{E}_+ for electronic and \mathbf{E}_- for positronic energies, respectively. According to this division, we can organize the eigenvectors as follows:

$$\mathbf{V} = [\mathbf{V}_+, \mathbf{V}_-] = \left[\begin{pmatrix} \mathbf{V}_{11} \\ \mathbf{V}_{21} \end{pmatrix}, \begin{pmatrix} \mathbf{V}_{12} \\ \mathbf{V}_{22} \end{pmatrix} \right]. \quad (156)$$

Now, \mathbf{V}_+ corresponds to \mathbf{E}_+

$$\mathbf{H}\mathbf{V}_+ = \mathbf{V}_+\mathbf{E}_+, \quad (157)$$

while \mathbf{V}_- corresponds to \mathbf{E}_-

$$\mathbf{H}\mathbf{V}_- = \mathbf{V}_-\mathbf{E}_-. \quad (158)$$

Using the properties of \mathbf{V}_+ , we obtain

$$\mathbf{H}_{11}\mathbf{V}_{11} + \mathbf{H}_{12}\mathbf{V}_{21} = \mathbf{V}_{11}\mathbf{E}_+, \quad (159)$$

and

$$\mathbf{H}_{21}\mathbf{V}_{11} + \mathbf{H}_{22}\mathbf{V}_{21} = \mathbf{V}_{21}\mathbf{E}_+. \quad (160)$$

Since the \mathbf{V}_{ij} blocks are assumed to be invertible, we can now determine \mathbf{E}_+ from Eq. (159),

$$\mathbf{E}_+ = \mathbf{V}_{11}^{-1}\mathbf{H}_{11}\mathbf{V}_{11} + \mathbf{V}_{11}^{-1}\mathbf{H}_{12}\mathbf{V}_{21}. \quad (161)$$

Inserting this expression into Eq. (160), we obtain

$$\mathbf{H}_{21} + \mathbf{H}_{22}\mathbf{V}_{21}\mathbf{V}_{11}^{-1} - \mathbf{V}_{21}\mathbf{V}_{11}^{-1}\mathbf{H}_{11} - \mathbf{V}_{21}\mathbf{V}_{11}^{-1}\mathbf{H}_{12}\mathbf{V}_{21}\mathbf{V}_{11}^{-1} = \mathbf{0}. \quad (162)$$

Introducing

$$\mathbf{Y} = \mathbf{V}_{21}\mathbf{V}_{11}^{-1}; \quad (163)$$

we can rewrite the above equation as follows:

$$\mathbf{Y}\mathbf{H}_{11} + \mathbf{Y}\mathbf{H}_{12}\mathbf{Y} - \mathbf{H}_{21} - \mathbf{H}_{22}\mathbf{Y} = \mathbf{0}, \quad (164)$$

that is, we come back to our starting point Eq. (152). Finally, we have a form for the solutions that lead to block diagonalization of \mathbf{H} . By multiplying Eq. (157) from the left side by \mathbf{V}_+ and using the orthogonality properties of \mathbf{V}_+ , we obtain the matrix representation of the electronic two-component Hamiltonian h_+ ,

$$\mathbf{h}_+ = \mathbf{\Omega}_+ \left(\mathbf{H}_{11} + \mathbf{H}_{12}\mathbf{Y}_1 + \mathbf{Y}_1^\dagger\mathbf{H}_{21} + \mathbf{Y}_1^\dagger\mathbf{H}_{22}\mathbf{Y}_1 \right) \mathbf{\Omega}_+, \quad (165)$$

where

$$\mathbf{\Omega}_+ = (\mathbf{1} + \mathbf{Y}_1^\dagger \mathbf{Y}_1)^{-1/2}, \quad (166)$$

which concludes all our efforts.

Now, one may wonder what the benefits are which we get from the solutions of nARE in relativistic quantum chemistry. We were looking for two-component Hamiltonians, but we finished with diagonalizing its four-component counterpart. The reasons for that are manifold:

1. There exists an exact solution of \mathbf{H} , and its form can be obtained within the nARE approach or other methods, like IOTC, or a series expansion of R .
2. Among all the existing solutions of Eq. (152), we have the freedom to choose those solutions that are important for chemistry. Specifically, we are interested in solutions that lead to a two-component Hamiltonian whose spectrum matches the electronic part of the Dirac spectrum.
3. \mathbf{H} can be any arbitrary Hamiltonian, for example, the Dirac Hamiltonian defined in the basis of the large and small components or the modified Dirac Hamiltonian in the basis of the large component only.

To summarize, the nARE approach was originally proposed for the IOTC Hamiltonian (Kędziera 2006; Kędziera and Barysz 2007). Iliáš and Saue (2007) used this approach for the Dirac Hamiltonian for the first time (in the basis of large and small component functions). Their approach is known as the eXact 2-Component (X2C) method (Iliáš and Saue 2007; Sikkema et al. 2009; Liu and Peng 2009). We should also mention that the matrix representation of the Hamiltonian allows us to efficiently correct for picture change errors, not only for one-electron terms but also for two-electron operators (Iliáš and Saue 2007; Sikkema et al. 2009). These advantages promoted the X2C method to a very popular approach among computational chemists and led to its further development. Recently, an efficient approximation to the decoupling matrix has been introduced in the X2C scheme that uses atomic basis sets rather than the complete molecular basis. This feature facilitates accurate studies of large molecules containing heavy elements (Peng and Reiher 2012; Peng et al. 2013). Furthermore, the X2C method has been used to accurately model magnetic properties in heavy-element chemistry (Autschbach et al. 2012).

Concluding Remarks on Two-Component Hamiltonians

Over the past few decades, a number of two-component Hamiltonians has been developed. The first big step toward an accurate description of the electronic part of the Dirac equation emerged with the DKH Hamiltonian, which allowed for reliably studying many-electron systems containing heavy elements for the first time. In the course of time, the ZORA Hamiltonian gained a lot of popularity, primarily because

of its simplicity. These traditional approaches are slowly being replaced by more robust methods, such as IOTC, nARE, and X2C.

While there is still some development going on in the field of relativistic two-component methods, it is, however, mostly focused on approximations and efficient implementations of the already-developed two-component Hamiltonians in quantum chemistry codes, rather than on the development of new approaches (Sikkema et al. 2009; Autschbach et al. 2012; Peng and Reiher 2012; Peng et al. 2013). Modern two-component methods reached the accuracy of the Dirac Hamiltonian leaving no need for further methodological improvements.

Two-Component Hamiltonians in Practice

We will redirect our so far theory-focused discussion about two-component Hamiltonians to some more practical aspects. The following sections summarize useful instructions on quantum chemistry software packages supporting two-component Hamiltonians, in which atomic basis sets should be chosen in molecular calculations and in which two-component Hamiltonians yield the most accurate results for the properties of heavy-element compounds.

Where to Find Two-Component Hamiltonians

Table 1 lists the most popular quantum chemistry codes that support quantum chemical calculations with relativistic two-component Hamiltonians. As indicated in the Table, not every two-component Hamiltonian is easily available in standard quantum chemistry software packages. Most programs support only one or two types of relativistic two-component Hamiltonians. Clearly, the DKH Hamiltonian is the most accessible one as we can find it in almost every code. We should emphasize that in most cases the DKH2 or DKH3 Hamiltonians are available. Only MOLPRO is an exception and supports higher-order corrections of the DKH Hamiltonian (Reiher and Wolf 2004a, b). The popularity of DKH is followed by the ZORA and X2C methods.

While the so-called scalar relativistic effects (one-component form) are usually accounted for on the same footing in all quantum chemistry software packages, the implementation of spin-orbit coupling varies from one software to another. In general, two strategies are used:

- treat spin-orbit coupling in a perturbative manner on top of a scalar relativistic calculation (e.g., MOLPRO)
- perform a two-component calculation with an explicit inclusion of spin-orbit coupling (e.g., ADF)

Yet, in the majority of applications, spin-orbit coupling is treated within an atomic mean field (AMF) (Hess et al. 1996; Schimmelpfennig et al. 1998a, b)

Table 1 Most popular two-component Hamiltonians available in quantum chemistry codes

RESPECT			✗		
TURBOMOLE			✗		✗

approximation. In AMF, the two-electron integrals are computed in an atomic mean field fashion. This procedure has considerable computational advantages, while the loss in accuracy is negligibly small (Tecmer et al. 2014).

Finally, we should note that the DIRAC and RESPECT software packages are fully four-component codes, and therefore their code structure is rather different from all the other quantum chemistry programs listed in Table 1.

Which Basis Sets to Use for Relativistic Calculations

Every relativistic calculation should be performed in a combination with a relativistic basis set. As mentioned at the beginning of this chapter, relativistic effects cause the shrinkage of the core s and p and the expansion of the valence d and f atomic orbitals. This dictates modification of the contraction coefficients compared to standard (nonrelativistic) basis sets (Hill 2013; Peterson and Dyal 2015). These differences are even larger the heavier the nuclei. Moreover, one should be aware of the fact that performing calculations with relativistic two-component methods, the basis set should, in principle, be optimized for a given two-component Hamiltonian. This general guideline is best understood using the following example:

Example 3. Let us assume that we have a basis set optimized for the DKH2 Hamiltonian. What will happen when we use this basis set in calculations with the IOTC Hamiltonian? To exemplify the interdependence of basis sets and Hamiltonians, we calculate total Hartree–Fock (HF) energies for the closed-shell atoms Zn ($Z = 30$), Cd ($Z = 48$), and Hg ($Z = 80$) using both the DKH2 and IOTC Hamiltonian. Furthermore, we optimize a global scaling parameter k , which scales all basis set

Table 2 HF energies for optimized values of the scaling parameter k using the DKH2 and IOTC Hamiltonians. $\Delta_{\text{IOTC-DKH2}}$ denotes the difference between the HF energies calculated with the IOTC Hamiltonian with k optimized for DKH2 and for IOTC, respectively

Atom	DKH2		IOTC		$\Delta_{\text{IOTC-DKH2}}$
	E_h	k	E_h	k	E_h (eV)
Zn	-1794.150 734	1.213	-1794.224 690	1.255	0.000 035 (0.001)
Cd	-5590.160 999	1.058	-5591.273 439	1.080	0.000 323 (0.009)
Hg	-19602.652 706	1.255	-19622.039 138	1.319	0.012 268 (0.334)

coefficients in such a way that the total energy is minimized. Note that, in general, all basis set coefficients are optimized when relativistic basis sets are “designed.” This is, however, not a trivial task to do and thus we will restrict our example to only one optimization parameter, which will be sufficient for a proof of principle analysis. The results of our example calculations are presented in Table 2. Most importantly, the basis set optimized for DKH2 is no longer suitable for IOTC when moving toward heavier nuclei. This basis set dependence constitutes an error of approximately 0.33 eV for Hg, which is unacceptable.

There is a large variety of relativistic basis sets available in the literature. We will briefly discuss those that are used in correlated and DFT calculations, i.e., the most important methods to accurately model electronic structures of heavy elements. One of the most popular relativistic basis set libraries is the ANO-RCC (atomic natural orbital-relativistic correlation consistent) basis set family, developed by Roos and coworkers (2004, 2005a, 2005b, 2008) and specifically optimized for the DKH2 Hamiltonian. This generally contracted Gaussian basis sets are available for the whole periodic table (Hill 2013). Another group of Gaussian basis sets optimized for the DKH Hamiltonian of different orders have been developed by Peterson and coworkers (Balabanov and Peterson 2005; Prascher et al. 2011; Bross and Peterson 2014; Peterson 2015). Their work represents an extension to the well-known correlation-consistent basis set collection. In analogy to its nonrelativistic counterpart, they are denoted as cc-pVnZ-DK, where n denotes the cardinal number. Similar basis sets were also developed by the Sapporo group (Sekiya et al. 2010; Noro et al. 2009, 2012, 2013). Pantazis and Neese introduced the so-called segmented all-electron relativistically contracted (SARC) Gaussian basis set library optimized for the DKH2 and the ZORA two-component Hamiltonians, which are denoted as SARC-DKH2 and SARC-ZORA, respectively (Pantazis et al. 2008; Pantazis and Neese 2009, 2011, 2012, 2014). Another basis set library optimized for the ZORA Hamiltonian comes in combination with the ADF software package (Van Lenthe and Baerends 2003). It covers all elements in the periodic table and is design for Slater-type orbitals (as ADF works with this type of orbital basis sets). If the ZORA Hamiltonian is activated in an ADF calculation, the program automatically selects the correct, relativistic basis set from its basis set library. To the best of our knowledge, there currently aren't any publicly available basis sets for the IOTC and X2C relativistic Hamiltonians.

In general, all basis sets are of comparable quality. The user should, however, ensure that the basis set was chosen in conjunction with the two-component Hamiltonian.

Which Two-Component Hamiltonians to Choose: The Good, the Bad, and the Ugly

Two-component methods are particularly useful for modeling electronic structures of heavy-element compounds and predicting their properties. Specifically, all of the two-component Hamiltonians described in this chapter allow for an accurate description of valence properties of atoms and molecules, such as excitation energies, vibrational spectroscopy, bond lengths, and potential energy surfaces. As an example, we will consider the spin-free (vertical) electronic spectra of the UO_2^{2+} molecule calculated by time-dependent density functional theory using the ZORA and DC Hamiltonians. The electronic spectra for each method are presented in Table 3. In general, the ZORA excitation energies match very well the DC reference data, with differences being between 0.01 and 0.2 eV. We should note that ZORA and DC have been calculated in different software packages, DIRAC and ADF, respectively, and hence different basis sets have been used. This, however, does not pose any problems because both basis sets are of similar quality (Tecmer et al. 2011). Another example of the good performance of two-component theories is the reproduction of the highly accurate, experimentally determined potential energy surface of the RbYb molecule using the DKH3 Hamiltonian, where an agreement with experiment was found within 1 cm^{-1} (Borkowski et al. 2013). Usually the accuracy of quantum chemistry methods spans an error bound of several tens of cm^{-1} . The remarkable agreement between theoretical chemistry and experiment represents one of the most impressive success stories of two-component theories.

Although two-component Hamiltonians are excellent in modeling valence properties, large differences between two-component approaches are observed for properties of core electrons. Table 4 lists selected eigenstates of the Rn^{85+} one-electron atom obtained from the IOTC, DKH2, scaled ZORA, and the ZORA Hamiltonians. Among those two-component Hamiltonians, IOTC is expected to be the most accurate one, i.e., yielding results closest to the four-component Dirac

Table 3 UO_2^{2+} vertical excitation energies obtained from the spin-free ZORA and DC Hamiltonians (in eV) (Data taken from Tecmer et al. (2011))

Electronic state	ZORA/B3LYP	DC/B3LYP
$1^3\Phi_g$	2.30	2.27
$1^1\Phi_g$	2.80	2.92
$1^3\Delta_g$	2.51	2.58
$1^1\Delta_g$	3.39	3.59
$1^3\Gamma_g$	4.01	4.04
$1^1\Gamma_g$	4.23	4.31
$1^3\Phi_u$	4.22	4.23
$1^1\Phi_u$	4.31	4.33

Table 4 Selected eigenstates of the Rn^{85+} one-electron system in E_h (Data taken from Iliáš and Saue 2007)

spinor	IOTC	DKH2	Scaled ZORA	ZORA
1 $s_{1/2}$	−4154.662 453	−4142.265 045	−4154.779 786	−4670.480 658
1 $p_{1/2}$	−1070.029 516	−1069.130 996	−1070.029 629	−1101.405 752
1 $p_{3/2}$	−948.451 386	−948.434 642	−948.451 386	−973.023 298
1 $d_{3/2}$	−425.136 259	−425.135 655	−425.136 259	−430.003 698
1 $d_{5/2}$	−415.485 189	−415.485 075	−415.485 190	−420.132 939
1 $f_{5/2}$	−234.522 726	−234.522 723	−234.522 727	−235.996 352
1 $f_{7/2}$	−234.564 803	−232.564 801	−232.564 803	−234.013 854

reference. It is evident from Table 4 that the ZORA eigenstates need to be scaled to match those of the other Hamiltonians. In the valence region, DKH2 and scaled ZORA give eigenstates that are almost indistinguishable from IOTC but considerably differ in the core region. Specifically, for the lowest eigenstate $s_{1/2}$, the DKH2 Hamiltonian is much less accurate than the scaled ZORA Hamiltonian. We should note that the quality of DKH can be increased by using higher-order corrections. In practical applications, the DKH10 Hamiltonian gives satisfactory results (Reiher and Wolf 2014), and higher-order corrections are usually not required (and usually not supported in quantum chemistry software). The erroneous behavior of the core region will have a significant effect on properties that depend on core electrons. Examples are X-ray spectra, Mössbauer spectra, and hyperfine interactions observed in electron paramagnetic resonance (EPR) and nuclear magnetic resonance (NMR) experiments.

Therefore, one should be particularly careful when calculating such hyperfine interactions. It is well known that these properties strongly depend on the applied nuclear model in heavy-element compounds. While for the lighter elements the point-charge-nucleus model is sufficiently accurate, finite-size-nucleus models are more appropriate for heavier elements, like the Gaussian charge distribution (Visser et al. 1987; Visscher and Dyaal 1997). For example, a recent study by Autschbach (2009) shows the reduction in the isotropic coupling between a sixth-row nuclei and a lighter nuclei of approximately 10 % when a finite-size-nucleus model was used instead of the point-charge model.

When Do We Need Spin–Orbit Coupling?

For the case of ground-state electronic structures of heavy-element compounds with *no* open-shell electrons, a scalar relativistic treatment is sufficiently accurate. Spin–orbit coupling becomes, however, important for open-shell systems with degenerate (ground or excited) states. An illustrative example to demonstrate the importance and effect of spin–orbit coupling is the CUO molecule diluted in a Ne and Ar noble gas matrix. Furthermore, the electronic structure of the CUO molecule embedded

Fig. 1 Spin-state splittings for the CUO molecule diluted in different noble gas matrices within a spin-free (SF) treatment (DKH10 Hamiltonian). Spin-orbit (SO) coupling was added in a perturbative manner. ${}^3\Phi_{(v)}$: vertically excited ${}^3\Phi$ state. ${}^3\Phi_{(a)}$: adiabatically excited ${}^3\Phi$ state. CASSCF: complete active space self-consistent field. DMRG: density matrix renormalization group (Reproduced from Tecmer et al. (2014) with permission from the PCCP Owner Societies)

in a noble gas environment is a particularly challenging system for present-day quantum chemistry. Experimentalists anticipate that the CUO unit reverts its ground-state electronic configuration when the noble gas matrix is changed from Ne to Ar. This ground-state reversal could not be confirmed theoretically for a long time and the interaction between the CUO molecule and the noble gas matrix remained a “mystery.” It was only recently when quantum chemistry was able to predict a ground-state change in the CUO unit. Most importantly, this ground-state change is only observable after inclusion of spin-orbit coupling (Tecmer et al. 2014). Figure 1 shows the spin-state splittings between the lowest-lying electronic states of the CUO unit with (SO) and without (SF) spin-orbit coupling determined for two different quantum chemistry methods (CASSCF and DMRG). Only if spin-orbit coupling is included, the ${}^1\Sigma$ and ${}^3\Phi$ state of CUO diluted in Ar becomes equienergetic (see SO-DMRG data in Fig. 1) suggesting that a ground-state reversal can occur.

Therefore, if one is interested in reaching spectroscopic accuracy for open-shell systems to predict spectroscopic constants and electronic spectra with two-component Hamiltonians, spin-orbit coupling should be included. All two-component methods are equally good for this purpose and the user is free to choose the Hamiltonian of their choice. We should, however, emphasize that the largest spin-orbit splittings are observed for degenerate core orbitals, for instance, the $2p$ atomic orbitals of heavy elements. As a result, all properties that involve core orbitals (e.g., X-ray spectra, hyperfine interactions) will be considerably affected by spin-orbit coupling. This means that even for a qualitative analysis of core properties the inclusion of spin-orbit coupling is indispensable. If such properties are to be modeled with two-component Hamiltonians, special care should be taken, primarily because the chosen Hamiltonian should be accurate in the core region. Good candidates for such an analysis are, for instance, Scaled ZORA, X2C, IOTC, nARE, and higher-order DKH (e.g., DKH10) Hamiltonians.

Concluding Remarks

In this chapter we have scrutinized the most promising relativistic two-component Hamiltonians used in quantum chemistry. These Hamiltonians can be grouped into two categories: those based on the elimination of the small component (ZORA, FORA, and NESC) and those using a unitary transformation (DKH, IOTC, X2C, and nARE). All of them are equally good for valence electronic structures of atoms and molecules and can accurately model valence properties such as geometries, vibrational frequencies, and excitation energies of heavy-element molecules. The largest differences between the relativistic two-component Hamiltonians are found for the core region. Specifically, one should only use the most accurate two-component methods (Scaled ZORA, X2C, IOTC, and nARE) whenever properties of heavy-element compounds are to be modeled that directly depend on the core orbitals. Furthermore, a relativistic calculation should be performed in combination with a relativistic basis set specifically optimized for a given two-component Hamiltonian.

Finally, we would like to stress that in order to achieve spectroscopic accuracy with two-component Hamiltonians, spin-orbit coupling should be included. Exceptions to this rule are valence properties of closed-shell molecules. Furthermore, one should also keep in mind that for the heaviest elements explicit inclusion of spin-orbit coupling is preferred as an perturbative treatment might not be sufficiently accurate.

Abstract

The accurate description of electronically excited states remains a challenge for theoretical chemistry. Among the vast body of quantum mechanical methods available to perform this task, time-dependent density functional theory

(TD-DFT) currently remains the most widely applied method, a success that one can explain not only by its very interesting accuracy/effort ratio but also by the ease to perform TD-DFT calculations for a large number of compounds and properties (absorption and emission spectra, band shapes, dipole moments, electron and proton transfers, etc.) in various environments. In the present chapter, we present TD-DFT as a tool for modeling such excited-state properties, with a focus on several practical aspects (choosing an exchange-correlation functional and an atomic basis set, analyzing the nature of the electronic transitions, comparing results with experiments, including environmental effects, etc.) that are useful to get a quick start. In that framework we rely on a series of examples of increasing complexity considering both organic and inorganic compounds as well as biomolecules.

Introduction

The chemistry occurring in electronically excited states (ES) tends to significantly differ from the one in the ground state (GS). This difference can be illustrated by considering photochemistry: the promotion of a molecule to one of its ES, induced by photon absorption, allows to perform chemical reactions that are impossible in the GS. However, the description and understanding of ES processes is very challenging for experimental methods because ES, which represent a less stable state of the matter than GS, are extremely short-lived, meaning that expensive experimental apparatus are often required to track the ES reactions and to extract relevant information. This is why theoretical chemistry is often used to complement experimental measures in this field: it offers insightful descriptions of ES properties at a reasonable cost. However, the quantum mechanical description of ES is not straightforward, as many of the theoretical “tricks” that are used for GS become inapplicable for ES, e.g., the total energy of an ES is not the minimal energy of the system, and such criterion cannot be used to help converging the calculations. Among the different *ab initio* and DFT theories that have been developed to model ES, time-dependent density functional theory (TD-DFT) is not only the most widely applied method (ca. 1000 papers/year during the last few years) but also one of the most handy. TD-DFT is the extension of DFT to ES and it originally relies on the theorem published by Runge and Gross in 1984. While DFT can provide, in principle, an exact solution of the time-independent Schrödinger equation, TD-DFT provides the same feat for its time-dependent counterpart. In a key contribution in 1995, Casida indeed provided an exact expression for calculating the excitation energies with TD-DFT (Casida 1995). However, to be applicable in practical calculations, TD-DFT generally requires two major approximations. First, one applies the adiabatic approximation (Casida 1995), that is, a frequency-independent exchange, and correlation kernel is considered, which induces a loss of memory

effects. It should be clear to the readers that all the results and advices given below are within this adiabatic approximation framework. Second, like in GS DFT, one has to select an approximate exchange–correlation functional (XCF) to perform the calculations. Over the years, there has been an impressive quantity of benchmarks performed in the TD-DFT framework, and it turned out that TD-DFT tends to be more sensitive than DFT to the chosen XCF (Laurent and Jacquemin 2013). As the present contribution is designed to be a practical guide rather than a general review, we will not describe in the following the underlying mathematical aspects of TD-DFT nor the latest fundamental developments in the field, and we refer the interested readers to other contributions for these aspects (Marques et al. 2012; Ullrich 2012; Barbatti and Crespo-Otero 2015; Huix-Rotllant et al. 2015).

The popularity of TD-DFT can be explained by several advantages compared to alternative theories: (i) it is a single-reference method that does not require to build complex input files contrary to most multi-reference theories; (ii) through the so-called Z-vector approach, one has access to the ES density at a reasonable computational cost, which offers an appropriate way to describe the changes of electron localization between the GS and ES; (iii) one can combine TD-DFT with a vast panel of models describing the environment so that one can model compounds in “real-life” situations, e.g., anchored on a semiconducting surface, near a metallic nanoparticle, embedded in a protein or solvated in an organic solvent; (iv) both analytic first (gradient) and second (Hessian) derivatives are available, making ES geometry optimizations and vibrational calculations efficient and giving access to a large panel of properties, e.g., fluorescence spectra and band shapes; (v) it is possible to efficiently determine spin–orbit couplings (SOC) with TD-DFT and hence to describe phenomena that imply changes of the spin multiplicity, e.g., triplet–singlet transitions; (vi) the scaling of TD-DFT with system size is formally $\mathcal{O}(N^4)$ which is more advantageous than most wave function approaches designed for ES; and (vii) the associated computational requirements are low enough to allow calculations on large molecules (ca. 300 atoms) that are more and more the focus of experimental studies. In short, TD-DFT is now a mature theory that can be routinely used to treat realistic chemical problems. Of course, as any approximated theory, adiabatic TD-DFT suffers from several problems and limitations, some of which will be discussed here.

In section “Getting Started with TD-DFT: Vertical Absorption,” we present the key elements necessary to perform the relatively simple vertical TD-DFT calculations. Which method to select? How to interpret the obtained results? This section can therefore be viewed as a “cookbook” for first-time users and is not intended to cover all possibilities nor problems. In section “Emission and Vibronic Effects,” we turn to the calculation of emission wavelengths, 0-0 energies and band shapes. Sections “Photophysics of Transition Metal Complexes: Effect of SOCs, Phosphorescence, and TD-DFT Performance” and “Complex Environments and Biomolecules” are devoted to the specific challenges of inorganic complexes and biomolecules, respectively.

Getting Started with TD-DFT: Vertical Absorption

As a generic rule, the modeling of ES properties with TD-DFT generally starts by performing a so-called vertical calculation. In such calculation, one uses a frozen GS geometry, typically obtained through a DFT optimization or from experimental inputs, and determines the transition energies to the first few low-lying ES using TD-DFT. These transition energies are referred to as vertical absorption energies, $E^{\text{vert-a}}$, in the following. They can be formalized as:

$$E^{\text{vert-a}} = E^{\text{ES}}(R^{\text{GS}}) - E^{\text{GS}}(R^{\text{GS}}), \quad (1)$$

where E^{ES} and E^{GS} are, respectively, the total energies of the ES and GS determined on the frozen GS geometry (R^{GS}). A large number of quantum chemistry packages allow to perform such calculations, and the number of parameters specific to TD-DFT that need to be set before running a vertical TD-DFT computation is often very limited: the total number of ES states (or *roots*) that should be computed and the multiplicity of the final states (e.g., singlet-singlet or singlet-triplet transitions). Of course, like in GS DFT calculations, one has also to select an atomic basis set (BS) and an XCF to perform the computations. At the end of the TD-DFT run, one obtains the $E^{\text{vert-a}}$ corresponding to each states as well as several associated information that can be analyzed.

Setting Up the Calculation

Selecting an Atomic Basis Set

As for GS calculations, the appropriate selection of a BS for TD-DFT can be a difficult task. It has been generally noticed that (i) TD-DFT is less sensitive to the size of the atomic BS than the correlated wave function theories, (ii) a basis set that is suited for a DFT calculation needs to be expanded with (at least) diffuse functions for TD-DFT, (iii) the nature of the ES has a dramatic impact on the BS requirements (while a double- ζ BS augmented with polarization and diffuse functions, e.g., 6-31+G(d), might be sufficient for low-lying ES of conjugated organic and inorganic molecules, much larger BS, e.g., *aug-cc-pVTZ*, might be necessary for describing higher-lying (Rydberg) ES), and (iv) as a consequence the ordering of the different ES might change with the size of the selected atomic BS. These different statements are well illustrated by considering the fifteen lowest-lying ES of benzene (Ciofini and Adamo 2007). For the three valence ES, Ciofini and Adamo reported that the mean absolute errors (MAE) with respect to experimental values attain 0.48, 0.25, and 0.23 eV with the 6-31G(d), 6-31+G(d,p), and 6-31++G(3df,3pd) BS, respectively, confirming the key importance of diffuse orbitals. In the same time, for the twelve first Rydberg states of benzene, the same authors obtained MAE of 2.27, 0.31, and 0.18 eV, with the same three BS, showing the difficulty to describe Rydberg states. Nevertheless, we also underline that very large BS tend

Table 1 Wavelength (in nm) corresponding to $E^{\text{vert}-a}$ of the first ES of indigo. All values obtained with the B3LYP XCF on a frozen geometry. See Jacquemin et al. (2006) for details

BS	Wavelength	BS	Wavelength
6-31G	564	6-311G(2d,2p)	581
6-31G(d,p)	566	6-311+G(2d,p)	591
6-31+G(d,p)	585	6-311++G(2d)	594
6-311G(d,p)	576	6-311++G(2d,2p)	591
6-311++G(d,p)	587	6-311+G(3d,p)	592

to yield stronger mixing between Rydberg and valence ES, and hence, TD-DFT results are harder to interpret (Isegawa et al. 2012; Baerends et al. 2013). When possible, it is always welcome to check the convergence of the transition energies of the considered ES using increasingly large atomic basis sets so to assess the magnitude of the residual error obtained with the selected BS. When treating a series of homologous molecules, such BS convergence test can be performed on a representative member of the series. This procedure is illustrated in Table 1 for the lowest ES of indigo, where the non-negligible impact of a second set of d polarization orbitals appears (Jacquemin et al. 2006). From that table, one would probably choose to go with 6-311+G(2d,p) to be very close from BS convergence.

Choosing an Adequate Exchange-Correlation Functional

As stated in the “Introduction”, the selection of an adequate XCF is extremely important to obtain accurate results. For vertical TD-DFT calculations, there have been numerous benchmarks which we have been reviewed in Laurent and Jacquemin (2013). Though the most suited XCF for a given ES in a given compound cannot be predicted beforehand, several general conclusions have been obtained: (i) “pure” XCF that do not include *exact* exchange often provide too small transition energies, and as they also tend to create unphysical (*spurious*) ES, their use should be discouraged; (ii) hybrid XCF that incorporate *exact* exchange give significantly more accurate results, increasing the amount of *exact* exchange generally inducing an increase of the transition energies; (iii) for localized valence ES, standard global hybrids, e.g., B3LYP, M06, and PBE0, are often well suited in the vertical approximation; (iv) for both charge transfer (CT) and Rydberg ES, range-separated hybrid (RSH) XCF, e.g., CAM-B3LYP, LC- ω PBE, or ω B97X-D, appear to be more adequate; (v) one can use optimally tuned (OT) range-separated hybrids, where the parameter(s) of the XCF is(are) nonempirically optimized to minimize the delocalization error (Baer et al. 2010; Srebro and Autschbach 2012), to avoid an arbitrary XCF choice, but the optimization process has to be carried out for each molecule; and (vi) when a suitable XCF is chosen, the typical theory–experiment deviations that are to be expected are in the 0.20–0.30 eV range, though significantly better (and worse) results can be obtained for specific chemical families.

The statistical errors obtained with a representative panel of functionals considering two training sets in the vertical TD-DFT approximation are given in

Table 2 Mean signed (MSE) and absolute (MAE) errors in eV obtained two sets of organic compounds (see text) in the vertical approximation. A positive MSE indicates an overestimation of the experimental transition energies. Val. and Ryd. stand for valence and Rydberg ES, respectively. The percentage of exact exchange (%XX) is given for all XCF. See Jacquemin et al. (2009a), Caricato et al. (2010), and Isegawa et al. (2012) for details about the computational protocols and additional results

XCF	%XX	614 ES – Jacquemin et al. (2009a)		69 ES – Caricato et al. (2010) and Isegawa et al. (2012)		
		MSE	MAE	MAE (Val.)	MAE (Ryd.)	MAE (All)
LDA	0	−0.32	0.45	0.45	1.20	0.88
BP86	0	−0.32	0.38	0.38	1.62	1.08
PBE	0	−0.29	0.39	0.40	1.70	1.13
TPSS	0	−0.20	0.34	0.26	1.63	1.03
TPSSh	10	−0.05	0.26	0.18	1.27	0.80
B3LYP	20	−0.01	0.23	0.20	1.03	0.67
PBE0	25	0.08	0.22	0.22	0.80	0.55

M05-2X	52	0.29	0.38	0.37	0.35	0.36
CAM-B3LYP	19–65	0.25	0.30	0.31	0.35	0.33
LC- ω PBE	0–100	0.46	0.48	0.41	0.32	0.36

Table 2. The performances of many more XCF have been evaluated in the original works (Jacquemin et al. 2009a; Caricato et al. 2010; Isegawa et al. 2012). In the first set, 614 low-lying ES of small, medium, and large organic molecules have been considered (Jacquemin et al. 2009a), whereas in the second, 69 ES in small molecules, almost equally divided between valence (30) and Rydberg (39) states, have been used (Caricato et al. 2010; Isegawa et al. 2012). Consistently with the above statements, for valence states, the smallest MAE are obtained with three global hybrids, namely, TPSSh, B3LYP, and PBE0, a result illustrative of the large weight of localized $n \rightarrow \pi^*$ and $\pi \rightarrow \pi^*$ transition in these training sets. For the Rydberg states, only range-separated hybrids or global hybrids including a large share of *exact* exchange deliver accurate results, the same holding for CT states (Peach et al. 2008). We underline that CAM-B3LYP, M05-2X, and M06-2X (not shown in Table 2) provide relatively similar errors irrespective of the nature of the ES.

Including Solvent Effects

Most experiments are carried out in condensed phase. As the impact of the environment is generally larger in the ES than in the GS, taking the medium into account is often necessary to reach chemically valuable conclusions. The total model is typically divided into two parts: on the one hand, the center of interest, where the electronic excitation takes place, which is described with TD-DFT, and, on the other hand, the surroundings that are modeled with a simpler model. To describe solvation effects, continuum models, such as the well-known polarizable continuum model (PCM) (Tomasi et al. 2005), have been combined with TD-DFT

and we limit ourselves to such combination at this stage. In PCM-TD-DFT, the solute undergoing the GS-to-ES transition is embedded in a cavity formed in a structureless material presenting the macroscopic properties of the actual solvent. In the GS, charges located on the surface of this cavity are determined self-consistently to account for the electrostatic interactions between the solute and the solvent (Tomasi et al. 2005). For ES calculations, two new difficulties, not present in GS, appear. First, as photon absorption is an extremely fast process, only the electrons of the environment have the time to adapt to the new electronic configuration of the solute, the nuclei of the solvent being frozen in their GS configuration. This corresponds to the so-called nonequilibrium (neq) regime, and the vertical transition energy now becomes

$$E^{\text{vert-a}}(\text{neq}) = E^{\text{ES}}(R^{\text{GS}}, \text{neq}) - E^{\text{GS}}(R^{\text{GS}}, \text{eq}). \quad (2)$$

In this neq regime, the effective dielectric constant for the specific ES terms of the PCM-TD-DFT calculation is the optical permittivity (ϵ_∞), that is of the order of the square of the refractive index, i.e., around 2 for most solvents. This may induce significant differences for polar solvents compared to the equilibrium (eq) regime where the complete permittivity (ϵ_r) is used. Various default regimes (eq/neq) are applied by different computational chemistry packages, and we advice a careful check before starting the calculation. Secondly, one should determine how the charges located on the surface of the cavity are determined at the ES. In the linear-response (LR) PCM approximation (Cammi and Mennucci 1999; Cossi and Barone 2001), the variations of these charges from the GS to the ES are determined using the TD-DFT transition densities. As these densities are available in any TD-DFT calculation, this allows to rapidly include solvent effects for all ES considered in the calculation at a moderate computational cost, but this LR model is not suited when there is a strong variation of the electronic cloud between the two states, e.g., for CT ES. In those cases, more refined models that rely on the ES density to determine the polarization of the cavity in the ES could be used, an aspect discussed in more details in section “Emission and Vibronic Effects.”

Analyzing the Results

Determining the Nature of an Electronic Transition

As can be seen from the above considerations, it is useful to know beforehand the nature of the ES that is investigated as this might influence the selection of the atomic BS, XCF, and even solvent model. However, if this is not the case, one can use the results of a TD-DFT calculation to determine this nature. Indeed, besides the $E^{\text{vert-a}}$ values, a typical TD-DFT output contains (i) the oscillator strengths (f) associated to these ES, which are related to the transition probabilities from the GS to the ES (the larger the f , the more intense the absorption), (ii) the point group symmetry of each ES, and (iii) the contributions of transitions between molecular orbitals (MO) corresponding to each ES. Altogether, they can be used to assign

Fig. 1 Representation of the three key MO in *trans*-azobenzene as computed at PBE0/6-31+G(d) level. From *top* to *bottom*: LUMO, HOMO, and HOMO-1 of π^* , π , and n nature, respectively. Contour threshold: 0.05 a.u.

the nature to each ES. A simple example of such procedure can be given by *trans*-azobenzene that belongs to the C_{2h} point group. A TD-DFT calculation provides two low-lying ES. The first of B_g symmetry presents a $E^{\text{vert-a}}$ of 2.64 eV associated to f of 0.00 and is mainly ascribed to a HOMO-1 to LUMO transition, whereas the second ES of B_u symmetry presents a $E^{\text{vert-a}}$ of 3.78 eV associated to f of 0.78 and corresponds to a HOMO to LUMO transition. These orbitals are sketched in Fig. 1. The first transition is forbidden by symmetry (zero oscillator strength) and implies a transition from the nitrogen lone pairs toward an unoccupied orbital delocalized on the whole system. It is therefore a valence $n \rightarrow \pi^*$ transition. The second ES is strongly dipole allowed and corresponds to an increase of the number of nodes in the frontier π MO: it is $\pi \rightarrow \pi^*$ transition. Interestingly, there has been a reversal between the energetic ordering of the occupied MO and the corresponding ES, which illustrates the importance of the electronic reorganization accounted for in TD-DFT. These assignments are in line of experiment and are also consistent with the solvatochromic shifts that can be measured or calculated. Indeed, the same calculation considering a PCM(water) environment yields a small hypsochromic shift (from 2.64 to 2.66 eV) for the first ES, but a larger bathochromic shift (from 3.78 to 3.63 eV) for the second ES, which are typical signatures of $n \rightarrow \pi^*$ and $\pi \rightarrow \pi^*$ transitions, respectively.

Unfortunately, it is generally not so straightforward to assign a clear nature to each ES mainly because the orbital compositions of the TD-DFT transitions often include very large numbers of MO pairs of different nature, especially in large molecules and/or higher-lying ES. In those situations, three strategies might be applied. First, one can compute natural transition orbitals (NTO) (Martin 2003), which is inexpensive. NTO are designed to provide a compact representation of the transition density (matrix) and allow to express the TD-DFT results for each ES

as a transition between (often a single pair of) an excited particle and an empty hole. Therefore NTO can provide a simple “MO-like” picture, irrespective of the complexity of the actual MO blend of the original TD-DFT calculation. A second approach, often used in inorganic chemistry, is to evaluate the contribution of each atom in all the starting and final MO implied in the electronic transition, so to obtain an averaged contribution of each atom in the electronic process. This can be useful to rapidly distinguish metal-to-ligand from ligand-to-ligand transitions in transition metal complexes (see section “Photophysics of Transition Metal Complexes: Effect of SOCs, Phosphorescence, and TD-DFT Performance” for specific challenges for these compounds). Finally, one can compute the ES density (ρ^{ES}) of the state(s) of interest. By making the difference with the GS density, one obtains a single picture of the “electron displacement” irrespective of the complexity of the considered ES. The drawback of this approach is that it implies the calculation of the ρ^{ES} for each ES of interest, which requires a significant additional computational effort. We illustrate this approach in the section “Going Further: ES Dipoles, Charges, and Densities.”

Comparing with Experiments

In many cases, and in particular in the high-energy range of the spectrum and/or for inorganic compounds, there are much more ES returned by the calculation than experimentally observed peaks in the optical spectrum. This is originating in the overlapping of contributions of several ES with different transition probabilities that appear as a single band, e.g., forbidden $n \rightarrow \pi^*$ transitions are often hidden in the experimental spectra by nearby strongly allowed $\pi \rightarrow \pi^*$ transitions. Consequently, to compare the TD-DFT output values ($E^{\text{vert-a}}$ and f) to experimental UV/Vis spectra, a common initial step is to convolute the computed “stick” values with a broadening Gaussian (typically with a width at half maximum in the 0.2–0.8 eV range). Many codes can be used to perform such task and refined procedures have been designed to reach an optimal fit (Brémond et al. 2010). The result of such process is illustrated in Fig. 2 where the TD-DFT sticks and convoluted spectra are compared to experiment for a Pt(II) complex (Latouche et al. 2015). The fact that numerous ES contribute to a single band in the 200–300 nm range is obvious.

As will become evident in section “Emission and Vibronic Effects,” there are often no experimental data that can be directly compared to the computed $E^{\text{vert-a}}$, so that the comparisons between experimental UV/Vis spectra and (convoluted) TD-DFT spectra remains only qualitative. Indeed, while it is usual to compare TD-DFT $E^{\text{vert-a}}$ (or the spectra obtained with a broadening Gaussian) to experimental λ_{max} (Laurent et al. 2014), it should be made clear that this approach that completely disregard geometrical and vibrational relaxation effects is not physically well grounded and is not to be favored, despite its popularity. In a homologous series of compounds, in which the vibronic couplings are rather weak, such approximation can nevertheless be useful to extract some trends regarding the impact of the substituents (Laurent et al. 2014). For instance, for 169 compounds presenting an easily identifiable low-lying $n \rightarrow \pi^*$ band, Fig. 3 provides a comparison between PCM-TD-PBE0 $E^{\text{vert-a}}$ and measured λ_{max} , and the general correlation is obvious

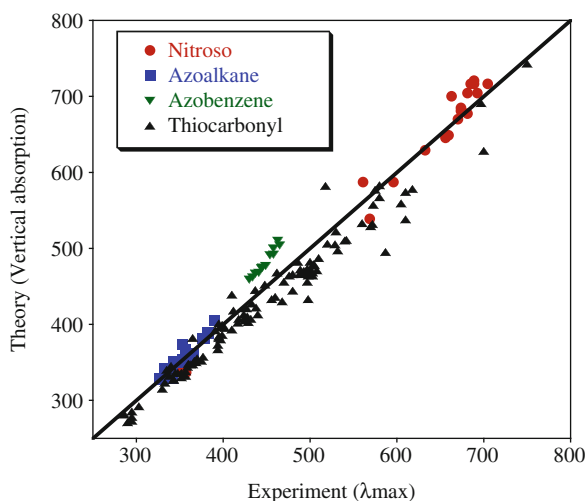

Fig. 2 Comparison between TD-DFT (two different atomic basis sets, corresponding to *blue* and *red* sticks and *curves*) and experimental (*black dashed line*) for the shown Pt complex. The position of each stick is given by $E^{\text{vert}-a}$, its height being proportional to the corresponding f (Adapted with permission from Latouche et al. (2015). Fig. 3 Comparison between PCM-TD-PBE0 $E^{\text{vert}-a}$ and measured λ_{max} for four families of $n \rightarrow \pi^*$ dyes. All values are in nm. The *central line* indicates a perfect match (Reproduced from Laurent et al. (2014) with permission from the PCCP Owner Societies)

despite the presence of several outliers. For the full set of compounds, the obtained MAE is limited to 19 nm or 0.12 eV only, a success probably related, on the one hand, to the localized nature of the considered transitions and, on the other hand, to error compensation mechanisms.

Going Further: ES Dipoles, Charges, and Densities

One can also compute ES dipole moments, partial atomic charges, and total electron densities with TD-DFT. This provides information about the variations of polarity and charge localizations between the GS and the ES. However, determining these data require an additional effort, similar to a determination of TD-DFT forces for

Fig. 4 *Top:* GS (*left*) and ES (*right*) dipole moments for a typical push–pull dye. *Bottom:* partial Merz-Kollman atomic charges borne by several moieties of the molecule in the GS (*left*) and ES (*right*). The first ES corresponding to a CT process is considered here (Adapted from Adamo and Jacquemin (2013) with permission from the Royal Society of Chemistry)

each considered ES. Indeed, contrary to GS, the ES density is not a “free” by-product of the calculation. In other words, if one wishes to determine ρ^{ES} for the 10 lowest-lying ES, a substantial increase of computational effort is necessary compared to standard TD-DFT calculations. Figure 4 illustrates the result of such calculation for a dye designed for dye-sensitized solar cell applications (Adamo and Jacquemin 2013). First one notes that while the overall direction of the dipole moment is similar in the GS and the ES, its magnitude has been increased by 2.93 D (from 5.31 to 8.24 D) which is typical of a CT ES. This is confirmed by investigating the partial atomic charges: the electronic charge borne by the cyano-acetic moiety (in blue) increases, while the electronic charge borne by the diketopyrrolopyrrole group (in green) decreases. It is possible to correlate these variations to experimental solvatochromic effects, that is, to investigations of the evolutions of experimental spectra with solvent polarity.

Having determined the ES density, one can easily compute the difference of electron density compared to the GS,

$$\Delta\rho(\mathbf{r}) = \rho^{\text{ES}}(\mathbf{r}) - \rho^{\text{GS}}(\mathbf{r}), \quad (3)$$

for each relevant ES, and the corresponding plot provides a one-picture representation of each electronic transition, sometimes called electron density difference map (EDDM). Examples of such maps are given in Fig. 5 for two large BODIPY dyes in their neutral and diprotonated forms (Chibani et al. 2013). In very simplified terms, the electron density moves from blue to red regions of these plots upon photon absorption. Both the left and right compounds of Fig. 5 are very sensitive to pH experimentally: the former undergoes a strong hypsochromic shift upon

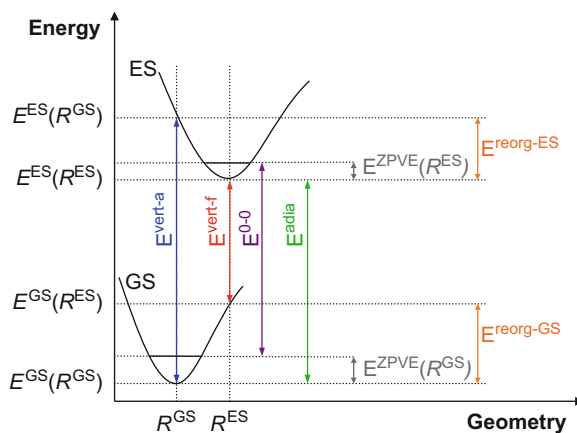

Fig. 5 $\Delta\rho(\mathbf{r})$ plots (EDDM) obtained for two BODIPY dyes in their neutral and di-protonated forms at the PCM-TD-M06-2X/6-311+G(2d,p) level. The red (blue) zones indicate increase (decrease) of density upon electronic transition (Adapted from Chibani et al. (2013) with permission from the Royal Society of Chemistry)

protonation of the two dimethylamino groups, whereas the second undergoes a significant bathochromic shift when the two pyridine rings are protonated. This can be qualitatively explained from the change of the $\Delta\rho(\mathbf{r})$ plots computed for the neutral and diprotonated derivatives. Indeed, in its neutral form, the ES of the first dye (left) is characterized by a strong CT from the dimethylamino moieties (mostly in blue, acting as donor groups) to the BODIPY core (mostly in red, acting as the accepting center), but this CT is annihilated at low pH as the lone pairs of the donor group are no longer available. In turn, this decrease of CT explains the hypsochromic displacement. The scenario is reversed for the second BODIPY (right): the pyridine rings are passive elements in the neutral form but act as strong acceptors after protonation. Therefore, the CT is enhanced at low pH, explaining the concomitant bathochromic evolution of the experimental spectrum. Eventually, we note that $\Delta\rho(\mathbf{r})$ can also be used to obtain qualitative indices quantifying the magnitude of the GS-to-ES CT (Le Bahers et al. 2011; Jacquemin et al. 2012b), a topic that we will not cover here.

Emission and Vibronic Effects

In this section, we show how going beyond the vertical absorption allows to determine vertical fluorescence energies (and hence estimate Stokes shifts) as well as 0-0 energies and band shapes. The two latter allow physically well-grounded comparisons with experimental optical spectra and are therefore extremely useful. All these data come at an increase computational cost compared to the properties listed in section “Getting Started with TD-DFT: Vertical Absorption” but this cost is mitigated by the existence of analytic first and second TD-DFT derivatives (Furche and Ahlrichs 2002; Scalmani et al. 2006; Liu and Liang 2011). The main parameters that are used in the following are represented in Fig. 6.

Fig. 6 Simplified energy diagram representing only two singlet states without intersections and describing the key theoretical parameters used in section “Emission and Vibronic Effects” (Reproduced with permissions from Jacquemin et al. (2012a). Copyright 2012, American Chemical Society)

Fluorescence

Vertical fluorescence is the transition energy determined at the optimal geometry of the relevant excited state (R^{ES}). In gas phase, it reads:

$$E^{\text{vert-f}} = E^{\text{ES}}(R^{\text{ES}}) - E^{\text{GS}}(R^{\text{ES}}), \quad (4)$$

which obviously parallels Eq. 1. One therefore needs to optimize the geometry of the ES, a task that can be performed with numerous computational chemistry packages. In many cases, one is interested in the first (lowest-energy) ES that is often responsible for fluorescence according to Kasha's empirical rule. Optimizing the geometry of higher-lying ES is technically possible but is often more challenging due to the possible crossings between the potential energy surfaces (PES) of different ES.

Setting Up the Calculation

For computing the vertical emission energy, that is, the $E^{\text{vert-f}}$ in Eq. 4, the indications given in section "Selecting an Atomic Basis Set" can be followed to select an atomic BS. However, using a more compact BS to perform the ES geometry optimization, that is, to determine R^{ES} , can be an interesting option to fasten the calculations. Indeed, one needs a BS that is typically smaller for R^{ES} than for transition energies, but typically larger than for GS structural optimizations, as the PES of the ES tend to be flatter than their GS counterparts. In a study of organic compounds, it was found that 6-31+G(d) was providing accurate ES geometries with TD-DFT (Jacquemin et al. 2012a), but significantly more extended BS may be necessary for flexible molecules.

The choice of the XCF to perform the TD-DFT geometry optimizations is crucial. For rigid molecules and for states in which the density reorganization between the GS and ES remains relatively limited (localized $\pi \rightarrow \pi^*$ transitions), global hybrids containing a small fraction of *exact* exchange, e.g., B3LYP and PBE0, perform adequately. However, when stronger variations of the density are noticed, e.g., $n \rightarrow \pi^*$ transitions, a larger share of *exact* exchange should be included in the functional to obtain accurate structures (Guido et al. 2010). This also holds for CT ES. Indeed, for these states, low-*exact* exchange hybrid functionals might lead to qualitatively incorrect ES PES. For instance, for the simple 4-(dimethylamino)-benzonitrile, B3LYP incorrectly predicts a twisted ES geometry with the dimethylamino group orthogonal to the aromatic ring (Wiggins et al. 2009). Such overtwisted PES is not uncommon with amino groups (Jacquemin et al. 2012a) and remains a common pitfall of fluorescence calculations performed with TD-DFT. Our experience is that the M06-2X XCF is a very valuable compromise as it tends to deliver chemically meaningful GS and ES structures for a vast majority of fluorophores (see also section "Adiabatic and 0-0 Energies").

In solution, the geometrical relaxation of the molecule is a relatively slow process, and the R^{ES} should be determined in the equilibrium regime. However,

the emission of a photon is a fast process and the nonequilibrium effects cannot be neglected. Indeed, in solution Eq. 4 becomes

$$E^{\text{vert-f}}(\text{neq}) = E^{\text{ES}}(R^{\text{ES}}, \text{eq}) - E^{\text{GS}}(R^{\text{ES}}, \text{neq}), \quad (5)$$

and it can be noticed that the neq regime is now applied to the GS energy, contrasting with Eq. 2. For fluorescence calculations, the charges on the PCM cavity should be equilibrated with the ES density. In practice, applying Eq. 5 requires the selection of a quite advanced PCM approach. Three models have been developed to carry out this task: the corrected linear response (cLR) (Caricato et al. 2006), the state-specific (SS) (Improta et al. 2007), and the vertical excitation models (VEM) (Marenich et al. 2011). All rely on the one-particle TD-DFT density matrix [basically on $\rho^{\text{ES}}(\mathbf{r})$] to compute the charges of the cavity in the ES but with significantly different procedures: cLR is a fast perturbative approach, whereas both SS and VEM are two more computationally demanding self-consistent schemes, the former (latter) implying a modification (no modification) of the GS density. Of course, cLR, SS, and VEM models can also be used to determine vertical absorption energies. However, contrary to absorption, the LR-PCM scheme is not well suited for emission, as $E^{\text{GS}}(R^{\text{ES}}, \text{neq})$ is not accessible with LR-PCM. This calls for two additional remarks: (i) while the transition energy obtained at the end of a gas-phase TD-DFT ES optimization corresponds to the vertical fluorescence energy, it is not the case in solution, and a separate (two-step) calculation has to be performed to determine $E^{\text{vert-f}}(\text{neq})$; (ii) to date analytic TD-DFT optimizations are only available with LR-PCM, and the cLR-PCM, SS-PCM, or VEM-PCM fluorescence energies are typically computed on geometries obtained with LR-PCM. We recall that different programs have different default eq/neq regime and that a careful check is necessary prior to starting the computations.

Analyzing the Results

Similar to absorption, one obtains at the end of a fluorescence calculation the vertical transition (emission) energy, the corresponding oscillator strength, as well as MO composition of the transition. All can be analyzed using the approaches described above. Of course, one advantage of TD-DFT compared to most experimental approaches is that it provides the ES geometry and hence allows to quantify the structural relaxation between the GS and ES. From the computed vertical absorption and fluorescence energies, one can also directly estimate this Stokes shift, although such estimation would neglect vibronic couplings. In first approximation, the Stokes shift is proportional to the structural relaxation between the two states. To avoid misunderstandings, we also underline that: (i) performing a TD-DFT geometry optimization is not equivalent to investigating photochemistry, i.e., the optimization steps connecting R^{GS} to R^{ES} are not providing a proper photochemical reaction path, and (ii) the oscillator strengths corresponding to $E^{\text{vert-f}}$ are not directly comparable to experimental emission quantum yields (Φ_f), because the latter are also affected by the (often numerous) non-radiative deactivating processes that are

not accounted for in Eq. 4, whereas the oscillator strengths are related to the radiative rate constant only.

0-0 Energies and Band Shapes

Let us now turn to properties that can be rightfully compared to experimental values: (i) 0-0 energies that correspond to the measured absorption-fluorescence crossing point (AFCP) and (ii) band shapes that (mainly) result from vibronic couplings and can also be compared to experiment. We underline that for both properties, it is nevertheless necessary to transform the experimentally reported spectra into normalized line shapes (Avila Ferrer et al. 2013). Additionally, the calculation of vibronic couplings and 0-0 energies allows one to determine molar absorptivities that also offer a direct confrontation with measurements. All these properties require the determination (or at least the estimation) of the (harmonic) ES Hessian, that is, of the second-order geometrical derivatives of the TD-DFT energy. Consequently, a significant computational effort is required but molecules with ca. 100 atoms can now be routinely modeled.

Adiabatic and 0-0 Energies

We directly discuss the solvated case here, as the simplification to the gas-phase limit is trivial. As can be seen in Fig. 6, the adiabatic energy, an equilibrium property, can be obtained as a simple by-product of absorption and emission calculations:

$$E^{\text{adia}}(\text{eq}) = E^{\text{ES}}(R^{\text{ES}}, \text{eq}) - E^{\text{GS}}(R^{\text{GS}}, \text{eq}). \quad (6)$$

To determine the 0-0 energies,

$$E^{0-0}(\text{eq}) = E^{\text{adia}}(\text{eq}) + \Delta E^{\text{ZPVE}}(\text{eq}), \quad (7)$$

one needs to determine the difference of zero-point vibrational energy (ZPVE) between the ES and GS,

$$\Delta E^{\text{ZPVE}}(\text{eq}) = E^{\text{ZPVE}}(R^{\text{ES}}, \text{eq}) - E^{\text{ZPVE}}(R^{\text{GS}}, \text{eq}). \quad (8)$$

In practice $\Delta E^{\text{ZPVE}}(\text{eq})$ can only be computed in the harmonic approximation and remains the time-limiting step of 0-0 calculations. As explained above, the PES tends to be flatter in the ES than in the GS, and $\Delta E^{\text{ZPVE}}(\text{eq})$ is negative for the vast majority of molecules and states. Consequently, $E^{0-0}(\text{eq})$ are smaller than $E^{\text{adia}}(\text{eq})$, and the difference between the two is typically in the -0.04 to -0.12 eV range (Goerigk and Grimme 2010; Send et al. 2011; Jacquemin et al. 2012a; Laurent and Jacquemin 2013) and is therefore not negligible. As the experimental AFCP energy corresponds to the crossing point between two nonequilibrium curves, the results of Eq. 7 should be further corrected using

$$E^{\text{AFCP}}(\text{neq}) = E^{0-0}(\text{eq}) + \frac{1}{2} [\Delta E^{\text{vert-a}} + \Delta E^{\text{vert-f}}], \quad (9)$$

where the two correcting terms read

$$\Delta E^{\text{vert-a}} = E^{\text{vert-a}}(\text{neq}) - E^{\text{vert-a}}(\text{eq}), \quad (10)$$

$$\Delta E^{\text{vert-f}} = E^{\text{vert-f}}(\text{neq}) - E^{\text{vert-f}}(\text{eq}). \quad (11)$$

The rationale explaining the form of these correction terms, which are strictly zero in gas phase, can be found in Jacquemin et al. (2012a).

To determine $E^{\text{AFCP}}(\text{neq})$, one can follow the advices given above, that is, use a diffuse containing atomic basis set, select a functional adapted to the nature of the investigated ES (see also below), and apply a refined environmental model. Nevertheless, we underline that $\Delta E^{\text{ZPVE}}(\text{eq})$ is less sensitive to BS and XCF effects than most other ES properties but depends significantly on the considered molecule and ES. In other words, one can generally use a less demanding approach to determine this term. Nevertheless, the calculation of $E^{\text{AFCP}}(\text{neq})$ will require a substantial number of steps, typically ordered as (i) optimization of the GS geometry, (ii) calculation of the vibrational frequencies of the GS, (iii) determination of vertical absorption energies in both equilibrium and nonequilibrium regimes, (iv) optimization of the ES geometry, (v) calculation of the vibrational frequencies of the ES, and (vi) determination of vertical emission energies in both equilibrium and nonequilibrium regimes. Detailed protocols can be found in Chibani et al. (2013) and Jacquemin et al. (2012a).

As AFCP energies allow comparisons with experiment, let us now briefly comment on the expected results and the XCF dependency. For a set of 40 representative medium-sized dyes, the $E^{\text{AFCP}}(\text{neq})$ energies have been determined using: (i) the 6-31+G(d) BS for structures (R) and the 6-311++G(2df,2p) ES for total and transition energies (E); (ii) the LR-PCM model for structures and the cLR-PCM model for energies; and (iii) 12 hybrid XCF (Jacquemin et al. 2012a, 2014; Moore et al. 2014). Selected results are given in Table 3. It turns out that the smallest MSE and MAE are obtained with PBE0 and M06, but these XCF significantly fail in a few specific compounds presenting strong CT, yielding a moderate correlation with experiment. By contrast, M06-2X tends to systematically overestimate the experimental $E^{\text{AFCP}}(\text{neq})$, but the correlation with experimental trends is significantly improved. In choosing the XCF, there is thus a tradeoff between absolute and relative accuracies. The most satisfying results are reached with the OT LC-PBE* but at the price of an additional preliminary step (determination of the range-separation parameter) for each molecule.

The valuable correlation between the experimental and theoretical evolution of the $E^{\text{AFCP}}(\text{neq})$ energies in a homologous series of compounds can be illustrated by considering BODIPY derivatives (Chibani et al. 2013). This class of molecules can be viewed as a subgroup of the cyanine family. Although TD-DFT has a strong tendency to overestimate the absolute transition energies in cyanines (Le Guennic

Table 3 Statistical analysis (w.r.t. experiment) obtained for cLR-PCM $E^{\text{AFCP}}(\text{neq})$ of 40 compounds. and Jacquemin 2015), the relative trends, that is, the auxochromic shifts, are restored very satisfactorily. This is illustrated in Fig. 7 where, starting from the central BODIPY core, a diverse panel of chemical modifications (adding substituents, extending the π -delocalization, stiffening the core, etc.) has been considered. As can be seen, for most variations, TD-DFT (in red) either accurately reproduces the measured (in blue) auxochromic shifts or slightly overshoots them. This figure illustrates that TD-DFT can be effectively used to screen dyes belonging to a given family (Laurent et al. 2014).

Band Topologies

Besides AFCP energies, the band topologies offer another option allowing direct comparisons between experimental and theoretical optical spectra. As stated above, it is nevertheless necessary to renormalize the measured spectra to obtain data directly comparable to the calculation (Avila Ferrer et al. 2013). In addition to the GS and (at least estimates of the) ES vibrational levels, band shapes require the determination of the vibronic couplings, that is, the couplings between the different vibrational states of the GS and the ES. This may be a very demanding task and many different approaches and programs have been designed to tackle this goal (Dierksen and Grimme 2004; Santoro et al. 2008; Avila Ferrer et al. 2011; Baiardi et al. 2013). To determine these couplings, a Taylor series of the transition moment is considered: the two first terms give rise to the so-called Franck–Condon (FC) and Herzberg–Teller (HT) contributions. As a rule of thumb, the former dominates the total response for strongly dipole allowed transitions, whereas the latter is crucial for forbidden or weakly allowed transitions. In practice, besides the ingredients necessary to compute AFCP energies, one should pay notably attention to (i) the choice of the FC, HT, or FC-HT approximation, (ii) the importance of temperature effects, and (iii) the adequacy of the harmonic approximation. Indeed, when large

Fig. 7 Comparison between the experimental (in blue) and theoretical (in red) evolution of the AFCP energies determined for 12 BODIPY derivatives. The theoretical data have been determined at SS-PCM-TD-M06-2X/6-311+G(2d,p)//LR-PCM-TD-M06-2X/6-31G(d) level of theory. See Chibani et al. (2013) for solvent used, experimental references, and additional examples

deformations between the GS and ES are at play, anharmonic contributions can become crucial. An example of a vibronic calculation is given in Fig. 8 (Barone et al. 2014). As can be seen, several ES with significant vibronic contributions overlap to generate the experimentally observed spectrum that could be restored with a good accuracy.

Fig. 8 Absorption spectrum of chlorophyll *a* (with two explicit methanol molecules) computed with vibronic couplings. The individual contribution of the different ES (*full lines*) and the total (*dashed lines*) are compared to experiment (Reproduced from Barone et al. (2014) with permission from Wiley)

Photophysics of Transition Metal Complexes: Effect of SOCs, Phosphorescence, and TD-DFT Performance

As discussed above the photophysical properties of systems containing metals are in most cases more intricate than purely organic systems. This is not only due to the high density of ES contributing to a single band (see Fig. 2) but also to the fact that their ES can be of very different character. Mainly five types of electronic transitions are found in transition metal (TM) complexes (González et al. 2012):

- (i) Ligand field (LF) excitations, also called d-d or metal-centered (MC) electronic excitations. In centrosymmetric environments, they are strictly not allowed by Laporte rules, but they gain intensity due to vibronic and/or spin-orbit couplings. Consequently, they generally possess lower extinction coefficients than CT transitions.
- (ii) Ligand-to-metal CT (LMCT) excitations. These are electronic excitations from occupied ligand orbitals to the partially empty d-shell of the metal.
- (iii) Metal-to-ligand CT (MLCT) excitations. These are excitations from metal-based orbitals to low-lying empty orbitals located on the ligand, typically of π^* character.

- (iv) Ligand-centered (LC) transitions. These are excitations within the ligand-based orbitals that are also present in the UV/Vis spectrum of the uncomplexed ligands.
- (v) Ligand-to-ligand CT (LLCT) states. These excitations involve ligand-based orbitals, but located in different ligands.

The characterization of the ES of TM complexes may already lead to some problematic situations, since in some cases there is a certain degree of admixture between different ES (leading, e.g., to MLCT/LC or MLCT/LLCT mixed states). Toward their characterization, as discussed above, the transformation of canonical MOs into more “compact” NTOs and the evaluation of atomic contributions in the involved molecular orbitals are useful strategies. In very problematic cases, the best option is to provide the EDDM plots. Exemplarily, in Fig. 9, are shown the different orbital representations of the first excited state of a Ru(II) complex (Jäger et al. 2015). This ES is described by two main MLCT contributions in the canonical representation. The NTOs representation allows one to clearly identify the $d_{xz} \rightarrow \pi^*$ as the main contribution to the ES. Finally, the EDDM plot provides the most compact representation.

Analogously to organic compounds, vibronic and solvent effects are also crucial for the ES of TM complexes, and they will not be further discussed here. Nevertheless, having in mind that metal complexes are often highly charged species, the comparison with experiments should always be done carefully, since solvent effects may induce very important shifts of the excitation energies. In this regard, in some cases, a combination of both explicit and implicit solvation approaches is needed to reach spectroscopic accuracy. Furthermore, and more specifically, inorganic compounds present several inherent complexities. Among them, we highlight the importance of relativistic effects (especially SOCs, see below), near degeneracies and double or multiply ES (not exclusively for these systems). Therefore, having in mind these challenges, it is necessary in many cases to play with various ab initio- and DFT-based methods in a proper relativistic framework to provide an appropriate description of the diversity of electronic structure situations and problematics. Spin-orbit effects are needed to interpret many spectroscopic phenomena, e.g., from zero-field splittings (ZFS) to intersystem crossings (ISC). To reach affordable relativistic calculations including SOCs, 2-component approaches are often used, such as the zero-order regular approximation (ZORA) or the Douglas–Kroll–Hess (DKH) Hamiltonians. These approaches can be adapted to DFT, perturbation, and wave function theories. From a technical viewpoint, SOC can be incorporated in the orbital optimization step, such as in the self-consistent SOC-TD-DFT method (Wang et al. 2005), or as a perturbation based on the scalar relativistic orbitals, such as in the quadratic response (QR) TD-DFT method (Minaev et al. 2014).

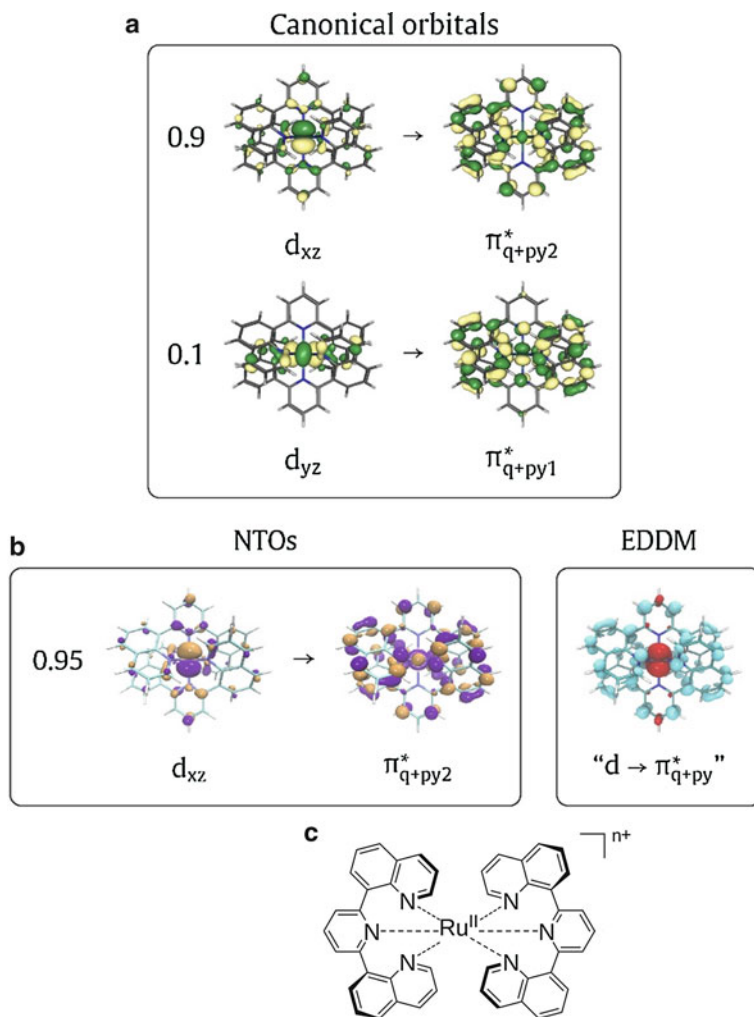

Fig. 9 Orbital representations of the character of the first excited state for the shown Ru(II) complex (Adapted from Jäger et al. (2015), Copyright (2015), with permission from Elsevier)

Influence of SOCs on the UV/Vis Properties

As in other playgrounds, TD-DFT is widely employed for TM spectroscopy, because of its simplicity and apparent black-box nature, in particular for medium/large TM complexes, which are still out of reach for more accurate ab initio methods. In many scenarios, TD-DFT can provide a reasonable agreement with the experiment, provided, on the one hand, that a judicious selection of XCF and atomic basis set is made and, on the other hand, that a proper treatment of

environmental effects is considered (see also below). As discussed above, from TD-DFT calculations, we can access to the electronic excitation and emission energies, oscillator strengths (related to the intensities), ES characters, and optimal geometries of the relevant ES. These properties are sufficient in principle to reproduce the UV/Vis absorption and emission spectra. However, for TM, due to the high density of states in the UV/Vis region and the large nuclear dimensionality of the problem, a deeper understanding of the actual photodeactivation mechanisms taking place after light irradiation is often needed to interpret the experimental evidences. This requires the assignment of (i) the photoactive excited states and (ii) the relevant nuclear deformations (which are affected by spin-orbit and vibronic interactions) along the photodeactivation pathways.

Importantly, SOCs impact the ES characters, the UV/Vis absorption and emission properties, the relaxation dynamics, as well as the radiative and non-radiative decay pathways. To illustrate the effect of SOCs in the UV/Vis absorption properties, we show in Fig. 10a the experimental UV/Vis spectra superimposed to the PCM-TD-B3LYP vertical excitations for two Ru(II) complexes (Santos et al. 2015). The long tail between 470 and 520 nm (highlighted in red in Fig. 10a), where singlet-to-singlet excitations are dark or do not exist, is attributed to singlet-to-triplet excitations. This is a common scenario for many other TM complexes. In fact, there is often an important grade of admixture between pure spin-free states *via* SOCs, which leads to mixed spin-orbit (SO) states. Not only the spectroscopic properties are modulated by the grade of admixture, but also the classical picture of pure (triplet, singlet, or any other possible multiplicity) states may become meaningless. This is illustrated in Fig. 10b, where the correlation of the calculated TD-PBE0 singlets (left) and triplets (right) spin-free states with respect to the SO-TD-PBE0 states (middle) is shown for a Re(I) complex (Baková et al. 2011). First, there are more SO states than spin-free states, since the three triplet substates split after the inclusion of the SOCs. Second, some of the SO states are energetically shifted with respect to the spin-free states. Third, some of the SO states contain significant triplet contributions.

Two main factors, that is, (i) the amplitude of the SOCs and (ii) the singlet-triplet splittings, control the final mixing at the SO states. Numerous investigations of TM complexes demonstrated that the photophysical properties are often uncorrelated to the strength of the SOC constant of the metal atom, contrary to the expectations based on the so-called heavy atom effect in organic photochemistry (Chergui 2015). As a consequence, to obtain some qualitative description of the photophysical properties, it is very often more suited to analyze the SOC contributions on the involved photoactive states, since typically $^1,^3\text{MC}$ and $^1,^3\text{MLCT}$ ES are more prone to couple *via* SOCs than $^1,^3\text{LC}$ and $^1,^3\text{LLCT}$ ES.

Phosphorescence

As discussed in the previous sections, modeling fluorescence and/or phosphorescence implies finding the optimal geometry of the relevant singlet and/or triplet

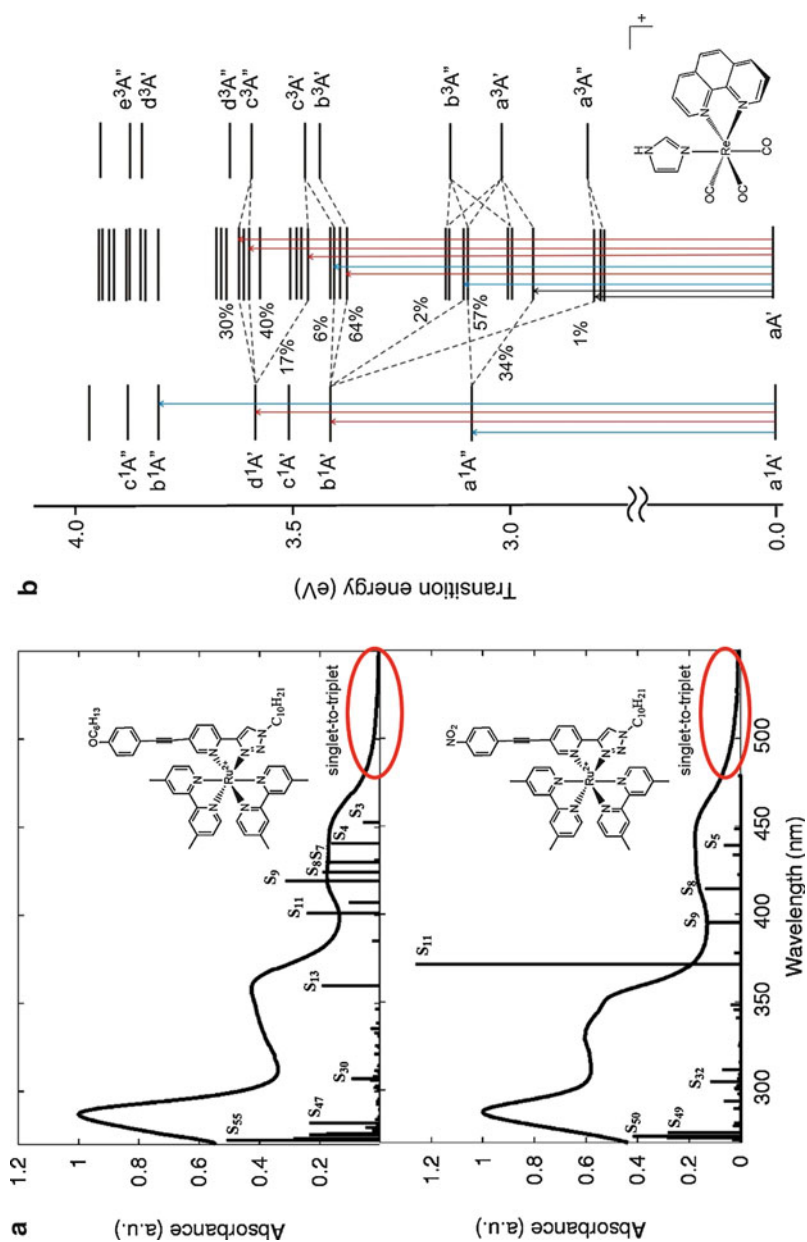

Fig. 10 (a) Experimental spectra in *solid lines* superimposed to the TD-DFT (B3LYP/6-31G(d) in CH_2Cl_2) vertical excitations for the shown Ru(II) complexes (Adapted with permissions from Happ et al. (2010). Copyright 2010, American Chemical Society). (2011), Copyright (2011), with permission from Elsevier)

excited state, followed by the computation of the vertical transition energy (see Eq. 4). In TM complexes photoluminescence usually originates from the lowest triplet ES, but violations of the Kasha rule and dual emissions have been reported (Escudero and Jacquemin 2015). Recent progresses in *ab initio* and DFT-based methods in quasi-relativistic frameworks have expanded the range of applications in TM spectroscopy from a quantitative assignment of absorption and emission colors to a semiquantitative interpretation of emission spectroscopy and photochemical reactivity (Minaev et al. 2014). Today the calculation of ISC and radiative rates has become feasible. We prognose that these recent improvements will permit in the next years the estimation of more intricate photophysical properties, such as the photoluminescence quantum yields Escudero, D. (2016). *Chemical Science*, 7, 1262.

TD-DFT Performance

As described above, the results of TD-DFT are not extremely sensitive to the size of the atomic basis set when low-lying ES are considered. Therefore, a relatively compact atomic basis set, such as 6-31G(d), was often sufficient for TM complexes. However, as in other playgrounds, the selection of an adequate XCF in the TD-DFT calculations is extremely important to reach accurate results. In the following discussion, we will not mention states with a strong multi-reference character, as they cannot be handled with TD-DFT in its adiabatic approximation. Numerous investigations show that obtaining an accurate and balanced description of all the different ES is particularly challenging for inorganic systems. Consequently, the development of general rules of thumb for TM spectroscopy still remains difficult. Among the different XCF flavors, it is generally observed that hybrid functionals with intermediate amounts of exact exchange, such as PBE0 (25%) or B3LYP (20%), outperform the rest of functionals and provide a well-balanced description of several types of singlet and triplet excitations, especially for overall positively charged Ru(II), Os(II), Pt(II), Ir(III), Re(I), and Au(I) complexes (to mention some of the most widely spread TM and organometallic complexes) (González et al. 2012; Zálaiš 2007; Niehaus et al. 2015; Daniel 2015). In contrast, pure functionals, e.g., BP86 and PBE, are more suited for negatively charged TM complexes (e.g., bearing Fe(II) and Cr metal centers). Hence, despite the systematic overestimation of the MC states by pure XCF and their inadequacy for organic compounds, they outperform the rest of TD-DFT flavors for these systems, especially in the description of CT excitations involving the metal (Escudero and Thiel 2014). More surprising is the fact that RSH XCF, such as CAM-B3LYP, do not provide an accurate description of these CT states, regardless of the nature of the TM complex. This is illustrated in Fig. 11, where we show the experimental UV/Vis spectrum of a Ru(II) complex superimposed to the convoluted PCM-TD-B3LYP and PCM-TD-CAM-B3LYP predictions (Santos et al. 2015). Both the intense absorption band peaking at ca. 260 nm, which is mainly due to LC excitations and the low-energy band centered at ca. 460 nm, which results from MLCT excitations, are clearly better described at the PCM-TD-B3LYP level of theory. Indeed, for these positively

Fig. 11 UV/Vis absorption spectrum for the shown complex in methanol (*solid line*) and computed PCM-TD-DFT vertical excitation energies using the CAM-B3LYP (**a**) and B3LYP (**b**) functionals the *dashed line* represents a Gaussian convolution of the vertical excitation energies. Phen stands for phenanthroline (Adapted from Santos et al. (2015) with permission from Wiley)

charged TM complexes, PCM-TD-CAM-B3LYP substantially overestimates the excitation energies of both local and CT excitations. Therefore, these RSH XCF are generally not ideal for TM complexes. Finally, as the inclusion of exact exchange exacerbates the triplet instability problems, it is often recommended to use the Tamm–Dancoff (TDA) approximation in TD-DFT to determine triplet excitation energies, though extensive benchmarks on TM complexes have yet to appear.

In a nutshell, the assignment of the UV/Vis spectrum of very well-behaved systems is nowadays possible with TD-DFT. In some problematic cases, the assignment of the experimental data exclusively based on TD-DFT can become dangerous without a careful validation. Indeed, a simple matching of theoretical and experimental bands might be misleading, because there may be fortuitous

matches due to the large number of low-lying transitions, the inherent inaccuracies of TD-DFT calculations, the possible error cancelations, and the interplay with other effects (solvent effects, spin-orbit, and vibronic couplings).

Complex Environments and Biomolecules

In this last section we aim to show how to deal with the photophysical properties of large biomolecules rather than “isolated” organic and inorganic molecules. Indeed, during the last decades, huge experimental and theoretical efforts have been made to mimic and improve natural processes allowing to capture, transfer, and store solar energy. Such photobiological reactions are possible only if the organisms contain one or more chromogens. These light-sensitive compounds are not only essential for light harvesting plants that produce energy but also play a central role in new technological applications (artificial molecular motors, biosensors, etc.). For such photobiological systems, it is usual to combine quantum mechanics (QM) to a lower level of theory, very often molecular mechanics (MM) or fragment-based methods such as effective fragment potential (EFP), to model both the chromophore and its full environment. A detailed description of such hybrid approaches is beyond our scope and we redirect the interested readers to Senn and Thiel (2009) and Gordon et al. (2012).

Setting Up the Calculation

In practice, the site responsible for the photophysical properties is treated with QM, typically with TD-DFT, though highly correlated wave function method has also been used, while the remaining of the biomolecules (e.g., protein) are described thanks to a force field.

Initial Set of Biomolecule Coordinates

In most cases the structures (and hence the coordinates) of the biomolecule of interest have been published in the Protein Data Base (PDB). These coordinates can be directly used and in first approximation, considered as an averaged structure of the dynamic of the system. However, caution is necessary, especially when two or more conformations of the systems coexist. It is therefore valuable to perform molecular dynamic (MD) simulation of the systems before running QM/MM computations. Indeed the MD simulations allow to retrieve several possible conformations that might play an important role in the final optical signatures, especially when significant geometrical changes are made close to the chromophore. After such MD simulations, ES energies can be computed either: (i) on an averaged structure meaning that the information on the dynamics is lost or (ii) on several snapshots extracted from the MD simulation, if one aims to get more accurate insights and/or define an uncertainty on the theoretical values. For the evaluation of ES energies, the convergence is usually obtained rapidly, e.g., single-point computations on

Fig. 12 Histograms showing the distribution of the excitation energies depending of the protein conformation (one bin is equal to 0.02 eV) (Adapted with permission from Laurent et al. (2012) from Wiley. Copyright 2012 American Chemical Society)

ca. 20 snapshots typically yield a standard deviation of ca. 0.04 eV – ionization energies and electronic affinities require much more calculations. This is illustrated in Fig. 12, where the numerous computed ES energies are represented through histograms for two conformations of the mStrawberry fluorescent protein. In this system both polar (serine) and a charged (lysine) residues are playing a pivotal role on the absorption spectra. We underline that the experimental spectrum is only reproduced when weighting the excitation energies by the population of each conformation (Laurent et al. 2012).

Another choice to obtain initial coordinates is to use QM/MM MD, e.g., Car–Parrinello or Born–Oppenheimer dynamics. Though these approaches have become increasingly popular, they remain rather limited due to: (i) the accessible simulation time (maximum 1 ns) and (ii) the plane-wave description of the systems that facilitates the use periodic condition but renders the applications of TD-DFT with hybrid XCF very challenging. When no precise structure of the system is available, homology modeling followed by MD simulations might also be way to obtain consistent coordinates.

Determination of the Size of the QM Region

In most of QM/MM computations, a preliminary study needs to be performed to determine the adequate size of the QM part where the TD-DFT calculations will be

performed. The sensitivity of QM/MM results to the extension of the QM part has been assessed for several properties including UV/visible signatures (Altun et al. 2009; Sanchez-Garcia et al. 2010). In photobiological systems, the chromophore was indeed historically the sole component included in the QM region. However, recently it has been highlighted that the residues surrounding the (photo)active site should also be included within the QM region (Hu et al. 2011; Liao and Thiel 2012). The number of residues rapidly becomes very large (>200 atoms), but typically the treatment of such enlarged QM part is manageable with TD-DFT. Despite these works, no general rule might be given regarding the size of the QM region, as this size is highly dependent upon the details of the considered systems (solvent exposed, polar binding pocket, van de Waals interactions, salt bridge, etc.). Comparisons of the structural and optical properties with experimental data remain generally necessary.

In addition to the size of the QM part, an additional difficulty appears in QM/MM computations in which the QM part is chemically linked to the MM part. Dealing with a covalent bond between the QM and the MM parts is always delicate, but is rather common as such bond is present in the most widely studied biological systems, i.e., fluorescent proteins, retinal, and rhodopsins. The three major boundary schemes are: the very popular link atom (LA) scheme, the boundary atom approach, and the localized-orbitals method. Once more, it is difficult to give general advices, but one should be aware that the selection of boundary model might affect the simulated spectral signatures.

Importance of the Embedding

Within TD-DFT/MM approaches, the density of the QM part should be influenced by the MM surrounding. One generally splits this total interaction into three components: mechanical (ME), electrostatic (EE), and polarization (PE) embeddings, which should ideally be all simultaneously accounted for. Briefly, in the ME only structural effects induced by the environments are taken into account, the QM density remaining non-polarized by the electrostatic MM charges. In contrast, in the EE scheme, this polarization effect is accounted for. When both the QM and the MM parts are polarizing each other, the PE is also taken into account. In the computation of optical properties with TD-DFT, PE has been often neglected because: (i) consistent polarizable force fields are not widely available and (ii) the associate computational cost is significant. However, polarizable force fields and the QM-based EFP methods are now well developed (Gordon et al. 2001; Ghosh et al. 2013; Kaliman and Slipchenko 2013). It is therefore not surprising that several approaches have been applied in the recent years to account for PE (Jacquemin et al. 2009b; Labat et al. 2009; Laurent and Assfeld 2010; Neugebauer et al. 2010; Biancardi et al. 2013; Presti et al. 2014). One of these schemes is the so-called ERS (electronic response of the surroundings) (Laurent and Assfeld 2010), which takes into account for the PE in an implicit way by making a usual QM/MM computation combined to a continuum surrounding (with the adequate dielectric constant) for the QM part. For instance, for a squaraine/tetralactam complex, the experimental bathochromic shift due to the caging effect of the squaraine cannot be reproduced by the ME+EE

scheme (which predicts a hypsochromic displacement) but is correctly captured by TD-DFT/MM when PE is accounted for (Jacquemin et al. (2009b)). Likewise, a complete study has been performed on rhodopsin and its mutants comparing several force fields as well as the LoProp approaches in an important contribution (Söderhjelm et al. 2009), which cannot be briefly summarized. In the LoProp scheme, the electrostatic contribution is described not only with point charges (as usual for classical force field) but also through dipole and quadrupole contributions. In the same time, the PE is computed thanks to anisotropic polarizabilities.

Toward Optical Properties

Most of the TD-DFT/MM approaches are currently employed to simulate the absorption spectra of chromophore embedded into biomolecules within the vertical approximation. Indeed the computations of the excited state for the whole system remain challenging as the force fields have been mainly developed to characterize ground state properties. However, by assuming that the surrounding relaxation in the ES is rather weak, one can account for the chromophore relaxation only and hence obtain first insights into the emission properties of biomolecules. Further developments in this direction are necessary to reach the complete ES properties for a protein.

The usual approach to analyze the QM/MM computations is to apply a bottom-up strategy going from the description of the isolated or solvated chromophore using methods described in the previous sections and next considering the chromophore in its real environment. As clear from the above statements, the intrinsic features of QM/MM computations allow one to decompose the characteristic λ_{\max} into four contributions compared to the isolated structure ($\lambda_{\max}^{\text{isolated}}$):

$$\lambda_{\max} = \lambda_{\max}^{\text{isolated}} + \Delta\lambda_{\max}^{\text{ME}} + \Delta\lambda_{\max}^{\text{EE}} + \Delta\lambda_{\max}^{\text{PE}}, \quad (12)$$

where $\lambda_{\max}^{\text{ME}}$, $\lambda_{\max}^{\text{EE}}$, $\lambda_{\max}^{\text{PE}}$ account, respectively, for the geometrical modifications due to the presence of the biomolecule, for the polarization of the QM density by the force field mono- and multipoles, and for the mutual polarization between the QM and the MM parts. None of these contributions can be neglected as they typically present similar magnitudes.

Conclusions

Time-dependent density functional theory now stands as a mature tool to interpret and predict the optical spectra of organic, inorganic, and biological molecules. One can indeed determine a large number of properties (absorption, fluorescence, phosphorescence, dipoles, etc.) with a large variety of flavors of TD-DFT (different families of functionals adequate for specific excited states, accounting or not for vibronic and spin-orbit couplings, etc.) in a wide range of environments (gas phase,

solution, embedding in proteins, etc.). For the simplest cases, TD-DFT can even be applied as an almost black-box approach and nevertheless yield important insights into the excited states (geometrical relaxations, nature of the states, importance of the vibronic couplings, possibility to have intersystem-crossing, etc.). This is a nice and efficient tool; use it to model your excited-state properties!

However, TD-DFT in its adiabatic form suffers from several flaws and the theoretical community is very active in trying to circumvent them. Although this is beyond the scope of the present contribution, it is certainly worth to mention that schemes have been developed to model conical intersections (Huix-Rotllant et al. 2015) as well as to go beyond the adiabatic approximation and treat more consistently and more accurately all families of excited states (Casida and Huix-Rotllant 2012; Ziegler et al. 2015).

Abstract

The majority of organic and inorganic chemical reactions relevant for synthesis or industrial applications take place in the solution phase. Similarly, almost all biological reactions proceed in an aqueous environment. Theoretical descriptions of chemical reactions in solution differ in the way they treat the surrounding solvent molecules. Their large number excludes an explicit treatment. Nevertheless, the elucidation of the solvated structure plays a key role in obtaining an accurate description of chemical reactions as well as the activity of biomolecules. In this chapter, we review recent theoretical developments for the description of solvated molecules during chemical reactions, employing statistical physics to treat the solvent. The reference interaction-site model (RISM) theory, and some of its extensions, coupled with recent quantum mechanical theories, are described, and applications to various systems in solution, from conventional chemical reactions to the activities of biomolecules in biological systems, are presented. The solvent

distribution around the solute and solute–solvent interactions is critical for the reactions and structures of such systems. The theories described here offer the possibility to obtain detailed information on the molecular origin of solvation and may contribute to discover and elucidate novel phenomena in chemistry, physics, and bioscience.

Introduction: Role of the Solvent in Chemistry

A liquid or solution may be considered as a system composed of a large number of molecular particles. The macroscopic properties of this system can be finally traced back to the microscopic properties of the particles. Statistical mechanics plays an essential role in the emergence of macroscopic properties from microscopic ones (Hirata 2003). Statistical mechanics can also be applied to describe chemical reactions in solution, where a solute or a reaction center is located in the surrounding solvent particles, the number of which is of the order of the Avogadro constant.

How does a solvent behave during a chemical reaction in solution? In the case of conventional organic or inorganic reactions in solution, solid or liquid reactants are dissolved in the solvent, or liquid reactants are mixed. The system may be heated or cooled, if necessary. After the reaction has finished, products are separated or extracted. In this series of reactions, the solvent – including the case of liquid–liquid reactions – functions as the heat bath supplying the activation energy to the reactants. This feature is unique to liquid reactions. In the gas-phase, in contrast, reactions are mostly initiated by collisional interactions between the reacting molecules, which are essentially independent of the surrounding molecules (Levine 2005).

In addition to conventional organic or inorganic reactions, the solvent also plays a significant role in biological systems. Almost all biomolecules require water in order to develop their biological functions. Many biomolecules are not able to maintain their structure outside of the aqueous environment. Removing a biomolecule from the water where the system is functioning and transferring it into another solvent may lead to an immediate collapse of the molecular structure of the biomolecule, thus rendering it incapable to exert its usual biological function. Here, we list proteins, deoxyribonucleic acid (DNA), and sugars as examples of such biomolecules. The hydrogen bonds between these biomolecules and the water molecules, the hydrophobic or hydrophilic interactions among biomolecules, as well as those in biomolecule–cofactors are absolutely critical to express their usual functions.

Given such many-body, complicated interactions between the components, how can we describe chemical reactions in solution and biomolecules? A method on which such a treatment may be based is provided by statistical mechanics, which describes the connection between the properties of microscopic particles and the behavior of macroscopic systems. Historically, statistical mechanics has been firstly applied to the solid-state properties of metals and magnetic materials. On the other hand, theories of statistical mechanics to handle the liquid state have been developed

Fig. 1 Explicit (*left panel*) and implicit (*right panel*) solvent models

since the 1970s (Hansen and McDonald 2006). Another class of models treat the solvent as a dielectric continuum, where the molecular nature of the solvent is hidden (Fig. 1) (Tomasi et al. 2005). Such a continuum model is quite intuitive, and these models can be easily implemented as a computational algorithm. However, for many phenomena we need more elaborate theoretical frameworks which allow a more realistic description of interactions in these systems, such as hydrogen bond interactions.

In this chapter, we survey theories targeting liquids and molecular assemblies that have been developed based on statistical mechanics. The remainder of this chapter is organized as follows. Section “[Distribution Function Theory of Molecular Liquids](#)” covers the theory of distribution functions used to describe the structure of molecular liquids, providing also some background of the theory of statistical mechanics. In section “[Solvent Effects on the Electronic Structure of Solvated Molecules](#)” we summarize how statistical mechanics can be coupled with quantum mechanical treatments in order to describe the effect of the solvent on the electronic structures of solvated molecules. For biological systems, hydration is of critical importance, and some topics of biological functions employing recent theoretical formulations are presented in section “[Solvation of Biomolecules.](#)” Finally, section “[Summary and Future Perspective](#)” provides a summary and outlook to future developments.

Distribution Function Theory of Molecular Liquids

We begin with the theory of distribution functions for a pure solvent. Particles in the liquid state can move around inside the system and interact strongly with each other. This is a prominent feature of the liquid state, which distinguishes it from gas or solid phases. Therefore, in the liquid state, a rigorous description of the position

of particle i , as r_i , is not practical. We need to introduce statistical and probability theories to describe liquid-state structures.

The distribution probability of a molecule is given by a distribution function. The pair density distribution function is defined as:

$$\rho(\mathbf{r}, \mathbf{r}') = \langle v(\mathbf{r}) v(\mathbf{r}') \rangle. \quad (1)$$

where $\langle \bullet \rangle$ stands for an ensemble average and $v(\mathbf{r}) = \sum_i \delta(\mathbf{r} - \mathbf{r}_i)$ is the density field at the position \mathbf{r} inside a molecular distribution. The pair density distribution function defined above describes the probability to find a molecule at \mathbf{r}' if at the same time another molecule is present at \mathbf{r} . When the distance between \mathbf{r}' and \mathbf{r} is infinite, the probability of finding both molecules can be simply given as the product of the single molecular densities:

$$\lim_{|\mathbf{r}-\mathbf{r}'| \rightarrow \infty} \rho(\mathbf{r}, \mathbf{r}') \rightarrow \rho(\mathbf{r}) \rho(\mathbf{r}'). \quad (2)$$

In particular, in a homogeneous liquid without an external field acting on it, the molecular density is independent of \mathbf{r} , i.e., $\rho(\mathbf{r}) = \rho$. Using this property we can define a normalized distribution function by:

$$g(\mathbf{r}, \mathbf{r}') = \frac{\rho(\mathbf{r}, \mathbf{r}')}{\rho^2}, \quad (3)$$

which is called a pair distribution function. Furthermore, we define the total correlation function as:

$$h(\mathbf{r}, \mathbf{r}') = g(\mathbf{r}, \mathbf{r}') - 1. \quad (4)$$

The pair correlation function expresses the correlation of the density fluctuation between the positions \mathbf{r} and \mathbf{r}' . An equation governing these correlation functions is the Ornstein–Zernike (OZ) equation:

$$h(\mathbf{r}, \mathbf{r}') = c(\mathbf{r}, \mathbf{r}') + \rho \int c(\mathbf{r}, \mathbf{r}'') h(\mathbf{r}'', \mathbf{r}') d\mathbf{r}''. \quad (5)$$

Here, $c(\mathbf{r}, \mathbf{r}')$ is the direct correlation function, which is defined in the context of the OZ equation. Originally, Ornstein and Zernike proposed the equation rather intuitively. However, further studies have shown that the OZ equation can be derived rigorously from the theory of distribution functions (Hansen and McDonald 2006).

The OZ equation has two unknown functions, $h(\mathbf{r}, \mathbf{r}')$ and $c(\mathbf{r}, \mathbf{r}')$. To solve the OZ equation, we therefore need another relation that “closes” the set of equations. A representative closure is the hypernetted chain (HNC) approximation:

$$g(\mathbf{r}, \mathbf{r}') = \exp \left\{ -\frac{1}{k_B T} u(\mathbf{r}, \mathbf{r}') + h(\mathbf{r}, \mathbf{r}') - c(\mathbf{r}, \mathbf{r}') \right\}, \quad (6)$$

where k_B , T , and $u(\mathbf{r}, \mathbf{r}')$ are the Boltzmann constant, thermodynamic temperature, and the pair interaction potential, respectively. Two kinds of procedures are known to derive the closure: one procedure is based on Feynman diagrams; the other one employs the functional Taylor expansions.

The pair distribution function, which provides information on the structure of the liquid, can be obtained numerically. In this numerical process, we solve the combination of the OZ equation and closure by iteration, assuming additionally an appropriate pair potential between the particles.

The distribution function of a liquid consisting of polyatomic molecules is a function both of the position of the molecules, \mathbf{r} , as well as their orientation Ω . The pair density distribution function of a molecular liquid is defined as:

$$\rho(\mathbf{r}, \mathbf{r}', \Omega, \Omega') = \left\langle \sum_i \sum_{j \neq i} \delta(\mathbf{r} - \mathbf{r}_i) \delta(\mathbf{r}' - \mathbf{r}_j) \delta(\Omega - \Omega_i) \delta(\Omega' - \Omega_j) \right\rangle. \quad (7)$$

The pair distribution function is then derived as:

$$g(\mathbf{r}_{12}, \Omega_1, \Omega_2) = \left(\frac{\Omega}{\rho} \right)^2 \rho(\mathbf{r}_{12}, \Omega_1, \Omega_2), \quad (8)$$

where we have used the relations $\mathbf{r}_{12} = \mathbf{r}_2 - \mathbf{r}_1$ and $\Omega \equiv \int d\Omega$. The molecular OZ (MOZ) equation is then given by:

$$h(\mathbf{r}_{12}, \Omega_1, \Omega_2) = c(\mathbf{r}_{12}, \Omega_1, \Omega_2) + \frac{\rho}{\Omega} \int c(\mathbf{r}_{13}, \Omega_1, \Omega_3) h(\mathbf{r}_{32}, \Omega_3, \Omega_2) d\mathbf{r}_3 d\Omega_3. \quad (9)$$

A method to solve the MOZ equation is to use expansions in spherical harmonics. In particular, the spherical harmonic expansion of the pair correlation function is written as:

$$h(\mathbf{r}_{12}, \Omega_1, \Omega_2) = \sum_{\substack{mnl \\ \mu\nu}} h_{\mu\nu}^{mnl}(r_{12}) \sum_{\mu'\nu'\lambda'} \begin{pmatrix} m & n & l \\ \mu' & \nu' & \lambda' \end{pmatrix} R_{\mu\mu'}^m(\Omega_1) R_{\nu\nu'}^n(\Omega_2) R_{0\lambda'}^l(\hat{\mathbf{r}}_{12}), \quad (10)$$

where $R_{\mu\mu'}^m$ is Wigner's generalized harmonic and $\hat{\mathbf{r}}$ denotes the orientation of the vector \mathbf{r} (Blum 1972, 1973; Blum and Torruella 1972). With this expansion, the MOZ equation can be reduced to:

$$\begin{aligned} \tilde{h}_{\mu\nu}^{mnl}(k) &= \tilde{c}_{\mu\nu}^{mnl}(k) + \rho \sum \frac{(2l+1)}{(2n'+1)} (-)^{m+n+n'} \begin{Bmatrix} l'' & l' & l \\ m & n & n' \end{Bmatrix} \begin{pmatrix} l'' & l' & l \\ 0 & 0 & 0 \end{pmatrix} \\ &\times \sum_{\nu'} (-)^{\nu'} \tilde{h}_{\mu\nu'}^{mnl'}(k) \tilde{c}_{\nu'v}^{n'l''}(k) \end{aligned} \quad (11)$$

where the underlined subscript denotes a negative value. The parentheses $\{\dots\}$ and (\dots) indicate the 6j and 3j symbols, respectively. In this context, $\tilde{h}_{\mu\nu}^{mnl}(k)$ is given by the Hankel transform of $h_{\mu\nu}^{mnl}(r)$,

$$\tilde{h}_{\mu\nu}^{mnl}(k) = 4\pi i \int r^2 j_l(kr) h_{\mu\nu}^{mnl}(r) dr, \quad (12)$$

where j_l is an l th order spherical Bessel function. Coupling the MOZ equation with a corresponding closure, we can obtain the molecular pair correlation function. A commonly used closure for this purpose is a molecular HNC closure:

$$g(\mathbf{r}_{12}, \boldsymbol{\Omega}_1, \boldsymbol{\Omega}_2) = \exp \left[-\frac{1}{k_B T} u(\mathbf{r}_{12}, \boldsymbol{\Omega}_1, \boldsymbol{\Omega}_2) + h(\mathbf{r}_{12}, \boldsymbol{\Omega}_1, \boldsymbol{\Omega}_2) - c(\mathbf{r}_{12}, \boldsymbol{\Omega}_1, \boldsymbol{\Omega}_2) \right]. \quad (13)$$

If the spherical harmonic expansion is expanded up to infinite order, the MOZ equation is exact. In practice, however, we have to cut off the expansion at a finite order, which is usually low. As a consequence, the MOZ equation has some difficulties when it is applied to molecules with complicated geometries.

Another method to obtain the correlation function of molecular liquids is to use an interaction-site model for the pair correlation function (Hirata 2003). The site–site pair correlation function can be obtained by integration of the molecular pair correlation function over the orientation of molecules:

$$h_{\alpha\gamma}(r) = \frac{1}{\Omega^2} \iint h(\mathbf{r}_{12}, \boldsymbol{\Omega}_1, \boldsymbol{\Omega}_2) \delta(\mathbf{r}_{12} + l_{2\gamma}(\boldsymbol{\Omega}_2) - l_{1\alpha}(\boldsymbol{\Omega}_1) - \mathbf{r}) d\boldsymbol{\Omega}_1 d\boldsymbol{\Omega}_2, \quad (14)$$

where $l_{1\alpha}$ denotes the vector connecting the molecular center and the interaction-site α on molecule 1. On the other hand, a superposition approximation is applied to the direct correlation function (Chandler and Andersen 1972):

$$c(\mathbf{r}_{12}, \boldsymbol{\Omega}_1, \boldsymbol{\Omega}_2) = \sum_{\alpha\gamma} c_{\alpha\gamma}(r). \quad (15)$$

With these equations, the MOZ equation can be reduced to the site–site OZ equation:

$$h_{\alpha\gamma} = \sum_{\alpha'\gamma'} [\omega_{\alpha\alpha'} * c_{\alpha'\gamma'} * \omega_{\gamma'\gamma} + \omega_{\alpha\alpha'} * c_{\alpha'\gamma'} * \rho_{\gamma'} h_{\gamma'\gamma}], \quad (16)$$

where $*$ denotes the convolution integral and $\omega_{\alpha\alpha'}$ is the intramolecular correlation function:

$$\omega_{\alpha\alpha'}(r) = \delta_{\alpha\alpha'} \delta(r) + \frac{1}{4\pi l_{\alpha\alpha'}^2} (1 - \delta_{\alpha\alpha'}) \delta(r - l_{\alpha\alpha'}), \quad (17)$$

with $l_{\alpha\alpha'}$ the distance between the interaction sites α and α' . This expression is called the reference interaction-site model (RISM). A closure relation that can be used for RISM is also given by the site–site correlation function. We use the HNC closure:

$$g_{\alpha\gamma}(r) = \exp \left[-\frac{1}{k_{\text{B}}T} u_{\alpha\gamma}(r) + h_{\alpha\gamma}(r) - c_{\alpha\gamma}(r) \right]. \quad (18)$$

A more useful closure relation was proposed by Kovalenko and Hirata, which we call the Kovalenko–Hirata (KH) closure (Kovalenko and Hirata 1999a, b, 2000):

$$g_{\alpha\gamma}(r) = \begin{cases} \exp [d_{\alpha\gamma}(r)] & \text{for } d_{\alpha\gamma}(r) < 0 \\ 1 + d_{\alpha\gamma}(r) & \text{for } d_{\alpha\gamma}(r) \geq 0 \end{cases} \quad (19)$$

$$d_{\alpha\gamma}(r) = -\frac{1}{k_{\text{B}}T} u_{\alpha\gamma}(r) + h_{\alpha\gamma}(r) - c_{\alpha\gamma}(r).$$

Using the KH closure leads to a large improvement of the convergence behavior. The KH closure has been applied for example to structures of supercritical water, yielding very reasonable physical properties such as density fluctuations (Matsugami et al. 2014).

The RISM theory has been applied to various chemical and physical processes in solution. However, it is difficult for the RISM theory to handle large solute molecules with large structural anisotropies, such as proteins. To treat the solvation structure of large and anisotropic solute molecules, a three-dimensional (3D)-RISM theory has been proposed (Beglov and Roux 1997; Kovalenko and Hirata 1999b). In the 3D-RISM formalism, the molecular pair correlation function of the solute–solvent system is integrated over the orientation of solvent molecules, which yields the molecular-site or three-dimensional pair correlation function:

$$h_{\gamma}(\mathbf{r}) = \frac{1}{\Omega} \int h(\mathbf{r}_{12}, \boldsymbol{\Omega}_1, \boldsymbol{\Omega}_2) \delta(\mathbf{r}_{12} + l_{2\gamma}(\boldsymbol{\Omega}_2) - \mathbf{r}) d2, \quad (20)$$

where the position of molecule 1 is located at the origin, and the molecule has a fixed orientation. The MOZ equation can be further reduced to:

$$h_{\gamma} = \sum_{\gamma'} [c_{\gamma'} * \omega_{\gamma'\gamma} + c_{\gamma'} * \rho_{\gamma'} h_{\gamma'\gamma}], \quad (21)$$

where $h_{\gamma'\gamma}$ on the right-hand side is the solvent site–site pair correlation function, which is evaluated using RISM theory. The closure relation is also given by the 3D expression, i.e., the HNC closure is:

$$g_{\gamma}(\mathbf{r}) = \exp \left[-\frac{1}{k_{\text{B}}T} u_{\gamma}(\mathbf{r}) + h_{\gamma}(\mathbf{r}) - c_{\gamma}(\mathbf{r}) \right], \quad (22)$$

and the KH closure is:

$$g_\gamma(\mathbf{r}) = \begin{cases} \exp[d_\gamma(\mathbf{r})] & \text{for } d_\gamma(\mathbf{r}) < 0 \\ 1 + d_\gamma(\mathbf{r}) & \text{for } d_\gamma(\mathbf{r}) \geq 0 \end{cases} \quad (23)$$

$$d_\gamma(\mathbf{r}) = -\frac{1}{k_B T} u_\gamma(\mathbf{r}) + h_\gamma(\mathbf{r}) - c_\gamma(\mathbf{r})$$

The 3D-RISM theory has been successfully applied to the solvation of biomolecules and nanomaterials (Yoshida et al. 2009).

Following the notable breakthrough of the 3D-RISM theory, an extension of the MOZ theory for anisotropic molecules in solute–solvent systems has also been proposed, which we call the extended MOZ (XMOZ) theory (Ishizuka and Yoshida 2013). In the XMOZ theory, the solute molecule is fixed at the origin of the coordinates. The spherical harmonic expansion of the pair correlation function is only applied to the orientation of the solvent molecules, whereas the coordinates of the solvent molecules remain as Cartesian coordinates. Hence, the molecular pair correlation function of the solute–solvent system is expressed as:

$$h(\mathbf{r}_{12}, \boldsymbol{\Omega}_1, \boldsymbol{\Omega}_2) = h(\mathbf{r}_2, \boldsymbol{\Omega}_2) = \sum_{\substack{n \\ vv'}} h_{vv'}^n(\mathbf{r}_2) R_{vv'}^n(\boldsymbol{\Omega}_2). \quad (24)$$

The XMOZ equations in terms of the harmonic expansion coefficients are:

$$\tilde{h}_{vv'}^n(\mathbf{k}) = \tilde{c}_{vv'}^n(\mathbf{k}) + \sum_{\substack{m \\ \mu\mu'}} \tilde{c}_{\mu\mu'}^m(\mathbf{k}) (-)^{\mu-\mu'} \tilde{X}_{vv'\underline{\mu}\underline{\mu}'}^{nm}(\mathbf{k}) \quad (25)$$

$$\tilde{X}_{vv'\underline{\mu}\underline{\mu}'}^{nm}(\mathbf{k}) = \frac{\rho}{2m+1} \sum_{l\lambda'} \begin{pmatrix} m & n & l \\ \mu' & v' & \lambda' \end{pmatrix} \tilde{h}_{\mu v}^{mnl}(k) R_{\lambda'0}^l(\hat{\mathbf{k}}).$$

The closure relation for the XMOZ equations is basically the same as the one used for the MOZ theory. Thus, the HNC closure is given as:

$$g(\mathbf{r}_2, \boldsymbol{\Omega}_2) = \exp \left[-\frac{1}{k_B T} u(\mathbf{r}_2, \boldsymbol{\Omega}_2) + h(\mathbf{r}_2, \boldsymbol{\Omega}_2) - c(\mathbf{r}_2, \boldsymbol{\Omega}_2) \right]. \quad (26)$$

The molecular KH closure is:

$$g(\mathbf{r}_2, \boldsymbol{\Omega}_2) = \begin{cases} \exp[d(\mathbf{r}_2, \boldsymbol{\Omega}_2)] & \text{for } d(\mathbf{r}_2, \boldsymbol{\Omega}_2) < 0 \\ 1 + d(\mathbf{r}_2, \boldsymbol{\Omega}_2) & \text{for } d(\mathbf{r}_2, \boldsymbol{\Omega}_2) \geq 0 \end{cases} \quad (27)$$

$$d(\mathbf{r}_2, \boldsymbol{\Omega}_2) = -\frac{1}{k_B T} u(\mathbf{r}_2, \boldsymbol{\Omega}_2) + h(\mathbf{r}_2, \boldsymbol{\Omega}_2) - c(\mathbf{r}_2, \boldsymbol{\Omega}_2).$$

The applicability of the XMOZ theory is much more versatile compared with that of the MOZ theory. We should note, though, that the XMOZ theory has

a large computational cost at present. However, future contributions to reduce the computational cost can be envisaged, which will make this theory useful for calculations of biomolecules.

Solvent Effects on the Electronic Structure of Solvated Molecules

The majority of chemical reactions and almost all biochemical processes proceed in solution, the latter processes taking place in an aqueous phase. The solvent may significantly affect the progress of the reaction, as well as the properties of the solute. Thus, a knowledge of the electronic structure of solvated molecules is required, which in general is the central concern of theoretical and computational chemistry. Conventional procedures of quantum chemistry, which explicitly treat all of the molecules in the system in a quantum-chemical manner, are hardly applicable to liquids and solutions because the number of solvent molecules in the system is in the range of the Avogadro constant. For the same reason, the Schrödinger equation including the solute molecule and a large number of solvent molecules cannot be solved in practice. Thus, quantum–classical hybrid approaches have been developed. In those approaches, the solute molecule is treated quantum mechanically, while the solvent molecules are treated classically.

A popular method to treat solvated molecules is to approximate the solvent as a dielectric continuum. The quantum mechanics/molecular mechanics (QM/MM) method is also often employed, where the solvent is treated with molecular mechanics. Another approach to treat the solvent is an integral equation theory, which can be applied to molecular liquids. A pioneering work on a hybridized method of the integral equation and electronic state theories is the RISM–self-consistent field (RISM–SCF) theory introduced by Ten-no et al. (1993, 1994). Sato et al. (1996) reformulated the RISM–SCF method and derived a method to compute the analytical free energy gradient. Further extensions of this theory have been proposed, such as the 3D-RISM or MOZ theory, and have been applied to various chemical reactions in solution (Kovalenko and Hirata 1999b; Sato et al. 2000; Yoshida and Kato 2000; Yoshida 2007b).

In the hybrid method of the integral equation and electronic structure theories, first, the integral equation is solved under the electric field that is produced by the solute electronic structure. Then, an initial solvent distribution is determined and the solute electronic structure is calculated under the influence of this solvent distribution. This process is iterated, until the solute electronic structure and solvent distribution are finally determined in a self-consistent manner. In this method, the solvent distribution function and the solute electronic-density distribution connect integral equation theory and electronic structure theories. As mentioned above, RISM, 3D-RISM, and MOZ theories use different formulae for the solvent distribution functions and different methods to determine the solute electrostatic potential acting on the solvent. In a practical calculation, we need to develop a methodology to link these distributions and structures between the different theoretical frameworks.

Sato et al. (1996) derived the variational condition for the RISM–SCF framework and analytical first derivative of the Helmholtz energy of the system. In their work, they established a sound theoretical foundation for the RISM–SCF framework, which has been used to implement various properties, such as analytical free energy derivatives. 3D-RISM–SCF and MOZ theories also employ similar theoretical frameworks (Kovalenko and Hirata 1999b; Sato et al. 2000; Yoshida and Kato 2000).

We define the overall Helmholtz free energy of the system, A , as the sum of the energy of the solute, E_{solute} , and the excess chemical potential, $\Delta\mu$:

$$A = E_{\text{solute}} + \Delta\mu. \quad (28)$$

E_{solute} can be obtained via ab initio MO calculations as follows:

$$E_{\text{solute}} = \sum_{a>b} \frac{Z_a Z_b}{R_{ab}} + \sum_{ij} \gamma_{ij} h_{ij} + \frac{1}{2} \sum_{ijkl} \Gamma_{ijkl} \langle \phi_i | g_{kl} | \phi_j \rangle, \quad (29)$$

where h_{ij} and $\langle \phi_i | g_{kl} | \phi_j \rangle$ are one- and two-electron integrals, respectively. Z_n (with $n = a, b$) and R_{ab} denote the nucleus charge of the atom n and the distance between these atoms, respectively. Further, γ and ϕ_j are the density matrix and an atomic basis function, respectively. Singer and Chandler (1985) introduced $\Delta\mu$ as follows, assuming the HNC approximation as the closure:

$$\begin{aligned} \Delta\mu &= -\frac{\rho}{k_B T} \sum_{\alpha,s} \int d\mathbf{r} \left(c_{\alpha s}(r) - \frac{1}{2} h_{\alpha s}^2(r) + \frac{1}{2} h_{\alpha s}(r) c_{\alpha s}(r) \right) \\ &= -\frac{\rho}{k_B T} \sum_{\alpha,s} \int d\mathbf{r} \left\{ e^{-\frac{1}{k_B T} u_{\alpha s}(r) + t_{\alpha s}(r)} - 1 - t_{\alpha s}(r) - h_{\alpha s}(r) t_{\alpha s}(r) + \frac{1}{2} h_{\alpha s}^2(r) \right\} \\ &\quad - \frac{1}{(2\pi)^3 k_B T} \int d\mathbf{k} \left\{ -\sum_{\alpha,s} \hat{c}_{\alpha s}(k) \rho \hat{h}_{\alpha s}(k) + \frac{1}{2} \sum_{\alpha,\gamma,s,s'} \hat{c}_{\alpha s}(k) \hat{c}_{\gamma s'}(k) \hat{\omega}_{\alpha\gamma}(k) \hat{\chi}_{s s'}(k) \right\}. \end{aligned} \quad (30)$$

Here, Greek subscripts represent the solute site, while s and s' denote solvent sites. $u_{\alpha s}$ is the interaction potential between the solute and solvent sites, α and s , respectively. The potential $u_{\alpha s}$ may, for example, be given as a sum of the Coulomb interaction between partial charges and the Lennard–Jones potential between two sites:

$$u_{\alpha s}(r) = \frac{q_\alpha q_s}{r} + 4\varepsilon_{\alpha s} \left\{ \left(\frac{\sigma_{\alpha s}}{r} \right)^{12} - \left(\frac{\sigma_{\alpha s}}{r} \right)^6 \right\}, \quad (31)$$

where ε and σ are the Lennard–Jones parameters and q_x with $x = a$ and s is the partial charge on site x . The solute partial charge q_α is determined by:

$$q_\alpha = \sum_{ij} \gamma_{ij} \langle \phi_i | b_\alpha | \phi_j \rangle. \quad (32)$$

We note that q_α depends on the solute charge distribution. In this expression, b_α is an operator to estimate the partial charge, which is called the electrostatic potential (ESP) fitting. A least-square fitting process is carried out to reproduce the ESP created by the solute electrons on the solvent molecules. Thus, q_α changes with a changing solvent environment.

So far, we have treated mainly RISM–SCF theory; extensions of this theory to incorporate 3D-RISM and MOZ formulations, i.e., 3D-RISM–SCF and MOZ–SCF, have also been proposed. Recently, such frameworks have been extended to treat the electronic structure and the solvation effects of biomolecules, such as proteins and DNA. To estimate the electronic structure of biomolecules, QM/MM theory can be employed (Gao 1996).

In a general QM/MM method, the reactive moiety of proteins, for example, is treated by QM, and the other sites are treated by MM. Solvents are handled by MM or are approximated by the continuum model. Yoshida et al. (2011) proposed the QM/MM/RISM theory, where a QM/MM method is combined with the 3D-RISM–SCF theory. In this procedure, the macromolecule is treated with QM/MM and the solvent is treated using 3D-RISM, respectively. The electronic structure, which is calculated by QM, and the solvent distribution are determined self-consistently, as is done in the 3D-RISM–SCF theory.

A fragment molecular orbital (FMO)/3D-RISM method has been proposed, where the 3D-RISM–SCF theory and the FMO method are combined (Yoshida 2014). The FMO method allows us to evaluate the electronic structure of whole macromolecules by fragmentation of the molecule (Kitaura et al. 1999). Such an attempt to apply the FMO/3D-RISM method to biomolecules is expected to be developed further, along with significant upgrades of related theoretical methodologies.

To conclude this section, we show an example of recent theoretical explanation for experimental spectroscopic results. Experimentally, absorption and fluorescence spectra of an organic dye molecule can be measured as a function of the solvent polarity. The difference of the absorption and fluorescence spectra, or Stokes shift, is correlated with the solute dipole moment, which has been known as the Mataga–Lippert equation for about 60 years (Lippert 1955; Mataga et al. 1955). With the aid of RISM–SCF theory, the correlation is rationalized in terms of the solute electronic structure and the precise distribution of solvent (Nishiyama et al. 2012, 2013). Specifically, it was found that the solvent located in close vicinity of the solute (0.4 nm) significantly contributes to the Stokes shift, whereas solvent in the second solvation shell (2 nm) plays an important role in solvent rearrangement.

Moreover, using the RISM–SCF theory it was possible to reproduce the Stokes shift of particular solvents, such as tetrahydrofuran, where conventional theory using a continuum model was unable to explain the experimental data. To date, the Mataga–Lippert equation has been employed by numerous experimentalists to estimate the solute dipole moment in the photoexcited state, because of its simplicity and intuitive understanding. Therefore, the RISM–SCF theory fulfills the requirements from experimentalists in an adequate format. As another example, the

3D-RISM theory yielded clear descriptions of the distinct ion-binding modes and reinforced the proposed mechanisms based on the experimental observations.

Solvation of Biomolecules

Biomolecules are, nearly without exception, surrounded by water. This fact is essential for biomolecules to retain their structure and to perform their biological functions. Therefore, information on the solvation structure or, more specifically, the hydration structure of biomolecules is critical to understand their structures and functions. Recent developments in the statistical mechanics of the liquid phase represented by the 3D-RISM theory have been dedicated to the elucidation of solvation structures of biomolecules (Hirata 2003; Yoshida et al. 2009). Such attempts can also be applied to the analysis of biological functions. In this section, we introduce very recent research on molecular recognition using the latest developments based on statistical mechanics.

When applying the 3D-RISM theory to treat solvated biomolecules, the biomolecules are regarded as “solute molecules” surrounded by “solvents,” i.e., water molecules and ions. As has been mentioned earlier, the 3D-RISM theory yields what chemical species are distributed around what specific atoms or moieties of the particular biomolecule and to what extent. As input for such a calculation, we have to provide a solute–solvent pair correlation potential, the solvent density, and the temperature.

Figure 2 shows ion distributions of the human lysozyme mutant, determined by the 3D-RISM theory (Yoshida et al. 2006, 2007a). This theoretical result corresponds to the experimental study by Kuroki and Yutani (1998). The comparison establishes that 3D-RISM theory is able to predict the selective ionic bonds for proteins, where ions are located in a highly anisotropic environment. It is

Fig. 2 Position of Ca^{2+} binding site of the Q86D/A92D mutant of human lysozyme determined using X-ray crystallography (Kuroki and Yutani 1998) and 3D-RISM theory (Yoshida et al. 2006) in the *left* and *right* panels, respectively

noted here that these results could not be found by a simple electrostatic field approach. Because the ion recognition by protein or, more commonly, the molecular recognition by protein is a thermodynamic process which is derived by a free energy change due to the recognition. Not only direct electrostatic interactions between protein and ion but those between protein–water and ion–water and also the entropy change and the reorganization of the solvent distribution should be considered. For example, the A92D mutant of the human lysozyme shows greater affinity to Na^+ than to Ca^{2+} , in spite of its smaller charge. This may be because Ca^{2+} suffers a greater dehydration penalty upon binding compared with the case of Na^+ .

Another application example of the 3D-RISM theory is ion permeation of the KcsA channel. The KcsA channel is a channel protein derived from bacteria, which functions as a control of K^+ concentration inside the cell. The KcsA channel has an excellent selectivity for K^+ to permeate through the channel, even though concentrations of Na^+ on both sides of the cell are very large (Hill 2001).

Experiments in 2009 indicated that these ions, K^+ and Na^+ , have different distributions or bonding modes (Thompson et al. 2009). Figure 3 shows the distributions of ions inside the KcsA channel obtained using the 3D-RISM theory, which properly reproduces the experimental results (Phongphanphanee et al. 2014a, b). Furthermore, the theory determines the water distribution in the channel, which provides the Li^+ and K^+ distributions in more detail. In the stable structure, Li^+ takes a six-coordinated structure: four carbonyl oxygens are coordinated in a square geometry and two waters are in the above and below positions. In contrast, K^+ is not in immediate contact with water molecules; this ion is positioned in the center of a cage provided by eight carbonyl oxygens. The predicted bonding modes for these ions correspond well with experimental and simulation results.

The 3D-RISM theory has also been used to describe the molecular recognition processes of various biomolecules, such as the escaping process of carbon monoxide from myoglobin (Kiyota et al. 2009), proton exclusion mechanism of aquaporin (Phongphanphanee et al. 2008), and proton permeation mechanisms at the M2

Fig. 3 K^+ position in the KcsA channel taken from the experimental result (Zhou et al. 2001) is presented as the *purple spheres* in the *left panel*. The isosurface plot of the ion distributions of K^+ and Li^+ evaluated by 3D-RISM theory are colored by *green* and *red* in the *center* and *right panels*, respectively

channel of influenza A (Phongphanphanee et al. 2010). In addition to small molecules such as water and ions, the theory can also be applied to realistic drug recognition (Imai et al. 2009; Kiyota et al. 2011).

In the example mentioned above, the 3D-RISM calculations were performed based on the static X-ray structure of protein. For a large biomolecule, the effects of the dynamics and fluctuations of the molecular structure may be far from negligible and need to be considered. In order to include the effects of fluctuations of the protein structure, a combination of 3D-RISM with molecular dynamics (MD) simulation has been proposed, which may reveal more detailed information on solvated biomolecules for a larger variety of systems (Luchko et al. 2010; Miyata and Hirata 2008; Miyata et al. 2010, 2011). In the proposed methods, the multiple time step technique has been employed to reduce the computational cost. More recently, Omelyan and Kovalenko (2015) developed an efficient hybrid algorithm employing a generalized solvation force extrapolation approach to accelerate the multiple time step MD. With this method, the folding of a miniprotein, starting from a fully denatured state, could be simulated successfully.

Another way to take into account the fluctuation of the structure of a solvated protein has been proposed by Kim and Hirata (2013). In this method, the fluctuations of the protein, coupled with that of the solvent, is treated using methodologies based on the generalized Langevin equation and 3D-RISM theory with the aid of linear response theory.

Relying on these methods, it may be soon possible to treat biological events accompanied with large structural changes of protein molecules computationally.

Summary and Future Perspective

In this chapter, we have outlined the development of a theoretical treatment to describe molecular liquids and assemblies based on statistical mechanics. The theory of molecular liquids has been developed to cover the wide area of physics, chemistry, and biology.

Examples of the application of this theoretical description include chemical reactions in solution (Sato 2013). The treatment of chemical reactions in solution has been developed successfully in the last decades by combining electronic structure theory and the molecular theory of liquids. The recent progress in theoretical methods enables a detailed explanation of novel phenomena that have been found by experiment, by including a molecular view of individual molecules participating in the reaction.

Another important aspect of the recent molecular theory should include the description of biological processes (Yoshida et al. 2009). To our knowledge, the 3D-RISM theory is one of the most developed and practical frameworks among the theoretical procedures available so far that can be applied to biological processes taking place in solution.

In the future, further close collaborations between experimentalists and theoreticians will be required to discover and analyze novel phenomena. We believe that

such collaborations among scientists in the field of solution chemistry and physics and bioscience will be extremely fruitful. One may also envisage that current attempts of theoretical development may be used to solve social problems we are facing currently, such as energy problems, environment, and food problems.

Abstract

This chapter reports experimental investigations and theoretical approaches devoted to analyze the electronic, optical, and vibrational properties occurring in semiconducting photoactive materials in their bulk form or as nanosized objects. An original cluster approach was developed to describe the physical features of nanoparticles and the impact of their surface on photoinduced charge transfer phenomena.

Photovoltaic and photocatalysis are two major applications for both clean environment and sustainable sources of energy as well. In this context, semiconducting nanocrystals from defined oxide families have attracted increasing interest during the last decade for their promising potential in renewable energy applications because of their versatile and coupled optical and electronic properties. More specifically, the semiconductor oxides as titanium oxide and bismuth vanadate-based materials can be tailored in nanosized and mesoporous structures. The electronic and optical features may be modulated in large extents when dye molecules are used as sensitizing vectors enhancing the efficiency of solar cells, energy storage, and photocatalyst. These applications depend on the reactive surface area, morphology and nanostructuring, doping and sensitizing agents, as well as controlled vacancy rates acting on the charge transfer peculiarities.

In parallel to experimental investigations dedicated to selected forms of photoactive semiconducting oxides, original theoretical approaches were developed to analyze the key features of the considered functional systems. Using an integrated approach associating theoretical models and numerical simulations, the influence of the size and morphology of nanoparticles on their electronic and optical properties was pointed out. The cluster approach methodology was developed to simulate the electronic properties of semiconducting nanocrystalline materials as isolated objects or functionalized by organic dye molecules. The construction of the system proceeds by the crystal structure frozen in the cluster core while the surface is modified according to the environmental interactions. Theoretically, it was proved that nanostructures exhibit patchwork properties coming from the bulk material including core crystal structure and from surface effects caused by environment. On the other hand, the role of doping of the considered structures by metallic elements was investigated on the photoactivity mechanism involved in nanoparticles. The nature of vacancies located close to the dopants plays a crucial role on the electronic and optical features in the photoactive materials. Thus, the theoretical approaches and the carried out numerical simulations contribute to draw quantitative insights of the physical properties of functional semiconducting oxides in agreement with relevant experimental analyses.

Introduction

Photoactive semiconducting oxides are subject of intensive investigations during the last two decades with a major aim to realize active media for photovoltaic and photocatalytic processes. The applications concern important societal challenges, such as green energies based on alternative and nonfossil resources and environmental problems related to water and atmosphere purification and preservation. Particularly, hydrogen production from water dissociation and depollution of environment from contaminants are major concerns of the twenty-first-century society. Increased industrial activity due to the emergence of new economic powers along with important demographic pressure contributes to high energy demand. Average estimates indicate energy resources exploited nowadays consummate around 80 % from nonrenewable energy origin even if the part of other energy sources (solar, wind) increase continuously in industrial countries during the last 20 years. Similarly, the improvement of living conditions in emerging countries through technological developments requires an increasing energy demand and water consumption. It is obvious that the factors listed above (water, energy, industry, demography, development) generate an impact on the environment. The increasing air and water pollution is a crucial health and societal problem which requires control and regulation and then the societal issues must find upstream solutions to prevent crises. Beyond the precautionary principles and good practices from the societies, scientific approaches at large scale should be conducted to support changes in the demand for energy and environmental preservation required for suitable evolution of the human life standards.

In this context, the scientific activity related to photocatalytic processes has been exploited intensively for more than two decades in the active research area dealing with energy and environment. In particular, harvesting efficiently the solar spectrum in the visible light-driven photocatalysis is subject of important developments to create photoactive materials with an implementation of experimental protocols devoted to increase the efficiency of the photocatalysts. These mechanisms may be applied to the production of clean energy sources such as hydrogen production obtained by water splitting. They also apply to the degradation of organic pollutants or bacterial organisms that can affect water reserves or some critical atmospheres as required in medical environments. Other large-scale applications of photocatalytic reaction principles were tested on road surfaces containing photocatalysts to destroy polluting gases such as oxynitrides or hydrocarbons. These examples demonstrate the wealth of applications that rely on photocatalysis from the point of view of the active material designs as well as for the optimization of photocatalytic reactions. Among the wide classes of active materials, two families of semiconducting oxides are worthy of interest and were subject of important developments. They are

related, on the one hand, to titanium dioxide (TiO_2) materials as pure or associated with organic or inorganic components following the searched applications from photovoltaics or photocatalysis. On the other hand, bismuth vanadate (BiVO_4) and related structures are emerging smart materials for photocatalysis.

The experimental developments on such classes of photoactive materials are supported by theoretical and numerical models able to predict and analyze quantitatively the experimental properties of bulk and nanosized materials from charge transfer peculiarities to optical absorption and structural organization. Original approaches were developed on clusters with different size giving rise to behaviors related to molecular scales, nanosized clusters, or to macroscopic media. For photovoltaic or photocatalytic processes activated by light irradiation in semiconducting materials, the phenomena of charge transfer and the optical absorption features are of primary importance, and the simulation methods can contribute to shed light on the strength of the phenomena and orient the ways of their optimization. For such approaches, quantum chemistry codes and software packages based on quantum mechanics are active and hot topics for the simulations in material sciences. The density functional theory (DFT) method is an efficient tool to predict the physical properties of materials. The built of realistic geometries of the materials, the optimization of the structures and atomic position, as well as the evaluation of the related properties by DFT approach are currently applied to wide classes of functional materials including semiconducting photoactive media.

Several models were explored on selective classes of photoactive materials such as TiO_2 , BiVO_4 , and NiTiO_3 dedicated to photocatalysis and photovoltaic applications. For titanium dioxide structures, original theoretical studies have been realized to model anatase structure of nanocrystals with sizes ranging from 0.7 nm up to 2.0 nm organized as $(\text{TiO}_2)_n$ clusters. Also, the systems like BiVO_4 or close ones as NiTiO_3 were modeled by applying the cluster approach developed in our previous work (Makowska-Janusik and Kassiba 2012). For the nanostructures, the influence of surface and environment at their electronic properties was studied. Similar theoretical and numerical modeling studies were applied to predict and describe quantitatively the key physical properties of BiVO_4 and NiTiO_3 . Numerical approaches based on cluster model and quantum-chemical calculations were implemented to explain the electronic properties of nanoparticles and to elucidate the influence of surface effects on photocatalytic-driven mechanism such as charge transfer. The developed approaches are emanating from former works developed on bulk BiVO_4 structures leading to their electronic properties (Walsh et al. 2009; Yin et al. 2011; Cooper et al 2014; Ma and Wang 2014).

The implemented theoretical approach applies to model the features of mesoporous structure offering high specific surfaces which enhance photocatalytic and photovoltaic properties. The experimental investigations ensuring the synthesis of such structures and the evaluation of related vibrational, electronic, and optical features are confronted to the predicted properties obtained by numerical simulations.

Experimental Insights on Materials and Related Features

Titanium Dioxide (TiO₂)

Photoactivity of Titanium Dioxide

Among the efficient materials for their photocatalytic applications, titanium dioxide (TiO₂) is undeniably the most known and investigated. The green energy such as hydrogen production and the new generation of solar cells as well as the photocatalysis dedicated to the preservation of the environment have been massively exploiting active materials based on TiO₂. Particularly, photovoltaic applications were investigated using TiO₂ in its pure or doped forms by metallic or nonmetallic ions or alternatively associated with other components including metallic clusters or organic groups. Various morphologies were considered such as micrometric or nanometric powders (Ishigaki et al. 2003), mesoporous structures or photoactive gels (Pattier et al. 2010), and thin films (Nam et al. 2004) or nanocomposites. The morphology and structural organization of titanium dioxide plays key roles on its electronic and optical features and was concerned by exhaustive investigations by a large scientific community. Thus, nanostructured titanium oxide as thin films, nanoparticles (Reyes-Coronado et al. 2008), or mesoporous organizations (Kassiba et al. 2012) were realized with the relevant parameters leading to the requested structural organization (rutile, anatase, amorphous), morphologies (nanoparticles, nanodots, nanotubes), as well as self-assembled media with controlled porosity. The functionalization of titanium dioxide surface by active vectors was realized in order to improve the photovoltaic performances of devices based on such class of composites (Melhem et al. 2013). However, such elaboration processes are relevant to graft other functional groups on high specific surface materials. This is the case of hybrid networks composed by inorganic nanocrystals – polymer blend for new generation of hybrid solar cells (Lin et al. 2009). Other structures based on titanium oxides were also considered to improve the photo-conversion efficiency by high specific surfaces between the active components of solar cells (Hwang et al. 2009). Thus, sol–gel batches based on titanium oxide gels (Pattier et al. 2010) were realized, and their photoactivity under UV was investigated in the aim to realize new generation of hybrid solar cells. Nevertheless, despite the major limitations of TiO₂ due to a wide band gap (3.2 eV), large-scale applications have been conducted and extensively used as appropriate structures for photovoltaic and photocatalysis. For applications, the photoactivity enhancement can be achieved by mechanisms as doping by metallic or nonmetallic ions able to modulate the electronic structure. The combination of TiO₂ in composites with semiconductor structures such as ZnO (Chandiran et al. 2014) and CdS (Biswas et al. 2008) has been made, and the photoinduced effects were compared to those involved in pure materials. However, even with an increase in the efficiency by such experimental modifications, the UV radiation required for the photoactivity is costly,

and it is necessary to develop alternative media with visible driven photoactivity or for high-efficient solar cells. Also, the well-known chemical procedure based on dyes sensitized solar cells (DSSC) has created the most investigated systems based on TiO_2 and offers the best efficiency compared to heterostructure-based devices. Other hybrid nanostructured architectures were realized by using titanium dioxide and graphene to ensure challenging energy sources in new-generation of Li-ion batteries (Wang et al. 2014). Recently other approaches have created oxygen-deficient titanium dioxide associated with conjugated polymer. The realized functional media shows a noticeable improvement of efficiency of the based solar cell and the optoelectronic device such as OLEDs.

In addition to these structural or composition of the functional materials based on titanium dioxide, the doping process is worthy of interest to modulate the electronic and optical responses of the materials. Also, several strategies were used for doping with metallic (Fe, Ag, Mo, Eu, etc.) or nonmetallic elements (N, C, etc.). Exhaustive investigations of the doping effects were carried out to analyze the electronic, optical, and magnetic features of the substitutional ions and to identify their local environments and the quality of their distribution in the host titanium dioxide structures. Such studies have been made on mesoporous architectures where several chemical reactions were also involved and catalyzed by oxygen being adsorbed in voids or incorporated in the bulk as anti-sites. This contributes to create new electronic states allowed in the band gap of the doped material and were discussed in several works as illustrated in the forthcoming part. However, instead of the doping effect, electronic and optical features of photoactive gels composed by titanium oxide can be also modified by UV irradiation leading to photoinduced electrons localized as Ti^{3+} centers (Pattier et al. 2010). The mechanism of the Ti^{3+} formation is well described by a series of reactions starting by the creation of a photoinduced electron–hole pairs. This process makes titanium oxide as efficient as dye sensitized one and can be also as crucial as doping agents may do on the electronic behavior. Such photoactive media ($\text{Ti}_i^{4+} \xrightarrow{h\nu} \text{Ti}_i^{3+}$) was tested for new generation of solar cells (Pattier et al. 2010). The experimental investigations need quantitative analysis by using theoretical and modeling approaches in order to improve the photovoltaic or photocatalytic activities based on doped titanium dioxide-based materials (Makowska-Janusik et al. 2014). Several theoretical works have focused on the study of the electronic and optical features of titanium oxide possessing different stoichiometry and applying different computational approaches. The performed numerical simulations deal mainly with the electronic properties of the infinite crystal (Stausholm-Møller et al. 2010). Other performed approaches consider titanium oxide clusters with sizes up to 1–2 nm possessing crystalline core structure emanating from anatase or rutile (Makowska-Janusik et al. 2014). In all cases, the surface structure, morphology, and organization are inherent problem in numerical simulations on nano-objects with regard to their key role on the predicted properties.

Synthesis of Mesoporous TiO₂ Material and Selected Investigations

The synthesis of mesoporous TiO₂ is dedicated to create high specific surface. Titanium oxide-based mesoporous structures were synthesized by using the sol-gel method (Kassiba et al. 2012; Mei et al. 2010) with precursors as titanium tetraisopropoxide and thiourea for nitrogen doping. Surfactants as pluronic P123 are usually used to realize porous (structured) titanium dioxide with or without nitrogen doping. The materials can be obtained in the form of mesoporous powders or thin films. The as-formed systems were submitted to annealing treatments at temperatures up to 500 °C in order to improve the crystalline structure of the titanium dioxide with a stable polytype such as anatase.

The experimental investigations were carried out to identify the crystalline structures involved at defined synthesis conditions and after treatments by using X-ray diffraction and particularly wide-angle X-ray scattering (WAXS) technique well adapted for mesoporous structures. The major information concern also the porosity features and in the case of doped structures the doping efficiency through the location of substitutional ions in the crystalline sites of the host structure. In this aim, electron paramagnetic spectroscopy (EPR) is a relevant technique to characterize the active electronic centers in mesoporous structures. Beyond to identify the nature of the active centers, EPR informs on the local environments of doping agents and their electronic, optical, and magnetic properties. The microstructure of the samples plays a key role in the stability of the paramagnetic centers and their incorporation in the network (gel, mesoporous) (Pattier et al. 2010; Kassiba et al. 2012). Thus, comparative investigations performed on mesoporous materials inform on the efficiency of the doping process and on the concentration and nature of the involved oxygen-based radicals and vacancies. The large specific surfaces of these nanostructured systems enhance the concentration of oxygen- or nitroxide-based radicals and contribute to lower the doping efficiency.

X-ray diffraction measurements were conducted on TiO₂ powders with porous morphologies (structured) or without pores (nonstructured) with or without doping. Figure 1 (top) shows WAXS patterns recorded on nonstructured samples with and without nitrogen doping (N-TiO₂-400-4.5 and TiO₂-400-4.5); the samples were annealed at 400 °C during 4.5 h under air (Mei et al. 2010). The analysis of the diffraction line features by using the MAUD software program (Ferrari and Lutterotti 1994) evaluates the involved crystalline polytypes and their respective fractions. The structural investigations reveal the role of the doping and the morphology (structured or nonstructured) on the stabilized crystalline polytypes. Thus, the appropriate annealing conditions have been defined at 500 °C during 12 h to realize pure anatase structure with suitable substitutional doping in the crystal sites. In this case, the same WAXS patterns show similar crystalline features whatever the samples such as structured or not and doped or free from any doping agents.

Fig. 1 WAXS patterns showing the involved crystalline structures in nonstructured TiO₂ samples (*top*) with nitrogen doping or without (*:anatase, +: rutile, ⊠: brookite) and in mesoporous sample (*bottom*) doped with nitrogen and annealed for 4.5 h at 400 °C

Sol-gel method and spin-coating technique were used to realize mesoporous thin films (Pattier et al. 2010; Pattier 2010). The structural analysis can be made by X-ray reflectivity which informs on the ordering of pore lattices as a function of the thermal treatment of the films. Thus, characterizations by X-ray reflectivity were performed on mesoporous samples as a function of their annealing temperature and the time duration of this process. The existence of ordered porous structure

Fig. 2 X-ray reflectivity measurements performed on thin films of mesoporous TiO_2 with nitrogen doping. The organization of the pores is uniform at defined annealing temperature and time duration. The period of the pore on the layer changes from 10.9 nm for the as-formed sample to 5.4 nm in mesoporous film annealed at 400°C during 30 min (Pattier et al. 2010)

is demonstrated as well as the evolution of the pore sizes with the annealing conditions (Fig. 2). Evaluations of the pore sizes were obtained by adjusting the X-ray reflectivity curves. The pore size was estimated to 10.9 nm in the as-formed sample and change to 5.4 nm when the annealing is performed at 400°C during 4.5 h. This behavior is well understood by the contraction of the porous phase after extraction of the surfactant by annealing (Pattier et al. 2010; Kassiba et al. 2012).

When doping is performed, the location of the substitutional ions in defined crystal sites or alternatively the existence of clusters or aggregates made from doping species can be identified by EPR. Such experiments were carried out to analyze the nitrogen doping from thiourea precursors as well as all active electronic centers (oxygen radicals, titanium ions, nitro-oxide radicals, etc.) which can contribute to the conductivity or act as traps for charge carriers. For the considered mesoporous structures, the existence of high specific surface favors the location of doping elements at the surface. Thus, Fig. 3 shows the EPR spectra recorded on the mesoporous samples and nonporous samples, annealed under air or argon at 400°C during 30 min. These experiments show that the atmosphere has a drastic effect on the nature of involved paramagnetic centers. Instead of the observation of nitrogen radicals, a variety of paramagnetic species, e.g., O_2^- , O_3^- , NO , Ti^{3+} , was demonstrated. However, the nature of paramagnetic radicals and the role of the annealing temperatures and its duration were clarified on the considered N- TiO_2 -doped samples. The nitrogen doping is effective but without to be incorporated in oxygen sites. Resolved signals implying nitrogen was observed for mesoporous samples annealed at 500°C during 12 h with the formation of NO radicals located on the surface of the porous structure. For nonporous samples, the paramagnetic species such as oxygen radicals were suppressed for the same

Fig. 3 EPR spectra of N-TiO₂ samples annealed at 500 °C. Nitrogen ions are substituted in the crystalline sites of TiO₂ only for samples without porous structures (a-experiment, b-simulation). For the porous one, only surface (NO)* radicals dominate the paramagnetic species behind the observed EPR signal (c-experiment, d-simulation)

treatment (500 °C, 12 h) with the formation of nitrogen radicals (N^{*}). The developed EPR signal which appears after annealing is characterized by narrow lines (Fig. 3) which indicate well-crystallized sites around the nitrogen ions. Thus, only in the case of nonstructured (nonporous) TiO₂, nitrogen ions are indeed incorporated in the bulk structures as substitutional species. This contrast with the observations on structured (mesoporous) samples where nitrogen remains associated with oxygen as NO radicals located on the pore surfaces. As a matter of fact, doping with nitrogen is inefficient in mesoporous structures due to the tendency of doping ions to migrate at the outermost pore surfaces.

The applications of titanium dioxide-based structures in photovoltaic devices or for visible light-driven photocatalytic reactions require appropriate electronic structure and band gap leading to maximum absorption of the solar spectrum. Intrinsically, TiO₂ possesses wide band gap (3.1–3.2 eV) and only UV radiation can contribute to create photoinduced charge transfers from valance to conduction band. The electronic structure of TiO₂ crystalline structure is characterized by O-2p orbitals which form the valence band, while Ti³⁺ (3d¹) states form the conduction band. In nitrogen-doped samples, it was shown from former work (Melhem et al. 2013) that reduction of the band gap occurs and a spectral extension of the

absorption of solar radiation. Quantitative analysis is outlined in the theoretical approach developed below and supported by numerical simulations.

BiVO₄ Nanostructures for Photocatalysis

The semiconducting oxide BiVO₄ Bismuth vanadate (BiVO₄) is currently a subject of intensive investigations devoted to create several morphologies such as nanoparticles, thin films, or composites associating metallic clusters. As thin films, BiVO₄ represents an ideal photo-anode with a high quantum efficiency in the decomposition of water and hydrogen production (Kim and Choi 2014). The application as photocatalyst is also a very active research area, for example, in water depollution from organic contaminants (Wang et al. 2012). The realization of nanostructures with large specific surfaces by using suitable deposition conditions of *rf*-sputtered films or by the growth of mesoporous architectures or nanoparticles are well-improved approaches. The synthesis methods and annealing modify in a large extent the structural and morphological characteristics of the BiVO₄ (Venkatesan et al. 2012). The physical properties can be modulated by several procedures to enhance the efficiency of the reaction mechanisms in visible light-driven photocatalytic processes or for photovoltaic conversion based on the photoinduced charge transfers (Zhang et al. 2007; Yu and Kudo 2006; Ng et al. 2010). Indeed, the efficiency of the phenomena depends on the charge densities involved in the semiconducting structure, on the optical band gap, as well as on the lifetimes of photogenerated excitons. However, the intrinsic properties of BiVO₄ give rise to limited performances as, for example, in the photodegradation of organic molecules under visible light. A challenging strategy consists of doping the considered structures by suitable elements such as metallic ions incorporated in the structure or clusters contributing to realize composites with improved photocatalytic properties. Suitable doping was realized by using Cu, Mo, or other ions (Merupo et al. 2015a, b) as substitutional ions or using silver nanoparticles associated with BiVO₄ to enhance visible light photocatalytic degradation of organic dyes in aqueous solutions. Other complex BiVO₄-based materials were also realized to enhance the photoactivity by increasing the rates of photogenerated carriers as well as their lifetimes required for photocatalysis. Thus, nanostructured-conducting media such as graphene layers have been associated with BiVO₄ to limit the rate of recombination of photogenerated electron-hole pairs in water dissociation (Ng et al. 2010) or for degradation of organic dyes (Gawande and Thakare 2012). The association of TiO₂ and BiVO₄ with particular bridging agents was also investigated leading to remarkable photoactivity (Xie et al. 2015). In similar approaches, nanocomposites were also synthesized based on other oxides (Bajaj et al. 2013; Madhusudan et al. 2011).

The relevant methodology ensuring the best composition and features of the efficient photocatalysts based on BiVO₄ associates exhaustive experimental contribution for the synthesis and characterizations and theoretical approaches with numerical simulations to validate and analyze quantitatively the phenomena. The

developed numerical approaches were partially conducted in our former works devoted to functional semiconducting systems (Makowska-Janusik and Kassiba 2012). The methodology proceeds by modeling at macroscale the structural, vibrational, and electronic properties of bulk crystal. Prediction and quantitative description are achieved for the key physical properties of BiVO_4 . In the second step, numerical approaches based on cluster model and quantum-chemical calculations were implemented to explain the electronic properties including quantum confinement effects and related optical changes of nanoparticles and elucidate the influence of surface effects on photocatalytic-driven mechanism such as charge transfers.

Structural Properties of BiVO_4

BiVO_4 crystallizes in three main polytypes such as tetragonal zircon, monoclinic scheelite, and tetragonal scheelite structures. For applications in photocatalysis, it was shown that the monoclinic structure offers the best photocatalytic efficiency (Merupo et al. 2015b; Venkatesan 2014). On the other hand, the specific surface of nanomaterials is an important parameter which acts on the reaction area at the interfaces between the photocatalysts and its reactive environment.

Suitable methods for the synthesis of BiVO_4 were developed including ball milling or hydrothermal for micro- and nanosized particles as well as *rf*-sputtering for thin films with nanostructured surface profiles. For ball milling technique, mechanochemical processes were carried out with initial pure reactants Bi_2O_3 and V_2O_5 . Suitable operating conditions were chosen (time of reactions, speed of rotating reaction chambers, nature of the used grinding balls) to obtain homogeneous powders with defined stoichiometry and stable crystalline structure (Merupo et al. 2015b). An example of powder obtained by mechanochemical process during short milling time (6 h) is shown in Fig. 4 by field effect scanning electron microscopy (FE-SEM) (Venkatesan 2014). The microstructure exhibits individual aggregates made from small nanoparticles with sizes in the order of 20 nm.

Fig. 4 FE-SEM image of BiVO_4 powders obtained by ball milling

Structural investigations were carried out to identify the involved crystalline phase as a monoclinic scheelite in agreement with lattice parameters $a = 5.1950 \text{ \AA}$, $b = 11.701 \text{ \AA}$, and $c = 5.092 \text{ \AA}$ (JCPDS no. 14-0688) (Fig. 5). The vibrational properties give complementary information due to their sensitivity to local distortions of chemical bonding involved in defined environments of the materials. The investigations by Raman spectrometry determine the vibrational modes allowed by the symmetry of the crystal structure. The analysis of the corresponding Raman bands including their full width at half maximum (FWHM) or the shift of their wave number position are related to the quality of the crystalline order of the atomic environments submitted to stretching or bending. Thus, Raman active modes (Fig. 6) of monoclinic *clinobisvanite* bismuth vanadate are involved at wave number positions at $211, 327, 369, 710,$ and 831 cm^{-1} (Venkatesan et al. 2012). These active

Fig. 5 XRD pattern of ball-milled BiVO_4 , its refinement by Fullprof software is in agreement with the monoclinic scheelite structure according to the diffraction data reference (JCPDS no. 14-0688)

Fig. 6 Raman spectrum of BiVO_4 obtained by mechanochemical method

modes are associated with stretching and bending modes of VO_4 groups involved in the unit cell of the monoclinic BiVO_4 structure. The intense band at 831 and the weak shoulder at 710 cm^{-1} are assigned to the symmetric A_g and asymmetric stretching modes of VO_4 groups. The modes at 369 and 327 cm^{-1} correspond to the symmetric and antisymmetric bending modes for the vanadium oxide tetrahedrons. Such modes are sensitive to bond angles and length distortions within the VO_4 groups. The low wave number mode at 211 cm^{-1} is assigned to an external mode associated with Bi-VO_4 .

Electronic Active Centers of BiVO_4

The existence of high specific surfaces in the ball-milled synthesized powders and crystalline defects such as oxygen vacancies favor the appearance of active electronic centers. F -centers from electrons trapped in the vacancy sites or valence change of vanadium ions as V^{4+} ($3d^1$) play a crucial role on the photoinduced charge transfer process. Both centers are characterized by an effective electron spin $S = 1/2$ leading to an EPR signal which can be used to evaluate the nature of the center, its local environment, thermal stability, and behavior under light irradiation. For the ball-milled sample, the characteristic experimental EPR spectrum is reported in Fig. 7. The simulation of the experimental spectrum is made by superimposition of an EPR signal from isolated V^{4+} ions in orthorhombic local environments, while a second signal is related to vanadium clustering. These results are inferred from the magnetic interactions between close V^{4+} ions which alter the EPR line widths (FWHM) and average the anisotropy of the environments. Vanadium pairs or clustering of V^{4+} ions accounts for the EPR signal with the features of a broad background absorption line. The structured details observed on the EPR signal such as several sharp lines are emanating from isolated ions with anisotropic local environments (Venkatesan et al. 2013). In one hand, magnetic interactions are characterized by g -tensor reflecting an orthorhombic local symmetry around V^{4+} . This is understood by the occurrence of similar electronic structure and local environment of V^{4+} in the sample BiVO_4 irrespective to the sample microstructures.

Fig. 7 EPR spectra (experiment and simulation) related to isolated V^{4+} ions due to charge compensation from oxygen vacancies and from clustering of vanadium ions on the surfaces of BiVO_4 particles (Venkatesan et al. 2013)

The location of V^{4+} within crystal sites of the particle cores accounts for the experimental observations. On the other hand, the clustering of V^{4+} is probably involved at the outermost particle surfaces.

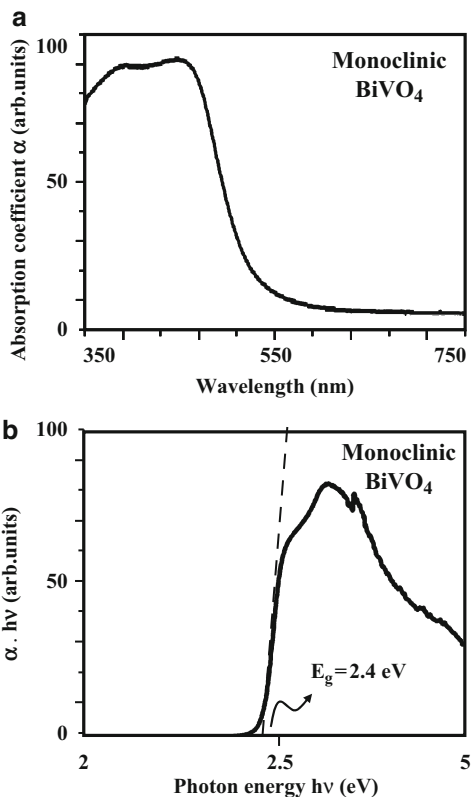

The exhaustive analysis of the magnetic interactions has been carried out in the former report (Venkatesan et al. 2013) and points out the high probability of occupation of excited orbitals of vanadium ions. The photoinduced charge transfer under light irradiation can be then favored and contribute to the efficiency of photocatalytic reactions which exploit $BiVO_4$ with such active electronic centers. Additional investigations have been carried out in order to characterize the evolution of the electrical conductivity in $BiVO_4$ samples with different microstructures as function of V^{4+} concentration which is found in the range 10^{16} - 10^{17} ion/gram. As the molecular bonding $V^{5+}-O^{2-}$ accounts for the charge carrier motions within the crystalline structure, the presence of high or low concentration of V^{4+} did not alter the effective conductivity. This fact excludes the possibility for such electronic active centers to act as trap for charge carriers. The photoinduced processes are expected to be enhanced in samples with higher concentration of V^{4+} ions.

Optical Behavior of $BiVO_4$

The optical absorption spectrum informs on the electronic structure and can be used to evaluate the band gap of materials. Previous theoretical investigations were developed on $BiVO_4$ which possesses the features of direct band gap with the extreme of the valence (VB) and conduction band (CB) away from the center of the Brillouin zone (Walsh et al. 2009). Indeed, electronic band structure calculations demonstrate the occurrence of direct transitions between VB and CB at the Brillouin zone boarder, i.e., at the Z point associated with (0.000, -0.500, 0.500) point. The electronic states which compose the valence band (VB) and the conduction band (CB) were identified. Thus, the contributing orbitals to VB consist in interacting of Bi (6 s) and O (2p) states. For the CB, the main contribution occurs from V (3d) orbitals which can interact with Bi (6p) and O (2p). The optical band gap is then defined by transitions between (VB) and (CB) with finite probability at the Z point.

The experimental investigations are traduced in Fig. 8 which reports the UV-vis absorption spectrum of $BiVO_4$ versus the photon energy. The photon absorption range indicates the possibility of investigated structure to act as visible light-driven photocatalyst. In order to evaluate precisely the electronic band gap, the so-called Tauc plot is usually exploited through the equation $(\alpha \cdot h\nu)^2 = C \cdot (h\nu - E_g)$ where α , C , and E_g represent, respectively, the absorption coefficient, a proportionality constant, and the direct band gap energy. The asymptotic extrapolation of the plot with the photon energy ($h\nu$) axis gives the direct band E_g with a good approximation. By this representation we evaluate the band gap of the considered ball-milled powder with the monoclinic sheelite structure of $BiVO_4$ to $E_g = 2.40(5)$ eV. It is worth to notice that the optical behavior depends on the microstructure of the material, on its crystalline order, and on the eventual electronic active centers as discussed above notably for V^{4+} . Annealing treatment of the powders at temperatures up to 500 °C is relevant. As an example, as-formed milled powder and

Fig. 8 (Top) Experimental UV–vis optical absorption spectrum of ball-milled powders of BiVO_4 . (Bottom) Tauc plot allows determining precisely the direct band gap of the sample

that obtained after annealing show different absorption edges of the BiVO_4 (Fig. 9) with a net tendency to lower the band gap for annealed samples. These experimental results will be discussed based on the theoretical calculations developed for the mentioned materials.

Theoretical Background

Modeling of Crystalline Structures: Preamble

Theoretical models and numerical simulation programs were extensively developed in the last decades with the aim to describe the physical properties of semiconducting materials and to offer qualitative and quantitative supports for experiments. These approaches are used to predict physical properties (electronic, optic, magnetic, etc.) in a wide class of functional materials. In this context, electronic band structures have been evaluated, and several models were developed to ensure the calculations within reasonable time duration of the required computational

Fig. 9 Optical absorbance spectra of ball-milled BiVO₄ with different milling times modifying the microstructure (Venkatesan 2014) and after post-annealing treatment (A). Annealing contributes to widen the absorption band to higher wavelengths (lower band gap)

operations. In all situations, the starting point deals with the Hamiltonian describing mutual interactions between electrons and nuclei and summarized as follows:

$$\begin{aligned}
 H = & \sum_i \frac{p_i^2}{2m_i} + \sum_j \frac{p_j^2}{2m_j} + \frac{1}{2} \sum_{i,i'} \frac{e^2}{4\pi\epsilon_0 |r_i - r_{i'}|} - \\
 & - \sum_{i,j} \frac{Z_j e^2}{4\pi\epsilon_0 |r_i - R_j|} + \frac{1}{2} \sum_{j,j'} \frac{Z_j Z_{j'} e^2}{4\pi\epsilon_0 |R_j - R_{j'}|}
 \end{aligned}
 \tag{1}$$

where r_i and $r_{i'}$ indicate the position of the i -th and i' -th electron, R_j and $R_{j'}$ are the positions of the nucleus, Z_j denotes the atomic number of the nucleus, and p_i , p_j are, respectively, the momentum operators of the electrons and nuclei. However, as written, the eigenstates and eigenvalues of such Hamiltonian cannot be found simply and same approximations must be introduced to solve the problem. One of the approaches consists of separation of the electrons into the core and valence parts with the possibility to frozen the first one.

The frozen-core approximation is thus fundamental in the pseudopotential approach. In this frame, the introduced pseudopotential reproduces the true potential outside the core region (valence electrons) while smoothing of such potential for the core electrons inside some defined radius and contributing then to eliminate the oscillations of the electron wave function inside the core region. According to norm-conserving condition, the pseudopotential $V_i(r)$ can be composed by a long-range local part (V^{LR}) and a short-range semi-local one (V^{SR}) as follows:

$$V^{NC-PP} = V^{LR} + V^{SR},
 \tag{2}$$

where $V^{LR} = -(Z_v e^2)/r$ is a radial function, and the semi-local part is the deviation from the all-electron potential inside the core region. In the same context, the ultrasoft pseudopotential approximation (Vanderbilt 1990) uses more than one projector for each momentum and further smooth the electron wave function.

Within the Born–Oppenheimer approximation and for crystalline structure, the mean-field approximation should be implemented to solve the Schrodinger equation. In such approach, each electron feels the same average potential $V(r)$ and its Schrodinger equation takes the form:

$$\left(\frac{p^2}{2m} + V(r) \right) \Phi_N(r) = E_N \Phi_N(r), \quad (3)$$

where $\frac{p^2}{2m} + V(r)$ denotes one-electron Hamiltonian (H_{eI}) identical for all valence electrons. $V(r)$ possesses the symmetry of the lattice and contains both electron–electron and core–electron interactions. Additionally, the potential $V(r) = V(r + R_n)$ has periodicity of the lattice, where R is the lattice vector. Bloch theorem states that the eigenstates of a periodic Hamiltonian can be written as a product of periodic function with a plane wave of momentum k restricted to the first Brillouin zone (BZ).

The quantum-chemical calculations of the crystal structure are based on a supercell method. The wave function in periodic potential named as Bloch function is defined as (Payne et al. 1992):

$$\Phi_k(r) = \exp(i\mathbf{k} \cdot \mathbf{r}) u_k(r), \quad (4)$$

where $u_k(r) = u_k(r + R)$ is a periodic function with the translational period equal to R as it was mentioned for the potential $V(r)$. As defined, the plane wave character of the wave function is seen with an amplitude modulated by the periodic function $u_k(r)$. Therefore, the wave function satisfies:

$$\Phi_k(r + R) = \exp(i\mathbf{k} \cdot R) \Phi_k(r) \quad (5)$$

Since the $u_k(r)$ has the periodicity of the lattice, it can be expanded in Fourier series:

$$u_k(r) = \sum_j A_j(j) \exp(iG_j \cdot r), \quad (6)$$

where A_j is the minimum translation vector and G_j is the reciprocal lattice vector.

When translation parameter T_R acts at the Bloch function:

$$T_R \Phi_k(r) = \Phi_k(r + R) = \exp(i\mathbf{k}R) \Phi_k(r) \quad (7)$$

This is an eigenfunction of the T_R with its eigenvalue equal to $\exp(i\mathbf{k}R)$. According to the commutator rules, the eigenfunction of the one-electron Hamiltonian (Eq. 3) may be defined as the sum of Bloch functions:

$$\Phi(x) = \sum_k A_k \Phi_k(x) = \sum_k A_k \exp(i\mathbf{k}x) u_k(x) \quad (8)$$

Thus the one-electron wave functions can be indexed by k , which are the wave vectors of the plane waves forming the “backbone” of the Bloch function. A plot of the electron energies in (Eq. 3) versus k is known as the electronic band structure of the crystal.

The electronic states for the crystal structure are calculated over the numbers of k -points. The symmetry considerations suggest that only k -points within the irreducible segment of the Brillouin zone should be taken into account (Srivastava and Weaire 1987; Payne et al. 1992). Using the mentioned method, it can be obtained an accurate approximation of the electronic potential and the total energy of an insulator by calculating electronic states at restricted number of k -points. The calculations for metallic systems require a more dense set of k -points to determine the Fermi level accurately. One of the most popular schemes for generating k -points proposed by Monkhorst and Pack (1976, 1977) produces a uniform grid along the three axes in reciprocal space. They defined a uniform set of special k -points as:

$$k = u_p b_1 + u_r b_2 + u_s b_3, \quad (9)$$

where b_1 , b_2 , and b_3 are the reciprocal lattice vectors, and u_p , u_r , and u_s are numbers from the sequence:

$$\begin{aligned} u_r &= (2r - q - 1) / 2q \\ r &= 1, 2, 3, \dots, q \end{aligned} \quad (10)$$

The total number of k -points is q^3 , but the number of the irreducible k -points can be drastically decreased by symmetry.

DFT Methodology and Related Functionals

Another approach widely developed to compute the electronic structure of materials consists of the density functional theory (DFT) used in wide variety of approaches (Bermudez 2010; Na-Phattalung et al. 2006; Le et al. 2005; Chretien and Metiu 2011; Martinsovich et al. 2010; Persson et al. 2003; Albaret et al. 2000; Walsh et al. 1999; Qu and Kroes 2006, 2007; Gałyńska and Persson 2013; Sahoo et al. 2011; Barnard and Zapol 2004a, b; Blagojevic et al. 2009; Hamad et al. 2005; Albuquerque et al. 2012; Zhang et al. 2005 ; Labat et al. 2007). Initially, DFT was developed by Hohenberg and Kohn (Hohenberg and Kohn 1964) and then by Levy (1979). They define the charge density ρ as the key parameter in energy functions instead of the electron wave functions. Thus, the total energy is composed of the kinetic energy $T[\rho]$ of a system of noninteracting particles superimposed to the electrostatic part due to Coulomb interactions $U[\rho]$ and to the many-body interaction $E_{xc}[\rho]$ called as the exchange and correlation energy. To achieve computational tasks within reasonable time delays, the exchange-correlation energy requires some approximation. In this aim, DFT methodology was implemented

within two different approximations, namely, local (LDA) and gradient-corrected (GGA) one.

The LDA approximation is based on the exchange-correlation energy of uniform electron gas (Hedin and Lundqvist 1971; Ceperley and Alder 1980). The local density approximation assumes that the charge density varies slowly on an atomic scale. The total exchange-correlation energy can be obtained by integrating over the uniform electron gas:

$$E_{XC}^{LDA}[\rho] \cong \int \rho(r) \varepsilon_{XC}[\rho(r)] dr, \quad (11)$$

where $\varepsilon_{xc}[\rho]$ represents the exchange-correlation energy per particle in the considered uniform electron gas. Slater proposed that the exchange part of the mentioned potential may be defined as equal to $\varepsilon_{XC}=\rho^{1/3}$ (Slater 1951) where in fact the correlation is not included. Generally, the exchange-correlation energy is described by the approximation implemented by Vosko, Wilk, and Nusair (VWN) (Vosko et al. 1980) or by Perdew and Zunger (PW) (Perdew and Zunger 1981).

To investigate the character of the non-homogeneity of the electron gas, the LDA approximation is not sufficient. This phenomena is taken into account by the density-gradient expansion referred to the nonlocal spin-density approximation (NLS) based on the GGA functional and depends on the derivative $d\rho/dr$ as well as on ρ . This provides a considerable increase in the accuracy of predicted energies and structures, but with an additional computational time delay. The mentioned methodology was implemented by Perdew and Wang in 1991 (Perdew et al. 1992) with the energy defined as:

$$E_{XC}^{GGA}[\rho] \cong \int \rho(r) \varepsilon_{XC}[\rho(r), \nabla\rho(r)] dr \quad (12)$$

One of the GGA functionals is the Perdew–Burke–Ernzerhof (PBE) one (Perdew et al. 1996), which is used in several problems related to material sciences. However the BLYP functional (Becke 1988) is exploited to evaluate accurately the energy parameters of organic groups leading to more relevant results than the PBE model. The situation is quite different for the correlation energy related to metallic systems where the BLYP potential gives unsatisfactory results.

So far, DFT methodology contributes to precise insights on the electronic properties of different class of materials (Hohenberg and Kohn 1964). This seems related to the development of new and more accurate approaches through the used functionals as well as the versatility of numerical methods with regard to different classes of computed systems. As a major drawback of all functionals, the underestimation of the calculated electronic band gap (Hybertsen and Louie 1989) for semiconductors and insulators is frequently encountered due to the large uncertainty in the calculations of the electron self-interaction energies. The pure LDA (Kohn and Sham 1965) or the GGA approximation (Langreth and Perdew 1980) or even the hybrid functional (Stephens et al. 1994; Perdew et al. 1996;

Heyd et al. 2003) may suffer from lack of precision for the so called “strongly correlated” systems.

Hybrid functionals were introduced by Becke (1993) replacing a fraction of GGA exchange with HF exchange. Such an approach represents a judicious compromise between Hartree–Fock exchange and DFT exchange and correlation part. The hybrid version of PBE and BLYP was proposed as PBE0 (Perdew et al. 1996), HSE (Krukau et al. 2006), and B3LYP (Becke 1993). B3LYP is currently the most popular functional used for organic groups. The formulation is based on Becke 88 exchange functional and LYP correlation functional (Becke, three parameter, Lee–Yang–Parr):

$$E_{XC}^{B3LYP} = E_{XC}^{LDA} + a_0 (E_X^{HF} - E_X^{LDA}) + a_x (E_X^{B88} - E_X^{LDA}) + a_c (E_C^{LYP} - E_C^{VWN}), \quad (13)$$

where $a_0 = 0.20$, $a_x = 0.72$, and $a_c = 0.81$.

The PBE0 functional can be traduced as follows:

$$E_{XC}^{PBE0} = 0.25E_X^{HF} + 0.75E_X^{PBE} + E_C^{PBE} \quad (14)$$

and HSE uses an error function screened Coulomb potential to calculate the exchange part of the energy in order to improve the computational evaluation, especially for metallic systems:

$$E_{XC}^{HSE} = 0.25E_X^{SR}(\mu) + 0.75E_X^{PBE,SR}(\mu) + E_X^{PBE,LR}(\mu) + E_C^{PBE}. \quad (15)$$

The separation of the electron–electron interaction into a short- and long-ranged part, labeled SR and LR respectively, is realized only in the exchange interactions.

It is generally known that classical DFT potentials do not reproduce the correct far-nucleus asymptotic behavior (Almbladh and Pedroza 1984; Levy et al. 1984) and underestimate the excitation energies notably for charge transfer (Dreuw et al. 2003) as also noticed for calculation based on time-dependent DFT (TDDFT) functional (Appel et al. 2003; Dreuw et al. 2003). It is presumed that classical functionals overestimate local contributions and underestimate nonlocal ones. The long-range electron–electron exchange interaction is neglected in pure functionals and is supposed that the appropriate inclusion of the mentioned interaction into DFT calculations improves the obtained results (Tawada et al. 2004). Therefore, the potential solution leads to the partitioning of the total exchange energy into short-range and long-range contributions:

$$E_X = E_X^{sr} + E_X^{lr} \quad (16)$$

Such methodology is called long-range correction (LC) scheme (Iikura et al. 2001). It uses the standard error function to modify and improve the exchange functional for evaluating the long-range electron–electron interaction by the HF exchange

integral. In LC approach, the repulsion electron operator is also divided into short-range and long-range part and can be defined as:

$$\frac{1}{r_{ij}} = \frac{1 - [\alpha + \beta \operatorname{erf}(\mu r_{ij})]}{r_{ij}} + \frac{\alpha + \beta \operatorname{erf}(\mu r_{ij})}{r_{ij}}, \quad (17)$$

where $r_{ij} = |r_i - r_j|$ is the distance between two electrons located in position r_i and r_j . The parameter μ represents the weighting factor which controls the separation between short-range exchange functional and the long-range part of HF exchange integral. The optimal μ factor corresponds to the atomic bond length and hence is expected to be dissimilar for different atoms. When μ is equal to zero, the LC DFT calculation corresponds to pure DFT methodology, and conversely $\mu = \infty$ corresponds to the standard HF calculation. The α and β parameters define the exact exchange percentage between short- and long-range exchange functionals. Since $\alpha + \beta = 1$, the exchange potential in LC functionals has the exact asymptotic behavior. Also, the parameter α determines the contribution of the HF exchange at the short-range region. At a distance of about $2/\mu$ the short-range interactions become negligible. The LC-BLYP method uses $\alpha = 0$ and $\beta = 1$.

The CAM-B3LYP functional (Yanai et al. 2004) (Coulomb-attenuating method applied to B3LYP) also eliminates the long-range self-interaction error. In this case, the parameters are assigned to $\alpha = 0.19$ and $\beta = 0.46$, and hence the exact asymptote of the exchange potential is lost. To sum up, the parameter α allows incorporating the HF exchange contribution over the whole range of distance. Similarly, the parameter β defines the DFT counterpart over the whole range by a factor of $1 - (\alpha + \beta)$.

Another major problem of standard LDAs and GGAs is that they could not describe the system when the electrons tend to be localized and strongly interacting, such as for transition metal oxides or rare earth elements and compounds. One of the successful models to describe correlated electrons in solids is the Hubbard model (Anisimov et al. 1991) based on extended LDA approach to what is termed LDA+U. It decreases the electron self-interaction error by selectively adding an energy correction to localized electron states as for d or f orbitals, where the self-interaction is particularly large. The additional interactions is usually considered only for high localized atomic-like orbitals on the same site, as the ‘‘U’’ interactions in Hubbard models:

$$E^U = \frac{1}{2}U \sum_{i \neq j} n_i n_j. \quad (18)$$

In the multiband Hubbard model, the effective LDA+U energy functional is written as:

$$E^{LDA+U} = E^{LDA} + E^U + E^{dc}, \quad (19)$$

where E^{LDA} denotes standard LDA energy functional and the $E^{dc} = UN(N-1)/2$ is called the double-counting term, to remove the energy

contribution of these orbitals which are twice introduced by the Hubbard term ($N = \sum_i n_i$).

In the LDA + U approach, the Kohn–Sham equation is supplemented by the nonlocal potential. From the other side, the DFT/Hubbard method fails to compute the correct energy difference in systems with localized/correlated and delocalized/uncorrelated electronic states (Jain et al. 2011). Also, the LDA/GGA + U methodology was successfully applied to compute the electronic properties of different ternary oxides such as CuAlO₂ (Laskowski et al. 2009), CuAl₂O₄ (Liu and Liu 2011), Pr₂Ti₂O₇ or Ce₂Ti₂O₇ (Sayede et al. 2013), and MnFe₂O₄ (Huang and Cheng 2013). Based on the outlined theoretical framework and as discussed below, the influence of the Hubbard parameter U on the electronic properties of NiTiO₃ was investigated on the crystalline structure in bulk material or in nanosized clusters taking into account the strong correlation of the d-orbital electrons.

Cluster Approach to Model Nanostructures

The study of nanosized systems is of great interest with regard to the critical role of the specific active surface in physical phenomena. Particularly, interfaces between the active material and the surrounding media contribute critically to the efficiency of heterogeneous catalysis. In this context, theoretical modeling and numerical simulations to predict electronic, optical, structural, vibrational, and related properties of nanoparticles are challenging tasks. Among the numerical approaches for prediction of the physical properties of nanoscale system, the cluster approach is worthy of interest with respect to combined aspects from molecular physics methodology as well as from that applied to macroscopic systems. Such approach requires DFT methodology supported by the semiempirical PM6 and PM7 parameterized approach due to the cluster size.

Some of quantum-chemical methodologies use bulk crystal approach to predict the electronic properties of nanosized materials by building various surfaces and by reducing the periodicity of the crystal lattice (Martsinovich et al. 2010). Other methods proceed by full optimization of atomic positions of nano-clusters without defined crystal structure (Qu and Kroes 2006; Galyńska and Persson 2013). In the present work, the cluster approach is developed within a methodology based on crystalline structure inside the core of the investigated nanoparticles surrounded by a reconstructed surface according to surface energy requirement and interactions with the environment. The nanostructures are built from their native bulk crystals with specified atomic positions as involved in defined space groups. Modeling of bulk systems is of primary importance to settle the methodology for the structural, vibrational, and electronic properties of nanostructures.

In order to simulate realistic structures able to traduce experimental data, the clusters should be constructed with the appropriate size (Makowska-Janusik and Kassiba 2012). However, experimental observations are usually made on nanoparti-

cles with diameters in the range of a few nanometers, but numerical modeling based on quantum-chemical methods are highly time consuming and cannot be applied on such large systems. In this context, semiempirical approaches are more relevant, and the parameterized PM6 or PM7 methods are preferred because their bases include parameterized data for frequently studied atoms. The following section reports selected semiconducting nanostructures which were modeled based on the above cited approach.

Structural Features of TiO_2 , NiTiO_3 , and BiVO_4 Crystals

The crystal structures of investigated semiconducting oxides were computed for two different configurations of the material. One of them was considered like bulk monocrystal and the second one was created in nanosized crystal future. In this case the TiO_2 , NiTiO_3 , NiTiO_3 and BiVO_4 crystals were chosen. To build all structures, the Materials Studio program package was used. The structural parameters of all investigated crystals are presented in Table 1. These data are in agreement with those from experimental and other theoretical works (Burdett et al. 1987; Sleight et al. 1979; Zhao et al. 2011). The example of semiconducting NiTiO_3 crystal unit cell and its nanostructure are shown in Fig. 10.

Computational Parameters

The electronic properties of all investigated single crystal were calculated using DFT method. The quantum-chemical calculations were performed using Cambridge Serial Total Energy Package (CASTEP), the module of Materials Studio program. The CASTEP is based on total energy plane wave pseudopotential method. In the first step, the geometries of the investigated structures were optimized with respect to the total energy minimization within the Broyden–Fletcher–Goldfarb–Shanno (BFGS) algorithm (Pfrommer et al. 1997). The symmetries of all structures were frozen during the geometry optimization procedure, but in some cases the size of the unit cell was allowed to be modified. The convergence parameters were chosen for the energy as low as 2×10^{-5} eV/atom, the force on the atom was less than 0.01 eV/Å, the stress on the atom limited below 0.02 GPa, and the atomic displacement less than 5×10^{-4} Å.

The electronic exchange-correlation energy was treated within the frame of the generalized gradient approximation (GGA) using Perdew–Burke–Ernzerhof (PBE) (Perdew et al. 1996) potential. The calculations were performed with the cutoff energy of the plane wave basis set equal to 350 eV for BiVO_4 and 500 eV for TiO_2 and NiTiO_3 crystals. To accelerate the computational runs, the functional such as ultrasoft pseudopotential was used for the calculations related to the following

Table 1 Structural parameters of investigated crystals: TiO₂ in anatase phase, NiTiO₃ in ilmenite phase, and the BiVO₄ in monoclinic scheelite structure

TiO ₂ anatase phase (Burdett et al. 1987)

electronic configuration: Ti $3s^2 3p^6 3d^2 4s^2$, Ni $3d^8 4s^2$, Bi $6s^2 6p^3$, V $3s^2 3p^6 3d^3 4s^2$, and O $2s^2 2p^4$. The numerical sampling integration over the Brillouin zone was carried out using the Monkhorst–Pack method with a $8 \times 8 \times 8$ and $5 \times 5 \times 7$ special k -point mesh for $(\text{TiO}_2, \text{NiTiO}_3)$ and BiVO_4 , respectively. The total energy was assumed to converge when the self-consistent field (SCF) tolerance is equal to 10^{-5} eV/atom.

The electronic properties were computed using the same parameters as used during the geometry optimization procedure. The calculations were performed in spin restricted as well as spin unrestricted procedures applying GGA/PBE potential. For the TiO_2 and NiTiO_3 crystals, the Kohn–Sham equation was also solved using the GGA/PBE functional with the Hubbard parameters.

As for bulk systems, Materials Studio software was also used to build the nanostructures. The clusters possess spherical shape and were realized by limiting defined volume within the bulk crystal. According to stoichiometry, the clusters were built as n -multiple of the (TiO_2) , (NiTiO_3) , or (BiVO_4) units with sizes ranging from 0.7 nm up to 2.6 nm. For NiTiO_3 , the clusters consist of $(\text{NiTiO}_3)_2$ up to $(\text{NiTiO}_3)_{183}$ units. The atomic positions within the cluster were frozen to the ones related to bulk crystal. All clusters were modeled without any external saturation. Only the $(\text{TiO}_2)_n$ clusters were saturated by using hydrogen atoms or by hydroxyl ($-\text{OH}$) groups.

The electronic properties of clusters were computed by using the parameterized PM6 and PM7 method (Stewart 2007). This procedure allows pertinent evaluation of physical features of clusters with large sizes and with involvement of heavy atoms. The numerical simulations were then performed using MOPAC (Stewart 2012) and GAMESS (Schmidt et al. 1993) packages. All the calculations were carried out under restricted Hartree–Fock (RHF) regime with the SCF convergence criterion sets at 10^{-5} Hartree and no more than 500 iterations. The eigenvalues were calculated for the frozen atomic positions in the clusters with the molecular point group C1.

On the other hand, the DFT calculations were performed by using DMol3 software (Delley 1990, 2000) with implemented PBE and B3LYP functionals applying DND basis set. No symmetry rules were imposed during the electronic structure analysis and the SCF density convergence criterion was fixed to 10^{-5} eV. In order to reduce the required computational time, all core electrons were represented by effective core pseudopotentials (ECP) (Dolg et al. 1987; Bergner et al. 1993). The electronic properties of the $(\text{TiO}_2)_n$ clusters were also calculated applying DFT methodology implemented in GAMESS program package with the 6-31G basis set and the effective core potential named Stevens–Basch–Krauss–Jasien–Cundari (SBKJC) (Stevens et al. 1984; Cundari and Stevens 1993) required to limit the number of contributing electron wave functions. The calculations were performed with different exchange–correlation (XC) potentials in generalized gradient approximation. The BLYP and B3LYP potentials have been chosen, and the results were compared to different long-correlated hybrid and CAM-B3LYP functional.

Physical Properties of NiTiO₃ and BiVO₄ Crystals

Structural Aspects

Quantum-chemical calculations of all investigated crystals proceed first by optimizing their geometries using the GGA/PBE functional. The evaluated atomic distances were relaxed, but their changes remain limited below 5 % compared to experimental results reported elsewhere (Rajalingam et al. 2012). The small discrepancies could be attributed to the fact that the present calculations were made at $T = 0$ K, whereas the experimental measurements are generally recorded at finite temperature. However, the small deviations between theoretical and experimental values indicate that GGA/PBE is satisfactory as a computational method to describe the structures of all investigated crystals.

Following the geometry optimization, the investigated ilmenite NiTiO₃ structure exhibits layered organization (see Fig. 10) with the Ti and Ni atoms forming the layers separated by oxygen atoms. Figure 11 shows that for the optimized BiVO₄ crystal structure, the Bi–O and V–O bonds are more symmetric compared to the starting geometry. All Bi–O and V–O bonds have tendency to align at the same values. The geometry of monoclinic scheelite structure tends to the tetragonal geometry during the total energy minimization procedure. The possible reason of such isotropic bond lengths for Bi–O may be due to strong correlation between the Bi (6 s) and O (2p) orbitals (Ma and Wang 2014).

Electronic Properties of BiVO₄

The electronic parameters of the geometry optimized structure of BiVO₄ were calculated using DFT/PBE potential. The coordinates of the special points of the BZ

Fig. 11 Primitive unit cell of NiTiO₃ single crystal (*left panel*) and of the BiVO₄ single crystal (*right panel*)

Fig. 12 Band structures calculated for frozen BiVO_4 monoclinic structure

are (in units of the reciprocal lattice vectors) L $(-1/2, 0, 1/2)$; M $(-1/2, 1/2, 1/2)$, A $(-1/2, 0, 0)$, Γ $(0, 0, 0)$, M $(0, -1/2, 1/2)$, and V $(0, 0, 1/2)$. The features of the obtained energy dispersion curves are similar to former results of Zhao et al. (Zhao et al. 2011), but the value of the band gap is significantly different. The minimum band gap obtained for such structure is equal to 2.25 eV compared to 2.17 eV reported in Zhao et al. study. The energy band calculations were also performed for BiVO_4 structure without any geometry optimization. The energy gap calculated for the frozen structure shows a departure of 0.16 eV higher than the band gap obtained by the same methodology for the relaxed geometry. Figure 12 reports the energy band structure calculated for the frozen BiVO_4 monoclinic structure where the band gap value is equal to 2.41 eV. The obtained energy band structure has the same shape for both relaxed and frozen structures. The valence band maximum (VBM) is located at the A point of BZ, while the minimum of conduction band (CBM) is realized at the Z point. The evaluated indirect band gap agrees with experimental values predicted by Rajalingam et al. (2012) and contrasts with former evaluation performed by Walsh et al. (2009) where they characterize the BiVO_4 crystal as direct semiconducting material.

The main contributions to the valence band states for the frozen structure are from O (2p) orbitals slightly hybridized with Bi (6 s) and V (3d) states (see Fig. 13). Metal oxide semiconductors such as ZnO or TiO_2 usually have wide band gaps because the valence band has mainly O 2p character and is located at a positive potential (Kudo et al. 1999). The hybridization between the Bi (6 s) state and the O (2p) state at the top of the VB is indeed responsible for the relatively smaller band gap of BiVO_4 monoclinic scheelite structure (Walsh et al. 2009). In contrary to the frozen structure, the partial DOS of optimized monoclinic BiVO_4 underlines that the VBM

Fig. 13 Partial density of states of monoclinic BiVO_4 frozen structure

possesses contribution mainly from V (3p) states hybridized with O (2p) electrons. The mentioned oxygen–vanadium interaction decreases the calculated energy gap. In both frozen and optimized structure, the bismuth and oxygen contributions to the VBM are similar.

The conduction band of the frozen BiVO_4 crystal is dominated by V (3d) states with small contribution from Bi (6p) and O (2p) states. The same data were also obtained for relaxed crystal. These results are in agreement with the data measured by XPS (Payne et al. 2011). The oxygen and bismuth contribute to antibonding orbitals forming the CB states. The energy band structure obtained for frozen BiVO_4 single crystal gives better results compared to the experimental data. This indicates that the no-relaxed structure gives sound analysis for the electronic features. The distortions of Bi–O and V–O bond lengths enhance the impact of the Bi (6 s) states and contribute to more dispersion in the valence band.

Electronic Properties of NiTiO₃

The same calculations performed for the frozen and relaxed NiTiO₃ single crystal give unrealistic energy band gap values. Therefore, the electronic properties of the mentioned crystal were calculated at the spin-polarized approach for a primitive unit cell applying Hubbard parameters. These calculations were performed in k space within the BZ directions where the coordinates of the special points are (in units of the reciprocal lattice vectors) F (1/2, 1/2, 0), Γ (0, 0, 0), K (1/4, 1/4, 1/4), and Z (1/2, 1/2, 1/2). The DFT/PBE method with or without Hubbard approximation was taken into account. Such functional when used in the spin-polarized regime underestimates the electronic energy band gap. The obtained value equal to 0.77 eV is far from experimental data which is in the range 2.12–2.18 eV (Singh et al. 1995; Wang et al. 2013). The reason of such large discrepancy is probably due to the presence of titanium and nickel atoms which possess strongly correlated electrons. An improvement of the predicted results requires the use of Hubbard approximation. Figure 14 reports the electron density calculated by DFT/PBE potential and shows the covalent character of the O–Ti, O–Ni, and Ti–Ni bonds. This behavior makes us confident in the relevance of the statement about the studied material characterized by strongly correlated electrons. The Hubbard-modified Hamiltonian is required to obtain band energy gaps in agreement with experimental data.

The different Hubbard parameter (U) values were chosen for the valence Ti (3d) and Ni (3d) electrons and the energy gap values were calculated. The chosen U values summarized in Table 2. show that the close agreement between estimated band gap and experimental results are obtained for the Hubbard parameters equal

Table 2 Hubbard U parameter values chosen for the Ti d and Ni d orbitals with the calculated energy gap value by using PBE + U methodology

Ti d	Ni d	E_g [eV]
0	0	0.77
2.5	2.5	1.75
3.5	4.5	2.33
4.5	3.5	1.94
4.5	4.5	2.46

Fig. 15 Electron band structure calculated by PBE/LDA+U methodology with the energy levels created by alpha electron – *black* and energy levels created by beta electron – *red* (Ruiz Preciado et al. 2015)

to 3.5 eV and 4.5 eV for Ti (3d) and Ni (3d) electrons, respectively. These results underline that the PBE + U method provides a satisfactory qualitative electronic structure calculations with the Hubbard parameters U_{Ti} and U_{Ni} in a reasonable range. The electronic band structure computed with $U_{Ti} = 3.5$ eV and $U_{Ni} = 4.5$ eV is presented in Fig. 15. and indicates a direct semiconducting nature of $NiTiO_3$ crystal with an energy gap at 2.33 eV. The top of valence band is build by alpha electrons and the bottom of conduction band is composed by beta ones. The alpha electrons are involved in hybridized orbitals based on the Ni (3d) and O (2p) (see Fig. 16). The bottom of conduction band is also composed by the hybridization of the Ti (3d) and Ni (3d) states in agreement with former report by Salvador et al. (1982).

In both investigated materials, $NiTiO_3$ and $BiVO_4$, the valence band is created by the oxygen O (2p) electron possessing anion character, while the conduction band contains mostly V (3d) and Bi (6p) of the monoclinic $BiVO_4$ and Ti (3d) and Ni (3d) cations in the ilmenite $NiTiO_3$ crystal. Similarly, as discussed below, the valence band of TiO_2 is dominated by the O (2p) electrons, while the conduction band is populated mainly by the unoccupied Ti (3d) electron states.

Structural and Electronic Properties of TiO_2 , $NiTiO_3$, and $BiVO_4$ Nanosized Systems

TiO_2 Nanostructures

The built of nanocrystalline structures with defined geometries was described in Chapter, “[Cluster approach to model the nanocrystals and nanostructures](#)”. The

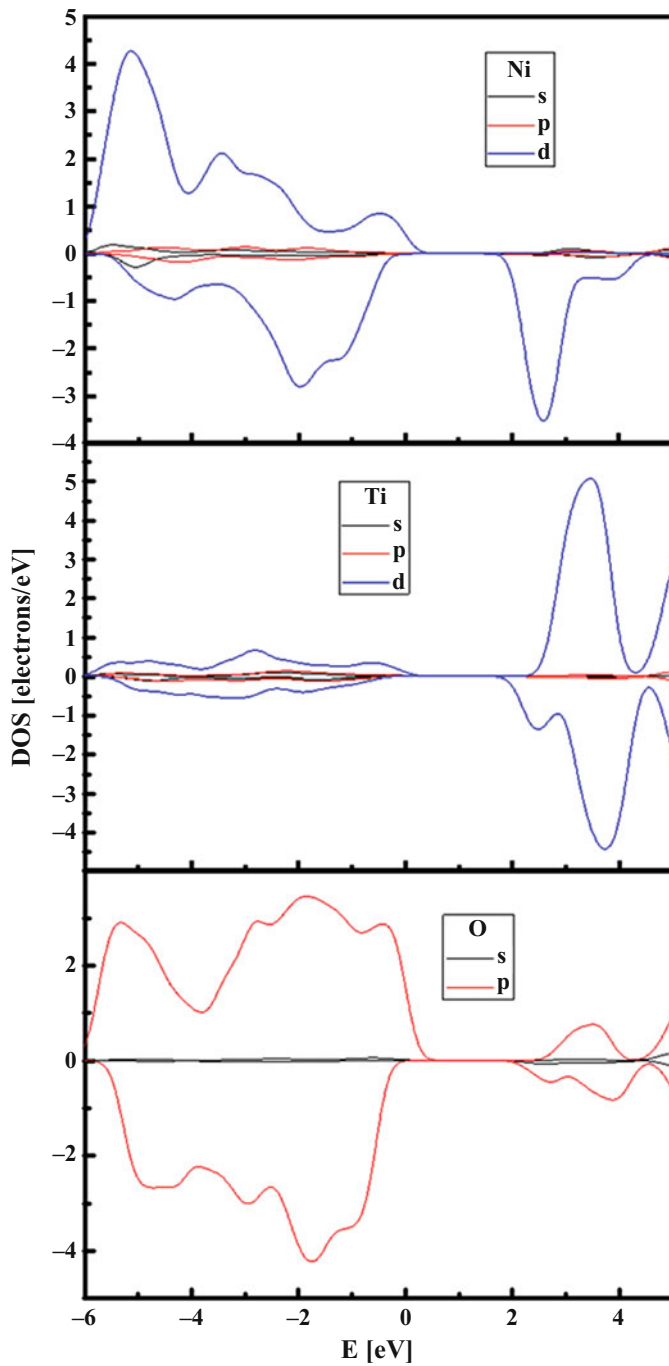

Fig. 16 Electron density of state (*DOS*) calculated for NiTiO₃ crystal using PBE+U method (Ruiz Preciado et al. 2015)

Fig. 17 HOMO–LUMO energy gap splitting versus size obtained by using parametrized PM6 semiempirical method for $(\text{TiO}_2)_n$ applying different passivation elements (Makowska-Janusik et al. 2014)

computational procedure considers $(\text{TiO}_2)_n$ clusters with size ranging from 0.6 up to 2.0 nm possessing indivisible number of TiO_2 units as $n = 2 \div 140$. All the clusters were spherical in agreement with the work of Kshirsagar et al. (Kshirsagar and Kumbhojkar 2008) establishing that small crystallites exhibit a spherical shape. The HOMO–LUMO energy gap splitting ($\Delta E_{\text{HOMO-LUMO}}$) was calculated for $(\text{TiO}_2)_n$ clusters using the semiempirical PM6 parameterized method. The electronic parameters were evaluated versus the cluster size and the different surface passivation nature such as hydrogen, oxygen, or $-\text{TiOH}$ groups. The obtained results point out the occurrence of quantum size confinement effect for all clusters. The size effect and the nature of surface passivation show correlated impact on the $\Delta E_{\text{HOMO-LUMO}}$ values for all clusters (see Fig. 17). Indeed, the most pronounced size effects were obtained with different features for unpassivated and oxygen-passivated clusters. Passivation by oxygen contributes to drastic shift of $\Delta E_{\text{HOMO-LUMO}}$ with a particular strength for the clusters with sizes less than 0.8 nm. These results are different than those from the work of Sahoo et al. (2011) probably due to our approach in the present work taking into account the cluster surface reconstruction which was implemented in accordance to the energy minimization procedure and environmental impact. According to our former analysis (Makowska-Janusik et al. 2014), in the surface reconstruction process, atoms at $(\text{TiO}_2)_n$ outermost cluster shell were moved according to the conjugated gradient algorithm with RMS gradient convergence equal to $0.01 \text{ kcal } \text{Å}^{-1} \text{ mol}^{-1}$.

Table 3 HOMO–LUMO energy gap splitting calculated by using different DFT functionals for unpassivated $(\text{TiO}_2)_n$ anatase clusters versus its size variation

Number of $(\text{TiO}_2)_N$ units n	Cluster size [nm]	BLYP	B3LYP	LC-BLYP $\mu = 0.33$	CAM-B3LYP	LC-BLYP $\mu = 0.80$
		$\Delta E_{\text{HOMO-LUMO}}$ [eV]				
2	0.6	0.97	1.04	4.63	2.92	4.76
9	0.8	0.77	0.83	3.62	2.28	3.97
18	1.0	0.47	0.50	2.94	1.85	3.03
40	1.2	0.42	0.45	2.91	1.46	3.03

These calculations indicate the important role of saturating atoms and surface reconstruction for small clusters, but for the clusters with diameter larger than 1.0 nm, the saturation effects can be omitted. This is convenient from the point of view of computer simulations because choosing realistic physical passivation is always problematic, even if it can bring satisfactory results (Kassiba et al. 2002). Therefore, for the detailed studies, only the unpassivated $(\text{TiO}_2)_n$ clusters were taken into account.

An evaluation of the $\Delta E_{\text{HOMO-LUMO}}$ of $(\text{TiO}_2)_n$ clusters was also calculated for structures with various sizes and different DFT functionals. The calculations were performed by using pure BLYP and hybrid B3LYP functional, as well as the different LC and CAM-B3LYP potentials. The obtained data are reported in Table 3. The HOMO–LUMO energy gap values obtained by BLYP and B3LYP functionals are quite small, but their evolution as a function of cluster size reproduces the quantum confinement effect. It is known that the band gap in semiconductors is underestimated by more than 30–50 % within the LDA approximation (Burke 2012). The calculations show also that the evaluated energy gap value can be substantially smaller than the real gap for semiconducting solids (Grüning et al. 2006). To overcome these discrepancies, a possibility consists of treating the exchange term of KS theory as orbital dependent by using hybrid functional (Seidl et al. 1996). However, in bulk crystal approach, the B3LYP potential does not match with the prediction of electronic features of the $(\text{TiO}_2)_n$ clusters.

For representative clusters, the use of LC-BLYP, LC-BOP, LC-BECK, or LC-BVWN functionals with a range separation parameter $\mu = 0.33$, gives similar values of the HOMO–LUMO energy gap splitting. In Table 3 only data obtained for LC-BLYP potential are presented. The LC and CAM functionals give better predictions of the electronic features than the pure BLYP or B3LYP hybrid functionals. However, LC-BLYP and CAM-B3LYP underestimate the HOMO–LUMO energy gap splitting compared to the band gap energy of experimental bulk anatase which is about 3.02 eV (Amtout and Leonelli 1995). The more relevant results are obtained by using the LC-BLYP functional, leading to a HOMO–LUMO gap of 2.94 eV and 2.91 eV for clusters with diameters of 1.0 nm [$(\text{TiO}_2)_{18}$] and 1.2 nm [$(\text{TiO}_2)_{40}$], respectively. Thus, the LC functional smoothly replaces the DFT exchange by the HF exchange at long inter-electron distances. Furthermore, it is possible to obtain larger HOMO–LUMO energy gap values by using different

Table 4 HOMO–LUMO energy gap splitting calculated for unpassivated $(\text{TiO}_2)_{18}$ anatase cluster with diameter equal to 1.0 nm using LC-BLYP functional versus range separation parameter μ

DFT functional	$\mu = 0.10$	$\mu = 0.33$	$\mu = 0.50$	$\mu = 0.80$
	$\Delta E_{\text{HOMO-LUMO}}$ [eV]			
LC-BLYP	2.88	2.94	2.99	3.03

range separation parameter μ . Several works on the LC scheme suggested that the separation parameter should be larger than the standard one equal to 0.33 in order to reproduce atomization energies or barrier height energies, for example (Gerber and Ángyán 2005). In this case, the HOMO–LUMO energy gap splitting was calculated for $(\text{TiO}_2)_{18}$ clusters of 1 nm diameter using different range separation parameters, within the LC-BLYP potential (see Table 4).

The $\Delta E_{\text{HOMO-LUMO}}$ value increases with the separation parameter μ . A relevant evaluation of the HOMO–LUMO energy gap is obtained for a μ parameter equal to 0.8 (see Table 3 last column). Higher values of μ from 0.9 to 1.5 were also examined, but they did not influence significantly the band gap. These results are consistent with former works of Iikura et al. (Iikura et al. 2001). It is important to notice that an increase of μ leads to a higher contribution of long-range exchange interactions from the HF exchange potential limiting also the self-exchange and self-correlation effect for the interacting electrons at the long inter-charge distance. The performed calculations are consistent with data obtained for strongly correlated systems with the electron density distributed close to the nuclei, as it is observed for ionic bonds. In the considered TiO_2 system, Ti atoms possess octahedral coordination, and the strong ionic character of the bonds results in localized charges around the O^{2-} anions. The HOMO orbital is dominated by the O (2p) electrons, while the LUMO is populated mainly by the unoccupied Ti (3d) electron states. The same results were obtained for the valence and conduction bands of TiO_2 crystal.

It was found that LC functionals in DFT method quantitatively reproduces energies of frontier orbitals including HOMO and LUMO. It is shown that for the strongly correlated systems, the LC functional with appropriate long-range separation factor may accurately reproduce the orbital energies in agreement with the prediction of Singh and Tsuneda (Singh and Tsuneda 2013). Within the developed approach, the performed calculations indicate that the choice of the separation coefficient μ modulates critically and in large extent the electronic properties of the considered system.

NiTiO₃ Nanostructures

The implementation of LC functional to calculate the electronic parameters of NiTiO_3 clusters did not evaluate coherently the HOMO–LUMO energy gap splitting. Reliable results were obtained by applying the semiempirical methodology. In Fig. 18, the evaluation of the energy difference between HOMO and LUMO calculated for the NiTiO_3 clusters is presented and the size quantum confinement effect is clearly seen. Thus, the results obtained by using PM6 methodology

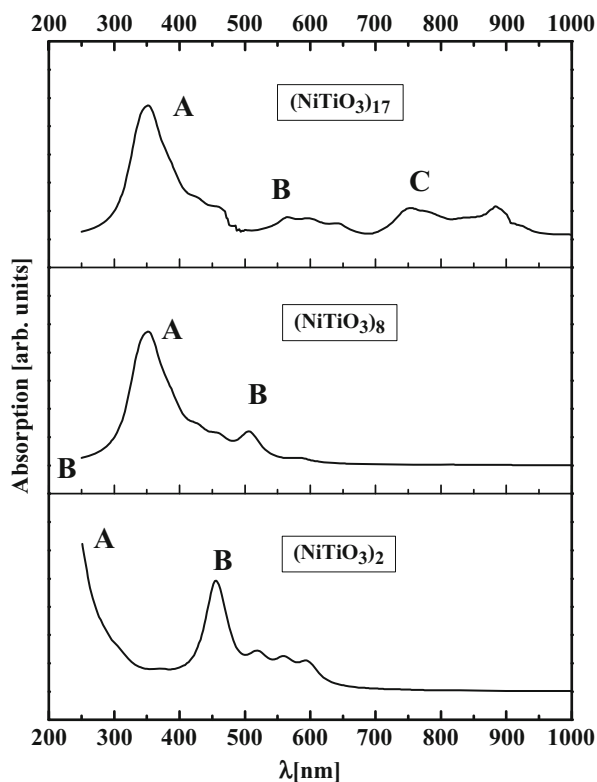

Fig. 18 Evaluation of the $\Delta E_{\text{HOMO-LUMO}}$ energy splitting versus number n of NiTiO_3 units calculated by PM6 methodology for the different $(\text{NiTiO}_3)_n$ clusters (Ruiz Preciado et al. 2015)

reproduce quantitatively the energy gap of nanosized NiTiO_3 . In the work of Vijayalakshmi and Rajendran (Vijayalakshmi and Rajendran 2012), it was specified that the size reduction of the NiTiO_3 nanoparticle gives blue shift in the absorption spectra compared to the bulk material.

To evaluate the electronic properties of NiTiO_3 nanostructures versus their size, UV–vis absorption spectra were calculated by PM6 methodology. Three different clusters were used, namely, $(\text{NiTiO}_3)_2$, $(\text{NiTiO}_3)_8$, and $(\text{NiTiO}_3)_{17}$. Large-sized clusters were not evaluated because of the computer memory problem. The calculated spectra are presented in Fig. 19. These results for the cluster $(\text{NiTiO}_3)_{17}$ agree with the experimental data obtained on NiTiO_3 powder (Fig. 20 top panel). The increase of the cluster size shifts the spectral A peak position to red range (see Fig. 19). The peak B which is well pronounced for the smallest cluster is also shifted to red side but in less marked rate for larger particles. The additional broad peak (C) at the position of 750–900 nm appears for the cluster $(\text{NiTiO}_3)_{17}$. The two peaks B and C are not observed in the spectrum calculated for the bulk NiTiO_3 single crystal (Fig. 20 down panel). Probably this behavior results from surface influence on the electronic properties of nanocrystal material. In our previous work (Ruiz Preciado et al. 2015), it was shown that the HOMO and LUMO orbitals observed for the investigated NiTiO_3 clusters are located at the separated atoms. The valence band minimum and conduction band maximum are diffused through the different atoms as it was shown in part concerning crystal electronic properties evaluation. The mentioned separation of HOMO and LUMO orbitals is not seen for the bulk materials where band structure exhibits different behavior. Probably, this explains

Fig. 19 The UV–vis absorption spectra calculated by the PM6 methodology for different clusters

why the B and C peaks are not visible in UV–vis absorption spectra of the single crystal.

The comparison between the theoretical UV–vis absorption spectrum calculated for the cluster $(\text{NiTiO}_3)_{17}$ and the experimental one (see Fig. 20, top panel) assigns quantitatively the origin of the observed features. The broad absorption edge situated at 410 nm is attributed to $\text{O}^{2-} \rightarrow \text{Ti}^{4+}$ charge transfer interaction. The lower energetic shoulder is associated with the crystal field splitting of NiTiO_3 , associated with the $\text{Ni}^{2+} \rightarrow \text{Ti}^{4+}$ charge transfer (Lopes et al. 2009). However, in contrast to experimental features, additional peaks are obtained on the theoretical UV–vis absorption spectra. These discrepancies are explained by the absence of temperature influence which causes structural relaxation of the nanoparticles. Indeed, taking into account such temperature influence, the electron–phonon interaction and the Franck–Condon rule lead to the calculated absorption peaks with more broad shapes.

Taking into account appropriate passivation of clusters and their reconstructed surfaces, the theoretical modeling of the nanosized structures reproduces their main physical features. This is illustrated on the vibrational properties through the calculated Raman spectra for selected clusters. Therefore, ilmenite crystal nanostructure

Fig. 20 The UV-vis absorption spectra measured for NiTiO₃ powder samples (*top panel*) and the spectrum calculated by PBE/LDA + U functional (*top right panel*) and the experimental data (*bottom right panel*)

with frozen atomic positions and nanoparticle with optimized geometry according to the total energy minimization was chosen. The studied structures possess common starting geometry indexed as (NiTiO₃)₁₇ cluster. The calculated and experimental Raman spectra are presented in Fig. 21 for the cluster (NiTiO₃)₁₇ with ilmenite structure. One may note that only one peak at position C is obtained. The origin of such vibrational band around 700 cm⁻¹ is attributed to the Ti–O–Ti stretching mode which can be slightly shifted in real crystal structure up to 720 cm⁻¹ (Su and Balmer 2000; Llabrés i Xamena et al 2003; Baraton et al. 1994). The peaks A, B, and D observed for the optimized nanostructure indicate the relaxed distance between Ni, Ti, and O bonds. Figure 21 reports also the convolution of the spectrum obtained for ilmenite nanocrystal and optimized structure with ratio 9/1. The strength of the developed theoretical and numerical modeling is clearly illustrated from the close correspondence between predicted Raman signatures and the experimental ones of nanopowder systems.

The obtained results such as vibrational or optical absorption support the fact that the nanocrystalline oxides give rise to two defined contributions from the core of particles and the external and outermost surface with amorphous or reconstructed

Fig. 21 Raman spectra of $(\text{NiTiO}_3)_{17}$ cluster calculated by the parametrized PM6 method and compared to experimental spectrum (Ruiz Preciado et al. 2015)

atomic positions. They traduce the properties of bulk nature and those traducing the surface broken periodicity.

BiVO_4 Nanostructures

Beyond NiTiO_3 , similar behavior was also noticed from the size quantum confinement effect involved in BiVO_4 nanostructures. Using the semiempirical PM6 parameterized method, the electronic structures of isolated $(\text{BiVO}_4)_n$ clusters were calculated. The number n of structural units was changed from $n = 1$ up to $n = 56$ leading to cluster diameter up to 2.0 nm. The calculated $\Delta E_{\text{HOMO-LUMO}}$ energy gap splitting is presented in Fig. 22. The predicted values of the HOMO–LUMO difference are divided into two parts as marked by rectangles and triangles. The first class of mentioned data can be fitted by an exponential curve. Qualitatively, this behavior is in agreement with quantum confinement size effect. The second class of data (triangles) represents the clusters with frozen structure as for bulk system. These data fluctuate with increasing the cluster size but have tendency to be aligned by one asymptotic value close to 2.4 eV. Such behavior is in agreement with the experimental value of the energy gap defined for bulk BiVO_4 . The area marked by dashed line contains cluster size range where the frozen bulk-like and surface-relaxed structures defining the property of nanoparticle compete one with the other. This area corresponds to cluster sizes ranging from 1.1 up to 1.8 nm where the surface and volume atoms contribute differently to the electronic band structure of the cluster. The origin of the calculated $\Delta E_{\text{HOMO-LUMO}}$ is the effect of emulation

Fig. 22 The $\Delta E_{\text{HOMO-LUMO}}$ energy gap splitting versus size of BiVO_4 cluster represented by the number of $(\text{BiVO}_4)_n$ units. *Dashed line* indicates the intermediate area between bulk frozen atoms and nanoparticle behavior with contributions from core and surface atoms

between two competing mechanisms. One is believed to come from the crystalline cores of the nanometer-sized BiVO_4 and the other one is attributed to the surface layer. Similar mechanism was used to explain the photoexcitation effect occurring in the crystalline Si cores (Wilcoxon et al. 1999).

The electronic properties of the BiVO_4 nano-clusters computed by PM6 semiempirical method confirm that the HOMO orbital is built by the oxygen states, while LUMO orbital include vanadium states. It confirms that the limitation of the cluster size did not change drastically its electronic configuration and properties. The obtained results show that the electronic structure of nanoparticle is the consequence of bulk crystal material. The HOMO and LUMO orbitals agree with the VBM and CBM of frozen BiVO_4 single crystal, and performed calculations are in agreement with the works of Huang et al. (Huang et al. 2014) and Jo et al. (Jo et al. 2012).

The theoretical calculations are consistent with the experimental features reported in the first part of the presented chapter. This fact makes us confident in the developed numerical approach to analyze the electronic and optical effects of this class of semiconducting oxides. The quantum confinement effect is well demonstrated theoretically on the optical spectrum of nanosized cluster. However, our experimental synthesis did not allow so small nanocrystal sizes, and only the features 20–30 nm particles were indeed demonstrated experimentally. Dealing with the photoinduced charge transfer required for visible-driven photocatalysis, the experimental results point out the visible light absorption in a wide spectral range. The nanoparticle sizes 20–50 nm contribute to enhance the specific surface which is critical in heterogeneous photocatalysis. Indeed, as the contacts at the interfaces increase between photocatalysts and surrounding media, an improvement occurs on the efficiency of photocatalysis reactions. The benefit from nanosized clusters

Fig. 23 Calculated optical absorption spectra of BiVO_4 as nanocrystalline object and infinite bulk system. The blue shift due to quantum confinement effect is traduced on the nanocrystal absorption curve

is thought to be related to drastic enhancement of specific surfaces. However, as it was shown from the calculations (Fig. 23), the spectral range of absorbed sun light is shifted to higher energies limiting then the absorption quantum efficiency. Thus, a balance must be achieved between the size reduction (specific surface) and the induced widening of the band gap.

Conclusions

Exhaustive experimental investigations and theoretical approaches supported by numerical simulations were dedicated to selected classes of semiconducting oxides such as TiO_2 , BiVO_4 , and NiTiO_3 characterized by promising visible-driven photoactive responses. The ambition consists of tailoring original smart materials from chemical composition, structural and morphological features for pphotovoltaic and photocatalysis applications. Original synthesis strategies were developed to obtain these materials as thin films, mesoporous structures, as well as nanoparticles. To create visible-driven photoactive media with higher efficiency, suitable doping was realized to modulate the electronic and optical properties. Structural and vibrational investigations were carried out and inform on the stabilized crystalline polytypes and their evolution with the synthesis and treatment conditions. The physical properties including electronics and optics, as well as the role of electronic active centers realized by doping or intrinsically induced by oxygen vacancies or form the stoichiometry departure, were also investigated, and their interpretation was made quantitatively with the support of exhaustive computational work. Quantum theory approaches based on DFT and semiempirical models were applied to predict the

physical peculiarities of photoactive semiconducting oxides. Original approaches were tested and the appropriate functionals (potentials) were defined coherently with the chemical nature of the materials. Computer simulations were performed for single crystals and implemented successfully for nanosized structures. For all chosen nanoparticles as TiO_2 , NiTiO_3 , and BiVO_4 , the appearance of the size quantum confinement effect was demonstrated on the electronic and optical features. The HOMO orbitals of all investigated nanocrystals are composed of the O (2p) states and the LUMO depends, respectively, on the V (3d) or Ti (3d) atoms. The hybridization of the O (2p) orbitals in the area of occupied orbitals with the other orbitals as Bi (6 s) decreases the energy gap for BiVO_4 . For structural aspects, surfaces of nanostructured objects are reconstructed due to the environmental influence inducing changes on the interatomic distances. Orbital hybridization contributing to extremes of valence and conduction bands is modified by such surface effects with particular strength for low-sized clusters as traduced from the carried out numerical simulations.

The close correlation between the experimental investigations on such semiconducting oxide systems and the theoretical approaches supported by numerical simulation paves the way to understand quantitatively the physical peculiarities of such photoactive systems. Charge transfer effects, role of doping, and structural arrangements as function for the material morphology are understood by such combined experimental investigations and theoretical models. Our ambition is to contribute by such methodology to design the relevant structures with improved photoactive properties able to be implemented in new technologies required for societal challenges like clean energy and safe environment.

Abstract

This chapter describes general principles in the stability and bonding of empty fullerenes, endohedral fullerenes, and exohedral derivatives of empty fullerenes. First, an overview of the structural properties of empty fullerenes is given. The problem of isomers' enumeration is described and the origin of the intrinsic steric strain of the fullerenes is discussed in terms of POAV (π -orbital vector analysis) leading to the isolated pentagon rule (IPR). Finally, theoretical studies of the isomers of fullerenes are discussed. In the second part of the chapter,

A.A. Popov (✉)

Leibniz-Institute for Solid State and Materials Research (IFW Dresden), Dresden, Germany

e-mail: A.Popov@ifw-dresden.de

bonding phenomena and molecular structures of endohedral metallofullerenes (EMFs) are reviewed. First, the bonding situation in EMFs is discussed in terms of ionic/covalent dichotomy. Then, the factors determining isomers of EMFs, including those favoring formation of non-IPR cage isomers, are reviewed. In the third part, general principles governing addition of atomic addends and trifluoromethyl radicals to fullerenes are analyzed.

Introduction

Carbon cluster research, originally the field of scientists interested in C_n species that might exist in deep space, “landed” on Earth with two discoveries that eventually changed the face of carbon science in particular and the nanoscience/nanotechnology in general. The first discovery was reported in 1985, when Kroto, Curl, Smalley, and coworkers made the Nobel-prize-winning suggestion that the high-mass peaks in the mass spectra of laser-evaporated graphite belonged to closed-cage structures now known as fullerenes (Kroto et al. 1985). These molecules remained the playthings of mass spectrometrists, the only scientists who could “observe” fullerenes by producing them in situ in infinitesimal amounts, until 1990 when Krätschmer and coworkers discovered that this “new form of carbon” can be produced in bulk (i.e., macroscopic) amounts by the arc burning of graphite (Krätschmer et al. 1990). C_{60} followed by C_{70} is the major fullerenes produced by arc burning; however, starting from C_{72} , classical fullerene cages are possible for each even number, and many of such fullerenes (known as *higher fullerenes*) are produced as well. Studies of higher fullerenes are complicated by the increasing number of possible isomers, even if the strict isolated pentagon rule (IPR; see below for more details) is applied. The fullerenes with the number of atoms less than 60 are also available, but still remain exotic objects. Thus, the world of fullerenes themselves is very rich, but they also provide uncountable possibilities for further chemical modifications.

One of the attractive properties of fullerenes intrinsic to their closed-cage structure is the possibility of using them as robust containers for other species. The first evidence that metal atoms can be put inside fullerenes was reported in 1985 and was based on mass spectrometry (Heath et al. 1985), while the first bulk samples of fullerenes with metal atoms inside (endohedral metallofullerenes; hereinafter EMFs) were obtained in 1991 by laser evaporation (Chai et al. 1991) or arc discharge (Alvarez et al. 1991) of the graphite rods mixed with lanthanum oxide. In the first decade after the discovery of macroscopic fullerene production, the field of EMFs remained very “hot.” Many metals were put inside fullerenes during this time, and many new molecules were reported (Shinohara 2000; Popov et al. 2013), but the yields of EMFs were very low (usually on the order of 1 % of the empty fullerenes in the arc-discharge soot). Until 1999, EMFs were mostly molecules with one to three metal atoms encapsulated in the carbon cage. In 1999 it was found that the presence of nitrogen gas in the arc-burning reactor resulted in metal nitride cluster fullerenes (NCFs) with the composition $M_3N@C_{2n}$ ($M = Sc,$

Y, Gd–Lu; $2n = 68–96$; the symbol “@” in the formula denotes how the EMF molecule is divided into the endohedral cluster, the composition of which is given before this symbol, and the carbon cage with optional exohedrally attached groups, which follow after this symbol) to be produced (Dunsch and Yang 2007; Stevenson et al. 1999). In 2001 it was discovered that some “conventional” EMFs actually had C_2 carbide units inside the cage. For example, “ $Sc_3@C_{82}$ ” and “ $Sc_2@C_{86}$ ” were shown to be $Sc_3C_2@C_{80}$ and $Sc_2C_2@C_{84}$, respectively (Iiduka et al. 2005; Wang et al. 2001). Judicious choice of the nitrogen source led the group in Dresden to the invention of the reactive atmosphere method, in which the use of ammonia in the arc-burning reactor resulted in NCFs as major fullerene products (Dunsch et al. 2003, 2004). The same method with the use of CH_4 resulted in $Sc_3CH@C_{80}$ (Krause et al. 2007). Oxides $Sc_4O_{2,3}@C_{80}$ were synthesized using copper nitrate as the source of oxygen (Stevenson et al. 2008), while the use of guanidinium thiocyanate afforded formation of sulfide clusterfullerenes $M_2S@C_{82}$ ($M = Sc, Y, Dy, Lu$) (Dunsch et al. 2010). The chemical route to open the empty fullerene cage, insert the small molecule inside (e.g., H_2), and then close the carbon cage was also recently reported (Komatsu et al. 2005). Finally, it is also possible to introduce one or two atoms of inert gases into the fullerene by high-pressure–high-temperature treatment (Saunders et al. 1993). An extended review of the field was published in 2013 (Popov et al. 2013).

Another important property of fullerenes from the chemist’s point of view is a very rich π -system based on the formal sp^2 hybridization state of all carbon atoms. In chemical reactions fullerenes behave as polyalkenes (original expectations of the “superaromatic” properties were not confirmed) and thus exhibit very rich addition chemistry. That is, numerous cycloaddition reactions and addition of the groups forming one single bond to the fullerene core (such as atoms, e.g., halogens or hydrogen, or radicals, e.g., alkyl groups) are reported (Hirsch and Brettreich 2005).

Development of fullerene science was always accompanied – and sometimes preceded – by theoretical studies. The principles governing stability of fullerenes were revealed in the late 1980s and early 1990s with the use of computational approaches, and such important data as relative energies of the fullerene isomers are still available only from the results of quantum-chemical calculations. Likewise, the most mysterious question about the fullerenes – why and how they are formed – is successfully addressed by theoreticians (Irlé et al. 2003, 2006). The rise of the fullerene era to a large extent coincided with a dramatic increase in the capabilities of computational chemistry – either from advances in hardware, software, or theory itself. If studies of fullerenes in the mid-1980s, even by semiempirical approaches, were possible only in special laboratories, presently (at 2015), accurate DFT calculations can be done by virtually any scientist using a standard office computer. Yet, the large size of fullerenes and their derivatives still imposes serious limitations: even now it is barely possible to perform post-Hartree–Fock *ab initio* calculations. Thus, DFT is the main method of choice in fullerene chemistry and will probably remain so in years to come. Although MP2 calculations are becoming more feasible (Darzynkiewicz and Scuseria 1997; Haser et al. 1991; Krapp and Frenking 2007), a significant increase of computational demands in many cases is not justified by

the reliability of the results when compared to DFT (the modeling of noncovalent interaction, the weak point of DFT, is, however, an important exception). Routine use of methods with higher scaling than MP2 is still very difficult at present.

In this chapter we will show how quantum-chemical calculations can assist in studies of fullerenes. In particular, we will discuss prediction and elucidation of the molecular structures of the empty fullerenes, endohedral metallofullerenes, and selected fullerene derivatives. Taking into the account the huge amount of literature published on this subject, any review of the field is necessarily incomplete. We will not try to cover the whole field; instead, we will focus on several representative examples.

Structures and Stability of Empty Fullerenes

Definition of Fullerenes and Enumeration of Their Isomers

IUPAC defines a fullerene as a “compound composed solely of an even number of carbon atoms which form a cage-like fused-ring polycyclic system with twelve five-membered rings and the rest six-membered rings.” In practice, all other closed-cage structures built from three-coordinate carbon atoms are also called fullerenes. The definition of fullerenes is based on the Euler theorem, which states that for a given polyhedron, the numbers of vertices (n), edges (e), and faces (f) are related by:

$$n + f = e + 2 \quad (1)$$

Each carbon atom in a fullerene is bonded to three other atoms; therefore, for a fullerene C_n , the number of edges is $e = 3n/2$, which yields the number of faces $f = n/2 + 2$. Since all arc-discharge produced fullerenes have only five- and six-membered faces (it is possible to obtain fullerenes with four- or seven-membered rings only by chemical modification), one can calculate the number of vertices and faces through the number of pentagons (p) and hexagons (h):

$$\begin{aligned} (5p + 6h) / 3 &= n \\ p + h &= n/2 + 2 \end{aligned} \quad (2)$$

Solution of Eq. 2 yields $p = 12$ (and hence the number in the definition given above) and $h = n/2 - 10$. Obviously, the smallest structure with 12 pentagons is C_{20} (it has no hexagons), and starting from $n = 24$ at least one fullerene structure is possible for each even n (note that it is not possible to build a fullerene for C_{22}). The structural consequences from Euler's theorem applied to fullerenes with pentagons, hexagons, and heptagons were discussed in detail by Fowler and coworkers (Fowler et al. 1996). The difference between the number of pentagonal and heptagonal faces is always 12. Therefore, addition of a heptagon increases the number of pentagons by one, while decreasing the number of hexagons by two.

Fig. 1 Unwinding C_{60} and C_{70} into spirals (*thick black line*)

The number of the isomers is rapidly increasing with n , raising the problem of systematic enumeration of all possible isomers. The problem was solved for all practical fullerene sizes by the invention of the spiral algorithm (Manolopoulos et al. 1991; Fowler and Manolopoulos 1995). The algorithm is based on the spiral conjecture, which states that *The surface of a fullerene polyhedron may be unwound in a continuous spiral strip of edge-sharing pentagons and hexagons such that each new face in the spiral after the second share an edge with both (a) its immediate predecessor in the spiral and (b) the first face in the preceding spiral that still has an open edge* (Fowler and Manolopoulos 1995).

Figure 1 shows one of the ways in which C_{60} and C_{70} can be unwound into a spiral. The spiral can be coded by a sequence of “5” and “6” digits corresponding to the positions of the pentagons and hexagons. For instance, the spiral of the fullerene C_{60} shown in Fig. 1 can be written as:

$$566665656565656656565656566665 \quad (3)$$

Enumeration of all fullerene isomers is now straightforward: one should generate all possible spiral codes consistent with the given number of atoms (i.e., for C_n fullerene the length of the code is $f = n/2 + 10$, and positions of the pentagons can be used as running indices) and then check for each spiral if it can be wound up into a fullerene. The task, however, is not complete at this point since the fullerene molecule can be unwound into up to $6n$ spirals, and hence each fullerene will be generated many times. For instance, if C_{60} is unwound into a spiral starting from a hexagon, the following codes can be also obtained:

$$\begin{aligned} 656565666566566566566565656566 \\ 665656565665665665665665666565656 \end{aligned} \quad (4)$$

There is a simple way to solve the problem of checking the uniqueness of the given fullerene. One can consider the spiral codes given in Eqs. 3 and 4 as numbers, which can then simply be compared to each other. For the spirals of C_{60} under discussion,

(Eq. 3) < (Eq. 4) < (Eq. 4). The spiral with the smallest number is called a *canonical spiral*; all noncanonical spirals should be sorted out. Thus, in addition to checking whether a given spiral can be wound up into a fullerene, one should also check if it is canonical. This problem can be also solved straightforwardly: if it is found that the spiral forms a fullerene, this fullerene should then be unwound into all possible spirals and the canonical one should be found among them and compared to the testing spiral.

The algorithm outlined above has been proved to be very successful, and its use in enumeration of the fullerene isomers is now standard. Importantly, the sequential number of the given fullerene isomer (i.e., the number of the isomer in the list of all isomers generated for the given fullerene by the spiral algorithm) is its sufficient and unique identifier. Usually, in designation of the fullerene isomer, one also adds its symmetry (to be precise, the highest symmetry possible for this topology of atoms; the ground state structure of the molecule can have lower symmetry), and we will use this notation in this chapter.

To conclude this section, we note that the spiral codes in Eqs. 3 and 4 can be further simplified, taking into account that each fullerene has only 12 pentagons, and hence the spiral code can be uniquely defined by the numbers of the pentagon positions. In this notation, the spiral of C_{60} in Eq. 3 is written as:

$$1\ 7\ 9\ 11\ 13\ 15\ 18\ 20\ 22\ 24\ 26\ 32 \quad (5)$$

This notation is usually used in the literature, including the famous “An Atlas of Fullerenes” (Fowler and Manolopoulos 1995).

The Isolated Pentagon Rule and Steric Strain

The importance of exhaustive systematic enumeration of all isomers for a given fullerene becomes clear when the problem of structure elucidation of fullerenes is raised. Highly symmetric structures of C_{60} and C_{70} were proposed as a result of playing with the models. However, the success of this approach was to a large extent fortuitous, and this is hardly possible for other fullerenes. Of course, an unambiguous elucidation of the molecular structure might be possible through single-crystal X-ray diffraction studies. However, the quasi-spherical shape of fullerene molecules results in strong disorder, which in most cases precludes reliable elucidations of the isomeric structures. This problem can be solved by chemical functionalization of fullerenes (in particular, chlorination and perfluoroalkylation of higher fullerenes have been extensively studied during the last decade) and X-ray studies of their derivatives (Kareev et al. 2008a; Shustova et al. 2007; Simeonov et al. 2007; Troyanov and Tamm 2009; Troyanov and Kemnitz 2012; Boltalina et al. 2015), but this promising approach is not always applicable. Thus, since early 1990s and up to now, ^{13}C NMR spectroscopy has been the most important method in structural studies of newly isolated fullerenes. However, through the number of lines and their relative intensities, ^{13}C NMR spectrum gives at best only the symmetry of

Table 1 The total number of isomer of C₆₀–C₁₀₂ fullerenes and the number of fullerene C₉₀ isomers of different symmetry types compared to the number of corresponding IPR isomers

C _n	Total	IPR	C _n	Total	IPR	C ₉₀ -symmetry group	Total	IPR
60	1812	1	86	63761	19	C ₉₀ -C ₁	97936	16

84	51592	24	102	445092	616	C ₉₀ -D _{5h}	2	1

the fullerene molecule, but not the exact isomeric pattern. Therefore, it is necessary that *all* isomers with NMR-determined symmetry are considered as possible structural guesses. Quantum-chemical calculations and studies by other spectroscopic techniques can be then used to determine the most appropriate structure.

Table 1 lists the total amount of possible isomers of fullerenes C_n for different *n*. These numbers clearly show that consideration of *all* isomers is hardly feasible for the low-symmetric structures. For instance, 99918 isomers are possible for C₉₀, and the information that an experimentally studied isomer has C₂ symmetry allows one to reduce the structural guesses to 1266 isomers, which is still not very feasible. On the other hand, the number of isomers formed in arc-discharge synthesis is usually rather low. Therefore, it seems possible and highly desirable to develop some simple rules to reduce the number of isomers that should be considered.

The most successful rule of this sort is the isolated pentagon rule (IPR) proposed by H. Kroto back in 1987 on the basis of general considerations (Kroto 1987) and by Schmalz and coworkers in 1988 on the basis of more careful considerations of the sources of strain in carbon clusters and Hückel calculations (Schmalz et al. 1988). The IPR rule states that the fullerene isomers with adjacent pentagons are less stable than the isomers in which pentagons are surrounded only by hexagons (i.e., pentagons are *isolated*). In subsequent works numerous isomers of fullerenes were studied and the number of the pentagon–pentagon edges was found to be a parameter exhibiting very good correlation to the stability of the fullerenes. Figure 2a shows the correlation between the number of pentagon–pentagon edges and the relative energies of all 1812 isomers of C₆₀ calculated at the QCFF/PI level of theory (Austin et al. 1995) (QCFF/PI is an inexpensive semiempirical computational approach combining classical mechanics for σ-bonds and the Pople–Pariser–Parr method for π-system). The correlation is close to the linear form, and the energy penalty for one pentagon–pentagon edge, 111 kJ/mol for C₆₀, can be estimated from the slope of the fitted line. In a detailed study of the C₃₀–C₆₀ fullerene isomers at the QCFF/PI level (Campbell et al. 1996), it was found that the penalty is increasing with the cage size (Fig. 2b), from 72 kJ/mol for C₃₀ to 105 kJ/mol for C₅₀. The study of 55 C₇₆ isomers of D₂ and higher symmetry at the QCFF/PI level (Austin et al. 1994) has shown that

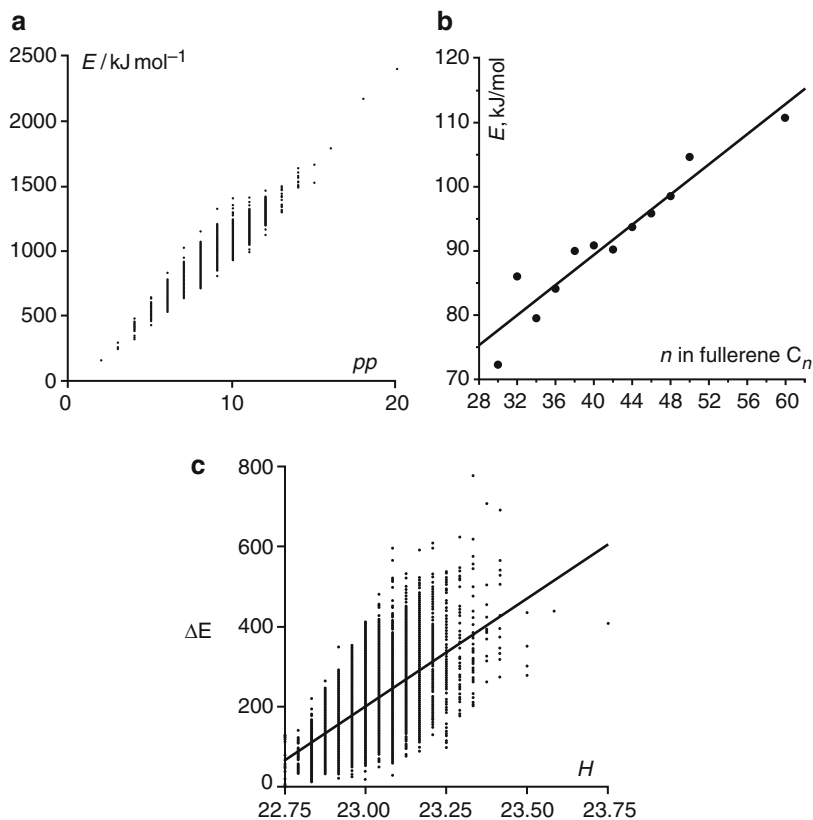

Fig. 2 (a) The relative energy of C_{60} isomers computed at the QCFF/PI level as a function of the number of pentagon–pentagon edges (Reproduced with permission from (Austin et al. 1995), © (1995) American Chemical Society); (b) energy penalty for the pentagon adjacency as a function of the fullerene size (Based on the data from Campbell et al. 1996); (c) relative energy of the IPR isomers of C_{116} computed at the QCFF/PI level as a function of the steric strain parameter H (Reproduced with permission from (Achiba et al. 1998a), © (1998) American Chemical Society)

the penalty of the pentagon adjacency can be estimated as 150 kJ/mol (but this value is probably overestimated since the non-IPR isomers with lower symmetry can be more stable). The study of all 40 isomers of C_{40} at various levels of theory, including DFT (B3LYP, BLYP, and LDA), the Hartree–Fock method, semiempirical methods (AM1, PM3, MNDO, QCFF/PI), the density-functional based tight-binding method (DFTB), and molecular mechanics (MM), has shown that for all methods except for MM, the penalty for C_{40} isomers falls in the narrow range of 82–100 kJ/mol (Albertazzi et al. 1999). In particular, B3LYP/STO-3G and QCFF/PI values are 92 and 91 kJ/mol, respectively, which confirms that the predictions on the broader range of isomers obtained at the QCFF/PI levels are also reliable. It should be noted, however, that the increase of the basis set to 6-31G* resulted in a 13 % increase

in the penalty at the BLYP level, showing that the basis set effects can be rather important.

The energy penalty for the pentagon adjacency is sufficiently large to suggest that all non-IPR isomers can be sorted out for higher fullerenes (relative energies of the isolable fullerene isomers are usually less than 100 kJ/mol; see below). Increase of the energy penalty with the cage size is another factor favoring the application of the IPR. Indeed, the rule is strictly followed by all experimentally available empty fullerenes (the notable exclusion is C_{72} , which is discussed below). For the experimentally accessible fullerenes, the IPR reduces the number of possible isomers to be considered from many thousands to tens and hundreds (Table 1). It is, however, possible to stabilize pentagon adjacencies by exohedral derivatization or by coordination to the metal atoms in EMFs (Tan et al. 2009), and hence larger sets of isomers have to be considered in these cases.

High energy penalty is the result of the combination of at least two factors. First, a pair of adjacent pentagons (pentalene) has an 8-electron π -system and is anti-aromatic. Another factor, which is probably more important, is the steric strain induced by adjacent pentagons. The formal hybridization state of carbon in fullerenes is sp^2 . Thus, carbon atoms should be planar (by this, we mean that it has three neighboring carbon atoms in the same plane). From the geometrical point of view, planarity is achieved when a carbon atom is located on the fusion of three hexagons. In this case, π -orbitals (p_z) of the neighboring atoms are exactly parallel and the optimal overlap of these orbitals is achieved. However, one cannot build fullerene only from hexagons – pentagons are necessary to make closed-cage structures. The carbon atoms in pentagons are not planar anymore (the small angle of 108° vs. 120° in hexagons has to be compensated by the out-of-plane shift of the central atom), which results in *rehybridization*, the effect easily explainable in terms of π -orbital axis vector (POAV) analysis. POAV is defined as the vector that forms equal angles (POAV angles $\theta_{\sigma\pi}$) to all three σ -bonds (it is assumed that σ -orbitals are aligned toward the neighboring atoms). Admixing of s -orbitals into the hybrid π -orbital (the essence of rehybridization) can be quantified from geometrical point of view as:

$$m = \frac{2\sin^2(\theta_{\sigma\pi} - \pi/2)}{1 - 3\sin^2(\theta_{\sigma\pi} - \pi/2)} \quad (6)$$

where m determines admixture of s -orbital to the hybrid π -orbital ($\pi = s^m p$; for perfect sp^2 hybridization, $\theta_{\sigma\pi} = 90^\circ$ and $m = 0$). When m is not equal to zero, π -orbitals of the neighboring atoms are not parallel anymore. Because of this misalignment, the π -orbital overlap is reduced, and therefore the π -bonding is weakened, the effect being the stronger the larger the value of m . Figure 3b shows possible junctions of pentagon and hexagons and hybrid π -orbital of the central atom computed for idealized polygonal bond angles. Misalignment of π -orbitals increases with the increase of the number of fused pentagons, and the IPR is a manifestation of this tendency.

Fig. 3 (a) Definition of the $\theta_{\sigma\pi}$ angle in the POAV approach; (b) the component of the hybrid π -orbital of the central atom in different junctions of pentagons and hexagons computed for idealized polygonal bond angles (Based on the data from Fowler and Manolopoulos 1995)

It is obvious from Fig. 3 that all fullerenes are inherently strained. For instance, it was estimated that the steric strain constitutes approximately 80 % of the excess energy of C_{60} with respect to graphite (Haddon 1993). To quantify the steric strain, Raghavachari introduced the concept of hexagonal indices (Raghavachari 1992). The neighbor index k of a given hexagon is the number of its edges which are shared with other hexagons, and every fullerene isomer can be characterized by a set of indices h_k ($k = 0-6$), where h_k is the number of hexagons with neighbor index k . In the aforementioned study of 1812 isomers of C_{60} , it was shown that the parameter

$$H = \sum_k k^2 h_k \quad (7)$$

also gives good linear correlation with the relative energies of the isomers.

The concept of hexagonal indices was in fact invented to explain relative stabilities of the IPR isomers. As each hexagon in the IPR isomer is adjacent to at least three other hexagons, h_0 , h_1 , and h_2 indices are equal to 0, and the combination of four indices (h_3 , h_4 , h_5 , h_6) is sufficient to characterize hexagon adjacencies in a given fullerene isomer (Fowler and Manolopoulos 1995; Raghavachari 1992). Raghavachari suggested that to minimize the steric strain, the indices of all hexagons should be as close to each other as possible. In other words, the lowest strain energy can be achieved when the non-planarity is uniformly distributed over the whole carbon cage. Hence, the lowest strain is expected for those structures, in which all hexagons have the same neighborhood (all indices are equal), the condition fulfilled only for highly symmetric $C_{60}-I_h(1)$, $C_{80}-I_h(7)$, and $C_{80}-D_{5h}(6)$ in the whole range of IPR fullerenes C_{2n} with $2n < 120$ (Fowler and Manolopoulos 1995). More complex conditions were derived for other IPR fullerenes, namely:

Table 2 Optimal hexagon indices, the IPR isomers with optimal hexagon indices, and the lowest energy IPR C_{2n} and C_{2n}^{6-} isomers ($2n = 76-90$)

C_{2n}	(h_3, h_4, h_5, h_6)	The least-strain IPR isomers ^a	The lowest energy C_{2n} IPR isomers ^b	The lowest energy C_{2n}^{6-} IPR isomers ^c

^aBased on the data from (Fowler and Manolopoulos 1995)

^bSee Table 3 for more details

^cBased on the data from (Popov and Dunsch 2007)

$$(h_3, h_4, h_4, h_6) = \begin{cases} (80 - n, 3n/2 - 90, 0, 0); \rightarrow 60 \leq n \leq 80 \\ (0, 70 - n/2, n - 80, 0); \rightarrow 80 \leq n \leq 140 \\ (0, 0, 60, n/2 - 70); \rightarrow 140 \leq n \end{cases} \quad (8)$$

Table 2 lists optimal combinations of hexagonal indices as well as fullerene isomers in the range of C_{70} - C_{90} with such sets of indices. Importantly, C_{72} is the only fullerene that has no isomers satisfying these conditions.

As a numerical parameter to quantify the steric strain in IPR fullerenes, one can use the standard deviation of the index distribution (Fowler and Manolopoulos 1995):

$$\sigma_h = \sqrt{\langle k^2 \rangle - \langle k \rangle^2} \quad (9)$$

where

$$\langle k^i \rangle \Big|_{i=1,2} = \left(\sum_{k=3}^{k=6} k^i h_k \right) \cdot \left(\sum_{k=3}^{k=6} h_k \right)^{-1} \quad (10)$$

It was also shown that σ_h correlates well with the standard deviation of the square of POAV pyramidalization angle, $\sigma(\theta_p^2)$ ($\theta_p = \theta_{\sigma\pi} - 90$), as can be seen in Fig. 4a for a set of 24 IPR isomers of C_{84} (Boltalina et al. 2009). Therefore, σ_h and $\sigma(\theta_p^2)$ can be used interchangeably to quantify the steric strain, the latter parameter being more universal (for instance, it can be equally used for fullerene derivatives, in which some carbon atoms are in sp^3 hybridization state). Figure 4b also plots the relative energies (ΔE) of C_{84} computed at the B3LYP/6-31G* level of theory versus $\sigma(\theta_p^2)$.

Fig. 4 (a) Correlation between $\sigma(\theta_p^2)$ and σ_h parameters for 24 IPR isomer of C_{84} (Based on the data from Boltalina et al. 2009); for a fitted line, $R^2 = 0.97$; (b) Correlation between $\sigma(\theta_p^2)$ and B3LYP/6-31G*-computed relative energies of 24 IPR isomer of C_{84} (Based on the data from Sun and Kertesz 2001b)

The lack of correlations between ΔE and $\sigma(\theta_p^2)$ for the isomers with medium values of these parameters indicates that for IPR fullerenes, the other factors (e.g., electronic) are at least equally important as the steric strain. As a result, the lowest energy isomers for C_{76} – C_{90} are usually not the isomers with the lowest steric strain (see Table 2), and steric strain analysis is not widely used now in the studies of higher fullerenes of medium size. If a larger set of isomers is considered (e.g., 6,063 IPR isomers C_{116}), then the steric strain indicators (such as H in Eq. 7) indeed show correlation with the relative energies, at least at the QCFF/PI level (Fig. 2c; Achiba et al. 1998a). However, the standard deviation of 75 kJ/mol is still too large, and such data can be of help only to sort out some high-energy isomer. Below we will show that more precise schemes have been developed based on the combination of topological motifs and their increments (Cioslowski et al. 2000).

The Isomers of IPR Fullerenes

With the advent of the IPR, the number of fullerene isomers to be considered was drastically reduced, and detailed computations of reasonable (i.e., IPR) isomers and comparison to the experimental results became feasible. In this section we will review the results of the search of the most stable isomers of fullerenes beyond C_{70} (starting from C_{70} , at least one IPR isomer is possible for each even number of atoms). It is necessary to point out that the term *stability* comprises some ambivalence. It can be used in terms of *thermodynamic* stability, which in the studies of isomers means low relative energy, or in terms of *kinetic* stability, which implies reactivity of the compound in the given experimental conditions (in the studies of fullerenes, it is usually determined by the HOMO–LUMO gap).

When predicting the possible isomeric structure of fullerenes, it is necessary to consider a combination of both thermodynamic and kinetic stability factors, the former determining the possibility of the formation of the given fullerene and the latter showing whether a given fullerene can be extracted from the soot and further processed by standard fullerene separation techniques. In fact, conclusions based on thermodynamic stability can be valid only when the reaction is close to the equilibrium (which is hard to prove for fullerenes). Moreover, for the equilibrium, Gibbs energies (rather than relative energies) should be taken into account, and it was shown by Slanina and coworkers that the equilibrium composition can be significantly altered at high temperatures (Slanina et al. 2004b). On the other hand, there are some examples (see below) showing that if thermodynamically stable fullerene has small HOMO–LUMO gap, it is possibly produced but remains in the insoluble part of the soot after extraction (presumably because of its polymerization). In this respect, a combination of the relative energy and the HOMO–LUMO gap still seems to be convenient parameters for the basic characterization of the fullerene isomers. Table 3 lists the data on the relative energies of some higher fullerene isomers obtained using B3LYP and PBE0 (also known as PBE1PBE) hybrid DFT functionals. B3LYP results are compiled from several works by different groups and are obtained mainly with the use of 6-31G or 6-31G* basis sets (Chen et al. 2001; Slanina et al. 2000; Sun and Kertesz 2000, 2001b, 2002; Sun 2003a, b; Zhao et al. 2003), while PBE0 values are results of single-point calculations with 6-311G* basis set and DFTB-optimized atomic coordinates (Shao et al. 2006, 2007). Table 3 also lists PBE0-obtained HOMO–LUMO gaps. Figure 5 shows the structures of the major isomers of C_{60} and C_{70} – C_{84} .

The first fullerene after C_{70} , C_{72} , is a “missing” fullerene since it has never been obtained in considerable amounts. The sole IPR isomers of C_{72} with D_{6d} molecular symmetry are predicted to have large HOMO–LUMO gap (1.42 eV at the PBE/TZ2P level), however, DFT calculations (Kobayashi et al. 1997; Kobayashi and Nagase 2002b; Slanina et al. 2004a) supported also by the measurements of electron affinity of C_{72} (Boltalina et al. 2000a) show that trace amounts of C_{72} present in the fullerene extract are most probably based on the non-IPR C_{2v} (11188) isomer, which is 46–48 kJ/mol more stable than the IPR D_{6d} (1) isomer at the DFT level of theory (Table 3). Thus, C_{72} is the only empty fullerene C_n ($n > 70$) which violates IPR.

C_{74} represents to some extent the opposite situation to C_{72} : according to DFT calculations, the sole IPR isomer of C_{74} , D_{3h} (1), has small HOMO–LUMO gap and probably has a triplet ground state (Kovalenko and Khamatgalimov 2003). This fullerene was also thought to be “missing” for a long time, until it was found that it is insoluble in common fullerene solvents (Karataev 1998), most probably because of polymerization. C_{74} as well as some other “insoluble” fullerenes can be solubilized by either electrochemical (Diener and Alford 1998) or chemical modification (Goryunkov et al. 2004b; Shustova et al. 2006, 2007). For instance, trifluoromethylation of “insoluble” fullerene mixture afforded $C_{74}(\text{CF}_3)_{12}$ as a major product and D_{3h} (1) carbon cage in this compound was unambiguously confirmed by single-crystal X-ray diffraction (Shustova et al. 2007).

Fig. 5 Molecular structures of C_{60} , C_{70} , and selected higher fullerenes. The atoms in adjacent pentagon pair in C_{72} are highlighted

Identity of C_{76} as $D_2(1)$ isomer was unambiguously confirmed by ^{13}C NMR spectroscopy in the very early studies of the higher fullerenes (Ettl et al. 1991). According to DFT calculations, $D_2(1)$ is considerably more stable than the second IPR isomer, $T_d(2)$. Moreover, the latter is subject to Jahn–Teller distortion (the actual symmetry is D_2) and has a small HOMO–LUMO gap. Recently, it was shown that C_{76} – $T_d(2)$ is probably also formed in the fullerene synthesis but remains insoluble; however, it can be solubilized and characterized in the form of trifluoromethyl derivative (C_{76} – $T_d(2)$)(CF_3)₁₂ (Shustova et al. 2006).

C_{78} has five IPR isomers; four of them are quite stable (their ΔE covers the range of 41 kJ/mol) and are proved to be formed in the arc-discharge synthesis. Three isomers, $D_3(1)$, $C_{2v}(2)$, and $C_{2v}(3)$, are obtained in approximately comparable amounts (the actual ratio depends on the pressure used in the synthesis) and can be easily extracted from the soot as they have comparably high HOMO–LUMO gaps (Kikuchi et al. 1992; Wakabayashi et al. 1994). The isomer $D_{3h}(5)$, although it is the second in the stability order (Table 3), can be found in the fullerene extract in much smaller amounts (Simeonov et al. 2008). A possible reason is the low HOMO–LUMO gap, which results in the poor solubility. Indeed, this isomer was found among the “insoluble” fullerenes, its structure being unambiguously confirmed by the single-crystal X-ray structure of the trifluoromethyl derivative, (C_{78} – $D_{3h}(5)$)(CF_3)₁₂ (Shustova et al. 2007).

From seven IPR isomers of C_{80} , only the two most stable structures (Table 3), $D_2(1)$ and $D_{5d}(2)$, are obtained in the form of empty fullerenes (Hennrich et al.

1996; Wang et al. 2000b). DFT predicts that they are almost isoenergetic (the $D_2(1)$ isomer is somewhat more stable), but $D_{5d}(2)$ isomer has considerably smaller HOMO–LUMO gap. Besides, the higher symmetry of $D_{5d}(2)$ isomer also reduces its content if entropy factors at higher temperatures are taken into account. As a result, the yield of $D_2(1)$ is about 30 times higher (Wang et al. 2000b). Isolation of $(C_{80}-C_{2v}(5))(CF_3)_{12}$ after trifluoromethylation of the “insoluble” fullerene mixture has shown that $C_{80}-C_{2v}(5)$ is also produced in the arc-discharge synthesis (Shustova et al. 2006). $C_{2v}(5)$ isomer is rather stable but has small HOMO–LUMO gap ($\Delta E = 25$ kJ/mol, gap = 0.71 eV at the B3LYP/6-31G* level). Importantly, icosahedral $C_{80}-I_h(7)$ isomer, which should have the least steric strain among all IPR isomers of C_{80} , is in fact the least stable isomer ($\Delta E = 114$ kJ/mol at the B3LYP/6-31G* level of theory (Slanina et al. 2008). The reason is its electronic instability – in the ideal icosahedral symmetry, its HOMO is fourfold degenerate and is occupied by two electrons. BP/TZVP studies have shown that it has D_{2h} symmetry in the ground state, and its singlet and triplet states are isoenergetic (Furche and Ahlrichs 2001). However, this isomer becomes the most stable C_{80} isomer in the hexaanionic state, when its HOMO is fully occupied, which makes it a key structure for the endohedral metallofullerenes (see section “Bonding, Structures, and Stability of Endohedral Metallofullerenes” of this chapter).

C_{82} has seven IPR isomers, but only one of them, $C_2(3)$, was isolated in pure form (Kikuchi et al. 1992; Zalibera et al. 2007). $C_2(3)$ is the most stable isomer of C_{82} and has large HOMO–LUMO gap (Sun and Kertesz 2001a), so its high abundance is not surprising. Meanwhile, $C_s(4)$ isomer is also rather stable and has similar gap, but this isomer has never been isolated in a pure form. However, its presence in the fullerene soot was unambiguously confirmed by the characterization of its chloro-derivative $(C_{82}-C_s(4))Cl_{20}$ (Yang et al. 2013). The studies of the “insoluble” fullerene fraction have shown that $C_2(5)$ isomer is also formed in the arc-discharge synthesis, as verified by the isolation and characterization of its CF_3 derivative, $(C_{82}-C_2(5))(CF_3)_{12}$ (Shustova et al. 2006).

Starting from C_{84} , the increase in the number of possible structures becomes quite significant (see Table 1), which seriously complicates the studies, both experimentally and theoretically. This fact also increases the value of theoretical studies, since they can help in sorting out unrealistic isomers. The question of high importance in this situation is how to handle the rapidly increasing number of isomers. The obvious strategy of choice is to use several (usually two) computational approaches, first the “cheap” one (for instance, semiempirical method) for the whole set of isomers and then the more expensive but more reliable approach (usually DFT) for a reduced set of structures. It is important that the “cheap” method should be also sufficiently reliable so that the possible errors in the relative energies should be not very high, and a reasonable cutoff in the relative energies might be applied for the subsequent higher-level computations. Twenty-four IPR isomers of C_{84} form a convenient training set, since it is still feasible to perform a full DFT study for all of them. Figure 6 compares relative energies of 24 isomers obtained at the B3LYP/6-31G* level (Sun and Kertesz 2001b) to those obtained with three semiempirical approaches widely used in the fullerene chemistry, QCFF/PI, MNDO, and DFTB.

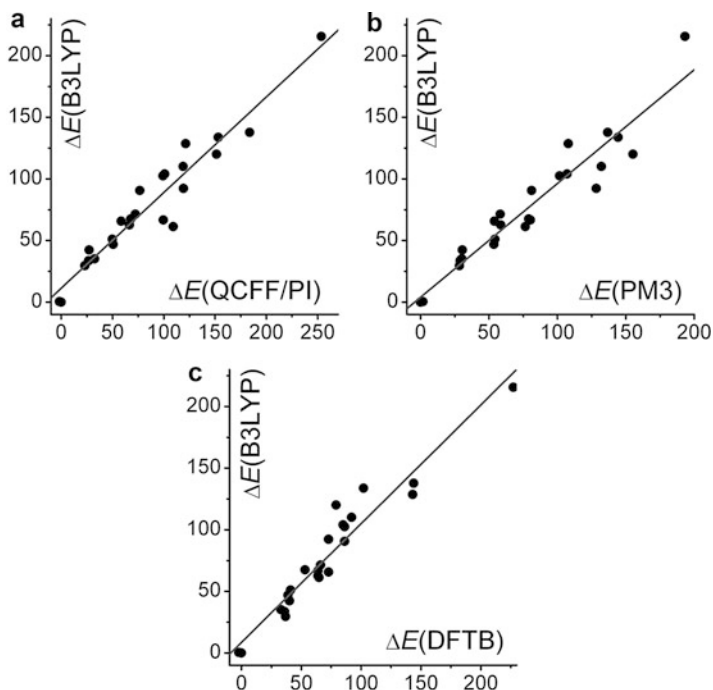

Fig. 6 Correlations between relative energies of 24 IPR isomer of C_{84} computed at the B3LYP/6-31G* level and those computed using QCFF/PI (a), PM3 (b), and DFTB (c), all values are in kJ/mol. R^2 values for the fitted lines are 0.925, 0.912, and 0.925, respectively

One can see that in all cases the correlation is quite reasonable ($R^2 \approx 0.92$), and the standard deviations (σ_E) are less than ~ 20 kJ/mol. Roughly estimating the energy cutoff for the isomers computed by means of “cheap” method as $3\sigma_E$, one can consider then only the isomers with $\Delta E < 3\sigma_E$ for the subsequent DFT study (the cutoff should be appropriately increased, of course, if one is interested in the whole set of isomers within the given energy window). Assessment study of three semiempirical approaches, MNDO, AM1, and PM3, in predicting relative energies of fullerene isomers in comparison to B3LYP/6-31G* was reported for a set of fullerenes including C_{30} – C_{50} , all IPR isomers of C_{72} – C_{86} , and selected isomers of C_{88} – C_{102} (Chen and Thiel 2003). Quite good correlations were found between the results of DFT and semiempirical calculations for higher fullerenes ($R^2 = 0.92$, 0.88, and 0.86, for MNDO, AM1, and PM3, respectively; standard deviations are 20–25 kJ/mol), while for small fullerenes with a large number of pentagon adjacencies, performance of semiempirical methods was significantly worse. In another work, AM1 and PM3 methods were compared to DFTB and B3LYP/6-31G* for all IPR isomers of C_{72} – C_{86} fullerenes and selected isomers of C_{28} – C_{36} (Zheng et al. 2005). At variance with the results in Chen and Thiel (2003), the authors have found that AM1 and PM3 performed rather bad ($R^2 = 0.77$ and 0.73,

respectively, for C_{72} – C_{86}), while DFTB-predicted values were close to B3LYP/6-31G* ($R^2 = 0.88$ and 0.93 for NCC and SCC-variants of DFTB, respectively). The significant difference in performance of AM1 and PM3 methods reported by two groups is quite remarkable. Close comparison of the relative energies from the two works shows that the difference in relative energies predicted for the *same* isomers by the *same* method can be as high as 50 kJ/mol and in one case ($C_{3v}(8)$ isomer of C_{82}) reaches 75 kJ/mol. At the same time, both works report the same values for the isomer of C_{84} and agree in that semiempirical methods give reliable predictions for this fullerene.

C_{84} is also a special case among the higher fullerenes since, on the one hand, it is the most abundant empty fullerene after C_{60} and C_{70} (at least, if all C_{84} isomers are taken together); on the other hand, it provides the broadest range of the isomers characterized for one fullerene. The lowest energy is predicted by many approaches for $D_2(22)$ and $D_{2d}(23)$ isomers, separated from the other isomers by the gap of ca 30 kJ/mol (Table 3). They are essentially isoenergetic (ΔE varies within few kJ/mol in favor of one or another isomer depending on the method) and have large HOMO–LUMO gaps. Indeed, these are the isomers produced in the largest amounts (the D_2 to D_{2d} ratio is ca 2:1 and varies depending on the conditions of synthesis) (Kikuchi et al. 1992). C_{84} also serves as a good example to emphasize that with the increase of the number of isomers, the density of their distribution in the energy scale is also increasing. The energies of at least 12 isomers fall in the range of $\Delta E = 30 - 71$ kJ/mol at the B3LYP/6-31G* level (Sun and Kertesz 2001b), and many of them can be isolated as “minor” isomers, including (in the order of their yield) $C_2(11)$, $C_s(16)$, $C_s(14)$, $D_{2d}(4)$, and $D_2(5)$ (Dennis et al. 1999). Isolation of $D_{6h}(24)$ and $D_{3d}(19)$ isomers from the arc-discharge soot of Gd-doped composite rods was also reported (note that these isomers were not formed in noticeable amounts with pure graphite rods) (Tagmatarchis et al. 1999). Perfluoroalkylation of the higher fullerene mixture resulted in the isolation and single-crystal X-ray characterization of the derivatives of several C_{84} isomers, including (C_{84} – $C_{2v}(18)$)(C_2F_5)₁₂, the carbon cage isomer of which has not been found in the previous studies (Tamm et al. 2009b).

For C_{86} , two isomers, with C_2 and C_s symmetry, could be isolated from the arc-discharge soot and characterized by ^{13}C NMR spectroscopy (Miyake et al. 2000). From 19 IPR isomer of C_{86} , 6 have C_2 symmetry and 3 have C_s symmetry. DFT calculations show that isomers $C_2(17)$ and $C_s(16)$ have the lowest energies and large HOMO–LUMO gaps and hence can be assigned to the experimentally observed structures (Sun and Kertesz 2002). The assignment was also confirmed by comparison of B3LYP/6-31G computed and experimentally measured ^{13}C NMR chemical shifts (Sun and Kertesz 2002) and by single-crystal X-ray diffraction study of the mixture of two C_{86} isomers (Wang et al. 2010).

In the most recent experimental study of C_{88} , three isomers of this fullerene were isolated and assigned by ^{13}C NMR spectroscopy to one C_s and two C_2 -symmetric structures (Miyake et al. 2000). Among 35 IPR isomers of C_{88} , 11 and 7 structures have C_s and C_2 symmetry, respectively. DFT calculations show that $C_s(17)$ has the lowest energy, followed by $C_2(7)$ and $C_2(33)$ isomers, all within the range of 10 kJ/mol (Table 3). These three structures have large HOMO–LUMO

gaps and are separated from the less-stable isomers by a gap of at least 30 kJ/mol. Therefore, they can be readily assigned to the experimentally observed structures, which are also confirmed by the comparison of the B3LYP/6-31G-computed ^{13}C NMR spectra to the experimental data (Sun 2003b). The presence of $C_2(7)$, $C_s(17)$, and $C_2(33)$ isomers in the arc-discharge produced fullerene mixture was confirmed by the isolation and single-crystal X-ray diffraction characterization of their chloro- and trifluoromethyl derivatives (Trojanov and Tamm 2009; Yang et al. 2012a; Wang et al. 2016).

Detailed experimental study of C_{90} has shown that at least five isomers are formed in the arc-discharge synthesis and that the major fraction is a mixture of C_2 - and C_{2v} -symmetric isomers (Achiba et al. 1995). The B3LYP/STO-3G calculations of all 46 IPR isomers with subsequent B3LYP/6-31G calculations of the isomers with $\Delta E < 100$ kJ/mol have shown that the lowest energy structures are $C_2(45)$ and $C_{2v}(46)$ (Sun 2003b). Analogous result was also obtained in the DFTB and PBE0/6-311G**/DFTB study (Shao et al. 2006). Therefore, $C_2(45)$ and $C_{2v}(46)$ are the most probable candidates for the main major isomers of C_{90} . Chlorination of the mixture of higher fullerenes (Kemnitz and Trojanov 2009) and several C_{90} fractions (Trojanov et al. 2011) resulted in a series of $C_{90}\text{Cl}_{2n}$ structures with six C_{90} isomers: $C_{2v}(46)$, $C_s(35)$, $C_1(30)$, $C_2(28)$, $C_1(32)$, and $C_s(34)$ cage isomers ($\Delta E = 14.2, 15.1, 28.5, 34.3, 38.5,$ and 92.0 kJ/mol, respectively, at the B3LYP/6-31G level). Likewise, trifluoromethylated derivatives were structurally characterized for $C_2(45)$ ($\Delta E = 0.0$ kJ/mol), $C_s(35)$, $C_1(30)$, and $C_1(32)$ isomers (Kareev et al. 2008b; Tamm and Trojanov 2014; Tamm and Trojanov 2015a). $D_{5h}(1)$ ($\Delta E = 76.2$ kJ/mol), $C_1(30)$, and $C_1(32)$ isomers were also isolated from the soot produced by vaporization of Sm_2O_3 /graphite rods and characterized by single-crystal X-ray diffraction (Yang et al. 2010, 2011).

Isolation and ^{13}C NMR characterization of five major isomers of C_{92} , of which two have C_2 symmetry and three have D_2 symmetry, have been reported (Achiba et al. 1998b); however, further spectroscopic details were not given. In another work, one C_2 -symmetric isomer and inseparable mixture of at least three other isomers were obtained from dysprosium arc-burned soot (Tagmatarchis et al. 2002). $C_{92}(\text{CF}_3)_{16}$ with either $D_2(81)$ or $D_2(82)$ carbon cage was identified among the other products of the trifluoromethylation of the higher fullerene mixture (Trojanov and Tamm 2009), whereas chlorination and trifluoromethylation of C_{92} fraction gave derivatives of the $C_1(38)$ isomer (Tamm and Trojanov 2015b). Results of DFT studies are more controversial for C_{92} than for smaller fullerenes discussed above (Table 3). Two detailed studies were reported, one based on the screening of the whole set of IPR isomers at the semiempirical SAM1 level with subsequent B3LYP/6-31G**/SAM1 calculations (Slanina et al. 2000), while another study included screening at the DFTB level followed by PBE0/6-311G**/DFTB calculations of the most stable isomers (Shao et al. 2006). As can be seen in Table 3, the two approaches resulted in substantially different relative energies and stability order of the isomers. While B3LYP//SAM1 approach favors $D_2(84)$ isomer as the most stable one, PBE0//DFTB predicts that $D_3(28)$ is 20 kJ/mol lower in energy than $D_2(84)$. Full optimization of $D_3(28)$ and $D_2(84)$ isomers at the B3LYP/6-311G*

and PBE0/6-311G* levels of theory in Shao et al. (2006) showed that the former is indeed more stable by 18.2 and 20.8 kJ/mol, respectively, in very close agreement with the results of PBE0//DFTB calculations. It appears thus that PBE0//DFTB values are more reliable than the results of B3LYP//AM1 calculations.

Experimental structural information on the empty fullerenes beyond C₉₂ is very scarce and usually limited to the mixtures of isomers. X-ray crystallographic studies of perfluoroalkylated and chlorinated higher fullerene mixtures or partially separated fractions characterized a series of isomer of C₉₄, C₉₆, C₁₀₀, and C₁₀₄ (Tamm et al. 2009a, 2015; Yang et al. 2012b, 2014; Fritz et al. 2014), but these data are inconclusive since the complete isomeric composition of the initial fullerene mixture remains unknown. Yet a lot of calculations were performed for larger fullerenes, and systematic information on the lowest energy isomers is available up to C₁₈₀.

The aforementioned PBE0/6-311G*//DFTB study was performed for all IPR fullerenes in the C₈₂–C₁₂₀ range as well as for all IPR and non-IPR isomers of C₃₈–C₈₀ fullerenes (Shao et al. 2006, 2007). For the most stable isomer, ¹³C NMR spectra were also predicted for comparison with experiment.

In another series of works, the most stable isomers of C₁₂₂ to C₁₈₀ were identified (Xu et al. 2006, 2008). To screen the huge number of the isomers, the authors used the empirical scheme of Cioslowski and coworkers (Cioslowski et al. 2000). According to the original scheme, formation enthalpies of fullerenes were factorized into contributions of 25 independent structural motifs, namely, six-member rings with their first and second neighbors, and the contributions of the motifs were fitted using the energies of 115 IPR fullerenes in the C₆₀–C₁₈₀ size range computed at the B3LYP/6-31G* level. In 2008, parameters were refitted using the energies of 536 fullerene molecules in the C₆₀–C₁₆₀ range (Xu et al. 2008). The serious advantage of this empirical method is that it is very inexpensive, and the energies can be estimated with high accuracy without quantum-chemical calculations. B3LYP/6-31G* calculations were then used by the authors to determine the lowest energy isomers (Xu et al. 2006, 2008). The same authors also performed benchmarking computations of C₁₁₆, C₁₁₈, and C₁₂₀ isomers to analyze performance of QCFF/PI, AM1, PM3, MNDO, and tight-binding (TB) methods in comparison to B3LYP/6-31G*//B3LYP/3-21G (Xu et al. 2007). It was found that, in contrast to the relative energies of the medium-size higher fullerenes such as C₈₄, for large fullerenes semiempirical methods performed badly and did not show any reasonable correlations with DFT-predicted relative energies. However, it should be noted that DFT is not a panacea itself. DFT has difficulties with description of the extended π -systems (Reimers et al. 2003), and hence it is possible that DFT is also not reliable for large fullerenes. Unfortunately, results of computations for larger fullerenes cannot be verified by experimental information at this moment.

In conclusion, numerous studies have shown that the most stable isomers of the middle-size higher fullerenes predicted by DFT are usually the major isomers in the experimentally produced fullerene mixtures. At the same time, it is also clear that experimental results cannot be fully described by considering only thermodynamic control (equilibrium), since some other *unknown* factors are also important in

determining the isomeric composition. For instance, it is not clear yet why some stable isomers are not formed in the arc-discharge synthesis; besides, the influence of the metals on the distribution of the arc-discharge produced fullerene isomers is not understood.

Bonding, Structures, and Stability of Endohedral Metallofullerenes

Metal–Cage Bonding in Endohedral Metallofullerenes

Since La@C_{82} was first isolated in 1991, the nature of the metal–fullerene bonding was of interest to researchers. Because of the radical nature of La@C_{82} as well as other $\text{M}^{\text{III}}\text{@C}_{82}$ ($\text{M} = \text{Y}, \text{Sc}$), the ESR spectroscopy appeared useful in revealing the main features of the electronic structure of EMFs. Small hyperfine splitting constant of the metal observed in the spectra indicated that the spin density in M@C_{82} is presumably localized on the fullerene cage. This, along with the high electron affinity of fullerenes, resulted in the concept of the endohedral metallofullerenes as non-dissociative salts (e.g., $\text{La}^{3+}\text{@C}_{82}^{3-}$), with the metal cation encapsulated in the negatively charged carbon cage. Likewise, ionic model is often used to describe electronic structure of endohedral fullerenes with more complex encapsulated species, such as dimetallofullerenes (e.g., $(\text{La}^{3+})_2\text{@C}_{80}^{6-}$), nitride clusterfullerenes (e.g., $(\text{Sc}_3\text{N})^{6+}\text{@C}_{80}^{6-}$), or carbide clusterfullerenes (e.g., $(\text{Sc}^{3+})_2\text{C}_2^{2-}\text{@C}_{82}^{4-}$).

The concept of the ionic metal–fullerene bonding was further developed by Kobayashi et al. (Kobayashi and Nagase 1998; Nagase et al. 1997). The authors analyzed the spatial distribution of electrostatic potential inside fullerene and showed that it has large negative values inside negatively charged carbon cages. This results in the strong stabilization of the metal cations if they are placed inside fullerene anions thus favoring formation of EMFs. Importantly, the minimum of the electrostatic potential in C_{82}^{3-} was found in the position where metal resides in M@C_{82} as predicted by calculations (Kobayashi and Nagase 1998; Lu et al. 2000) or shown by experimental X-ray diffraction studies (Takata et al. 2003). At the same time, it was also found that electrostatic potential inside C_{80}^{6-} has no distinguishable minima, and hence there are no distinct bonding sites for metal atoms or clusters in $\text{C}_{80}\text{-}I_h(7)$. This is indeed confirmed by several computational studies of $\text{La}_2\text{@C}_{80}\text{-}I_h(7)$ (Kobayashi et al. 1995; Shimotani et al. 2004; Zhang et al. 2007) and $\text{Sc}_3\text{N@C}_{80}\text{-}I_h(7)$ (Campanera et al. 2002; Gan and Yuan 2006; Kobayashi et al. 2001; Popov and Dunsch 2008; Yanov et al. 2006). For $\text{La}_2\text{@C}_{80}$ it is shown that there are two almost isoenergetic minima for positions of La atoms, with D_{2h} and D_{3d} molecular symmetries, and each minimum is multiplied by the group symmetry operations of I_h group. As a result, La_2 unit exhibits almost free rotation inside C_{80} cage, and the charge density of La atoms forms a pentagonal dodecahedron as revealed by synchrotron radiation powder diffraction study (Nishibori et al. 2001). Another important argument in favor of the ionic model is the carbon cage isomerism of EMFs, which shows a good correlation with

the relative stability of the appropriately charged empty cages, as will be discussed in detail below.

Although the ionic model explains some spectroscopic and structural properties of EMFs, there are numerous studies which indicate that this model is oversimplified. While the analysis of MO energy levels in the EMFs and the corresponding empty cages can be indeed interpreted as an electron transfer to the cage from the metal, experimental (Alvarez et al. 2002; Kessler et al. 1997) and theoretical (Campanera et al. 2002; Lu et al. 2000; Muthukumar and Larsson 2008; Nagase et al. 1997; Yang et al. 2008) studies clearly show a substantially non-zero population of *nd*-levels of the endohedral metal atoms. The mixing of the cluster and fullerene MOs as well as the corresponding change of the orbital energies in EMF when compared to the MOs of the empty cage is the most apparent for $\text{Sc}_3\text{N}@C_{78}$ (Fig. 7; Campanera et al. 2002; Krause et al. 2006). In many other EMFs, the metal contribution to individual π -MO orbitals of the cage is very small, yet the significant metal–cage interaction can be also revealed when the electron density distribution is analyzed (Liu et al. 2006; Popov and Dunsch 2008; Wu and Hagelberg 2008; Yang et al. 2008; Popov 2009). This can be best done with the use of promolecule deformation density approach, i.e., by visualizing the changes in the electron density distribution $\Delta\rho = [\rho(\text{Mol}) - \rho(\text{Ref})]$, where $\rho(\text{Mol})$ is the electron density of the molecule under study, while $\rho(\text{Ref})$ is the electron density of the reference system. A natural choice of the reference system in the studies of EMFs can be either noninteracting metal atoms or clusters (e.g., Sc_3N) and corresponding C_{2n} molecules or metal or cluster cations (e.g., Sc_3N^{6+}) and appropriately charged

Fig. 7 (a) Frontier Kohn–Sham MO levels in $\text{Sc}_3\text{N}@C_{78}\text{-}D_{3h}(5)$ and $C_{78}\text{-}D_{3h}(5)$, the *dash arrows* show correspondence between the orbitals of the empty cage and $\text{Sc}_3\text{N}@C_{78}$; (b) LUMO (A_2') MO of C_{78} and corresponding occupied orbital in $\text{Sc}_3\text{N}@C_{78}$; (c) LUMO + 1 (E' , only one component is shown) in C_{78} and corresponding occupied orbital in $\text{Sc}_3\text{N}@C_{78}$ (Based on the data from Krause et al. 2006 and Popov 2009)

C_{2n} anions (e.g., C_{2n}^{6-}). In particular, when two sixfold charged ions were taken as a reference, a considerable concentration of the density at Sc atoms was found in all $Sc_3N@C_{2n}$ ($2n = 68, 78, 80$) EMFs (Popov and Dunsch 2008; Popov 2009), the effect referred to by some researchers as “back donation” (Liu et al. 2006; Wu and Hageberg 2008). The $\Delta\rho$ plots have also revealed that metal–cage bonds are not localized (such as, e.g., carbon–carbon bonds) but can be better described by “coordination” bonds such as those found in transition metal complexes (Cortés-Guzmán and Bader 2005).

The cluster–cage bonding in $Sc_3N@C_{78}$ and $Sc_3N@C_{80}$ was also analyzed using the energy decomposition method (Campanera et al. 2002). The authors have shown that after the Sc_3N^{6+} cation is encapsulated inside $C_{78,80}^{6-}$ cages, a strong orbital mixing and an electronic reorganization take place.

Computed atomic charges are also much smaller than the values expected for the purely ionic bonding. For instance, net Bader, Mulliken, and NBO charges of the Sc_3N cluster in $Sc_3N@C_{80}$ are +3.50, +2.88, and +2.99, respectively, at the B3LYP/6-311G* level of theory (Popov and Dunsch 2008); another group reported the net Sc_3N charges of +1.28 (Mulliken), +1.10 (Hirshfeld), and +0.94 (Voronoi) (Valencia et al. 2008) at the BP/TZVP level of theory with ZORA relativistic corrections. Note that the charges strongly depend both on the method of theory used to compute wavefunction and on the electron density partitioning, but all reported values are significantly smaller than +6 expected for the ionic $Sc_3N^{6+}@C_{60}^{6-}$.

In summary, from the molecular orbital point of view, the mechanism of the metal(cluster)–cage interactions in EMFs can be described by the formal transfer of the appropriate number of electrons from the endohedral species to the carbon cage with subsequent coordination of the metal cations by the cage as a “ligand” and reoccupation of the metal nd orbitals (see also (Liu et al. 2006) for a more detailed discussion). Note that in most cases there are no special localized orbitals that could be responsible for the cage-to-cluster electron transfer. Instead, this kind of interaction occurs through the overlap of many cage π -orbitals with nd orbitals of the metal. One of the consequences of this type of bonding is a spin-charge separation found in the radical anions of the EMFs with the metal-localized LUMO (such as $Sc_3N@C_{80}$, $La_2@C_{72,78,80}$, $Ti_2C_2@C_{78}$). In these anions, the spin density is mostly localized on the metal atoms; however, the changes of the metal charges compared to the neutral state of the EMF molecule are rather small; instead, the surplus charge is mostly delocalized over the carbon cage (Popov and Dunsch 2008).

Since the effect of the metal–cage bonding in EMFs is best revealed in the analysis of the electron density as a whole, rather than by studying the individual MOs, it is natural to use the method based on the analysis of the electron density for the quantitative description of the metal–cage interactions in EMFs. The quantum theory of atoms in molecules (QTAIM) developed by Bader is probably the most refined and well-established method for the analysis of the topology of the electron density frequently used for the revealing and quantifying of the bonding situation between the atoms (Bader 1990; Matta and Boyd 2007). Kobayashi and Nagase analyzed a topology of the electron density distribution in $Sc_2@C_{84}$, $Ca@C_{72}$, and

Sc₂@C₆₆ using QTAIM (Kobayashi and Nagase 1999, 2002a). Their studies have shown that although the bond critical points (BCPs: critical points of the electron density, in which the density has a minimum along one axis and has a maximum in the plane perpendicular to this direction) could be found between Sc or Ca and certain carbon atoms of the cage, the values of the electron density at BCPs (ρ_{bcp}) were very small (0.05 a.u. for Sc-C and 0.01–0.02 a.u. for Ca-C), and the Laplacian of the density ($\nabla^2\rho_{bcp}$) at metal–carbon BCPs was always positive. The authors concluded that such values for these descriptors are signatures of the highly ionic character of the metal–cage bonding. However, care should be taken when the bonding in transition metal compound is analyzed with QTAIM (Cortés-Guzmán and Bader 2005). It was revealed that for transition metals $\nabla^2\rho_{bcp}$ values are usually positive, while ρ_{bcp} is small because of the diffuse character of electron distribution (Macchi and Sironi 2003), and hence these values alone cannot be proper descriptors of the bonding situation. Therefore, more specific descriptors should be applied in the analysis of the bonds involving transition metals, and the analysis of the *energy density* appears more useful than the analysis of the electron density alone. While kinetic energy density, G , is positive everywhere, potential energy density, V , is negative everywhere, and their sum, the total energy density H , defines which of the energy components is dominating. Cremer and Kraka suggested that bonding between the atoms can be considered as covalent if the total energy density at BCP, H_{bcp} , is negative (Cremer and Kraka 1984).

The in-depth study of the metal–cage and intra-cluster bonding by DFT and QTAIM was recently reported for the four major classes of endohedral metallofullerenes, including monometallofullerenes, dimetallofullerenes, metal nitride clusterfullerenes, metal carbide clusterfullerenes, as well as Sc₃CH@C₈₀ and Sc₄O_x@C₈₀ ($x = 2, 3$) (Popov and Dunsch 2009). The analysis of the bond critical point indicators showed that both the intra-cluster and the metal–cage interactions in EMFs were characterized by the negative total energy density, which means that bonding in EMFs exhibits a high degree of covalency. Furthermore, from the point of the electron density distribution, the interior of the EMF molecules was found to be a complex topological object, with many critical points, unpredictable number of the bond paths, and large bond ellipticities, similar to the bonding situation in the complexes of transition metals with π -carbocyclic ligands (Farrugia et al. 2009). In this respect, the analysis of the metal–cage bonding based only on the properties of the bond paths was found to be insufficient, and the metal–cage delocalization indices, $\delta(M, C)$, were also analyzed (by definition, $\delta(M, C)$ is number of the electron pairs shared by the atoms M and C, which is very similar to the “bond order” in Lewis definition). It was found that in the majority of EMFs, $\delta(M, C)$ values do not exceed 0.25; however, when summed over all metal–cage interactions, values of $\delta(M, \text{cage})$ close to 2–3 were obtained. While QTAIM atomic charges of the metal atoms were found to be approximately two times smaller than their formal oxidation states, the total number of the electron pairs shared by the metal atoms with the EMF molecule, $\Delta(M)$, was found to be close to the typical valence of the given element (Table 4).

Table 4 QTAIM atomic charges (q) of the metal atoms and the clusters and the metal–cage and metal–cluster electron-pair sharing in selected EMFs ^a

^a $\delta(\text{M}, \text{cluster})$ is the number of the electron pairs shared by the metal with the cluster; $\delta(\text{M}, \text{cage})$ is the number of the electron pairs shared by the metal with the carbon cage; $\Delta(\text{M})$ is the total number of the electron pairs shared by M with all other atoms of the molecule; when EMF has inequivalent metal atoms, corresponding values are averaged, unless they are significantly different; in the latter cases, different values are listed in the table separated by comma. Based on the QTAIM-B3LYP/6-311G* calculations from (Popov and Dunsch 2009)

To conclude the section on the metal–cage bonding in EMFs, it appears useful to distinguish two ways to determine the charge on the atom in endohedral fullerene: (1) a “formal” charge and (2) the “actual” charge. The formal charge is integer and implies that the metal (cluster)–cage bonding is purely ionic. As such, formal charges do not describe the actual electron distribution in the endohedral fullerenes, but still appear to be useful in understanding the spectroscopic and structural properties of endohedral fullerenes. For instance, compounds with the same formal cage and metal charges exhibit very similar absorption and vibrational spectra. In

the next section, we will show that the formal charge of the cage largely determines the isomeric structure of a given endohedral fullerene.

The “actual” charge should represent the electron density distribution in the endohedral fullerenes, but unfortunately there are no unique ways to partition the electron density between the atoms. Depending on the definition and the method of theory used to evaluate the charges, they can vary in a large range in the same molecule as already noted for $\text{Sc}_3\text{N}@C_{80}$. However, whatever method is used, computed charges are always considerably smaller than the formal charges, which is a clear manifestation of the covalent contribution to the metal–cage interactions. At the same time, the charges are still considerably large to indicate that ionic contribution to the cluster–cage bonding is also important.

Isomerism in Endohedral Metallofullerenes: Stability of the Charged Carbon Cages

One of the specific features of the endohedral metallofullerenes is that their carbon cage isomers are usually different from those of the isolated empty fullerenes. This fact can be understood by taking into account the electron transfer from the encapsulated species as discussed in the previous section. Using the semiempirical QCFF/PI method, Fowler and Zerbetto have shown that charging dramatically changes relative stabilities of the fullerene isomers (Fowler and Zerbetto 1995). For instance, $I_h(7)$ isomer of C_{80} , being the least stable structure for (+2) and (0) charge states, is the lowest energy structure for (−4) and (−6). In agreement with this finding, it was shown that the most stable isomer of $\text{La}_2@C_{80}$ has $I_h(7)$ cage, as opposed to the D_2 -symmetric empty C_{80} (Kobayashi et al. 1995). Variation of the relative energies of C_{82} isomers in the negatively charged states was analyzed by Kobayashi and Nagase at the HF/3-21G//AM1 level to rationalize experimentally observed isomers of $\text{M}@C_{82}$ (Kobayashi and Nagase 1997, 1998). The authors have found that while $C_2(3)$ is the lowest energy isomer of the neutral C_{82} , the $C_{2v}(9)$ cage is the most stable for both C_{82}^{2-} and C_{82}^{3-} as well as for $\text{M}@C_{82}$ ($\text{M} = \text{Ca}, \text{Sc}, \text{Y}, \text{La}, \text{etc.}$) (Kobayashi and Nagase 1997, 1998). This finding is confirmed by experimental ^{13}C NMR studies of $\text{La}@C_{82}$ and $\text{Ce}@C_{82}$ anions (Akasaka et al. 2000; Tsuchiya et al. 2005; Wakahara et al. 2004). More recently, DFT calculations of C_{82}^{4-} isomers were reported (Valencia et al. 2008) and the $C_{3v}(8)$ isomer was shown to be the most stable tetraanion, in line with the finding of this cage in the most abundant isomers of $\text{Sc}_2\text{C}_2@C_{82}$ (Iiduka et al. 2006; Nishibori et al. 2006a) and $\text{Y}_2\text{C}_2@C_{82}$ (Inoue et al. 2004; Nishibori et al. 2006b). The data on the relative energies of all IPR C_{82} isomers in (0)–(−6) charge states obtained at the PBE/TZ2P level (Popov 2009) are summarized in Fig. 8a. DFT calculations show that $C_{2v}(9)$ is the most stable isomer for all charge states starting from (−2), however, there is a change in favor of $C_{3v}(8)$ for (−4) (Valencia et al. 2008). Note also that starting from (−3) charge state, the IPR isomers $C_{2v}(9)$, $C_{3v}(8)$, and $C_s(6)$ are considerably more stable than the other IPR isomers; as a result, only these isomers are found for $\text{M}^{\text{III}}@C_{82}$ and $\text{M}_2\text{C}_2@C_{82}$.

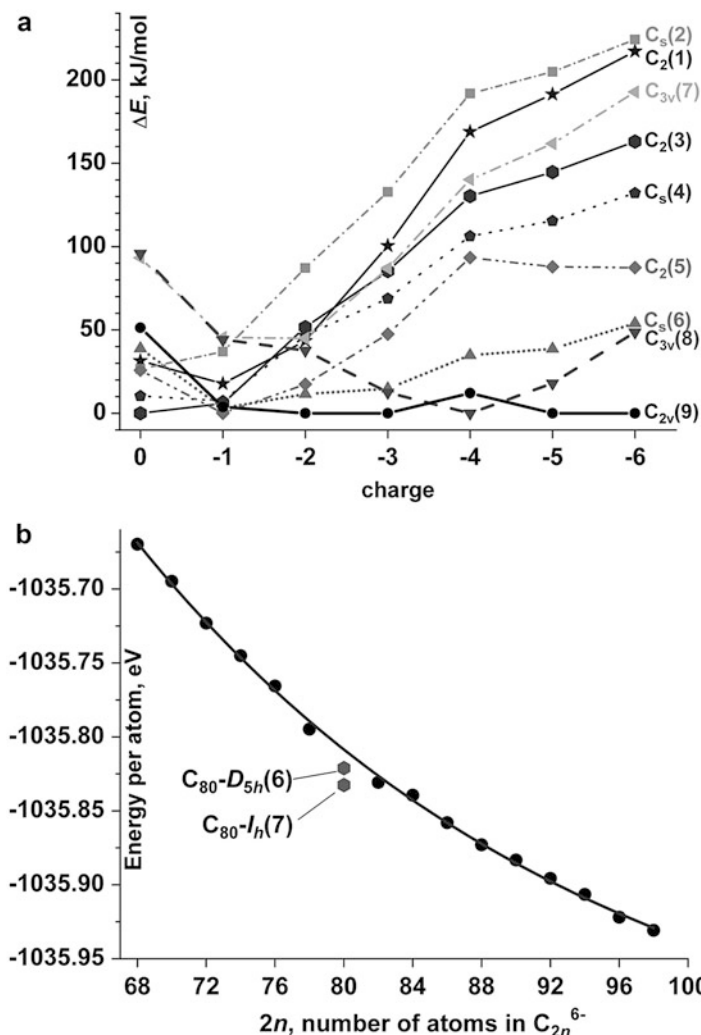

Fig. 8 (a) Relative energies IPR isomers of C_{82} computed at the PBE/TZ2P level in different charge states (Based on the data from Popov 2009); (b) PBE/TZ2P computed energies of the most stable C_{2n}^{6-} hexaanions on the per-atomic basis plotted as a function of the cage size (Based on the data from Popov and Dunsch 2007)

The data on representative fullerenes discussed above show that (1) the relative energies of the fullerene isomers are dramatically affected by the charge and (2) the stability of the isomers of appropriately charged empty fullerenes provides a good estimation to the relative stability of the cage isomers of endohedral fullerenes. Thus, though ionic model is not realistic for the description of the electron density distribution in endohedral metallofullerenes, it can be useful for understanding the carbon cage isomerism of endohedral fullerenes.

In the last decade, the higher yields, increased stability, and broad variety of the formed structures attracted special attention to the family of nitride clusterfullerenes. Their electronic structure may be conceived as a result of a formal sixfold electron transfer from the $M_3^{III}N$ cluster to the fullerene. Predicting of the lowest energy isomers of $M_3N@C_{2n}$ endohedral fullerenes is a difficult task since, in addition to the carbon cage isomerism, different orientation of the M_3N cluster inside the cage can give structures with substantially different relative energies; besides, DFT calculations of the molecules with transition metals are more complex than those of the empty fullerenes. In this respect, attempts were made to predict the possible structures of $M_3N@C_{2n}$ molecules based on the calculation for the empty fullerenes.

The simple use of this formal sixfold electron transfer in $M_3N@C_{2n}$ to predict the most suitable cage isomers capable of encapsulating a nitride cluster was proposed by Poblet and coworkers. It was supposed that only the fullerenes with a considerable gap between LUMO + 2 and LUMO + 3 (which become HOMO and LUMO, respectively, in the C_{2n}^{6-} hexaanion and presumably in $M_3N@C_{2n}$) should be considered as suitable hosts for nitride clusters (Campanera et al. 2005). With the application of this criterion, only C_{60} , $C_{78}-D_{3h}(5)$, $C_{80}-I_h(7)$, and $C_{80}-D_{5h}(6)$ were found to be suitable cage isomers among all IPR fullerenes in the C_{60} – C_{84} range. Indeed, besides C_{60} , which is too small to host a Sc_3N cluster, only these and no other IPR cage isomers were found for $Sc_3N@C_{2n}$ clusterfullerenes. Later this work was expanded by considering also all IPR isomers in the C_{86} – C_{100} range (Valencia et al. 2007), and the isomers with the largest orbital gaps found for C_{86} and C_{88} hexaanions ($D_3(19)$ and $D_2(35)$, respectively) were those proved to exist in $Tb_3N@C_{86}$ and $Tb_3N@C_{88}$ by single-crystal X-ray diffraction studies (Zuo et al. 2007).

A different approach to the search of the suitable cage isomers for nitride clusterfullerenes is based on the stability of the hexaanions (Popov and Dunsch 2007; Popov et al. 2007c; Yang et al. 2007a, b). In the view of the correlation found between the relative energies of the empty fullerenes in appropriate charge state and the relative energies of endohedral fullerenes, it was suggested that the suitable cage isomers of $M_3N@C_{2n}$ should be found among the most stable isomers of C_{2n}^{6-} . The growing number of endohedral fullerenes violating IPR shows that non-IPR isomers should also be included in the search. Importantly, good correlation was found between the relative energies of the C_{2n}^{6-} isomers computed at the AM1 and DFT levels of theory (Yang et al. 2007b). Since optimization of the structure of the fullerene at AM1 levels normally takes only about 1–2 min with the standard office computer, this fact dramatically facilitates the search of the stable isomers. That is, screening of *all* possible isomers can be done at AM1 level, and only few lowest energy C_{2n}^{6-} isomers (and corresponding $M_3N@C_{2n}$ isomers) can then be studied at the higher – and more computationally demanding – level of theory. By screening through the large number of the C_{70}^{6-} , C_{76}^{6-} , and C_{78}^{6-} isomers, the molecular structures of $Sc_3N@C_{70}$ (Yang et al. 2007b), $M_3N@C_{78}$ ($M = Dy, Tm$) (Popov et al. 2007c), and $DySc_2N@C_{76}$ (Yang et al. 2007a) were proposed, all violating the IPR. The structural guesses were then confirmed by comparison of the experimental and DFT-computed vibrational spectra.

The full search of the most favorable cage isomers of $\text{Sc}_3\text{N}@C_{2n}$ and $\text{Y}_3\text{N}@C_{2n}$ ($2n = 68-98$) at the PBE/TZ2P level was reported in 2007 (Popov and Dunsch 2007). For $C_{68} - C_{88}$, both IPR and non-IPR isomers were considered, which however resulted in the huge number of possible structures (for instance, there are totally 81,738 for C_{88}). Taking into account that metal atoms in all known non-IPR fullerenes are coordinated to the adjacent pentagon pairs, the authors suggested that only the isomers with such pairs should be considered (while the structures with three or more adjacent pentagons could be omitted). This assumption considerably reduced the number of the isomers (e.g., 16,717 isomers were studied for C_{88}), making the computations more feasible.

Table 5 lists the lowest energy isomers of C_{2n}^{6-} found in that work with their relative energies and HOMO–LUMO gaps computed at the PBE/TZ2P level; experimentally available structurally characterized EMFs are listed in the last column. Importantly, the isomers shown to exist by single-crystal X-ray studies can be found among the lowest energy isomers of C_{2n}^{6-} . $C_{78}\text{-}C_2(22,010)$ and $C_{82}\text{-}C_5(39,663)$ isomers were predicted as possible structures of $\text{M}_3\text{N}@C_{78}$ and $\text{M}_3\text{N}@C_{82}$ (Popov and Dunsch 2007; Popov et al. 2007c) before their structures were confirmed by single-crystal X-ray studies of $\text{Gd}_3\text{N}@C_{78}$ and $\text{Gd}_3\text{N}@C_{82}$ (Beavers et al. 2009; Mercado et al. 2008). Even better correlation with experimental data is found if the relative energies of $\text{Sc}_3\text{N}@C_{2n}$ and $\text{Y}_3\text{N}@C_{2n}$ isomers are considered (Popov and Dunsch 2007). It is remarkable that C_{2n}^{6-} isomers with high thermodynamic stability (i.e., low relative energy) quite often exhibit high kinetic stability (i.e., large HOMO–LUMO gap). As a result, the IPR isomers proposed by the group of Poblet (Campanera et al. 2005; Valencia et al. 2007) in most cases coincide with predictions based on the relative stability of the hexaanions (Popov and Dunsch 2007).

The broad range of the fullerene sizes studied (Popov and Dunsch 2007) enabled the authors to follow the general trends in their stabilities. To compare the energies of the fullerenes of different size, the absolute energies were normalized to the number of atoms in the given fullerene. Figure 8b plots the normalized energies of the most stable C_{2n}^{6-} isomers versus the number of atoms. The smooth decrease of the energy with the increase of the fullerene size is the result of a combination of two factors: (1) the decrease of the curvature of the cage, which results in smaller curvature-induced strain, and (2) the decrease of the on-site Coulomb repulsions of six surplus electrons in C_{2n}^{6-} with the increase of the cage size. There is, however, a significant deviation from the smooth curve found for $C_{80}\text{-}I_h(7)$ and $C_{80}\text{-}D_{5h}(6)$ isomers. These isomers are 185 and 98 kJ/mol more stable than they might be if they were like all other fullerenes (i.e., like those which obey the smooth decay in the normalized energy). The enhanced stability of the two C_{80}^{6-} isomers explains the increased yield of $\text{M}_3\text{N}@C_{80}$ compared to all other cage sizes. Besides, it explains why the $C_{80}\text{-}I_h(7)$ isomer is always the most preferable structure in other clusterfullerenes with formal sixfold electron transfer to the cage, such as $\text{La}_2@C_{80}$, $\text{Sc}_4\text{O}_{2,3}@C_{80}$ (Stevenson et al. 2008), and $\text{Sc}_4\text{C}_2@C_{80}$ (Wang et al. 2009).

Table 5 The lowest energy C_{2n}^{6-} ($2n = 68-88$) isomers with their relative energies (kJ/mol) and HOMO–LUMO gaps (eV) computed at the PBE/TZ2P level of theory and the experimentally available EMFs with corresponding carbon cages (Based on the data from Popov and Dunsch 2007)

C_{2n}	Isomer		ΔE	Gap	Exp. EMFs
C_{68}	$D_3(6140)$	Non-IPR	0.0	1.20	$Sc_3N@C_{68}$
C_{70}	$C_{2v}(7854)$	Non-IPR	0.0	1.24	$Sc_3N@C_{70}$
C_{72}	$D_2(10611)$	Non-IPR	0.0	1.12	$M_2@C_{72}$ ($M = La, Ce$)
C_{74}	$C_2(13295)$	Non-IPR	0.0	1.22	Not known

C_{82}	$C_{2v}(9)^b$	IPR	0.0	0.79	$Sc_3N@C_{82}$
	$C_{2v}(39705)^b$	Non-IPR	30.1	1.32	Not known
	$C_s(39663)^b$	Non-IPR	61.2	1.42	$M_3N@C_{82}$ ($M = Y, Gd, Tm, Dy, Tb$)
C_{84}	$D_2(21)$	IPR	0.0	0.80	Not known
	$C_s(51365)$	Non-IPR	1.8	1.34	$M_3N@C_{84}$ ($M = Y, Gd, Tm, Dy, Tb$)
C_{86}	$D_3(19)$	IPR	0.0	1.51	$M_3N@C_{86}$ ($M = Y, Gd, Tm, Dy, Tb$)
C_{88}	$D_2(35)$	IPR	0.0	0.97	$M_3N@C_{88}$ ($M = Y, Ce, Nd, Gd, Tm, Dy, Tb$)

^aFor $LaSc_2N@C_{80}$, the relative energies for isomers $I_h(7)$, $D_{5h}(6)$, and heptagon-containing $C_s(\text{hept})$ are 0, 61, and 27 kJ/mol, respectively, at the PBE/TZ2P level (Zhang et al. 2015)

^bFor $Y_3N@C_{82}$, the relative energies for isomers $C_{2v}(9)$, $C_{2v}(39,705)$, and $C_s(39,663)$ are 29.6, 0.0, and 32.6 kJ/mol, respectively, at the PBE/TZ2P level

The exclusive stability of the $I_h(7)$ and $D_{5h}(6)$ isomers of C_{80}^{6-} can be rationalized using the concept of hexagon indices (Raghavachari 1992) discussed in section “Structures and Stability of Empty Fullerenes.” The lowest strain condition (all indices are equal) is fulfilled only for $C_{60}-I_h(1)$, $C_{80}-I_h(7)$, and $C_{80}-D_{5h}(6)$ in the whole range fullerenes C_{2n} with $2n < 120$ (Fowler and Manolopoulos 1995). Thus, the exceptional stability of two C_{80}^{6-} isomers can be explained by the favorable distribution of the pentagons, which leads to the least steric strain. Moreover, the list of the least-strained IPR isomers (Table 2) perfectly corresponds to the lowest energy IPR isomers of $C_{76}^{6-}-C_{90}^{6-}$ (Popov and Dunsch 2007). For larger cages

these conditions are less instructive, because many of the IPR isomers satisfy them. Interestingly, the relative energies of the IPR C_{2n}^{6-} isomers follow the rationalization of the stability based on the steric strain much better than the relative energies of the uncharged IPR fullerenes, which usually violate the requirement of the minimized strain (the only exclusions are C_{84} and C_{90} ; see Table 2). Very recently, this phenomenon was clarified by Poblet and coworkers (Rodríguez-Fortea et al. 2010). The authors have suggested that the relative stabilities of the isomers of multiply-charged fullerene anions are largely determined by the on-site Coulomb repulsion. Since the negative charge in anions is mostly localized on the pentagons because of their non-planarity, the lowest energy structures should be those in which the maximal separation (and hence the most uniform distribution) of the pentagons is achieved. The authors have constructed the inverse pentagon separation index to show that its correlation with the relative stabilities of the isomers is improving with the increase of the charge. Thus, minimization of the on-site Coulomb repulsion and minimization of the steric strain are achieved by fulfillment of the same condition, namely, the most uniform distribution of the pentagons. If for the non-charged fullerenes, the steric strain factor can be outweighed by other factors such as stability of the π -system (and hence the lowest strain condition is usually violated), with the increase of the negative charge on the cage, the Coulomb repulsion sooner or later outweighs all other factors. Therefore, to predict the lowest energy isomers of the EMFs with high formal charge of the cage (such as $M_3N@C_{2n}$), one can apply the same arguments as were developed in early 1990s to find the isomers of empty fullerenes with the lowest steric strain. Another group has also shown that the most suitable host cages have the highest aromaticity, and so aromaticity criterion can be used to explain preference of certain isomers (García-Borràs et al. 2013).

Isomerism in Endohedral Metallofullerenes: Cage Form Factor

The carbon cage stability is very important in determining the molecular structure of endohedral fullerenes; however, the isolated structures are not always based on the lowest energy isomers of the hollow anions. In addition to the high stability, the fullerene cage should also provide a suitable shape for enclosed metal atoms or clusters; that is, there should be enough inner space in the cage for the endohedral species. If then a fullerene has adjacent pentagon pairs, they should be located in such a way that their coordination by the endohedral metal atoms is possible. This factor can be especially important for the nitride clusterfullerenes since the shape of the cluster itself imposes significant limitations on the possible location of the binding sites.

Figure 9a plots the relative energies of the 20 lowest energy isomers of C_{72}^{6-} and corresponding $Sc_3N@C_{72}$ isomers calculated at the PBE/TZ2P level. The significant difference between the two sets of data is observed. While the most stable isomer of C_{72}^{6-} is $D_2(10,611)$ (Slanina et al. 2006; Popov and Dunsch 2007), this cage isomer is destabilized for $Sc_3N@C_{72}$, and the lowest energy is found for $Sc_3N@C_{72}$

Fig. 9 (a) Relative energies of C_{72}^{6-} and corresponding $Sc_3N@C_{72}$ isomer computed at the PBE/TZ2P level (Based on the data from Popov and Dunsch 2007); (b) relative energies of C_{78}^{6-} and corresponding $Sc_3N@C_{78}$ and $Y_3N@C_{78}$ isomer computed at the PBE/TZ2P level (Based on the data from Popov et al. 2007c)

with $C_s(10,528)$ cage. The explanation of this phenomenon becomes clear when the structures of the cage isomers are analyzed. $C_{72}-D_2(10,611)$ has elongated shape with two adjacent pentagon pairs on the opposite poles of the cage (Fig. 10). It is impossible to coordinate both pentagon pairs at once with the Sc atoms of the triangular Sc_3N cluster, and hence one pentagon pair in $Sc_3N@C_{72}-D_2(10,611)$ is not stabilized by the metal, which explains the high relative energy found for

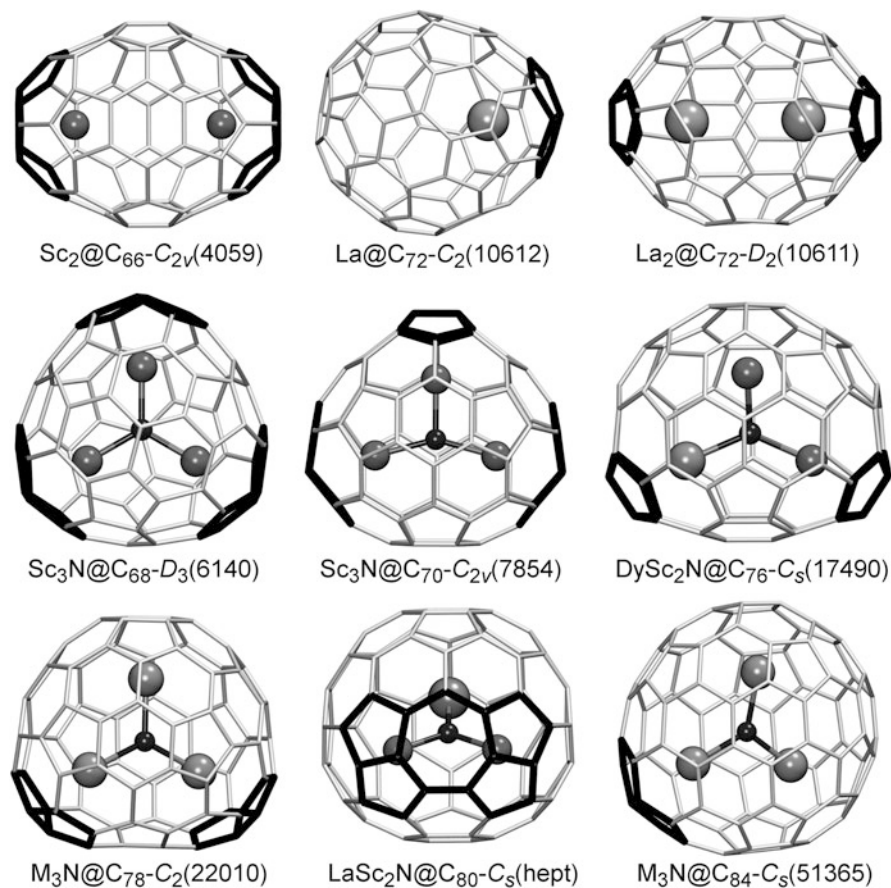

Fig. 10 Molecular structures of selected non-IPR endohedral metallofullerenes. Carbon cages are shown in *gray* except for the adjacent pentagon pairs, which are shown in *black*. Note that in $\text{Sc}_2@C_{66}-C_{2v}(4059)$ has two fragments with three fused pentagons in each. In $\text{M}_3\text{N}@C_{78}$, and $\text{M}_3\text{N}@C_{84}$, M can be Y, Gd, Dy, Tm, Tb, and possibly some other lanthanides

this isomer by theory. The lowest energy C_{72}^{6-} isomer with favorable location of adjacent pentagon pairs is $C_s(10,528)$, and it corresponds to the most stable isomer of $\text{Sc}_3\text{N}@C_{72}$. However, this isomer is based on the relatively unstable carbon cage and, besides, it has a small HOMO–LUMO gap (0.39 eV at the PBE/TZ2P level). As a result, the $\text{Sc}_3\text{N}@C_{72}$ nitride clusterfullerene has never been observed experimentally. Similar situation was also found for C_{74}^{6-} and $\text{Sc}_3\text{N}@C_{74}$, which also has never been observed. Since the bimetallic cluster is more flexible, the steric factor is less important for dimetallofullerenes, and $\text{La}_2@C_{72}$ is based on the lowest energy $D_2(10,611)$ cage isomer (Kato et al. 2003; Lu et al. 2008).

A different situation was found for the clusterfullerenes based on C_{78} (Popov et al. 2007c). Figure 9b compares relative energies of the lowest energy isomers of

C_{78}^{6-} and $M_3N@C_{78}$ ($M = Sc, Y$). The most stable C_{78}^{6-} isomer is IPR $D_{3h}(5)$, which is followed by the non-IPR $C_2(22,010)$ isomer with two adjacent pentagon pairs. The relative energies of $Sc_3N@C_{78}$ isomers closely follow those of C_{78}^{6-} , which agrees with the formation of the $Sc_3N@C_{78}-D_{3h}(5)$ isomer (Olmstead et al. 2001). $C_{78}-D_{3h}(5)$ was also proved for $M_2@C_{78}$ ($M = La, Ce$) and $Ti_2C_2@C_{78}$ (Cao et al. 2004, 2008; Tan and Lu 2005; Sato et al. 2006; Yumura et al. 2005; Yamada et al. 2008). However, with the increase of the cluster size from Sc_3N to Y_3N , the relative energies of the $M_3N@C_{78}$ isomers are changed dramatically. The isomer based on the $D_{3h}(5)$ cage is significantly destabilized, and the lowest energy is now found for the $Y_3N@C_{78}-C_2(22,010)$ (84 kJ/mol more stable than $Y_3N@C_{78}-D_{3h}(5)$). The dramatic change in the stability of the isomers can be explained by insufficient size of the $C_{78}-D_{3h}(5)$ cage for encapsulation of the clusters larger than Sc_3N . As a result, Y_3N cluster is forced to be pyramidal in $Y_3N@C_{78}-D_{3h}(5)$ (nitrogen atoms is displaced from the plane of the metal atoms by 0.554 Å), which is an indication of the strong strain exerted by the cage. On the contrary, the inner space in $C_{78}-C_2(22,010)$ isomer is sufficient to retain the planar shape of the Y_3N cluster (Fig. 10). Results of these calculations were supported by experimental spectroscopic studies of $Tm_3N@C_{78}$ and the major isomer of $Dy_3N@C_{78}$ (Popov et al. 2007c) and by single-crystal X-ray diffraction studies of $Gd_3N@C_{78}$ (Beavers et al. 2009).

$M_3N@C_{80}-I_h(7)$ represents another important example of the cluster size influence on the stability of the clusterfullerenes (Popov and Dunsch 2007). The lowest energy isomers for C_{80}^{6-} and $Sc_3N@C_{80}$ are $I_h(7)$ and $D_{5h}(6)$, and there is a gap of approximately 80 kJ/mol between these two isomers and the gap of approximately 120 kJ/mol between $D_{5h}(6)$ and all other, less-stable isomers. Stability order of C_{80}^{6-} and $Sc_3N@C_{80}$ isomers is rather close, but relative energies of unstable $Sc_3N@C_{80}$ isomers are 20–40 kJ/mol smaller than those in C_{80}^{6-} . These data agree with formation of $Sc_3N@C_{80}-I_h(7)$ as the most abundant product of the $Sc_3N@C_{2n}$ clusterfullerene synthesis, followed by $Sc_3N@C_{80}-D_{5h}(6)$ as the second most abundant structure. With the increase of the cluster size to the Y_3N , the $I_h(7)$ isomer is still the most stable one, and the energy difference between $I_h(7)$ and $D_{5h}(6)$ isomers is almost the same as in the $Sc_3N@C_{80}$ series, but all other isomers of $Y_3N@C_{80}$ are significantly stabilized with respect to the $I_h(7)$ isomer. For instance, relative energies of the $D_{5h}(6)$ and non-IPR $C_1(28,325)$ isomers are quite close (70.2 and 90.0 kJ/mol, respectively). Similar to the case of $M_3N@C_{78}$, this can be explained by the relatively small size of almost spherical $C_{80}-I_h(7)$ and $C_{80}-D_{5h}(6)$ cages, which leads to the increase of the strain when large M_3N clusters are encapsulated. As a result, $M_3N@C_{80}-I_h(7)$ is still the most abundant nitride clusterfullerene for the clusters up to the size of Gd_3N , but overall yields are suppressed compared to the clusterfullerenes with smaller clusters (Krause and Dunsch 2005). For the larger cluster size ($M = Nd, Pr, Ce, La$). Echegoyen and coworkers have shown that the larger cages (in particular, C_{88}) are produced in higher yield than that of $M_3N@C_{80}$ (Chaur et al. 2008).

Violation of the Isolated Pentagon Rule in Endohedral Metallofullerenes

The specific feature of endohedral fullerenes is that the isolated pentagon rule, which imposes a strict limitation on the possible isomers of empty fullerenes, is often violated when a metal or a cluster is encapsulated inside the cage. Such possibility was first suggested by Kobayashi et al. in theoretical studies of $\text{Ca}@C_{72}$ isomers (Kobayashi et al. 1997; Nagase et al. 1999), and the first experimental evidence was provided in 2000 when $\text{Sc}_2@C_{66}-C_{2v}(4,059)$ (Wang et al. 2000a; Yamada et al. 2014) and $\text{Sc}_3\text{N}@C_{68}-D_3(6,140)$ (Stevenson et al. 2000) were isolated. Since that time, a lot of non-IPR endohedral fullerenes have been reported (Fig. 10), including $\text{Sc}_3\text{N}@C_{70}-C_{2v}(7,854)$ (Yang et al. 2007b), $\text{Sc}_2\text{S}@C_{70}-C_2(7,892)$ (Chen et al. 2013), $\text{Sc}_2\text{S}@C_{72}-C_s(10,528)$ (Chen et al. 2012), $\text{Sc}_2\text{C}_2@C_{72}-C_s(10,518)$ (Feng et al. 2013), $\text{La}@C_{72}-C_2(10,612)$ (Wakahara et al. 2006), $\text{La}_2@C_{72}-D_2(10,611)$ (Kato et al. 2003; Lu et al. 2008), $\text{DySc}_2\text{N}@C_{76}-C_s(17,490)$ (Yang et al. 2007a), $\text{La}_2@C_{76}-C_s(17,490)$ (Suzuki et al. 2013), $\text{Sm}@C_{76}-C_{2v}(19,138)$ (Hao et al. 2015), $\text{M}_3\text{N}@C_{78}-C_2(22,010)$ ($\text{M} = \text{Dy, Tm, Gd}$) (Beavers et al. 2009; Popov et al. 2007c), $\text{Gd}_3\text{N}@C_{82}-C_s(39,663)$ (Mercado et al. 2008), and $\text{Y}_2\text{C}_2@C_{84}-C_1(51,383)$ (Zhang et al. 2013), and $\text{M}_3\text{N}@C_{84}-C_s(51,365)$ ($\text{M} = \text{Tb, Gd, Tm}$) (Beavers et al. 2006; Zuo et al. 2008). The state of the art in the studies of non-IPR fullerenes has been reviewed (Tan et al. 2009). Recently, $\text{LaSc}_2\text{N}@C_{80}-C_s(\text{hept})$ with one heptagon and 13 pentagons (two pentalene units) has been synthesized (Zhang et al. 2015).

The tendency to violate the IPR in endohedral fullerenes can be explained by the changes of the relative energies of the fullerene isomers with the increase of the cage charge. It was shown already in 1995 that for C_{60} , the non-IPR $C_{2v}(1,809)$ isomer with two pairs of adjacent pentagons is substantially less stable than the IPR isomer in the neutrally charge state, but with the increase of the negative charge on the cage, the difference in the relative energies is diminishing, reaching almost zero for (-4) and inverting for (-6) states (Fowler and Zerbetto 1995). Semiempirical and DFT calculations for the whole set of 6,332 isomers of C_{68} in 0, (-2) , (-4) , and (-6) charge states were reported (Chen et al. 2008). This study has shown that the lowest energy isomers of C_{68}^{4-} and C_{68}^{6-} are $C_{2v}(6,073)$ and $D_3(6,140)$, in agreement with isolation of these isomers for $\text{Sc}_2\text{C}_2@C_{68}$ (Shi et al. 2006) and $\text{Sc}_3\text{N}@C_{68}$ (Olmstead et al. 2003; Stevenson et al. 2000), respectively. By plotting the relative energies of the isomers of the same charge versus the number of pentagon adjacencies, the authors have found that the penalty for a pentagon adjacency is decreasing from 92 kJ/mol in C_{68} to 70 kJ/mol in C_{68}^{6-} at the AM1 level, confirming that the increase of the charge stabilizes pentagon adjacencies.

An explanation of the stabilization of the pentagon adjacencies in metallofullerenes was proposed by Slanina et al. (2006). The authors noted that the pentalene (a unit of two fused pentagons) is an 8π anti-aromatic system in the neutrally charged state, but becomes 10π aromatic in the dianionic state (Zywietz et al. 1998). In a similar fashion, when the metal in the non-IPR endohedral

fullerenes is coordinated to the pentagon pair, it donates two electrons to the pentalene unit to make it aromatic. This reasoning agrees with the fact that the maximum number of pentagon pairs found in endohedral fullerenes is equal to the half of the formal charge of the cage: three pairs for (6⁻) charge as in Sc₃N@C₆₈-D₃(6,140) or Sc₃N@C₇₀-C_{2v}(7,854), two pairs for (4⁻) state as in Sc₂S@C₇₂-C_s(10,528) (Chen et al. 2012) or Sc₂C₂@C₇₂-C_s(10,518) (Feng et al. 2013), and one pair for (3⁻) and (2⁻) states as in La@C₇₂-C₂(10,612) or Sm@C₇₆-C_{2v}(19,138).

A correlation of the total number of adjacent pentagon pairs in the lowest energy isomers of C_{2n}⁶⁻ (2n = 68–88) with the cage size was revealed in Popov and Dunsch (2007). The authors found a pronounced tendency to decrease the number of pentagon pairs in the molecules with the increase of the cage size: while three pairs are common for C₆₈⁶⁻ and C₇₀⁶⁻ isomers, two and one pairs are preferable for C₇₂⁶⁻-C₇₈⁶⁻ and C₈₀⁶⁻-C₈₆⁶⁻, respectively. At the same time, relative energies of the non-IPR isomers are increasing with respect to the IPR isomers, and starting from C₈₆ formation of the non-IPR fullerenes is not expected (at least, for the cages with the formal charge of 6⁻ and smaller). Indeed, the largest cage reported to date for any non-IPR fullerene is C₈₄-C_s(51,365) (Beavers et al. 2006; Zuo et al. 2008). This tendency agrees with the increase of energy penalty for the adjacent pentagon pair in the empty fullerenes with increase of the cage size as discussed in the section “The Isolated Pentagon Rule and Steric Strain.” With the increase of the cage size, a more uniform distribution of the pentagon-induced strain over the fullerene is possible, and hence, localization of such a strain in pentagon adjacencies should become more unfavorable than for the smaller cages. Besides, for the charged cages, the influence of the charging of the fullerene should be diminished with the growth of the cage size, and hence its stabilizing role for the pentagon adjacencies is leveled down for larger fullerenes.

Structures and Stability of Fullerene Derivatives

Addition of X₂ to C₆₀: Isomers of C₆₀X₂ and General Considerations

The C₆₀ molecule has two types of C–C bonds, hexagon/hexagon (hex/hex) edges, and pentagon/hexagon (pent/hex) edges. Determination of their bond lengths by different experimental and theoretical methods gives the values of ca 1.40 and 1.45 Å, respectively. As might be expected, these values fall in the range of the bond lengths typical for conjugated systems; yet, they also show that there are formal *double* and *single* bonds in C₆₀, and it is more appropriate to call it polyalkene rather than superaromatic molecule. The chemical properties of fullerenes are to a large extent determined by the presence of the conjugated double bonds, and vast majority of fullerene reactions are *addition* reactions. We will not cover here the cycloaddition, mainly because quantum-chemical approaches are not so helpful in predicting and elucidation molecular structures of the reaction products. Thus, we will focus on the addition of atoms or groups that form single bonds to the fullerene

core (i.e., atoms or radicals, “X” hereafter). Such reactions, on the one hand, often occur at rather high temperatures allowing close-to-equilibrium distribution of the products, and on the other hand, addition of such groups allows multiple possibilities from the point of the distribution of the groups on the surface of the fullerene. For instance, there are 23 possible isomers of $C_{60}X_2$; 4,190 isomers of $C_{60}X_4$; and 418,470 isomers of $C_{60}X_6$, and the number of possible isomers is growing rapidly with the further increase of the number of the added groups (Balasubramanian 1991). It is therefore desirable to find the principles which govern addition of the addends to the fullerenes, the task to be naturally addressed by theoreticians. It should be also noted that equilibrium or close-to-equilibrium distribution of the products in the addition reaction (i.e., thermodynamic control) is a necessary prerequisite for the conclusions based on the relative energies of isomers to be valid. Otherwise, kinetic factors can be equally or even more important than the relative stability of the isomers, and theoretical predictions of the products are severely complicated.

All possible isomers which can be obtained by the addition of two hydrogen atoms to C_{60} (addition of the odd number of groups leads to the highly reactive radicals and therefore is not considered here) were studied at the PM3 level of theory by Dixon and coworkers (Matsuzawa et al. 1992). An AM1 study of the relative stabilities of $C_{60}X_2$ isomers for $X = H, F, Cl, Br, CH_3$, and $t-C_4H_9$ was reported in 2003 (Clare and Kepert 2003a). Let us consider several possible isomers of $C_{60}X_2$ (Fig. 11a). The simplest addition pathway is when two X groups are added to one double bond of C_{60} ; the rest of the π -system of the fullerene remains unchanged (in other words, this is 1,2-addition to a cyclohexatriene). If then two groups are attached to one hexagon in *para* position (1,4-addition to a cyclohexatriene), the π -system of the fullerene has to be adjusted by relocating one double bond to the pent/hex edge. All other variants of addition require more pronounced changes in the π -system of C_{60} and lead to the larger number of double bonds in pentagons

Fig. 11 (a–c) Fragments of the lowest energy isomers of $C_{60}H_2$: (a) 1,2-addition to hexatriene fragment; (b) 1,4-addition to hexatriene fragment; (c) 2,6-addition to naphthalene fragment; (d) relative energies of $C_{60}H_2$ isomers computed at the AM1 level as a function of the number of double bonds in pentagons (DBIPs) (Based on the data from Clare and Kepert 2003a)

(DBIPs). It was found that the number of DBIPs is an important parameter showing perfect correlation with the stability of the isomers of $C_{60}X_2$ (Fig. 11b): the larger the number of DBIPs, the lower the stability of the given isomer (Matsuzawa et al. 1992). From the slope of the fitted line, the penalty for each DBIP in $C_{60}H_2$ can be estimated as 36 and 37 kJ/mol at the PM3 and AM1 levels, respectively. The penalty is virtually independent on the nature of X, being 39 kJ/mol for $C_{60}F_2$ and 37 kJ/mol for $C_{60}(t-C_4H_9)_2$ at the AM1 level (Clare and Kepert 2003a). Obviously, “1,2”-addition should be the most preferable from the energetic point of view, and 1,2- $C_{60}X_2$ is indeed the most stable isomer for X = H and F (Dixon et al. 1992; Clare and Kepert 2003a) in good agreement with the experimental structures of $C_{60}H_2$ (Henderson and Cahill 1993) and $C_{60}F_2$ (Boltalina et al. 2000b). However, in the 1,2- $C_{60}X_2$, the X groups are experiencing eclipsing interactions. With the increase of the size of the groups, the influence of the steric factor is increasing and can balance the destabilizing effect of DBIP. Indeed, either semiempirical or DFT calculations show that for the bulky groups (such as Br or CF_3), 1,4-addition is more preferable (Dixon et al. 1992; Clare and Kepert 2003a; Goryunkov et al. 2003). Furthermore, for even larger groups such as $t-C_4H_9$, the isomer with two DBIPs and $t-C_4H_9$ groups on different hexagons (Fig. 11d) is the most stable at the B3LYP/6-31G**/AM1 level (at the same time, AM1 method predicts that 1,4- $C_{60}(C_4H_9)_2$ is the lowest energy isomer) (Clare and Kepert 2003a).

The studies of $C_{60}X_2$ isomers allow one to conclude that the structures of the products of the multiple addition of X groups should be a result of the interplay of at least two factors: (1) destabilizing double bonds in pentagons and (2) destabilizing eclipsing interactions of bulky groups. It can be expected that for the relatively small atoms such as H or F, multiple 1,2-addition is preferable, while for the bulky groups, multiple 1,4-addition is to be expected. Detailed studies of the multiple additions of various groups (in particular, H and Br) to fullerenes performed by Clare and Kepert in 1990s using AM1 method confirmed these suggestions (Clare and Kepert 1993, 1994a, b, c, 1995a, b, 1999a, b, 2002a; Kepert and Clare 1996). In brief, the methodology of the authors included a search of the most stable isomers of $C_{60}X_n$, sorting out majority of the unstable structures, and then a search of the most stable isomers of $C_{60}X_{n+2}$ based on the several most stable isomers of $C_{60}X_n$. Gradual increase of n allowed Clare and Kepert to cover broad range of compositions, reveal some general principles of the multiple addition to C_{60} and other fullerenes, and predict several addition patterns which were indeed found later in the experimental studies. In the remaining parts of this chapter, we will discuss several examples of the addition patterns to C_{60} and C_{70} .

Addition of H and F to C_{60} : Contiguous Addition, Benzene Rings, and Failures of AM1

Early on semiempirical calculations of $C_{60}H_2$ and $C_{60}F_2$ have shown that 1,2-isomers are 18–19 kJ/mol lower in energy than 1,4-isomers, and then all other structures are substantially less stable (Dixon et al. 1992; Matsuzawa et al. 1992;

Fig. 12 Addition patterns typical for small groups (H, F). (a) *S* and *T* addition motifs; (b) lowest energy C_5 -isomer of $C_{60}F_8$; (c) C_3 - $C_{60}F_8$ with *S*-motif; (d) T_h - $C_{60}X_{12}$ with isolated CX–CX edges; (e) crown C_{3v} - $C_{60}X_{18}$ with isolate benzene ring; (f) D_{5d} - $C_{60}X_{20}$ with *S*-type loop around equator; (g) T - $C_{60}X_{36}$; (h) C_3 - $C_{60}X_{36}$; (i) C_1 - $C_{60}X_{36}$

Clare and Kepert 1993). Based on this fact, in their investigation of the multiple addition of hydrogen atoms to C_{60} , Clare and Kepert considered only 1,2-addition (addition to hex/hex edges). In the AM1 study (Clare and Kepert 1993), they have found that the most energetically favorable would be consequent addition of H_2 molecules to hex/hex edges in a pathway, which eventually leads to T_h -symmetric $C_{60}H_{12}$ with all CH–CH edges separated from each other (Fig. 12d). While this addition pattern has never been experimentally verified for $C_{60}H_{12}$ or $C_{60}F_{12}$, it was indeed proved for many hexakis-cycloadducts such as $C_{60}(C(COOEt)_2)_6$ (Lamparth et al. 1995; Hirsch and Vostrowsky 2001).

Further addition to hex/hex edges in T_h - $C_{60}H_{12}$ inevitably requires formation of longer $CH-(CH)_x-CH$ strings. It was, however, found that formation of C_6H_6 is energetically unfavorable, and $-(CH)_x-$ strings should be built up from the edge-sharing C_6H_4 hexagons. Two motifs of the string growth, *S* and *T* (Fig. 12a), have been indicated (Clare and Kepert 1994b).

Among many addition patterns studied by Clare and Kepert for $C_{60}H_n$ ($n \leq 20$), two are of particular interest. For $C_{60}H_{18}$, C_{3v} -symmetric “crown” structure built from combination of *S* and *T* motifs (Fig. 12e) was shown to be one of the most stable isomers (Clare and Kepert 1994b). In this molecule, $-(CH)_x-$ string forms a loop, which isolates one hexagon from the rest of the π -system. The isolated hexagon is highly aromatic, and the carbon cage is flattened in its neighborhood. Discovered first in 1994 in the theoretical study, in 1996 this addition pattern was proved by 1H NMR spectroscopy for the experimentally available $C_{60}H_{18}$ (Darwish et al. 1996), and later the same pattern was found in $C_{60}F_{18}$ (Neretin et al. 2000). Consecutive extension of the *S*-motif leads to the closure of the $-(CH)_{20}-$ string in a loop around the fullerene equator with formation of the D_{5d} -symmetric $C_{60}H_{20}$ (Fig. 12f) (Clare and Kepert 1994a). This addition pattern was found experimentally in $C_{60}F_{20}$ (Boltalina et al. 2001), whose structure was recently confirmed by a single-crystal X-ray diffraction study (Shustova et al. 2010).

The crown motif with isolated benzene-like ring proposed for $C_{60}H_{18}$ was then found common for highly hydrogenated C_{60} (Clare and Kepert 1994a, b, 1999a). In particular, $C_{60}H_{36}$ was studied in detail because a compound with this composition was among the first C_{60} derivatives ever synthesized by different methods (Hauffer et al. 1990; Attalla et al. 1993; Ruchardt et al. 1993), but its structure remained unclear for more than a decade. For $C_{60}H_{36}$, combination of several crown motifs can lead up to four isolated benzene ring as in the *T*-symmetric isomer (Fig. 12g), but in the AM1 studies, some isomers with two or three benzene rings were found to be equally stable (Clare and Kepert 1999a). Almost identical results were obtained at the AM1 level for isomers of $C_{60}F_{36}$ (Clare and Kepert 1999a), whose structure also could not be unambiguously elucidated in the first synthetic studies. It was also found in the studies of $C_{60}X_{36}$ and $C_{60}X_{48}$ that double bonds in pentagons are not destabilizing anymore at high degrees of functionalization (Clare and Kepert 1997, 1999a, 2002a). For instance, the most stable isomers of $C_{60}F_{48}$ have all their six double bonds in pentagons (Clare and Kepert 1997).

In early 2000s, when routine DFT calculations have become feasible for the fullerene derivatives, Clare and Kepert reconsidered some of their earlier results by comparing AM1 to B3LYP/6-31G**/AM1. One of the main conclusions of these studies was the understanding that one should treat results of AM1 calculations with caution.

First, it was found that AM1 underestimated the energy difference between 1,2- and 1,4-isomers of $C_{60}X_2$ by ca 10 kJ/mol (at least, when compared to the results of DFT calculations) and the error accumulated at higher degrees of addition. As a result, while AM1 calculations predicted the $C_{60}H_6$, $C_{60}H_{12}$, and $C_{60}H_{18}$ structures with, respectively, one, two, and three *skew pentagonal pyramidal* (SPP) motifs (Fig. 13d) to be the most stable isomers for their compositions (Clare and Kepert 1996), DFT calculations showed that these addition motifs are energetically unfavorable. For instance, $C_{60}H_{18}$ with three SPP motifs is 73.8 kJ/mol more stable than the “crown” C_{3v} - $C_{60}H_{18}$ isomer at the AM1 level, but the latter is 256.8 kJ/mol more stable at the B3LYP/6-31G**/AM1 level (Clare and Kepert 2003b). This

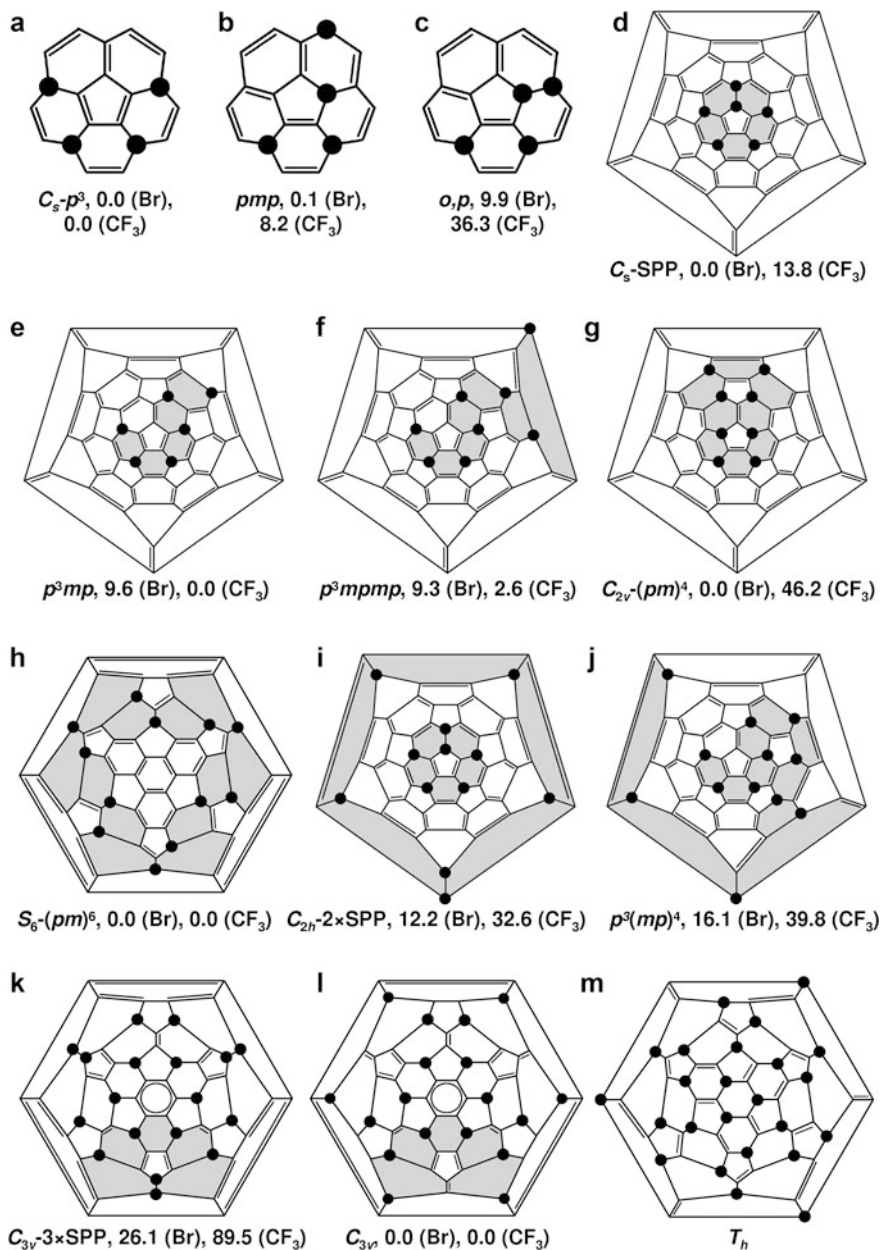

Fig. 13 $C_{60}X_n$ addition patterns typical for bulky groups (for $C_{60}Br_n$ and $C_{60}(CF_3)_n$, PBE/TZ2P-computed relative energies (kJ/mol) are listed). (a–c) isomers of $C_{60}X_4$; (d–e) isomers of $C_{60}X_6$; (d–e) isomers of $C_{60}X_8$; (h–j) isomers of $C_{60}X_{12}$; (k–l) isomers of $C_{60}X_{18}$; (m) T_h - $C_{60}X_{24}$. Symmetry group of the isomer is indicated only when it is different from C_1 . Ribbons of edge-shared C_6X_2 -hexagons are shaded (except for $C_{60}X_{18}$, here shaded are one SPP and one isolated fulvene moiety, respectively)

agrees with the fact that hydro- or fluorofullerenes with SPP motifs have never been observed experimentally.

Second, DFT studies have shown that for the low degree of additions, the most stable are those isomers, which have $-(CH)_x-$ strings, rather than isolated CH–CH fragments (Clare et al. 2003a). At the AM1 level, the most stable isomer of $C_{60}H_4$ is 13.4 kJ/mol level lower in energy than the C_s -symmetric isomer with C_6H_4 fragment, while at the B3LYP/6-31G* level, the latter is lower in energy by 15.3 kJ/mol. Likewise, the isomer of $C_{60}H_6$ with the *S*-motif is 31.5 kJ/mol lower in energy at the B3LYP/6-31G*//AM1 level than the isomer with three isolated CH–CH fragments, while at the AM1 level, the latter is more stable by 24 kJ/mol. For the isomers of $C_{60}H_8$, analogous energy differences increase to 59.7 and 31.1 kJ/mol, respectively. The preference of the contiguous addition at the early stages of fluorination was proved experimentally by ^{19}F NMR spectroscopy (Boltalina et al. 2002).

It is instructive to show that although contiguous addition appears to be the rule supported by both experimental and DFT studies, the other possibilities should not be completely abandoned. In the experimental studies of low C_{60} fluorides, C_s -symmetric isomer of $C_{60}F_8$ was isolated (Boltalina et al. 2002). C_s symmetry is not compatible with the *S*-type string, and the authors proposed a contiguous addition pattern with *T*-motif and two additional fluorine atoms attached at both ends of the string. However, later calculations have shown that such a structure would be unstable. Sandall and Fowler performed a broad search of all possible structures of C_s symmetry compatible with NMR data (Sandall and Fowler 2003). After calculations of more than 500 isomers using MNDO, AM1, and PM3 methods and – for selected structures – Harree-Fock method with STO-3G and 6-31G* basis sets, the authors have found that the most suitable isomer indeed has *T*-motif, but two additional fluorine atoms are added in a noncontiguous way with formation of 1,4- C_6F_2 hexagon (Fig. 12b). In a recent study, it was shown that two isomers of $C_{60}F_8$ are actually formed in the synthesis, aforementioned isomer with C_s symmetry and another one, also with C_s symmetry (Goryunkov et al. 2006b). Exhaustive DFT PBE/TZ2P calculations performed by the authors confirmed assignment of the C_s -isomer to the structure proposed by Sandall and Fowler and showed that another C_s -isomer is based on the *S*-motif. At the PBE/TZ2P level, *S*- C_s -isomer of $C_{60}F_8$ is 5.5 kJ/mol lower in energy.

The third failure of semiempirical methods revealed in the comparative AM1/DFT studies is that AM1 strongly underestimates stabilizing factor of the isolated benzene rings. Comparison of the relative energies of the isomers of $C_{60}H_{36}$ with different number of benzene rings computed at the AM1 and B3LYP/6-31G*//AM1 levels of theory shows that AM1-predicted relative energies should be adjusted by ca 60 kJ/mol per benzene ring to match the DFT-predicted values (Clare and Kepert 2002b). For instance, at the AM1 level, the relative energies of S_6 (2 rings), C_3 (3 rings), and *T* (4 rings) isomers of $C_{60}H_{36}$ are 0.0, 19.4, and 52.0 kJ/mol, while at the B3LYP/6-31G*//AM1 level, the values change to 0.0, –40.7, and –77.5 kJ/mol, respectively (Clare and Kepert 2002a). In a similar study of $C_{60}H_{36}$ isomers at the PM3 and PBE/TZ2P levels of theory, it was found that

PM3-computed relative energies should be corrected by approximately 67 kJ/mol per benzene ring to match the DFT results (Popov et al. 2004). For the isomers of $C_{60}F_{36}$, AM1-predicted relative energies should be corrected by approximately 30 kJ/mol per ring to match B3LYP/6-31G**/AM1 energies (Clare and Kepert 2002b). At the same time, relative energies of the isomers with the same number of benzene ring are reliably predicted by semiempirical approaches (Clare and Kepert 2002b; Popov et al. 2006). Thus, semiempirical methods were unable to predict the most stable isomers of $C_{60}H_{36}$ and $C_{60}F_{36}$. At the same time, DFT calculations correctly predict that *T*, C_3 , and C_1 isomers shown in Fig. 12g–i are the most stable isomers, in perfect agreement with the experimental results, which show that both $C_{60}H_{36}$ and $C_{60}F_{36}$ are obtained as mixtures of these three isomers (Boltalina et al. 1998; Gakh and Tuinman 2001; Gakh et al. 2003; Avent et al. 2002; Hitchcock and Taylor 2002; Popov et al. 2006). It should be noted that formation of isolated benzene rings is a very important stabilizing factor in the multiple addition to fullerenes, and it has been observed for many addends and many fullerenes. The failure of semiempirical methods in adequate prediction of the relative energies of isomers with such fragments is therefore a very serious problem and makes these methods hardly applicable when the broad search of the possible isomers is necessary. Good results demonstrated by DFTB in the studies of the fullerenes of different size show that this method might be useful for fullerene derivatives as well, but to our knowledge, benchmark calculations for fullerene derivatives with DFTB are not available yet.

Addition of Bulky Groups to C_{60} : Bromination and Perfluoroalkylation

In contrast to H and F, bromine atom is sufficiently large to make eclipsing interactions strongly repulsive, so that 1,4-addition of two Br atoms is more energetically preferable than 1,2-addition either at the AM1 ($\Delta E = 5.1$ kJ/mol) or DFT levels of theory (2.4 kJ/mol at B3LYP/6-31G**/AM1, 2.1 kJ/mol at LDA/DNP//AM1, and 14.0 kJ/mol at the PBE/TZ2P levels) (Dixon et al. 1992; Clare and Kepert 1995a, 2001). At the same time, the difference in the energy of 1,2- and 1,4-isomers is not very large, and hence the possibility of 1,2-addition should be also considered. Indeed, in the AM1 study of $C_{60}Br_4$ isomers, it was found that two lowest energy isomers are results of the consecutive 1,4-additions, while the third most stable isomer was a result of a combined 1,2- and 1,4-additions (Fig. 13a–c; Clare and Kepert 1995a). Regression analysis of the relative energies of $C_{60}Br_4$ isomers as a function of the number of different structural motifs (such as C_6Br , C_6Br_2 , C_6Br_3 , etc. hexagons) revealed that the most stable isomer of bromofullerenes might be obtained through formation of ribbons (also referred to as “strings”) of edge-sharing C_6Br_2 hexagons, rather than by addition of pairs of bromine atoms to the distant parts of C_{60} . Thus, the most stable isomer has *para-para-para* string (p^3 hereafter), while the second most stable isomer has *para-meta-para* string (*pmp* hereafter) (Fig. 13a, b). The relative energy of *pmp* isomer at the PBE/TZ2P (AM1) level

of theory with respect to the p^3 isomer is 0.1 (6.7) kJ/mol, while the next in stability order with one *ortho*- and one *para*-C₆Br₂ hexagons is 9.9 (11.0) kJ/mol less stable (the DFT calculations reported hereafter for bromofullerenes at the PBE/TZ2P level with effective-core potential basis set for the Br atoms were performed specifically for this chapter).

Further addition of Br atoms to the three most stable isomer of C₆₀Br₄ confirmed the preference of the string formation (Clare and Kepert 1995a). However, the most stable isomer at the AM1 level has a special C_s-symmetric addition pattern titled by some authors as “skew pentagonal pyramid” (SPP, Fig. 13d). This addition pattern includes one pair of Br atoms bonded to neighboring carbon atoms and is 21.8 kJ/mol more stable than the second most stable isomer with a p^3mp ribbon (Fig. 13e). At the PBE/TZ2P level, the energy difference between SPP and p^3mp isomers is reduced to 9.6 kJ/mol. Experimentally isolated C₆₀Br₆ indeed has the SPP pattern (Birkett et al. 1992), and this addition motif was also found for some other addends, including Cl (Birkett et al. 1993) and CF₃ (Kareev et al. 2006). It should be noted that formation of SPP-C₆₀X₆ derivatives for relatively large X is also favorable kinetically if the radical addition mechanism is adopted (Rogers and Fowler 1999).

Next two added Br atoms continue the tendency of the ribbon formation. At the AM1 level, the most stable isomer of C₆₀Br₈ has p^3mpmp ribbon (Fig. 13f), while DFT (PBE/TZ2P) shows that the isomer in which the ribbon is closed to a C_{2v}-symmetric loop ((*pm*)⁴, Fig. 13g) is 9.3 kJ/mol more stable. The latter motif is indeed observed in the experimentally isolated C₆₀Br₈ (Birkett et al. 1992). AM1 calculations have also shown that the isomers with the SPP motif and an additional *para*-C₆Br₂ hexagon on the opposite part of C₆₀ are also equally stable (Clare and Kepert 1995a).

While there are no experimentally isolated C₆₀Br_x compounds between C₆₀Br₈ and C₆₀Br₂₄, theoretical studies of the intermediate compositions were still very useful for predicting the general trends in the addition of bulky groups (Clare and Kepert 1995a, b). In particular, a remarkable prediction was done for C₆₀Br₁₂. The authors have shown that the most stable isomers in SPP and ribbon series are the C_{2h}-isomer with two SPP motifs on the opposite sides of C₆₀ and the S₆-symmetric isomer in which the ribbon is closed to a loop around the equator of the carbon cage (Fig. 13h, i). At the AM1 level, C_{2h} isomer is 6.8 kJ/mol more stable, while PBE/TZ2P favors the S₆-isomer by 12.2 kJ/mol. Though not available experimentally for C₆₀Br₁₂, both addition patterns have been found for C₆₀(CF₃)₁₂ derivatives (Popov et al. 2007b; Troyanov et al. 2006). In further addition of Br atoms, the competition between SPP motifs and ribbons is continued up to C₆₀Br₁₈, for which the isomer with three SPP moieties was predicted to be the lowest energy structure (Clare and Kepert 1995b). For even larger number of Br atoms, SPP motif does not provide stable structures anymore, and the most stable isomer of C₆₀Br₂₄ is T_h-symmetric structure in which all Br atoms are bonded to the non-neighboring carbon atoms (24 is the largest number of addends for which such a restriction is possible) (Clare and Kepert 1995a; Fowler et al. 1999). This isomer corresponds to the experimentally available structure of C₆₀Br₂₄ (Tebbe et al. 1992).

Significant progress achieved in the last years in the perfluoroalkylation of fullerenes (Boltalina et al. 2015) initiated exhaustive theoretical studies of $C_{2n}(CF_3)_x$ isomers with the aim to find the most stable structure(s) for each composition. Since the studies were performed almost a decade after the AM1-based analysis of $C_{60}Br_x$ addition patterns by Clare and Kepert, they have strongly benefited from the serious progress in hardware. Instead of the maximum of about 100 structures reported in the early exploratory studies, up to thousands and tens of thousand isomers were routinely studied for CF_3 derivatives, and results of the AM1 studies were then verified by DFT calculations. Besides, the isolation of $C_{60}(CF_3)_n$ derivatives with each even n from 2 to 18 (in many cases each composition is also presented by several isomers) enabled more detailed comparison between experimental and theoretical results.

Both AM1 and DFT (PBE/TZ2P) unambiguously show that 1,4-isomer of $C_{60}(CF_3)_2$ is much more stable than the 1,2-isomer, the DFT relative energy of the latter being 34.7 kJ/mol (Goryunkov et al. 2004a). The energy difference is more pronounced than for the $C_{60}Br_2$, which clearly shows that CF_3 is bulkier than bromine. Therefore, in the compounds with larger number of CF_3 groups, 1,2-addition is to be avoided. Indeed, the most stable isomers of $C_{60}(CF_3)_4$ are p^3 ($\Delta E = 0.0$ kJ/mol at the PBE/TZ2P level) and pmp ($\Delta E = 8.2$ kJ/mol) structures, just like for $C_{60}Br_4$; however the o,p - $C_{60}(CF_3)_4$ isomer, the third stable for $C_{60}Br_4$, is 36.3 kJ/mol less stable than p^3 - $C_{60}(CF_3)_4$ (for $C_{60}Br_4$ its relative energy is 9.9 kJ/mol) (Goryunkov et al. 2004a). The pmp is the major isolable isomer of $C_{60}(CF_3)_4$, while the more stable p^3 isomer is very reactive (Whitaker et al. 2013) and is usually isolated in the form of its epoxide $C_{60}(CF_3)_4O$ (Goryunkov et al. 2003; Kareev et al. 2006).

The trend revealed for $C_{60}(CF_3)_4$ in comparison to $C_{60}Br_4$ is further emphasized for six added groups. For CF_3 , the ribbon addition motifs are noticeably more preferable than the SPP motif. The most stable isomer of $C_{60}(CF_3)_6$ has p^3mp addition pattern, while the SPP isomer is 13.8 kJ/mol less stable (for $C_{60}Br_6$, SPP is 9.6 kJ/mol lower in energy) (Dorozhkin et al. 2007). The SPP- $C_{60}(CF_3)_6$ still can be isolated, but its yield is ca 20 times lower than the yield of the major, p^3mp isomer (Kareev et al. 2006).

Another difference between CF_3 and Br which becomes apparent for further additions is that CF_3 groups are sufficiently bulky to experience repulsive interaction when two groups are in one pentagon, even though they are not bonded to the neighboring carbon atoms. Thus, the stable ribbon addition pattern of $C_{60}Br_x$ with C_5Br_2 pentagons are destabilized for CF_3 groups (although some stable isomer still can have them). For instance, the most stable C_{2v} -symmetric addition pattern of $C_{60}Br_8$ (9.3 kJ/mol more stable than p^3mpmp) is 46.2 kJ/mol less stable than the p^3mpmp isomer of $C_{60}(CF_3)_8$ at the PBE/TZ2P level (Goryunkov et al. 2007). The p^3mpmp isomer itself is the second most stable ($\Delta E = 2.6$ kJ/mol, PBE/TZ2P), while the lowest energy was predicted for one of the isomers with p^3mp,p addition pattern (i.e., addition pattern of the lowest energy p^3mp - $C_{60}(CF_3)_6$ isomer with an additional isolated $para$ - $C_6(CF_3)_2$ hexagon). Theoretical results agree well with

experimental isolation of one p^3mpmp , three p^3mp,p , and one $pmpmpmp$ isomers of $C_{60}(CF_3)_8$ (Goryunkov et al. 2007; Popov et al. 2007b).

Fortuitously, performance of the AM1 method for addition of bulky groups is much better than for the consecutive 1,2-additions of H and F, which encourages the use of AM1 for the prescreening of thousand isomers of $C_{60}(CF_3)_n$. Although there is rather poor correlation between AM1 and PBE/TZ2P values (Fig. 14a), the trend in the energies of the most stable isomers is correctly predicted by AM1. For instance, when all isomers of $C_{60}(CF_3)_{10}$ obtained by a combination 1,4-additions were studied at the AM1 level and then a cutoff of 40 kJ/mol was applied to the AM1 results for the consequent PBE/TZ2P calculations, the most stable isomers within the range of ca 15 kJ/mol could be identified (Popov et al. 2007b). Figure 14 shows addition patterns and relative energies of the eight most stable isomers of $C_{60}(CF_3)_{10}$. Except for one isomer, which has two symmetry-related p^3m^2 loops, all other structures have ribbon addition patterns similar to those of $C_{60}(CF_3)_8$. From the eight theoretically predicted structures in Figure 14, six isomers of $C_{60}(CF_3)_{10}$ are characterized experimentally by single-crystal X-ray diffraction and/or ^{19}F NMR spectroscopy. The splitting of the ^{19}F NMR lines due to the through-space interaction of the fluorine atoms of CF_3 groups in the same hexagon allows experimental identification of the lengths of the ribbon, and when combined with results of DFT calculations of the relative energies, these data allow unambiguous identification of the addition pattern. Molecular structures of several isomers of $C_{60}(CF_3)_{10}$ were elucidated this way by a combination of NMR and DFT, and some of them were later confirmed by X-ray studies (Popov et al. 2007b).

Two key addition motifs predicted by Clare and Kepert for $C_{60}Br_{12}$, double-SPP pattern and S_6 -symmetric loop (Fig. 13h, i), have been identified experimentally for $C_{60}(CF_3)_{12}$ (Popov et al. 2007b; Troyanov et al. 2006). Extensive AM1 and DFT calculations showed that the S_6 -loop isomer is at least 19 kJ/mol more stable than all other isomer of $C_{60}(CF_3)_{12}$, while the C_{2h} -($2 \times$ SPP) isomer is 32.6 kJ/mol less stable (Kareev et al. 2007). The isomer of $C_{60}(CF_3)_{12}$ with ribbon motif and two $C_5(CF_3)_2$ pentagons (Fig. 13j) has been found to be 39.8 kJ/mol less stable than the S_6 -isomer, showing that kinetic factors can be also important in the isomeric distribution of $C_{60}(CF_3)_x$ derivatives even at 500 °C (Kareev et al. 2007).

When addition of more than 12 CF_3 groups is considered, one has to consider that fullerenes have only 12 pentagons, and hence it is impossible to avoid formation of destabilizing $C_5(CF_3)_2$ pentagons. Therefore, when CF_3 groups are too crowded on the fullerene surface, results of 1,2-addition can be not as destabilizing as at the lower addition stages. Exhaustive AM1 and DFT calculations have shown that for $C_{60}(CF_3)_{14}$, the lowest energy isomer with one SPP fragment is only 0.4 kJ/mol less stable than the most stable ribbon isomer with two $C_5(CF_3)_2$ pentagons; however, experimentally characterized isomers of $C_{60}(CF_3)_{14}$ do not have SPP fragments (Omelyanyuk et al. 2007). Likewise, for $C_{60}(CF_3)_{16}$, SPP and ribbon isomers are equally stable; moreover, it was found that stable addition patterns with CF_3 groups on adjacent carbon atoms can be realized without formation of the SPP moiety, and one of the experimentally characterized $C_{60}(CF_3)_{16}$ isomers has o - $C_6(CF_3)_2$

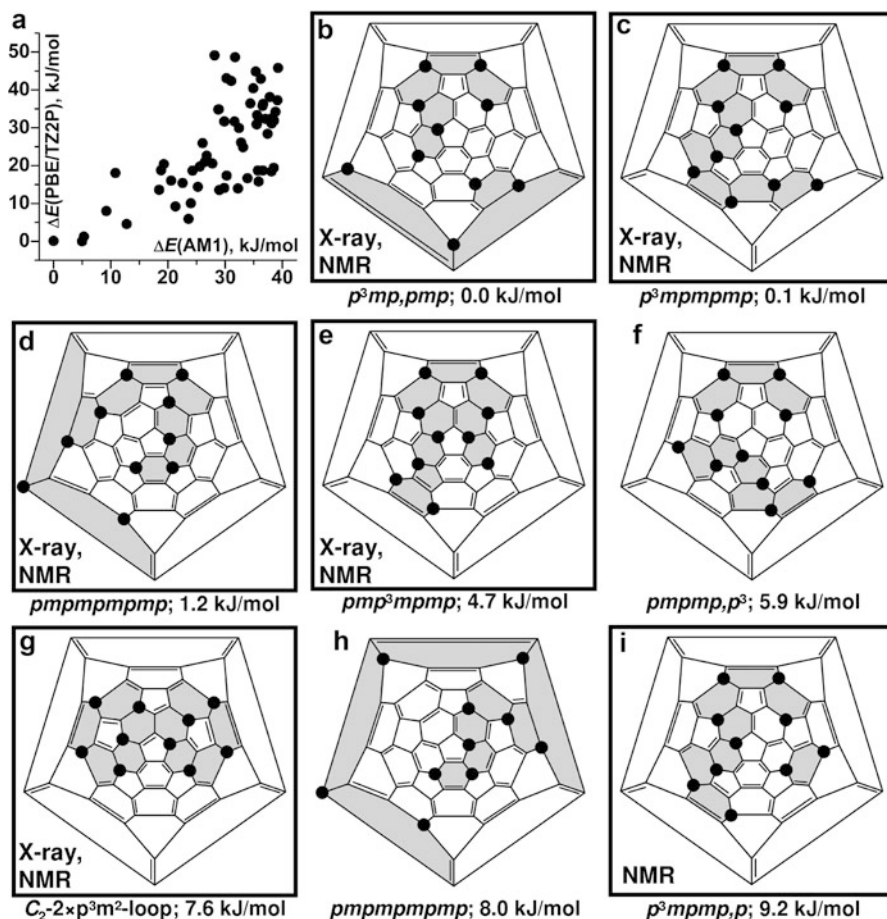

Fig. 14 (a) Correlation between relative energies of $\text{C}_{60}(\text{CF}_3)_{10}$ isomers computed at the AM1 and PBE/TZP levels of theory; (b–i) Schlegel diagrams of the eight lowest energy isomers of $\text{C}_{60}(\text{CF}_3)_{10}$ (PBE/TZ2P-computed relative energies are also listed, based on the data from Popov et al. 2007a). Experimentally characterized compounds are framed in black (“X-ray” means single-crystal X-ray diffraction; “NMR” means ^{19}F NMR spectroscopy). Ribbons of edge-shared $\text{C}_6(\text{CF}_3)_2$ -hexagons are shaded

hexagon (Trojanov et al. 2007). For $\text{C}_{60}(\text{CF}_3)_{18}$, theoretical studies have shown that the most stable isomer has C_{3v} -symmetry, two isolated benzene rings, three isolated fulvene fragments, nine $\text{C}_5(\text{CF}_3)_2$ pentagons, and no CF_3 groups on adjacent carbon atoms (Fig. 13j; Trojanov et al. 2007). DFT calculations show that this isomer is 89.5 kJ/mol more stable than the isomer with triple SPP motif, which also has one benzene ring (Fig. 13k). Moreover, even for $\text{C}_{60}\text{Br}_{18}$ this isomer is 26.1 kJ/mol more stable than the structure with three SPP moieties. Recently, the isomer of $\text{C}_{60}(\text{CF}_3)_{18}$ with this addition pattern has indeed been isolated and characterized

by single-crystal X-ray diffraction (Samokhvalova et al. 2009). Up to now, 18 is the largest number of CF_3 groups in structurally characterized $\text{C}_{60}(\text{CF}_3)_x$ derivatives; the T_h -symmetric $\text{C}_{60}\text{X}_{24}$ motif known for $\text{X} = \text{Br}$ and Cl could not be reached yet for CF_3 derivatives.

Addition to C_{70} and Higher Fullerenes

I_h - C_{60} has only two types of C–C bonds, which can be straightforwardly classified according to their bond lengths as “single” and “double” bonds. For C_{70} and higher fullerenes, the symmetry in most cases is much lower, and the lengths of C–C bonds are more uniformly distributed. It is therefore almost impossible to make an unambiguous classification of the bond types, and the relevant chemical properties (such as addition pathways) are much harder to predict.

The structure of C_{70} can be described as a combination of two C_{60} -like hemispheres on the poles separated by the belt of ten carbon atoms and five benzene-like rings around the equator (Fig. 15a). The bonds between the belt carbon atoms are significantly elongated compared to C_{60} values; besides, these atoms are located on triple hexagon junctions. Clare and Kepert reported AM1 study of the addition patterns of C_{70}X_n derivatives ($n = 2$ –12, $\text{X} = \text{H}, \text{F}, \text{Br}, \text{C}_6\text{H}_5$) (Clare and Kepert 1999b). For C_{70}H_2 , the authors have found that 1,2-addition is energetically preferable in the pole region, while the lowest energy 1,4-addition occurs at the equator. The AM1-computed energy difference between the most stable 1,2- and 1,4-isomers is only 4.4 kJ/mol, which can be compared to 18 kJ/mol for C_{60}H_2 . Such a considerable difference between the relative energies of C_{70}H_2 and C_{60}H_2 isomer can be explained by the fact that the 1,4-addition at the equator of C_{70} does not generate destabilizing double bond in any pentagon. For C_{70}H_4 , the isomer with p^3 -string at the equator (Fig. 15) is in fact 9.1 kJ/mol lower in energy than the isomer obtained by two 1,2-additions. The studies of C_{70}H_n with $n = 6$ –10 further emphasized the preference of consecutive 1,4-additions with formation of the p^{n-1} -ribbon along the equator of the carbon cage. The most stable C_{70}H_6 and C_{70}H_8 isomers in these series are, respectively, 28.0 and 54.3 kJ/mol lower in energy than the isomers obtained by 1,2-addition. Note that p^5 and p^7 -strings at the equator of C_{70} can be realized as either C_s or C_2 -symmetric isomers. For C_{70}H_6 , C_2 - p^5 isomer is 76.6 kJ/mol more stable than the C_s - p^5 pattern (56.6 kJ/mol at the PBE/TZ2P level (Dorozhkin et al. 2006a), while for C_{70}H_8 , the C_s - p^7 isomer is 34.7 kJ/mol (21.6 kJ/mol at the PBE/TZ2P level) more stable than C_2 - p^7 . The most stable isomer at the next addition step is obtained by the closure of the p^7 ribbon via addition of two atoms to pent/hex junction with formation of the C_s - p^9o -loop (Fig. 15), which cuts the π -system of the fullerene into two noncommunicating parts. This structure is 26.9 kJ/mol more stable than the C_2 - p^9 isomer, obtained by the growth of the equatorial ribbon via one more 1,4-addition step. Computations for the bulkier Br and C_6H_5 groups have also shown that formation of the ribbon around the cage equator is the most referable addition motif in C_{70} (Clare and Kepert 1999b). Even for C_6H_5 , the sterically strained C_s - p^9o -loop addition pattern

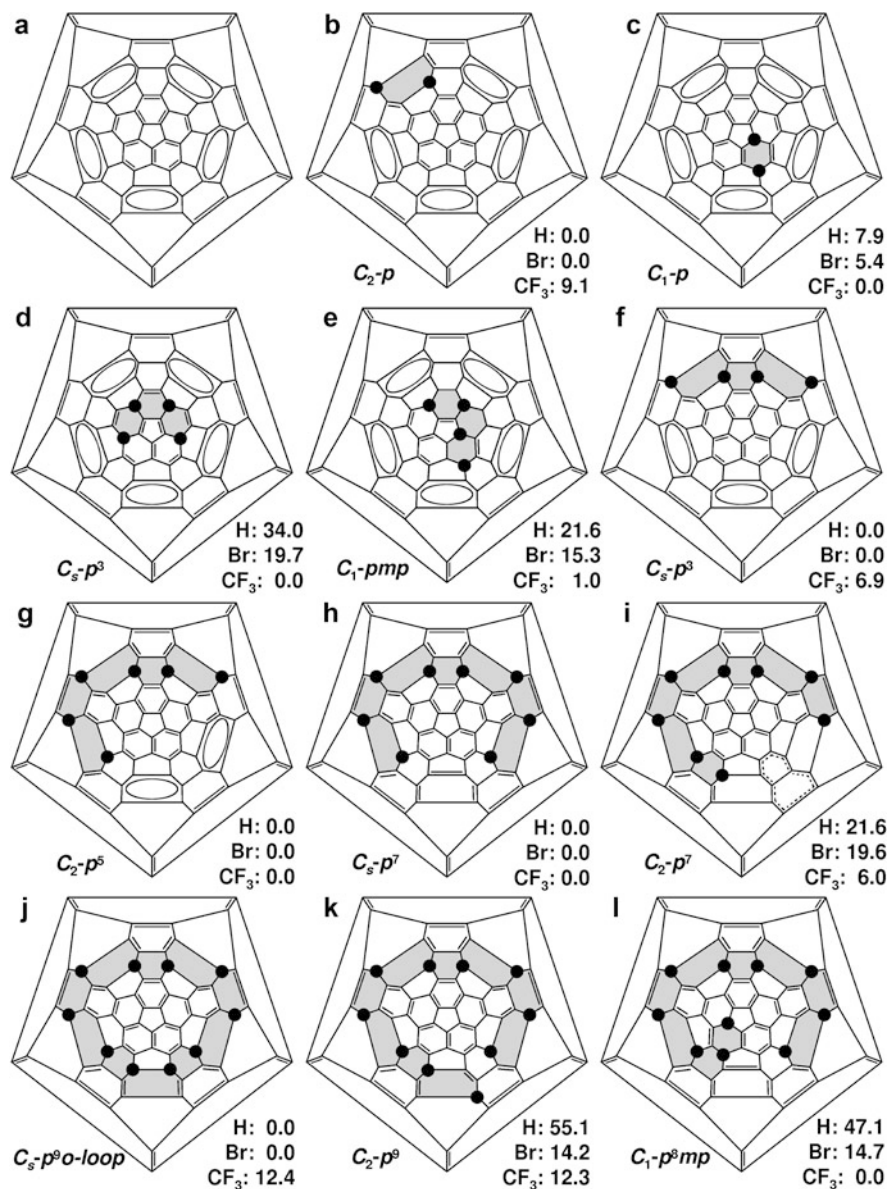

Fig. 15 (a) Schlegel diagram of C_{70} ; (b–i) addition patterns of selected $C_{70}X_n$ ($n = 2-10$) derivatives and the relative energies of their isomer (kJ/mol, PBE/TZ2P level of theory) for $X = H, Br,$ and CF_3 ; ribbons of edge-shared C_6X_2 -hexagons are shaded. Based on the data from (Dorozhkin et al. 2006a) and additional computations performed for this chapter

is more stable for $C_{70}X_{10}$ than C_2-p^9 isomer. Results of these calculations agree very well with experimental data. Except for $C_{70}(CF_3)_{10}$ discussed below, the majority of experimentally available $C_{70}X_{10}$ compounds ($X = H, Cl, Br, Ph, CH_3$) have C_s-p^9o -loop (Birkett et al. 1995; Avent et al. 1997; Spielmann et al. 2000; Al-Matar et al. 2002; Troyanov et al. 2003), and only bulky OO^tBu groups form the decakis adduct with C_2-p^9 addition pattern (Xiao et al. 2005). Some $C_{70}X_n$ compounds with less than ten added groups have also been reported, and most of them also have equatorial string addition patterns. Thus, both computational and experimental data confirm that the most energetically stable addition motif for C_{70} is formation of the string from *para*- C_6X_2 hexagons around the cage equator, and even for hydrogen this motif might be more preferable than the consecutive 1,2-additions.

Trifluoromethylation of C_{70} deserves separate attention since, like for C_{60} , this reaction was studied recently in great details, and many compounds from $C_{70}(CF_3)_2$ to $C_{70}(CF_3)_{20}$ (each composition being presented by several isomers) have been isolated and structurally characterized (Goryunkov et al. 2005, 2006a; Kareev et al. 2005; Dorozhkin et al. 2006a, b; Ignat'eva et al. 2006; Popov et al. 2007a; Boltalina et al. 2015). The experimental studies were usually combined with and sometimes preceded by detailed theoretical analysis at the AM1 and PBE/TZ2P level.

It was found that the two lowest energy isomers of $C_{70}(CF_3)_2$ have a *p*- $C_6(CF_3)_2$ hexagon on the pole of the molecule, and these structures are assigned to the experimentally available isomer (Dorozhkin et al. 2006a; Popov et al. 2007a). The most stable isomer with equatorial addition is 9.1 kJ/mol higher in energy at the PBE/TZ2P level of theory; meanwhile, the same method shows that the isomer of $C_{70}H_2$ with equatorial addition is 7.9 kJ/mol more stable than the isomer with *p*- C_6H_2 hexagon on the pole. The reason for such a difference is most probably a much higher curvature of C_{70} cage at the poles as compared to the almost flat equator. Therefore, the distance between two CF_3 groups is longer for *p*- $C_6(CF_3)_2$ hexagon on the pole than for the hexagon on the equator; hence the repulsion between the groups is weaker on the pole. For $C_{70}H_2$, repulsion between the atoms is a less important factor, and the equatorial addition is more preferable.

Addition on the pole is more preferable for $C_{70}(CF_3)_4$ as well. Similar to $C_{60}(CF_3)_4$, the most stable isomers have C_s-p^3 and C_1-pmp ribbons with the energy difference of only 1.0 kJ/mol (PBE/TZ2P) (Dorozhkin et al. 2006a). Both can be isolated experimentally; however the p^3 isomer is kinetically unstable, and the isolable form is its epoxide $C_{70}(CF_3)_4O$ (Popov et al. 2007a). DFT calculations have also shown that there are at least 15 other isomers of $C_{70}(CF_3)_4$ within the range of 20 kJ/mol, including the isomer with C_s-p^3 string at the equator ($\Delta E = 6.9$ kJ/mol, PBE/TZ2P), but no other structure has been characterized experimentally. Note that the model calculations of $C_{70}H_4$ and $C_{70}Br_4$ isomers at the PBE/TZ2P level have also shown that the equatorial addition is more energetically preferable for H and even Br (relative energy of the pole C_s-p^3 isomer is 19.7 and 34.0 kJ/mol for Br and H, respectively, versus the equatorial C_s-p^3 isomer).

Starting from $C_{70}(CF_3)_6$, CF_3 addition switches to the equatorial motif. Like for many other groups (H, Cl, Br, Ph), the lowest energy isomer has a C_2-p^5 ribbon at the equator, and this is indeed the most abundant experimentally characterized isomer (Dorozhkin et al. 2006a). For $C_{70}(CF_3)_8$, the two most stable isomers have C_s-p^7 and C_2-p^7 ($\Delta E = 6.0$ kJ/mol, PBE/TZ2P) ribbons, and both isomers could be isolated and characterized by single-crystal X-ray diffraction (Goryunkov et al. 2005; Mutig et al. 2008).

For $C_{70}(CF_3)_{10}$, the large size of CF_3 groups again makes the lowest energy addition pattern different from that for other addends. Repulsion of CF_3 groups on adjacent carbon atoms destabilizes the C_s-p^9 *o*-loop isomer of $C_{70}(CF_3)_{10}$, and the most stable isomer is obtained if the C_s-p^7 equatorial ribbon is continued by the *mp* fragment which is crawling to the pole again, as in the early stages of addition, and forming as a result C_1-p^7mp ribbon (Kareev et al. 2005). The C_2-p^9 string is 12.3 kJ/mol less stable followed by C_s-p^9 *o*-loop (12.4 kJ/mol). For comparison, the C_1-p^7mp isomer of $C_{70}Br_{10}$ is 14.7 kJ/mol less stable than the C_s-p^9 *o*-loop. In accordance with its DFT-predicted high thermodynamic stability, the C_1-p^7mp is the most abundant $C_{70}(CF_3)_{10}$ isomer, and it can be obtained with unprecedented high yield (Popov et al. 2007a). C_2-p^9 as well as three other less-stable minor isomers could be also structurally characterized, but their yield is much lower; the C_s-p^9 *o*-loop has never been found (Popov et al. 2007a).

The stable addition pattern of the major $C_{70}(CF_3)_{10}$ isomer is found in all except one lowest energy and experimentally isolated addition patterns of $C_{70}(CF_3)_{12-18}$. For instance, four isolated isomers of $C_{70}(CF_3)_{12}$ have p^7mp,p patterns, while $C_{70}(CF_3)_{16}$ and $C_{70}(CF_3)_{18}$ have SPP fragment on the pole with p^7mp and p^7mpmp ribbons, respectively (Avdoshenko et al. 2006; Goryunkov et al. 2006a; Ignat'eva et al. 2006).

One of the important findings revealed in the studies of the multiple addition to C_{70} is the fact that the isomers in which addends are bonded to the carbon atoms on the triple hexagon junctions (THJs) are very unstable. This rule is fulfilled for all C_{70} derivatives with low and medium addition rate, and from all known derivatives of C_{70} , the only violations of this rule are $C_{70}F_{38}$ (Hitchcock et al. 2005) and $C_{70}Cl_{28}$ (Troyanov et al. 2005). Moreover, it was found that this is also a strict rule for higher fullerenes (Troyanov and Kemnitz 2005; Shustova et al. 2006, 2007; Kareev et al. 2008b) when 12 or less groups are added. The energy penalty for addition of one CF_3 group to THJ position was estimated as 60 kJ/mol (Boltalina et al. 2015). Thus, when considering the possible isomers of $C_{2n}X_m$ ($m \leq 12$), one can exclude addition to triple hexagon junctions. This fact can dramatically reduce the number of possible isomers. For instance, in the experimental study of the trifluoromethylation of the “insoluble” small HOMO–LUMO gap fullerenes, the conditions were optimized to produce $C_{2n}(CF_3)_{12}$ as major products (Shustova et al. 2006). ^{19}F NMR spectroscopy then enabled identification of the symmetry of the derivatives and the relative location of the groups (i.e., number and length of the ribbons). Note that the cage isomers of the studied fullerenes were unknown.

As a result, million isomers were possible for these derivatives. However, when the rule about the triple hexagon junctions was taken into account and combined with the condition that CF_3 groups cannot share the same pentagon (12 is the largest number of the groups added to any fullerene which can be distributed with one group per pentagon), the number of possible isomers was reduced to only a few structures for all possible cage isomers, and the DFT studies of all compatible structures could easily identify the experimental structures and determine their carbon cage isomers (Shustova et al. 2006). Note that for higher degree of addition (more than 12 groups), the avoidance of THJ position by addends is not a strict rule anymore, and CF_3 -bearing THJ carbons have been found in several derivatives of higher fullerenes ($\text{C}_{76}(\text{CF}_3)_{14-18}$, $\text{C}_{94}(\text{CF}_3)_{20}$). Interestingly, in contrast to the empty fullerenes, multiple addition of CF_3 groups to THJ carbon atoms was found for $\text{Sc}_3\text{N}@C_{80}$ (Shustova et al. 2009, 2011) already at early stages of addition proving that the endohedral cluster and electron transfer to the carbon cage dramatically change chemical properties of fullerenes.

Abstract

Materials that exhibit an electrical resistivity between that of conductor and insulator are called semiconductors. Devices based on semiconductor materials, such as transistors, solar cells, light-emitting diodes, digital integrated circuits, solar photovoltaics, and much more, are the base of modern electronics. Silicon is used in most of the semiconductor devices while other materials such as germanium, gallium arsenide, and silicon carbide are used for specialized applications. The obvious theoretical and technological importance of semiconductor materials has led to phenomenal success in making semiconductors with near-atomic precision such as quantum wells, wires, and dots. As a result, there is a lot of undergoing research in semiconductor clusters of small and medium

sizes both experimentally and by means of computational chemistry since the miniaturization of devices still continues. In the next pages, we are going to learn which the most studied semiconductor clusters are, we will explore their basic structural features and visit some of the most representative *ab initio* studies that are considered as works of reference in this research realm. Also, we are going to be introduced to the theory of the electric properties applied in the case of clusters by visiting some of the most illustrative studies into this research area. It is one of the purposes of this presentation to underscore the strong connection between the electric properties of clusters and their structure.

Introduction

About two decades ago Robert Pool stated: “Clusters are strange morsels of matter: when metals or semiconductors are shrunk down to clumps only 10 or 100 atoms in size, they become a “totally new class of materials” with potentially valuable applications” (Pool 1990). This distinctive behavior of clusters has triggered an explosion of scientific work in this area and it is in close relation with the dramatic development of a new field in science. This field is now widely known as “nanoscience.” The term nanoscience comes from the terms “nano” and “science.” The word “nano” is used to define a specific length of one billionth of a meter. This size scale resides between bulk materials and typical molecular dimensions. Thus, nanoscience is associated with the study of structures, materials, and devices, which are larger than the typical molecules but extremely small, usually in the range from 0.1 to 100 nm. The increasing importance of this area and its rapid expansion is owed mainly to the requirements of modern technologies for a vast diversity of new materials with more than one function. The field of nanoscience is highly multidisciplinary and joins different disciplines such as chemistry, applied physics, materials science, colloidal science, device physics, supramolecular chemistry, and even more, mechanical and electrical engineering. As a matter of fact, nanoscience can be viewed as extension of most of existing sciences into the nanoscale or the upgrade of the existing molecular sciences to the nanoscale dimensions.

Among nano-objects clusters occupy a large part of the big picture. The so-called nanoclusters apart from a bridge between molecules and solids are systems with properties of their own which are considerably different from those of the bulk materials and from those of their constituent parts (atoms and molecules). Under specific conditions those species can be considered as the building modules of nano-objects which are the foundations of nanoscience. Clusters are aggregates of atoms or molecules in the size of few nanometers and their constitution ranges between 10 and 10^6 atoms. They can be built from only one type of atoms such as the homogeneous silicon clusters, or from more than one element such as the heterogeneous gallium arsenide binary clusters. Atomic clusters can be met in neutral or charged forms while their atoms bind together by almost all of the main bond types such as covalent, ionic, van der Waals, and metallic.

Amongst the different types of clusters that have been the subject of numerous studies in the past, clusters which originate from semiconductor materials have attracted considerable attention. In spite of their origin, these entities are not necessarily semiconductors. Their basic bonding features resemble those of the metals but they keep as well some of the covalent bonding characteristics which dominate in semiconductor nanocrystals.

The purpose of this presentation is to bring together the most representative *ab initio* studies of the non-bulk-like structural and electric properties of semiconductor clusters. Both of these two different property classes are closely related to each other and have occupied the interest of the researcher in numerous studies.

Structural Properties of Semiconductor Clusters

Excluding clusters built from carbon (fullerenes) then the most studied semiconductor clusters are those made from silicon (Si) and gallium arsenide (GaAs). GaAs clusters belong to the so-called III–V group of semiconductors which are formed between the elements of groups 13 and 15. Also, there is a significant amount of work focusing on the II–VI semiconductor clusters which are formed between the elements of the 12 and 15 groups. Especially for the latter clusters there is significant amount of reported experimental and theoretical work due to their unique optical properties. The most studied II–VI semiconductor clusters are those built from cadmium sulfide which have served as prototypes for studies of the effect of quantum confinement on electronic and optical properties of semiconductor nano-objects. For instance, CdS quantum dots which are water soluble and biocompatible (Bruchez et al. 1998), are potentially useful as fluorescent biological labels since they are characterized by large optical gaps. Also, cadmium selenide and telluride clusters have attracted considerable attention due to their narrow bandgaps and large Bohr exciton radii. The last characteristic implies that nanostructures built from those systems are expected to exhibit strong quantum confinement and this feature makes both CdSe and CdTe nano-objects very interesting to explore their properties. Other kinds of semiconductor clusters that have been the subject of a notable number of computational studies are clusters built from GaN, GaP, InP, InAs, ZnO, ZnS, AlP, HgTe, Ge, SnTe, BeTe, BiTe, BN, BAs, and BP.

The Ground-State Structure

In principle, the most favorable atom arrangement of a cluster should be the one that is characterized by the smallest total energy. This structure is generally called the ground-state structure and at zero or low enough temperatures should be the mathematical global minimum of the potential energy of a cluster as a function of the coordinates of the atomic centers (the potential energy surface, PES). The arrangement of the atoms in the ground-state structure is the one that is considered in the majority of cluster property studies, assuming that most of

those properties are defined by the properties of the lowest energy configuration. As a result, a respectable number of various computational schemes have been developed and proposed in order to treat the ground-state structure problem in an accurate and efficient manner. However, the solution to this problem is neither obvious nor simple. In the contrary, it corresponds to a task of extremely high computational complexity. The problem becomes even harder given that the available experimental methods are not yet in the position to provide the necessary microscopic structural details for the complete understanding of clusters structures in order for the developed theoretical methods to be verified or improved. Also, the developed computational methods face certain difficulties that are mainly delivered from “practical” limitations of the algorithms used or restrictions of the quantum chemical methods in the precise calculation of the potential energy surface of a given cluster. Accordingly, in several cases the global minimum of the potential energy cluster surface exhibits a strong dependence on the quantum chemical method one uses in order to explore it (Karamanis et al. 2007b). A classical example of the above statement is the case of C_{20} . This cluster is the smallest possible fullerene, and experiments suggest that it should be a planar ring (Castro et al. 2002; Dugourd et al. 1998; Prinzbach et al. 2000). However, detailed theoretical studies (Grossman et al. 1995) by means of quantum Monte Carlo, all-electron fixed-node quantum Monte Carlo (Sokolova et al. 2000), single- and multireference MP2 methods (Grimme and Mück-Lichtenfeld 2002) and high-level ab initio methods (An et al. 2005) pointed out the bowl and the cage structures as more stable. The answer to this puzzle is that both experiments and theory are correct since if one introduces finite-temperature corrections to the calculations then ring structure becomes more stable (see Fig. 1).

Furthermore, some specific clusters show a peculiar behavior well known as “fluxional behavior.” This behavior is connected with the fact that at a given temperature the clusters are expected to be in some sort of thermal equilibrium rapidly interconverting from one stable isomer to the other due to fast and sometimes drastic atomic rearrangements. During a structural rearrangement of this kind, the resulting “isomerization” leads to structures characterized by different bonding patterns. Thus, it would not be irrational for one to claim that there is no guarantee that the theoretically predicted ground states are favored in all situations and condition.

In order to overcome such problems many studies extend their property investigations to stationary points which correspond to cluster conurations energetically

Fig. 1 The three different structures of C_{20} competing for the ground state

Fig. 2 Ground state structures and low lying isomers of AlSi_7 in comparison with the lowest energy structures of Si_7 and Si_8

close to the ground state. These clusters are meta-stable species and their study is expected to complement the investigations which focus on the narrow area of the global minima. A demonstration of the numerous stable local minima that exist even for clusters of small size is given in Fig. 2 which depicts the ground-state structures of aluminum-doped clusters along with several low-lying isomers which are extremely close in energy (Karamanis et al. 2010).

Structural Determination

There are two major classes of global computational methods: the unbiased and the seeded methods. The first class works independently of initial cluster configurations

and is considered as the most significant and reliable but the more computationally demanding. The second class utilizes a set of initial structures as seeds and they are usually faster than the unbiased; however, there is always the possibility of disregarding configurations of low energy that are not expected. Another optional way of finding the most favorable structures of clusters is based on guiding principles and structural rules stability principles, such those that have been originally developed and tested over the years for boranes and carboranes and bisboranes. Although this kind of approach is more of an art than of an automatic algorithmic computational approach it has been utilized with remarkable success in various systems such as pure or doped silicon cluster, or clusters made from gallium arsenide, cadmium sulfide, selenide, or telluride (see for instance, Al-Laham and Raghavachari 1991, 1993; Lipscomb 1966; Zdetsis 2008, 2009; Williams 1992; Gutsev et al. 2008a, b; Raghavachari and Logovinsky 1985, Raghavachari and Rohlfing 1988; Matxain et al. 2000, 2001, 2003, 2004). In any case though, whatever the method chosen, one has to deal with the existence of a vast number of local minima even in the case of clusters composed by few atoms.

Let us now see in brief some of the developed algorithms that have been used in cases that involve semiconductor clusters. The most commonly used computational schemes in finding the ground-state structures of semiconductor clusters are those based on genetic algorithms that simulate the evolution in nature through natural selection. This approach utilizes concepts such as chromosome mixing, mutations, and the selection of the fittest. Another family of algorithms is the so-called basin hopping which use canonical Monte Carlo simulations at a certain temperature. The basic idea of the basin hopping algorithms is to lower the energetic barriers that separate the various local minima of a cluster by leaving the number and the kinds of the local minima unchanged. This has been proven very efficient in scanning different areas of the potential energy surface and has been successfully applied in cases of clusters up to 100 atoms. A different approach which has been applied in a great variety of systems is the thermal simulated annealing. This method lets the system to evolve initially at a high temperature and then a cooling down procedure starts by reducing gradually the temperature of the system to zero temperature. At each step some neighbor structures are considered based on probability rules and then it is decided whether this new structures are accepted or not following certain energy criteria (e.g. by moving to states of lower energy). As a result, the search space which contains appropriate solutions to the problem considerably narrows down. However, if the free energy global minimum changes at low temperatures where dynamical relaxation is slow, the algorithms may become stuck in the structure corresponding to the high-temperature free energy global minimum. Thus, although this algorithm is easy to follow and understand because of its physical concepts, it is less efficient than methods based on genetic and basin hopping algorithms. Finally, another method that has been developed to treat the problem of rich potential energy surfaces close to the minimum is the so-called Global Search Algorithm of Minima (GSAM) (Marchal et al. 2009, 2010, 2011). In brief, the GSAM includes three major parts: the first part is devoted to the generation of an initial guess set of structures for a large number of cluster structures

randomly generated by several techniques. The second part performs an automatic selection of the most appropriate structures through a special pattern recognition technique (Karamanis et al. 2009), which are expected to lead to different local minima. Finally, the third part comprises full geometry optimizations of the selected configurations. This last part yields the most stable cluster structures and the structure which corresponds to the ground state among them.

Further information into the subject of the methods that have been used to treat cluster structural problems in a global manner can be found in the Refs. Bazterra et al. (2004), Biswas and Hamann (1986), Blaisten-Barojas and Levesque (1986), Hamad et al. (2005), Ho et al. (1998), Hossain et al. (2007), Jelski et al. (1991), Menon and Subbaswamy (1995), Nair et al. (2004), Pedroza and Da Silva (2007), Sokolova et al. (2000), Tekin and Hartke (2004), Yoo et al. (2004, 2008), Yoo and Zeng (2005, 2004).

Silicon Clusters

Selected Structural Studies

As we have already mentioned, among the various semiconductor clusters studied during the past two decades, those made from silicon have attracted most of the attention. A significant number of algorithms and computational strategies have been employed to identify the ground states and the low-lying isomers of silicon clusters of small and medium size with remarkable success. As a result, it is now a common sense that the silicon atoms of a cluster are “different” from those of the bulk material.

It is evident that most of the studies on silicon clusters concern their neutral forms. However, it is impossible to neglect investigations on charged clusters since they have led to very significant results and conclusions (Lyon et al. 2009; Xiao et al. 2002; Nigam et al. 2004; Wei et al. 1997; Li et al. 2003, Li 2005; Zhou and Pan 2008). One of the most impressive investigations on this subject is the recent study reported by Lyon et al. who studied for the first time the experimental infrared spectra of positively charged silicon bare clusters up to 21 atoms in the gas phase. In this study the experimental spectra were compared to theoretical spectral predictions and the authors managed to make unambiguous structural assignments for these species (Fig. 3). This work is one of the most recent proofs confirming that the silicon clusters which have been predicted one way or another by theory also exist in the gas phase.

In the case of the neutral clusters up to 13 atoms, the most stable structures are not planar except Si_3 and Si_4 . Mainly they prefer polyhedral structures of rather high symmetry. Raghavachari and Logovinsky (1985), Fournier et al. (1992), Li (2005), and Yu et al. (2002) have established the basic structural patterns of those small species which nowadays are considered as systems of reference. For those species, Zhu and Zeng (2003) provided accurate geometries computed at high levels of theory. A recent study performed by Zdetsis (2007a, b) have showed that silicon clusters of 5 up to 13 atoms, and their dianions follow common structural

Fig. 3 Ground-state structures of neutral and charged silicon clusters. Stable structures of neutral silicon clusters

motifs of the corresponding closo-boranes. Among the small clusters with 2 up to 13 atoms there are two species of remarkable interest. These species are the Si_6 and Si_{10} which are considered as magic clusters because of their high stability. The six-atomic silicon cluster has attracted the attention of many researchers due the existence of three almost isoenergetic structures that compete for the ground state. Namely, the distorted (compressed) octahedron of D_{4h} symmetry and two trigonal bipyramidal shapes of lower C_{2v} symmetry, the edge-capped and face-capped trigonal bipyramids. On the other hand Si_{10} is also known as an extremely stable entity and it has been used as a building module of larger structures (Raghavachari and Rohlffing 1988; Mitas et al. 2000; Rohlffing and Raghavachari 1990; Grossman et al. 1995).

From $n = 14$ the shapes of the most stable structures become prolate (Zhu et al. 2004; Yoo and Zeng 2005). An interesting structural feature of the stacked prolate structures is that they are built from blocks that in fact are smaller stable clusters such as the Si_9 tricapped trigonal prism or the Si_6 puckered-hexagonal-ring. For instance Si_{11} and Si_{15} are built upon the tricapped-trigonal-prism of Si_9 while Si_6 puckered-hexagonal-ring motifs can be identified for silicon clusters with 16–20 atoms. This is the most reliable explanation of their stability since it is related to the stability of their building blocks. This finding is of crucial importance since it may open new directions in the nanomaterial and single nanoparticle design.

After $n = 19$, hollow near-spherical shapes start to show significant stability. From $n = 24$, the near-spherical structure with interior atoms becomes nearly degenerated with the prolate configurations (Jarrold and Bower 1992; Jarrold and Constant 1991; Kaxiras and Jackson 1993). However, up to $n = 25$, the stacked prolate structures are still the most stable. Finally, although clusters with more than 25 atoms are not very well studied and their ground-state structures are either unknown or under debate (Bai et al. 2006), there are recent studies that yielded very interesting results. For instance, Yoo and coworkers (Avramov et al. 2007; Yoo et al. 2008, 2004; Yoo and Zeng 2006, 2005) searched for generic structural features as well as patterns of structural evolution for the low-lying silicon clusters up to the size of 80 atoms by studying the structures and relative stability of different cluster shapes families. Their results indicate that for some cluster sizes such as Si_{39} , Si_{40} , and Si_{50} , the fullerene cage motifs consistently are more stable than other kind of cage structures.

The Si_6 and Si_{36} Cases

To demonstrate the difficulty in studying the structures and properties of clusters even of small size even when are built from only one element, and the complexity in interpreting computational and experimental results of diverse sources we shall revisit two distinctive cases: One concerns the small Si_6 cluster and the other the larger Si_{36} . As mentioned, Si_6 is a particularly stable cluster and along with Si_{10} coincides with clusters found abundantly in the experiment. Figure 4 shows three optimized structures of Si_6 at the CCSD(T) level and the natural atomic charges

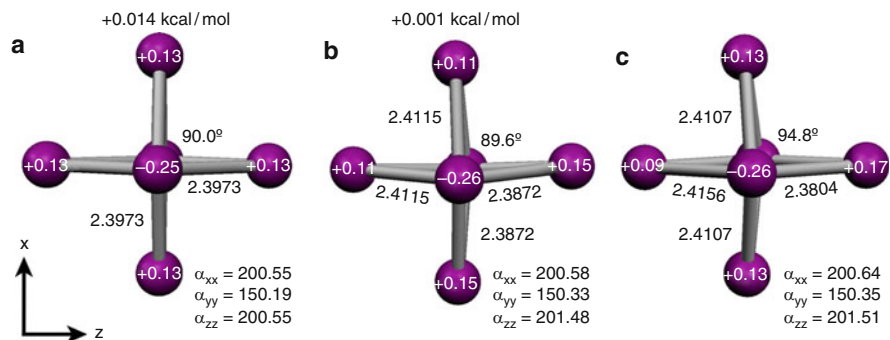

Fig. 4 CCSD(T)/6-311G(2d) optimized structures of the three isomers of Si₆ atomic charges after a natural bond orbital analysis at the CCD level and MP2/6-311G(2d) polarizabilities (au). All drawn bondlengths are in Å and dihedral angles in degrees. Structure (a) is of D_{4h} symmetry, structures (b) (face-capped) and (c) (edge-capped) of C_{2v} symmetry.

computed with the CCD density. It is obvious that although the two C_{2v} isomers keep the characteristics of their symmetry group as they were defined in the starting point geometries, they are almost identical with the distorted octahedron and their energy separations are extremely smaller than expected. The C_{2v} face-capped isomer and the distorted octahedron are lying only 0.001 and 0.014 kcal/mol higher in energy than the edge-capped isomer, respectively. Additionally, MP2 polarizability tensor values (au) at the CCSD(T) optimized geometries (also included in Fig. 2) show that the two C_{2v} structures are almost as polarizable as the D_{4h} structure in all three directions. Consequently, the two trigonal bipyramid structures could be viewed as slightly distorted tetragonal bipyramidal shapes belonging to the C_{2v} point group.

A careful literature search shows that these three structures compete for the ground state. More specifically, all electron and core potential geometry optimizations at Hartree–Fock (HF) level by Raghavachari and Rohlfing prefer an edge-capped trigonal bipyramidal shape of C_{2v} symmetry while MP2 geometry optimizations favor a distorted octahedron of D_{4h} symmetry. On the other hand, higher order correlated method based on Möller–Plesset perturbation theory with the standard 6-31G(d) basis set by Zdzetsis (2001) showed that the MP2 predicted structure of D_{4h} symmetry is unstable. Additionally, density functional theory (DFT) (Karamanis et al. 2007b) shows an fluctuating preference between the C_{2v} face-capped, C_{2v} edge-capped trigonal bipyramids. It is evident that there is an obvious disagreement between different theoretical approaches.

Let us now explore the most important experimental results concerning this problem. Raman experiments by Honea et al. (1993) of matrix isolated clusters, supported indirectly the MP2/6-31G(d) structure of D_{4h} symmetry. Their conclusions were based on two arguments: The first was the number of visible bands in both spectra which characterize species of D_{4h} symmetry, and second, the agreement between the experimental and scaled theoretical harmonic frequencies computed at the MP2/6-31G(d) level with the small 6-31G(d) standard basis

set. The strongest arguments used to reject the other two candidates were two: first, geometry optimizations at MP2 level starting from either face-capped or edge-capped trigonal bipyramidal shapes collapsed to the distorted octahedron of D_{4h} symmetry; second, the other two structures were predicted to have a larger number of active vibrational bands than observed in both experimental Raman and IR spectra. Obviously such a puzzling problem rarely has solely one answer. Indeed, the resolution to this puzzle is twofold. On one hand the source of the disagreement among the various methods used hides in the particular capabilities of each method in the treatment of the pseudo Jahn–Teller effect (PJTE) (Karamanis et al. 2007b). According to general Jahn–Teller theory the only source of instability in any molecular systems is the proper Jahn–Teller effect, for degenerated states (Renner Teller effect in linear systems), and pseudo-Jahn–Teller for non-degenerated ones. PJTE is a part of modern JT interaction theory (Bersuker 2001) and its importance in the formation of the equilibrium structures of clusters has been demonstrated by Garcia-Fernandez et al. (2006) and by Pushpa et al. (2004). In the Si_6 case, geometry optimizations with methods based on Møller–Plesset perturbation theory, which have been demonstrated not to treat the PJTE correctly, predict that the distorted octahedron of D_{4h} symmetry is the ground-state structure, while, methods which do provide PJTE treatment (DFT, HF) suggest that the distorted octahedron is unstable and undergoes PJTE distortions. On the other hand, the flat potential energy surface is connected with a fluxional behavior of Si_6 (Zdetsis 2007b) caused by the couplings between the electronic motion and soft nuclear vibrations due to the second-order Jahn–Teller effect under the influence of “electron deficiency” and the resulting charge smoothing process. The soft nuclear motion that is implied by the calculation is shown in Fig. 5. Of course, this kind of discrepancies in cluster structures can hardly be identified by experimental means since in such a flexible (or fluxional) system with low barriers, the consideration of separate “conformers” is probably not appropriate at all, and experimental spectroscopic properties are just an average of all structures. This has been highlighted in the recent work of Fielicke et al. (2009) who used tunable far-infrared-vacuum-ultraviolet two-color ionization to obtain vibrational spectra of neutral silicon clusters in the gas phase. Their results show clearly that it is almost impossible to distinguish the three different structures by means of vibrational spectroscopy.

Another example that demonstrates the complexity in determining the ground-state structures of larger clusters, and the importance of exploring the complete space when searching for atomic cluster is the case of Si_{36} (Bazterra et al. 2002; Sun et al. 2003). This cluster is one of the first large species that have been studied using first principles within the density functional framework (Sun et al. 2003). The structure that was initially proposed as the most stable was a stuffed fullerene-like configuration of near-spherical shape (Fig. 6 structure a). This structure seemed to confirm the up to that time experimental findings according to which a shape transition from prolate shapes to compact ones is occurring as the size of silicon clusters grows. Nonetheless, a subsequent study (Bazterra et al. 2002) based on a global approach using genetic algorithms, showed that a totally different structure lies lower in energy than the one previously adopted (Fig. 6 structure b). Once more,

Fig. 5 Schematic representation of the three competing structures of Si_6 based on the normal modes of the imaginary frequencies at CCSD(T) level of theory with the split valence Pople-like Basis set 6-311G(2d)

the structure of Si_{36} proposed by Bazterra et al. can be envisioned as an assembly of smaller, stable clusters.

III–V and II–VI Semiconductor Clusters

General Features

The III–V and II–VI semiconductor clusters are isoelectronic with the elements of the group 13 and 15. For instance, gallium arsenide clusters of the type Ga_nAs_n have the same number of electrons with Ge_{2n} clusters while the analogue Al_nP_n clusters are isoelectronic with the corresponding Si_{2n} cluster species. For clusters

Fig. 6 Two competing structures of Si₃₆

of these two semiconductor families with even number of electrons, the preferred spin multiplicity is the singlet, where all electrons are in pairs. Triplets and larger spin multiplicities are always higher in energy (Gutsev et al. 2010). In the case of nonstoichiometric GaAs clusters which are species with even number of electrons, thus, open shell systems the preferred spin multiplicity is the doublet (Karamanis et al. 2009).

The basic bonding pattern in the compound III–V and II–VI semiconductor clusters is the alternating arrangement of their atoms (Figs. 7 and 8). The alternating A–B type of bonding is a result of the polarity of these entities which is owed to the electronegativity difference between their atoms. As a result, the bonding in clusters formed by atoms with large electronegativity differences is expected to be more ionic than in clusters built from atoms characterized by smaller differences. For instance, the spectroscopic electronegativity differences $\Delta\chi_{spec}$ converted to Pauling scaling between the As and the atoms Ga and In are 0.455 and 0.555, respectively. Accordingly, the bonding in III–V compound clusters built from As and Ga is expected to be of less ionic (or of more covalent character) than clusters built from In and As. However, although the alternating A–B type of bonding is generally observed for this class of semiconductor clusters due to the polarity of their bonding, there are some cases in which homo-atomic bonds are detected between the electronegative atoms. For example the ground-state structures of Ga₄As₄ (Fig. 9) and Al₅P₅ (Fig. 8) are characterized by As–As and P–P bonds. On the other hand, this bonding feature is not favorable for II–VI semiconductors which also do not favor endohedral structures.

Gallium Arsenide Clusters

Combined experimental and computational studies have led to very interesting and important conclusions concerning microscopic feature of those systems such as their bonding and electronic structures. For instance, the revealed even/odd alternation in the photoionization cross section obtained with an ArF excimer laser (6.4 eV) indicated that clusters of any composition composed by even numbers of atoms (e.g., Ga₁As₅, Ga₂As₄, Ga₃As₃, Ga₄As₂, Ga₅As₁) have singlet ground states, whereas odd numbered clusters of any composition (e.g., Ga₁As₅, Ga₁As₄, Ga₂,

Fig. 7 Established ground-state structures of Ga_nAs_n clusters with $n = 2-5$ and 9. Such structure as for $n = 9$ is the most stable also in the cases of Al₉P₉ and Cd₉(S, Se, Te)₉

Fig. 8 Fullerene and bulk-like structures of large GaAs clusters (Gutsev et al. 2010)

As₃, Ga₃, As₂, Ga₄, As₁) have doublet ground states with an unpaired electron in a weakly bound HOMO. This sort of electronic structure clearly indicates that the structural and bonding features of the produced small GaAs clusters should be dramatically different from the tetrahedral sp³ hybridization of the bulk. Both of those indirect experimental conclusions—assumptions have been verified by all the later computational studies on those species which clearly showed that the singlet closed shell forms of the even-numbered GaAs clusters are the most stable than any other electronic configuration and their structures are completely different from the bulk (see: O'Brien et al. 1985; Lou et al. 1992; Karamanis et al. 2007a; Gutsev et al. 2008a, b).

Fig. 9 Structures of aluminum phosphide clusters

Let us now make a brief review of the most representative studies of those important species starting from GaAs clusters which are the most studied species from those belonging to the III–V semiconductor family. Current and future applications of those species, in their nano or bulk, forms are very promising and interestingly diverse, extending from fuel cells Schaller and Klimov (2006) and optoelectronic sensors (Chen et al. 2004) to spintronics (spin-based electronics), medical diagnostics, and quantum computing (see Calarco et al. 2003; Michalet et al. 2005; Wolf et al. 2001).

Pioneering studies performed by O'Brien et al. on supersonic cluster beams of GaAs clusters generated by laser vaporization of discs made from pure GaAs brought theory closer to the experimental reality by providing cluster species of sizes suitable for very precise theoretical computations. As a result, the structural and bonding features of small GaAs clusters have occupied the interest of the researchers in the early cluster computational studies. For instance, Graves and Scuseria (1991) studied the first members of these systems using the Hartree–Fock (HF) method. Liao and Balasubramanian (1992) by means of the multireference configuration interaction method with singles and doubles (MRCISD) made a reference estimation of the bond lengths and angles of $(\text{GaAs})_2$; Lou et al. (1992)

studied the structures and the bonding of small GaAs clusters up to 10 atoms while Andreoni within the Car–Parinello molecular dynamics approach studied the stoichiometric systems up to the ten-atomic Ga_5As_5 . Later, Song et al. (1994) applied a fourth-order many body perturbation theory to study species from 2 to 4 atoms (Ga_nAs_n with $n = 2\text{--}4$). The interest in studying those systems remains intense even the recent years and a respectable variety of different methods have been applied. For instance, Costales et al. (2002) applied a DFT-GGA method for the systems up to the trimer, Zhao et al. (2006), Zhao and Cao (2001), Zhao et al. (2000) used another level of DFT-GGA approach for $(\text{GaAs})_n$ ($n = 6\text{--}9$) while Karamanis et al. (2007b) revisited the previous reported results using second-order many body perturbation theory (MP2) up to clusters with 18 atoms. More recently, Gutsev et al. (2008a, b) extended the earlier studies and reported structures up to 32 atoms with the DFT framework. In addition, there are some reported attempts in studying nonstoichiometric species and the influence of the composition on their properties. One of the most representative works in this field is the investigation of structural and electronic properties of Ga_mAs_n clusters reported by Feng et al. (2007); Gutsev et al. (2010) studied the electronic and geometrical structures of neutral $(\text{GaAs})_n$ clusters using density functional theory with generalized gradient approximation and relativistic effective core potentials for $n = 17\text{--}40$, 48, and 54. Also, they examined the energetic preference of tubular and non-tubular cages with increasing n and found that tubular cages are generally lower in total energy than the other cage isomers. Along with the cage structures, they probed structures cut off from a zinc blende lattice, tailoring the surface atoms in such a way as to have no dangling bonds. They found that the lowest energy state of $(\text{GaAs})_{36}$ has a bulk-like structure with 12 tetrahedrally coordinated inner atoms (Fig. 7). Finally, Gutsev and coworkers (Karamanis et al. 2011) studied the structure and properties of prolate $(\text{GaAs})_n$ clusters up to 120 atoms corresponding to the (2, 2) and (3, 3) armchair and (6, 0) zigzag capped single-wall tubes within the generalized gradient approximation (DFT-GGA). It was found that the bandgap in all three series does not converge to the GaAs bulk value when the cluster length increases.

II–VI Semiconductor Clusters

The synthesis of ZnO, ZnS, ZnSe, CdS, CdSe, and CdTe nanostructures which shape an important category of optically active materials with strong size dependence of their exciton energy (see: Alivisatos 1996; Swaminathan et al. 2006; Murray et al. 2000; Peng et al. 1998, 2000) have inspired most of the studies on II–VI semiconductor clusters. The respective nanomaterials can be synthesized in a great variety of sizes and shapes (spheres, rods, tetrapods or branched and core-shell structures) and they have been used for a wide assortment of applications, including quantum light emitting diodes pigments, biological tagging, and solar cells (Gur et al. 2005). Particularly, for CdSe clusters, correlations between their structure and properties have been highlighted by Jose et al. (2006).

One of the most fascinating features of this class of semiconductor clusters is the size dependence of the HOMO–LUMO bandgap which is distinguishable in their luminescence properties. For instance, it has been shown that by adjusting the

particle size of colloidal CdSe–CdS core–shell nanoparticles the fluorescence can be tuned between blue and red. Motivated by those finding, in nanoparticles, Sanville et al. (2006) used direct laser ablation to produce ZnS, CdS, and CdSe clusters and found that clusters composed of 6 and 13 monomer units were ultrastable in all cases. Kasuya et al. (2004) by means of mass spectral analysis of CdSe nanoparticles found that $(\text{CdSe})_{33}$ and $(\text{CdSe})_{34}$ are so stable that they grow in preference to any other chemical compositions to produce macroscopic quantities with a simple solution method. First-principles calculations predict that these clusters are puckered $(\text{CdSe})_{28}$ -cages, with four- and six-membered rings based on the highly symmetric octahedral analogues of fullerenes, accommodating inside their framework either $(\text{CdSe})_5$ or $(\text{CdSe})_6$ to form a three-dimensional network with essentially heteropolar sp^3 -bonding.

Let us now see in brief the most cited computational studies for this very interesting class of cluster species. Behrman et al. (1994) have shown that ZnO clusters can form stable, fullerene-like structures while Hamad et al. (2005) provided evidences that ZnS clusters can form onion-like or alternatively “double bubble” structures. Matxain et al. (2000) studied systematically the structures of small ZnO clusters with up to nine atoms and demonstrated that three-dimensional structures may be envisioned as being built from Zn_2O_2 and Zn_3O_3 rings. Also, the same group (Matxain et al. 2001, 2003) have found that clusters built from ZnS, ZnSe, and CdO clusters can form stable one-dimensional ring structures (Fig. 10).

For species made from Cd and the chalcogenides S, Se Gurin(1998) studied small Cd_xS_y and Zn_xS_y ($x, y \leq 6$) clusters, Troparevsky and Chelikowsky(2001), Troparevsky et al. (2002) reported structures of $\text{Cdn}(\text{S, Se})_n$ with up to 8 atoms, Deglmann et al. (2002) used density functional theory potential surface investigations to study small CdS, and CdSe clusters, up to the heptamer while CdSe large clusters have been investigated further using large crystal structure sections

Fig. 10 Ring structure-types of MnX_n ($M = \text{Zn, Cd}$ and $X = \text{S, Se, Te}$) small clusters

Fig. 11 Displacement patterns and ground-state structure of Cd_5Te_5

with up to 198 atoms. Also, Matxain et al. (2004) and Jha et al. (2008) reported ring and spherical structures with up to 16 atoms while Sanville et al. (2006) obtained geometries and energies of the neutral and positively charged M_nX_n clusters up to $n = 16$ ($\text{M} = \text{Zn}, \text{Cd}$ and $\text{X} = \text{S}, \text{Se}$). Their results showed that one-dimensional structures are favored for some cluster sizes while three-dimensional structures may be envisioned as being built from $\text{Cd}_2(\text{S}, \text{Se})_2$ and $\text{Cd}_3(\text{S}, \text{Se})_3$ rings. At this point it is important to stress that contrary to what is reported in several studies about CdX clusters, the five-atom rings are not totally planar. Instead, they maintain distorted envelope structures of cm^{-1} symmetry due to the weakening of the steric repulsion between the metal atoms as the size of the ring increases. As, a result the planar structure is a transition point in each cluster's potential energy surface characterized by soft imaginary frequencies frequencies of a few cm^{-1} which indicate a very floppy system that is expected to exhibit fluxional behavior (Fig. 11).

Lastly, small Cd_nTe_n and Hg_nTe_n clusters have attracted the attention of several groups (see for instance Wang et al. 2004, 2008, 2009). Especially HgTe clusters are very interesting since this material is considered as a semimetal with a small negative bandgap around $=0.14$ eV at 300 K and a semimetal-to-semiconductor can be produced by size quantization making HgTe nano-objects promising candidates as optical amplifiers (Fig. 12).

Electric Polarizabilities and Hyperpolarizabilities of Clusters

Definitions and Theory

The electric dipole (hyper)polarizabilities describe the response of a molecular system to an external electric field. Briefly, the polarizabilities (or linear polarizabilities) are used to express the ability of the electronic density of a molecular or cluster entity to distort under the influence of weak external fields such as the field generated by a charge in close distance. The hyperpolarizabilities (or nonlinear polarizabilities) describe the same response to laser beams. Large polarizabilities imply easily polarized molecules, whereas, small polarizabilities correspond to molecules in which the electronic density is considerably insensitive

Fig. 12 Typical cage structures of Cd_nX_n ($X = S, Se, Te$) clusters

to electric field perturbations. Large hyperpolarizabilities involve molecules which can interact with intense electric fields in a “nonlinear” manner and the corresponding materials are known as nonlinear optical materials. The polarizabilities are associated with fundamental chemical concepts such as global softness (Vela and Gázquez 1990), basicity–acidity (Headley 1987), electronegativity (Nagle 1990), and stability (Hohm 2000), (Parr and Chattaraj 1991). On the other hand, the hyperpolarizabilities are closely related to the nonlinear optical behavior of materials in such processes as the second harmonic generation (SHG) (or frequency doubling), the third harmonic generation (THG), the sum frequency generation (SFG), the optical Kerr effect, and others which are expected to find application in a wide range of future technologies (see Bloembergen 1996 and references therein).

For clusters, polarizability is one of the few microscopic quantities that are available from experiment (Backer 1997) and is linked both to macroscopic and microscopic features of the matter such as the bulk dielectric constants and chemical bonding, respectively. Hence, this property can provide valuable information about crucial microscopic cluster features and the behavior of low dimensional systems that may be used in nanotechnology applications where nano-objects are subjected in small electric perturbations. On the other hand, given that the macroscopic nonlinear optical properties of materials are governed by the microscopic molecular hyperpolarizabilities, the study of those properties on clusters (Leitsmann et al. 2005) may offer a new ground in the search of new nonlinear optical materials with potential applications in future nanostructure technologies. The nonlinear behavior could be employed for amplification, modulation, and changing the frequency of

optical signals, similar to how nonlinearities of valves and transistors are used to govern the processes in traditional electric chips and circuits.

The microscopic (hyper)polarizabilities are studied by means of the so-called theory of the response functions which is of importance for all molecular and cluster entities (Roman et al. 2006). The most commonly used approach in studying the linear and nonlinear optical properties of clusters is the so-called semiclassical one. According to this approach a classical treatment is used to describe the response of the cluster to an external field (radiation) while the system itself is treated using the laws and techniques of quantum mechanics. This is done by using a Hamiltonian which combines both of the above treatments:

$$H = H^0 - \hat{\mu}_a F_a - \frac{1}{3} \hat{\Theta}_{\alpha\beta} F_{a\beta} - \frac{1}{15} \hat{\Omega}_{\alpha\beta\gamma} F_{\alpha\beta\gamma} - \frac{1}{105} \hat{\Theta}_{\alpha\beta\gamma\delta} F_{\alpha\beta\gamma\delta} + \dots \quad (1)$$

H^0 is the Hamiltonian which represents the free of the field system and the coefficients denoted with the Greek capital letters stand for the tensors of the dipole, quadrupole, octupole, and hexadecapole moments which are used to implement the field perturbation (F) into the new Hamiltonian. The expectation value after the implementation of this modified operator on the wavefunction is the perturbed energy of the system due to the influence of the field which in the case of a static field F can be written using a Taylor series expansion as

$$\begin{aligned} E^p = E^0 - \mu_a F_a - \frac{1}{3} \Theta_{\alpha\beta} F_{a\beta} - \frac{1}{15} \Omega_{\alpha\beta\gamma} F_{\alpha\beta\gamma} - \frac{1}{105} \Phi_{\alpha\beta\gamma\delta} F_{\alpha\beta\gamma\delta} + \dots & \frac{1}{2} a_{a\beta} F_a F_\beta \\ - \frac{1}{3} A_{\alpha,\beta\gamma} F_{a,\beta\gamma} - \frac{1}{6} C_{\alpha\beta,\gamma\delta} F_{a\beta,\gamma\delta} - \frac{1}{15} E_{\alpha,\beta\gamma\delta} F_{a,\beta\gamma\delta} + \dots & - \frac{1}{6} \beta_{\alpha\beta\gamma} F_a F_\beta F_\gamma \\ - \frac{1}{6} B_{\alpha\beta,\gamma\delta} F_a F_\beta F_{\gamma\delta} - \frac{1}{24} \gamma_{\alpha\beta\gamma\delta} F_a F_\beta F_\gamma F_\delta + \dots & \end{aligned} \quad (2)$$

E^p is the energy of the atomic or molecular system in the presence of the static electric field (F), E^0 is its energy in the absence of the field, μ_a corresponds to the permanent dipole moment of the system, $\alpha_{\alpha\beta}$ to the static dipole polarizability tensor and $\beta_{\alpha\beta\gamma}$, $\gamma_{\alpha\beta\gamma\delta}$ to the first and second dipole hyperpolarizabilities, respectively. Greek subscripts denote tensor components and can be equal to x, y, and z and each repeated subscript implies summation over x, y, and z as follows:

$$\frac{1}{2} a_{a\beta} F_a F_\beta = \frac{1}{2} \sum_{\alpha,\beta=x,y,z} a_{\alpha,\beta} F_\alpha F_\beta \quad (3)$$

In the case of a weak uniform (homogenous) field, the above expression becomes more simplified:

$$E^p = E^0 - \mu_\alpha F_\alpha - \frac{1}{2}\alpha_{\alpha\beta} F_\alpha F_\beta - \frac{1}{6}\beta_{\alpha\beta\gamma} F_\alpha F_\beta F_\gamma - \frac{1}{24}\gamma_{\alpha\beta\gamma\delta} F_\alpha F_\beta F_\gamma F_\delta + \dots \quad (4)$$

The properties that are routinely computed and discussed are the mean (or average) static dipole polarizability ($\bar{\alpha}$), the anisotropy ($\Delta\alpha$) of the polarizability tensor, the vector component of the first hyperpolarizability tensor in the direction of the ground state permanent dipole moment ($\beta_{||}$), the total first-order hyperpolarizability β_{tot} , and the scalar component of the second hyperpolarizability tensor $\bar{\gamma}$. Those quantities are related to the experiment and in terms of the Cartesian components are defined as

$$\bar{\alpha} = \frac{1}{3} (\alpha_{xx} + \alpha_{yy} + \alpha_{zz}) \quad (5)$$

$$\Delta\alpha = \left(\frac{1}{2}\right)^{1/2} \left[(\alpha_{xx} - \alpha_{yy})^2 + (\alpha_{xx} - \alpha_{zz})^2 + (\alpha_{zz} - \alpha_{yy})^2 + 6(\alpha_{xy}^2 + \alpha_{xz}^2 + \alpha_{zy}^2) \right]^{1/2} \quad (6)$$

$$\beta_{||} = \frac{3/5 (\beta_x \mu_x + \beta_y \mu_y + \beta_z \mu_z)}{|\mu|} \quad (7)$$

where $\beta_x = \beta_{xxx} + \beta_{xyy} + \beta_{xzz}$
 $\beta_y = \beta_{yxx} + \beta_{yyy} + \beta_{yzz}$
 $\beta_z = \beta_{zxx} + \beta_{zyy} + \beta_{zzz}$

$$\beta_{tot} = \left(\beta_x^2 + \beta_y^2 + \beta_z^2\right)^{1/2} \quad (8)$$

$$\bar{\gamma} = 1/5 (\gamma_{xxxx} + \gamma_{yyyy} + \gamma_{zzzz} + 2\gamma_{xxyy} + 2\gamma_{yyzz} + 2\gamma_{xxzz}) \quad (9)$$

Cluster (Hyper)Polarizabilities: Computational Approach

The majority of the undergoing theoretical (hyper)polarizability studies on semiconductor clusters rely on conventional ab-initio and density functional methods (DFT) As it is broadly accepted the ab initio approach leads to accurate (hyper)polarizability predictions and most of the reported attempts rely on a hierarchy of ab initio methods of increasing predictive capability such as the Hartree–Fock approximation (HF), the Møller–Plesset (MP) many body perturbation theory, and

also on the coupled cluster theory such as singles and doubles coupled-cluster (CCSD), and singles and doubles coupled-cluster with an estimate of connected triple excitations via a perturbational treatment (CCSD(T)) (further reading for those quantum chemical methods can be found in Szabo and Ostlun(1989), and Helgaker et al. (2000). Although this computational strategy is not always straightforward and in most of the cases computationally demanding, leads to reliable predictions of cluster (hyper)polarizabilities giving also crucial and detailed information about the electron correlation effects on the properties of interest. On the other hand the density functional approach (Koch and Holthausen 2000) is by far less computationally costly and allows the treatment of large systems; however, the reliability of DFT results rely heavily on the ability of the functional applied each time to describe the response of the system to an external electric field (see Karamanis et al. 2011 and references therein)

Looking carefully at Eq. 4 it becomes obvious that the computation of polarizabilities and hyperpolarizabilities in the case of static fields is in fact a mathematical derivation issue of the cluster energy with respect to the applied field. Consequently, the best accuracy can be achieved by finding and using the analytic expressions of the following relations:

$$-\left(\frac{\partial^2 E}{\partial F^2}\right) = \alpha_{\text{static}, F=0} \quad (10)$$

$$-\left(\frac{\partial^3 E}{\partial F^3}\right) = \beta_{\text{static}, F=0} \quad (11)$$

$$-\left(\frac{\partial^4 E}{\partial F^4}\right) = \gamma_{\text{static}, F=0} \quad (12)$$

In the case of the linear polarizability, the majority of the available quantum chemical software is able to evaluate analytically the first field derivative of the energy yielding in a straightforward manner all components of the polarizability tensor. In most of the cases the type of the calculation has to be indicated in the command line of the input file and the polarizabilities of the system are returned after the calculation ends. Unfortunately no analytical evaluation of the high-order field derivatives of the energy is available in all commercial packages for all methods. What is more, for methods of high accuracy such as the CC methods, this option is not available even for the linear polarizabilities. To overcome this problem several numerical procedures have been developed. The most applied numerical solution to this mathematical problem is the one provided by the so called finite field approach. According to this approach, first a field perturbation of different magnitudes and along different directions is added to the Hamiltonian. Then the wavefunction is “solved” for each perturbation and the energy of the perturbed system is obtained. Lastly the differentiation of energy of the system with respect to the applied field is performed numerically and the coefficients of the Eq. 4 are obtained (Figs. 13 and 14).

Fig. 13 Method performance on the computation of the mean polarizabilities of Ga_nAs_m clusters with $m + n = 6$ in comparison with the performance on the computation of the mean polarizabilities of Ga_6 and As_6 clusters

Fig. 14 Gallium arsenic clusters of various symmetries

Let us now demonstrate a simple example of the above process which will show us how the Eq. 4 can be utilized in order to calculate all the components of the polarizability tensor for a cluster without symmetry (C_1 point group). For

this symmetry group there are three independent components of the dipole moment (μ_x , μ_y and μ_z) and the six for the dipole polarizability: three principal (axial) components α_{xx} , α_{yy} , and α_{zz} and three transversal ones $\alpha_{xy} = \alpha_{yx}$, $\alpha_{zy} = \alpha_{yz}$, and $\alpha_{xz} = \alpha_{zx}$. The three principal ones can be computed by applying a weak electric field (of 0.0005–0.005 au strength) along each Cartesian direction, as follows:

$$\mu_a \approx \frac{E(-F_a) - E(F_a)}{2F_a} \quad (13)$$

$$\alpha_{aa} \approx \frac{2E(0) - E(-F_a) - E(F_a)}{F_a^2} \quad (14)$$

In the same manner, the transversal components can be obtained by applying fields in each $\alpha\beta$ plane along each $\pi/4$ diagonal between x , y , and z axis (this is done by applying fields of equal strengths ($F_\alpha = F_\beta$) at each xy , yz and xz planes). In this case one obtains the following equation:

$$\alpha_{a\beta} \approx \frac{E(F_a) + E(F_\beta) - E(F_a, F_\beta) - E(0)}{F_a F_\beta} \quad (15)$$

In the case of centrosymmetric structures, the computation of the dipole polarizability becomes more straightforward since the permanent dipole moment and the transversal components of dipole polarizability of those systems are vanishing. In this case we have

$$\alpha_{aa} \approx \frac{E(0) - E(F_a)}{F_a^2} \quad (16)$$

Provided that a suitable field is chosen, the above computational approach leads to quite reliable polarizability values. The advantage of this approach is that it gives the flexibility to the user to compute the polarizabilities of a given system using a variety of post Hartree–Fock methods only by computing the energies of the free clusters with and without the field.

The described approach can be applied to other response properties apart from the perturbed energies provided that the method used for their computations satisfy the Hellmann–Feynman theorem (Feynman 1939; Hellmann 1937) according to which the derivative of the total energy with respect to the field is equivalent with the expectation value of the derivative of the Hamiltonian with respect to the field. In this case, one can safely use the following relationships:

$$-\left(\frac{\partial^4 E}{\partial F^4}\right) = \left(\frac{\partial^3 \mu}{\partial F^3}\right) = \left(\frac{\partial^2 \alpha}{\partial F^2}\right) = \left(\frac{\partial \beta}{\partial F}\right) = \gamma_{static, F=0} \quad (17)$$

$$-\left(\frac{\partial^3 E}{\partial F^3}\right) = \left(\frac{\partial^2 \mu}{\partial F^2}\right) = \left(\frac{\partial \alpha}{\partial F}\right) = \beta_{\text{static}, F=0} \quad (18)$$

$$-\left(\frac{\partial^2 E}{\partial F^2}\right) = \left(\frac{\partial \mu}{\partial F}\right) = a_{\text{static}, F=0} \quad (19)$$

These relations can be used in all cases where the approximation to the true wavefunction is variationally optimized with respect to the Hamiltonian. This holds in the case of the SCF approach and all the DFT methods in which the energy of the systems is obtained through an iterative process. Contrary, in the case of the finite-order Møller–Pleset perturbation theory, (MP2, MP3, MP4), which is not variational, the relations Eqs. 17–19 do not hold and the calculations of the properties of interest should be extracted using only the energy derivatives.

Another key point in (hyper)polarizability calculations of clusters, as in all molecular systems, is the basis set choice. This has been clearly demonstrated in previous basis set studies on semiconductor clusters (see for instance Karamanis et al. 2006a, b, 2007a, 2008a; Maroulis et al. 2003, 2007; Papadopoulos et al. 2005, 2006). In general the polarizabilities are less sensitive to the basis set used than the first and second hyperpolarizabilities (see Fig. 15). Systematic basis set studies on cluster polarizabilities using basis sets of increasing size emphasize the importance of the diffuse s p Gaussian type functions (GTFs) and the effect of GTFs of polarization functions and functions of higher angular momentum such as ffunctions. Also it has been illustrated that as the cluster size increases the overall basis set effect on the mean polarizability gradually decreases (Karamanis et al. 2011).

Besides the methods and techniques described above there are also some theoretical methods that have been developed to treat the polarizabilities of clusters in a different manner from that described above. One of those schemes has been used by Jackson et al. (2007) and relies on partitioning the volume of a system into atomic volumes and using the charge distributions within the atomic volumes to define quantities such as atomic dipole moments and polarizabilities. In a second step each of the latter quantities are further decomposed into two components: the dipole (or local) and the charge-transfer component. The summation of each component over all of the atoms gives the local and charge-transfer parts of the total system dipole moment and polarizability. This treatment allows one to perform a site-specific analysis of dielectric properties of finite systems and, also, to obtain an insight about the contribution of each atom or of any desired building block of the cluster. The specific method has been applied to silicon clusters with up to 28 atoms which were subjected to a small external electric field. The obtained results showed clearly a strong dependence of the individual atomic polarizabilities, as well as their dipole and charge-transfer components, on the site location of the atom within the cluster. For atoms at peripheral sites those properties are substantially larger than for

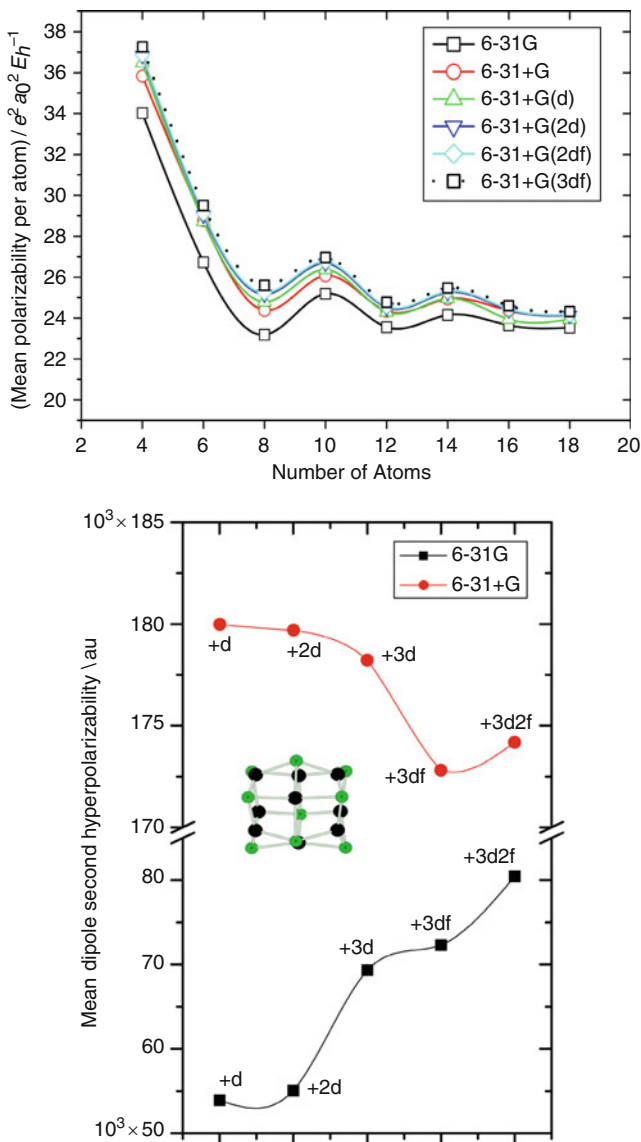

Fig. 15 Basis set effect, at the Hartree–Fock level of theory, on the mean dipole polarizabilities per atom of the ground state structures of aluminum phosphide cluster of the type Al_nP_n with $n = 2–9$, and basis set effect on the mean second hyperpolarizability of Al_9P_9

atoms at the interior sites, and the more peripheral atoms are characterized by larger polarizabilities. The same conclusion was drawn later by Krishtal et al. (2010).

An alternative methodology which uses electrostatic interaction schemes to predict the evolution of cluster polarizabilities has been developed and tested on

silicon clusters by Guillaume et al. (2009). This approach accepts the electrostatic nature of the dominant intra- and intermolecular interactions of a bulk material which is under the influence of external electric fields. This bottom-up approach allows the treatment very large clusters, enabling to reach the convergence of the response of the bulk material up to a point where adding new cluster units in the system would not change significantly the response of the material.

Further reading about the computational aspects of (hyper)polarizabilities on clusters and other molecules can be found in the following: Buckingham(1967), McLean and Yoshimine(1967), Marks and Ratner(1995), Kanis et al. (1994), Brédas et al. (1994), Bishop et al. (1997), Xenides(2006), Xenides and Maroulis(2000, 2006), Champagne et al. (2002), Maroulis(2008, 2004, 2003), Maroulis et al. (2007, 2003), Pouchan et al. (2004), Maroulis and Pouchan (2003), Papadopoulos and coworkers (Avramopoulos et al. 2004; Raptis et al. 1999; Reis et al. 2000); Karamanis and coworkers (Hohm et al. 2000; Kurtz et al. 1990; Luis et al. 2000).

Semiconductor Cluster (Hyper)polarizabilities: General Trends and Selected Studies

General Trends

Semiconductor cluster polarizabilities have been the subject of some very important experimental studies via beam-deflection techniques (Backer 1997; Schlecht et al. 1995; Schnell et al. 2003; Schäfer et al. 1996; Kim et al. 2005) while they have been extensively studied using quantum chemical and density functional theory. In this research realm, one of the areas intensively discussed is the evolution of the cluster's polarizabilities per atom (PPA) with the cluster size. The PPA is obtained by dividing the mean polarizability of a given system by the number of its atoms. Such property offers a straightforward tool to compare the microscopic polarizability of a given cluster with the polarizability of the bulk (see Fig. 16) as the latter is obtained by the "hard sphere" model with the bulk dielectric constant via the Clausius–Mossotti relation :

$$\bar{\alpha} = \frac{3}{4\pi} \left(\frac{\varepsilon - 1}{\varepsilon + 2} \right) v_{at} \quad (20)$$

where v_{at} is the volume per atom in the unit cell of the bulk and ε is the static dielectric constant of the bulk.

Most of the obtained knowledge on the polarizabilities of semiconductor clusters has emerged as the result of extensive studies of such species as silicon and gallium arsenide which have served well as models for the better understanding of the (hyper)polarizability evolution of semiconductor clusters. Also other kinds of clusters built from different elements such as aluminum phosphide, cadmium sulphide, selenide, and telluride have attracted the attention of several researchers and the corresponding studies have led to interesting conclusions. Those studies suggest that cluster polarizabilities are very different from the known polarizabilities

Fig. 16 Comparison between computed polarizabilities of small GaAs clusters and the polarizability of the bulk. The polarizabilities have been computed at the MP2 level of theory

of bulk materials. In general the PPAs of small semiconductor cluster are larger than the polarizability of the bulk (Fig. 16). For instance, in all studied cases the theoretical predicted polarizabilities of small semiconductor clusters (e.g., Si, AlP, CdSe, CdS, GaAs) are found higher than the bulk polarizability and converge to the bulk limit from above. Also, the polarizability dependence of the cluster size is strong and as a rule cluster species exhibit strong and nonmonotonic size variations. In addition there is a strong dependence of the polarizability on the shape of the cluster. It has been shown that for species which maintain closed cage-like structures (i.e., close to the spherical shape), the polarizability per atom (PPA) decreases with clusters size (Fig. 15) (see for instance (Jackson et al. 2004, 2005; Karamanis et al. 2008b, c; Zhang et al. 2004). On the other hand the per atom polarizabilities of clusters which maintain prolate structures (e.g., tubular clusters) increase as a function of the cluster size (Jackson et al. 2005; Karamanis et al. 2008b, 2011). Another important issue is the dependence of the electric polarizabilities

on the cluster bonding. It has been shown that semiconductor clusters which favor structures characterized by covalent bonds are expected to exhibit larger polarizabilities than clusters which tend to form ionic structures. This dependence is significantly more intense in the case of the second hyperpolarizability. The general rule that holds in this case is that semiconductor clusters which are characterized by significant electron transfer from the electropositive atoms (ionic bonding) to the electronegative ones are less hyperpolarizable than species in which the electron transfer is smaller (covalent bonding) (Karamanis et al. 2008d; Krishtal et al. 2010). This variation explains the nonmonotonic size variations of the mean PPAs of small binary semiconductor clusters. Also, both polarizabilities and hyperpolarizabilities of clusters have been proven very sensitive to the cluster elemental constitution. For instance, InAs clusters are more (hyper)polarizable than GaAs, AlP, AlAs, InP, and GaP clusters while CdTe clusters, are far more (hyper)polarizable than CdS and CdSe clusters (Karamanis and Pouchan 2009). What is more, the strong correlation between the polarizabilities of semiconductor clusters and their composition is also significant. In the case of GaAs clusters it has been demonstrated both experimentally and theoretically that Ga-rich gallium arsenide clusters are more polarizable than As-rich clusters due to the larger polarizability of Ga (Fig. 17) (Karamanis et al. 2009). Lastly, it was shown that the cluster shape dominates the magnitude of the second hyperpolarizabilities of large clusters (Karamanis and Pouchan 2011).

Selected Studies

Polarizabilities

Let us now briefly explore some of the most representative studies in the subject of the polarizabilities of Si and GaAs clusters that have attracted considerable attention. One of the first studies has been reported by Vasiliev et al. (1997). In

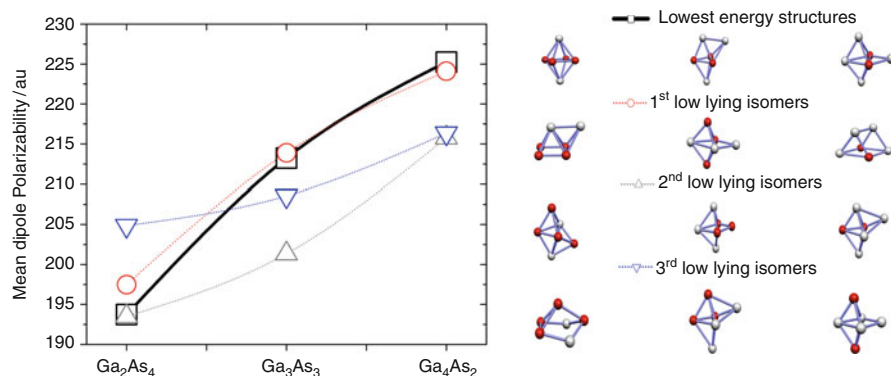

Fig. 17 Composition-dependent polarizabilities of small Ga_nAs_m with clusters $n + m = 6$ computed at the B2PLYP/aug-cc-pVDZ-PP level

that work the authors computed the polarizabilities of small Si_n , Ge_n ($n \leq 10$) and Ga_nAs_m ($n + m \leq 8$) clusters and they found that the polarizabilities of all systems are higher than the values estimated from the “hard sphere” model using Eq. 20. Also they evidenced that the computed per atom polarizabilities tend to decrease with increasing the cluster size and they related this trend to the one observed in the case of metallic clusters, for which the polarizability bulk limit is approached from above. This observation was considered as an evidence for the “metallic-like” nature of small semiconductor clusters. Two similar studies about silicon clusters up to 20 atoms by Jackson et al. (1999) and up to 28 atoms by Deng et al. (2000) confirmed the reported trends regarding to the PPA evolution with size and the metallic nature of silicon semiconductor clusters. The same conclusion has been reported also in later studies by Bazterra et al. (2002) and Maroulis et al. (2003). In the case of GaAs clusters the early results reported by Vasiliev et al. (1997) have been confirmed by Torrens(2002) with an interacting-induced-dipoles polarization model and have been extended up to 18 atoms by Karamanis et al. (2007a, 2008). Furthermore, the polarizability ordering in the case of the III–V dimers has been established: $\text{In}_2\text{As}_2 > \text{In}_2\text{P}_2 > \text{Al}_2\text{As}_2 > \text{Ga}_2\text{As}_2 > \text{Al}_2\text{P}_2 > \text{Ga}_2\text{P}_2$ (Karamanis et al. 2008a).

Hyperpolarizabilities

In the domain of the nonlinear polarizabilities of semiconductor clusters (i.e., the second dipole hyperpolarizability and third polarizability) the reported studies are fewer than in the case of the linear polarizabilities. However, this field is very promising due to the properties that the compound semiconductors possess. With respect to their interaction with intense electric fields compound semiconductors are characterized by high sensitivity, high speed, and they may operate at a wide variety of wavelengths in the near-infrared range. In particular the compound III–V and II–VI semiconductors such as GaAs, InP, and CdS possess the two properties needed for the existence of the photorefractive effect, the photoconductivity, and the electro-optic effect. These properties are very crucial in electro-optical technology; and alloptical information technology, thus the study of clusters and nano-objects of those materials are essential, first for better understanding the properties of the bulk material and second for the research of new nano-materials with improved nonlinear optical properties (Bechstedt et al. 2007; Adolph and Bechstedt 1998; Hughes and Sipe 1996; Bergfeld and Daum 2003; Bloembergen 1996; Butcher and Cotter 1990; Powell et al. 2002; Vijayalakshmi et al. 2002).

At the microscopic level, one of the first studies into this matter was reported by Korambath and Karna(2000) who studied the first dipole hyperpolarizabilities of GaN, GaP, and GaAs clusters within the ab initio time-dependent Hartree–Fock method using an even-tempered Gaussian basis set and demonstrated that the magnitudes of the calculated (hyper)polarizabilities depend on the size of the cluster. Lan et al. (2003) studied the hyperpolarizabilities of Ga_3As_3 , Ga_3Sb_3 , In_3P_3 , and In_3Sb_3 clusters using a similar approach based on the time-dependent Hartree–Fock (TDHF) formalism combined with sum-over-states (SOS) method and found that the charge transferred from the π - bonding to π - antibonding orbitals between III and V group atoms under the influence of an electric field make a significant

contribution to the second-order polarizability. The first ab initio attempt in treating the hyperpolarizabilities of semiconductor using methods of high sophistication such as CC and MP has been reported by Maroulis and Pouchan who explored the second hyperpolarizabilities of cadmium sulfide clusters. Their results showed that the mean second hyperpolarizability per atom of those species decreases rapidly with the cluster size. A second attempt on systems of increasing size has been reported by Lan et al. (2006). These authors studied several small GaAs clusters up to 10 atoms within the time-dependent density functional theory and reported that the dynamic behavior of β and γ show that the small Ga_nAs_m clusters are expected as good candidates for nonlinear optical properties due to the avoidance of linear resonance photoabsorption. An application of the time-dependent DFT (TD-DFT) theory on the hyperpolarizabilities of clusters can be found in the work of Sen and Chakrabarti(2006) who studied the second hyperpolarizabilities of CdSe clusters. In their conclusions, it is highlighted that these clusters have a high nonlinear optical activity. Karamanis et al. (2007a) reported ab initio values at the HF, MP2 level of theory for stoichiometric GaAs clusters up to 18 atoms and showed that as the size of the cluster increases the per atom mean second hyperpolarizability decreases fast and converges to a specific value. Finally, the significance of the bonding on the nonlinear polarizabilities of small clusters has been demonstrated by Karamanis and Leszczynski(2008) in a hyperpolarizability study of stoichiometric aluminum phosphide clusters up to 18 atoms. The conclusions of investigations on aluminum phosphide clusters have been extended later to several types of III–V semiconductor in a comparative hyperpolarizability study by Karamanis et al. (2008a). In that study the relative mean static dipole hyperpolarizabilities of the X_2Y_2 type ($\text{X} = \text{Al}, \text{Ga}, \text{In}$ and $\text{Y} = \text{P}, \text{As}$) clusters have been established in several levels of theory, $\bar{\gamma} : \text{In}_2\text{As}_2 > \text{In}_2\text{P}_2 \cong \text{Al}_2\text{As}_2 > \text{Al}_2\text{P}_2 \cong \text{Ga}_2\text{As}_2 > \text{Ga}_2\text{P}_2$. This classification follows the size ordering of the electropositive atoms. Ga is slightly smaller than Al, while In is far more larger than both Ga and Al. The atomic radius of $\text{Ga}(3d^{10}4s^{24}p^1)$ is slightly smaller than the $\text{Al}(3s^23p^1)$ atomic radius, despite its larger number of electrons. This is caused by the insufficient shielding that the $3d^{10}$ electrons provide to the $4s^24p^1$ valence electrons of Ga. As a result, the valence electrons of Ga experience a larger attraction from the nuclear charge than the electrons of Al. Considering that the (hyper)polarizabilities are valence-related properties, the described peculiarity of the Ga atoms can explain qualitatively the smaller hyperpolarizabilities of both Ga_2P_2 and Ga_2As_2 compared to Al_2P_2 and Al_2As_2 clusters.

The dynamic-second order hyperpolarizabilities of Si_3 and Si_4 have been explored by Lan et al. (2008) using the coupled cluster cubic response theory. These authors reported that Si_3 and Si_4 clusters exhibit wide non-resonant optical region. The same approach has been used by Lan and Feng (2009) in the study of the nonlinear response of another class of semiconductor clusters, namely, the SiC_n and Si_nC . In this work it was demonstrated that the size dependence of the first-order hyperpolarizabilities of the SiC_n clusters, which have approximate Si-terminated linear chain geometry, is similar to that observed in π -conjugated organic molecules. Lastly concerning the (hyper)polarizabilities of other II–VI clusters apart

Fig. 18 Comparisons between the second-order mean hyperpolarizabilities (divided by 10^3) of CdS, CdSe, and CdTe clusters computed at the HF/aug-cc-pVDZ-PP level of theory

from CdS there two reported studies on their hyperpolarizabilities. The first (Li et al. 2008) deals with the ground states and low-lying isomers of stoichiometric $(\text{ZnO})_n$ clusters with $n = 2-12$ using finite field approach within density functional theory framework and the second (Karamanis et al. 2009) involves a comparative study of CdS, CdSe, CdTe with respect to their second hyperpolarizabilities (Fig. 18). Both of those studies demonstrate the structural and size dependence of those properties while the second one reveal that CdTe clusters are far more (hyper)polarizable than CdS and CdSe, verifying previous experimental work reported by Wu et al. (2003) which provided evidences that that CdTe nanoparticles exhibit stronger nonlinear optical properties than nanoparticles built from CdS and CdSe.

Concluding Remarks

In this brief review, we made an attempt to present some of the most illustrative computational investigations of the structural properties of semiconductor clusters. We have chosen to present studies that had as subject cluster species which have attracted most of the attention of the researchers the last two decades and have served as models in the better understanding of cluster properties. Therefore it must be emphasized that although this chapter does not cover the vast number of studies

that have been reported during the previous years, it can be utilized as starting material for those who are interested in contributing in this field, or simply, as a guide for those who wish to get some general information about the structural and bonding features of semiconductor clusters. Finally, in this chapter we have revisited most of the recent studies that focus on the electric properties of those species which also demonstrate in a comprehensive manner that clusters and electric properties such as the dipole polarizabilities and especially hyperpolarizabilities are strongly related.

Abstract

This chapter discusses the structures, energetics, and vibrational spectra of the first few ($n \leq 24$) water clusters obtained from high-level electronic structure calculations. The results are discussed in the perspective of being used to parameterize/assess the accuracy of classical and quantum force fields for water. To this end, a general introduction with the classification of those force fields is presented. Several low-lying families of minima for the medium cluster sizes

are considered. The transition from the “all surface” to the “fully coordinated” cluster structures occurring at $n = 17$ and its spectroscopic signature is presented. The various families of minima for $n = 20$ are discussed together with the low-energy networks of the pentagonal dodecahedron $(\text{H}_2\text{O})_{20}$ water cage. Finally, the low-energy networks of the tetrakaidecahedron (T-cage) $(\text{H}_2\text{O})_{24}$ cluster are shown and their significance in the construction of periodic lattices of structure I (sI) of the hydrate lattices is discussed.

Introduction

Water's function as a universal solvent and its role in mediating several biological functions that are responsible for sustaining life has created tremendous interest in the understanding of its structure at the molecular level (Ball 2008). Due to the size of the simulation cells and the sampling time needed to compute many macroscopic properties, most of the initial simulations are performed using a classical force field, whereas several processes that involve chemistry are subsequently probed with electronic structure based methods. A significant effort has therefore been devoted toward the development of classical force fields for water (Robinson et al. 1996). Clusters of water molecules are useful in probing the intermolecular interactions at the microscopic level as well as providing information about the subtle energy differences that are associated with different bonding arrangements within a hydrogen-bonded network. They moreover render a quantitative picture of the nature and magnitude of the various components of the intermolecular interactions such as exchange, dispersion, induction, etc. They can finally serve as a vehicle for the study of the convergence of properties with increasing size.

Over the last decade, there have been tremendous advances in the experimental (Cruzan et al. 1996a, b, 1997; Liu et al. 1994, 1996a, b, 1997a, b; Pugliano and Saykally 1992; Suzuki and Blake 1994; Viant et al. 1997) and theoretical (Xantheas 1994, 1996a; Xantheas and Dunning 1993a, b) studies of the structural, spectral, and energetic properties of water clusters, as well as refinements of the macroscopic structural experimental data for liquid water (Hura et al. 2000; Soper 2000; Sorenson et al. 2000). These developments have created a unique opportunity for incorporating molecular level information into classical force fields for water as well as using the available database of cluster energetics for the assessment of their accuracy. The process of developing interaction potentials is by no means straightforward, and the different approaches that are used to model the various components of the underlying physical interactions have their own advantages and shortcomings. Some of the outstanding issues that are associated with the development of models based on molecular level information are the shortage or scarcity of experimental data for clusters. To this end, an alternative approach based on the use of ab initio results for water clusters can be put into practice.

Assuming that the route of parameterization of an interaction potential for water from the cluster results is adopted, the question naturally arises of the level of accuracy that needs to be attained so the models can produce meaningful and

accurate results for the macroscopic properties of extended systems such as the bulk liquid and ice. In the subsequent sections, we will present the results of ab-initio electronic structure calculations for cluster sizes up to 24 water molecules and we will address some important features of their structural and spectral properties. We will finally present results on the first few water cages that are the constituents of the three-dimensional hydrate networks.

Models of Intermolecular Interactions

Intermolecular interactions Force fields describing intermolecular interactions can be in general classified into two categories: (1) classical and (2) quantum models, the characteristics of which are outlined in Fig. 1. Classical potentials consist of force fields that employ an analytic expression, in conjunction with several adjustable parameters, for the potential energy surface (PES) as a function of the coordinates of the atoms in the system. In contrast, for quantum models, the PES is computed by considering both the position of the nuclei and the distribution of the electrons of the system, and it is obtained by solving Schrödinger's equation.

The choice of the adjustable parameters used in conjunction with classical potentials can result to either effective potentials that implicitly include the nuclear quantization and can therefore be used in conjunction with classical simulations (albeit only for the conditions they were parameterized for) or transferable ones that attempt to best approximate the Born–Oppenheimer PES and should be used in nuclear quantum statistical simulations. Representative examples of effective force fields for water consist of TIP4P (Jorgensen et al. 1983), SPC/E (Berendsen et al. 1987) (pair-wise additive), and Dang-Chang (DC) (Dang and Chang 1997) (polarizable, many-body). The “polarizable” potentials contain – in addition to the pairwise additive term – a classical induction (polarization) term that explicitly

	Quantum		Classical			
Wave function	$\psi(\tilde{r}; \tilde{R})$		No electronic degrees of freedom			
Energy	$E = \langle \psi \hat{H} \psi \rangle$		$E = E(\tilde{R}; a_i)$			
Potential energy surface	Born-Oppenheimer		“Effective”		Born-Oppenheimer	
Zero-point energy	Explicitly included		Implicitly included		Explicitly included	
Simulation methodology	Classical	Quantum	Classical	Quantum	Classical	Quantum
Transferability across different environments	NO	YES	NO [§]	NO [¶]	NO	YES

[§] appropriate only for the environment that the ZPE has been effectively included

[¶] double-counting

Fig. 1 Characteristics of classical and quantum potential models

(albeit approximately) accounts for many-body effects to infinite order. These effective potentials are fitted to reproduce bulk-phase experimental data (i.e., the enthalpy at $T = 298$ K and the radial distribution functions at ambient conditions) in classical molecular dynamics simulations of liquid water. Despite their simplicity, these models describe some experimental properties of liquid water at ambient conditions quite well but usually fail for conditions and environments that are not parameterized for, and so they have limited predictive power. On the other hand, force fields such as the Effective Fragment Potential (EFP) (Adamovic et al. 2003; Day et al. 1996; Gordon et al. 2001; Jensen and Gordon 1998; Netzloff and Gordon 2004), the SAPT-5 (Bukowski et al. 2007; Szalewicz et al. 2009), and the family of Thole-type models (TTM (Burnham et al. 1999), TTM-2F (Burnham and Xantheas 2002a), TTM2.1-F (Fanourgakis and Xantheas 2006), TTM3-F (Fanourgakis and Xantheas 2008), and TTM4-F (Burnham et al. 2008)) are examples of transferable potentials that are fitted to high-level first principles electronic structure results of the PESs of small water clusters, usually the water dimer and trimer, and should be used in conjunction with nuclear quantum statistical simulations.

The availability of energetic information for water clusters (such as binding energies) is of paramount importance in both fitting transferable potentials as well as assessing their performance. Currently, binding energies of small water clusters, even the water dimer, are not available experimentally but can only be obtained from high-level electronic structure calculations.

Quantum Models from Electronic Structure Calculations

Figure 2 shows the spectrum of methods that are used to describe intermolecular interactions ranging from the classical descriptions, such as Molecular Mechanics (MM), up to the highly correlated ones, including Coupled Cluster with Single,

Fig. 2 Models of intermolecular interactions: from classical to highly correlated

Double, and perturbative estimates of Triple excitations [CCSD(T)] and Multi Reference Singles and Doubles Configuration Interaction (MRSDCI). Methods on the left part of the spectrum have the advantage of low formal scaling and as such allow for the treatment of large systems, but they are also associated with large inaccuracies. In contrast, methods to the right side of Fig. 2 have the disadvantage of high formal scaling (as much as $\sim O(N^9)$, where N is the system size) and are more appropriate for smaller systems for which high accuracy is achieved. Currently, the state of the art consists of the application of highly correlated methods such as CCSD(T) to a cluster of about 24 water molecules ($\sim 1,100$ basis functions and 270 electrons), a calculation that can sustain a performance of 1.4 Petaflop/s (Apra et al. 2009).

Electron Correlation and Orbital Basis Set

The cluster energies are obtained from the solution of the nonrelativistic Schrödinger equation for each system. The expansion of the trial many-electron wave function delineates the level of theory (description of electron correlation), whereas the description of the constituent orbitals is associated with the choice of the orbital basis set. A recent review (Dunning 2000) outlines a path, which is based on hierarchical approaches in this double expansion in order to ensure convergence of both the correlation and basis set problems. It also describes the application of these hierarchical approaches to various chemical systems that are associated with very diverse bonding characteristics, such as covalent bonds, hydrogen bonds and weakly bound clusters.

As regards the description of the electron correlation problem it has been recognized that the coupled cluster method (Bartlett and Purvis 1978; Cizek 1966, 1969; Coester 1958; Coester and Kümmel 1960; Kucharski and Bartlett 1992; Purvis and Bartlett 1982), which includes all possible single, double, triple, etc. excitations from a reference wave function, represents a viable route toward obtaining accurate energetics for hydrogen-bonded dimers (Halkier et al. 1999; Peterson and Dunning 1995). Among its variations, the CCSD(T) approximation (Raghavachari et al. 1989, 1990), which includes the effects of triple excitations perturbationally, represents an excellent compromise between accuracy and computational efficiency and has been recently been coined as the “gold standard of quantum chemistry.” The CCSD(T) approximation scales as N^6 for the iterative solution of the CCSD part, plus an additional single N^7 step for the perturbative estimate of the triple excitations. This represents a substantial additional expense over the widely used second-order perturbation level (Møller and Plesset 1934) of theory (MP2) which formally scales as N^5 .

For the basis set expansion, the correlation-consistent (cc-pV nZ) orbital basis sets of Dunning and coworkers (Dunning 1989; Dunning et al. 1998; Kendall et al. 1992), ranging from double to quintuple zeta quality ($n = D, T, Q, 5$), offer a systematic path in approaching the complete basis set (CBS) limit. These sets were constructed by grouping together all basis functions that contribute roughly equal amounts to the correlation energy of the atomic ground states. In this approach, functions are added to the basis sets in shells. The sets approach the complete basis

set (CBS) limit, for each succeeding set in the series provides an evermore accurate description of both the atomic radial and angular spaces. The extension of those sets to include additional diffuse functions for each angular momentum function present in the standard basis yields the augmented correlation consistent (aug-cc-pVnZ) sets. The exponents of those additional diffuse functions were optimized for the corresponding negative ions.

The Basis Set Superposition Error Correction

The use of a finite basis set in electronic structure calculations as been known to overestimate the interaction energy (Clementi 1967) (ΔE) of a weakly bound dimer complex, a quantity defined as

$$\Delta E = E_{AB}^{\alpha\cup\beta}(AB) - E_A^\alpha(A) - E_B^\beta(B), \quad (1)$$

where superscripts indicate the basis set; subscripts, the molecular system; and parentheses, the geometries for which the energies are obtained. In this notation, the term $E_{AB}^{\alpha\cup\beta}(AB)$ is the energy of the dimer (AB) at its equilibrium geometry AB with the basis set of the two fragments aUb. The overestimation comes from the fact that the basis functions that are centered on the one fragment help lower the energy of the other fragment and vice versa, a situation first termed “Basis Set Superposition Error” (BSSE) by Liu and McLean (1973). Boys and Bernardi (1970) originally proposed two approaches to circumvent this problem, introducing corrections via the “point counterpoise” (pCP) and the “function counterpoise” (fCP) methods, the latter being nowadays almost exclusively adopted in electronic structure calculations of intermolecular interaction energies (Chalasinski and Szczesniak 1994; van Duijneveldt et al. 1994).

For a dimer of two interacting moieties (extension to larger clusters is straightforward), the fCP correction is:

$$\Delta E \text{ (fCP)} = E_{AB}^{\alpha\cup\beta}(AB) - E_{AB}^{\alpha\cup\beta}(A) - E_{AB}^{\alpha\cup\beta}(B). \quad (2)$$

Equations 1 and 2 will not converge to the same result as the basis set increases toward the Complete Basis Set (CBS) limit since the reference energies of fragments A and B are computed at different geometries, viz. the dimer vs. the isolated fragments. Alternatively, if the BSSE correction is estimated via the equation (Xantheas 1996b)

$$\Delta E \text{ (BSSE)} = E_{AB}^{\alpha\cup\beta}(AB) - E_{AB}^{\alpha\cup\beta}(A) - E_{AB}^{\alpha\cup\beta}(B) + E_{\text{rel}}^\alpha(A) + E_{\text{rel}}^\beta(B) \quad (3)$$

where

$$E_{\text{rel}}^\alpha(A) = E_{AB}^\alpha(A) - E_A^\alpha(A) \quad (4)$$

$$E_{\text{rel}}^\beta(B) = E_{AB}^\beta(B) - E_B^\beta(B) \quad (5)$$

represent the energy penalty for distorting the fragments from their isolated geometries to the ones that adopt due to their interaction in the complex, then it is readily seen that after substitution of Eqs. 4 and 5 into Eq. 3 and collecting terms, the BSSE correction (Eq. 3) can be cast as:

$$\Delta E (\text{BSSE}) = \Delta E - \left\{ E_{\text{AB}}^{\alpha\cup\beta} (\text{A}) - E_{\text{AB}}^{\alpha} (\text{A}) \right\} - \left\{ E_{\text{AB}}^{\alpha\cup\beta} (\text{B}) - E_{\text{AB}}^{\beta} (\text{B}) \right\}. \quad (6)$$

Equations 1 and 6 do converge to the same result at the CBS limit since the terms in the brackets in Eq. 6 will numerically approach zero as the basis sets α and β tend toward CBS, viz.

$$\lim_{\alpha, \beta \rightarrow \text{CBS}} \Delta E (\text{BSSE}) = \lim_{\alpha, \beta \rightarrow \text{CBS}} \Delta E. \quad (7)$$

The importance of this correction, although previously recognized (Emsley et al. 1978; Smit et al. 1978; van Lenthe et al. 1987), has rarely been applied (Eggenberger et al. 1991; Kendall et al. 1989; Leclercq et al. 1983; Mayer and Surjan 1992; van Duijneveldt-van de Rijdt and van Duijneveldt 1992) until the problems arising from omitting it, especially for (1) strongly bound hydrogen-bonded complexes exhibiting large fragment relaxations and (2) calculations employing large basis sets, were noted. It should be emphasized that for some strongly hydrogen-bonded dimers such as $\text{F}^-(\text{H}_2\text{O})$ and $\text{OH}^-(\text{H}_2\text{O})$, the energy penalty term is quite large (≥ 5 kcal/mol) and its omission will lead to erroneous results as regards the magnitude and convergence of the uncorrected and BSSE-corrected values of the interaction energy as the basis set increases. This large energy penalty is caused by the strong interaction between the ion and water, a fact that results in a large elongation of the hydrogen-bonded OH bond causing the water molecule to adopt a configuration that is far from its isolated equilibrium geometry. A further consequence of this effect is the large red shift in the corresponding OH stretching vibration, a fact that has been experimentally verified.

Extrapolation to the Complete Basis Set Limit

Application of the family of these sets to a variety of chemical systems (see Reference Dunning (2000) and references therein) – ranging from the very weakly bound (by around 0.01 kcal/mol) rare gas diatomics, to intermediate strength hydrogen-bonded neutral (2–5 kcal/mol), singly charged ion-water (10–30 kcal/mol) clusters, and single-bond diatomics (50–100 kcal/mol), to very strong (>200 kcal/mol) multiply charged metal–water clusters and multiple bond diatomics – has permitted a heuristic extrapolation of the computed electronic energies and energy differences to the CBS limit. Among the various approaches that have been proposed (Bunge 1970; Fast et al. 1999; Feller 1992; Halkier et al. 1999; Klopper 1995; Martin 1996; Termath et al. 1991; Wilson and Dunning 1997; Xantheas and Dunning 1993c) in order to arrive at the CBS limit, we have relied on the following two:

1. A polynomial with inverse powers of 4 and 5 (4–5 polynomial):

$$\Delta E = \Delta E_{\text{CBS}} + \gamma/(\ell_{\text{max}} + 1)^4 + (\ell_{\text{max}} + 1)^5 \quad (8)$$

where ℓ_{max} is the value of the highest angular momentum function in the basis set and

- An exponential dependence on the cardinal number of the basis set n ($n = 2, 3, 4, 5$ for the sets of double through quintuple zeta quality, respectively):

$$\Delta E = \Delta E_{\text{CBS}} + \alpha \bullet \exp(-\beta \bullet n). \quad (9)$$

It should be noted that in nearly every case, this “extrapolation” procedure only accounts for a very small change when compared to the “best” computed quantity with the largest basis set [usually the (aug)-cc-pV5Z or, computer resources permitting, the (aug)-cc-pV6Z]. This result suggests that effective convergence of the respective properties (such as structure and relative energies) has already been achieved with the largest basis sets of this family.

Global Minimum Structures of then = 2–10 Water Clusters

Figure 3 shows the global minimum structures of the water clusters $n = 2-5$ and Fig. 4 shows the variation of their uncorrected and BSSE-corrected binding energies from MP2 calculations with the correlation-consistent basis sets (Xantheas et al. 2002). The CBS limit of -15.8 kcal/mol for the cyclic trimer was estimated from MP2 binding energies with basis sets up to aug-cc-pV5Z.

It is worth noting that extrapolating the uncorrected and BSSE-corrected binding energies using Eqs. 8 and 9 yields CBS limits that are within 0.01 kcal/mol from each other, while the extrapolation process itself results in minimal (<0.2 kcal/mol) changes with respect to the best computed numbers with the largest aug-cc-pV5Z set. For the cyclic water tetramer, the CBS limit estimated using the 4–5 polynomial (see Eq. 8) is -27.6 kcal/mol. The extrapolation of the uncorrected and BSSE-

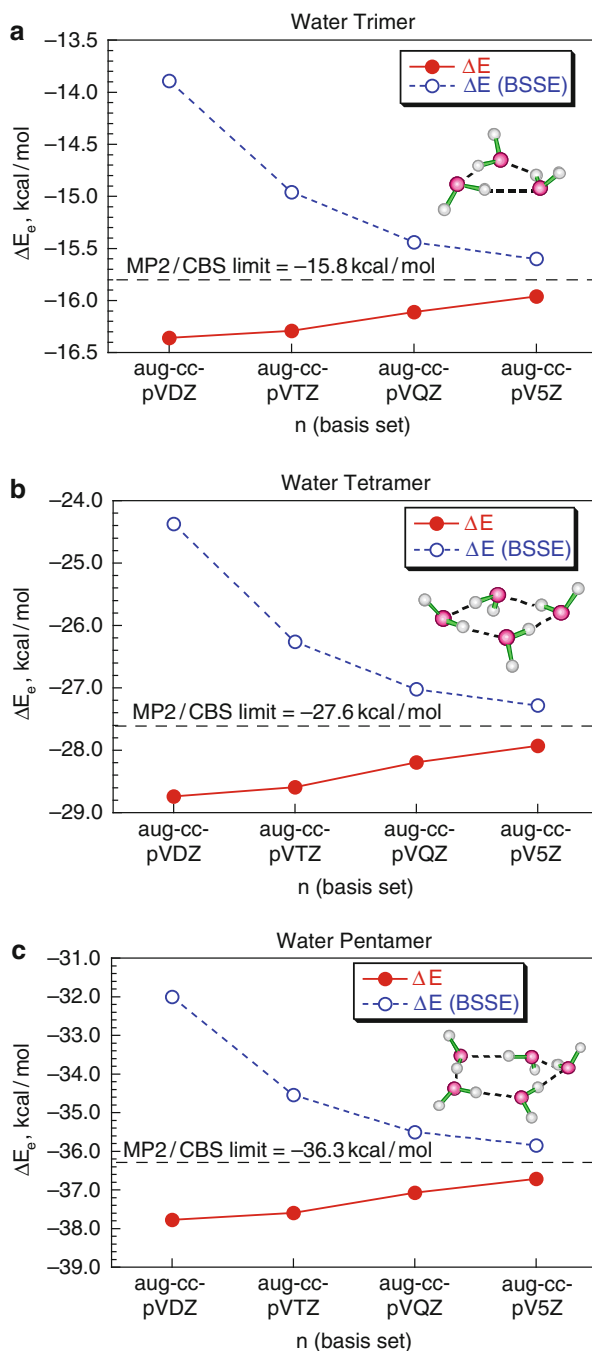

Fig. 3 Global minimum energy structures for $(\text{H}_2\text{O})_n$, $n = 1-5$ are the same for the TIP4P and TTM3-F potentials and the MP2 level of theory. The binding energies (D_e) at the MP2 level of theory (kcal/mol) were calculated with the aug-cc-pVTZ basis set

Fig. 4 The variation of the uncorrected (solid circles) and BSSE-corrected (open circles) binding energies from MP2 calculations with different basis sets for the global minimum structures of water clusters $n = 3-5$. The figure is reprinted with permission from reference Xantheas et al. (2002). © 2002 American Institute of Physics

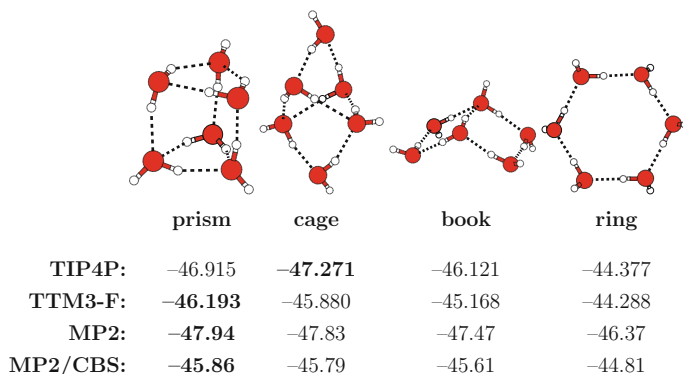

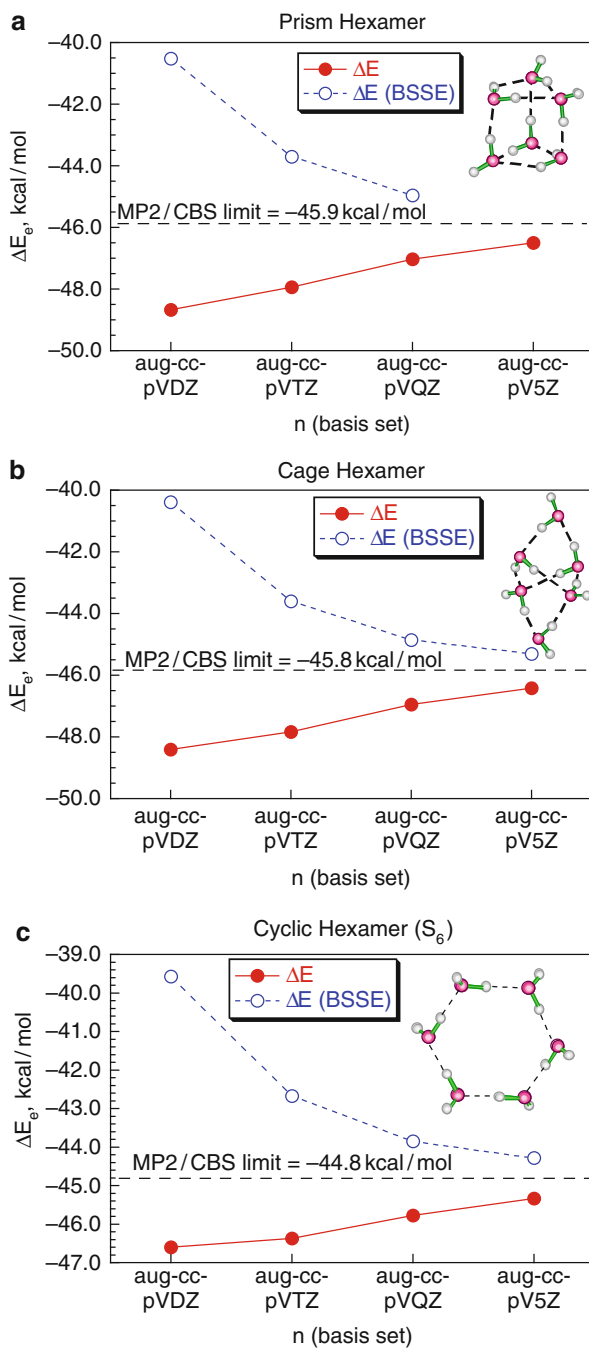

Fig. 5 Global minimum energy structures and binding energies (kcal/mol) for $(\text{H}_2\text{O})_6$. The TIP4P potential prefers the cage-like hexamer, while the TTM3-F potential the prism-like one. The prism-like hexamer becomes the global minimum structure at the MP2/aug-cc-pVTZ level of theory

corrected binding energies results in identical estimates for the CBS limit, which is just 0.3 kcal/mol away from the best computed value with the aug-cc-pV5Z set. The same trend is observed for the cyclic water pentamer with an estimated CBS limit of -36.3 kcal/mol. Both the effective pair-wise TIP4P (Wales and Hodges 1998) potential and the transferable, polarizable, many-body TTM3-F do yield these structures as the global minima, in agreement with the results of the MP2 calculations. The unique common feature of the global minimum structures of water clusters in the $n = 3-5$ size range is a cyclic (or ring) structure motif with the same direction of in-the-ring hydrogen bonding network in a homodromic direction (Xantheas 2000). These homodromic hydrogen bonding networks, i.e., those exhibiting donor-acceptor (da) arrangements between all water molecules, are associated with the largest non-additivities among other networks present in low-lying minima of small ($n = 3-5$) water clusters. These cyclic (or ring) structures, especially for $n = 4$ and 5 are of particular importance since they consist of the building blocks for the global minimum structures of water clusters in the size range $n = 6-20$.

The water hexamer has four distinct almost isoenergetic isomers that lie within 1 kcal/mol from each other (see Figs. 5 and 6) (Xantheas et al. 2002). Four distinct low-lying isomers are known as the prism, cage, book, and ring (S_6) structures. The prism isomer (bilayer of a trimer ring) is the global minimum at the MP2 level of theory with all basis sets, while the cage isomer becomes the global minimum when zero-point energy corrections are included. The MP2/CBS limits are estimated at -45.86 kcal/mol for the prism isomer and at -45.79 kcal/mol for the cage isomer, respectively. We have also estimated MP2/CBS limits of -45.61 kcal/mol for the book isomer and -44.81 kcal/mol for the ring isomer of S_6 symmetry. The calculations indicate that the “transition” from a quasi-planar, ring motif to a more compact, cage-like structure occurs for $n = 6$. A first difference among the results with classical water potentials was found for this cluster. The TIP4P potential

Fig. 6 The variation of the uncorrected (solid circles) and BSSE-corrected (open circles) binding energy from MP2 calculations with different basis sets for the water hexamer ($n = 6$). Fig. 7 The global minimum energy structures and binding energies (kcal/mol) for $(\text{H}_2\text{O})_7$ and $(\text{H}_2\text{O})_8$. For $n = 7$, the TIP4P and TTM3-F potentials have the same global minimum. For $n = 8$, the TIP4P potential favors the parallel circular arrangement of hydrogen bonds of two ring tetramers, while TTM3-F, the antiparallel arrangement. At the MP2/aug-cc-pVTZ level of theory, the antiparallel arrangement is preferred in agreement with the TTM3-F result

predicts the cage isomer as the global minimum (Wales and Hodges 1998), while the TTM3-F potential favors the prism isomer in agreement with the result of the MP2 calculations.

The water heptamer ($n = 7$) is an intermediate structure between the hexamer and the octamer. Note that water hexamer prefers to be a prism isomer (bilayer of cyclic ring trimer) and the water octamer a bilayer of the cyclic tetramer. The global minimum structure of the water heptamer consists of a cyclic trimer and cyclic tetramer on each layer as shown in Fig. 7. The water octamer ($n = 8$) has two nearly isoenergetic forms having D_{2d} and S_4 symmetry as the low-energy structures (see Figs. 7 and 8) (Xantheas and Aprà 2004). These are comprised of two stacked cyclic tetramers and the distinction between those two isoenergetic isomers lies in the direction of the two in-the-ring hydrogen bonding networks that can be either along the same (or parallel) for the S_4 isomer or opposite (or antiparallel) for the D_{2d} isomer. The variation of the MP2 binding energies with basis set is graphically illustrated in Fig. 8 for the two isomers. The best estimated BSSE-corrected MP2/CBS limits obtained with the 4–5 polynomial (cf. Eq. 8) are -72.94 kcal/mol and -72.78 kcal/mol for the antiparallel (D_{2d}) and the parallel (S_4) isomers, respectively. The corresponding BSSE-corrected MP2/CBS limits estimated with the exponential extrapolation (via Eq. 9) are -72.42 kcal/mol for the antiparallel and -72.35 kcal/mol for the parallel isomers, respectively. Note that the MP2 energy difference between both isomers is quite small of ~ 0.2 kcal/mol for both extrapolation methods. Given the heuristic nature of the two extrapolation methods to arrive at the CBS limit and these caveats, it is difficult and probably futile to assign a CBS limit for the binding energy with an “error bar” smaller than this quantity (~ 0.4 kcal/mol), which arises from the extrapolation procedure. As can be seen from Fig. 8, we suggest a value of -72.7 ± 0.4 kcal/mol for the MP2/CBS limit of the binding energy for both isomers of the water octamer, keeping in mind

Fig. 8 The variation of the uncorrected (solid circles) and BSSE-corrected (open circles) binding energy from MP2 calculations with different basis sets for the water octamer ($n = 8$). The figure is reprinted with permission from reference Xantheas and Aprà (2004). © 2004 American Institute of Physics

that the antiparallel isomer is always lower in energy by ~ 0.05 kcal/mol than the parallel one. As regards the results of classical potentials, TIP4P predicts the parallel isomer (Wales and Hodges 1998), while TTM3-F the antiparallel isomer as the global minimum structure in agreement with the results of the MP2 calculations.

Figure 9 shows the global minimum structures for $n = 9$ and 10. The TIP4P and TTM3-F potentials predict the same global minimum structure of $(\text{H}_2\text{O})_9$ consisting of the cyclic tetramer and the cyclic pentamer on each layer. The water decamer ($n = 10$) has two nearly isoenergetic isomers consisting of two stacked cyclic pentamers. These two isoenergetic isomers are distinguished by the direction of the in-the-ring hydrogen bonding networks as we have previously discussed for the two isomers of the water octamer. The antiparallel isomer of water decamer has the opposite direction of the in-the-ring hydrogen bonding networks on each layer, while the parallel isomer has the same direction. The TIP4P potential predicts the parallel isomer (Wales and Hodges 1998), whereas the TTM3-F potential predicts the antiparallel isomer as the global minimum structure that is consistent with the results of the MP2 calculations.

Fig. 9 The global minimum energy structures and binding energies (kcal/mol) of $(\text{H}_2\text{O})_9$ and $(\text{H}_2\text{O})_{10}$. The TIP4P and TTM3-F potentials predict the same global minimum structure for $(\text{H}_2\text{O})_9$, which is based on the antiparallel arrangement of hydrogen bonding in $(\text{H}_2\text{O})_8$. For $(\text{H}_2\text{O})_{10}$ (stacking of two pentagon rings), the TIP4P potential favors the parallel arrangement, while the TTM3-F potential the antiparallel arrangement. The binding energies at the MP2/aug-cc-pVTZ level of theory are listed

The Global Minima of Medium-Sized Water Clusters in the Range $11 \leq n \leq 16$

During the last 20 years, the search for the global minima of medium-sized water clusters has received much theoretical attention (Bulusu et al. 2006; Day et al. 2000; Fanourgakis et al. 2004, 2005; Hartke 2003; Kazimirski and Buch 2003; Koga et al. 2000; Lagutchenkov et al. 2005; Lee et al. 1995, 2001; Nigra and Kais 1999; Sadlej 2001; Tsai and Jordan 1993; Wales and Hodges 1998) and several previous ab initio calculations (Day et al. 2000; Fanourgakis et al. 2004, 2005; Koga et al. 2000; Lee et al. 1995, 2001; Sadlej 2001; Tsai and Jordan 1993) suggested that the global minima of medium-sized water clusters in the $n = 11$ –16 range mainly consist of the building blocks of the antiparallel octamer and the antiparallel decamer isomers. Figure 10 shows the global minimum structures for $n = 12$, 14, 15, and 16 at the MP2 level of theory. In detail, the global minima of $(\text{H}_2\text{O})_{12}$ and $(\text{H}_2\text{O})_{16}$ are stacked cube structures with the antiparallel arrangement of the in-the-ring hydrogen bonding networks that are built from the building blocks of the antiparallel octamer. For the global minimum of $(\text{H}_2\text{O})_{15}$, the antiparallel decamer was used as the building block to form a stacked pentagonal prism. In the case of the global minimum structure of $(\text{H}_2\text{O})_{14}$, two building blocks of the antiparallel octamer and decamer were used to obtain a fused square-pentagon prism structure. The TIP4P potential fails in predicting these arrangements as the global minima for $n = 12$, 15 and 16. It rather uses the parallel octamer and the parallel decamer isomers as starting points to build the global minimum structures of water clusters for $n = 12$, 15, and 16 since these were the most stable isomers for $n = 8$ and $n = 10$ (see Figs. 7 and 9) (Wales and Hodges 1998). In contrast, the TTM3-F potential again predicts the arrangements in agreement with the MP2 results.

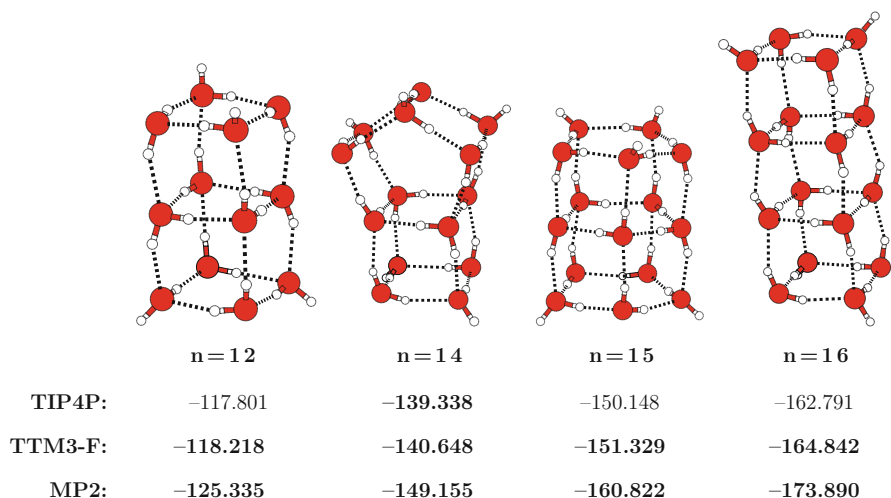

Fig. 10 The global minimum of $(\text{H}_2\text{O})_n$ for $n = 12, 14-16$. The TIP4P potential predicts a different global minimum for $n = 12, 15$ and $n = 16$. The MP2/aug-cc-pVDZ energies are listed

Fig. 11 The isomers of $(\text{H}_2\text{O})_{11}$. The (443) isomer is the global minimum structure with the TIP4P and TTM3-F potentials. The (434) isomer has the lowest binding energy (D_e) at the MP2/aug-cc-pVTZ level theory. Binding energies are shown in kcal/mol. The figure is reprinted with permission from reference Bulusu et al. (2006). © 2006 American Chemical Society

In the case of the odd-numbered water clusters ($n = 11$ and 13), it is not as easy to build the global minimum structures starting from most stable networks of the octamer and decamer clusters. Figure 11 shows the four distinct structural families of the low-lying isomers of $(\text{H}_2\text{O})_{11}$ (Bulusu et al. 2006). Two families labeled as (515) and (551) are built from the stacked pentagon $(\text{H}_2\text{O})_{10}$ (antiparallel decamer, the global minimum of $(\text{H}_2\text{O})_{10}$ as shown in Fig. 9). The (515) isomer can be viewed as constructed by adding one water molecule between the top and middle layers of

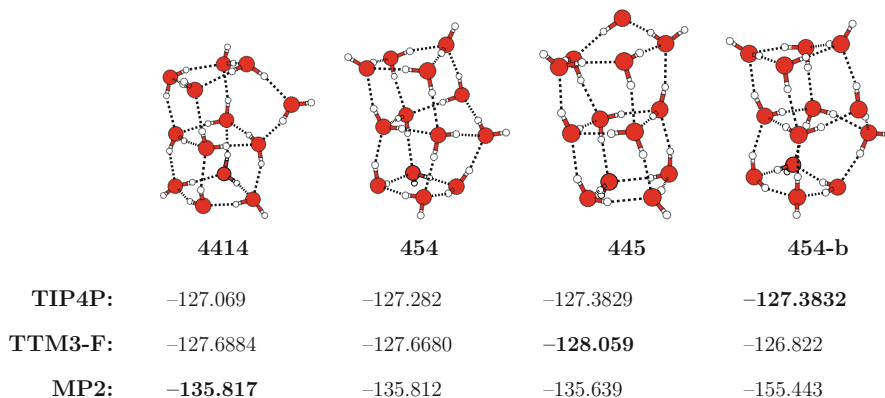

Fig. 12 The isomers of $(\text{H}_2\text{O})_{13}$. The MP2 energies were calculated with the aug-cc-pVDZ basis set. The figure is reprinted with permission from reference Bulusu et al. (2006). © 2006 American Chemical Society

the antiparallel decamer isomer, whereas the (551) isomer from inserting one water molecule into the top layer. The families labeled as (443) and (434) are built from the stacked cube $(\text{H}_2\text{O})_{12}$ isomer, which consists of three layers of cyclic tetramers: the (443) isomer can be built by removing one water molecule from the top layer of the global minimum of $(\text{H}_2\text{O})_{12}$ and the (434) isomer by removing one water molecule from the middle layer of the stacked cube structure of $(\text{H}_2\text{O})_{12}$. The MP2 results indicate that the low-lying isomers of the (434) and (515) families are the most probable candidates for the global minimum. Since the maximum MP2 energy difference for all four distinct almost isoenergetic isomers is very small (~ 0.5 kcal/mol), the inclusion of zero-point energy corrections is important to identify the global minimum. When zero-point energy corrections (albeit at the harmonic level) were included, the (515) isomer becomes the global minimum structure of $(\text{H}_2\text{O})_{11}$. Both the TIP4P and TTM3-F potentials predict the (443) isomer as the global minimum.

Figure 12 shows four distinct isomers for $(\text{H}_2\text{O})_{13}$ as the low-lying isomers of $(\text{H}_2\text{O})_{13}$ (Bulusu et al. 2006). Note that the three isomers (414), (454), and (445) can be built from the antiparallel global minimum of $(\text{H}_2\text{O})_{12}$, as shown in Fig. 10. However, the (454-b) isomer, which is the global minimum structure predicted by TIP4P, is built from the parallel $(\text{H}_2\text{O})_{12}$ in accordance with the fact that this is the global minimum structure of $(\text{H}_2\text{O})_{12}$ predicted by TIP4P. For completeness, the (4414) isomer can be built by adding one water molecule vertically between the top and middle layers of the antiparallel isomer of $(\text{H}_2\text{O})_{12}$. The (454) and (454-b) isomers can be built by inserting one water molecule into the middle layer of the antiparallel and parallel $(\text{H}_2\text{O})_{12}$ isomers, respectively. The (445) isomer can be constructed by inserting one water molecule into the top water layer. The MP2 calculations predict that the (4414) isomer is the most stable isomer of the $(\text{H}_2\text{O})_{13}$ cluster and the (454) isomer is the next lowest isomer. Since the maximum

MP2 energy difference for four distinct isoenergetic isomers of $(\text{H}_2\text{O})_{13}$ is very small (~ 0.4 kcal/mol), we furthermore estimate the effect of the zero-point energy correction to the relative stability of the isomers. The (4414) isomer remains as the global minimum structure of $(\text{H}_2\text{O})_{13}$ after including harmonic zero-point energy corrections. The TTM3-F potential predicts the (445) isomer as the global minimum structure of $(\text{H}_2\text{O})_{13}$.

The Transition from “All-Surface” to “Internally Solvated” Clusters at $n = 17$

So far we have discussed in section “[Global Minimum Structures of the \$n = 2\$ – \$10\$ Water Clusters](#)” that the structural “transition” from a quasi-planar ring motif to a more compact, cage-like structure, which occurs at $n = 6$. For the smaller clusters, the need to maximize hydrogen bonding results in all the atoms being on the surface of the cluster. However, as the cluster grows, there is a point where more compact, fully connected structures are formed, in which water molecules are fully coordinated (i.e., they have two donors and two acceptors of hydrogen bonds) like in an average arrangement in the liquid environment. Several experiments (Beuhler and Friedman 1982; Haberland 1984; Hermann et al. 1982; Lin 1973; Nagashima et al. 1986; Niedner-Schatteburg and Bondybey 2000; Schindler et al. 1996; Searcy and Fenn 1974; Stace and Moore 1983; Yang and Castleman 1989) such as expansion of ionized water vapor (Beuhler and Friedman 1982; Searcy and Fenn 1974), ion bombardment of ice surfaces (Haberland 1984), as well as black-body-radiation-induced dissociation studies (Niedner-Schatteburg and Bondybey 2000; Schindler et al. 1996) suggested a prevailed magic cluster of the $\text{H}_3\text{O}^+(\text{H}_2\text{O})_{20}$ cluster consisting of a clathrate-like pentagonal dodecahedron structure. This magic cluster of $\text{H}_3\text{O}^+(\text{H}_2\text{O})_{20}$ indicates the transition from the “all-surface” to “internally solvated” clusters. Note that this kind of transition for the neutral water clusters has not yet been identified experimentally. For a cluster of that size, the number of isomers increases dramatically with size. A detailed discussion of this problem will be presented in the following section “[The Family of Minima for \$\(\text{H}_2\text{O}\)_{20}\$](#) .” In brief, a global search algorithm (Hartke 2003; Li and Scheraga 1987; Wales and Scheraga 1999) has been previously used in order to identify low-energy structures of clusters of that size. That global search approach of an evolutionary algorithm combined with the TTM2-F potential predicted that for the neutral water clusters, the transition from “all-surface” to “internally solvated” occurs for $(\text{H}_2\text{O})_{17}$ (Hartke 2003). Figure 13 shows the alternation between the all-surface and interior minima at the $n = 17$ – 21 cluster regime predicted by the TTM2-F interaction potential. The solvated water molecule with a tetrahedral network is highlighted in green color. The TIP4P potential predicts that the transition from “all-surface” to “internally solvated” clusters occurs for $(\text{H}_2\text{O})_{19}$. Both the TIP4P and TTM3-F potentials predicted the same global minimum structures for $n = 18$ and 20. The lowest energy structure predicted with TIP4P has a slightly different hydrogen bonding orientation for $n = 19$ when compared to the global minimum structure predicted by TTM2-F.

Fig. 13 The transition from “all-surface” to “internally solvated” clusters in the range of $n = 17$ – 21 . The binding energies were calculated at the MP2/aug-cc-pVDZ level of theory. The figure is reprinted with permission from reference Lagutchenkov et al. (2005). © 2005 American Institute of Physics

Validation from Electronic Structure Calculations

Since the TIP4P and TTM3-F classical water potentials predicted different global minimum structures for $n = 17$ and 21 , we concentrated our efforts in comparing the relative stabilities of the two different arrangements predicted by the two models from electronic structure calculations. The results (Lagutchenkov et al. 2005) obtained at the MP2 level of theory with the aug-cc-pVDZ and aug-cc-pVTZ basis sets are shown in Fig. 13. For the $n = 17$ cluster, MP2 calculations with both basis sets predicted the “interior” structure to be more stable, in agreement with the predictions of the TTM2-F potential. Inclusion of differential zero-point energy corrections (0.45 kcal/mol at B3LYP/TZVP level of theory) furthermore tends to increase the energy difference between the two isomers in favor of the “interior” configuration. Our best estimate for the energy difference between the “all-surface” and “interior” isomers of $n = 17$ is 1.43 kcal/mol (1.88 kcal/mol including zero-point energy corrections) at the MP2/aug-cc-pVTZ level of theory. For the $n = 21$ cluster, a similar behavior was found between the most stable “all-surface” and “interior” isomers. The basis set effect at the MP2 level of theory also results in decreasing the energy difference, where as the inclusion of zero-point energy corrections tends to stabilize the “interior” configuration with respect to the “all-surface” one. The TTM2-F potential predicts the correct ordering between the two different arrangements, yielding an energy difference that is almost half of the MP2/aug-cc-pVTZ value. At this level of theory, the “interior” configuration is stabilized by 3.71 kcal/mol (4.11 kcal/mol including zero-point energy corrections) with respect to the “all-surface” one for $n = 21$. Therefore,

the MP2 calculations provided a reliable benchmark that validated the predictions of the TTM2-F potential as regards the onset of the “all-surface” to “interior” configurations occurring at $n = 17$.

Spectroscopic Signature

As noted earlier, the *ab initio* investigation of the relative stability of the various hydrogen bonding networks in the $n = 17$ – 21 cluster regime has identified the existence of a transitional size regime where preferential stabilization alternates between “all-surface” (all atoms on the surface of a cluster) and “internally solvated” (one water molecule at the center of the cluster, fully solvated) configurations with the addition or the removal of a single water molecule.

This behavior has been previously suggested based on the results of the TTM2-F interaction potential. It is qualitatively different from the picture that simple, pairwise-additive potentials like TIP4P suggest. The onset of the appearance of the first “interior” configuration in water clusters occurs for $n = 17$. The observed structural alternation between “interior” ($n = 17, 19, 21$) and “all-surface” ($n = 18, 20$) global minima in the $n = 17$ – 21 cluster regime is accompanied by a corresponding spectroscopic signature, namely the undulation in the position of the most red-shifted OH stretching vibrations (indicated by the shaded area in Fig. 14) according to the trend: “interior” configurations exhibit more red-shifted OH stretching vibrations than “all-surface” ones (see Fig. 14). These most red-shifted OH stretching vibrations form distinct groups in the intramolecular region of the spectra and correspond to localized vibrations of donor OH stretches that have the following characteristics: (1) the hydrogen-bonded OH group belongs to a water molecule that has a “free” (non-hydrogen-bonded) OH stretch and (2) the bound OH group acts as a donor to a neighboring water molecule via a water dimer-like hydrogen bond (i.e., a hydrogen bond in which the dihedral angle between the free OH of the donor molecule and the bisector of the HOH angle of the acceptor molecule is 180° , as seen in the lower panel of Fig. 14).

The Family of Minima for $(\text{H}_2\text{O})_{20}$

Interest in the family of water clusters for $n = 20$ stems from the fact that one of the families of minima is the dodecahedron which has been proposed as a model for inclusion compounds and constitutes a building block of type I ice clathrate (we will discuss this in detail in section “[The First Few Water Cages](#)”) The structure of $(\text{H}_2\text{O})_{20}$ has been the subject of debate due to the existence of various major families of minima which are energetically in close proximity and the disagreement as to which was the global minimum (Fanourgakis et al. 2004).

We have previously briefly discussed (see section “[The Transition from ‘All-Surface’ to ‘Internally Solvated’ Clusters at \$n = 17\$](#) ”) the issue regarding the number of isomers increasing dramatically with cluster size. The assignment of the structural

Fig. 14 Intramolecular spectra in the 3,000–4,000 cm^{-1} region associated with the hydrogen-bonded and free OH stretching vibrations for $n = 17$ –21 [(a)–(e)] at the B3LYP/TZVP level of theory. The stick diagram of the computed frequencies is also shown. Shaded area denotes the most red-shifted OH stretching vibrations. motif of the neutral $(\text{H}_2\text{O})_{20}$ cluster represents a much more difficult task especially in the absence of experimental information (such as rotational constants or infrared spectra) that can yield definitive structural information. For typical clusters of that size, even for a fixed position of the Oxygen atom network, there exists a multitude of arrangements of the hydrogen atoms in a manner consistent with the cluster analog of the Bernal–Fowler ice rules (Hobbs 1974; Petrenko and Whitworth 1999). For instance, just for the dodecahedral arrangement of the oxygen atom network in $(\text{H}_2\text{O})_{20}$, the application of graph theoretical techniques (Kuo et al. 2001; McDonald et al. 1998) yields an estimate of 30,026 symmetry-distinct hydrogen bond topologies which are likely candidates for local minimum structures. For this reason, extensive sampling of the $n = 20$ cluster potential energy surface (PES) has been performed only with classical interaction potentials. Using the “basin-hopping” method combined with the TIP4P potential, Wales and Hodges (Wales and Hodges 1998) identified four major families of $(\text{H}_2\text{O})_{20}$ which, based on the arrangement of the oxygen atom network, they classified as (a) dodecahedron, (b) fused cubes, (c) face-sharing pentagonal prisms, and (d) edge-sharing pentagonal prisms. Representative candidates of these families of minima are illustrated in Fig. 15. The relative energetic order of the four families is predicted to be (d)-(b)-

Fig. 15 The lowest energy isomers within the four-families of minima for $(\text{H}_2\text{O})_{20}$: (a) dodecahedron, (b) fused cubes, (c) face-sharing pentagonal prisms, and (d) edge-sharing pentagonal prisms. The figure is reprinted with permission from reference Fanourgakis et al. (2004). © 2004 American Institute of Physics

(c)-(a) with TIP4P. An evolutionary algorithm used by Hartke in conjunction with TTM2-F interaction potentials resulted in the edge-sharing pentagonal prism as the global minimum. The global minimum structure is in fact qualitatively identical for TTM2-F and TIP4P, and it is an all-surface one. The edge-sharing pentagonal prism (d) is lower by 11.2 (TIP4P) and by 13.98 kcal/mol (TTM2-F) than the dodecahedral family (a).

The Four Major Families of Minima

First principles electronic structure calculations at the MP2 level of theory with the family of augmented correlation-consistent basis sets up to quadruple zeta quality were used to estimate complete basis set (CBS) binding energies D_e for the lowest energy structures within each of the four low-lying families of minima as follows: (a) dodecahedron (−200.1 kcal/mol, 30 hydrogen bonds), (b) fused cubes (−212.6 kcal/mol, 36 hydrogen bonds), (c) face-sharing pentagonal prisms (−215.0 kcal/mol, 35 hydrogen bonds), and (d) edge-sharing pentagonal prisms (−217.9 kcal/mol, 34 hydrogen bonds) (Fanourgakis et al. 2004). Among the various interaction potentials, TTM2-F (Burnham and Xantheas 2002b) was found to predict the absolute cluster binding energies to within 1% from the corresponding

MP2/CBS values. These calculations also yielded the first harmonic vibrational spectra of the lowest energy isomers within each family as a means of providing the necessary information for their future spectroscopic identification.

Zero-point energy corrections do not change the relative order of the four different networks, although they reduce the separation between the highest-lying dodecahedron structure and the lowest-lying edge-sharing pentagonal prism isomer from 17.8 kcal/mol to 15.0 kcal/mol.

Vibrational Spectra

The IR spectra of the four low-lying families of minima of $(\text{H}_2\text{O})_{20}$ exhibit different features in the OH stretching region that can be used for their spectroscopic assignment. These are shown in Fig. 16. Some of these spectral features are reminiscent of their constituent water tetramer and pentamer fragments. The dodecahedral network is associated with the most red-shifted (by 700–800 cm^{-1} with respect to the monomer) OH stretching vibrations among the four isomers and shows the richest structure in the 3,000–4,000 cm^{-1} range. The lowest edge-sharing pentagonal prisms family of isomers displays IR intense bands that are red-shifted by $\sim 600 \text{ cm}^{-1}$ with respect to the average of the symmetric and antisymmetric OH stretching vibrations in the water monomer. A common feature of the vibrational spectra that is shared by all four networks is that the most red-shifted, IR-active OH stretching vibrations exhibit the same characteristics previously found for the most stable isomers of $n = 17\text{--}21$ (Fig. 14), namely that they belong to fragments that have a “free” OH stretch and act as donors to a neighboring water molecule along a hydrogen bond which resembles a gas-phase dimer arrangement. It is conceivable that the second characteristic directly affects the energetic stability of the isomer within the corresponding family.

The computed spectra can be used as guides for the spectroscopic assignment of the lowest energy edge-sharing pentagonal prism isomer in molecular beams or the higher-lying networks in other environments such as helium droplets or cryogenic para-hydrogen solids that can facilitate the formation of higher energy cluster isomers.

The First Few Water Cages

Significance

Gas hydrates are naturally occurring in situ in the deep oceans and permafrost regions of the earth (Mao et al. 2007; Sloan 1998). Their potential importance as inclusion compounds relevant to energy problems such as hydrogen storage has been recently highlighted. All of the clathrate hydrate forming natural gases adopt one of the following three crystal structures (Jeffrey et al. 1967; Ripmeester et al. 1987): (1) sI (cubic, $Pm\bar{3}n$), (2) sII (cubic, $Fd\bar{3}m$) and (3) sH (hexagonal, $P6/mmm$). These

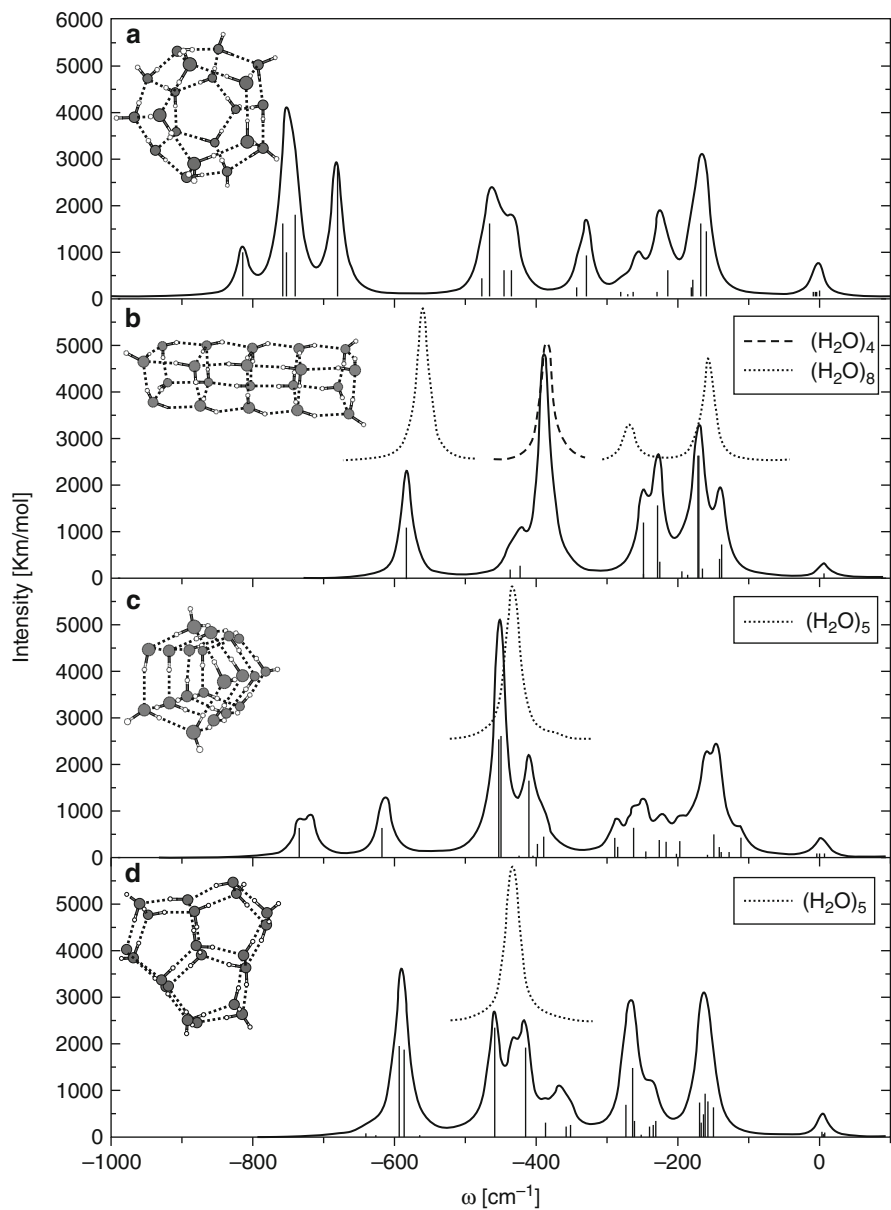

Fig. 16 Intramolecular spectra in the $3,000\text{--}4,000\text{ cm}^{-1}$ region associated with the OH stretching vibrations. The stick diagram of the frequencies is also shown. The IR spectra for the water ring tetramer, pentamer, and octamer cube are shown for comparison. The figure is reprinted with permission from reference Fanourgakis et al. (2004). © 2004 American Institute of Physics

three-dimensional lattices are constructed from the following water cages: (1) the pentagonal dodecahedron (D-cage), which consists of 20 water molecules that form 12 pentagonal faces (5^{12}); (2) the tetrakaidecahedron (T-cage), which consists of 24 water molecules that form 12 pentagonal and 2 hexagonal faces ($5^{12}6^2$); (3) the hexakaidecahedron (H-cage), which consists of 28 water molecules that form 12 pentagonal and 4 hexagonal faces ($5^{12}6^4$); (4) the irregular dodecahedron, which consists of 20 water molecules that form 3 tetragonal, 6 pentagonal, and 3 hexagonal faces ($4^35^66^3$); and (5) the icosahedron, that consists of 36 water molecules that form 12 pentagonal and 8 hexagonal faces ($5^{12}6^8$). In the previous notation, $p^n q^m$ identifies the underlying Oxygen atom network of the constituent cages, with p , q being the size of the polygons and n , m the number of faces; for instance, $5^{12}6^2$ denotes 12 pentagonal and 2 hexagonal faces. The unit cell of the three-dimensional (sI) hydrate periodic structure is made of 2 units of the 5^{12} cage and 6 units of the $5^{12}6^2$ cage. In a similar manner, the unit cell of the (sII) hydrate lattice is constructed from 16 units of the 5^{12} cage and 8 units of the $5^{12}6^4$ cage. This hydrate lattice (sII) has been recently considered for practical applications in energy storage as it was shown to meet current US Department of Energy's target densities for an onboard hydrogen storage system (Mao et al. 2006; Schüth 2005). Finally, the unit cell of the (sH) hydrate is more complex since it is constructed from 3 units of the 5^{12} cage, 2 units of the $4^35^66^3$ cage, and 1 unit of the $5^{12}6^8$ cage. The constituent cages of those three hydrate lattices are often used as models to probe the relevant guest/host interactions from electronic structure calculations to derive intermolecular potentials that can be then used for the full system of the periodic lattice and the molecular guests.

The Pentagonal Dodecahedron (D-cage)(H₂O)₂₀ Cluster

The analysis of the relative energetics of the various dodecahedron isomers is performed using the previous results (Wales and Hodges 1998) of Wales and Hodges as the starting point. These authors have used the basin-hopping Monte Carlo method (Li and Scheraga 1987; Wales and Scheraga 1999) in conjunction with the classical TIP4P (Jorgensen et al. 1983) potential in order to obtain the global and low-lying local minima of the pentagonal dodecahedron family of isomers. The list of the first 19 minima obtained with the TIP4P potential by Wales and Hodges were used as starting geometries for optimization with the TTM2-F (Burnham and Xantheas 2002b, c; Burnham et al. 1999) interaction potential (see Fig. 17). In that figure, the global minimum obtained with TIP4P for the dodecahedron corresponds to minimum #2 in the list and is indicated by an arrow. In general, there is a good correspondence between the TIP4P and TTM2-F relative isomer energetics, except for the isomer indicated as minimum "0" in the list. That isomer labeled by "0" is the one suggested as the global minimum from the combinatorial optimization with the "strong" and "weak" hydrogen bonds (SWB) model (Kirov 1996) when the intermolecular interactions were computed with the ST2 (Stillinger and Rahman 1974) interaction potential.

Fig. 17 Binding energies of the first 19 isomers of the pentagonal dodecahedron (H_2O)₂₀ cluster with the TIP4P (filled circles) and TTM2-F (open circles) potentials. The TIP4P global minimum corresponds to minimum #2 and is indicated with an arrow. Minimum “0” is the isomer predicted from the SWB model. The figure is reprinted with permission from reference Kirov et al. (2008). © 2008 Elsevier

In order to further assess the validity of the predictions of the empirical interaction potentials regarding the relative stability of isomers for the pentagonal dodecahedron, we have carried out electronic structure calculations for the 20 minima that are included in Fig. 17 (Kirov et al. 2008). The TTM2-F optimal structures (which are qualitatively similar to the ones obtained by TIP4P) for the 20 minima labeled 0–19 were used as starting points in the geometry optimization at both the density functional (DFT) (Hohenberg and Kohn 1964; Kohn and Sham 1965) and MP2 (Møller and Plesset 1934) levels. In the DFT calculations, Becke’s gradient-corrected exchange-correlation density functional (B3LYP) (Becke 1988, 1993) was used in conjunction with Ahlrichs’ polarized triple- ζ (TZVP) basis set (Schäfer et al. 1994). As for the previous cases, the MP2 optimizations were performed using Dunning’s (Dunning 1989; Kendall et al. 1992) augmented correlation-consistent basis sets of double- ζ (aug-cc-pVDZ) quality.

The binding energies of these 20 isomers of the dodecahedron (H_2O)₂₀ are shown in Fig. 18 at the B3LYP/TZVP (open circles) and MP2/aug-cc-pVDZ (filled squares) levels of theory (Kirov et al. 2008). The order of isomers has been maintained the same as in Fig. 16 for a direct comparison. We first note

Fig. 18 Binding energies of the first 19 isomers of the pentagonal dodecahedron (H_2O)₂₀ cluster at the B3LYP/TZVP (open squares) and MP2/avg-cc-pVDZ (filled squares) levels of theory. The TIP4P global minimum corresponds to minimum #2 and is indicated with an arrow. Minimum “0” is the isomer predicted from the SWB model. The figure is reprinted with permission from reference Kirov et al. (2008). © 2008 Elsevier

that B3LYP/TZVP also predicts minimum “0” to be more stable than minimum #2 (the global dodecahedron minimum of TIP4P model) as was the case with TTM2-F potential. However, it yields an even lower energy structure (minimum #15). The energetic stabilization of minimum #15 is also confirmed during subsequent MP2/avg-cc-pVDZ optimizations. Based on the results of the DFT and MP2 calculations, we therefore suggest minimum #15 as the global minimum for the dodecahedron family of (H_2O)₂₀. Its binding energy (D_e) is -231.01 kcal/mol (B3LYP/TZVP) and -212.10 kcal/mol (MP2/avg-cc-pVDZ). The three-dimensional structure and its two-dimensional mapping onto the corresponding Schlegel diagram (Schlegel 1883) for the newly found global minimum are shown in Fig. 19. Schlegel diagrams assist in categorizing the various isomers by offering a helpful two-dimensional visual representation of the connectivity of the underlying hydrogen bonding network. Their construction is based on the principle that the nodes and lines of the graph correspond to the vertices and edges of the corresponding polyhedron. The hydrogen bonding network is naturally preserved upon this dimensional reduction from the 3D structure (left) to the 2D graph (right). In order to better indicate the correspondence between the two representations, we also indicate the numbering of the oxygen atoms in Fig. 19.

Fig. 19 The lowest energy isomer of the dodecahedron predicted at the MP2 level of theory. Left panel: 3D structure. Right Panel: Schlegel diagram indicating the “strong” (dimer-like, solid lines) and “weak” (dashed lines) nearest-neighbor (n–n) molecular arrangements. The Tetrakaidecahedron (T-Cage)(H₂O)₂₄ Cluster

For a fixed position of the Oxygen atoms in the $5^{12}6^2$ (H₂O)₂₄ cage cluster, there are 3,043,836 symmetry distinct configurations arising from the different hydrogen positions that are consistent with the ice rules. The application of the SWEB discrete model with subsequent refinement at the DFT and MP2 levels of theory yields the first few (~100) low-lying networks. The Schlegel diagrams (Schlegel 1883) (2D projections of the 3D structures) of the ten lowest minima of the T-cage (fully optimized at the MP2/aug-cc-pVDZ level of theory) are shown in Fig. 20 (Yoo et al. 2009). The various networks are labeled using the R or L designation, depending on whether the direction of the donor H atoms in the three concentric rings starting from the inner one is either clockwise (R) or counterclockwise (L). For example, the RLR isomer corresponds to an arrangement in which the H atoms are arranged in a clockwise (for the inner and outer circles) and a counterclockwise direction (for the middle circle). Primes are used to indicate different arrangements of the vertical H atoms that connect the three rings. Therefore, the L'LR network has the same connectivity and direction as LLR for the three rings but differs in the direction of the vertical H atoms. The ten lowest-lying minima of the T-cage can be furthermore grouped into three families (indicated as I, II and III in Fig. 20) depending on the donor–acceptor connectivity of the top hexagonal face. For this six-member hydrogen-bonded ring, isomers in family (I) isomers have only donor–acceptor (da) water molecules, whereas isomers in families (II) and (III) have both double donor (dd) and double acceptor (aa) water molecules. The (dd)/(aa) molecules are indicated with blue and gray colors in Fig. 20. It should be noted that all ten minima shown in Fig. 20 have a zero total dipole moment. Their relative order at the MP2/aug-cc-pVDZ level of theory with respect to the most stable LLR network of family (I) (I-LLR) is identical with the larger aug-cc-pVTZ basis set at the MP2 level of theory.

Fig. 20 Schlegel diagrams of the ten lowest minima of the T-cage $(\text{H}_2\text{O})_{24}$ cluster obtained at the MP2/aug-cc-pVDZ level of theory. The figure is reprinted with permission from reference Yoo et al. (2009). © 2009 American Chemical Society

Starting from any of those low-lying isomers of the T-cage the three-dimensional periodic lattice of the (sI) hydrate can now be constructed. In the 46-molecule unit cell of the (sI) lattice two adjacent T-cages are surrounded by six D-cages. When two T-cage isomers sharing a common hexagonal face are used as the building blocks, the positions of the hydrogen atoms of the rest of 36 molecules ($2 \times 24 - 6 - 6$) can be determined. In this manner, the possible networks of the (sI) hydrate unit cell are dramatically reduced. The proposed “bottom-up” approach, which starts from the constituent cages and builds up the three-dimensional lattice, can be used to construct three-dimensional unit cells of the (sI) hydrate from the low-energy networks of their constituent cages. In Fig. 21 the process of constructing a periodic unit cell of the (sI) hydrate lattice starting from the lowest-lying I-LLR isomer is illustrated.

Outlook

The study of small- to medium-sized water clusters offers an important, molecular-level insight into the fundamental interactions between water molecules. It provides information about the nature and magnitude of the cooperative effects that govern the structural and dynamic properties of the more complex aqueous environments. The structures of the first few water clusters are controlled by the need to maximize the amount of hydrogen bonding and as such they are inhomogeneous and under-coordinated, resulting in structures in which all atoms are on the surface of the cluster. This hydrogen bonding environment is very different than the on-the-average homogeneous, fully coordinated one that is found in aqueous systems.

Fig. 21 Schematic approach for building the (sI) hydrate lattice from the low-lying networks of the T-cage. The connectivity of the O atoms between the two cages (without hydrogen atoms) is highlighted in gray. The blue box indicates the (sI) cubic unit cell (46 water molecules). The figure is reprinted with permission from reference Yoo et al. (2009). © 2009 American Chemical Society

As the cluster grows there is a point where fully coordinated molecules in the inside on the cluster are observed. The onset of this transition from the “all-surface” to “fully coordinated” molecules occurs at $n = 17$. Classical force fields for water are essential in probing the plethora of isomers especially for the larger ($n > 21$) clusters. They can be used in conjunction with new approaches for the efficient sampling of the configuration space in order to obtain the low-lying isomers of clusters in this size regime. The structures of the small- and medium-sized water clusters are essential in order to assess the accuracy of those force fields in developing transferable models that can be used in different environments such as liquid water, ice, at aqueous interfaces, or around charged species or hydrophobic surfaces. Given the fact that accurate energetics for the interaction even between two water molecules is not currently available experimentally, the use of high-level first principles electronic structure calculations to obtain the cluster energetics represents an indispensable and currently irreplaceable path toward understanding aqueous environments.

Abstract

This chapter provides information on various carbon allotropes and in-depth details of structural, electronic, and chemical properties of graphene, fullerenes, and single-walled carbon nanotubes (SWCNTs). We have written an overview of different computational methods that were employed to understand various properties of carbon nanostructures. Importance of application of computational methods in exploring different sizes of fullerenes and their isomers is given. The concept of isolated pentagon rule (IPR) in fullerene chemistry has been revealed. The computational and experimental studies involving Stone–Wales (SW) and vacancy defects in fullerene structures are discussed in this chapter. The relationship between the local curvature and the reactivity of the defect-free and defective fullerene and single-walled carbon nanotubes has been revealed. We reviewed the influence of different defects in graphene on hydrogen addition. The viability of hydrogen and fluorine atom additions on the external surface of the SWCNTs is revealed using computational techniques. We have briefly pointed out the current utilization of carbon nanostructures and their potential applications.

Introduction to Carbon Nanostructures

Carbon is one of the first few elements known in antiquity. The pure forms of this element include diamond and graphite, which have been known for few thousand years (<http://www.nndc.bnl.gov/content/elements.html>; Pierson 1993; Wikipedia – <http://en.wikipedia.org/wiki/Carbon>). Both of these materials are of immense importance in industry and in everyday life. Diamond and graphite are termed as giant structures since, by means of a powerful microscope, one could see millions and millions of atoms, all connected together in a regular array. Diamond would appear as a rigid and rather complex system like some enormous scaffolding construction. Carbon is also the major atomic building block for life. All life-forms on Earth have carbon central to their composition. More than 10 million carbon-containing compounds are known. Compounds containing only carbon atoms, particularly nano-sized materials, are intriguing and attract attention of scientists working in various disciplines. Before 1985, scientists deemed that there were only three allotropes of carbon, namely, diamond, graphite, and amorphous carbon such as soot and charcoal. Soccer ball-shaped molecule comprising of 60 carbon atoms, C₆₀ buckyball named fullerene, was discovered in 1985, and it is another interesting carbon allotrope (Kroto et al. 1985). Carbon nanotubes (CNTs), a spin-off product of fullerene, were reported in 1991 by Iijima (1991). Important well-known carbon materials are depicted in Fig. 1. The publication of transmission electron microscope (TEM) images of CNTs by Iijima was a critical factor in

Fig. 1 Well-known carbon materials

convincing a broad community that “*there is plenty of room at the bottom*” and many new structures can exist at the nanoscale. Figure 2 shows eight allotropes of carbon. In addition to graphene, fullerenes, and carbon nanotubes, there are few other uncommon carbon nanostructures such as nanohorns (Iijima et al. 1999; Poonjarernsilp et al. 2009), nano-onions (Palkar et al. 2008; Zhou et al. 2009), nanobuds (He and Pan 2009; Nasibulin et al. 2007a, b; Wu and Zeng 2009), peapods (Launois et al. 2010; Li et al. 2009a; Smith et al. 1998), nanocups (Chun et al. 2009), and nanotori (Liu et al. 1997; Sano et al. 2001).

We performed a quick search in SciFinder on “fullerene,” “carbon nanotubes,” and “graphene” to reveal their importance and growth in current science, engineering, and technology. We received a total of nearly 60,000 references for the word “fullerene,” ~145,000 references for “carbon nanotubes,” and 110,000 for “graphene” when we searched these topics in November 2015. This is indicative that carbon nanomaterials have gained a momentum with the development of nanotechnology as the driving force of the modern science and engineering. Among various carbon nanostructures, CNTs play a special role in the nanotechnology era. The design and discovery of new materials is always exciting for the potential of new applications and properties (Cohen 1993; Serra et al. 1999). In this chapter, we aim to present an overview of carbon nanostructures, with a particular interest on structural, electronic, and chemical properties of graphene, fullerenes, and carbon nanotubes. Important topological defects in the graphene, fullerenes, and carbon nanotubes will be delineated. Thus, this chapter is intended to be an informative guide of carbon nanostructures and to provide description of current computational chemistry applications involving these species to facilitate the pursuit of both newcomers to this field and experienced researchers in this rapidly emerging area.

Graphene

Carbon displays a unique feature of making a chemically stable two-dimensional (2D), one-atom-thick membrane called graphene in a three-dimensional (3D) world. Each carbon atom in graphene is covalently bonded to three other carbon atoms with sp^2 hybridization. Graphene is the thinnest known material and in the same time is the strongest material ever to be measured. It can sustain current densities six orders of magnitude higher than that of copper. It has extremely high strength and very high thermal conductivity and stiffness and is impermeable to gases (Geim

Fig. 3 Carbon-containing molecules (graphite, buckminsterfullerene (C₆₀), and carbon nanotube) derived from graphene

2009). There are many challenges and opportunities for graphene research because graphene is not a standard solid state material. It should be noted that electrons in graphene do not behave in the same way as in ordinary metals and semiconductors due to the unusual energy–momentum relation (Neto 2010). Well-known forms of carbon-containing molecules that derived from graphene are graphite, fullerene, and carbon nanotube, which are depicted in Fig. 3. Graphite consists of stacked layers of graphene sheets separated by 0.3 nm and is stabilized by weak van der Waals forces (He and Pan 2009). Buckminsterfullerene (C₆₀) is formed from graphene balled into a sphere by including some pentagons and hexagons into the lattice (Kroto et al. 1985). The combined experimental and computational study showed the direct transformation of graphene to fullerene (Chuvilin et al. 2010). Carbon nanotubes can be viewed as rolled-up cylinders of graphene. Therefore, graphene can be called “the mother” of all these three sp² carbon structures.

It was presumed that planar graphene cannot exist in free state since they are unstable compared to curved structures such as soot, nanotubes, and fullerenes. This presumption has changed since Novoselov et al. prepared graphitic sheets including single graphene layer and studied their electronic properties (Novoselov et al. 2004, 2005a). The detailed information of growth and isolation of graphene has been provided in the recent review by Geim (2009). Graphene is a prospective material for nanoelectronics. The electron transport in graphene is described by Dirac-like equation (Geim and Novoselov 2007; Novoselov et al. 2005b; Ponomarenko et al. 2008). The experimental realization of graphene motivates several studies focusing on fundamental physics, materials science, and device applications (Abanin et al. 2006; Geim and Novoselov 2007; Novoselov et al. 2004; 2005a, b; Pereira et al.

2009; Ponomarenko et al. 2008). The studies pertinent to the chemistry of graphene sheets have also been reported (Abanin et al. 2006; Avouris et al. 2007; Geim and Novoselov 2007, Neto et al. 2009; Pereira et al. 2009). Graphene research is a hot topic in this decade, thanks to the recent advances in technology for growth, isolation, and characterization of graphene.

Graphene sheets need not always be as perfect as one thinks. Various defects such as Stone–Wales (SW) (Stone and Wales 1986), vacancies (Carlson and Scheffler 2006), pore defects (Jiang et al. 2009), and substitution atoms (Miwa et al. 2008; Zhu et al. 2005) can occur in the thin graphene sheet. Like the creation of vacancies by knocking atoms out of the graphene sheet, surplus atoms can be found as adatoms on the graphene surface. Ad-dimer defect can be introduced to graphene and is characterized by two adjacent five-membered rings instead of two adjacent seven-membered rings in Stone–Wales defect. Therefore, ad-dimer defect is called inverse Stone–Wales (ISW) defect. Figure 4 depicts some of the common defects in graphene sheet.

Experimental observations of defects in graphene have been reported recently (Meyer et al. 2008; Wang et al. 2008). Zettl and coworkers showed the direct image of Stone–Wales defects in graphene sheets using transmission electron microscopy (TEM) and explored their real-time dynamics. They found that the dynamics of defects in extended, two-dimensional graphene membranes are different than in closed-shell graphenes such as nanotubes or fullerenes (Meyer et al. 2008). High-resolution transmission electron microscopy (HRTEM) and atomic force microscopy (AFM) have been useful in identifying various defects in graphene. AFM and HRTEM images of graphene sheet with different defects are shown in Fig. 5. The effect of various defects on the physical and chemical properties of graphene was studied theoretically (Boukhvalov and Katsnelson 2008; Carpio et al. 2008; Duplock et al. 2004; Lherbier et al. 2008; Li et al. 2005). The characteristics of typical defects and their concentrations in graphene sheets are unclear.

Computational and experimental studies concerning defects in graphene sheet are critically important for basic understanding of this novel system, and such understanding will be helpful for scientists who actively work on applications of graphene-based materials. Although the surface physics of graphene sheets is currently at the center of attention, its chemistry has remained largely unexplored. Like any other molecule, graphene can involve in chemical reactions. The chemical functionalization is probably one of the best approaches to detect imperfections in a graphene sheet (Boukhvalov and Katsnelson 2008). The functionalized graphene can be suitable for specific applications. Research on bended, folded, and scrolled graphene is rapidly growing now.

Fullerenes

Discovery of fullerene C_{60} and other fullerene molecules is discussed below.

The fullerene era started in 1985; Kroto and his colleagues obtained cold carbon clusters when they carried out an experiment to simulate the condition of red giant

(2009) and Boukhalov and Katsnelson (2008). Copyright 2008 and 2009 American Chemical Society)

star formation. With the use of the mass spectrometer, they found a large peak commensurate with 60 carbon atoms (Kroto et al. 1985). The molecule C_{60} was proposed to have a football structure, known to mathematicians as the truncated icosahedron. The shape is composed of 12 pentagons located around the vertices of an icosahedron and 20 hexagon rings placed at the centers of icosahedral faces. The C_{60} molecule was named “buckminsterfullerene” in honor of the renowned architect Buckminster Fuller, who designed geodesic domes based on similar pentagonal and hexagonal structures. The carbon atoms in C_{60} fullerene are arranged in exactly the same way, albeit much smaller, as the patches of leather found on the common football (Fig. 6a).

Since the remarkable discovery of fullerenes in 1985 (Kroto et al. 1985), these new carbon allotropes have received significant attention from the scientific

community and still exhibit vast interest (Lu and Chen 2005; Thilgen and Diederich 2006). The 1996 Nobel Prize in Chemistry was awarded to Sir Harold W. Kroto, Robert F. Curl, and the late Richard E. Smalley for their discovery of fullerenes. Essentially, the most prominent representative of the fullerene family is C_{60} . In early 1990, a method was discovered for producing macroscopic amounts of this fascinating molecule (Krättschmer et al. 1990). This breakthrough allowed scientists to explore the properties of C_{60} and understand its chemistry. Krättschmer et al. characterized the fullerene C_{60} using mass spectroscopy, infrared spectroscopy, electron diffraction, and X-ray diffraction (Krättschmer et al. 1990). Both Kroto et al. (1985) and Krättschmer et al. (1990), by means of mass spectroscopy, also characterized the fullerene C_{70} . Pure C_{60} and C_{70} fullerenes were isolated and separated by Kroto and coworkers (Taylor et al. 1990). The stable fullerenes of C_{60} and C_{70} were reported in the ratio of approximately 5:1. ^{13}C nuclear magnetic resonance (NMR) spectroscopy was used to characterize the fullerenes (Taylor et al. 1990). These two molecules are members of a homologous series of hollow closed-cage molecules. The fullerene C_{70} belongs to a class of nonspherical fullerenes. It adopts an ellipsoidal shape (point group D_{5h}) and it looks like a “rugby ball” as

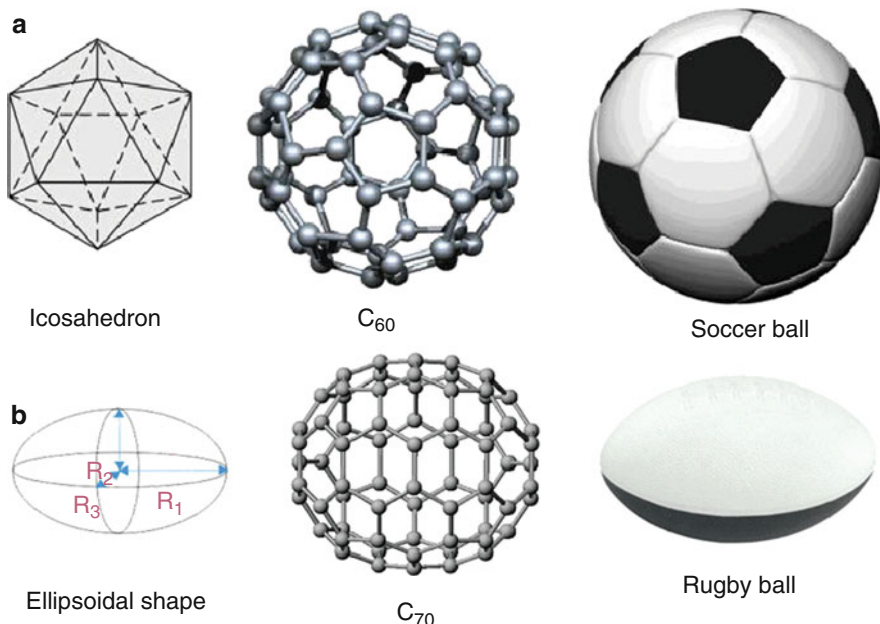

Fig. 6 The structures of fullerenes C_{60} and C_{70} and their familiar shapes. C_{60} and C_{70} are in icosahedron (I_h) and D_{5h} point groups

shown in Fig. 6b. Existence of C_{60} was predicted by Eiji Osawa (1970). However, his prediction did not reach Europe or America since it was published in Japanese magazine.

In the eighteenth century, the Swiss mathematician Leonhard Euler demonstrated that a geodesic structure must contain 12 pentagons to close into a spheroid, although the number of hexagons may vary. Later research by Smalley and his colleagues showed that there should exist an entire family of these geodesic-dome-shaped carbon clusters (Kroto et al. 1985). Fullerenes form with an even number $n \geq 20$ of three connected vertices, $3n/2$ edges, 12 pentagonal faces, and $(n-20)/2$ hexagonal faces (Fowler and Manolopoulos 1995; Kroto et al. 1985). Thus, C_{60} has 20 hexagons, whereas its “rugby ball”-shaped cousin C_{70} has 25 hexagons. As hexagons are added or removed, the molecule begins to lose its roundness. Giant fullerenes take on a pentagonal shape. Smaller fullerenes look like asteroids. One should note that all of the fullerenes have the same Gaussian curvature sign; therefore all of them have a convex surface. The buckminsterfullerene C_{60} , shown in Fig. 6, has a spherical-like shape and the full group of symmetry of the icosahedron (I_h), which means that it could be rotated by the angle of $2\pi/5$ around the center of each pentagon and reflected in the mirror located on each plane of its symmetry. Another class of spherical fullerenes like C_{140} and C_{260} lacks the mirror symmetry h ; hence, their maximum symmetry group is icosahedral (I) (Terrones et al. 2002).

The fullerenes C_{60} and C_{70} were identified in carbon flames, and their ratios depend on the temperature, pressure, carbon/oxygen ratio, and residence time in the flame (Howard et al. 1991). The molecular structure of C_{70} was deduced from electron diffraction using a simulated-annealing method (McKenzie et al. 1992). Scientists tried to understand the crystal structures of C_{60} and C_{70} using X-ray diffraction technique (David et al. 1991, 1992; Fischer et al. 1991; Valsakumar et al. 1993). At ambient temperature and pressure, C_{60} crystals have face-centered cubic (fcc) structure with a lattice constant of 14.17 Å (David et al. 1991), while the C_{70} crystals adopt to a hexagonal close-packed (hcp) structure with $a = 10.1$ Å and $c = 17.0$ Å (David et al. 1992). The average diameters of C_{60} and C_{70} fullerenes are about 7 and 9 Å, respectively. Since the discovery of C_{60} followed by C_{70} (Kroto et al. 1985; Taylor et al. 1990), different sizes of carbon cage fullerenes were revealed. In early 1990, the carbon cages of C_{76} , C_{84} , C_{90} , and C_{94} were characterized by mass spectrometry, ^{13}C NMR, electronic absorption (ultraviolet–visible), and vibrational (infrared) spectroscopy techniques (Diederich et al. 1991a). As compared with C_{60} and C_{70} , the isolation of higher fullerenes is really challenging, and their characterization is complicated by the presence of a varying number of isomers.

Fullerenes are generally represented by a formula C_n , where n is an even number and denotes the number of carbon atoms present in the cage. Theoretical calculations predicted that fullerenes larger than C_{76} should have at least two isomeric forms (Manolopoulos and Fowler 1991). For fullerenes C_{84} and C_{96} , 24 and 187 distinct isomers were predicted, respectively (Manolopoulos and Fowler 1991, 1992). Three isomers for C_{78} and two isomers for C_{84} were isolated and characterized by ^{13}C NMR spectroscopy (Kikuchi et al. 1992a). Some of the isomers of C_{78} and C_{82} proposed by experimental ^{13}C NMR spectroscopy are depicted in Fig. 7. Many of the unique properties of fullerenes originate from their unusual cage structures. Therefore, determining the ground-state geometries of the fullerenes was considered to be an important step in understanding their unusual properties.

Experimental works are very limited for higher fullerenes beyond C_{84} because such species are difficult to isolate in pure form in quantities suitable for comprehensive study. Synthesis of C_{60} , in isolable quantities, was achieved using flash vacuum pyrolysis (FVP) technique by Scott and coworkers by 12 steps in 2002, and no other fullerenes were formed as by-products (Scott et al. 2002). Larger fullerene C_{78} was synthesized using the same FVP technique used for C_{60} synthesis (Amsharov and Jensen 2008). This shows a promise for the synthesis of higher fullerenes. It is noteworthy to mention that there has been a lot of experimental and theoretical studies involving fragments of fullerenes, called “buckybowls” (Barth and Lawton 1966; Dinadayalane and Sastry 2001, 2002a, b; Dinadayalane et al. 2001, 2002, 2003, 2004; Mehta and Rao 1998; Mehta et al. 1997; Priyakumar and Sastry 2001a, b, c; Sakurai et al. 2003; Sastry and Priyakumar 2001; Sastry et al. 1993, 2000; Seiders et al. 1999; Sygula and Rabideau 1999; Wu and Siegel 2006). The smallest buckybowl “corannulene” was synthesized nearly 20 years prior to the discovery of fullerene C_{60} (Barth and Lawton 1966). Another small fragment of C_{60} called

“sumanene” was successfully synthesized in 2003 after so many futile attempts by different groups (Sakurai et al. 2003).

Fullerene can be classified into (a) classical fullerene and (b) nonclassical fullerene. The former one is a closed carbon cage containing 12 pentagons and any number of hexagons, while a nonclassical fullerene can have heptagons, octagons, and an additional number of pentagons or squares. Growing classical fullerenes from nonclassical fullerenes, for example, from C_{50} to C_{60} by the dimer addition, was proposed (Hernández et al. 2001). However, there is no clear experimental evidence for fullerene formation through this route. The experimental evidence was reported for the formation of fullerenes by collisional heating of carbon rings in the gas phase (Helden et al. 1993). Various mechanisms have been proposed so far for the formation of fullerenes. They can be divided into two major models: the pentagon road (PR) model (Klein and Schmalz 1990; Maruyama and Yamaguchi 1998; Smalley 1992) and the fullerene road (FR) model (Heath 1991).

Fig. 8 The structures of giant fullerenes (Reprinted with permission from Zope et al. (2008). Copyright 2008 by the American Physical Society)

Since the discovery of C_{60} , scientists showed vast interest in larger fullerenes. Therefore, the family of fullerenes increased, and now it also includes C_{70} , C_{76} , C_{78} , C_{82} , C_{84} , C_{86} , C_{88} , C_{90} , C_{92} , C_{94} , and C_{96} (Diederich et al. 1991a, b; Kikuchi et al. 1992b; Kimura et al. 1995; Miyake et al. 2000; Mizorogi and Aihara 2003; Taylor et al. 1992, 1993). The fundamental understanding of the size dependence of the closed carbon cage structures is important for tailoring these systems for possible nanotechnology applications. Larger fullerenes that have an icosahedral symmetry can also be constructed. This procedure generates 12 pentagons positioned around vertices of an icosahedron, while all other carbon rings are hexagonal. In general, there are two kinds of fullerenes with I_h symmetry, one being $n = 60 k^2$ and the other $n = 20 k^2$, where n is the number of carbon atoms and k is any positive integer (Miyake et al. 2000). Figure 8 depicts some of the giant fullerene structures, where C_{180} and C_{720} belong to $180 k^2$ family of icosahedral fullerenes, but all other structures belong to $60 k^2$ family of icosahedral fullerenes. For more than a decade, these giant fullerenes have been fascinating molecules for theoreticians (Calaminici et al. 2009; Dulap and Zope 2006; Dunlap et al. 1991; Gueorguiev et al. 2004; Lopez-Urias et al. 2003; Tang and Huang 1995; Tang et al. 1993; Zope et al. 2008).

The closed carbon cages smaller than C_{60} consist of adjacent pentagons. Such smaller fullerenes are predicted to have unusual electronic, magnetic, and mechanical properties that arise mainly from the high curvature of their molecular surface (Kadish and Ruoff 2002). A dodecahedron consisting of 20 carbon atoms with only pentagon rings is topologically the smallest possible fullerene. The well-known isomers of C_{20} are cage, bowl, and ring as shown in Fig. 9. The bowl-shaped isomer is reminiscent of corannulene. The realization of the smallest carbon closed-cage C_{20} , which exclusively contains 12 pentagons, was doubtful

Fig. 9 Isomers of C_{20} : cage-, bowl-, and ring-shaped structures (Reprinted with permission from Macmillan Publishers Ltd.: Nature, reference Prinzbach et al. (2000), Copyright 2000)

until 2000. The C_{20} closed cage has extreme curvature and high reactivity, which led to doubts about its existence and stability (Wahl et al. 1993). Prinzbach et al. produced the smallest fullerene C_{20} from its perhydrogenated form in the gas phase and also obtained the bowl- and ring-shaped isomers for comparison purposes (Prinzbach et al. 2000). All these structures were characterized by photoelectron spectroscopy (PES) and their electron affinities vary significantly (Prinzbach et al. 2000). Theoretical calculations at different levels predicted dissimilar energetic ordering for these three isomers. However, all revealed very small relative energies of isomers. MP2 method predicted the fullerene to be the most stable followed by the bowl and then the ring, and this prediction is very similar to the calculations of density functional theory (DFT) using the local density approximation (LDA). Complete reversal of the stability ordering was obtained in the calculations with Becke–Lee–Yang–Parr (BLYP) functional. Some other DFT functionals predicted the bowl to be the most stable structure, closely followed by the fullerene isomer (Scuseria 1996). Hybrid density functional theory and time-dependent DFT formalism validated the synthesis of the smallest cage fullerene C_{20} by comparing the computed photoelectron spectra with the experimental results (Saito and Miyamoto 2001).

Closed-cage structure of C_{36} was detected by mass spectroscopy in very early days of fullerene science (Kroto 1987; Rohlffing et al. 1994). Zettl's group claimed the first preparation of C_{36} in the solid form (Piskoti et al. 1998). However, the existence of C_{36} has not been fully confirmed to date. C_{36} has 15 conventional fullerene isomers, out of which the D_{6h} and D_{2d} have a minimal number of pentagons (Fowler and Manolopoulos 1995). Therefore, these two are potential candidates for the most stable structure. In general, the number of isomers increases as the carbon cage size increases for these small fullerenes as shown in Fig. 10.

Fullerenes from C_{20} to C_{58} have been extensively studied by theoreticians (Fowler and Manolopoulos 1995; Scuseria 1996; Shao et al. 2007). They have been predicted to have narrow HOMO–LUMO gaps and high reactivity. The structures, aromaticity, reactivity, and other properties of fullerenes smaller than 60 carbon atoms were reviewed (Lu and Chen 2005). Readers may refer to the review by

Fig. 10 Number of isomers for the closed carbon cages from C_{20} to C_{58} (Data was taken from reference Fowler and Manolopoulos 1995)

Lu and Chen and the references therein for detailed understanding and further knowledge if required (Lu and Chen 2005). Selected structures of smaller fullerenes and their isomers are depicted in Fig. 11. Schlegel diagram is commonly used by scientists to sketch the fullerenes in planar view, which is very helpful in identifying atoms and the C–C bonding networks (Fowler and Heine 2001; Thilgen and Diederich 2006; Troyanov and Tamm 2009). Figure 12 depicts the Schlegel diagram for fullerenes C_{20} , C_{36} , C_{60} , and C_{70} .

Natural Abundance of Fullerenes

Scientists discovered the presence of natural fullerenes on Earth. Interestingly, occurrence of fullerenes such as C_{60} and C_{70} was reported in shungite, a meta-anthracite coal from a deposit near Shunga, Russia (Buseck et al. 1992). The presence of C_{60} at very low concentrations in Cretaceous–Tertiary boundary sites in New Zealand was published (Heymann et al. 1994). Fullerenes (C_{60} and C_{70}) were found in a unit of shock-produced impact breccias (Onaping Formation) from the Sudbury impact structure in Ontario, Canada (Becker et al. 1994). The abundance of naturally occurring fullerenes was found in carbon materials, for example, coal, rocks, interstellar media, and even dinosaur eggs (Heymann et al. 2003).

Fig. 11 Representative structures of smaller fullerenes and low-energy isomers are given for some of them. The pentagon–pentagon fusions are highlighted in blue color only for C_{52} , C_{54} , C_{56} , and C_{58} . The point groups are given in parentheses (Reprinted with permission from reference Lu and Chen (2005). Copyright 2005 American Chemical Society)

Fullerene Nano-capsules

In the area of fullerene science, one should not forget to mention an interesting property of holding the atoms or ions or molecules inside the fullerene cage (Thilgen and Diederich 2006). Fullerenes are potential nano-capsules. Experimental detection of the nano-capsules of fullerenes such as $\text{La}@C_{60}$, $\text{La}@C_{70}$, $\text{La}@C_{74}$, $\text{La}@C_{76}$, $\text{La}@C_{78}$, $\text{La}@C_{82}$, and $\text{Ce}_2@C_{80}$ was reported (Kessler et al. 1997; Kubozono et al. 1996; Moro et al. 1993; Saunders et al. 1993; Thilgen and Diederich 2006; Yamada et al. 2005, 2010). Fullerenes are known in the field of radioactive chemistry/physics. Radioactive nuclear materials can be stored by encapsulating inside the fullerenes. $\text{U}@C_{28}$, $\text{Gd}@C_{60}$, and $\text{Gd}@C_{82}$ are few examples of encapsulated radioactive materials (Guo et al. 1992; Kubozono et al. 1996). The stability of these metallic fullerenes could bring the new effective solution of the radioactive waste elimination. For the substance enclosed in the fullerene nano-capsule, carbon atoms act like a defense shield, and the fullerene containers are good for protecting their contents from water and acid. The structures, stabilities, and reactivities of encapsulated fullerenes (nano-capsules) and doped fullerenes have been the subject of theoretical interest (Guo et al. 1992; Lu et al. 2000; Park et al. 2005; Simeon et al. 2005; Wang et al. 2003; Wu and Hagelberg 2008; Zhao and Pitzer 1996). The closed-cage “fullerenes” or “heterofullerenes” can be placed inside the

Fig. 12 Schlegel diagrams of C_{20} , C_{36} , C_{60} , and C_{70} fullerenes. The point groups are given in parentheses, systematic numbering recommended by IUPAC (Pictures were reprinted with permission from reference Thilgen and Diederich (2006). Copyright 2006 American Chemical Society. Reference Fowler and Heine (2001). Copyright 2001 Royal Society of Chemistry)

single-walled carbon nanotubes, for example, C_{60} @SWCNT (Hirahara et al. 2000; Okada 2007; Smith et al. 1999). Leszczynski and coworkers have explored the mechanism of the catalytic activity of fullerene derivatives using reliable computational methods (Sulman et al. 1999; Yanov et al. 2004). Fullerenes are certainly worthy of scientific study because of their unique shape and intriguing properties.

Isolated Pentagon Rule (IPR) in Fullerenes

A wide range of methods available for producing fullerenes concluded that C_{60} is the most abundant and is followed by C_{70} (Kadish and Ruoff 2002). The pristine C_{60} (I_h) contains two different C–C bonds: the one at the junction of two six-membered rings and the other one at the junction of a five- and a six-membered rings. These two bonds are usually labeled as a [6,6] and [5,6] C–C bonds, respectively. The pristine

Fig. 13 Fullerene size versus number of isolated pentagon rule (IPR) isomers (The data was taken from reference Manolopoulos and Fowler (1992))

C_{70} (D_{5h}) has eight distinguishable C–C bonds. It has been known to chemists that energetically it is not favorable to have two pentagons sharing the same C–C bond. There are 1812 mathematical ways of forming a closed cage with 60 carbon atoms (isomers), but the buckminsterfullerene C_{60} (I_h) is the most special and stable because all of its pentagons are isolated by hexagons. This condition is called the “isolated pentagon rule” (IPR), which tends to make fullerenes more stable (Fowler and Manolopoulos 1995).

In fact, C_{60} is the smallest fullerene cage that obeys the isolated pentagon rule. Fullerenes C_{62} , C_{64} , C_{66} , and C_{68} do not satisfy the IPR. The next fullerene, which follows the IPR, is C_{70} (it has 8149 possible isomers). Also, C_{72} has an IPR structure. Most of the higher fullerenes have proven to follow IPR (Kroto 1987). Only one IPR-obeying isomer exists for C_{60} and for C_{70} (Fowler and Manolopoulos 1995), while the number of possible IPR isomers increases rapidly with increase in the size of the fullerenes as shown in Fig. 13. Fullerene C_{78} has five isomers that satisfy the IPR. Three isomers (two with C_{2v} and one with D_3 symmetry) out of these five were identified and characterized using ^{13}C NMR spectra (Kikuchi et al. 1992a). The fourth isomer (D_{3h} - C_{78}) has been recently separated and characterized in the form of $C_{78}(\text{CF}_3)_{12}$ (Shustova et al. 2006, 2007), and the last one has been synthesized using FVP technique (Amsharov and Jensen 2008). Theoretical study predicted that

C_{82} has nine IPR-satisfying isomers (Manolopoulos and Fowler 1991), out of which three isomers with C_2 symmetry were experimentally characterized using ^{13}C NMR spectroscopy, which gave 41 NMR lines with nearly equal intensity (Kikuchi et al. 1992a).

There are 24 geometric isomers satisfying IPR and 51,568 non-IPR isomers are possible for fullerene C_{84} (Fu et al. 2009). Earlier experimental ^{13}C NMR spectroscopy studies characterized two IPR isomers with D_2 and D_{2d} point groups (Kikuchi et al. 1992a; Taylor et al. 1993). Third isomer was also identified and reported (Achiba et al. 1995; Crassous et al. 1999). Pure D_2-C_{84} was synthesized (Dennis and Shinohara 1998). A theoretical study revealed that C_{84} cage is special in the family of fullerenes from C_{60} to C_{90} since the number of preferable isomers is larger than in the case of other fullerenes. The geometries of all of the 24 IPR isomers of fullerene C_{84} along with their point groups were reported (Okada and Saito 1996). Two IPR isomers of C_{86} out of possible 19 isomers were separated using multistage HPLC (high-performance liquid chromatography) (Miyake et al. 2000), and these two isomers were characterized to have C_2 and C_s point groups by ^{13}C NMR spectroscopy (Taylor et al. 1993). Burda et al. showed the experimental evidence for the photoisomerization of higher fullerenes. They confirmed the theoretical prediction that C_{86} has less number of IPR-satisfying isomers (19 isomers) than C_{84} (24 isomers) (Fig. 14; Burda et al. 2002). Experimental studies based on ^{13}C NMR spectroscopy revealed that fullerenes C_{88} and C_{92} possess 35 and 86 IPR isomers, respectively, and HPLC was used to separate the isomers (Achiba et al. 1996; Miyake et al. 2000; Tagmatarchis et al. 2002). Computational methods

Fig. 14 Correlation between the number of isomers (dotted line as a visual guide) for each fullerene and the time constant for the formation of the lowest excited singlet state monitored at 550 nm (dots) (Reprinted with permission from reference Burda et al. (2002). Copyright 2002 American Chemical Society)

were used to calculate relative energies of the IPR isomers and the ^{13}C NMR spectra of fullerenes (Shao et al. 2006; Slanina et al. 2000a, b; Sun 2003). The computed ^{13}C NMR spectra were interpreted with the available experimental data (Beavers et al. 2006; Chaur et al. 2009a, b; Melin et al. 2007; Rojas et al. 2007; Scheina and Friedrich 2008; Shao et al. 2006; Slanina et al. 2000a, b; Sun 2003; Xie et al. 2004). Theoretical calculations predicted that C_{88} (**33**) is one of the most stable IPR isomers (Shao et al. 2006). The number provided in the parenthesis is the isomer number. In consistent to the theoretical prediction, Troyanov and Tamm reported the isolation and X-ray crystal structures of trifluoromethyl derivatives of C_{88} (**33**) and C_{92} (**82**) fullerene isomers complying with the isolated pentagon rule (Troyanov and Tamm 2009).

Rojas et al. showed the experimental evidence of the decreasing trend in the gas-phase enthalpy of formation and strain energy per carbon atom as the size of the cluster increases. Thus, the fullerenes become more stable as they become larger in size (Rojas et al. 2007). Interestingly, molecules encapsulated inside the carbon cages stabilize the fullerene isomers that violate IPR (Beavers et al. 2006; Fu et al. 2009; Thilgen and Diederich 2006). Several IPR and non-IPR endohedral fullerenes (single metal, di-metal, or tri-metal nitride encapsulated fullerenes) were isolated and characterized experimentally (Beavers et al. 2006; Chaur et al. 2009a, b; Fu et al. 2009; Melin et al. 2007; Thilgen and Diederich 2006), and their isolation motivated significant theoretical interest (Fu et al. 2009; Park et al. 2005; We and Hagelberg 2008). The structures and relative energies of the IPR isomers of buckybowls were examined using computational methods (Dinadayalane and Sastry 2003). Head-to-tail exclusion rule was proposed in explaining the stability of carbon cage structures that obey the IPR (Scheina and Friedrich 2008).

Fullerenes with less than 60 carbon atoms cannot have isolated pentagons and therefore they should be highly unstable and reactive. Xie et al. synthesized non-IPR $D_{5h}\text{-C}_{50}$ fullerene, which is a little sister of C_{60} , by introduction of chlorine atoms at the most reactive pentagon–pentagon vertex fusions. They confirmed the $D_{5h}\text{-C}_{50}$ structure by mass spectrometry, infrared, Raman, ultraviolet–visible, and fluorescence spectroscopic techniques (Xie et al. 2004). The report of novel small cage “Saturn-shaped” $\text{C}_{50}\text{Cl}_{10}$ structure encourages the possibility of obtaining other small non-IPR fullerenes and their derivatives. The investigations of the properties and applications of small fullerenes and their derivatives are now open.

Common Defects in Fullerenes

Stone and Wales examined rotation of C–C bonds in various fullerene structures using approximate Huckel calculations. The 90° rotation of C–C bond in fullerene is called Stone–Wales (SW) or “pyraclyene” rearrangement (Fig. 15; Stone and Wales 1986). Austin et al. reported that 94 % of all fullerene C_{60} isomers can rearrange to buckminsterfullerene by SW transformation (Austin et al. 1995). The C_{78} cage represents the smallest fullerene in which SW rearrangement can give

Fig. 15 (a) Stone–Wales or “pyracylene” transformation in fullerenes interchanges pentagons and hexagons; (b) Stone–Wales transformation of C_{2v} isomer of C_{60} with two adjacent pentagons gives the most stable I_h buckminsterfullerene; the C–C bond involved in 90° rotation is highlighted, and the two adjacent pentagons are marked in the fullerene structure in left-hand side

stable IPR isomers, $C_{78}:5$ (D_{3h}) \leftrightarrow $C_{78}:3$ (C_{2v}) \leftrightarrow $C_{78}:2$ (C_{2v}) \leftrightarrow $C_{78}:4$ (D_{3h}), where the numbers 5, 3, 2, and 4 indicate the isomer numbers (Austin et al. 1995). In case of higher fullerenes, the number of IPR isomers that can be transformed one into another by SW rearrangement considerably increases. For example, the SW transformation gives 9 and 21 stable IPR isomers for C_{82} and C_{84} , respectively (Fowler and Manolopoulos 1995). The SW transformation is usually thought to be the possible mechanism for achieving fullerene isomers (Austin et al. 1995; Fowler and Manolopoulos 1995; Stone and Wales 1986).

It was proposed that fullerenes can have seven-membered rings in addition to five- and six-membered rings (Taylor 1992). Troshin et al. isolated and characterized the C_{58} fullerene derivatives in which the cage structure contains the seven-membered ring. The structures were characterized using mass spectrometry, IR, and NMR spectroscopy (Troshin et al. 2005). Smalley and coworkers found that laser irradiation can fragment C_{60} into C_{58} , C_{56} , C_{54} , and other smaller cages with even number of carbon atoms via losing C_2 fragments (O’Brien et al. 1988). The formation of seven-membered rings was considered to play an important role in the fragmentation process of fullerenes (Murry et al. 1993). The laser desorption/ionization of products generated from the reactions of C_{60} with O_3 gives the odd-numbered clusters such as C_{59} , C_{57} , C_{55} , and C_{53} (Christian et al. 1992; Deng et al. 1993). Vacancy defects destroy the original topology of five- and six-membered rings in fullerenes (Christian et al. 1992; Deng et al. 1993; Hu and Ruckenstein 2003, 2004; Lee and Han 2004; Murry et al. 1993; O’Brien et al. 1988). They generate various sizes of rings such as four-, seven-, eight-, and nine-membered rings and also produce the new five- and six-membered rings depending on the number of carbon atom vacancies (Fig. 16; Christian et al. 1992; Deng et al.

Fig. 16 Buckminsterfullerene (perfect structure); vacancy defect fullerenes generated from C_{60} : (a) mono-vacancy, (b) di-vacancy, (c) tri-vacancy, (d) three different structures of tetra-vacancy (Reprinted with permission from Hu and Ruckenstein (2004). Copyright 2004, American Institute of Physics)

1993; Hu and Ruckenstein 2003, 2004; Lee and Han 2004; Murry et al. 1993; O'Brien et al. 1988).

Carbon Nanotubes (CNTs)

Discovery and Classification of CNTs

Modern “nanotechnology revolution” was flourished by the discovery of fullerenes and has been escalating since the isolation of multi- and single-walled carbon nanotubes. The detection of carbon nanotubes by Iijima in 1991 is one of the landmarks in nanotechnology (Iijima 1991). In the interview to Nature Nanotechnology, Iijima told that the discovery of carbon nanotubes was unexpected but not entirely accidental because he had accumulated a lot of experience in looking at short-range order in carbon species such as amorphous carbon and very thin graphite sheets (Iijima 2007). The discovery of buckminsterfullerene by Kroto, Curl, Smalley, and coworkers motivated Iijima’s interest in finding out new carbon allotropes (Kroto et al. 1985).

There are two structural forms of carbon nanotubes: multi-walled carbon nanotubes (MWCNTs) and single-walled carbon nanotubes (SWCNTs). The former one was reported by Iijima (1991). The SWCNTs were reported independently by Iijima as well as Bethune groups (Bethune et al. 1993; Iijima and Ichihashi 1993). The existence of carbon nanotubes was reported as early as 1952 and also in 1976

Fig. 17 Representative structures of (a) multi-walled and (b) single-walled carbon nanotubes

(Oberlin et al. 1976; Radushkevich and Lukyanovich 1952). However, those reports did not reach the wide range of scientific community because they were published in unpopular journals, and at that time, no fabrication process was known that would lead to the synthesis of macroscopic amounts of carbon nanotubes (Oberlin et al. 1976; Radushkevich and Lukyanovich 1952). Monthioux and Kuznetsov documented the history of carbon nanotube since 1952 (Monthioux and Kuznetsov 2006). Synthesis of carbon nanotube using coal pyrolysis was reported (Moothi et al. 2015).

High-resolution electron microscopy (HREM) images of the CNTs showed the resemblance of a “Russian doll” structural model that is based on hollow concentric cylinders capped at both ends. The model structures of multi-walled and single-walled carbon nanotubes are shown in Fig. 17. A wide range of methods, such as arc evaporation of graphite, laser ablation, chemical vapor deposition (CVD), vapor phase decomposition or disproportionation of carbon-containing molecules, etc., have been reported for the synthesis of multi-walled and single-walled carbon nanotubes (Dresselhaus et al. 2001). It remains unclear whether SWCNTs and MWCNTs are formed via the same mechanism. It is also unclear whether various methods used to produce carbon nanotubes are mechanistically consistent (Dresselhaus et al. 2001). For the transformation pathway, fullerenes are known to be a suitable carbon source for MWCNT growth under certain conditions (Suchanek et al. 2001). An ideal MWCNT consists of cylindrical tubes in which the neighboring tubes are weakly bonded through van der Waals forces. The MWCNT is incommensurate when each of its walls has its own chirality independent of other walls.

SWCNT, which is a one-dimensional (1D) system, can be considered as the conceptual rolling of a section of two-dimensional (2D) graphene sheet into a seamless cylinder forming the nanotube. The structure of SWCNT is uniquely described by two integers (n, m), which refer to the number of \vec{a}_1 and \vec{a}_2 unit vectors of the 2D graphene lattice that are contained in the chiral vector, $C_h = n\vec{a}_1 + m\vec{a}_2$. The chiral vector determines whether the nanotube is a semiconductor, metal, or semimetal. From the (n, m) indices, one can calculate the nanotube diameter (d_t), the chirality or chiral angle (θ), the electronic energy bands, and the density of electronic states. The nanotube diameter (d_t) determines the number of carbon atoms in the circular cross section of the nanotube shell, one atom in thickness (Saito et al. 1998). The tube diameter and chiral angle can be written in terms of (n, m) as

$$\text{Tube diameter, } d_t = \left(\sqrt{3}/\pi\right) a_{cc} \left(\sqrt{m^2 + mn + n^2}\right).$$

$$\text{Chiral angle, } \theta = \tan^{-1} \left\{ \sqrt{3} \frac{m}{2n + m} \right\},$$

where a_{cc} is the nearest-neighbor carbon atom distance of 1.421 Å.

Among the large number of possible C_h vectors, there are two inequivalent high-symmetry directions. These are termed “zigzag” and “armchair” and are designated by ($n,0$) and (n,n), respectively. Either achiral (armchair and zigzag) or chiral SWCNTs can be constructed depending on the orientation of the six-membered rings with respect to the nanotube axis. Schematic representation of the structures of armchair, zigzag, and chiral SWCNTs is shown in Fig. 18. Theoretical studies in 1992 predicted that the electronic properties of “ideal” SWCNTs depend on the width and chirality of the tubes (Hamada et al. 1992; Mintmire et al. 1992; Saito et al. 1992). The electronic properties of an SWCNT vary in a periodic way between being metallic and semiconductor. SWCNTs are metals if $(n-m)/3$ represent an integer; otherwise, they are called semiconductors (Dresselhaus et al. 2002).

Several metallic (n, m) nanotubes have almost the same diameter d_t (from 1.31 to 1.43 nm), but have different chiral angles: $\theta = 0, 8.9, 14.7, 20.2, 24.8,$ and 30.0° for nanotubes (18, 0), (15, 3), (14, 5), (13, 7), (11, 8), and (10, 10), respectively (Dresselhaus et al. 2002). Few people realize that CNTs constitute a large family with a wide variety of sizes and properties, which are determined by their structure and composition, including chirality, number of walls, ordering of the wall, defects, surface functionalization, and other features.

Strano sorted out chiral SWCNTs into left-handed and right-handed tubes (Strano 2007). Significant progress has been made in the area of carbon nanotubes. Scientists are able to disperse, identify, sort, and now also isolate various types of carbon nanotubes (Arnold et al. 2006; Peng et al. 2007; Strano 2003, 2007). Specific methods were found to grow long SWCNTs and control the nanotube diameters (Lu et al. 2008; Zhang et al. 2008). Controlled synthesis of nanotubes

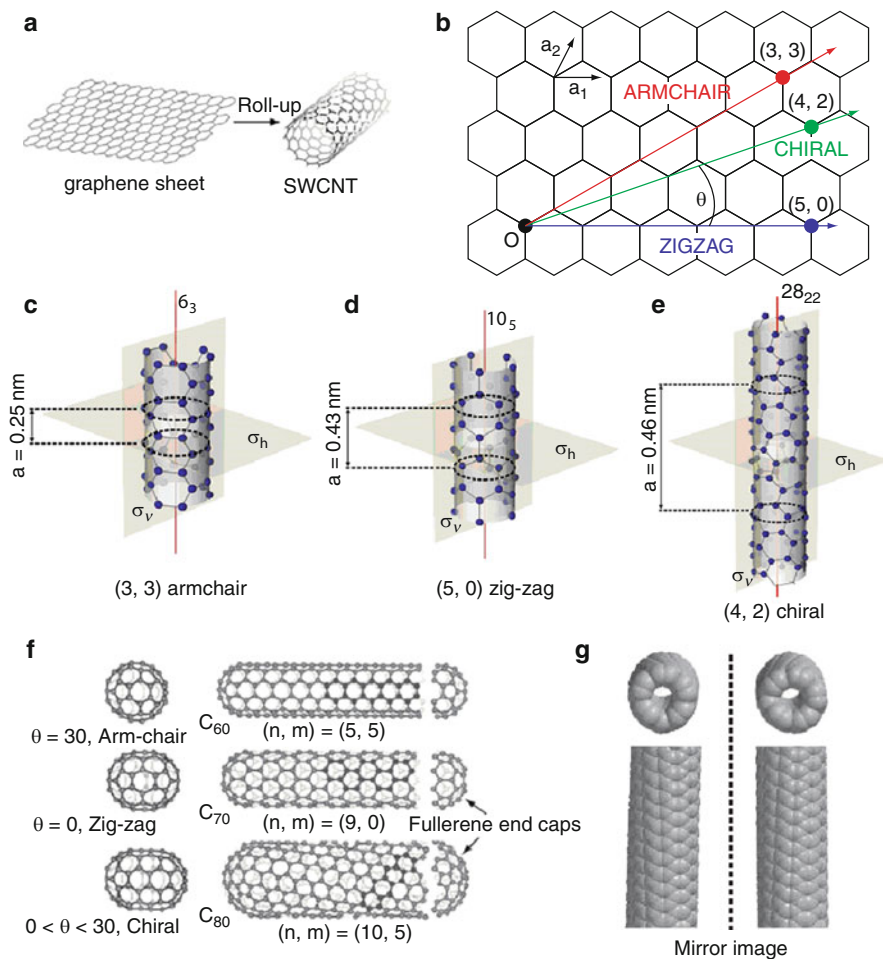

Fig. 18 (a) The roll-up of graphene sheet into SWCNT; (b) picture shows how to roll up graphene sheet to generate three different types of SWCNTs; (c) (3,3) armchair SWCNT; (d) (5,0) zigzag SWCNT; (e) (4,2) chiral SWCNT; (f) three types of SWCNTs (armchair, zigzag, and chiral) with fullerene end caps. These can be viewed as the growth of SWCNTs by adding several layers of hexagonal rings at the middle of different fullerenes; (g) mirror image of the chiral SWCNT; the structures (c), (d), and (e) are given exactly same types of SWCNTs that are mentioned in (b). In (c)–(e), σ_v and σ_h indicate the vertical plane of symmetry and horizontal plane of symmetry, respectively. Further, in these three structures, the red line is the axis of rotation; the distance of one unit cell for these three types of SWCNTs is provided; the number of carbon atoms (x) in each layer and the number of layers (y) required for one unit cell is given as x_y , for example, -6_3 means six carbon atoms in each layer and three layers required for one unit cell of (3,3) armchair SWCNT (Pictures (b) and (g) were reprinted with permission from Macmillan Publishers Ltd.: Nature Nanotech., reference Strano (2007), Copyright 2007)

opens up exciting opportunities in nanoscience and nanotechnology (Dai 2002). A range of methods was found for effective separation of metallic and semiconducting SWCNTs. Although some synthetic procedures have been known, they are not easy methods for synthesizing bulk quantities of metallic and semiconducting SWCNTs (Zhang et al. 2008). Scientists succeeded the preferential growth of SWCNTs with metallic conductivity (Rao et al. 2009a).

Raman and electronic spectroscopy techniques are useful in characterizing metallic and semiconducting SWCNTs. The radial breathing mode (RBM) in Raman spectra of SWCNTs is helpful in determining the diameter and chiral indices (n, m) of the nanotubes (Dresselhaus et al. 2002, 2005, 2007; Harutyunyan et al. 2009; Rao et al. 2009a). Experimental results pointed out decreasing band gap with increasing radius of the armchair SWCNTs (Fig. 19; Ouyang et al. 2002). Another breakthrough in carbon nanotube chemistry was accounted by Zhang and Zuo, who have determined a quantitative atomic structure of MWCNT containing five walls with diameter ranging from 17 to 46 Å and the C–C bond lengths of individual SWCNTs using electron diffraction technique (Zhang and Zuo 2009). Their results indicate that there are three different bond lengths in chiral walls and two different bond lengths in achiral walls (Zhang and Zuo 2009). Electron diffraction technique was used in determination of atomic structure of SWCNTs and the chiral indices (n,m) of CNTs (Jiang et al. 2007; Qin 2007). Rao et al. have revealed the efficient growth of SWCNTs of diameter 1–3 nm from diamond nanoparticles and fullerenes (Rao et al. 2009b). Recently, experimental reports are available to create three-dimensional graphene-CNT hollow fibers with radially aligned CNTs seamlessly sheathed by a cylindrical graphene layer through a

one-step chemical vapor deposition using an anodized aluminum wire template for efficient energy conversion and storage (Xue et al. 2015; Yu et al. 2014; Zhu et al. 2012).

SWCNTs have stimulated vast interest due to their unique structural, mechanical, electronic, thermal, and chemical properties and their potential applications in diversified areas. There has been enormous growth in patents related to carbon nanotubes, fuelled by predictions that the market for nanotubes will be \$9 billion by 2020. Between 1994 and 2006, it was estimated that 1865 nanotube-related patents were issued in the USA. Still, there is a cumulative backlog of more than 4500 patent applications relevant to CNT as reported in 2008 (MacKenzie et al. 2008).

Since there are reports of the natural abundance of fullerenes (Becker et al. 1994; Buseck et al. 1992; Heymann et al. 1994, 2003), the issue of the natural occurrence of carbon nanotubes has also attracted the attention of researchers. In 2004, TEM images that appear to be MWCNTs isolated from a Greenland ice core were reported (Esquivel and Murr 2004). The images of hollow carbon fibers from oil-well samples were reported (Velasco-Santos et al. 2003). However, we do not have any evidence for naturally occurring SWCNTs.

Various Defects in Carbon Nanotubes

Carbon nanotubes are not as perfect as they were thought to be earlier. Defects such as pentagons, heptagons, Stone–Wales defects, vacancies, adatoms, and dopants can occur in the nanotube during the growth or in processing and handling of the CNTs (Charlier 2002). Figure 20 depicts different types of defects in SWCNTs. Heptagon defects are found to play a crucial role in the topology of nanotube-based molecular junctions, for making X and Y type nanotube connections (Menon and Srivastava 1997). Long ago, theoretical studies proposed that pentagon–heptagon pair can be found in the intramolecular junctions of two SWCNT segments of different chiralities (Fig. 20d; Charlier et al. 1996; Chico et al. 1996). Experimental study revealed that ion irradiation-induced defects in the SWCNTs and the dangling bonds produced by irradiation are rapidly saturated (Chakraborty et al. 2007).

Low-energy electron and photon also induce damage in SWCNTs. The defect formation in SWCNTs is strongly dependent on the nanotube diameter, suggesting that the curvature-induced strain energy plays a crucial role in the damage (Suzuki and Kobayashi 2007). The defect formation and healing are reversible processes (Berthe et al. 2007; Suzuki and Kobayashi 2007). The defects in the SWCNTs affect their electronic, optical, and chemical properties. A competition between the defect formation and healing at room temperature or even below was reported. Raman spectroscopy, electrical measurements, and photoluminescence (PL) spectroscopy were used to examine the defect formation. However, the type of defects was not confirmed. Chemically stable topological defect, Stone–Wales defect, was ruled out because the activation energy for the defect healing was quite small (1 eV). Low-energy electron and photon can break C–C bonds in SWCNTs, as it was concluded

Fig. 20 (a) to (c) Nonchiral Haeckelite nanotubes of similar diameter; (b) nanotube segment containing only heptagons and pentagons paired symmetrically. (b) Nanotube segment exhibiting repetitive units of three agglomerated heptagons, surrounded by alternating pentagons and hexagons. (c) Nanotube segment containing pentalene and heptalene units bound together and surrounded by six-membered rings. based on energetic criterion. Thus, the experimental study proposed that the defects may be a vacancy and an adatom (Suzuki and Kobayashi 2007).

The Stone-Wales defect is one of the important defects in carbon nanotubes. Stone and Wales showed that a dipole consisting of a pair of five- and seven-membered rings could be created by 90° rotation of a C-C bond in a hexagonal

network (Stone and Wales 1986). Such a dipole was later called Stone–Wales defect. SW transformation is thought to play an important role during the growth of carbon nanotubes. Miyamoto et al. reported an unambiguous identification of SW defect in carbon and boron nitride nanotubes using photoabsorption and vibrational spectroscopy (Miyamoto et al. 2004). Experimental vibrational frequency of 1962 cm^{-1} was reported to be a signature in identifying SW defect in carbon nanotube (Miyamoto et al. 2004). Identifying and characterizing topological defects in SWCNTs are highly challenging tasks. A powerful microscope with high resolution and high sensitivity is required for characterizing the topological defects in CNTs. Using HRTEM, the first direct image of the pentagon–heptagon pair defect (Stone–Wales defect) in the SWCNT was reported (Suenaga et al. 2007). Computational studies examined the structures and defect formation energies of the SWCNTs with defects containing different sizes of rings (seven-, eight-, and nine-membered rings) (Nishidate and Hasegawa 2005) and different types of defects (Amorim et al. 2007; Dinadayalane and Leszczynski 2007a, b; Ding 2005; Wang et al. 2006; Yang et al. 2006a, b).

Computational Approaches Used to Study Carbon Nanostructures: An Overview

Theory and computation play an important role in understanding structures and reactivity of carbon nanosystems such as graphene, fullerenes, and carbon nanotubes. Computational nanoscience often complements the experiments and is very useful for the design of novel carbon nanomaterials as well as predicting their properties. Theory is helpful in obtaining knowledge on the mechanism of reactions and fragmentations of carbon clusters. Thus, we provide an overview of the computational approaches employed to study various carbon nanostructures in this chapter. Carbon nanostructures are very large systems. Hence, performing very high-level quantum chemical calculations is not possible even when using modern supercomputers.

Many-body empirical potentials, empirical tight-binding molecular dynamics, and local density functional (LDF) methods were used to perform electronic structure calculations of carbon nanosystems including fullerenes and model CNTs in early of the last decade (Robertson et al. 1992; Zhang et al. 1993). In the mid-1990s, electronic structure calculations for large fullerenes with I_h point group were performed using Huckel approximation (Tang and Huang 1995). In the late 1990s, scientists performed geometry optimizations for large fullerenes using molecular mechanics (MM3), semiempirical methods (MNDO (Dewar and Thiel 1977), AM1 (Dewar et al. 1985) and PM3 (Stewart 1989)), and Semi-Ab Initio Model 1 (SAM1) (Dewar et al. 1993). The single-point energy calculations were affordable at that time using ab initio Hartree–Fock (HF) method in combination with small basis sets such as 3-21G and 4-31G (Slanina et al. 1997). The computing power has been tremendously increasing since 2000. Thus, currently theoreticians enjoy

investigating medium-sized molecules using reliable quantum chemical methods and exploring carbon nanoclusters beyond molecular mechanics and semiempirical methods.

The popular B3LYP functional, which is a combination of Becke's three-parameter (B3) (Becke 1993) hybrid functional incorporating exact exchange with Lee, Yang, and Parr's (LYP) (Lee et al. 1988) correlation functional, has been employed with small- and medium-sized basis sets like STO-3G, 3-21G, 4-31G, and 6-31G(d) for calculations on fullerenes and carbon nanotubes (Bettinger et al. 2003; Dinadayalane and Leszczynski 2007b; Feng et al. 2005; Matsuo et al. 2003; Yumura et al. 2005a, b; Zhou et al. 2004). Computational studies indicate that the B3LYP functional can yield reliable answers for the properties of carbon compounds and carbon nanostructures (Bettinger et al. 2003; Dinadayalane and Leszczynski 2007b; Feng et al. 2005; Matsuo et al. 2003; Yumura et al. 2005a, b; Zhou et al. 2004). PBE1PBE/6-311G(d) level has been used for calculating relative energies and ^{13}C NMR spectra of fullerene isomers (Shao et al. 2006, 2007). The PBE1PBE functional was concluded to be very reliable DFT functional since it yields the same relative energy ordering as the high-level coupled cluster calculations for the top three isomers of C_{20} (cage, bowl, and ring isomers) (An et al. 2005).

In comparison with *ab initio* MP2 or CCSD methods, DFT is less time-consuming and computationally feasible for large carbon nanosystems. For studying chemical reactivity in fullerenes and nanotubes, ONIOM approach is more cost-effective than treating the whole molecule with DFT. ONIOM is a hybrid methodology in which the molecule is partitioned into two or more fragments. The most important part (one fragment) of the molecule is treated with high-level method, and the other parts are treated with low-level methods (Maseras and Morokuma 1995; Morokuma et al. 2006; Osuna et al. 2009). The performance of ONIOM approach by taking different density functional theory levels was examined against the experimental results for the Diels–Alder reaction between cyclopentadiene and C_{60} (Osuna et al. 2009). Two-layer ONIOM approach ONIOM(B3LYP/6-31G(d):AM1), where B3LYP/6-31G(d) and AM1 are used for high and low layers, was utilized to study chemisorption of alkoxide ions with the perfect and Stone–Wales defective armchair (5,5) SWCNTs of cap-ended and H-terminated structures (Wanbayor and Ruangpornvisuti 2008).

Independent theoretical studies considered DFT methods in investigating the structures and properties of SWCNTs (Akdim et al. 2007; Amorim et al. 2007; Andzelm et al. 2006; Bettinger 2005; Dinadayalane and Leszczynski 2007a, b; Govind et al. 2008; Lu et al. 2005; Nishidate and Hasegawa 2005; Robertson et al. 1992; Wang et al. 2006; Yang et al. 2006a, b; Zhang et al. 1993). The B3LYP functional with double- ζ basis set was often employed to investigate the electronic structures of pristine and defective SWCNTs and also the influence of defects on functionalization of SWCNTs (Akdim et al. 2007; Andzelm et al. 2006; Dinadayalane and Leszczynski 2007b; Govind et al. 2008; Lu et al. 2005). Sometimes, more than one basis set was utilized for exploration of defective SWCNTs and the viability of metal adsorption in the defect tubes (Yang et al. 2006b). DFT with periodic boundary condition (PBC) as implemented in Gaussian

03 program package (Frisch et al. 2003) was used to examine the reactivity of Stone–Wales defect in (5,5) and (10,0) SWCNTs (Bettinger 2005). The unit cell should be carefully chosen for the calculations involving PBC in order to simulate the tubes of infinite length. Popular DFT methods fail to provide reliable answers for π – π interactions involving fullerenes and other carbon clusters (Cuesta et al. 2006; Kar et al. 2008; Shukla and Leszczynski 2009). Although calculations at the MP2 and CCSD(T) levels are required to obtain very reliable results for π – π stacking interactions (Dinadayalane et al. 2007a; Lee et al. 2007; Sinnokrot and Sherrill 2004), they are not possible for such large systems with current computational facilities. Recently developed meta-hybrid density functional (M06-2X) has been reported to be a promising functional to calculate the binding energies for π – π interactions involving large carbon nanostructures (Zhao and Truhlar 2007, 2008).

Using powerful supercomputers, performing static and dynamic calculations at high-level ab initio and DFT methodologies is affordable for graphene and carbon nanotubes. Very recently, density functional theory (PBE functional, Perdew et al. 1996) calculations with plane-wave basis sets and periodic boundary conditions (PBCs) were employed to understand small-molecule interactions with the defective graphene sheets (Jiang et al. 2009). Vienna ab initio simulation package (VASP) has been used in several studies to perform static and dynamic calculations (Kresse and Furthmuller 1996a, b). Theoretical calculations are helpful to understand the electronic structure of graphene sheets and SWCNTs and their viability as ion separation systems and gas sensors (Jiang et al. 2009; Li et al. 2009b; Nishidate and Hasegawa 2005). The Stone–Wales defect formation energy for graphene and CNTs was calculated using DFT, invoking the local density approximation to the exchange–correlation potential as implemented in VASP (Ertekin et al. 2009).

The mechanical properties of CNTs have been investigated by theoreticians for the last two decades (Avila and Lacerda 2008; Chandra et al. 2004; Dereli and Sungu 2007; Yakobson et al. 1996). An array of methods has been employed for computing the Young's modulus of MWCNTs and different types of SWCNTs (armchair, zigzag, chiral). A wide range of Young's modulus values has been reported in the literature (Avila and Lacerda 2008; Chandra et al. 2004; Dereli and Sungu 2007; Mielke et al. 2004; WenXing et al. 2004; Yakobson et al. 1996). Most of the molecular dynamics methods used so far are classical or tight binding (Avila and Lacerda 2008; Chandra et al. 2004; Dereli and Sungu 2007; WenXing et al. 2004; Yakobson et al. 1996). Quantum chemical calculations on mechanical properties of carbon nanotubes or graphene sheets are scarce since they are still highly time-consuming (Mielke et al. 2004). It is not of our interest to discuss mechanical properties in this chapter since there are many papers and some of classic reviews on this subject available (Avila and Lacerda 2008; Chandra et al. 2004; Dereli and Sungu 2007; Mielke et al. 2004; WenXing et al. 2004; Yakobson et al. 1996). DFT and DFT-D approaches were used to study single and multiple Na adsorption and diffusion on graphene (Malyi et al. 2015). By using DFT and time-dependent DFT methods, one can obtain IR, Raman, NMR, and UV spectra. Recent advances in computer hardware and ab initio electronic structure methods have brought a substantial improvement in the capabilities of quantum chemists to predict and study

the properties of carbon nanostructures. However, the application of state-of-the-art quantum chemical methods to study the structures and properties of large carbon nanoclusters (graphenes, fullerenes, and CNTs) is still a great challenge.

Structural, Electronic, and Chemical Properties of Graphene, Fullerenes, and SWCNTs

Graphene

An experimental investigation of mechanical properties of monolayer graphene reported a breaking strength of 40 N/m and the Young's modulus of 1.0 TPa (Lee et al. 2008). Graphene displays a thermal conductivity of $5000 \text{ W m}^{-1} \text{ K}^{-1}$ at room temperature (Balandin et al. 2008). Graphene chemistry is expected to play an important role in producing graphene-based materials. Computational study using the density functional theory with generalized gradient approximation revealed the cooperative effects of degenerate perturbation and uniaxial strain on band gap opening in graphene. Furthermore, the band gap width could be continuously tuned by controlling the strain (Jia et al. 2016). In this chapter, we outline the Stone–Wales defect in graphene, chemisorption process (covalent functionalization) on graphene, and the influence of defects on chemisorption; particular interest is given to hydrogen chemisorption. Chemical functionalization in graphene should produce new 2D systems with distinct electronic structures and different electrical, optical, and chemical properties. Chemical changes can probably be induced even locally. The first known example of hydrogenated graphene is graphane, which is a 2D hydrocarbon with one hydrogen atom attached to every site of the honeycomb lattice (Elias et al. 2009; Sofo et al. 2007).

Stone–Wales defect is expected to enhance the tendency of graphitic layers to roll up into other carbon nanostructures such as fullerenes and nanotubes. Therefore, in-depth understanding of Stone–Wales defect in graphene is required. It is known that pentagons and heptagons induce curvature in graphitic materials. In perfect graphene, the equilibrium C–C bond length is reported as 1.42 Å using PBE functional with the plane-wave code CPMD (Hutter et al.). Further details of the calculations can be obtained from the paper of Ma et al. (2009). The C–C bond shared by two heptagons of the SW defect in graphene is compressed to 1.32 Å using the same method. Density functional theory and quantum Monte Carlo simulations reveal that the structure of the SW defect in graphene is not simple. Ma et al. systematically studied the polycyclic hydrocarbon size dependence on the structural distortion caused by the Stone–Wales defect formation. They considered different systems ranging from the smallest analog of SW defect, azulene ($\text{C}_{16}\text{H}_{10}$), to 1D tape-like structure of $\text{C}_{50}\text{H}_{28}$ and, finally, to 2D planar cluster of $\text{C}_{228}\text{H}_{38}$. As known earlier, azulene is planar. The optimized bond length of the C–C bond at the center of azulene is 1.38 Å, which is longer than the corresponding C–C bond length of 1.32–1.33 Å observed for the SW defect in graphene (Ma et al. 2009).

Fig. 21 (a) Stone–Wales transformation by 90° rotation of C–C bond in graphene sheet; (b) *top* and *side* views of sine-like and cosine-like buckled SW defect graphene sheets (The pictures were reprinted with permission from Ma et al. (2009). Copyright 2009 by the American Physical Society)

Large carbon clusters exhibit a tendency to buckle upon the creation of SW defects. Vibrational frequency calculations of the flat graphene sheet with the Stone–Wales defect reveal that the structure is not a local minimum, but instead has two imaginary frequencies. The true minimum is a sine-like structure in which the C–C bond at the defect core is 0.01 \AA longer than in the flat defect. Furthermore, many C–C bonds are slightly elongated in the buckled structure compared to the flat defect structure. The cosine-like SW defect structure was obtained as a transition state connecting to sine-like SW defect structure. The optimized structures of sine-like and cosine-like SW defect graphenes are depicted in Fig. 21. Vibrational frequencies also revealed that the maximum phonon frequencies corresponding to the stretch of the rotated C–C bond for the flat and buckled SW structure are 1880 and 1774 cm^{-1} , respectively. The corresponding frequency computed for perfect graphene is 1612 cm^{-1} (Ma et al. 2009). Theoretical study pointed out that for a graphene sheet of $\text{C}_{228}\text{H}_{38}$ containing a SW defect, the sine-like buckled structure becomes more stable (by $\sim 10 \text{ meV}$) than the flat SW defect (Ma et al. 2009).

Hydrogenation of Graphene With and Without Defects

Chemical modification of graphene has been less explored (Geim and Novoselov 2007). Attachment of atomic hydrogen to each site of the graphene lattice to create graphane is an elegant idea (Sofo et al. 2007). As a result, the hybridization of

Fig. 22 (a) Top (*upper*) and side (*lower*) view of a 2D graphene layer. Geometric structures of the (b) 7 zigzag and (c) 13 armchair graphene nanoribbons. Copyright 2009 American Chemical Society)

carbon atoms changes from sp^2 to sp^3 , thus removing the conducting p-bands and opening energy gap (Boukhvalov et al. 2008; Sofo et al. 2007). In experiment, the fully hydrogenated graphene called “graphane” was produced by exposing graphene to hydrogen plasma discharge. Raman spectroscopy and transmission electron microscopy confirmed the reversible hydrogenation of single-layer graphene (Elias et al. 2009).

The structural and electronic properties of graphane were investigated using DFT PW91 functional with plane-wave basis set applying periodic boundary conditions as implemented in VASP (Li et al. 2009b). Computations revealed that hydrogenation of graphene nanoribbon is experimentally viable and the electronic properties of graphane are completely different from graphene nanoribbons. Figure 22 depicts the structures of graphane. Two types of graphene nanoribbons (zigzag and armchair edge) can be obtained by cutting the optimized graphene layer. The edge carbon atoms were all saturated with H atoms to avoid the effects of dangling bonds. The bond lengths of edge C–C and C–H bonds are almost as the inner C–C (1.52 Å) and C–H (1.11 Å) bonds. The calculated C–C bond length is similar to the bond length of 1.53 Å in diamond (sp^3 carbon atoms) and is longer than 1.42 Å characteristic of sp^2 carbon in graphene. Both spin-unpolarized and spin-polarized computations yielded same energy for ground-state graphane nanoribbons (Li et al. 2009b).

Figure 23a shows that computed band gap decreases monotonically with increasing ribbon width for both zigzag and armchair nanoribbons. Graphane nanoribbons are semiconductors. The formation energy increases with increasing ribbon width (Fig. 23b) irrespective of the type, indicating that narrow ribbons are more likely to form than the wider ribbons (Li et al. 2009b). Sofo et al. investigated the structures, formation energies, and vibrational frequencies of graphane using DFT with plane-wave basis set (Sofa et al. 2007). They found two favorable conformations of

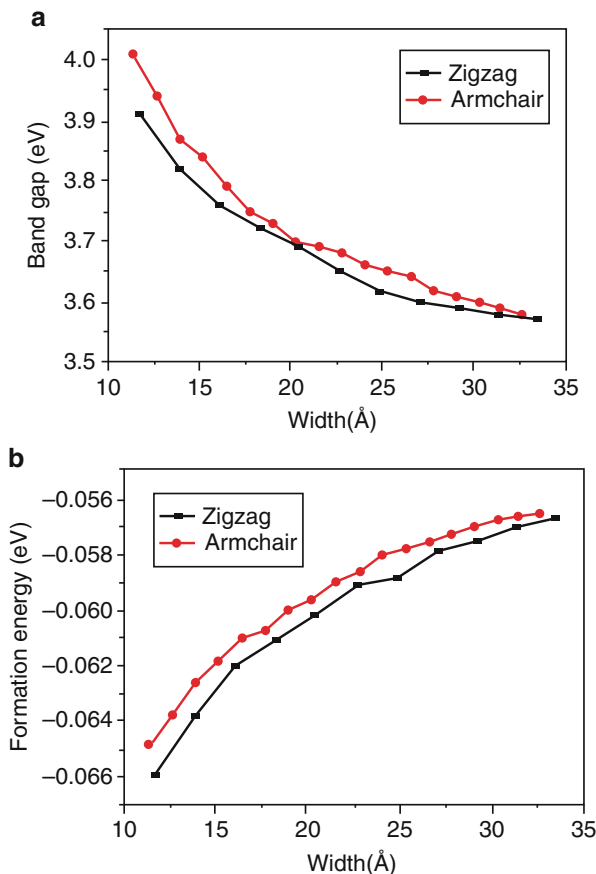

Fig. 23 Variation of the band gap (**a**) and the formation energy (**b**) of zigzag ($6 \leq N_z \leq 16$) and armchair ($10 \leq N_c \leq 27$) graphane nanoribbons as a function of ribbon width. graphane: chair-like conformer with the hydrogen atoms alternating on both sides of the plane and the boat-like conformer with the hydrogen atoms alternating in pairs. Chair conformer has one type of C–C bond (1.52 Å), while boat conformer possesses two different types of C–C bonds (bond lengths of 1.52 Å and 1.56 Å). The boat conformer is less stable than the chair conformer due to the repulsion of the two hydrogen atoms bonded to first-neighbor carbon atoms on the same side of the sheet. This repulsion results in slightly longer C–C bonds in boat conformer. Calculated C–H bond stretching frequencies are 3026 cm^{-1} and 2919 cm^{-1} for the boat and chair conformers, respectively. These C–H stretching modes are IR active, and they should be useful in characterizing these two types of conformers of graphane (Sofa et al. 2007). Molecular dynamics (MD) simulations using adaptive

intermolecular reactive empirical bond order (AIREBO) force field in LAMMPS package revealed the wrinkling characteristics in hydrogenated graphene annulus under circular shearing at the inner edge. Such hydrogenation-induced changes in topological and mechanical characteristics of graphene will be useful to develop novel graphene-based devices (Li et al. 2015).

Using density functional calculations, Boukhvalov and Katsnelson have studied hydrogenation of graphene sheets with defects such as Stone–Wales (SW), bivacancies, nitrogen substitution impurities, and zigzag edges. They performed calculations for chemisorptions of hydrogen atoms on the defects in the graphene from low to high coverage. The optimized geometries of the graphene supercells with various types of defects as well as their hydrogenated structures are depicted in Fig. 24, which also displays the computed chemisorption energy as the function of coverage for the graphene containing different defects. The chemisorption energy of a single hydrogen atom to the defect-free graphene was given as 1.5 eV, while those of 0.30 eV for SW defects, 0.93 eV for bivacancies, and 0.36 eV for substitution impurities of nitrogen in graphene were reported. This indicates the significant influence of defects on single hydrogen atom chemisorption energy in graphene. The calculated chemisorption energy for different nonequivalent carbon atoms of the graphene containing SW defect reveals that the chemisorption energy for the entire area surrounding the SW defect is lower compared to the perfect graphene.

Further, the defects also decrease the chemisorption energy of two hydrogen atoms at adjacent positions compared to the defect-free graphene. It was reported that, for the complete coverage, the binding energy is smaller for the hydrogen chemisorption of graphene with defects than the perfect graphene. Thus, completely hydrogenated graphene is less stable with defects than without them (Boukhvalov and Katsnelson 2008).

Graphenes with various kinds of defects may have different types of properties and applications. Therefore, obtaining knowledge on graphenes with defects is important. DFT calculations showed only physisorption of water molecule with perfect graphene, while the vacancy defect greatly assists the dissociative chemisorption of water molecules in the graphene (Cabrera-Sanfeliix and Darling 2007; Kostov et al. 2005). There can be many possible reaction pathways for the dissociation of water molecule over defective sites in the graphene (Kostov et al. 2005). Computational studies provide evidence that defects such as Stone–Wales and vacancy strongly influence the chemisorption of functional groups in the graphene (Boukhvalov and Katsnelson 2008; Boukhvalov et al. 2008; Cabrera-Sanfeliix and Darling 2007; Kostov et al. 2005).

Fullerenes

Computational Studies of Fullerene Isomers

Computational methods were employed to systematically search and study the low-lying isomeric structures of fullerenes, and such thorough investigations have been useful to predict the best candidates for the lowest-energy structures of higher fullerenes because of the growing experimental interest (Shao et al. 2006, 2007; Slanina et al. 2000a, b; Sun 2003; Sun and Kertesz 2002; Zhao et al. 2004a, b). Fullerene C_{86} has 19 possible isomers obeying IPR, and all of these isomers were studied using B3LYP functional with different basis sets (Sun and Kertesz 2002). Among 19 isomers, the isomer **17** with C_2 symmetry is the most stable followed by isomer **16** with C_s symmetry, and these two isomers are shown in Fig. 25. It should be noted that these two isomers were experimentally observed. At the B3LYP/6-31G level, isomer **16** was predicted to be about 6 kcal/mol less stable than isomer **17**, albeit the former one has slightly larger HOMO–LUMO gap than the latter. The variation of relative stability at different theoretical levels for all 19 IPR-satisfying isomers of C_{86} is depicted in Fig. 26. The relative stabilities were calculated with respect to the lowest-energy isomer (**17**). The HF/3-21G level and the semiempirical AM1 Hamiltonian overestimate the relative energies compared to the density functional theory (DFT) levels (Sun and Kertesz 2002).

Experimental study identified two isomers of fullerene C_{86} and characterized them using ^{13}C NMR spectroscopy (Miyake et al. 2000). Based on the experimental NMR spectra, C_2 and C_s point groups were assigned for the two isomers, but there are more than single C_2 and C_s isomers. Theoretical calculations play a crucial role in identifying the correct structure by comparing theoretical and experimental ^{13}C NMR spectra. The ^{13}C NMR chemical shifts were calculated for all of the 19

Fig. 26 The relative energy of IPR-satisfying isomers of C_{84} at various levels of theory. Isomers **1**, **5**, **7**, **11**, **12**, and **13** have C_1 symmetry. Isomers **2**, **3**, **4**, **6**, **14**, and **17** possess C_2 point group. Isomers **9** and **10** have C_{2v} point group. Isomers **8**, **15**, and **16** have C_s point group. Isomers **18** and **19** possess C_3 and D_3 point groups, respectively (The data was taken from reference Okada and Saito (1996))

IPR isomers of C_{86} , except isomer **8**. Theoretical ^{13}C NMR spectra complement the experimental spectra as evidenced from Fig. 27. Computational study revealed that isomer **17** has high thermodynamic and kinetic stability among the six IPR isomers of C_{84} possessing C_2 point group. The computed NMR spectrum of isomer **17** supports the results of experimental spectrum. Among the C_s isomers, the second

Theoretical spectra are labeled by isomer number and experimental spectrum labeled by symmetry (Reprinted with permission from reference Sun and Kertesz (2002). Copyright 2002 Elsevier)

most stable isomer **16** has large HOMO–LUMO gap (Sun and Kertesz 2002). Isomers **6**, **10**, **11**, **12**, **13**, and **18** were predicted to have relative energies less than 20 kcal/mol and moderate HOMO–LUMO gap, thus indicating the possibility of experimental realization (Sun and Kertesz 2002).

Okada and Saito proposed the number of extractable fullerenes among the IPR-satisfying isomers of fullerenes from C_{60} to C_{90} . They found that C_{84} is unique since the number of preferable isomers is more than for other fullerenes and this was attributed to the abundant production of C_{84} after C_{60} and C_{70} . All 24 IPR-satisfying isomers of C_{84} were studied computationally (Okada and Saito 1996). A complete set of 187 isomers that obey IPR of fullerene C_{96} was systematically investigated using various theoretical methods including molecular mechanics (MM3), semiempirical (AM1, MNDO, and PM3), and quantum mechanical (HF/4-31G and B3LYP/6-31G) methods. All of the theoretical levels unequivocally predicted that isomer **183** with D_2 point group is the lowest-energy one. The relative energies for some of the isomers were reported to be quite method sensitive and varied dramatically with different methods. The computational study highlighted the importance of the entropy effect in examining the relative stability of IPR-obeying isomers of fullerene C_{96} (Zhao et al. 2004a). A large set of 450 IPR

isomers of C_{100} has been explored using the abovementioned semiempirical and molecular mechanics (MM3) methods. Systematic theoretical calculations predicted the isomer with D_2 point group (isomer **449**) as the lowest energy by all of the methods employed (Zhao et al. 2004a).

Shao et al. searched the lowest-energy isomer of the fullerenes C_{38} to C_{80} and C_{112} to C_{120} . For the first set (C_{38} to C_{80}), all IPR and all non-IPR isomers were considered, and only IPR-satisfying isomers were considered for the second set of fullerenes (C_{112} to C_{120}). Thus, a large set of molecules was taken for optimizations at the semiempirical density functional-based tight-binding (DFTB) method and the single-point energy calculations at the DFT (Shao et al. 2007). It is known that the fullerene with large HOMO–LUMO gap and high symmetry is not necessarily the lowest-energy structure. The decreasing trend of HOMO–LUMO gap was reported with increasing the fullerene size (Shao et al. 2006, 2007). An unexpected manner of pentagonal adjacency was observed in the low-lying isomers in the series of fullerenes C_{38} to C_{80} (Shao et al. 2007).

In a comprehensive computational study, Shao et al. identified 20 isomers as the best candidates for the lowest-energy structures. Among the 20 isomers, 10 isomers with relative energies less than 1 kcal/mol are depicted in Fig. 28 (Shao et al. 2007). Thus, these 10 isomers can be observed experimentally. The ^{13}C NMR chemical shifts for these 10 isomers were calculated. Theoretical study predicted that C_{116} :**6061** can be more easily isolated and characterized in the laboratory than other higher fullerenes from C_{112} to C_{120} (Shao et al. 2007). In a different study, Shao et al. proposed the seven best candidates of the lowest-energy isomers for the fullerenes C_{98} to C_{110} based on the systematic study using DFTB and

Fig. 28 Best candidates for the lowest-energy structure of higher fullerenes (C_{112} to C_{120}). The isomer number and point group are given (Reprinted with permission from reference Shao et al. (2007). Copyright 2007 American Chemical Society)

DFT methods. They pointed out that C_{102} (C_1 : **603**) and C_{108} (D_2 : **1771**) isomers can be easily synthesized (Shao et al. 2006). The concepts of cage connectivity and frontier π -orbitals play important roles to understand the relative stability of charged fullerene isomers without performing extensive quantum chemical calculations. This theoretical study correctly predicted the structures observed experimentally and explained why the isolated pentagon rule is often violated for fullerene anions, but the opposite is found for fullerene cations (Wang et al. 2015b).

Fullerenes C_{50} and $C_{50}Cl_{10}$ were computationally studied using B3LYP/6-31G(d) level due to the experimental report of the latter compound (Lu et al. 2004). The computational study thoroughly explored the structures, relative energies, HOMO–LUMO energies, and HOMO–LUMO gap for low-lying isomers of C_{50} and its anions. The computed IR, Raman, ^{13}C NMR, and UV–Vis spectra of the $C_{50}Cl_{10}$ with D_{5h} symmetry showed very good agreement with the reported experimental data. The pentagon–pentagon fusions were found to be the active sites of addition reactions in both D_3 and D_{5h} symmetric isomers of fullerene C_{50} . It was observed that HOMO and LUMO coefficients of C_{50} (D_{5h}) are distributed around the equatorial pentagon–pentagon fusion sites. This was given as a reason for the binding of Cl atoms around the equatorial pentagon–pentagon fusion sites of C_{50} yielded $C_{50}Cl_{10}$ (Lu et al. 2004).

Giant Fullerenes

Giant fullerenes have been the subject of theoretical interests (Calaminici et al. 2009; Dulap and Zope 2006; Dunlap et al. 1991; Gueorguiev et al. 2004; Lopez-Urias et al. 2003; Zope et al. 2008). The structures and stabilities of the giant fullerenes C_{180} , C_{240} , C_{320} , and C_{540} were investigated using high-level density functional theory calculations (Calaminici et al. 2009). The results of the uncorrected binding energy (in eV) per carbon atom for the giant fullerenes obtained using the VWN functional are depicted in Fig. 29. The inclusion of the basis set superposition error (BSSE) decreases the calculated binding energies but does not alter the trend. The increasing trend of binding energy indicates that the large fullerenes become more and more stable with increasing size. Fullerene C_{540} has a similar binding energy to diamond, giving the hope that such giant fullerenes could be prepared. However, the binding energy per carbon atom of the fullerene, C_{540} , is considerably lower than that of graphene (Calaminici et al. 2009). Gueorguiev et al. performed the calculations for giant fullerenes using semiclassical approximation LR-LCAO (linear response model in the framework of the linear combination of atomic orbitals). They reported the decreasing trend of HOMO–LUMO gaps (except C_{20}) and the considerably large increase of the static polarizability as increasing the size of the fullerene cage (Fig. 30; Gueorguiev et al. 2004). The static dipole polarizability per atom in C_{2160} is three times larger than that in C_{60} (Dunlap et al. 1991).

Fig. 29 Binding energy (in eV) for C₁₈₀, C₂₄₀, C₃₂₀, and C₅₄₀ fullerenes. The calculations have been performed with the VWN functional in combination with DZVP basis sets (Reprinted with permission from reference Calaminici et al. (2009). Copyright 2009 American Chemical Society)

Local Strain in Curved Polycyclic Systems: POAV and Pyramidalization Angle

Fullerenes experience large strain energy because of their spherical shape. The curvature-induced pyramidalization of the carbon atoms of fullerenes weakens the π -conjugation. The curved π -conjugation in carbon networks of fullerenes has not only π -character but also substantial s-character. The π -orbital axis vector (POAV) analysis developed by Haddon is useful in measuring the local curvature of the nonplanar conjugated organic molecules, fullerenes, and SWCNTs (Haddon 1993; Haddon and Scott 1986). In general, the sp^2 -hybridized carbon atom prefers to be in the planar arrangement, but it is pyramidalized in fullerenes. The local strain of carbon framework in fullerenes and SWCNTs is reflected in the pyramidalization angle θ_P at the carbon atoms (Niyogi et al. 2002). The pyramidalization angle (θ_P) equals to the difference between the π -orbital axis vector (POAV) and the normal right angle 90° : thus, $\theta_P = (\theta_{\sigma\pi} - 90^\circ)$, where the $\theta_{\sigma\pi}$ is the angle between the π -orbital of the conjugated atom and the σ -orbital of the surrounding atoms. As shown in Fig. 31, the pyramidalization angle is 0° and 19.47° for a planar sp^2 -hybridized carbon and a tetrahedral sp^3 -hybridized carbon, respectively. All carbon atoms in the icosahedral C₆₀ have the same $\theta_{\sigma\pi}$ of 11.6° .

Pyramidalization angle of a carbon atom in fullerenes and SWCNTs is helpful in predicting the chemical reactivity (Akdin et al. 2007; Bettinger 2005; Dinadayalane and Leszczynski 2007a, b; Lu and Chen 2005; Lu et al. 2005). The larger pyramidalization angle of carbon atom indicates the higher reactivity toward addition reactions in the curved systems of fullerenes and SWCNTs. Curvature-induced pyramidalization and the π -orbital misalignment cause local strain in SWCNTs

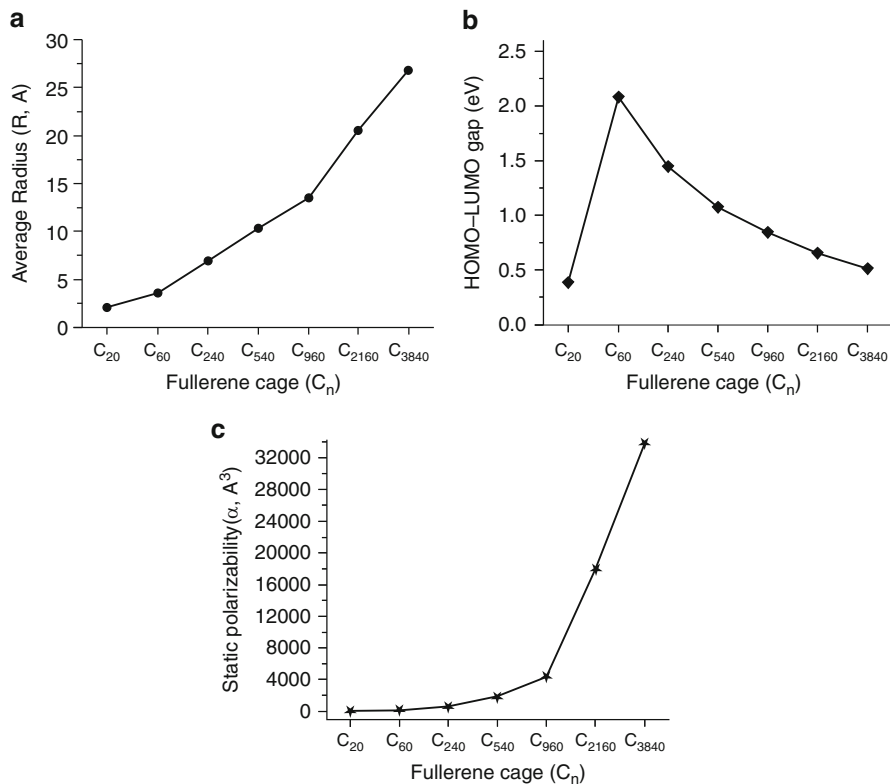

Fig. 30 The variation of (a) radius (R , Å), (b) HOMO–LUMO gap (eV), and (c) static polarizability as increasing the size of the fullerene cage (C_{20} , C_{60} , C_{240} , C_{540} , C_{960} , C_{2160} , and C_{3840}) (The data for the plots was taken from reference Gueorguiev et al. 2004)

(Fig. 32). Hence, carbon atoms of SWCNTs are more reactive than that of a perfect graphene sheet (Niyogi et al. 2002; Park et al. 2003). Cyranski et al. studied the structures and energetics of the 12 lowest-energy isomers of neutral, closed-shell IPR fullerenes C_{60} – C_{96} using B3LYP/6-31G(d) level. They obtained the decreasing values of pyramidalization angles, while no regular trend was obtained for HOMO–LUMO gaps with increasing size of fullerenes (Fig. 32; Cyranski et al. 2004).

Decachloro-derivative of C_{50} fullerene has been synthesized and experimental characterization confirmed the existence of C_{50} cage. Two C_{20} caps and five C_2 units around the equator are present in the C_{50} core of $C_{50}Cl_{10}$ (Xie et al. 2004). The calculated pyramidalization angle for the carbon atoms of the C_{20} caps of fullerene C_{50} ranges from 10.7 to 12.88°, which are comparable to that of C_{60} (11.68°). However, a large pyramidalization angle (15.58°) is obtained for the equatorial C atoms (pentagon–pentagon fusion). Such large value was attributed to high reactivity of those carbon atoms in addition reactions to form exohedral adducts (Chen 2004; Lu et al. 2004). Such structural features were reasoned for the instability of a bare C_{50} cage and the stability of $C_{50}Cl_{10}$ (Chen 2004).

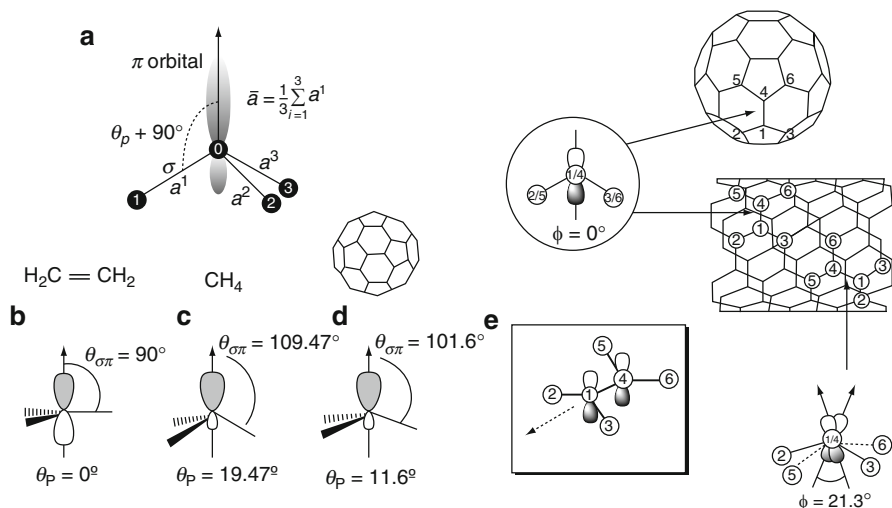

Fig. 31 (a) Pyramidalization angle (θ_p) is defined by the angle between the π -orbital and σ -bond minus 90° so that $\theta_p = 0^\circ$ for a graphene sheet and $\theta_p = 19.47^\circ$ for sp^3 -hybridized carbon. For practical reasons, we take the average of three θ_p values: (b) θ_p for a perfect planar sp^2 -hybridized carbon atom (e.g., in C_2H_4), (c) θ_p for a perfect tetrahedral sp^3 -hybridized carbon atom (e.g., CH_4), (d) θ_p for a nonplanar sp^2 -hybridized carbon atom (e.g., C atom in C_{60} or SWCNT). (e) The π -orbital misalignment angle (ϕ) along the C1–C4 bond in the (5,5) SWCNT and the fullerene C_{60} (Pictures were reprinted with permission from references Lu and Chen (2005), Niyogi et al. Stone–Wales Defect in C_{60}

Fullerene isomers are likely to interconvert through Stone–Wales transformation (Stone and Wales 1986; Troyanov and Tamm 2009). Very recently, experimental study has reported that the chlorine-functionalized D_2-C_{76} IPR isomer transformed to non-IPR isomer, and this transformation was proposed to include seven single Stone–Wales rearrangements (Ioffe et al. 2009). Computational chemists strived to understand the energy barriers for the Stone–Wales transformation and the possible mechanisms involved in this rearrangement, particularly considering the C_{60} fullerene (Bettinger et al. 2003; Eggen et al. 1996; Yumura et al. 2007).

Stone–Wales transformation is a thermally forbidden rearrangement by following the orbital symmetry considerations of Woodward and Hoffmann (1969). The icosahedral C_{60} fullerene (buckminsterfullerene) gives an isomer of C_{60} with C_{2v} point group that violates the isolated pentagon rule. Two different pathways, namely, concerted and stepwise pathways, and two different (symmetric and asymmetric) transition states were identified theoretically for the Stone–Wales transformation in C_{60} fullerene. The C_{60} - C_{2v} isomer, which is a Stone–Wales-type defect structure with two adjacent pentagons, was reported to be less stable by 33.9–38.7 kcal/mol (1.47–1.68 eV) than the buckminsterfullerene using various density functional theory levels (Yumura et al. 2007).

Bettinger et al. listed the C–C bond lengths of C_{60} (I_h) and the activation barrier for the Stone–Wales defect transformation through different transition states at various levels of theory. Computed geometries of buckminsterfullerene at different levels showed shorter [6,6] C–C bond length than the [5,6] C–C bond length, in consistent with experimental results (Bettinger et al. 2003). Figure 33 depicts the concerted C_2 symmetric transition state and asymmetric transition state involved in SW transformation of C_{60} - I_h to C_{60} - C_{2v} . The intrinsic reaction coordinate calculations by Bettinger et al. support the concerted pathway rather than stepwise pathway for the SW transformation in the C_{60} fullerene. Based on the computed activation energies, both concerted and stepwise pathways are highly competitive. The rigorous computational study of SW transformation in buckminsterfullerene revealed that the empirical schemes such as Tersoff–Brenner potentials and density functional-based tight binding (DFTB) underestimate the barrier heights, and semiempirical AM1 appears to be promising for such investigations (Bettinger et al. 2003).

Computational Studies on Vacancy Defects in Fullerene C_{60}

Vacancy defects in fullerene C_{60} were studied using quantum chemical methods (Hu and Ruckenstein 2003, 2004; Lee and Han 2004). They were generated by removal of 1–4 carbon atoms in C_{60} as shown in Figs. 34 and 35. Different modes are possible to remove carbon atoms from C_{60} to generate vacancy defects; hence, different sizes of rings (four-, seven-, eight-, and nine-membered rings) were produced by removing carbon atoms in C_{60} . Removing one, two, three, and four adjacent carbon atoms from the C_{60} cluster generates two, three, three, and six different isomers for the C_{59} , C_{58} , C_{57} , and C_{56} clusters, respectively (Hu and Ruckenstein 2004; Lee and Han 2004). The odd-numbered clusters have unsaturated carbon, which favors being located in a six-membered ring rather than a five-membered ring. Two-atom vacancies give structure with seven- and eight-membered rings, whereas one-atom vacancy gives the structure with nine-membered ring. Four-atom vacancies provide the most stable structure with only five- and six-membered rings. Thus, increasing the number of vacancies need not increase the size of the hole (Hu and Ruckenstein 2003, 2004).

Fig. 34 B3LYP/6-31G(d) optimized structures of C_{59} , C_{58} , and C_{57} clusters. Description indicates highlighted rings. “A-B” denotes A- and B-membered ring. Circle denotes an unsaturated atom (Reprinted with permission from reference Lee and Han (2004). Copyright 2004, American Institute of Physics)

The singlet structures are more stable than the triplet ones for C_{58} cluster, while the reverse is true in the case of C_{57} clusters. The reported stabilization energy per atom at the B3LYP/6-311G(d)//B3LYP/6-31G(d) level is 2.18, 1.49, and 3.10 kcal/mol for the C_{59} , C_{58} , and C_{57} , respectively. Quantum chemical calculations provide relationship between structure and stability of the defect fullerene clusters (Hu and Ruckenstein 2003, 2004; Lee and Han 2004). In case of removal of four adjacent carbon atoms in C_{60} , additional five-membered rings are formed in geometry optimizations (e.g., isomer **1** in Fig. 35). The isomer **4** has only five- and six-membered rings (12 five-membered rings and 18 six-membered rings) and was predicted to be the most stable among the isomers depicted in Fig. 35. The stability energy for the isomers generated by removing four carbon atoms has the following sequence: isomer **4** > isomer **3** > isomer **2** > isomer **5** > isomer **6** > isomer **1**. All defect clusters have lower stability energy per atom than C_{60} . The removal of carbon atoms from C_{60} increases the HOMO and decreases the

Fig. 35 Different modes to generate isomers of C_{60} with four vacancies by removing four adjacent atoms from the perfect C_{60} structure. Structures of isomers 1–6 of defect C_{60} with four vacancies. The ring size and the number of rings (in parentheses) for each isomer are given; for example, isomer 1-4(1)-5(13)-6(15)-9(1) means 1 four-membered, 13 five-membered, 15 six-membered, and 1 nine-membered rings (Reprinted with permission from reference Hu and Ruckenstein (2004). Copyright 2004, American Institute of Physics)

LUMO energy. Consequently, the defect structures exhibit lower HOMO–LUMO gap compared to C_{60} . No relationship was obtained between the stability energy per carbon atom and the HOMO–LUMO gap for the defective carbon clusters of C_{60} (Hu and Ruckenstein 2003).

Computational Studies of Single-Walled Carbon Nanotubes

Computational chemists explored the structures, electronic properties, and reactivities of SWCNTs of varying lengths and diameters (Bettinger 2004; Dinadayalane and Leszczynski 2009; Dinadayalane et al. 2007b; Galano 2006; Kaczmarek et al. 2007; Matsuo et al. 2003; Niyogi et al. 2002; Yang et al. 2006c). They also tried to understand the influence of different defects on these properties at reliable theoretical methods within the limitations of hardware and software (Akdım et al. 2007; Andzelm et al. 2006; Bettinger 2005; Dinadayalane and Leszczynski 2007a, b; Govind et al. 2008; Lu et al. 2005; Nishidate and Hasegawa 2005; Wanbaylor and Ruangpornvisuti 2008; Wang et al. 2006; Yang et al. 2006a, b). A series of finite-length hydrogen-terminated armchair SWCNTs have been computationally studied to obtain knowledge on the influence of diameter and length on the structural and electronic properties (Galano 2006). The optimized armchair (n,n) SWCNTs possess D_{nh} and D_{nd} point groups for $\vartheta/2$ even and odd, respectively. The different

Fig. 36 Calculated weighted average values of the C–C distance as a function of the tube length for armchair (n,n) SWCNTs (Reprinted with permission from reference Galano (2006). Copyright 2006 Elsevier)

lengths of the armchair SWCNTs have the general formula $C_{(2n)k}H_{4n}$ with $k = \vartheta/2$. Galano considered (3,3), (4,4), (5,5), and (6,6) armchair SWCNTs with k of 6 to 26 (i.e., from 6 to 26 carbon atom layers). There are two types of bonds in the perfect (n,n) armchair SWCNTs; one is perpendicular to the tube axis (r_I) and another one is nearly parallel to the tube axis (r_{II}). The maximum difference between r_I and r_{II} was obtained in the case of the narrow diameter (3,3) tube. The influence of diameter on the weighted average values of the C–C distances is larger than the influence of the tube length (Fig. 36; Galano 2006).

The frontier molecular orbitals (HOMO and LUMO) play an important role in SWCNTs since they are helpful in predicting a number of ground-state properties of molecules. According to Huckel theory, the (n,n) armchair SWCNTs should be metallic (Saito et al. 1998), but the finite-length armchair SWCNTs are semi-conducting with a finite size of the HOMO–LUMO gap (Cioslowski et al. 2002). The computed HOMO–LUMO gaps for (3,3) to (6,6) SWCNTs were reported to be lower than the corresponding value for fullerene C_{60} . The HOMO–LUMO gap oscillates as the tube length increases for all of these armchair tubes (Fig. 37). The behavior of narrow diameter (3,3) tube is different from other armchair SWCNTs (Galano 2006).

Matsuo et al. classified the structures of finite-length armchair (5,5) and (6,6) SWCNTs as Kekule, incomplete Clar, and complete Clar networks depending on the exact length of the tubes. The (5,5) and (6,6) SWCNTs were elongated layer by layer of 10 and 12 carbon atoms, respectively (Matsuo et al. 2003). The local aromaticity of different lengths of the tubes was evaluated using the NICS (nucleus-independent chemical shift) calculations (GIAO-SCF/6-31G*//HF/6-31G* level).

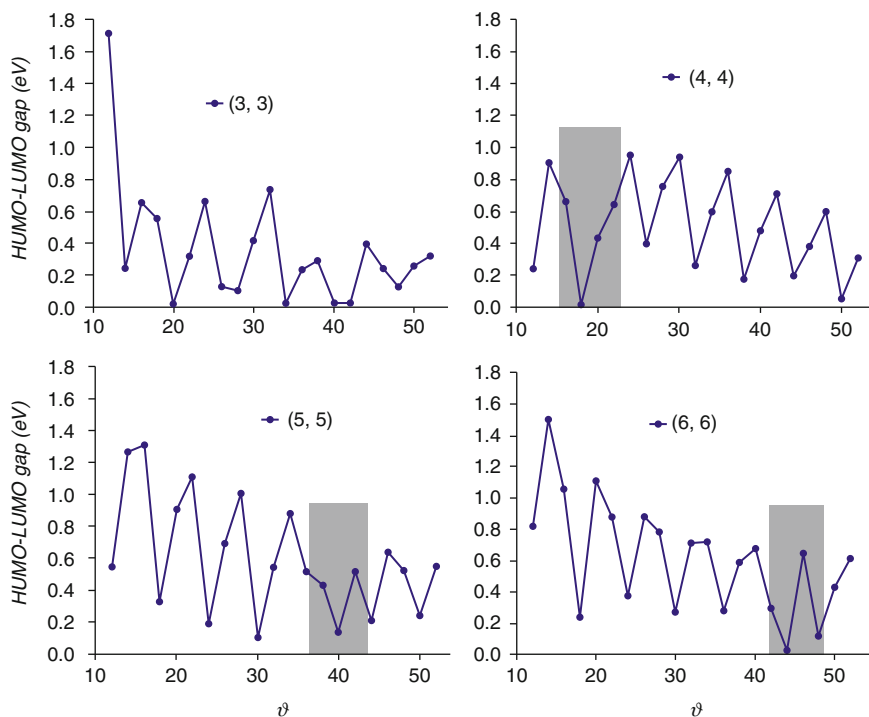

Fig. 37 Variations of HOMO–LUMO gaps as increasing the tube length for the armchair SWCNTs. There is no periodicity in (3,3) tube and the shaded region indicated the broken periodicity in other tubes (Reprinted with permission from reference Galano (2006). Copyright 2006 Elsevier)

Matsuo et al. pointed out that the geometry of $C_{50}H_{10}$ is similar to the equatorial belt of the fullerene C_{70} . Bond lengths of optimized structures exhibit oscillation with increase in tube length for both (5,5) and (6,6) armchair SWCNTs. The schematic structures of Kekule, incomplete Clar, and complete Clar networks for (5,5) and (6,6) SWCNTs are depicted in Fig. 38 along with the NICS values of dissimilar benzenoid rings. The energy of frontier molecular orbitals and HOMO–LUMO gap also oscillate as the length of the nanotube increases (Fig. 39). The Kekule structure shows larger HOMO–LUMO gap than the other two. It was reported that the band gap will eventually disappear at a certain tube length (Matsuo et al. 2003).

The pyramidalization angle (θ_P) and π -orbital misalignment angles are useful to gauge the reactivity of the carbon atom sites of SWCNTs. The end caps of SWCNTs resemble fullerene hemisphere; thus, the end caps are expected to be more reactive than sidewalls irrespective of the diameter of the SWCNTs. Carbon atoms in fullerene are more distorted than those in the corresponding SWCNTs. For example, the carbon atom of (10,10) armchair SWCNT has the pyramidalization angle (θ_P) of about 3.0° , while the carbon atom of the fullerene with corresponding

Fig. 38 Schematic structures and color-coded NICS maps of finite-length (5,5) and (6,6) SWCNTs. Hydrogen atoms are omitted for clarity. Chemical bonds are schematically represented by using single bond (*solid single line*; bond length > 1.43 Å), double bond (*solid double line*; bond length < 1.38 Å), single bond halfway to double bond (*solid dashed line*; 1.43 Å > bond length > 1.38 Å), and Clar structure (i.e., ideal benzene). NICS coding: *red*, aromatic < -4.5; *blue*, nonaromatic > -4.5 (Reprinted with permission from reference Matsuo et al. 2003. Copyright 2003 American Chemical Society)

radius (fullerene C_{240}) has the θ_P of about 9.7° (the hemisphere of fullerene C_{240} can be capped to (10,10) SWCNT) (Niyogi et al. 2002). Chen et al. mentioned that the pyramidalization angle of the C atoms of the sidewalls of SWCNTs is smaller compared to that of the fullerenes of same radius. As a consequence, the

Fig. 39 Variation of HOMO–LUMO energies and HOMO–LUMO energy gap with increase in tube length of (5,5) armchair SWCNT ($C_{10j}H_{20}$) (Reprinted with permission from reference Matsuo et al. (2003). Copyright 2003 American Chemical Society)

covalent functionalization to SWCNTs is less favorable compared to fullerenes of same radius (Chen et al. 2003). The π -orbital misalignment is likely to be a main source of strain in the SWCNTs. For both armchair and zigzag SWCNTs, the pyramidalization angle and the π -orbital misalignment angle decrease with increase in diameter of the tube (Fig. 40; Niyogi et al. 2002).

Covalent Functionalization of SWCNTs: H and F Atom Chemisorptions

The covalent functionalization of SWCNTs, which modifies the properties of the tubes, has become a challenging field of research for the past few years (Bettinger 2006; Hirsch 2002; Niyogi et al. 2002; Vostrowsky and Hirsch 2004). Functionalization of tubes is considered to be promising to produce carbon nanotube-based materials for selective applications (Bettinger 2006; Cho et al. 2008; Denis et al. 2009). The binding of hydrogen with SWCNTs has generated a lot of experimental and theoretical interests due to their potential application in hydrogen storage (Dillon et al. 1997; Dinadayalane and Leszczynski 2009; Dinadayalane et al. 2007b; Kaczmarek et al. 2007; Nikitin et al. 2005; Ormsby and King 2007; Yang et al. 2006c; Zhang et al. 2006). Scientists have tried to obtain knowledge on the mechanism of hydrogen adsorption in SWCNTs. They attempted to design the viable nanotube-based hydrogen storage material to meet the Department of Energy (DOE) target of 6.5 wt% at ambient temperature (Dillon et al. 1997; Dinadayalane

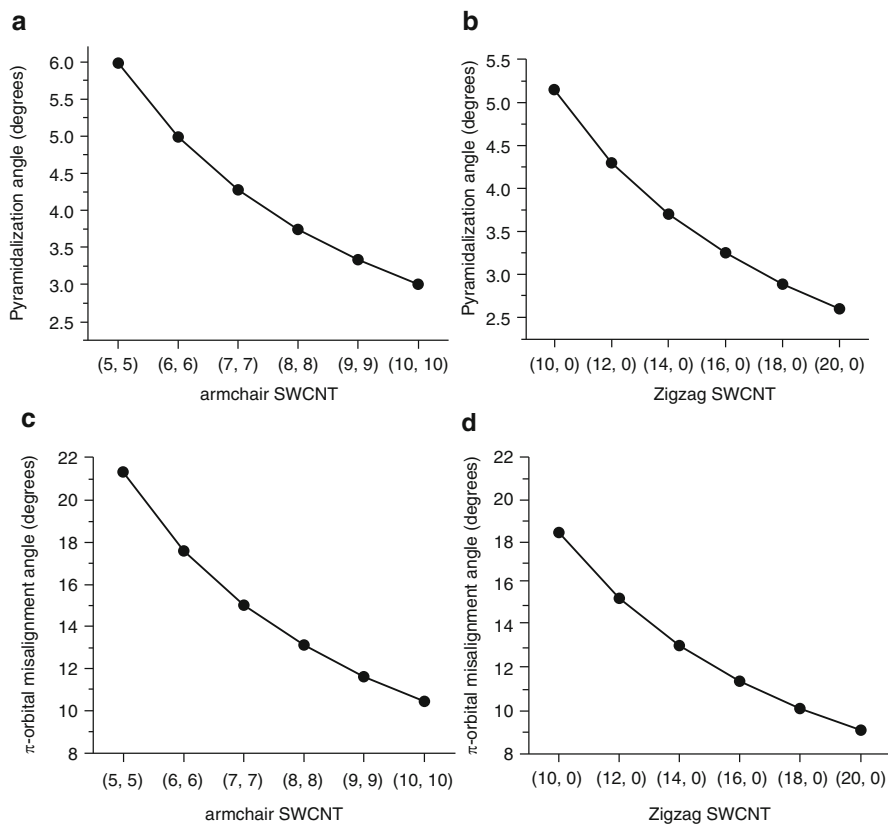

Fig. 40 The change of pyramidalization angle (**a, b**) at the carbon atom and the π -orbital misalignment angle (**c, d**) between two adjacent carbon atoms of armchair (**a, c**) and zigzag (**b, d**) SWCNTs. The π -orbital misalignment angle is zero for the carbon atoms of the circumferential bond in armchair tube and axial bond in zigzag tube (The data was taken from reference Niyogi et al. (2002))

and Leszczynski 2009; Dinadayalane et al. 2007b; Kaczmarek et al. 2007; Nikitin et al. 2005; Ormsby and King 2007; Yang et al. 2006c; Zhang et al. 2006). The experimental investigations reported the chemisorption of H atoms on the surface of SWCNTs as promising approach to meet DOE's target of hydrogen storage (Nikitin et al. 2005; Zhang et al. 2006). Chemisorptions of hydrogen atoms on the surface of SWCNTs were investigated (Dinadayalane and Leszczynski 2009; Dinadayalane et al. 2007b; Kaczmarek et al. 2007; Ormsby and King 2007; Yang et al. 2006c). The covalent functionalization of SWCNTs by H atoms is a hot topic. Thus, we discuss the quantum chemical studies of the hydrogen chemisorption on different types of SWCNTs.

Yang et al. studied, using DFT and ONIOM calculations, the chemisorption of atomic hydrogen(s) on the open-ended finite-sized (5,0), (7,0), and (9,0) zigzag and

Fig. 41 Finite-sized small carbon nanotube models of (5,0), (7,0), and (9,0) zigzag and (5,5) armchair SWCNTs considered for low occupancy of H chemisorptions (Reprinted with permission from reference Yang et al. (2006c). Copyright 2006 American Chemical Society)

(5,5) armchair SWCNTs (Fig. 41; Yang et al. 2006c). They compared the binding energies obtained for nanotubes with results of the model graphene sheet in order to examine the effect of curvature. It was reported that the chemisorptions of H atoms to the exterior wall of the SWCNTs are more favorable than the interior walls. The H chemisorption has strong dependence of tube diameter and helicity or chirality in both interior (endohedral) and exterior (exohedral) addition. In case of single H atom addition, the binding energy (chemisorption energy), which is the reaction energy for H chemisorption with SWCNT, decreases with increase in tube diameter. In the chemisorption of two hydrogen atoms in the interior and exterior walls of (5,0) and (7,0) SWCNTs, two hydrogen atoms prefer to bind at alternate positions rather than adjacent positions. This was attributed to the crowding effect when two hydrogen atoms occupy in the adjacent positions. In the case of (5,0) SWCNT, chemisorption of ten hydrogen atoms (33 % coverage) decreases the magnitude of chemisorption energy, which is further decreased by an increase in the coverage to 50 %. Similar to the situation in zigzag SWCNTs, two hydrogen atoms prefer to attach at alternate carbon sites rather than adjacent sites in the graphene sheet. Significantly large deviation of chemisorption energy between the graphene sheet and zigzag SWCNTs (H atoms chemisorbed on the exterior wall) was reported. It was found that the chemisorptions of H atoms with small diameter SWCNTs are much more favorable than with the graphene sheet (Yang et al. 2006c).

We investigated a single-hydrogen chemisorption, the preference of the positions (i.e., 1-2, 1-2', 1-3, or 1-4 positions) for the chemisorption of two hydrogen atoms considering (3,3), (4,4), (5,5), and (6,6) armchair SWCNTs of 9 and 15 carbon atom layers. The SWCNTs of 15 carbon layers considered in our study are shown in Fig. 42. The addition of H atoms on the outer wall of SWCNT (exohedral addition) has only been considered in our study. We performed DFT calculations using B3LYP/6-31G(d) level for full geometry optimizations. The finite-length SWCNTs were capped with hydrogen atoms to avoid dangling bonds. The reaction energies for hydrogen chemisorption (E_r) on the external surface of

Fig. 42 Structures of (3,3), (4,4), (5,5), and (6,6) armchair SWCNTs of 15 carbon layers (15 cl) considered for the chemisorption of one and two H atoms. The carbon atom sites for attachment of H atoms are shown (Reprinted with permission from reference Dinadayalane et al. (2007b). Copyright 2007 American Chemical Society)

SWCNTs have been calculated using the formula $E_r = E_{\text{SWCNT}+n\text{H}} - E_{\text{SWCNT}} - nE_{\text{H}}$, where $E_{\text{SWCNT}+n\text{H}}$ denotes the total energy of hydrogen-chemisorbed nanotube, n represents the number of hydrogen atoms chemisorbed, and E_{SWCNT} and E_{H} correspond to the energies of pristine nanotube and the hydrogen atom, respectively. The reaction energy E_r can also be considered as hydrogen chemisorption energy. The chemisorption of hydrogen is an exothermic process if the value of E_r is negative (Dinadayalane et al. 2007b).

We observed the rupture of circumferential C1–C2 bond when two hydrogen atoms were chemisorbed in the case of (3,3) SWCNT of 15 carbon layers. As shown in Fig. 43, the reactions of single as well as two hydrogen chemisorptions on the surface of armchair SWCNTs are highly exothermic. The reaction energy for the addition of two H atoms is more than two times that of one H chemisorption except for H(1,3) addition. Our computational study revealed a competition between H(1,2) and H(1,4) addition in the case of (5,5) and (6,6) SWCNTs, but such competition was not seen in the case of narrow diameter (3,3) and (4,4) SWCNTs. Increasing the length of the tube has pronounced effect on the reaction energy of hydrogen chemisorption. In case of armchair SWCNTs, the chemisorption of two hydrogen atoms at alternate positions is thermodynamically less favored compared to H(1,2) and H(1,2') additions regardless of the length and diameter of the tubes (Dinadayalane et al. 2007b). The least positional preference of H(1,3) for armchair SWCNTs is different compared to the results of zigzag-type nanotubes (Yang et al.

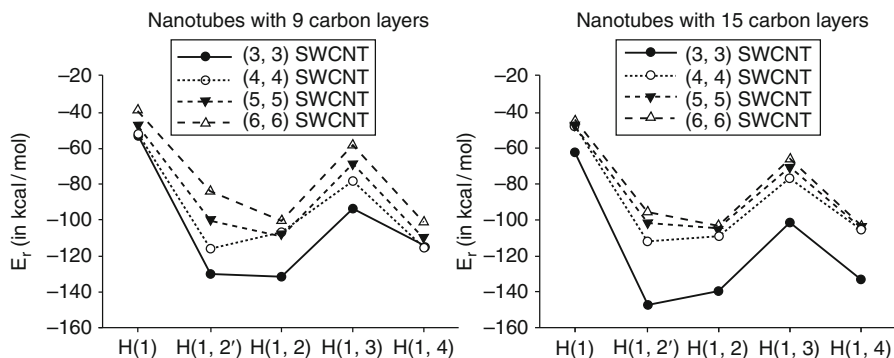

Fig. 43 The variation of reaction energies at the B3LYP/6-31G(d) level for the chemisorption of one and two hydrogen atoms on the external surface of (3,3), (4,4), (5,5), and (6,6) armchair single-walled carbon nanotubes (SWCNTs) (Reprinted with permission from reference Dinadayalane et al. (2007b). Copyright 2007 American Chemical Society)

2006c; Dinadayalane et al. 2007b). We found that the H chemisorption on nanotubes of different diameters and the positions of two hydrogen atoms chemisorbed on the surface of armchair SWCNTs can be characterized by C–H stretching frequencies of chemisorbed hydrogen atoms (Dinadayalane et al. 2007b). In the investigation of chemisorption of H atoms with (3,3) and (4,4) SWCNTs of different lengths, we found that changing the length of the nanotube has significant effect on the reaction energy of hydrogen chemisorption and HOMO–LUMO gap of pristine and hydrogen-chemisorbed SWCNTs (Kaczmarek et al. 2007).

The reactivity pattern was predicted for the hydrogenation in chiral SWCNTs (Ormsby and King 2007). Investigations involving chiral SWCNTs are more challenging than for zigzag and armchair SWCNTs because single unit cell contains many atoms; consequently, more computational resources are required. Computational study demonstrated that hydrogenation of the fully benzenoid (12,9) SWCNT was significantly less energetic (by 8 kcal/mol per mol H₂) than the hydrogenation of (12,7) and (12,8) SWCNTs (Fig. 44). Furthermore, the hydrogenation at an internal Clar double bond or bonds was reported to be more exothermic than at randomly selected internal bonds. Like other polycyclic aromatic hydrocarbons, hydrogenation of double bonds is energetically preferred over hydrogenation of aromatic sextets. The frontier molecular orbitals (HOMO and LUMO) of chiral SWCNTs have maximum amplitude at the double bonds suggesting that Clar's model also predicts the kinetic reactivity. Thus, the frontier molecular orbitals are useful in predicting the favorable sites for hydrogenation in chiral SWCNTs (Ormsby and King 2007).

In the early 2000s, experimentalists found that partial fluorination of the SWCNTs could be used as a technique for cutting the nanotubes of varying lengths. However, the mechanism of cutting the nanotube is not clear (Gu et al. 2002). In a computational study, Bettinger observed a strong oscillation of reaction energy for

Fig. 44 (a) Hydrogenation of equivalent vectors of (12,7), (12,8), and (12,9) chiral SWCNT segments (planar representation). (b) HOMO plotted on the isodensity surface for (12,7), (12,8), and (12,9) chiral SWCNTs. (c) LUMO plotted on the isodensity surface for (12,7), (12,8), and (12,9) chiral SWCNTs. the addition of F atom on the external surface of (5,5) SWCNT of varying lengths (Fig. 45). The computed reaction energy oscillation ranges from 43 to 68 kcal/mol at the UB3LYP/6-31G(d) level using UPBE/3-21G optimized geometries. The shortest tube exhibited the highest exothermicity. The energy oscillation was reported to be

Fig. 45 Variation of reaction energy for the addition of F atom to (5,5) armchair SWCNT of different lengths (n – increasing number of carbon layers) (Reprinted with permission from reference Bettinger (2004). Copyright 2004 American Chemical Society)

periodic with large exothermicity for the fully benzenoid frameworks, in agreement with their smaller band gaps compared to Kekule and incomplete Clar structures. Computational study demonstrated that the addition of F atom to the sidewall of SWCNT strongly depends on the length of the nanotube (Bettinger 2004). As observed in H atom addition (Dinadayalane et al. 2007b; Kaczmarek et al. 2007; Yang et al. 2006c), the F atom addition to the sidewalls of SWCNTs transforms the carbon atom hybridization from sp^2 to sp^3 (Bettinger 2004).

The chemical reactivity of carbon nanotubes is governed by the local atomic structure. As mentioned earlier, the pyramidalization angle is an important parameter in predicting the chemical reactivity of SWCNTs. Park et al. predicted the hydrogenation and fluorination energies of each carbon from its pyramidalization angle for zigzag SWCNTs (Fig. 46). They formulated the E_{total} for chemisorption of H and F atom on the external surface of zigzag tubes of different diameters as a function of pyramidalization angle of the binding site of tubes. They revealed that the metallic zigzag SWCNTs are slightly more reactive than the semiconducting SWCNTs. Furthermore, the fluorination is more viable than the hydrogenation (Park et al. 2003).

Theoretical Studies on Common Defects in SWCNTs

Investigating the atomic defects is important in tailoring the electronic properties of SWCNTs. Recent experimental study reported a method to selectively modify the electronic properties of semiconductor SWCNTs by the creation and annihilation of point defects on their surface with the tip of a scanning tunneling microscope (STM) (Berthe et al. 2007). Such experimental study motivates theoreticians to explore the structures, energetics, reactivities, and electronic properties of SWCNTs containing different types of defects.

Stone–Wales Defect

The Stone–Wales defect can be created by 90° rotation of one of the C–C bonds in the hexagonal network of SWCNTs. Two types of C–C bonds exist in each of armchair and zigzag SWCNTs. Therefore, one can generate Stone–Wales defect in two different orientations in both armchair and zigzag SWCNTs (Fig. 47). DFT calculations revealed that the formation energies of (5,5) SWD_II and (10,0) SWD_II are lower than those of (5,5) SWD_I and (10,0) SWD_I. The computed formation energies of (5,5) SWD_I, (5,5) SWD_II, (10,0) SWD_I, and (10,0) SWD_II are 66.4 (2.88 eV), 57.0 (2.47 eV), 68.9 (2.99 eV), and 63.0 (2.73 eV) kcal/mol, respectively. The formation energy was calculated as the relative energy of the Stone–Wales defective tube with respect to the corresponding defect-free SWCNT. It was reported that the formation of Stone–Wales defect causes no change in the HOMO–LUMO gaps (Yang et al. 2006a, b).

Fig. 47 Generation of Stone–Wales defect with different orientations in (5,5) armchair and (10,0) zigzag SWCNTs. The atoms in the Stone–Wales defect region are highlighted in *yellow color* (Reprinted with permission from reference Yang et al. (2006a). Copyright 2006 American Chemical Society. Reprinted with permission from Yang et al. (2006b). Copyright 2006, American Institute of Physics)

We investigated the structures, formation energies, and reactivities of Stone–Wales defect with two different orientations and different locations from the end of tube in armchair (5,5) SWCNTs of $C_{80}H_{20}$ (I) and $C_{100}H_{20}$ (II) (Fig. 48a; Dinadayalane and Leszczynski 2007b). We employed HF/4-31G, HF/6-31G(d), B3LYP/3-21G, and B3LYP/6-31G(d) levels of theory. HF/4-31G level overestimates the Stone–Wales defect formation energy compared to B3LYP/6-31G(d) level. Our study revealed that B3LYP/3-21G level, which provides reasonable energy estimation, may be employed for large nanotube systems to compute the defect formation energies when the calculations at the B3LYP functionals with large basis sets are prohibitive. Our study showed that the Stone–Wales defective (5,5) armchair SWCNTs generated by rotation of nearly axial bond (ABR) are more stable than those created by circumferential bond rotation (CBR) as shown in Fig. 48b. The SW defect structures generated by ABR show lower HOMO–LUMO gap than those created by CBR and the defect-free SWCNTs (Dinadayalane and Leszczynski 2007b).

Bettinger demonstrated in a comprehensive computational study that some of the bonds of SW defect show higher reactivity than pristine tube; others are less reactive (Bettinger 2005). Computational studies explained the reactivity of carbon atom sites based on the pyramidalization angles (Akdim et al. 2007; Bettinger 2005; Lu et al. 2005). Lu et al. investigated addition of O, CH_2 , and O_3 across C–C bonds of SW defective and defect-free armchair SWCNTs. They showed that the central C–C bond of the SW defect in armchair SWCNT (SW defect generated by CBR) is chemically less reactive than that in the perfect tube, and it was attributed to small local curvature in the carbon atoms of central C–C bond of the SW defect (Lu et al. 2005). We found that the values of pyramidalization angles do not completely

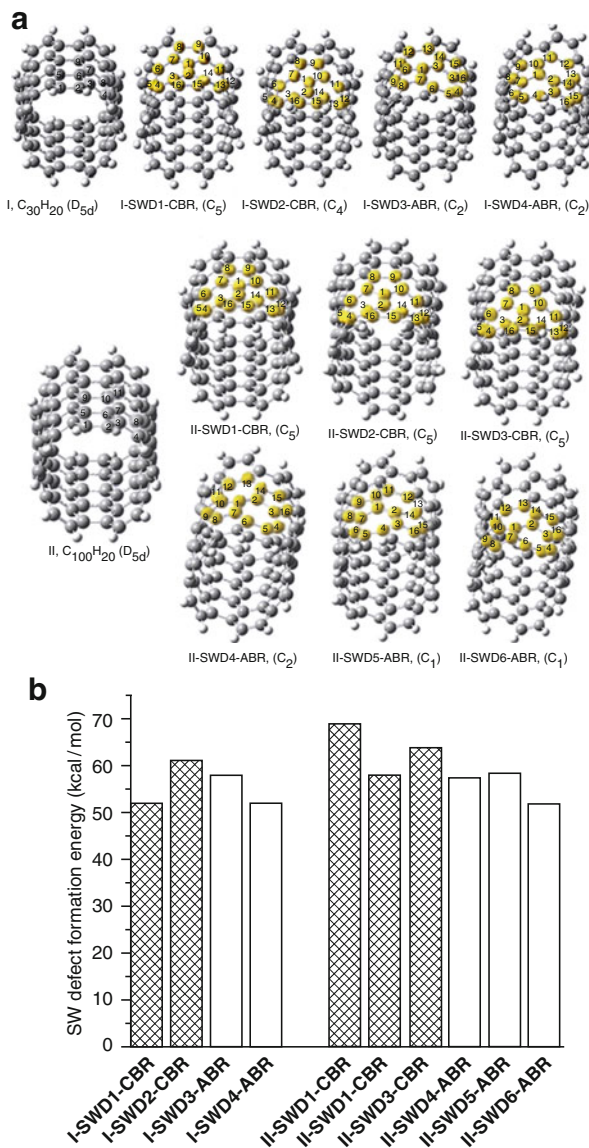

Fig. 48 (a) B3LYP/6-31G(d) level optimized structures of defect-free (5,5) armchair SWCNTs and the Stone–Wales defect tubes generated by the 90° rotation of circumferential and nearly axial C–C bonds. explain the reactivity of different bonds of SW defect region for cycloaddition reactions and the reactivity may arise from various other reasons, in addition to topology. We concluded that the cycloaddition reactions across the C–C bond

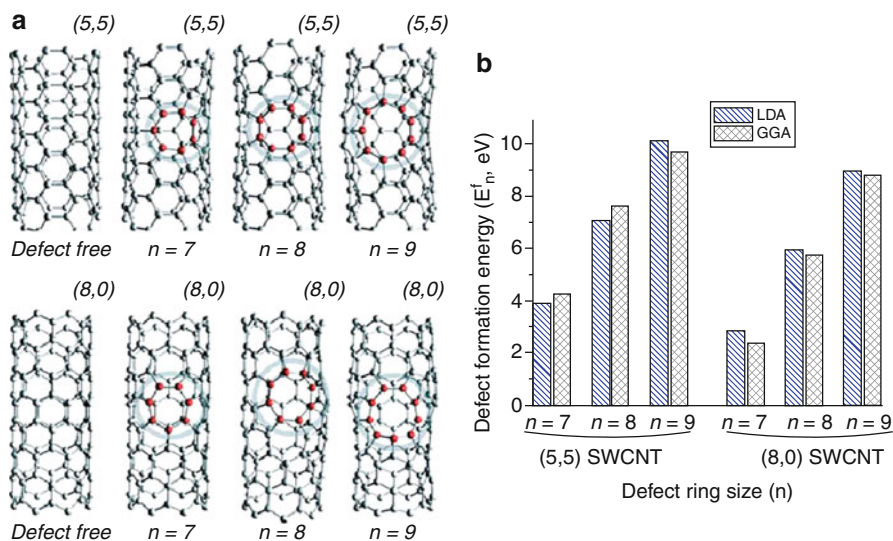

Fig. 49 (a) Fully relaxed structures of the defect-free and the defective (5,5) (upper panel) and (8,0) (lower panel) SWCNTs obtained by the GGA calculations. Gray balls and rods are the carbon atoms and bonds shorter than 1.5 Å, respectively. Carbon ring defects (given in red color) are indicated by the thick circles. shared by two heptagons (7-7 ring fusion) need not always be less reactive than the corresponding bond in the pristine structure and the reactivity of that bond depends on the orientation of the SWD in the SWCNTs (Dinadayalane and Leszczynski 2007b).

Topological Ring Defects

Nishidate and Hasegawa calculated the formation energies of n -membered topological ring defects with $n = 7$ (heptagon), $n = 8$ (octagon), and $n = 9$ (enneagon) in (5,5) armchair and (8,0) zigzag SWCNTs (Fig. 49a). They used both local density approximation (LDA) and the generalized gradient approximation (GGA: PW91). The spin-polarized projector augmented-wave (PAW) implemented in VASP code was employed for calculations, and periodic boundary condition was used (Nishidate and Hasegawa 2005).

The defect formation energy (E_f^n) of n -membered rings was calculated as the energy difference between the total energy of defective SWCNT (E_{tot}^n) and that of the pristine SWCNT (E_{tot}); i.e., $E_f^n = E_{tot}^n - E_{tot}$. The number of atoms of each defective SWCNT is the same as that of the corresponding SWCNT. Computational

study showed that the defect formation energy increases with increase in defect ring size (n) (Fig. 49b). In general, LDA method yielded higher defect formation energy than generalized gradient approximation. The SWCNTs were reported to be more fragile than the graphene sheet for defect formation. Distortion of the SWCNTs became larger as the defect ring size increases (Nishidate and Hasegawa 2005).

Single- and Di-vacancy Defects

An ideal single vacancy (SV) with three dangling bonds (DBs) was generated by removing one carbon atom from the perfect (5,5) and (10,0) SWCNTs. Upon geometry optimization, an ideal SV with three dangling bonds rearranged into a pentagonal ring and one DB (Yang et al. 2006a). Hence, this defect is called a 5-1DB defect (Lu and Pan 2004; Yang et al. 2006a). In case of (5,5) SWCNT, the optimization of the ideal SV resulted in two different 5-1DB defects. The structures were named as (5,5) SV_I and (5,5) SV_II as shown in Fig. 50. The latter structure

Fig. 50 Configurations of the single (SV) and double (DV) vacancies. Ideal SV and DV mean one and two carbon atoms removed from pristine SWCNT and the structures were not relaxed. Single and double vacancies in two different orientations (I and II) given for (5,5) and (10,0) SWCNTs. Carbon atoms in defect region are given in *yellow color* (Reprinted with permission from reference Yang et al. (2006a). Copyright 2006 American Chemical Society)

was reported to be energetically more favorable (by 1.20 eV) than the former one. A similar behavior was observed for (10,0) zigzag SWCNT. The bond length of the new C–C bond forming five-membered ring is 1.64 Å in (5,5) SV_I, while that of 1.55 Å was obtained for (5,5) SV_II (Yang et al. 2006a). Lu and Pan found using tight-binding calculations that the single-vacancy defect formation energy for (n,n) armchair SWCNTs increases monotonically with increasing tube radii. The formation energy curve of single-vacancy defects in the zigzag (n,0) SWCNTs is periodic, which is mainly characterized by metallic (n,0) tubes (such as (6,0), (9,0), (12,0), (15,0), etc.) (Lu and Pan 2004).

An ideal di-vacancy can be generated by removing two carbon atoms. Two different orientations are possible because of the presence of two different types of bonds in both (5,5) armchair and (10,0) zigzag SWCNTs. Upon geometry optimizations, SWCNTs with ideal di-vacancies yielded 5-8-5 (five-eight-five-membered rings) defects in two different orientations in both armchair- and zigzag-type tubes. Computational study revealed that (5,5) DV_II and (10,0) DV_II configurations are energetically more favorable than (5,5) DV_I and (10,0) DV_I by 0.97 and 0.63 eV, respectively. (5,5) DV_II and (10,0) DV_II can be obtained by removing the carbon atoms with the dangling bond from (5,5) SV_II and (10,0) SV_II, which are the most stable configurations among the possible types of SVs in each type of tubes (Yang et al. 2006a).

The di-vacancy in graphene as well as SWCNTs generates structures possessing two pentagons side by side with an octagon (585 structure) as a result of geometry optimization. The 585 configuration can reconstruct further into a complex structure composed of three pentagons and three heptagons, called 555777 defect structure. In fact, 555777 configuration is more stable than 585 configuration in graphene. Amorim et al. investigated the stability of these types of configurations, derived by di-vacancies, in armchair and zigzag SWCNTs considering different tube diameters (Amorim et al. 2007). The 585 defect in SWCNTs has two possible orientations with respect to the tube axis: perpendicular and tilted in armchair and parallel and tilted in zigzag SWCNTs. For the (5,5) SWCNT, the perpendicular orientation is less stable than the tilted one by 3.5 eV. In case of (8,0) SWCNT, the tilted orientation is less stable by 2.7 eV than the parallel one. Only the tilted and the parallel orientations of defects were considered for armchair and zigzag SWCNTs, respectively (Fig. 51; Amorim et al. 2007).

In contrast to graphene, the 585 defect was predicted to be more stable than the 555777 defect in both armchair and zigzag SWCNTs. Both 585 and 555777 defects in nanotubes (both armchair and zigzag) are more stable than in graphene. The defect formation energy increases monotonically as the diameter of the armchair SWCNT increases (Fig. 52a). The energy difference between the 585 defect and the 555777 defect was computed to be 1.6 eV in case of zigzag tubes, while the difference was reported to be 0.7 eV for armchair SWCNTs. Zigzag SWCNTs exhibited oscillations in the formation energies and the oscillations were related to the alternation between semiconductor and metallic character of the (n,0) zigzag SWCNTs (Fig. 52b; Amorim et al. 2007).

Fig. 51 Ball and stick models for the final geometries of the defects: (a) 585 and (b) 555777 in graphene; (c) 585 tilted and (d) 555777 in the (5,5) armchair SWCNT; (e) 585 parallel and (f) 555777 in the (8,0) zigzag SWCNT. The carbon atoms in pentagons are marked in *red*, the ones that complete either the octagons or the heptagons are colored in *blue*, and the ones at the center of the C_3 symmetry operation in the 555777 defects are colored in *green*. All the others are colored *gray* (Reprinted with permission from reference Amorim et al. (2007). Copyright 2007 American Chemical Society)

Outlook of Potential Applications of Carbon Nanostructures

Graphene is used as a base material for nanoelectromechanical systems (NEMS) due to its lightweight and stiffness properties (Bunch et al. 2007; Robinson et al. 2008). Functionalized graphene can be exploited for water splitting and hydrogen production. Scientists produce graphene-based materials with high structural and electronic quality for the preparation of transparent conducting electrodes for displays and touch screens. Solution processing and chemical vapor deposition are the ideal means to produce thin films that can be used as electrodes in energy devices such as solar panels, batteries, fuel cells, or in hydrogen storage (Bonaccorso et al. 2015). Graphene-based resonators have notable advantages in comparison with nanotubes. Reduced graphene oxide films are used to make drum resonators. The high Young's modulus, extremely low mass, and large surface area make the graphene-based resonators ideally suited for use as mass, force, and charge sensors (Ekinci et al. 2004; Knobel and Cleland 2003; Lavrik and Datskos 2003). Graphene can be used for metallic transistor applications and ballistic transport. One of the potential applications of graphene sheet is its use as membrane for separation (Jiang et al. 2009). Graphene may be useful for electro- and magneto-optics (Geim 2009). Graphane (fully hydrogenated graphene) nanoribbons have quite promising applications in optics and opto-electronics due to the wide band gap. Graphene may also be used for transistor applications (Novoselov et al. 2004). Research into applications for carbon graphene nanosheets has focused on their uses as platforms for next-wave microchips, active materials in field emitter arrays for flat panel screen displays; in gas sensors (Wang et al. 2015a), biological sensors, and medical imaging devices; in solar energy cells; and in high-surface area electrodes for use

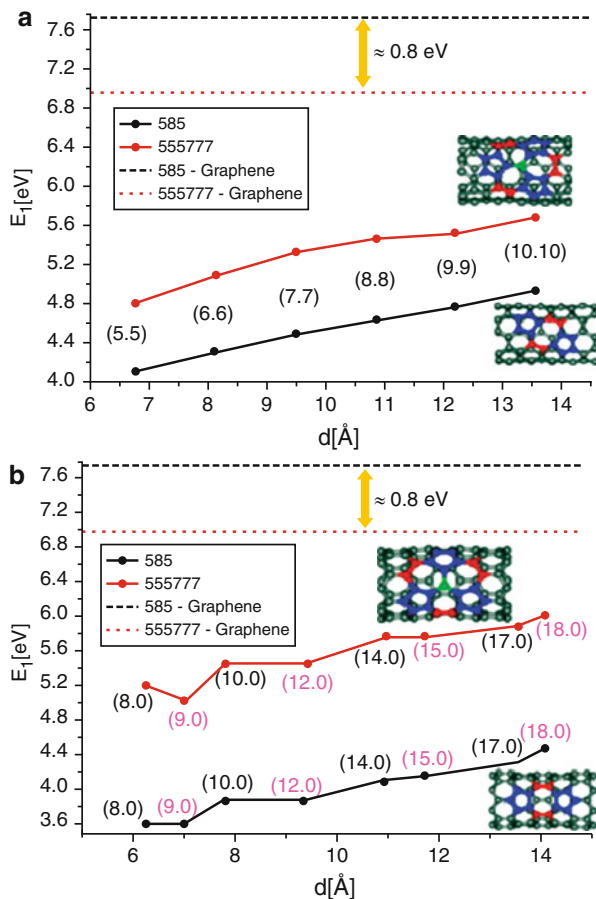

Fig. 52 Formation energy vs. diameter for the 585 and 555777 defects in (a) armchair and (b) zigzag SWCNTs. The limits for graphene were given in both graphs (Reprinted with permission from reference Amorim et al. (2007). Copyright 2007 American Chemical Society)

in bioscience. Graphene-based materials are known for energy and environmental applications (Bo et al. 2015; Chen et al. 2015; Yuan and He 2015). Graphene is a possible replacement material where carbon nanotubes are presently used (Xia et al. 2009). Graphene-based liquid crystal devices (LCD) show excellent performance with high contrast ratio. Thus, LCDs might be graphene's first realistic commercial application (Blake et al. 2008).

Fullerenes hold possibilities of application in many areas including antiviral activity, enzyme inhibition, DNA cleavage, photodynamic therapy, electron transfer, ball bearings, lightweight batteries, new lubricants, nanoscale electrical switches, new plastics, antitumor therapy for cancer patients, and combustion science and astrophysics (Dresselhaus et al. 1996; Lebedeva et al. 2015). The fullerene deriva-

tives obtained by attachment of electron donor moieties are used as photovoltaic devices. The supramolecular design of molecular assemblies involving fullerenes holds the possibility to reach new efficient photovoltaic devices (Hudhomme and Cousseau 2007). Fullerenes show promising biomedical applications (Bakry et al. 2007; Bosi et al. 2003; Mashino et al. 2003; Stoilova et al. 2007; Thrash et al. 1999). The fullerene derivatives showed antibacterial and antiproliferative activities; they inhibited bacteria and cancer cell growth effectively (Mashino et al. 2003). Cationic fullerenes were identified to work as antimicrobial photosensitizers. Bis-functionalized C_{60} derivatives have shown the activity against HIV-1 and HIV-2 strains (Bosi et al. 2003). The antiviral activity of fullerene derivatives is based on several biological properties including their unique molecular architecture and antioxidant activity (Bakry et al. 2007). Fullerenes derivatized by hydrophilic moieties are capable of carrying drugs and genes for the cellular delivery (Thrash et al. 1999). The localization of the metallofullerol in bone might be a useful chemotherapeutic agent for treatment of leukemia and bone cancer (Thrash et al. 1999).

Several potential applications have been proposed for carbon nanotubes, for example, conductive and high-strength composites, energy storage and energy conversion devices, sensors, field emission display and radiation sources, and nanotube-based semiconductor devices (Baughman et al. 2002; Sinha and Yeow 2005). Supercapacitors with carbon nanotube electrodes can be used for devices that require higher power capabilities than batteries. Nanotubes have potential application as hydrogen storage (Dinadayalane and Leszczynski 2009). CNTs can be added to aircraft to offer EMI (electromagnetic interference) shielding and lightning strike protection. They will also make the aircraft stronger and lighter, allowing for larger payloads and greater fuel efficiency. They may be used in commercial aircraft and in notebook computers to efficiently draw away generated heat without adding additional weight (Sinha and Yeow 2005). Nanotube films may be used by the automobile industry to make cars and trucks stronger yet lighter and, therefore, more fuel efficient. Three-dimensional graphene-CNT hollow fibers with radially aligned CNTs could be useful for efficient energy conversion and storage (Xue et al. 2015; Yu et al. 2014; Zhu et al. 2012).

MWCNTs show great potential for use in nanofluidic devices because of their high mechanical strength and fluid transport ability at near-molecular length scales (Sinha and Yeow 2005). Due to the advantages of miniature size of the nanotube and the small amount of material required, the carbon nanotubes are being explored for chemical sensing applications. SWCNTs are promising materials for building high-performance nano-sensors and devices (Close et al. 2008). Defects in SWCNTs play an important role in chemical sensing applications (Robinson et al. 2006). CNTs can be used as implanted sensors to monitor pulse, temperature, blood glucose, and heart's activity level and can also be used for repairing damaged cells or killing them by targeting tumors by chemical reactions (Sinha and Yeow 2005). Some of the selected applications of carbon nanotubes are shown in Fig. 53.

Potential biological and biomedical applications of CNTs are under investigation (Dhar et al. 2008; Karousis et al. 2009; Liu et al. 2007; Sinha and Yeow 2005).

Carbon nanotubes have potential to make miniature biological electronic devices, including probes and sensors (Sotiropoulou and Chaniotakis 2003; Stevens et al. 2000, 2004). Water-soluble peptidomimetic-functionalized carbon nanotubes have been reported to have antitrypsin activity (Dhar et al. 2008). Functionalized and water-soluble SWCNTs have been explored to find biological applications in the area of drug delivery (Dhar et al. 2008; Karousis et al. 2009; Liu et al. 2007). CNTs could be used as potential delivery tools for peptide-based synthetic vaccines. CNTs are currently being considered as suitable substrate for neuronal growth, as ion channel blockers, and as vectors for gene transfection (Sinha and Yeow 2005). Carbon nanotubes have provided possibilities for applications in nanotechnology. Continuous and optimistic research efforts in the area of carbon nanotubes are required to realize a lot of breakthrough commercial applications.

Summary and Outlook

In this chapter, we provided vital information and up-to-date research on carbon nanostructures, particularly graphene, fullerenes, and carbon nanotubes, which are critical in the nanotechnology revolution. This chapter also covered the modeling aspects, especially the current trends of computational chemistry applications in understanding the structures, reactivity, and other properties of abovementioned carbon nanostructures, and their importance in supporting the experimental results. Many aspects of basic research and practical application requirements have been motivating both theoreticians and experimentalists to gain better understanding about the carbon nanostructures. Obtaining knowledge on a specific class of chemical reactions with graphene, fullerenes, and SWCNTs is required for making novel materials as well as producing carbon-based nanomaterials for specific applications. Computational investigations provide opportunity to understand the structures, binding of atoms/molecules with the carbon nanotubes. A systematic and careful computational chemistry approaches could have important implications for the rational design of novel CNT composite materials, novel nanotube-based sensors, as well as for the development of new chemical strategies for SWCNT functionalization. Strong interactions between experimentalists and theoreticians working in the area of carbon nanostructures will enhance the real-time applications rapidly. Future efforts should not only provide high-tech nano-devices but also address fundamental scientific questions. Further exciting developments in nanoscience and nanotechnology are expected.

Abstract

This chapter reviews the fundamental concepts of excitons and excitonic polaritons and their extraordinary optical properties in quantum dot nano-composite materials. By starting with the optical excitation of an exciton in the nanostructure we show that the effective dielectric constant of the nanostructure becomes significantly modified due to the exciton generation and recombination, resulting

in high positive and negative dielectric constants. We also discuss single exciton generation by multiple photons and multiple exciton generation by single photon. All these nonlinear optical properties of quantum dot nano-composite materials offer novel possibilities and are expected to have deep impact in nanophotonics.

Introduction

Materials with nanoscale features have the potential to revolutionize optoelectronics, permitting new and interesting device and system capabilities. The key design element is the geometry, that is, size and shape, which defines the properties of the nanostructured material and has led to the expectation of new and/or significantly improved physical, electrical, and optical properties. To precisely engineer light-matter interaction at the nanoscale, electron-hole pairs, that is, excitons, and their coupling with photons, exciton-polaritons, are becoming increasingly important. Excitons are of great interest in nanoscience because it has been discovered that their properties can be dictated by the size and the shape of a nanostructure in which they are confined, in addition to the constitution of the nanostructure. The new aspect of excitons that is prevalent in or even defining nanoscience is that the physical size and shape of the nanostructure are parameters that significantly influence their properties.

Exciton polaritons were intensively studied in the 1960s and 1970s, and their manifestation in various optical phenomena, including light reflection and transmission, photoluminescence, and resonant light scattering are well established and documented by now, see, for example, the dedicated volume (Sturge and Rashba 1982) and references therein. We refer to Kavokin (2007) that presents detailed discussions of energy dispersion of exciton-polaritons in microcavities (largely about quantum wells, QWs), to Scholes and Rumbles (2006) for a very intuitive description of excitons in nanoscale systems and a detailed review about excitons in polymers and nanotubes, and to Weisbuch et al. (2000) for research and development of excitons and photons in confined structures from three-dimensionally (3D) extended states (bulk) to atom-like quantum dots (QDs) and their applications in light emitting devices.

In semiconductor technology, the geometric miniaturization of individual components and devices have been scaling according to Moore's Law (International Technology Roadmap for Semiconductors; Fu et al. 2006a). Photonics has also been catching up (Thylén et al. 2006) but at a slow pace due to the limitations imposed by the diffraction limit. Resonant excitonic states in nanostructures, after coupling with light to form excitonic polaritons, provide a source for both high and negative dielectric constant (Fu et al. 2006b, 2008; Zia et al. 2006), thus offering novel possibilities to drastically increase the integration density and new functionalities in photonics at the nanoscale. Rapid growth of nanotechnology also greatly expands the clinical opportunities. Colloidal QDs are highly fluorescent with excellent photochemical stability, extreme brightness, and broad excitation spectral range, which have been introduced successfully in many fluorescence-based optical imaging applications (Medintz et al. 2005). Surface-modified and water-soluble

QDs open a new era in cell imaging and bio-targeting as transport vehicles for therapeutic drug delivery to different diseases such as cancer and atherosclerosis (Derfus et al. 2007; Molnár et al. 2010; Vashist et al. 2006).

In this chapter we concentrate on nano-semiconductor systems, where it has become possible during the last 15 years to handle and control single excitons. More specifically we focus on excitons and exciton-polaritons in semiconductor QDs. This chapter presents first a theoretical background of the solid-state theory, the exciton and the coupling between the exciton and the photon (excitonic polariton). Optical properties of exciton polaritons in nanostructures and their photonic engineering are then discussed.

Solid-State k·p Theory

The theoretical description of electronic and optical properties of nanostructures is currently advancing using modern quantum methodologies such as pseudo potential, tight-binding, and atomistic semi-empirical pseudo potential methods (Allan and Delerue 2008; Franceschetti et al. 2006; Jiang et al. 2009; Rabani and Baer 2008). However, these studies have been limited to light atoms and small nanostructure sizes. Our target nanostructure systems are about 10 nm in diameter and even more where macroscopic micrometer scale solid-state theory is well developed.

In isolated atoms the energy levels are sharply defined. When two atoms are brought close to each other their electron wave functions overlap. As a result of the interaction between the electrons, it turns out that each single state of the isolated atom splits into two states with different energies. The degree of splitting increases as the inter-atomic separation decreases. Similarly, if five atoms are placed in close proximity, then each original energy level splits into five new levels. The same process occurs in a solid, where there are roughly 10^{28} atoms/m³: The energy levels associated with each state of the isolated atom spread into essentially continuous energy bands separated from each other by energy gaps.

Before further examining the various properties of semiconductors it is extremely useful to examine the atomic structure of some of the elements which make up commonly used semiconductors as listed in Table 1.

A very important conclusion can be drawn about the elements making up the semiconductors: The outmost valence electrons are made up of electrons in either the s- or p-type orbitals. While this conclusion is strictly true for elements in

Table 1 Atomic structures of typical elements making up common semiconductors

Element	Core electrons	Valence electrons
IV-Si	$1s^2 2s^2 2p^6$	$3s^2 3p^2$
IV-Ge	$1s^2 2s^2 2p^6 3s^2 3p^6 3d^{10}$	$4s^2 4p^2$
III-Ga	$1s^2 2s^2 2p^6 3s^2 3p^6 3d^{10}$	$4s^2 4p^1$
V-As	$1s^2 2s^2 2p^6 3s^2 3p^6 3d^{10}$	$4s^2 4p^3$
II-Cd	$1s^2 2s^2 2p^6 3s^2 3p^6 3d^{10} 4s^2 4p^6 4d^{10}$	$5s^2$
VI-Se	$1s^2 2s^2 2p^6 3s^2 3p^6 3d^{10}$	$4s^2 4p^4$

the atomic form, it turns out that even in crystalline semiconductors the electrons in the valence band (VB) and conduction band (CB) retain this s- or p-type character. The core electrons are usually not of interest, except of some special characterization-type experiments. Note that II–VI compounds such as CdSe are normally complicated and their lattice structures are hexagonal.

In general, it is found that when atoms exchange or share valence electrons so that the complement of quantum states is completed, they have a lower electrostatic energy for their combined electron patterns than when they are separate. For example, silicon has four valence electrons grouped in two closely spaced energy levels (3 s and 3 p, see Table 1); it can combine with other silicon atoms by sharing four valence electrons with four surrounding silicon atoms in an endless array. The atoms around any one atom are centered at the corners of a regular tetrahedron: the tetrahedral bond. This creates the diamond crystal structure.

Essentially all semiconductors of interest for electronics and optoelectronics have the face-centered cubic (fcc) structure. However, they have two atoms per basis. The coordinates of the two basis atoms are (000) and $(a/4)(111)$, indicated in d_1 and d_2 in Fig. 1b. Here a is normally denoted as the crystal lattice constant. If the two atoms of the basis are identical, the structure is called the diamond structure. Semiconductors such as silicon, germanium, and carbon fall into this category. If the two atoms are different, for example, GaAs, AlAs, and CdS, the structure is called zincblende.

The intrinsic property of a crystal is that the environment around a given atom or group of atoms is exactly the same as the environment around another atom or similar group of atoms. Many of the properties of crystals and many of the theoretical techniques used to describe crystals derive from such a periodicity of crystalline structures. This suggests the use of Fourier analysis in the form of real space–reciprocal space or wave vector space duality for crystal problem discussions. Many concepts are best understood in terms of functions of the wave vector. We prefer to describe a wave with wavelength λ as a plane wave with wave

Fig. 1 (a) Face-centered cubic (fcc) lattice with primitive translation vectors R_1 , R_2 , and R_3 (b) Zincblende crystal structure where d_1 and d_2 denote two different atoms (can be identical such as in Si crystal in which case the lattice structure is called diamond). In both (a) and (b), a denotes the lattice constant

vector \mathbf{k} of magnitude $2\pi/\lambda$ and propagation direction perpendicular to the wave front. The space of the wave vectors is called the reciprocal space.

The $\mathbf{k}\cdot\mathbf{p}$ method is much used in analyzing semiconductor nanostructures as it gives a good approximation of the states close to the Γ point ($k = 0$), which is the most relevant region for many device applications. The approximation is given with good accuracy, while in many nanostructure calculations, this is the only feasible numerical model that can be implemented (even though it is still much restricted due to the computational capability).

The goal is essentially to solve the Schrödinger equation for a nanostructure to get the eigenenergies and their associated eigenvectors (wave functions). The wave functions usually have too high frequencies to be feasible to calculate explicitly using numerical methods on computers as an inordinately high number of grid points would be necessary to capture an acceptable numerical representation of the wave function. A solution is to separate the wave functions into an oscillatory part and a modulating part which is of the same scale as the heterostructure. This is the basic idea of the envelope function approximation – the modulating part is called the envelope function. We write the envelope function as a Bloch function:

$$\psi_{nk}(\mathbf{r}) = e^{i\mathbf{k}\cdot\mathbf{r}} u_{nk}(\mathbf{r}) \quad (1)$$

where n is the state index and k is the wave vector. The Schrödinger equation for this wave function is simply

$$\left[\frac{\mathbf{p}^2}{2m_0} + V(\mathbf{r}) \right] \psi_{nk}(\mathbf{r}) = E_n(\mathbf{k}) \psi_{nk}(\mathbf{r}) \quad (2)$$

Substituting the factorization into the equation requires some care in evaluating the product of the momentum operator \mathbf{p} and the two parts of the wave function. With $\mathbf{p} = -i\hbar\nabla$ and knowing from vector calculus that $\nabla e^{i\mathbf{k}\cdot\mathbf{r}} = i\mathbf{k}e^{i\mathbf{k}\cdot\mathbf{r}}$, the product of the momentum operator and the wave function becomes

$$-i\hbar\nabla [e^{i\mathbf{k}\cdot\mathbf{r}} u_{nk}(\mathbf{r})] = -i\hbar e^{i\mathbf{k}\cdot\mathbf{r}} (\nabla + i\mathbf{k}) u_{nk}(\mathbf{r}) = e^{i\mathbf{k}\cdot\mathbf{r}} (\mathbf{p} + \hbar\mathbf{k}) u_{nk}(\mathbf{r}) \quad (3)$$

Applying the momentum operator a second time gives $e^{i\mathbf{k}\cdot\mathbf{r}} (\mathbf{p} + \hbar\mathbf{k})^2 u_{nk}(\mathbf{r})$, so the Schrödinger equation can be written in the following way that the oscillatory part will cancel out:

$$e^{i\mathbf{k}\cdot\mathbf{r}} \left[\frac{(\mathbf{p} + \hbar\mathbf{k})^2}{2m_0} + V(\mathbf{r}) \right] u_{nk}(\mathbf{r}) = e^{i\mathbf{k}\cdot\mathbf{r}} E_n(\mathbf{k}) u_{nk}(\mathbf{r}) \quad (4)$$

Expanding the $(\mathbf{p} + \hbar\mathbf{k})^2$ term gives

$$\left[\frac{\mathbf{p}^2}{2m_0} + V(\mathbf{r}) + \frac{\hbar\mathbf{k} \cdot \mathbf{p}}{m_0} + \frac{\hbar^2 k^2}{2m_0} \right] u_{nk}(\mathbf{r}) = E_n(\mathbf{k}) u_{nk}(\mathbf{r}) \quad (5)$$

Fig. 2 Energy band structures of electrons in GaAs and InAs bulk materials

The first two terms are identical to the original Hamiltonian, so if the two other terms are treated as a small perturbation the Hamiltonian can be expressed as $(H_0 + H_1 + H_2) u_{nk}(\mathbf{r}) = E_n(\mathbf{k}) u_{nk}(\mathbf{r})$, and treat $H_1 = (\hbar/m_0) \mathbf{k} \cdot \mathbf{p}$ and $H_2 = \hbar^2 k^2 / 2m_0$ as first-order and second-order perturbations, respectively.

If the equation is solved for $\mathbf{k} = 0$ with only H_0 remaining nonzero, the result is a set of eigenvectors $u_{n0}(\mathbf{r})$, typically at the optimal points such as the Γ point in Fig. 2 which shows the energy band structure of most common GaAs and InAs bulk materials. For the following discussion we express the eigenfunction using Dirac notation as $|n\rangle$, and eigenvalues E_n . These form a complete basis set with orthogonal eigenfunctions which can be used in perturbation calculations of states with $\mathbf{k} \neq 0$.

As the atoms of the elements making up the semiconductors are brought together to form the crystal, the valence electronic states are perturbed by the presence of neighboring atoms. While the original atomic functions describing the valence electrons, of course, no longer are eigenstates of the problem, their characteristics can be used as a good approximate set of basis states to describe the “crystalline” electrons. For most semiconductor materials of interest, the atomic functions required to describe the outermost electrons are s , p_x , p_y , and p_z types, as shown by Table 1. A common approach of choosing the above $|n\rangle$, at the Γ point is to follow Kane (1957) and define a set of eight states, that is, $u_{nk}(\mathbf{r})$ in Eq. 1 at $\mathbf{k} = 0$, $|S \uparrow\rangle$, $|X \uparrow\rangle$, $|Y \uparrow\rangle$, $|Z \uparrow\rangle$, $|S \downarrow\rangle$, $|X \downarrow\rangle$, $|Y \downarrow\rangle$, $|Z \downarrow\rangle$, where the arrows indicate spin up and down. $|X, Y, Z\rangle$, denotes degenerate VBs while $|S\rangle$ denotes the CB. Other remote bands are not included unless specifically required.

The eigen function for a given \mathbf{k} is a linear combination of the basis functions:

$$u_{nk}(\mathbf{r}) = \sum_m c_{nm}(\mathbf{k}) |m\rangle \quad (6)$$

so the objective is now to find the coefficients c_{nm} that form our envelope parts together with the basis functions at Γ .

If we substitute this linear combination into the Schrödinger equation, we get

$$H \sum_m c_{nm}(\mathbf{k}) |m\rangle = \sum_m c_{nm}(\mathbf{k}) H |m\rangle = E_n(\mathbf{k}) \sum_m c_{nm}(\mathbf{k}) |m\rangle \tag{7}$$

Multiply this on the left with the conjugate of any, say $|\ell\rangle$, of the basis functions, and we obtain

$$\sum_m c_{nm}(\mathbf{k}) \langle \ell | H | m \rangle = E_n(\mathbf{k}) \sum_m c_{nm}(\mathbf{k}) \langle \ell | m \rangle = E_n(\mathbf{k}) c_{n\ell}(\mathbf{k}) \tag{8}$$

The right-hand part is the result of wave function's orthonormal property.

Inserting the expanded $\mathbf{k}\cdot\mathbf{p}$ Hamiltonian Eq. 5, multiplying with the conjugate, and integrating over an unit cell using the fact that the basis functions are orthonormal gives

$$\sum_m \left[\left(E_m + \frac{\hbar^2 k^2}{2m_0} \right) \delta_{\ell m} + \frac{\hbar}{m_0} \langle \ell | \mathbf{k} \cdot \mathbf{p} | m \rangle \right] c_{nm}(\mathbf{k}) = E_n(\mathbf{k}) c_{n\ell}(\mathbf{k}) \tag{9}$$

The first-order approximation is thus

$$E_n(\mathbf{k}) = E_n + \frac{\hbar^2 k^2}{2m_0}, \quad c_{nm}(\mathbf{k}) = \delta_{nm} \tag{10}$$

The second-order approximation is thus given by

$$E_n(\mathbf{k}) = E_n + \frac{\hbar^2 k^2}{2m_0} + \frac{\hbar}{m_0} \sum_{\ell \neq n} \frac{|\langle \ell | \mathbf{k} \cdot \mathbf{p} | n \rangle|^2}{E_n - E_\ell} \tag{11}$$

The result can be expressed in terms of an effective mass m^* :

$$E_n(\mathbf{k}) = E_n + \sum_{i,j} \frac{\hbar^2}{2m_{ij}^*} k_i k_j \tag{12}$$

where $i, j = x, y, z$, and

$$\frac{m_0}{m_{ij}^*} = \delta_{ij} + \frac{2}{m_0} \sum_{\ell \neq n} \frac{\langle n | p_i | \ell \rangle \langle \ell | p_j | n \rangle}{E_n - E_\ell} \tag{13}$$

Note here that the effective mass can be anisotropic which can be utilized for optical coupling in quantum well photodetection (Xu et al. 1994).

It can be easily seen that a narrow bandgap, which leads to two states being close to each other, gives a small effective mass which agrees very well with the experimental data which indicates that InSb has both the smallest bandgap and the lowest effective mass. By a series of experiments the parameters for the $\mathbf{k}\cdot\mathbf{p}$ Hamiltonian can be determined, and the final result is a matrix with many material-dependent parameters and no arbitrary parameters to adjust. Details of the $\mathbf{k}\cdot\mathbf{p}$ Hamiltonian for III–V and II–VI semiconductor materials are well documented in reviews (Madelung 1991, 1992; Vurgaftman et al. 2001).

Excitons in Nanostructures

After reviewing some solid state theory, we are now capable of modeling excitons and exciton-polaritons in semiconductor nanostructures. We first study and model the exciton in general, then excitons in QD-based nanostructures, and finally applications of QD excitons and exciton-polaritons. Details of exciton theory can be found in Dimmock (1967) and Fu and Willander (1999).

As discussed in the previous section, the energy band structure of electrons in a semiconductor consists of energy bands separated by band gaps. At absolute zero temperature, a pure semiconductor is characterized by having only completely occupied and completely empty energy bands. The highest occupied bands are referred as VBs and the lowest unoccupied band is the CB. Let H_0 be the Hamiltonian of the nanostructure under investigation, then

$$H_0\psi_{vk_h}(\mathbf{r}_h) = E_v(\mathbf{k}_h)\psi_{vk_h}(\mathbf{r}_h)$$

denotes the VB state and

$$H_0\psi_{ck_e}(\mathbf{r}_e) = E_c(\mathbf{k}_e)\psi_{ck_e}(\mathbf{r}_e)$$

the CB state. We consider an optical absorption process in which an allowed electric dipole (not ultra intense excitation) transition raises an electron from a filled VB state to an empty CB state. The properties of a system with an electron missing from a VB state ψ_{vk_h} can be described by considering a single particle of positive charge in the state, that is, the VB hole. The exact expression of the interaction potential between the CB electron and VB hole is rather complicated. For commonly used semiconductor systems, and when the electron and hole are widely separated and moving relatively slowly with respect to one another, the Coulomb interaction between them is screened and given by Dimmock (1967)

$$V(\mathbf{r}_e - \mathbf{r}_h) = -\frac{e^2}{4\pi\epsilon_\infty |\mathbf{r}_e - \mathbf{r}_h|} \quad (14)$$

where ϵ_∞ is the high-frequency dielectric constant.

The exciton state is described by the two-particle wave function

$$\psi_{c\mathbf{k}_e}(\mathbf{r}_e) \psi_{v\mathbf{k}_h}(\mathbf{r}_h)$$

The total wave vector of the excited state is $\mathbf{K} = \mathbf{k}_e + \mathbf{k}_h$. Because of the Coulomb interaction, $\psi_{c\mathbf{k}_e}(\mathbf{r}_e) \psi_{v\mathbf{k}_h}(\mathbf{r}_h)$ does not represent an eigen state of the system. We approximate the eigen state of the exciton by a linear combination of electron-hole-states

$$\psi_{n\mathbf{K}}(\mathbf{r}_e, \mathbf{r}_h) = \sum_{c\mathbf{k}_e, v\mathbf{k}_h} A_{n\mathbf{K}}(c\mathbf{k}_e, v\mathbf{k}_h) \psi_{c\mathbf{k}_e}(\mathbf{r}_e) \psi_{v\mathbf{k}_h}(\mathbf{r}_h) \quad (15)$$

where n is the quantum index of the exciton state. By introducing the Fourier transform of $A_{n\mathbf{K}}(c\mathbf{k}_e, v\mathbf{k}_h)$,

$$\psi_{n\mathbf{K}}(\mathbf{r}_e, \mathbf{r}_h) = \frac{1}{\Omega} \sum_{\mathbf{k}_e, \mathbf{k}_h} e^{i\mathbf{k}_e \cdot \mathbf{r}_e} e^{i\mathbf{k}_h \cdot \mathbf{r}_h} A_{n\mathbf{K}}(c\mathbf{k}_e, v\mathbf{k}_h) \quad (16)$$

where Ω is the normalization volume, it is easy to show that $\psi_{n\mathbf{K}}(\mathbf{r}_e, \mathbf{r}_h)$ satisfies the differential equation

$$[E_c(-i\nabla_e) - E_v(-i\nabla_h) + V(\mathbf{r}_e - \mathbf{r}_h)] \psi_{n\mathbf{K}}(\mathbf{r}_e, \mathbf{r}_h) = E \psi_{n\mathbf{K}}(\mathbf{r}_e, \mathbf{r}_h) \quad (17)$$

where $E_c(-i\nabla_e)$ is the expression obtained by replacing \mathbf{k}_e in the power-series expansion of $E_c(\mathbf{k}_e)$ by $-i\nabla_e$. The result is valid provided $E_c(\mathbf{k}_e)$ and $E_v(\mathbf{k}_h)$ are analytic and can be expanded in powers of \mathbf{k}_e and \mathbf{k}_h . In the effective mass approximation of Eq. 12, the exciton Hamiltonian becomes

$$H_o = -\frac{\hbar^2 \nabla_e^2}{2m_e^*} - \frac{\hbar^2 \nabla_h^2}{2m_h^*} - \frac{e^2}{4\pi \epsilon_\infty |\mathbf{r}_e - \mathbf{r}_h|} \quad (18)$$

where m_e^* and m_h^* are effective masses of electron and hole.

It is easier to introduce the relative and centre-of-mass coordinates $\mathbf{r}_e - \mathbf{r}_h$ and $\mathbf{R} = (m_e^* \mathbf{r}_e + m_h^* \mathbf{r}_h) / (m_e^* + m_h^*)$ to solve the above exciton Hamiltonian

$$H_o = -\frac{\hbar^2 \nabla_{\mathbf{R}}^2}{2(m_e^* + m_h^*)} - \frac{\hbar^2 \nabla_{\mathbf{r}_e - \mathbf{r}_h}^2}{2m_h^*} - \frac{e^2}{4\pi \epsilon_\infty |\mathbf{r}_e - \mathbf{r}_h|} \quad (19)$$

where $1/m_r^* = 1/m_e^* + 1/m_h^*$ is the reduced effective mass.

For three-dimensionally extended bulk material, the part of the wave function in \mathbf{R} contains a factor of $e^{i\mathbf{K} \cdot \mathbf{R}}$, the part in the relative coordinates contains a hydrogenic $\psi_{n\mathbf{K}}(\mathbf{r}_e, \mathbf{r}_h) = \psi_{n\mathbf{K}}(\mathbf{r}_e - \mathbf{r}_h)$ so that the exciton wave function and its energy are

$$e^{i\mathbf{K}\cdot\mathbf{R}}\psi_{n\mathbf{K}}(\mathbf{r}_e, \mathbf{r}_h), \quad E_{n\mathbf{K}} = \frac{\hbar^2 K^2}{2(m_e^* + m_h^*)} - \frac{m_r^* e^4}{2\epsilon_\infty^2 n^2}, \quad (20)$$

and the wave function of the ground exciton state ($n = 1$) corresponding to the last two terms of the Hamiltonian Eq. 19 is

$$\psi_{1\mathbf{K}}(\mathbf{r}_e, \mathbf{r}_h) = \frac{1}{\sqrt{\pi a_{\text{Br}}^3}} e^{-|\mathbf{r}_e - \mathbf{r}_h|/a_{\text{Br}}} \quad (21)$$

where $a_{\text{Br}} = 4\pi\epsilon_\infty\hbar^2/m_r^*e^2$ is the Bohr radius of the exciton in the semiconductor material. In three-dimensionally confined nanostructures, the center of mass of the exciton is not mobile so that we simply let $\mathbf{K} = 0$ in Eqs. 20 and 21.

We now study the effect of excitons on the optical transition. The probability that the system makes an electronic transition from the ground state ψ_0 to an excited (exciton) state $\psi_{n\mathbf{K}}(\mathbf{r}_e, \mathbf{r}_h)$ is proportional to

$$|\langle \psi_{n\mathbf{K}} | e^{i\mathbf{q}\cdot\mathbf{r}} \mathbf{a} \cdot \mathbf{p} | \psi_0 \rangle|^2 \quad (22)$$

where p is the momentum operator, q and a are, respectively, the wave vector and polarization vector of the photon. By Eq. 15 we obtain

$$\langle \psi_{n\mathbf{K}} | \mathbf{p} | \psi_0 \rangle = \sum_{c\mathbf{k}_e, v\mathbf{k}_h} A_{n\mathbf{K}}(c\mathbf{k}_e, v\mathbf{k}_h) \langle \psi_{c\mathbf{k}_e} | \mathbf{p} | \theta \psi_{v\mathbf{k}_h} \rangle \quad (23)$$

where θ is the time-reversal operator and $\theta\psi_{v\mathbf{k}_h}$ is the unoccupied VB state out of which the electron was excited. Denoting $\theta\psi_{v\mathbf{k}_h} = \psi_{v-\mathbf{k}_h}$ as the hole state and making use of the negligible q (the photon wave vector is negligibly small so that $\mathbf{K} = 0$) so that $\mathbf{k}_e = -\mathbf{k}_h \equiv \mathbf{k}$,

$$\langle \psi_{n0} | \mathbf{p} | \psi_0 \rangle = \sum_{\mathbf{k}} A_{n0}(c\mathbf{k}, v-\mathbf{k}) \langle \psi_{c\mathbf{k}} | \mathbf{p} | \psi_{v\mathbf{k}} \rangle \quad (24)$$

where we have neglected the contribution from all other bands except the VB and CB in the vicinity of the Fermi level.

Under normal device operation conditions, $\langle \psi_{c\mathbf{k}} | \mathbf{p} | \psi_{v\mathbf{k}} \rangle \approx \mathbf{p}_{cv}$ which is independent of \mathbf{k} over the range of \mathbf{k} involved,

$$\langle \psi_{n0} | \mathbf{p} | \psi_0 \rangle = \mathbf{p}_{cv} \sum_{\mathbf{k}} A_{n0}(c\mathbf{k} - v\mathbf{k}) \quad (25)$$

By Eq. 16 the transition probability is therefore proportional to

$$|\langle \psi_{n0} | \mathbf{p} | \psi_0 \rangle|^2 = \mathbf{p}_{cv}^2 |\psi_{n0}(\mathbf{r}_e, \mathbf{r}_h)|_{\mathbf{r}_e=\mathbf{r}_h}^2 \quad (26)$$

Table 2 Excitons in common semiconductor (Fu et al. 2000; Madelung 1991, 1992) (low temperature for IV and III–V). denotes the band gap between VB and CB

	Si	GaAs	AlAs	InAs	CdSe	ZnO
m_h^* (heavy hole)	0.537	0.51	0.409	0.35	0.45/1.0	0.59
m_e^* (electron)	1.026	0.067	0.71	0.0239	0.13	0.28
E_g [eV]	1.170	1.519	2.229	0.418	1.842	3.435
a_{Br} [nm]	15.2	11.6	8.6	38.1	5.4	1.8
E_{10} [meV]	14.3	4.2	20.0		13.2	60.0

Note that the optical transition is also constrained to $\mathbf{K} = 0$ since the photon wave vector is negligibly small. For spherical state $\psi_{n0}(0)$ is nonzero only for s-type states of Eq. 21 (the reader can refer to the hydrogen atom in many quantum mechanics textbooks) and $|\psi_{n0}(0)|^2 \propto 1/n^3$ so that

$$|\langle \psi_{n0} | \mathbf{p} | \psi_0 \rangle|^2 \propto \frac{1}{n^3} \quad (27)$$

which shows that only the low-energy exciton states (small n) can be probed optically for bulk materials.

The exciton binding energy E_{10} in Eq. 20 for the ground exciton state ($n = 1$) in commonly used bulk semiconductors is less than 10 meV so that their room temperature luminescence is very weak (exciton thermally dissolved so that n is large). Moreover, exciton Bohr radii, that is, the effective spatial extensions of the excitons, in bulk materials are also quite extended, see Table 2.

In high quality semiconductor nanostructures, quantum size effects prevail and subband formation strongly influences the exciton as the electron and hole are forced to stay in a very confined spatial area. Coulomb interaction between the electron and hole, that is, the exciton binding energy, becomes much increased. Even at room temperature the sharp exciton lines can be detected in the absorption spectra of AlGaAs/GaAs multiple QWs (Miller et al. 1982), which can hardly be observed in bulk GaAs samples.

One of the reasons for the fast development of ZnO and related materials is their large excitonic binding of about 60 meV which binds the electron and hole strongly in bulk ZnO even at room temperature (Sun et al. 2002). A photonic switch operating by controlling exciton excitation in ZnO QWs via an optical near field has been reported, where ZnO QWs were in the form disks with a disk diameter of 80 nm and the heights of 2 nm (in a structure composed of one single-QW and three double-QW) and 3.5 nm in the one double-QW case (Yatsui et al. 2007, 2008). Another development based on the large exciton binding energy of ZnO was the room-temperature polariton laser (Zamfirescu et al. 2002).

Equation 27 tells us that the major reason for studying and developing semiconductor nanostructures for optical applications refers to the forced quantum confinement. The exciton will not dissolve even when the exciton binding is comparable or smaller than the thermal energy. Light–matter interaction in the

forms of optical exciton generation and radiative recombination is much enhanced, resulting in many novel nanostructure-based optoelectronic applications.

Polarization and Optical Properties of Exciton-Polaritons

In this section, we study the optical properties of excitons in nanostructures. We start with the detailed analysis of optical absorption in which an allowed electric dipole transition creates an exciton ψ_{nK} from a filled VB and in this scheme the wave function of the initial state (the filled VB) is simply unity denoted by ψ_0 in the formalism of second quantization. Assume that our electron-hole system is initially in its ground state ψ_0 for time $t < 0$. We switch on an external radiation of $\mathbf{E}(\mathbf{r}, t)$ for $t \geq 0$; the first-order perturbation Hamiltonian is

$$V = \int \mathbf{d}(\mathbf{r}) \cdot \mathbf{E}(\mathbf{r}, t) d\mathbf{r} \quad (28)$$

where $\mathbf{d}(\mathbf{r})$ is the dipole-moment operator given by,

$$\mathbf{d}(\mathbf{r}) = -e\mathbf{r}_e\delta(\mathbf{r} - \mathbf{r}_e) + e\mathbf{r}_h\delta(\mathbf{r} - \mathbf{r}_h) \quad (29)$$

where e is the charge unit. We denote the wave function of the electron-hole system as $|\mathbf{r}_e, \mathbf{r}_h, t\rangle$, its time-dependent Schrödinger equation is then

$$i\hbar \frac{\partial}{\partial t} |\mathbf{r}_e, \mathbf{r}_h, t\rangle = (H_0 + V) |\mathbf{r}_e, \mathbf{r}_h, t\rangle \quad (30)$$

where H_0 is given by Eq. 18.

By the first-order perturbation approximation where we consider only the exciton ground state ψ_0 to one excited excitonic state $\psi_{nK}(\mathbf{r}_e, \mathbf{r}_h, t)$ the time-dependent wave function

$$|\mathbf{r}_e, \mathbf{r}_h, t\rangle = |\psi_0(t)\rangle + c_{nK}(t) |\psi_{nK}(\mathbf{r}_e, \mathbf{r}_h, t)\rangle \quad (31)$$

Here we simply assume that $|c_{nK}(t)| \ll 1$. We will discuss this more closely in the coming sections.

We now formally denote both $\psi_0(t)$ and $\psi_{nK}(\mathbf{r}_e, \mathbf{r}_h, t)$ as eigen functions of H_0 such that

$$\begin{aligned} H_0\psi_0(t) &= E_0\psi_0(t) = \hbar\omega_0\psi_0(t) \\ H_0\psi_{nK}(\mathbf{r}_e, \mathbf{r}_h, t) &= E_{nK}\psi_{nK}(\mathbf{r}_e, \mathbf{r}_h, t) = \hbar\omega_{nK}\psi_{nK}(\mathbf{r}_e, \mathbf{r}_h, t) \\ \psi_0(t) &= \psi_0 e^{-i\omega_0 t} \\ \psi_{nK}(\mathbf{r}_e, \mathbf{r}_h, t) &= \psi_{nK}(\mathbf{r}_e, \mathbf{r}_h) e^{-i\omega_{nK} t} \end{aligned} \quad (32)$$

Substituting Eq. 31 into Eq. 30 leads to

$$\begin{aligned} & i\hbar \frac{\partial \psi_0(t)}{\partial t} + i\hbar \frac{\partial c_{nK}(t)}{\partial t} \psi_{nK}(\mathbf{r}_e, \mathbf{r}_h, t) + i\hbar c_{nK}(t) \frac{\partial \psi_{nK}(\mathbf{r}_e, \mathbf{r}_h, t)}{\partial t} \\ & = H_0 \psi_0(t) + c_{nK}(t) H_0 \psi_{nK}(\mathbf{r}_e, \mathbf{r}_h, t) + V \psi_0(t) + c_{nK}(t) V \psi_{nK}(\mathbf{r}_e, \mathbf{r}_h, t) \end{aligned}$$

By Eqs. 32,

$$\begin{aligned} & \hbar \omega_0 \psi_0(t) + i\hbar \frac{\partial c_{nK}(t)}{\partial t} \psi_{nK}(\mathbf{r}_e, \mathbf{r}_h, t) + \hbar \omega_{nK} c_{nK}(t) \psi_{nK}(\mathbf{r}_e, \mathbf{r}_h, t) \\ & = E_0 \psi_0(t) + c_{nK}(t) E_{nK} \psi_{nK}(\mathbf{r}_e, \mathbf{r}_h, t) + V \psi_0(t) + c_{nK}(t) V \psi_{nK}(\mathbf{r}_e, \mathbf{r}_h, t) \end{aligned}$$

which is

$$i\hbar \frac{\partial c_{nK}(t)}{\partial t} \psi_{nK}(\mathbf{r}_e, \mathbf{r}_h, t) = V \psi_0(t) + c_{nK}(t) V \psi_{nK}(\mathbf{r}_e, \mathbf{r}_h, t) \quad (33)$$

Multiplying the above equation by $\langle \psi_{nK}(\mathbf{r}_e, \mathbf{r}_h, t) |$ we come to

$$\frac{\partial c_{nK}(t)}{\partial t} = \frac{1}{i\hbar} \left\langle \psi_{nK}(\mathbf{r}_e, \mathbf{r}_h, t) \left| \int \mathbf{d}(\mathbf{r}) \cdot \mathbf{E}(\mathbf{r}, t) \, d\mathbf{r} \right| \psi_0(t) \right\rangle \quad (34)$$

It can be shown (Fu and Willander 1999)

$$\begin{aligned} & \left\langle \psi_{nK}(\mathbf{r}_e, \mathbf{r}_h) \left| \int \mathbf{d} \cdot \mathbf{E}(\mathbf{r}, t) \, d\mathbf{r} \right| \psi_0(\mathbf{r}_e, \mathbf{r}_h) \right\rangle \\ & = \frac{e}{\omega_{nK} m_0} \int \psi_{nK}^*(\mathbf{r}, \mathbf{r}) \mathbf{p}_{cv} \cdot \mathbf{E}(\mathbf{r}, t) \, d\mathbf{r} \end{aligned} \quad (35)$$

where $\psi_{nK}(\mathbf{r}, \mathbf{r})$ is obtained from $\psi_{nK}(\mathbf{r}_e, \mathbf{r}_h)$ by setting $\mathbf{r}_e = \mathbf{r}_h = \mathbf{r}$. Thus,

$$\frac{dc_{nK}(t)}{dt} - \frac{1}{i\hbar} \frac{e}{\omega_{nK} m_0} \int \psi_{nK}^*(\mathbf{r}, \mathbf{r}) \mathbf{p}_{cv} \cdot \mathbf{E}(\mathbf{r}, t) \, d\mathbf{r} e^{i(\omega_{nK} - \omega_0)t} \quad (36)$$

Note that optical couplings among excitonic states are zero because of the quantum selection rules. As well, only a limited number of excitonic states have nonzero optical couplings with the ground state.

In reality $\omega_0 = 0$ since this is the reference state where the VB is completely filled and the CB is empty. Furthermore, we can very well describe the excitation radiation as $\mathbf{E}(\mathbf{r}, t) = \mathbf{E}(\mathbf{r}, \omega) e^{-i\omega t}$, so that integrating the above equation we obtain immediately

$$c_{nK}(t) = \frac{e^{i(\omega_{nK} - \omega)t}}{\hbar(\omega_{nK} - \omega + i\gamma)} \frac{e}{\omega_{nK} m_0} \int \psi_{nK}^*(\mathbf{r}, \mathbf{r}) \mathbf{p}_{cv} \cdot \mathbf{E}(\mathbf{r}, \omega) \, d\mathbf{r} \quad (37)$$

Before we move on, let us discuss the spatial distribution of the exciton wave function. Excitons are normally categorized into two types. The Frenkel exciton is an excited electronic state where the electron and the hole are situated in

the same molecule or atom. Because of their small radius, the Frenkel excitons usually are considered to be local. The large-radius Wannier–Mott exciton in bulk semiconductors is relatively weakly bound due to a typically large exciton Bohr radius. A hybrid state of Wannier–Mott exciton and Frenkel exciton in different heterostructure configurations involving QDs was found to exist at the interfaces of the QDs and the surrounding organic medium with complimentary properties of both kinds of excitons (Birman and Huang 2007).

In heterostructures both the CB electrons and the VB holes will experience extra potential energies such as band offsets. For low-energy Frenkel excitons in a QD, the electrons and holes are confined within the same QD volume (type-I exciton) so that we will have a common potential energy $V(|\mathbf{R} - \mathbf{a}|)$ that confines the exciton, where \mathbf{R} is the center of mass of the exciton (see Eq. 19), \mathbf{a} denotes the center of the QD. For common semiconductor QDs, the radius of the QD, R_{QD} , is in the order of the exciton Bohr radius a_{Br} so that one may neglect the free motion of the center of mass of the electron-hole pair in the QD, that is, $\mathbf{K} = 0$ in Eq. 20. For the ground state of the exciton we can approximate $V(|\mathbf{R} - \mathbf{a}|) = 0$ when $|\mathbf{R} - \mathbf{a}| < R_{\text{QD}}$ and $V(|\mathbf{R} - \mathbf{a}|) = \infty$ elsewhere so that the wave function corresponding to the motion of the center of mass becomes (Gasiorowicz 1996)

$$\frac{1}{\sqrt{2\pi R_{\text{QD}} |\mathbf{R} - \mathbf{a}|}} \sin\left(\frac{\pi |\mathbf{R} - \mathbf{a}|}{R_{\text{QD}}}\right) \quad (38)$$

for $|\mathbf{r} - \mathbf{a}| \leq R_{\text{QD}}$. The wave function is zero elsewhere. We thus finally obtain the total wave function of the exciton ground state inside the QD

$$\frac{1}{\sqrt{2\pi R_{\text{QD}} |\mathbf{R} - \mathbf{a}|}} \sin\left(\frac{\pi |\mathbf{R} - \mathbf{a}|}{R_{\text{QD}}}\right) \frac{1}{\sqrt{\pi a_{\text{Br}}^3}} e^{-|r_e - r_h|/a_{\text{Br}}} u_c(\mathbf{r}_e) u_v(\mathbf{r}_h) \quad (39)$$

Here Bloch functions $u_c(\mathbf{r}_e)$ and $u_v(\mathbf{r}_h)$ at CB and VB bandedges are included, see Eqs. 1 and 6.

The polarization of the excited exciton in a QD centered at \mathbf{a} is

$$\mathbf{P}_a(\mathbf{r}, t) = \sum_{n\mathbf{K}} \langle \psi_{n\mathbf{K}}(\mathbf{r}_e, \mathbf{r}_h, t) | \mathbf{d}(\mathbf{r}) | \psi_0(\mathbf{r}_e, \mathbf{r}_h) \rangle c_{n\mathbf{K}}^*(t) c_0(t) + \text{c.c.} \quad (40)$$

where \mathbf{d} is the dipole of the exciton given by Eq. 29. Since the wave function Eq. 39 of the exciton is confined and real, the polarization of the exciton in the QD excited by an external electromagnetic field $\mathbf{E}(\mathbf{r}, t)$ is (Fu et al. 1997, 2000)

$$\begin{aligned} \mathbf{P}_a(\mathbf{r}, t) = & \sum_{n\mathbf{K}} \frac{e^2 \mathbf{p}_{cv} e^{-i\omega t}}{\hbar (\omega_{n\mathbf{K}} - \omega + i\gamma) \omega_{n\mathbf{K}}^2 m_0^2} \\ & \times \psi_{n\mathbf{K}}(\mathbf{r}, \mathbf{r}) \int \psi_{n\mathbf{K}}(\mathbf{r}', \mathbf{r}') \mathbf{p}_{cv} \cdot \mathbf{E}(\mathbf{r}', \omega) d\mathbf{r}' \end{aligned} \quad (41)$$

By assuming small spatial variation of the excitation field within the QD, an effective permittivity is defined for the QD exciton polariton by writing

$$\mathbf{D}(\mathbf{r}, \omega) = \epsilon_{\infty} \mathbf{E}(\mathbf{r}, \omega) + \mathbf{P}(\mathbf{r}, \omega) = \epsilon_{\text{QD}}(\mathbf{r}, \omega) \mathbf{E}(\mathbf{r}, \omega) \quad (42)$$

where ϵ_{∞} is the background dielectric constant of the QD material, and

$$\epsilon_{\text{QD}}(\mathbf{r}, \omega) = \epsilon_{\infty} \left(1 + \sum_{n\mathbf{K}} \frac{2\omega_{\text{LT}}}{\omega_{n\mathbf{K}} - \omega + i\gamma} \frac{\sin \alpha_{n\mathbf{K}}}{\alpha_{n\mathbf{K}}} \right) \quad (43)$$

where $\alpha_{n\mathbf{K}} = \pi |\mathbf{r} - \mathbf{a}| / R_{\text{QD}}$. $\epsilon_{\infty} \omega_{\text{LT}} a_{\text{Br}}^3 = e^2 p_{cv}^2 / \pi \hbar \omega_{n\mathbf{K}}^2 m_0^2$. ω_{LT} is normally referred to be the exciton longitudinal-transverse splitting. The above equation was obtained under the perturbation approximation and thus can also be accounted at a semiclassical level by adding a Lorentz-oscillator term to the dielectric function (Andreani et al. 2005).

Notice that $\epsilon_{\text{QD}}(\mathbf{r}, \omega)$ in the above equation is position-dependent. Making an average over the QD volume results in an effective dielectric constant

$$\epsilon_{\text{QD}}(\omega) = \epsilon_{\infty} \left[1 + \sum_{n\mathbf{K}} \frac{6\omega_{\text{LT}}}{\pi^2 (\omega_{n\mathbf{K}} - \omega + i\gamma)} \right] \quad (44)$$

For a normal system without any extra external modifications except the incident electromagnetic field of $\mathbf{E}(\mathbf{r}, t)$ under investigation, the occupation of excited excion state, $|c_{n\mathbf{K}}(t)|^2$, is small (the first-order perturbation condition). Moreover, this occupation of the excited state is also much smaller than the ground state, see Eq. 31, so that an optical absorption dominates. This means that the optical field is absorbed during the exciton excitation following its propagation through the QD. The situation is normally referred to as optical loss, for example, in photodetectors.

Optical gain is achieved in light-emitting and laser devices by population inversion. To achieve optical gain in the QD, we increase the occupation of the excion state. Here we consider such a pumping process that the excion population of the excited excion state $c_{n\mathbf{K}}^{(0)}$ is finite at time $t = 0$ so the time-dependent wavefunction becomes

$$|\mathbf{r}_e, \mathbf{r}_h, t\rangle = \left[c_0^{(0)} + c_0(t) \right] |\psi_0(\mathbf{r}_e, \mathbf{r}_h)\rangle + \sum_{n\mathbf{K}} \left[c_{n\mathbf{K}}^{(0)} + c_{n\mathbf{K}}(t) \right] |\psi_{n\mathbf{K}}(\mathbf{r}_e, \mathbf{r}_h, t)\rangle \quad (45)$$

due to the external electromagnetic field $\mathbf{E}(\mathbf{r}, t)$. We can obtain (Fu et al. 2008)

$$\epsilon_{\text{QD}}(\omega) = \epsilon_{\infty} \left[1 + \sum_{n\mathbf{K}} \frac{6 \left(2 |c_0^{(0)}|^2 - 1 \right) \omega_{\text{LT}}}{\pi^2 (\omega_{n\mathbf{K}} - \omega + i\gamma)} \right] \quad (46)$$

Let us write $\varepsilon = \varepsilon' + i\varepsilon''$,

$$\begin{aligned} \varepsilon'_{\text{QD}}(\omega) &= \varepsilon_{\infty} \left[1 + \sum_{n\mathbf{K}} \frac{6 \left(2|c_0^{(0)}|^2 - 1 \right) (\omega_{n\mathbf{K}} - \omega) \omega_{\text{LT}}}{\pi^2 \left[(\omega_{n\mathbf{K}} - \omega)^2 + \gamma^2 \right]} \right] \\ \varepsilon''_{\text{QD}}(\omega) &= \varepsilon_{\infty} \left[1 + \sum_{n\mathbf{K}} \frac{6 \left(2|c_0^{(0)}|^2 - 1 \right) \gamma \omega_{\text{LT}}}{\pi^2 \left[(\omega_{n\mathbf{K}} - \omega)^2 + \gamma^2 \right]} \right] \end{aligned} \tag{47}$$

Since ε'' represents the energy loss of the incident electromagnetic field, we observe that the QD is lossy when $|c_0^{(0)}|^2 < 1/2$, it becomes transparent when $|c_0^{(0)}|^2 = 1/2$, and optical gain will occur when $|c_0^{(0)}|^2 > 1/2$. At the same time, the polarization changes sign.

Figure 3 shows the calculated dielectric constant for one QD before and after some fraction of the exciton states becomes populated. In this example, II–VI PbSe/ZnSe QD in a CdSe background is assumed and $\hbar\omega_{n\mathbf{K}} = 1.5\text{eV}$. In Fig. 3 and throughout this chapter we write $\varepsilon = \varepsilon' + i\varepsilon''$ where ε' and ε'' are expressed in units of ε_0 . Here we observe the possibility of finding low-loss negative dielectric constant.

As shown in Fig. 3, a huge effective permittivity is expected in the vicinity of $\omega_{n\mathbf{K}}$, with which the energy dispersions of photonic crystals based on QD arrays were derived (Fu et al. 2000) to understand photonic band gaps observed in CdS

Fig. 3 Dielectric coefficients of the QD before (a) and after (b) the excited exciton state in the QD becomes populated $\varepsilon_{\infty} = 12.8$, $\hbar\omega_{n\mathbf{K}} = 1.5\text{eV}$, $\hbar\omega_{\text{LT}} = 5\text{meV}$, and $\hbar\gamma = 1\text{meV}$ for typical II–VI semiconductor QDs, for example, colloidal PbSe/ZnSe QD

QDs embedded in fcc porous silica matrices (Vlasov et al. 1997). A close-packed 3D array of spherical CuCl QDs in air was shown by extended Maxwell-Garnett theory and rigorous layer-multiple-scattering method to have a negative refractive index within the region of the excitonic resonance (Yannopapas 2007). The structure was proposed for subwavelength imaging (the loss is however formidably high) (Yannopapas 2008).

Exciton-Polariton Photonic Crystals

As shown by Eq. 43, the effective dielectric coefficient of the QD is strongly modified when the exciton state in the QD is resonantly excited by an incident electromagnetic field. The contrast between this exciton effective dielectric coefficient and the background material can thus be utilized to construct a photonic crystal when the QDs are positioned in space in a periodic manner. Equation 43 was coupled to the electromagnetic field to study the optical dispersion of exciton-polariton crystals (Fu et al. 2000; Ivchenko et al. 2000) stimulated by the experimental works of fcc structured silica opals (Vlasov et al. 1997).

Maxwell equations describing the incident electromagnetic field in the QD photonic crystal, free of charges and free of drift-diffusion current, are written as

$$\begin{aligned}\nabla \times [\nabla \times \mathbf{E}(\mathbf{r})] &= \mu_0 \omega^2 \mathbf{D}(\mathbf{r}) \\ \nabla \cdot \mathbf{D}(\mathbf{r}) &= 0\end{aligned}\quad (48)$$

in the MKS unit system, where $\mathbf{E}(\mathbf{r})$ is the electric field, $\mathbf{D}(\mathbf{r})$ is the displacement vector, and ω is the angular frequency of the incident electromagnetic field. Here we have assumed that the QD consists of uniform isotropic linear media, for which $\mathbf{D} = \epsilon_\infty \mathbf{E}$ and $\mathbf{B} = \mu_0 \mathbf{H}$. \mathbf{H} is the magnetizing field and \mathbf{B} is the magnetic field. μ_0 is the magnetic constant (permeability of free space). The nonlocal material equation relating $\mathbf{D}(\mathbf{r})$ and $\mathbf{E}(\mathbf{r})$ is (Fu et al. 1997)

$$\mathbf{D}(\mathbf{r}) = \epsilon_\infty \mathbf{E}(\mathbf{r}) + \sum_a \mathbf{P}_a(\mathbf{r}) \quad (49)$$

where $\mathbf{P}_a(\mathbf{r})$ is the polarization contribution from the excited exciton in a QD centered at \mathbf{a} , that is, Eq. 41. We have neglected the overlap of exciton envelope functions centered at different QDs so that excitons excited in different QDs are assumed to be coupled only via the electromagnetic field.

By denoting $\mathbf{P} = \sum_a \mathbf{P}_a(\mathbf{r})$, it follows from the second Eq. 48 and Eq. 49 that

$$\nabla \cdot \mathbf{E}(\mathbf{r}) = -\frac{1}{\epsilon} \nabla \cdot \mathbf{P}(\mathbf{r}) \quad (50)$$

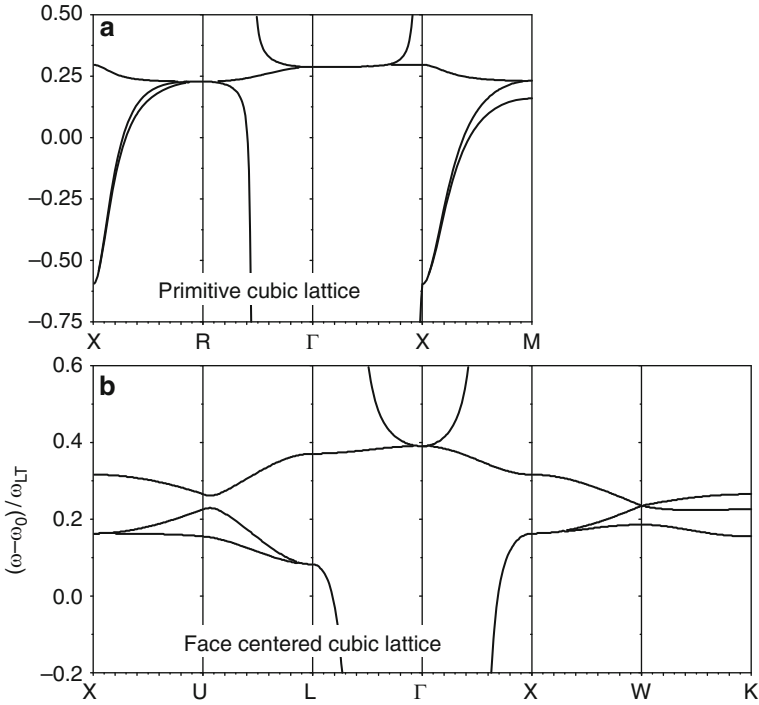

Fig. 4 Photonic dispersion relation of QD photonic crystals. (a) Primitive cubic lattice. (b) Face-centered cubic lattice

so that the first Eq. 48 can be rewritten as

$$\nabla^2 \mathbf{E}(\mathbf{r}) + k^2 \mathbf{E}(\mathbf{r}) = -\frac{k_0^2}{\varepsilon_0} \left\{ \mathbf{P}(\mathbf{r}) + \frac{1}{k^2} \nabla [\nabla \cdot \mathbf{P}(\mathbf{r})] \right\} \quad (51)$$

where $k_0 = \omega/c$, $k = k_0 n = \omega n/c$, and $n = \sqrt{\varepsilon_\infty / \varepsilon_0}$.

Bloch-like solutions of Eq. 51 satisfying

$$\mathbf{E}_q(\mathbf{r} + \mathbf{a}) = e^{iq \cdot \mathbf{a}} \mathbf{E}_q(\mathbf{r}) \quad (52)$$

is the photonic band structure. Figure 4 shows the dispersion relationships of primitive-cubic and fcc QD photonic crystals (Fu et al. 2000). An overall bandgap, most prominent along the $\Lambda(\Gamma-L)$ line (the [111] direction) is observed in the fcc lattice (Zeng et al. 2006a).

Photonic Dispersion of QD Dimer Systems

As demonstrated by Eqs. 47 and 3, ε'_{QD} can be adjusted to be positively large as well as negative by tuning the initial occupation condition of the exciton state in

Fig. 5 Schematic QD dimer system in a face-centered cubic (fcc) lattice structure. R_1 and R_2 denote the radii of the QDs and a the lattice constant of the fcc lattice

the QD. However, optical loss is not avoidable when a single type of QDs is used. To tackle the loss issue, we construct a QD dimer photonic crystal by positioning two types of spherical QDs, having radii R_1 and R_2 respectively, in a fcc lattice having a lattice constant a , see Fig. 5. The lossy QDs, that is, type-I QDs (exciton energies are $\hbar\omega_1$) occupy the normal fcc lattice sites, while the already excited QDs, type-II QDs ($\hbar\omega_2$) are displaced from the type-I QDs by τ . Let c_{ai} be the occupation of the ground state of QD i positioned at lattice site a , that is, the valence band is completely filled and the conduction band is completely empty, the contribution of an excited exciton state in a QD ai to the dielectric polarization is given by

$$P_{ai}(\mathbf{r}) = \frac{e^2 \mathbf{p}_{cv} (2|c_{ai}|^2 - 1)}{\hbar (\omega_{ai} - \omega + i\gamma) \omega_{ai}^2 m_0^2} \psi_{ai}^*(\mathbf{r}, \mathbf{r}) \int \psi_{ai}^*(\mathbf{r}', \mathbf{r}') \mathbf{p}_{cv} \cdot \mathbf{E}(\mathbf{r}') d\mathbf{r}' \tag{53}$$

by referring to Eqs. 41 and 46.

We seek again for Bloch-like solutions of Eq. 51 satisfying Eq. 52. We expand the vector function $E_q(\mathbf{r})$ in the Fourier series

$$\mathbf{E}_q(\mathbf{r}) = \sum_{\mathbf{g}} e^{i(\mathbf{q}+\mathbf{g})\cdot\mathbf{r}} \mathbf{E}_{q+\mathbf{g}} \quad (54)$$

Where \mathbf{g} are the reciprocal lattice vectors. Denote $a_1 = \sqrt{2|c_1|^2 - 1}$, $a_2 = \sqrt{2|c_2|^2 - 1}$, $v_0 = a^3/4$ is the volume of the primitive unit cell of the fcc lattice, $\phi_i = a_i \psi_i$ and $t = \varepsilon \omega_{\text{LT}} \pi a_{\text{Br}}^3$, the excitonic polarization becomes

$$\mathbf{P}(\mathbf{r}) = \sum_{ai} \frac{t}{\omega_i - \omega + i\gamma} \phi_{ai}(\mathbf{r}, \mathbf{r}) \int \phi_{ai}^*(\mathbf{r}', \mathbf{r}') \mathbf{E}(\mathbf{r}') d\mathbf{r}' \quad (55)$$

Note that the excitonic wave function is real so that we have dropped off the complex conjugation of the wave function in the integrals in Eq. 53. The two integrals in the above equation can be transformed into

$$\begin{aligned} \int \phi_{1,a}(\mathbf{r}) \mathbf{E}(\mathbf{r}) d\mathbf{r} &= e^{i\mathbf{q}\cdot\mathbf{a}} \sum_{\mathbf{g}} I_{1,\mathbf{q}+\mathbf{g}} \mathbf{E}_{q+\mathbf{g}} \equiv e^{i\mathbf{q}\cdot\mathbf{a}} \Lambda_1 \\ \int \phi_{2,a}(\mathbf{r}) \mathbf{E}(\mathbf{r}) d\mathbf{r} &= e^{i\mathbf{q}\cdot\mathbf{a}} \sum_{\mathbf{g}} I_{2,\mathbf{q}+\mathbf{g}} \mathbf{E}_{q+\mathbf{g}} \equiv e^{i\mathbf{q}\cdot\mathbf{a}} \Lambda_2 \end{aligned} \quad (56)$$

where $I_{1,\mathbf{q}+\mathbf{g}} = \int \phi_{1,0}(\mathbf{r}) e^{i(\mathbf{q}+\mathbf{g})\cdot\mathbf{r}} d\mathbf{r}$, $I_{2,\mathbf{q}+\mathbf{g}} = \int \phi_{2,0}(\mathbf{r}) e^{i(\mathbf{q}+\mathbf{g})\cdot(\mathbf{r}+\boldsymbol{\tau})} d\mathbf{r}$. The sums $\sum_a \phi_{1,a}(\mathbf{r}) e^{i\mathbf{q}\cdot\mathbf{a}}$ and $\sum_{a+\boldsymbol{\tau}} \phi_{2,a+\boldsymbol{\tau}}(\mathbf{r}) e^{i\mathbf{q}\cdot\mathbf{a}}$ satisfy the translational symmetry and can be presented as

$$\begin{aligned} \sum_a \phi_{1,a}(\mathbf{r}) e^{i\mathbf{q}\cdot\mathbf{a}} &= \sum_{\mathbf{g}} e^{i(\mathbf{q}+\mathbf{g})\cdot\mathbf{r}} \frac{I_{1,\mathbf{q}+\mathbf{g}}^*}{v_0} \\ \sum_{a+\boldsymbol{\tau}} \phi_{2,a+\boldsymbol{\tau}}(\mathbf{r}) e^{i\mathbf{q}\cdot\mathbf{a}} &= \sum_{\mathbf{g}} e^{i(\mathbf{q}+\mathbf{g})\cdot\mathbf{r}} \frac{I_{2,\mathbf{q}+\mathbf{g}}^*}{v_0} \end{aligned} \quad (57)$$

The linear equations for the space harmonics $\mathbf{E}_{q+\mathbf{g}}$ can thus be written

$$\begin{aligned} &(|\mathbf{q} + \mathbf{g}|^2 - k^2) \mathbf{E}_{q+\mathbf{g}} \\ &= \frac{k_0^2 t}{v_0} \left[1 - \frac{1}{k^2} (\mathbf{q} + \mathbf{g})^2 \right] \left[\frac{I_{1,\mathbf{q}+\mathbf{g}}^*}{\omega_1 - \omega + i\gamma} \Lambda_1 + \frac{I_{2,\mathbf{q}+\mathbf{g}}^*}{\omega_2 - \omega + i\gamma} \Lambda_2 \right] \end{aligned} \quad (58)$$

Let $S(\mathbf{Q})_{\alpha\beta} = \delta_{\alpha\beta} - Q_\alpha Q_\beta / k^2$, $\alpha, \beta = x, y, z$, $\delta_{\alpha\beta}$ is the Kronecker symbol. Dividing Eq. 58 by $(|\mathbf{q} + \mathbf{g}|^2 - k^2)$, multiplying it by $I_{1,\mathbf{q}+\mathbf{g}}$, and summing over \mathbf{g} :

$$\begin{aligned}
\sum_g I_{1,q+g} \mathbf{E}_{q+g} &= \Lambda_1 \\
&= \frac{k_0^2 t}{v_0} \sum_g \frac{\widehat{S}(\mathbf{q} + \mathbf{g})}{|\mathbf{q} + \mathbf{g}|^2 - k^2} \left[\frac{|I_{1,q+g}|^2}{\omega_1 - \omega + i\gamma} \Lambda_1 + \frac{I_{1,q+g} I_{2,q+g}^*}{\omega_2 - \omega + i\gamma} \Lambda_2 \right] \\
&= \widehat{M}_1(\omega, \mathbf{q}) \Lambda_1 + \widehat{M}_2(\omega, \mathbf{q}) \Lambda_2
\end{aligned} \tag{59}$$

where

$$\begin{aligned}
\widehat{M}_1(\omega, \mathbf{q}) &= \frac{k_0^2 r}{(\omega_1 - \omega + i\gamma) v_0} \sum_g \frac{\widehat{S}(\mathbf{q} + \mathbf{g})}{|\mathbf{q} + \mathbf{g}|^2 - k^2} |I_{1,q+g}|^2 \\
\widehat{M}_2(\omega, \mathbf{q}) &= \frac{k_0^2 r}{(\omega_1 - \omega + i\gamma) v_0} \sum_g \frac{\widehat{S}(\mathbf{q} + \mathbf{g})}{|\mathbf{q} + \mathbf{g}|^2 - k^2} I_{1,q+g} I_{2,q+g}^*
\end{aligned} \tag{60}$$

Similarly, dividing Eq. 58 by $(|\mathbf{q} + \mathbf{g}|^2 - k^2)$, multiplying it by $I_{2,q+g}$, and summing over g ,

$$\begin{aligned}
\sum_g I_{2,q+g} \mathbf{E}_{q+g} &= \Lambda_2 \\
&= \frac{k_0^2 t}{v_0} \sum_g \frac{\widehat{S}(\mathbf{q} + \mathbf{g})}{|\mathbf{q} + \mathbf{g}|^2 - k^2} \left[\frac{I_{2,q+g} I_{1,q+g}^*}{\omega_1 - \omega + i\gamma} \Lambda_1 + \frac{|I_{2,q+g}|^2}{\omega_2 - \omega + i\gamma} \Lambda_2 \right] \\
&= \widehat{M}_3(\omega, \mathbf{q}) \Lambda_1 + \widehat{M}_4(\omega, \mathbf{q}) \Lambda_2
\end{aligned} \tag{61}$$

where

$$\begin{aligned}
\widehat{M}_3(\omega, \mathbf{q}) &= \frac{k_0^2 t}{(\omega_1 - \omega + i\gamma) v_0} \sum_g \frac{\widehat{S}(\mathbf{q} + \mathbf{g})}{|\mathbf{q} + \mathbf{g}|^2 - k^2} I_{2,q+g} I_{1,q+g}^* \\
\widehat{M}_4(\omega, \mathbf{q}) &= \frac{k_0^2 t}{(\omega_1 - \omega + i\gamma) v_0} \sum_g \frac{\widehat{S}(\mathbf{q} + \mathbf{g})}{|\mathbf{q} + \mathbf{g}|^2 - k^2} |I_{2,q+g}|^2
\end{aligned} \tag{62}$$

We arrive at the vector equations

$$\begin{aligned}
\left[\mathbf{I} - \widehat{M}_1(\omega, \mathbf{q}) \right] \Lambda_1 &= \widehat{M}_2(\omega, \mathbf{q}) \Lambda_2 \\
\left[\mathbf{I} - \widehat{M}_4(\omega, \mathbf{q}) \right] \Lambda_2 &= \widehat{M}_3(\omega, \mathbf{q}) \Lambda_1
\end{aligned} \tag{63}$$

where \mathbf{I} is a 3×3 unit matrix. We can rewrite the above equations as

$$D \begin{pmatrix} 1 - M_{1,11} & -M_{1,12} & -M_{1,13} & -M_{2,11} & -M_{2,12} & -M_{2,13} \\ -M_{1,21} & 1 - M_{1,22} & -M_{1,23} & -M_{2,21} & -M_{2,22} & -M_{2,23} \\ -M_{1,31} & -M_{1,32} & 1 - M_{1,33} & -M_{2,31} & -M_{2,32} & -M_{2,33} \\ M_{3,11} & M_{3,12} & M_{3,13} & M_{4,11} - 1 & M_{4,12} & M_{4,13} \\ M_{3,21} & M_{3,22} & M_{3,23} & M_{4,21} & M_{4,22} - 1 & M_{4,23} \\ M_{3,31} & M_{3,32} & M_{3,33} & M_{4,31} & M_{4,32} & M_{4,33} - 1 \end{pmatrix} \quad (64)$$

$$M_{1,\alpha\beta}(\Omega, \mathbf{q}) = \frac{8}{\pi v_0} \frac{\omega_{\text{LT}} R_1^3 |a_1|^2}{(\omega_1 - \omega + i\gamma)} \sigma_{11,\alpha\beta}(\Omega, \mathbf{q})$$

$$M_{2,\alpha\beta}(\Omega, \mathbf{q}) = \frac{8}{\pi v_0} \frac{\omega_{\text{LT}} (R_1 R_2)^{3/2} a_1 a_2^*}{(\omega_2 - \omega + i\gamma)} \sigma_{12,\alpha\beta}(\Omega, \mathbf{q})$$

$$M_{3,\alpha\beta}(\Omega, \mathbf{q}) = \frac{8}{\pi v_0} \frac{\omega_{\text{LT}} (R_1 R_2)^{3/2} a_1^* a_2}{(\omega_1 - \omega + i\gamma)} \sigma_{21,\alpha\beta}(\Omega, \mathbf{q})$$

$$M_{4,\alpha\beta}(\Omega, \mathbf{q}) = \frac{8}{\pi v_0} \frac{\omega_{\text{LT}} R_2^3 |a_2|^2}{(\omega_2 - \omega + i\gamma)} \sigma_{22,\alpha\beta}(\Omega, \mathbf{q})$$

$$\sigma_{st,\alpha\beta}(\Omega, \mathbf{q}) = \sum_{\mathbf{g}} \frac{f(|\mathbf{g} + \mathbf{q}| R_s) f(|\mathbf{g} + \mathbf{q}| R_t) S_{\alpha\beta}(\mathbf{g} + \mathbf{q})}{\Omega^2(\mathbf{g} + \mathbf{q}) - \Omega^2} e^{i(s-t)(\mathbf{g} + \mathbf{q}) \cdot \boldsymbol{\tau}}$$

$$f(x) = \frac{\pi^2 \sin x}{x(\pi^2 - x^2)}$$

$$\Omega = \frac{\omega}{\omega_1}$$

$$\Omega(\mathbf{Q}) = \frac{c|\mathbf{Q}|}{\omega_1 n} \quad (65)$$

where $s, t = 1, 2$. The exciton-polariton dispersion $\omega(\mathbf{q})$ satisfies the equation

$$\text{Det}|D| = 0 \quad (66)$$

Note that by setting $|c_1|^2 = 0$ and $|c_2|^2 = 0.5$ (type-II QDs are totally transparent) we retrieve the case of a photonic crystal composed of only type-I QDs (Fu et al. 2000), see Fig. 4. By setting $|c_1|^2 = |c_2|^2 = 0$ and $\omega_1 = \omega_2$ we retrieve the case of a compound QD photonic crystal (Zeng et al. 2006b).

The dispersion relationship $\omega(\mathbf{q})$ for a QD dimer fcc lattice is presented in Fig. 6. The lattice is denoted by its lattice constant a , which is set to be $(0.95 a_{\text{Bragg}})$ (which is 116 nm for GaAs), where $a_{\text{Bragg}} = c\pi/\omega_1 n$. The lossy type-I QDs ($\hbar\omega_1 = 1.5$ eV) occupy the normal fcc lattice sites, while the excited type-II QDs ($\hbar\omega_2 = 1.503$ eV) are displaced by $\boldsymbol{\tau} = (a/2, a/2, a/2)$. $\hbar\omega_{\text{LT}} = 5$ meV. Here we observe the modification of the photonic band structure of the QD dimer system

Fig. 6 Energy dispersion relationships of QD dimer systems in the fcc lattice. $R_1 = a/4$, $R_2 = a/5$, $\hbar\omega_1 = 1.5$ eV, $\hbar\omega_2 = 1.503$ eV, $\hbar\omega_{LT} = 5$ meV, $a = 0.95a_{\text{Bragg}}$, $\tau = (a/2, a/2, a/2)$. $|c_1|^2 = 0$. (a) $|c_2|^2 = 1.0$ (complete excitation), (b) $|c_2|^2 = 0.4$, (c) $|c_2|^2 = 0.5$ (type-II QDs are total transparent)

by pumping one type of the QDs (type-II QDs), which evolves from the one of only type-I QDs ($|c_1|^2 = 0$), i.e., at their ground exciton state) when type-II QDs are transparent [$|c_2|^2 = 0.5$, Fig. 6c] to the compound system [$|c_2|^2 = 1.0$, Fig. 6a]. We can observe modified but still characteristic features of the photonic dispersions of individual type-I and type-II QDs in their separate photonic crystal formats in the compound system, see Fig. 4. More specifically, the resonance features of type-I QDs around $(\omega - \omega_1) / \omega_{LT} = 0.3$ in Fig. 6d become compressed by the radiative

interaction between type-I QDs and type-II QDs, and they are also shifted down to around 0.18 in Fig. 6a.

By varying $|c_2|^2$ from 0.0 to 1.0 we find that the solutions of Eq. 66 are symmetric with respect to $|c_2|^2$ and $1 - |c_2|^2$ when $c_1 = 0$. Thus, Fig. 6a represents also the photonic dispersion of the QD dimer system when both type-I and type-II QDs are all initially at their ground exciton states, that is, $|c_1|^2 = |c_2|^2 = 0$. Thus the modification of the exciton state (from ground state to excited state) in one type of QDs in the dimer system does not affect the feature of the dispersion structure.

Lossless Dielectric Constant of QD Dimer Systems

As shown by Fig. 4, the exciton polarization provides possibilities of generating positively high dielectric constant as well as negative dielectric constant at the cost of disturbing the external electromagnetic field (either loss or gain). At least in the photonic crystal composed of one type of QDs (either lossy or gain), the dielectric modulation is always accompanied by loss or gain. The idea of the QD dimer system discussed in the previous sub-section is to compensate the loss of type-I QDs by the gain of type-II QDs, while still maintaining dielectric modulation. More specifically, we require $\varepsilon'' = 0$ at some frequencies in order to achieve lossless dielectric modulation for various optoelectronics applications.

In the following, we consider a PbSe/ZnSe QD assembly such as Fig. 5 immersed in a medium of dielectric constant ε_1 . The macroscopic dielectric constant ε for the ensemble of the QDs can be described by the dielectric theory of Maxwell-Garnett (1906) and Gittleman and Abeles (1977), which for two QD species can be written as

$$\frac{\varepsilon - \varepsilon_i}{\varepsilon + 2\varepsilon_i} = x_1 \frac{\varepsilon_{\text{QD1}} - \varepsilon_i}{\varepsilon_{\text{QD1}} + 2\varepsilon_i} + x_2 \frac{\varepsilon_{\text{QD2}} - \varepsilon_i}{\varepsilon_{\text{QD2}} + 2\varepsilon_i} \quad (67)$$

where x_i is the volume fraction of the i -th QD species. While Eq. 67 works best for x_1 less than 0.4, there is evidence that useful information can be available with higher concentrations (Cohen et al. 1973). Figure 7a shows the spectra of ε'_{QD} and $\varepsilon''_{\text{QD}}$ of the two types of QDs. For the combination of two types of QDs, that is, the QD dimer system, one type is lossy and the other gain, immersed in a conducting polymer with an effective dielectric constant $\varepsilon_1 = 1.8$ the optical spectrum is presented in Fig. 7b.

Figure 7 shows that a mixture of two types of QDs such as Fig. 5 can produce an effective dielectric constant that is lossless and negative, thus permitting, in concept, arbitrarily small scaling of the optical mode volume in the field of nanophotonics (Fu et al. 2008). Another binary mixture of lossy QDs and plasmonic silver nanorods was also shown to have a negative ε and compensated optical loss by using finite-difference time-domain calculations (Bratkovsky et al. 2008).

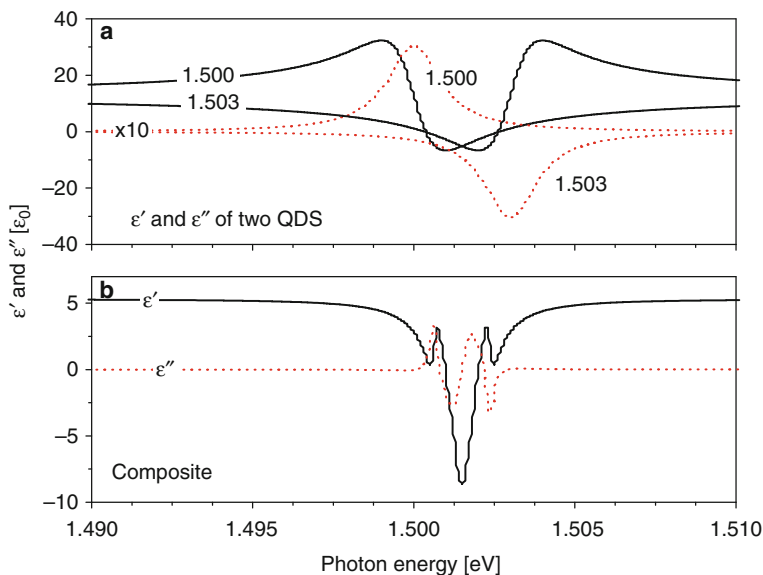

Fig. 7 (a) Dielectric constants of type-I QDs at 1.500 eV and $|c^{(0)}|^2 = 1.0$, and type-II QDs at 1.503 eV and $|c^{(0)}|^2 = 0.0$. *Solid lines: ϵ' ; Dotted lines: ϵ''* . Note that ϵ'' is magnified by 10. (b) QD dimer system after immersing the two types of QDs in $\epsilon_1 = 1.8$. The densities of two types of QDs are $7 \times 10^{16} \text{ cm}^{-3}$ Adapted from Fu et al. (2008)

Multiple-Photon and Multiple-Carrier Processes

Multiphoton Process

Another important aspect about the optical properties of QDs is the multiphoton process which has been widely applied in recent years in biological and medical imaging after the pioneer work of Goepfert-Mayer (1931), Lami et al. (1996), Helmchen et al. (1996), Yokoyama et al. (2006). The multiphoton process has largely been treated theoretically by steady-state perturbation approaches, for example, the scaling rules of multiphoton absorption by Wherrett (1984) and the analysis of two-photon excitation spectroscopy of CdSe QDs by Schmidt et al. (1996). Non-perturbation time-dependent Schrödinger equation was solved to analyze the ultrafast (fs) and ultra-intense (in many experiments the optical power of laser pulse peak can reach GW/cm^2) dynamics of multiphoton processes in QDs that are highly fluorescent with excellent photochemical stability, extreme brightness, and broad excitation spectral range (Fu et al. 2006c, 2007).

For spherical QDs the exciton wave function can be expressed by a radial function and spherical harmonics. The degeneracy of each exciton state is $2(2\ell + 1)$, where ℓ is the quantum number of the angular momentum. Figure 8 shows the exciton states (open circles) confined in the QD as well as their corresponding

Fig. 8 Exciton states (*open circles*) confined in the QD and their corresponding light-matter interactions (*vertical lines*). Adapted from Fu et al. (2009)

light-matter interactions (vertical lines). For spherical QDs, only exciton states having zero angular momenta ($\ell = 0$) have nonzero relaxation energies. Moreover, only confined exciton states (i.e., both the electron and hole states that compose the exciton state under discussion are confined) have significant light-matter interaction.

In the ultrashort regime, after a continuous-wave optical excitation is switched on at $t = 0$, Fig. 9 shows that the time to reach peak two-photon excitation is much shorter than the one-photon excitation. Moreover, the multiphoton excitation spectral range is very broad. From about 1.0 to 2.5 eV (i.e., two-photon excitation range), the calculated excited exciton rate is much larger than the occupation of the first-excited exciton so that the emission spectrum is expected to be dominated by the recombination of the ground-state exciton. It was concluded by the theoretical simulation that experimentally observed strong multiphoton excitations can be reproduced when optical transitions among all confined states in the QD and an additional few hundred extended states in the barrier are taken into account (Fu et al. 2006c). This agrees with the experimental results of multi-particle (Huxter and Scholes 2006) and multi-exciton dynamics (Suffczyński et al. 2006).

Impact Ionization and Auger Recombination

Nozik proposed that impact ionization might be enhanced in semiconductor QDs to increase the efficiency of solar cells up to about 66 % (Nozik 2002). This was later verified experimentally by Schaller and Klimov (2004). Impact ionization was

Fig. 9 Multiphoton excitation of QD exciton in an ultrashort period excited by a continuous wave light source switched on at $t = 0$. S denotes the optical power of the excitation light source. Adapted from Fu et al. (2006c)

reported to produce multiple exciton generation (MEG) per photon in a QD that results in a very high quantum yield (up to 300 % when the photon energy reaches four times the QD bandgap) in QD solar cells (Hanna et al. 2004). Multiple carrier extraction (>100 %) was observed at photon energies greater than 2.8 times the PbSe QD bandgap with about 210 % measured at 4.4 times the bandgap (Kim et al. 2008). In a recent communication in Nano Letters, Trinh et al. (2008) showed compelling support for carrier multiplication in PbSe QDs.

We concentrate here on reviewing impact ionization and Auger recombination in QDs using the solid-state theory. As shown in Fig. 10, a highly photoexcited electron and hole pairs can evolve into a multiple-exciton state through impact ionization. The carrier-carrier interaction is expressed by the Coulomb potential in the form of

$$V = \frac{e^2}{4\pi\epsilon |\mathbf{r}_1 - \mathbf{r}_2|} \tag{68}$$

to account for the two-body interaction of two electrons from an initial state $\phi_j(\mathbf{r}_1)\psi_i(\mathbf{r}_2)\exp[-i(E_j + E_i)t/\hbar]$, that is, one electron occupying a VB state

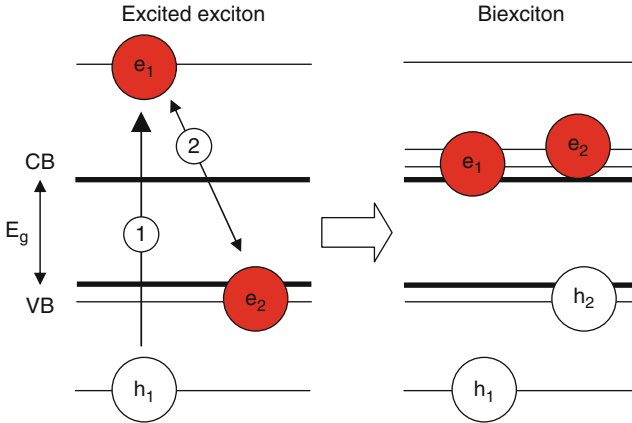

Fig. 10 Schematic depiction of impact ionization of a high-energy electron-hole pair. (1) Electron-hole pair (e_1 and h_1) is generated, for example, by a photon. (2) e_2 gets excited from a VB state to a CB state via Coulomb interaction with e_1 , leaving hole h_2 behind. The reverse process is referred to be Auger recombination

$$\phi_j(\mathbf{r}_1) \exp(-iE_j t/\hbar)$$

and another electron occupying a CB state

$$\psi_i(\mathbf{r}_2) \exp(-iE_i t/\hbar)$$

to a final state

$$\frac{1}{\sqrt{2}} \left| \begin{matrix} \psi_n(\mathbf{r}_1) & \psi_m(\mathbf{r}_1) \\ \psi_n(\mathbf{r}_2) & \psi_m(\mathbf{r}_2) \end{matrix} \right| \exp[-i(E_n + E_m)t/\hbar] \tag{69}$$

in the CB. Notice that the two electrons in the final state are not distinguishable so that we use a Slater determinant.

Other ionization pathways exist such as one electron occupying a low-energy VB state falls into h_1 and the released energy excites another electron from the VB to the CB. Auger recombination can be expressed similarly.

Before discussing the QD case, let us consider the computation of an Auger-type process in solid states that an incident high-energy CB electron with a wave vector k_1 collides with a second electron that occupies a VB state k_2 resulting in two CB electrons k'_1 and k'_2 . The general expression for the scattering matrix element of this process is

$$\iint \psi_{ck_1}^*(\mathbf{r}_1) \Phi_{vk_2}^*(\mathbf{r}_2) \frac{1}{|\mathbf{r}_1 - \mathbf{r}_2|} \psi_{ck'_1}(\mathbf{r}_1) \psi_{ck'_2}(\mathbf{r}_2) d\mathbf{r}_1 d\mathbf{r}_2 \tag{70}$$

where $\psi_{ck}(\mathbf{r})[\Phi_{vk}(\mathbf{r})]$ denotes the total wave function of the CB electron (VB hole) state k . For semiconductor systems and within the effective mass approximation $\psi_{ck}(\mathbf{r}) = \psi_{ck}(\mathbf{r})u_{ck}(\mathbf{r})$ and $\Phi_{vk}(\mathbf{r}) = \phi_{vk}(\mathbf{r})u_{vk}(\mathbf{r})$, where ψ and ϕ are envelope functions of the CB electron and VB hole, respectively, and u 's are periodic Bloch functions, the above expression becomes

$$\int \int \psi_{ck_1}^*(\mathbf{r}_1)u_{ck_1}^*(\mathbf{r}_1)\phi_{vk_2}^*(\mathbf{r}_2)u_{vk_2}^*(\mathbf{r}_2)\frac{1}{|\mathbf{r}_1 - \mathbf{r}_2|} \quad (71)$$

$$\times \psi_{ck'_1}(\mathbf{r}_1)u_{ck'_1}(\mathbf{r}_1)\psi_{ck'_2}(\mathbf{r}_2)u_{ck'_2}(\mathbf{r}_2) d\mathbf{r}_1 d\mathbf{r}_2 \quad (72)$$

See, for example, Eq. 6.128 in Ridley (1988). Following overlap integrals are thus involved

$$I_1 = \int_{\text{cell}} u_{ck_1}^*(\mathbf{r}_1)u_{ck'_1}(\mathbf{r}_1) d\mathbf{r}_1 \quad (73)$$

$$I_2 = \int_{\text{cell}} u_{vk_2}^*(\mathbf{r}_2)u_{ck'_2}(\mathbf{r}_2) d\mathbf{r}_2$$

in the evaluation of the Auger-type scattering processes. The first overlap integral can be approximated to unity. Because of the orthogonality of u functions for different bands but the same \mathbf{k} , the second overlap integral I_2 is, in crudest approximation, zero. This, however, is not correct since the periodic Bloch functions are functions of wave vectors. More specifically, we can write

$$u_{ck}(\mathbf{r}) = u_c(\mathbf{r}) + \mathbf{k}\nabla_k u_c(\mathbf{r}) + \dots \quad (74)$$

$$u_{ck}(\mathbf{r}) = u_c(\mathbf{r}) + \mathbf{k}\nabla_k u_c(\mathbf{r}) + \dots$$

for small \mathbf{k} , where $u_c(\mathbf{r})$ and $u_v(\mathbf{r})$ are periodic Bloch functions at the CB and VB bandedges, respectively. $\int_{\text{cell}} u_v^*(\mathbf{r}_2)u_c(\mathbf{r}_2) d\mathbf{r}_2 = 0$. Substituting these expressions into the overlap integrals we obtain the squared overlap integral in terms of the heavy-hole mass m_v (Landsberg and Adams 1973; Ridley 1988)

$$|I_2|^2 = \frac{\hbar^2}{2E_g} \left(\frac{1}{m_0} + \frac{1}{m_v} \right) |\mathbf{k}_2 - \mathbf{k}'_2|^2 \quad (75)$$

where E_g is the energy band gap of the bulk material. By using the inverse Bohr radius of shallow impurities as a measure about the \mathbf{k} values, Landsberg and Adams obtained $|I_2| = 0.223$ for shallow-impurity-assisted Auger-type processes in bulk CdS and $|I_2| = 0.265$ in GaAs (Landsberg and Adams 1973). Note that the inverse Bohr radius of shallow impurities in bulk semiconductors is small. For QDs under investigation, the effective Bohr radius of the electron and hole distribution is largely determined by the QD size, which is about 5 nm, that is, very small compared with

the Bohr radius of shallow impurities in bulk semiconductors (about 100 nm in CdS and GaAs Landsberg and Adams 1973). This results in a large value of $|I_2|$. Under this specific circumstance we approximate $|I_2| = 1$. In other words, the electrons and holes in QDs, described by effective masses in the presence of the QD confinement potentials, interact with each other via the Coulomb force of Eq. 68 (Abrahams 1954). The approach has been adopted for describing carrier interactions in many electronic devices such as tunnel junctions where the kinetic energies of relevant carriers are large, see for examples Takenaka et al. (1979) and Rodina et al. (2002).

By the scattering theory and the generalized Golden rule (Landau and Lifshitz 1965) and denoting $\langle \phi_j \psi_i | \hat{T}(t) | \phi_j \psi_i \rangle \approx e^{-w_{ji}t/2}$ as the temporal development $\hat{T}(t)$ of state ji , it is easy to obtain

$$w_{ji} = \frac{2\pi}{\hbar} \sum_{nm \neq ji} |\langle \phi_j \psi_i | V | \psi_n \psi_m \rangle|^2 \delta(E_j + E_i - E_n - E_m) \tag{76}$$

$\Gamma_{ji} = \hbar w_{ji}/2$ is the relaxation energy and $1/w_{ji}$ the decaying time. In numerical calculations the δ functions in the above equation are replaced by $\Gamma_{ji} / [\Gamma_{ji}^2 + (E_j + E_i - E_n - E_m)^2]$ and Γ_{ji} is to be calculated by the above equation in a self-consistent way that the left and right sides of Eq. 76 equal after knowing the interaction values of $\langle \phi_j \psi_i | V | \psi_n \psi_m \rangle|^2$.

Numerical calculations of the Coulomb interaction Eq. 68 are not trivial. They were simplified in Allan and Delerue (2008) by using a screened Coulomb potential involving one-electron wave functions which were derived for bulk semiconductor materials (Landsberg 1991). To calculate the impact ionization interaction from an initial state of $R_{\ell_1}(\mathbf{r}_1) Y_{\ell_1 m_1}(\theta_1, \phi_1) R_{\ell_2}(\mathbf{r}_2) Y_{\ell_2 m_2}(\theta_2, \phi_2)$ to a final state $R_{\ell_3}(\mathbf{r}_1) Y_{\ell_3 m_3}(\theta_1, \phi_1) R_{\ell_4}(\mathbf{r}_2) Y_{\ell_4 m_4}(\theta_2, \phi_2)$ (the first term one in Eq. 69), we notice

$$\frac{1}{4\pi |\mathbf{r}_1 - \mathbf{r}_2|} = \sum_{\ell=0}^{\infty} \sum_{m=-\ell}^{\ell} \frac{1}{2\ell + 1} \frac{r_{<}^{\ell}}{r_{>}^{\ell+1}} Y_{\ell m}^*(\theta_2, \phi_2) Y_{\ell m}(\theta_1, \phi_1) \tag{77}$$

where $r_{<} = \min\{|\mathbf{r}_1|, |\mathbf{r}_2|\}$ and $r_{>} = \max\{|\mathbf{r}_1|, |\mathbf{r}_2|\}$ so that the impact ionization energy consists of

$$\begin{aligned} & \frac{r_{<}^{\ell}}{r_{>}^{\ell+1}} R_{\ell_1}(\mathbf{r}_1) R_{\ell_2}(\mathbf{r}_2) R_{\ell_3}(\mathbf{r}_1) R_{\ell_4}(\mathbf{r}_2) Y_{\ell_1 m_1}^*(\theta_1, \phi_1) Y_{\ell_2 m_2}^*(\theta_2, \phi_2) \\ & \times Y_{\ell_m}^*(\theta_2, \phi_2) Y_{\ell m}(\theta_1, \phi_1) Y_{\ell_3 m_3}(\theta_1, \phi_1) Y_{\ell_4 m_4}(\theta_2, \phi_2) \end{aligned} \tag{78}$$

for which we utilize the addition theorem for spherical harmonics (Cohen-Tannoudji et al. 1991)

$$Y_{\ell_1 m_1} Y_{\ell_2 m_2} = \sum_{\ell=|\ell_1-\ell_2|}^{\ell_1+\ell_2} \sqrt{\frac{(2\ell_1+1)(2\ell_2+1)}{4\pi(2\ell+1)}} \times C(\ell 0 | \ell_1 0; \ell_2 0) C(\ell m_1 + m_2 | \ell_1 m_1; \ell_2 m_2) Y_{\ell m_1+m_2} \quad (79)$$

where $C(\ell m_1 + m_2 | \ell_1 m_1; \ell_2 m_2)$ is the CG-coefficient.

A more detailed analysis shows a few selection rules for ℓ 's and m 's such as $m_4 - m_3 = m_1 - m_3$. However, these selection rules can be easily fulfilled in nanoscale QDs because of the large number of available states confined in the QDs (see further discussion below). The most important qualitative selection rules refer to the radial functions that

$$\begin{aligned} & \int \int \frac{r_1^\ell}{r_1^{\ell+1}} R_{\ell_1}(r_1) R_{\ell_2}(r_2) R_{\ell_3}(r_1) R_{\ell_4}(r_2) \\ &= \int_0^a R_{\ell_1}(r_1) R_{\ell_3}(r_1) \left[\int_0^{r_1} \frac{r_2^\ell}{r_1^{\ell+1}} R_{\ell_2}(r_2) R_{\ell_4}(r_2) r_2^2 dr_2 \right. \\ & \left. + \int_{r_1}^a \frac{r_1^\ell}{r_2^{\ell+1}} R_{\ell_2}(r_2) R_{\ell_4}(r_2) r_2^2 dr_2 \right] r_1^2 dr_1 \end{aligned} \quad (80)$$

which shows that a direct spatial overlap between $R_{\ell_2}(r_2)$ (VB hole state) and $R_{\ell_4}(r_4)$ (CB electron state) will result in a large impact ionization. Impact ionization in type-II QDs is thus negligible since the electron-hole wave function overlap is small. Furthermore, to ensure energy conservation, $R_{\ell_1}(r)$ is normally a high-energy CB state, while both $R_{\ell_3}(r)$ and $R_{\ell_4}(r)$ are low-energy CB states. Impact ionization in many core-shell-structured QDs (e.g., Fu et al. 2007) could be small since the high-energy wave functions are much more extended (extended into shells) than the ground-state wave function (deeply confined in the core region).

We now consider a spherical CdSe QD in vacuum with a radius of a . The energy bandgap of bulk CdSe material is 1.74 eV (room temperature) and the exciton Bohr radius is 4.9 nm, the quantum confinement energies for CB electrons is 4.95 and 2.5 eV for the VB holes, and the electron and hole effective masses are $m_c^* = 0.14m_0$ and $m_v = 0.46m_0$ respectively, m_0 is the electron rest mass (Madelung 1992). In numerical calculations we also include a shell of vacuum with a thickness of 20 nm to account for the penetration of wave functions of high-energy states from the QD volume to the vacuum (the results are compared with the ones when a shell of 10 nm thick vacuum shell is included and no significant differences are observed). We include all the confined energy states in the QD (i.e., energy levels below the vacuum state) of all possible combinations of CB electron states and VB hole states that form the initial state of the impact ionization, then all possible combinations of two final CB electron states. Each single-particle state is denoted by its energy, $R(r)$, ℓ and m . Spherical harmonics (i.e., ℓ and m) is calculated using the addition theorem, while the radial integration is to be performed numerically.

Fig. 11 (a) Conduction-band (CB) electron states and (b) valence-band (VB) hole states confined in a spherical CdSe QD with a radius of 4 nm as functions of angular momentum quantum number ℓ

Figure 11 shows the CB electron states and VB hole states confined in a spherical CdSe QD with a radius of 4 nm as functions of angular momentum quantum number ℓ . Note that states with $\ell \neq 0$ are $(2\ell + 1)$ -fold degenerate. We pick up one of the CB state from Fig. 11a and one VB state from Fig. 11b to calculate the total impact ionization energy to all possible combinations of two final CB states in Fig. 11a, which is shown in Fig. 12a.

Figure 12a conforms with what can be expected intuitively that the initial CB state has to be high while the VB state low in order to fulfil the energy conservation requirement. Furthermore, high-energy states can be highly degenerate because of large ℓ so Γ can be also high. For the case of Fig. 12 where $a = 4$ nm, we observe a maximal Γ of about 7 meV. We further observe tens of Γ over 4 meV while majorities are about 1 meV. These are very high as compared with the light–matter interaction of only 0.065 meV in a similar CdSe QD (Fu et al. 2009), thus we can be very optimistic about MEG processes in colloidal QDs, as has been much reported and also anticipated for significant solar cell applications. For the CdSe QDs under investigation, the MEG effect can be expected when the excitation radiation energy exceeds a threshold of about $2E_g$ (note that E_g is the energy of the ground exciton state, that is, nanocrystal energy gap in Schaller et al. (2005) when the QD radius $a = 4.8$ nm, while the threshold energy will be $2.8 E_g$ when $a = 4.0$ nm, and $3.5 E_g$ for $a = 3.0$ nm).

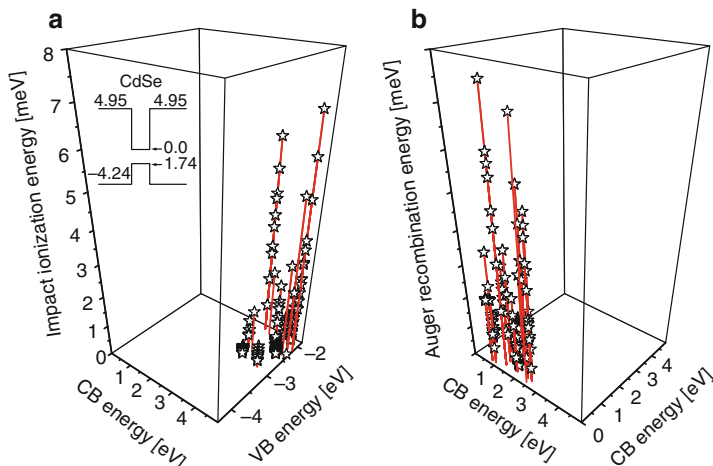

Fig. 12 (a) Impact ionization energy between initial CB state(s) and initial VB state(s). *Inset* shows the band structure of the CdSe QD in vacuum. (b) Auger recombination. The QD radius $a = 4$ nm. Adapted from Fu et al. (2010)

The Auger recombination process (reverse process of the impact ionization) shown in Fig. 12b can be similarly analyzed. Note that the energy range of the initial CB states in the Auger recombination processes is much wider than the impact ionization, especially for small QDs. This is due to the large density of states at high energy so that there are more available final CB states for two initial CB states to interact via the Auger recombination process.

Summary

We have briefly reviewed fundamental theory of excitons and excitonic polaritons in nanostructures. Experimental characterization and application-specific developments using excitons and excitonic polaritons in nanostructures at the electronic and photonic engineering levels have also been briefly discussed. A realization of the potential applications is intimately tied to the control of the geometry and localization of the nanoscale features. Positioning of the nanostructures not only allows for reproducible communication with the environment, but is also necessary for defining the interaction between nanostructures. Solid-state-based nanostructures such as self-assembled QDs provide excellent communication to the environment. The geometry control of these QD size is though relatively poor by the current molecular beam epitaxy (MBE) and metal-organic vapour phase epitaxy (MOVPE) techniques. The size of colloidal II–VI QDs can be very well controlled during the chemical synthetic processes and many colloidal II–VI QDs used in bioimaging applications are core-multishells formed so that possible effects of the surface and external environment on the exciton in the central core region

are minimal. However, the interconnection to the environment becomes a major issue, for example, for photocarrier extraction in solar cell applications. We will, nevertheless, surely witness a further fast development in the research and we hope that this chapter provides some foundation for the understanding and simulation of excitons and exciton polaritons in nanostructures.

and to understand the physical mechanisms taking place at the molecular level. We will place a special emphasis in theoretical works utilizing density functional theory. We assume that the reader is familiar with the basics of density functional theory as well as the electronic properties of single-walled carbon nanotubes and graphene nanoribbons (GNRs). We do not intend to present an extensive review; instead, we focus on several examples to illustrate the powerful predictive capabilities of current computational approaches.

Density Functional Theory with Periodic Boundary Conditions

The focus of this chapter is on carbon structures that are elongated, predominantly one-dimensional systems. For most modeling purposes, these structures can be considered as periodic in one dimension. There are many software packages either free or commercially available to perform density functional theory (DFT) calculations using periodic boundary conditions. In fact, these type of calculations are routine in condensed matter physics and became very popular recently in the quantum chemistry community. One of the most widely used approaches for DFT calculations with periodic boundary conditions is the combination of the local density approximation (LDA) or the generalized gradient approximation (GGA) and plane waves. This approach usually involves only valence electrons, while the effect of core electrons is represented with pseudopotentials. Many modern pseudopotential calculations use ultrasoft pseudopotentials, which were first developed by Vanderbilt in the early 1990s (Vanderbilt 1990). Full-potential all-electron calculations can also be performed using plane waves, although they are somewhat computationally expensive for routine calculations. On the other hand, another class of software packages employ localized basis functions such as Gaussians. These basis functions allow not only an all-electron treatment of the system but also present the flexibility of pseudopotential calculations when heavy atoms are involved. In most cases, dealing with systems involving first- and second-row elements in an all-electron fashion can be routinely done. Another advantage of localized basis functions is that periodic boundary conditions can be explicitly imposed in either one, two, or three dimensions, in contrast to plane waves, which are naturally periodic in three dimensions and therefore approaches such as the super-cell are commonly used to reduce the dimensionality from three to two or one at the price of increasing the computational cost. The main advantage of plane waves over Gaussian basis functions is that the basis set convergence is more controlled. The basis set convergence of Gaussian-type orbitals is well known for molecules and there are tens of available basis sets developed for different purposes (see for instance the EMSL library Feller 1996, 2007). However, the basis set convergence of Gaussian functions is less known for periodic systems, especially for properties like the bandgap. Another disadvantage of Gaussians is that available basis for molecular systems cannot always be straightforwardly employed in periodic boundary conditions calculations due to linear dependencies that occur in periodic structures, limiting in practice the use of large exponents (Gruneich and Hess 1998).

Table 1 Bandgaps (in eV) for the (10,0) SWNT obtained with different functionals (LDA, PBE, and HSE, shown row-wise) and basis sets (3-21G, 3-21G*, and 6-31G*, shown column-wise)

	LDA optimized			PBE optimized			HSE optimized		
	3-21G	3-21G*	6-31G*	3-21G	3-21G*	6-31G*	3-21G	3-21G*	6-31G*
LDA	0.79	0.79	0.78	0.77	0.77	0.76	0.79	0.79	0.77
PBE	0.80	0.80	0.79	0.78	0.78	0.76	0.79	0.79	0.78
HSE	1.00	1.00	0.98	0.97	0.97	0.96	0.99	0.99	0.98

The structure was optimized using the functional and basis set indicated in each column. Calculations were performed with the Gaussian development program (Frisch et al. 2006)

When using localized functions, in general, the basis set needs to be carefully chosen in order to obtain sensible results. It is important to point out that using either localized basis or plane waves, different properties can have different basis set convergence behavior, and the fact that one property such as the energy is converged (within a given criterion) does not imply that all properties are converged. In single-walled carbon nanotubes (SWNTs), for instance, the choice of the Gaussian basis set does not seem to have a significant impact on the bandgap. In Table 1, we show the bandgap (obtained as Kohn–Sham band energy differences) of the (10,0) SWNT calculated with different functionals and standard Gaussian basis sets. The initial SWNT geometry was obtained with the *Tubegen* program (Frey and Doren 2005) and then relaxed using the different functionals and basis sets indicated in each column. For each optimized structure, we calculate the bandgap of the system with the different functionals and basis sets. As shown in Table 1, the bandgap does not depend significantly on the level of theory utilized for the geometry optimization, or the basis set. Table 1 illustrates, however, the dependence of the bandgap upon the choice of the exchange–correlation (XC) functional. This shows that for SWNTs, the choice of the XC functional has a larger impact on the calculated bandgap and related properties.

There are several options available in DFT software packages for the choice of the approximate XC functional. The most widely used XC functionals depend either on the electronic density (local[–spin] density approximation or L[S]DA) or on the electronic density and its gradient (generalized gradient approximation or GGA). For example, in Table 1 we employ the combination of Dirac exchange and the parameterization of Vosko et al. (1980) for correlation in the LSDA functional and the GGA functional of Perdew, Burke, and Ernzerhof (PBE) (1996). Comparing with available experimental data, these families of functionals usually perform well for structural properties but have some deficiencies for energetics and electronic properties. Other type of approximate XC functionals include an orbital dependency either through quantities such as the kinetic energy density or Hartree–Fock (HF) type of exchange (for a thorough review, see Kümmel and Kronik 2008). Examples of orbital-dependent functionals are the meta-GGA TPSS (Tao et al. 2003), or the hybrid functionals PBE0 (Adamo and Barone 1999; Ernzerhof and Scuseria 1999; Perdew et al. 1997) (also known as PBEh), and B3LYP (Becke 1993). These type of functionals generally show some improvement over the LSDA and GGA but

are computationally more demanding. In particular, due to the nature of the HF approximation, hybrid functionals in extended systems can be extremely demanding for metallic and small bandgap systems (Paier et al. 2007). An alternative to standard hybrid functionals for extended systems are the short-range hybrid functionals such as HSE (Heyd et al. 2003, 2006). These functionals truncate the long-range tail of the electron–electron interaction in the exchange contribution to the electronic energy. In this way, the remaining (short-range) part of the HF exchange can be efficiently evaluated (Adamson et al. 1996, 1999). It has been shown that this truncation has little effect on the properties of finite systems and at the same time provides an efficient route for hybrid DFT calculations in extended systems (Heyd and Scuseria 2004).

Most commonly available functionals, either derived from nonempirical grounds or using fitting procedures, are meant to approximate only the electronic ground state, and not excited states. Moreover, although in “static” DFT, Kohn–Sham eigenvalues are often used to evaluate the energy bandgap, there is no formal justification for this: The formal theoretical framework is provided by time-dependent DFT (Runge and Gross 1984). For a review, see Onida et al. (2002). Therefore, the evaluation of the energy bandgaps and related properties from DFT calculations needs to be carried out with care. From a pragmatic viewpoint, Kohn–Sham eigenvalues are often used to distinguish between metals and semiconductors and to estimate excitation energies. LSDA and GGA Kohn–Sham gaps usually underestimate experimental data and sometimes small-gap semiconductors are erroneously predicted to be metallic. Kohn–Sham gaps from hybrid functional calculations, on the other hand are, in general, in better agreement with experimental gaps (Barone et al. 2005a, b; Heyd et al. 2005; Kümmel and Kronik 2008; Peralta et al. 2006), although they tend to overestimate, in general, the available experimental data. Short-range hybrid functionals improve upon regular hybrids and provide good agreement with experiments and more sophisticated many-electron approaches (Barone et al. 2005b; Batista et al. 2006).

Structure–Property Relations in Single-Walled Carbon Nanotubes and Graphene Nanoribbons

Single-Walled Carbon Nanotubes

Carbon nanotubes are one of the most fascinating carbon nanostructures. Although soon after the discovery of fullerenes in 1985 (Kroto et al. 1985) there were many speculations about the possibility of synthesizing long and narrow graphitic cage-like structures, the synthesis of the first carbon nanotubes was reported by Iijima in 1991. After that seminal work, several new routes toward the synthesis of single- and multi-walled carbon nanotubes were developed.

The electronic properties of SWNT were first studied within the so-called zone-folding scheme (ZF) (Hamada et al. 1992; Saito et al. 1992, 1998). This

scheme is based on the tight-binding (TB) approximation for the two-dimensional honeycomb lattice and the subsequent quantization of the wave vector associated with the radial direction of the nanotube. In this framework, the electronic structure of SWNTs is determined by the allowed values of the quantized wave vector. Within this approach, each nanotube, characterized by the indices (n, m) , can be either metallic if $(2n + m)/3 = k$, with k integer, or semiconducting for k non-integer (with a bandgap that depends on the inverse diameter, $1/d$). This versatility in the electronic behavior, that depends *only* on the geometric structure of the tubes, ignited a large amount of experimental and theoretical efforts with the promise of novel technological applications based on these unique nanostructured materials.

In 1998, Tang et al. produced SWNTs grown in zeolite channels with diameters of about 4 Å (Tang et al. 1998). From the optical spectrum and the possible diameter distributions, these tubes were identified as the (3,3), (4,2), and (5,0) (Li et al. 2001). In 2004, the thinnest SWNTs, with diameters of about 3 Å were grown inside multi-walled nanotubes. Because of the small diameter, the possible (n, m) indices of these narrow SWNT were predicted to be (2,2), (4,0), and (3,1) (Zhao et al. 2004). DFT calculations pointed out the importance of curvature effects, especially for narrower nanotubes which present a significant $\sigma - \pi$ hybridization not accounted for in the ZF scheme (Blase et al. 1994; Gülsiren et al. 2002; Mintmire et al. 1992; Reich et al. 2002). Although the ZF scheme works reasonably well for the average diameter SWNT of about 10 Å, several studies confirmed the profound effect of the $\sigma - \pi$ hybridization in small diameter SWNT on their electronic properties.

DFT calculations have shown that the zigzag (5,0) SWNT, which should be a semiconductor according to the zone-folding scheme, is indeed metallic (Barone and Scuseria 2004; Cabria et al. 2003; Li et al. 2001; Liu and Chan 2002; Machón et al. 2002; Springborg and Satpathy 1994). The same holds true for the zigzag (4,0) SWNT (Barone and Scuseria 2004; Cabria et al. 2003). Although it is tempting to assume that narrower tubes tend to be metallic due to the $\sigma - \pi$ hybridization, it has been shown that the narrowest chiral tubes (4,3) and (3,1) present the largest bandgaps of all SWNTs (1.7 and 1.3 eV, respectively, obtained with the HSE functional) (Barone and Scuseria 2004). Due to curvature effects, most narrow semiconducting SWNTs become indirect gap semiconductors and largely deviate from the ZF $1/d$ predictions.

On the modeling side, we note that the calculated electronic properties of narrow nanotubes strongly depend on the exchange-correlation functional used. In Fig. 1 we show the band structure and density of states (DOS) for the three narrow (5,0), (3,3), and (4,2) nanotubes obtained with LDA and the hybrid PBE0 functionals. The largest differences are found for the chiral semiconducting tube for which PBE0 predicts a bandgap as large as 1.36 eV. However, as we show in section “[Modeling the Optical Spectrum of Single-Walled Carbon Nanotubes and Graphene Nanoribbons](#),” while the bandgap of SWNTs is largely underestimated by LSDA, it is also significantly overestimated by PBE0.

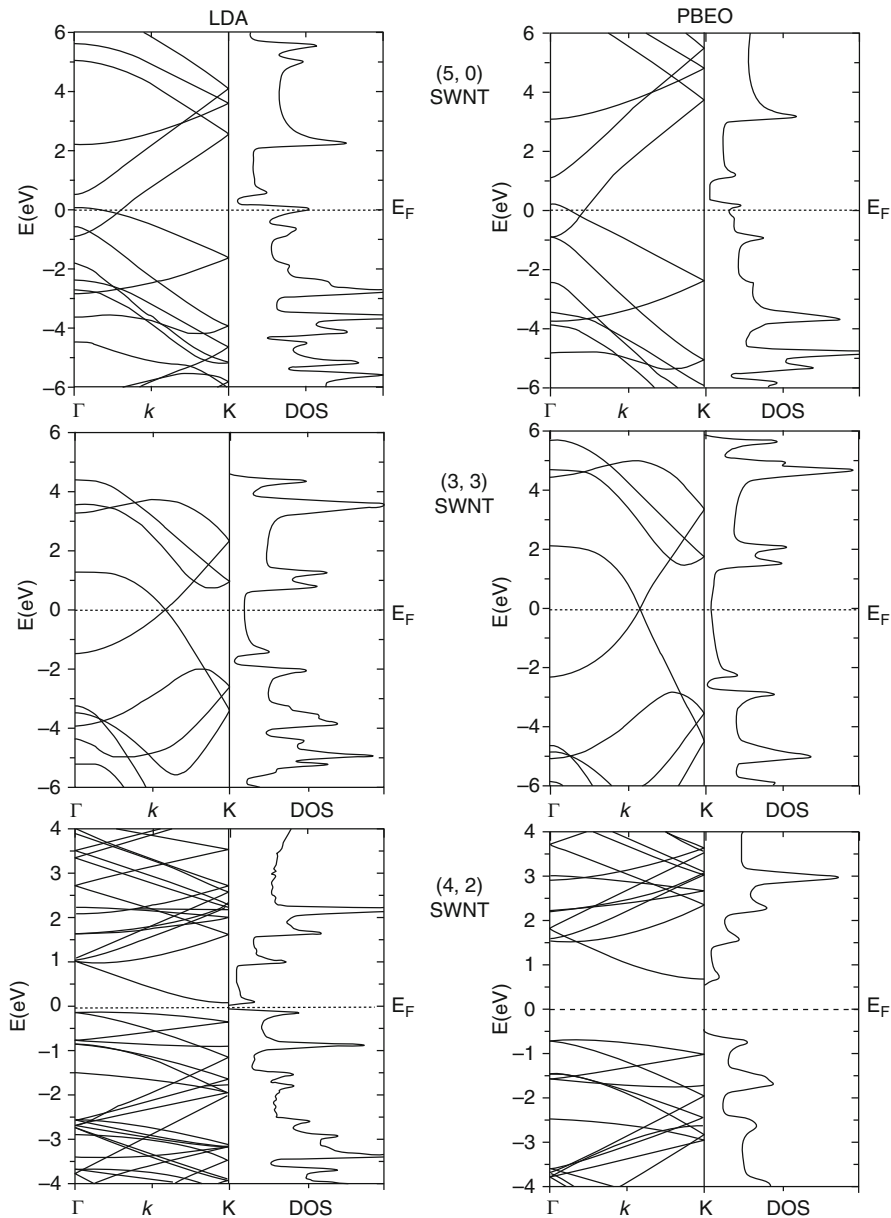

Fig. 1 Band structure and electronic density of states for the (5,0), (3,3), and (4,2) SWNT. (a) Obtained at the LDA/6-31G* level. (b) Obtained at the PBE0/6-31G* level

Graphene Nanoribbons

Graphene, a single layer of graphite, has attracted a lot of attention since 2004 when it was isolated for the first time as a stand-alone two-dimensional all-carbon network (Novoselov et al. 2004). Since then, major accomplishments in their production have been achieved and now, lower dimensional graphene derivatives are routinely created in the lab (Berger et al. 2006; Cai et al. 2010; Han et al. 2007; Ritter and Lyding 2009; Wang et al. 2008; Yang et al. 2008). Recent studies point to graphene and its derivatives as one of the most promising materials for technological applications ranging from spintronic devices to energy storage media (Bhardwaj et al. 2010; Son et al. 2006b).

By cutting a quasi-one-dimensional structure out of a two-dimensional graphene sheet, it is possible to obtain a flat structure usually referred to as a graphene nanoribbon (GNR). These ribbons can also be thought of as unwrapped nanotubes of a given chirality. In Fig. 2 we present a scheme of the two extreme crystallographic orientations of the GNRs axis: armchair (AGNR) and zigzag (ZGNR). Dangling bonds at the edges are usually passivated with hydrogen atoms for the purpose of

Fig. 2 Schematic representation of the fundamental cell of an armchair and a zigzag graphene nanoribbon. The horizontal line represents the translational vector

performing computational studies as it is very difficult to experimentally determine the chemical nature of the edges.

One of the earliest theoretical investigations of the electronic properties of these materials was reported by Fujita et al. (1996). In that work, the authors report striking differences between armchair and zigzag GNRs. Most notably, the authors found that magnetism can arise in nanometer-scale graphitic fragments in the zigzag configuration due to the appearance of localized edge states. According to TB calculations these edge states are manifested as flat bands near the Fermi energy in the band structure of the system. We will return to the case of ZGNRs later in this section. AGNRs do not present such edge states. Instead, the bandgap of these ribbons is predicted to vary with a threefold periodicity as a function of their width, changing from metallic to semiconducting as one consecutively increases their width (Ezawa 2006). When electronic correlation effects are taken into account via DFT, similar bandgap oscillations appear. Nevertheless, a major difference is identified. While in the TB calculations, at certain widths, AGNRs appear to become metallic, DFT calculations predict all AGNRs to be semiconducting (Barone et al. 2006; Son et al. 2006a). In Fig. 3, we present DFT results for the bandgap of armchair ribbons as a function of their width. As shown in this figure, ultra-narrow graphene nanoribbons with widths up to 1 nm present the largest bandgaps in

Fig. 3 Bandgap of H-terminated armchair GNRs as a function of the width obtained with the HSE functional (Reprinted (Adapted) with permission from Barone et al. (2006). © (2006) American Chemical Society)

the range of 1–3 eV. For the range of widths covered by the DFT calculations (up to 3 nm), no significant quenching of the energy gap oscillations is observed (Barone et al. 2006). However, GNRs are expected to reach the graphene limit of zero bandgap for sufficiently large widths.

We note that the armchair GNRs bandgaps presented in Fig. 3 can be separated into three groups, namely, the points forming the envelope of the maxima of the oscillations, those forming the envelope of the minima of the oscillations, and the remaining intermediate points. It is possible then to extrapolate the behavior of each of these subgroups independently to larger widths. Such an extrapolation can be performed using an inverse power law with two fitting parameters (Barone et al. 2006). This simple rule presents the correct asymptotic behavior and provides qualitative information on the electronic structure of ribbons beyond the range of widths studied by first-principles calculations. From these calculations, it is shown that in order to obtain an AGNR with a bandgap comparable to that of Ge (0.67 eV) or InN (0.7 eV), it will be necessary to go to a range of widths between 2 and 3 nm. If a larger band gap material is needed (like Si, 1.14 eV, or GaAs, 1.43 eV), the width of the AGNR must be reduced to as low as 1–2 nm. The extrapolation to wider ribbons also shows that an AGNR of about 8 nm will present a bandgap smaller than 0.2 eV. It is interesting to note that when the first DFT calculations on these systems were carried out, it seemed impossible to produce nanoribbons as narrow as a few nanometers. Only 3 years later, the fabrication and electrical measurement of nanoribbons with widths down to a few nanometers are performed routinely in many laboratories around the world (Wang et al. 2008; Yang et al. 2008; Berger et al. 2006; Cai et al. 2010; Han et al. 2007; Ritter and Lyding 2009).

Experimentally, it has been demonstrated that the energy gap in graphene nanoribbons can be tuned during fabrication and that the energy gap scales inversely with the ribbon width (Chen et al. 2007; Han et al. 2007). Suspended GNRs with widths below 10 nm have been synthesized by a chemical route (Wang et al. 2008). However, the uncontrollable character of these methods restrict the quality of the GNR's edges and consequently limit their applications. Novel, organic synthetic protocols leading to graphene type molecules with different sizes have been presented recently (Yang et al. 2008; Cai et al. 2010). This route should provide perfect edged narrow graphene nanoribbons with widths up to 12 nm.

In zigzag graphene nanoribbons, quantum confinement is accompanied by the existence of pronounced edge states localized around the zigzag edges. As mentioned before, the existence of these edge states have been suggested theoretically more than a decade ago (Fujita et al. 1996; Klein 1994; Kobayashi 1993; Nakada et al. 1996; Tanaka et al. 1987). Recently, such states along the zigzag edges of graphite have been experimentally observed (Kobayashi et al. 2005, 2006; Niimi et al. 2005). One of the most interesting characteristics of these edge states in graphite is their predicted magnetic character (Fujita et al. 1996; Kusakabe and Maruyama 2003; Son et al. 2006a; Wakabayashi et al. 1999). Early theoretical predictions of graphene edge states were based on TB and Hubbard models

(Fujita et al. 1996; Nakada et al. 1996; Tanaka et al. 1987), Huckel theory (Klein 1994), and the DV- $X\alpha$ method (Kobayashi 1993; Tsukada et al. 1983). A more chemically oriented interpretation of the structure and electronic character of the different edges has recently been given using Clar's sextet theory, a well-known tool for the study of aromaticity in organic materials (Balaban and Klein 2009; Baldoni et al. 2008; Wassmann et al. 2008).

The magnetic character carried by the zigzag edge states has a dominant effect on the electronic structure of the system. If one views a ZGNR as unrolling an armchair SWNT, one would naively expect both systems to have similar electronic character while replacing the symmetry of a "particle in a ring" type of boundary conditions with that of a "particle in a box." Therefore, since all armchair SWNTs are metallic in nature, it can be assumed that all ZGNRs would be metallic as well. When performing spin-restricted DFT calculations, this indeed turns out to be the case (Son et al. 2006b). Nevertheless, if the spin degree of freedom is taken into account via the unrestricted DFT scheme, the spin-polarized character of the electronic ground state of the ZGNR is revealed (Son et al. 2006b). Here, the electronic edge state on one zigzag edge has one spin flavor while the corresponding state on the other zigzag edge has the opposite spin flavor. This antiparallel edge spin alignment is a direct consequence of the antiferromagnetic coupling of spins on adjacent sites within the hexagonal carbon lattice. In contrast to the case of the metallic armchair SWNTs, the magnetic ground state exhibits a finite bandgap, and therefore, all ZGNRs become semiconducting (Son et al. 2006b). This is an excellent example showing how edge states may dominate the electronic character of the system.

The existence of such spin-polarized edge states opens a venue for controlling the electronic properties of GNRs. One possible scheme was recently suggested where an in-plane electric field, applied perpendicular to the axis of the ribbon, drives the system into a half-metallic state (Son et al. 2006b). Due to the field-induced charge separation, a local gating with opposite charge polarization occurs at the edges of the ribbons. This in turn, shifts the local DOS at both edges with respect to one another thus increasing the bandgap of electrons with one spin flavor and reducing the bandgap of the opposite spins (see Fig. 4). By changing the intensity of the applied electric field, one can control the ratio of the bandgaps of the two spin components up to a point where the bandgap of one spin flavor completely vanishes while the other spin flavor presents a large bandgap. A system in such a half-metallic state may serve as a perfect spin filter in nanospintronic devices.

The half-metallic behavior exhibited by zigzag ribbons under an external electric field was first obtained using the LSDA functional. Shortly after, calculations in a large cluster model of a zigzag GNR performed using the hybrid B3LYP challenged those findings arguing that the inclusion of HF exchange prevents the half-metallic behavior (Rudberg et al. 2007). However, Kan et al. (2007) and Hod et al. (2007a) independently found half-metallicity in periodic zigzag nanoribbons using the B3LYP and HSE functionals, respectively.

Modeling the Optical Spectrum of Single-Walled Carbon Nanotubes and Graphene Nanoribbons

Single-Walled Carbon Nanotubes

Characterization methods for single-walled carbon nanotubes based on optical absorption have attracted much attention during the past few years. Experiments based on photoluminescence (Bachilo et al. 2002; Weisman and Bachilo 2003), resonant Raman spectroscopy (Fantini et al. 2004; Telg et al. 2004), and Rayleigh scattering (Sfeir et al. 2006) have been reported in which optical transitions are obtained as fingerprints of a certain (n, m) SWNT. Optical transitions were first studied theoretically within the tight-binding approach considering the excitations as inter-band transitions. Within this framework, the optical spectra is generally obtained by utilizing the random-phase approximation (RPA) for the imaginary part of the dielectric function ϵ (for a review, see Onida et al. 2002)

$$\text{Im}(\epsilon) = \frac{1}{\omega^2} \sum_k \sum_{o,u} \left| \langle \psi_o^k | \mathbf{p} | \psi_u^k \rangle \right|^2 \delta(\epsilon_0^k - \epsilon_u^k - \omega), \quad (1)$$

where \mathbf{p} is the linear momentum operator and the indices o and u stand for occupied and unoccupied Bloch orbitals, respectively. An example of the band structure and optical spectrum for a semiconducting tube obtained from DFT calculations is shown in Fig. 5. Allowed optical transitions, marked with arrows in the band structure of panel (a), produce a peak in the optical spectrum (panel (b)). Within the RPA the first-order optical transition corresponds to the fundamental gap of the semiconducting SWNT (generally dipole-allowed).

The relation between the optical transitions and the diameter of the nanotubes (Kataura plot) (Kataura et al. 1999) was used as a useful guide for experimentalists in characterizing nanotubes samples. However, Kataura plots based on conventional TB calculations present serious limitations (Bachilo et al. 2002). DFT calculations utilizing local and semi-local functionals are well known to underestimate the bandgap of semiconductors significantly. This holds also true for higher order optical transitions. Hybrid functionals have been shown to improve significantly the description of the bandgap in semiconducting materials (Heyd and Scuseria 2004; Heyd et al. 2005). In the specific case of semiconducting nanotubes, commonly employed hybrid functionals, like B3LYP or PBE0 significantly overestimate the bandgap (Barone et al. 2005b).

Despite the excitonic character of optical transitions in SWNTs (Spataru et al. 2004), the hybrid meta-GGA TPSS and the screened-exchange hybrid HSE provide excellent agreement with experiments for the optical gap (Barone et al. 2005b) as depicted in Fig. 6 where the mean error for the first-order optical transition with respect to experimental values in a set of ten semiconducting nanotubes is shown. It is worth pointing out, however, that DFT-based approaches cannot

Fig. 6 E_{11} mean errors in a set of ten semiconducting SWNTs calculated with different functionals

predict the strength of exciton binding energies due to the mean-field nature of the approximation.

First-principles calculations including electron–electron interactions beyond the mean field theory have shown the excitonic character of optical transitions in SWNTs with large exciton binding energies (of up to 1 eV for the (8,0) SWNT) (Spataru et al. 2004). These predictions have been corroborated by experiments (Shaver et al. 2007; Wang et al. 2005). Unfortunately, these calculations are too demanding for routine calculations in large diameter tubes, and unlikely to be practical to study the effect of defects and functionalization.

The success of the hybrid functionals HSE and TPSSh in predicting the peak position of optical transitions has been attributed to unknown error cancellations (Kümmel and Kronik 2008; Spataru et al. 2008). However, excitonic effects in metallic nanotubes are up to two orders of magnitude smaller than in semiconducting tubes (Deslippe et al. 2007) and remarkably, the same hybrid functionals that are able to describe the optical peaks in semiconducting tubes also produce excellent results in metallic tubes (Barone et al. 2005a).

As a first example of the predictive capabilities of these functionals, we show in Fig. 7 calculated first-order optical transitions, E_{11} as a function of the corresponding experimental values in a set of five semiconducting and five metallic chiral nanotubes. All non-hybrid functionals employed here (LDA, PBE,

and TPSS) underestimate E_{11} in metallic tubes by approximately 0.3 eV. This error is comparable to the error for E_{11} in semiconducting tubes. The best overall performance is achieved by the hybrids TPSSh and HSE, which yield comparable first-order transitions in the case of metallic SWNTs.

As a second example, we compare in Table 2 first-order transitions calculated using the hybrid TPSSh and HSE functionals (Barone et al. 2005a), and calculations considering GW plus electron–hole interactions (GW + e–h) (Spataru et al. 2008), with experimental values. Here, it is worth to point out the results obtained with hybrid functionals, that predict peak positions in agreement with more complex quasiparticle and excitonic effects approaches. An explanation for this behavior has been recently presented by Brothers et al. (2008).

Graphene Nanoribbons

Theoretical and experimental studies reveal that the optical peaks of AGNRs might be utilized as tools to determine the nature of their edges (Barone et al. 2006; Pimenta et al. 2007). The first calculations of the optical spectrum of GNRs was presented by Barone et al. (2006) by means of DFT using the screened-exchange hybrid HSE functional. As expected from an inter-band transitions framework, first optical excitations present the corresponding oscillations as a function of the width. Second-order transitions also exhibit these oscillations, as shown in Fig. 8.

For armchair ribbons with hydrogen terminations there is a shift between the oscillation of the first and second optical transition energies such that the local maxima of E_{11} coincide with the local minima of E_{22} . This is expected to give rise to a doublet in the optical spectrum. A similar doublet is expected to appear for bare GNRs with widths smaller than 1.2 nm. Nevertheless, for larger widths, the bandgap oscillations of the first and second optical transition energies of bare ribbons are in phase and the doublet is expected to disappear. This effect should provide a practical way of revealing information on the size and the nature of the edges of GNRs. Many-body approaches later pointed out that due to the one-dimensional nature of GNRs, and like in the case of SWNTs, their optical spectrum is dominated by excitonic

Fig. 8 Dependence of the first (E_{11}) and second (E_{22}) optical transition energies on the width of bare (*left panel*) and hydrogen-terminated (*right panel*) GNRs, at the HSE/6-31G* level of theory (Reprinted (Adapted) with permission from Barone et al. (2006). © (2006) American Chemical Society)

effects with binding energies as high as 1.4 eV for a 1.2 nm wide ribbon (Prezzi et al. 2008; Yang et al. 2007).

Chemistry at the Edges of Graphene

The question of what is at the edges of graphene has fascinated researchers in the area (Radovic and Bockrath 2005), especially, since the possibility of finding magnetic edge states was openly discussed in terms of the type of chemical bond that is expected to appear for bare and hydrogen-terminated edges (Radovic and Bockrath 2005). The question of how magnetic and electronic properties of nanoribbons depend upon chemical functionalization and doping has been partially addressed by several studies. One of the first studies along this line of research was presented by Hod et al. (2007a). In this study, the authors assumed that in most synthetic scenarios GNRs edges will most likely be oxidized with an unknown effect on their electronic properties. The oxidation schemes considered in these calculations included hydroxyl, lactone, ketone, and ether groups. The authors have shown that these oxidized ribbons are, in general, more stable than hydrogen-terminated GNRs (see Fig. 9). These configurations maintain a spin-polarized ground state with antiferromagnetic ordering localized at the edges, similar to the fully hydrogenated counterparts. Edge oxidation has been found to lower the onset electric field required to induce half-metallic behavior (see section “Graphene Nanoribbons”) and extend the overall field range at which the systems remain half-metallic. When the edges of the ribbon are fully or partially hydrogenated, the field intensity needed to switch the

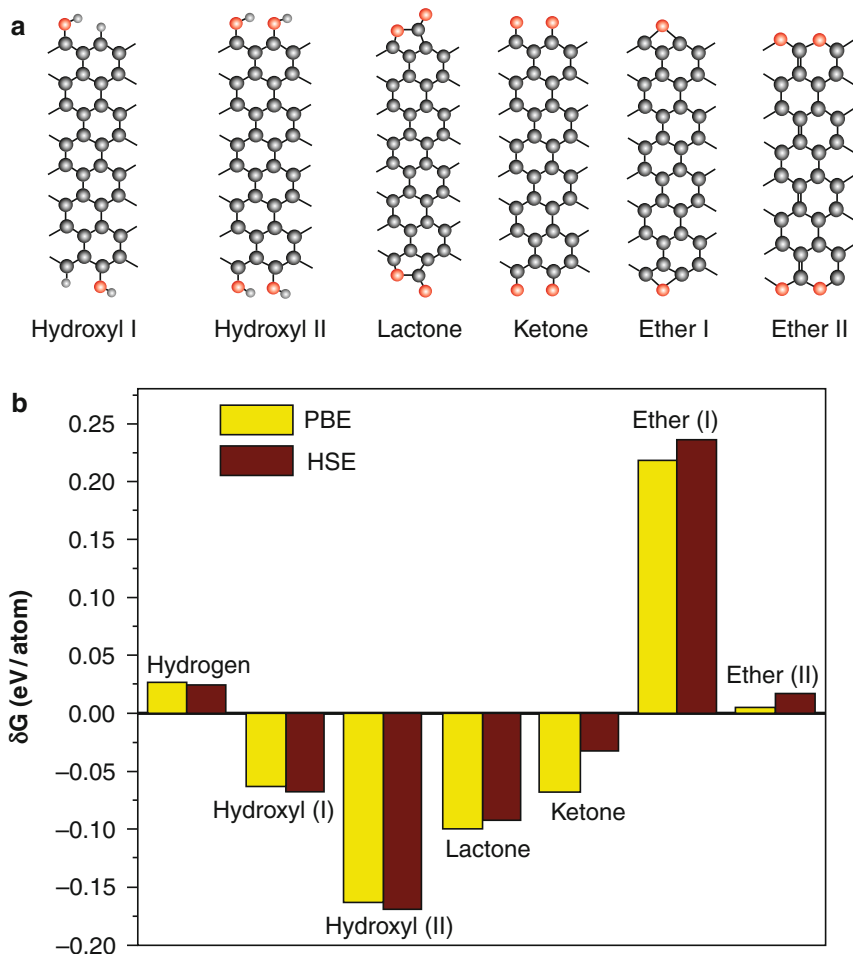

Fig. 9 (a) Scheme of the oxygen-containing groups considered. (b) Relative stability of the different chemical groups at the edges as calculated using the enthalpy of formation with respect to molecular oxygen and hydrogen, and graphene as shown in Hod et al. (2007a) (Reprinted (Adapted) with permission from Hod et al. (2007a). © (2007) American Chemical Society)

system to the half-metallic regime is about 0.4 V/\AA and the range at which the half-metallic behavior is maintained is of 0.3 V/\AA . Nevertheless, when the edges are fully oxidized, the system turns half-metallic at a lower field intensity (0.2 V/\AA) and the range of half-metallic behavior is doubled to 0.6 V/\AA . Unfortunately, it is found that oxygen-containing groups at the edges have a minor effect on the energy difference between the antiferromagnetic ground state and the above-lying ferromagnetic state. This indicates a weak site-to-site exchange coupling and therefore oxygen terminations do not increase the spin coherence length in these systems.

Gunlycke et al. (2007) also studied the effect of oxygen and imine groups and found that transport and magnetic properties are greatly affected by the nature of the chemical groups at the edges. The electronic properties of ribbons with edge carbons presenting two hydrogen or two fluorine atoms were also studied and it was found that in narrow GNRs the sp^3 type of edge carbon results in a non-spin-polarized state (Kudin 2008). Kan et al. (2007) studied the effect of combining donor and acceptor groups at different edges of zigzag nanoribbons using DFT in the GGA. Within this approach, the authors found a half-metallic behavior without an external field for some particular chemical decorations. Cervantes-Sodi et al. (2008a, b) investigated the electronic properties of chemically modified ribbons and observed that chemical modifications of zigzag ribbons can lift the spin degeneracy which promotes a semiconducting-metal transition, or a half-semiconducting state, with the two spin channels having a different bandgap, or a spin-polarized half-semiconducting state, where the spins in the valence and conduction bands are oppositely polarized. The authors find that edge functionalization studied in their work gives electronic states a few eV away from the Fermi level in armchair ribbons and does not significantly affect their bandgap. Lee and Cho (2009) presented calculations based on the local spin density approximation and found that edge-oxidated ZGNRs present a metallic behavior. This was rationalized in terms of the electronegativity of O with respect to C. However, it needs to be stressed that while LSDA or PBE calculations might yield a metallic solution, hybrid functionals still predict all oxidation schemes to be semiconducting (Hod et al. 2007a).

Chemical functionalization of rectangular graphene nanodots has been studied in detail using the DFT-B3LYP approach (Zheng and Duley 2008). This study shows that edge chemical modifications in finite ribbons significantly alter their electronic structure. Finite size effects in this type of dots will be further discussed in the next section.

It is interesting to note that besides chemical functionalization at the edges of graphene it is possible to introduce adatoms on the graphene surface. Usually, this type of interaction is governed by a charge transfer mechanism. Rigo et al. (2009) presented DFT calculations on Ni adsorption on graphene nanoribbons. The adsorption takes place preferentially along the edges of zigzag nanoribbons and the interaction of the adatom with the carbon backbone quenches the magnetization of the latter in the neighborhood of the adsorption site. Other transition metal atoms adsorbed on GNRs were studied using DFT (Sevincli et al. 2008). Interestingly, Fe or Ti adsorption makes certain armchair GNRs half-metallic with a 100% spin polarization at the Fermi level. These results indicate that the properties of graphene nanoribbons can be strongly modified through the adsorption of 3d transition metal atoms. Alkaline and alkali metal adsorption on graphene nanoribbons were found to exhibit a strong site-dependent interaction (Choi and Jhi 2008). Similar results have been obtained by Uthaisar et al. (2009) when considering the interaction of Li adatoms and graphene nanoribbons. The strength of the interaction is much larger in zigzag GNRs than in armchairs and occurs preferentially along the edges. This enhancement is rationalized in terms of the larger number of electron acceptor states in ZGNRs compared to AGNRs. Energy barriers for Li migration also present

important characteristics along the edges which can result in faster kinetics than in regular graphene (Uthaisar and Barone 2010). In addition, recent computational studies suggest lithium doping as a possible route for bandgap engineering of graphitic systems (Krepel and Hod 2011).

Finite Size Effects in Low-Dimensional Graphitic Materials

Finite size effects play a central role in dictating the electronic properties of materials at the nanoscale. Due to their unique electronic structure, quasi-zero-dimensional (quantum dots) graphitic structures may exhibit fascinating physical phenomena, which are absent in their quasi-one-dimensional (nanowires, nanotubes, and nanoribbons) counterparts. Many factors govern the effect of reduced dimensions on the electronic properties of nanoscale materials. Here we focus on two such important factors, which are strongly manifested in the electronic characteristics of graphitic materials, namely, quantum confinement and edge effects:

1. Quantum confinement is related to the boundary conditions enforced on the electronic wave function by the finite size of the system. When the typical de-Broglie wavelength associated with the Fermi electrons becomes comparable to the dimensions of the system, its electronic and optical properties deviate substantially from those of the bulk system. As the confining dimension decreases and reaches this limit (which is typically within the nanometer regime) the energy spectrum turns discrete and the energy gap becomes size dependent.
2. Edge effects in graphitic materials are dominated by localized states, which are physically located at the boundaries of the system and energetically positioned in the vicinity of the Fermi energy. These states influence not only the electronic properties of these systems but also their chemical reactivity.

Quantum Confinement in Graphitic Systems

As shown in previous sections, combining the unique electronic structure of the two-dimensional graphene sheet with the quantum confinement in quasi-one-dimensional graphene derivatives, results in unique electronic properties, which are governed by the specific geometry and dimensions of the relevant system. In section “[Structure–Property Relations in Single-Walled Carbon Nanotubes and Graphene Nanoribbons](#),” it was shown that one of the most notable examples of such effects is found in the strong dependence of the electronic character of carbon nanotubes on their specific diameter and chirality. This diversity in the electronic structure obtained from a single material just by changing its spatial symmetry, is one of the most promising characteristics of carbon nanotubes for applications as basic components in future nanoscale electronic devices.

Recent experimental procedures have allowed the production of ultra-short carbon nanotubes (Chen et al. 2006a, b; Gu et al. 2002; Javey et al. 2004; Khabashesku et al. 2002; Mickelson et al. 1998; Nakamura et al. 2003). The electronic structure of these quasi-zero-dimensional systems is expected to be considerably different from their elongated counterparts, since the reduction of dimensionality implies additional confinement restrictions which may result in the emergence of new and interesting physical phenomena. Several theoretical investigations have addressed the importance of quantum confinement on the electronic properties of finite carbon nanotubes (Baldoni et al. 2007; Li et al. 2002; Liu et al. 2001; Rochefort et al. 1999b). Using a variety of methods including the HF approximation, semiempirical calculations, and the GGA, Rochefort et al. (1999b) have investigated the change in bandgap, density of states, and binding energies as a function of the length of armchair carbon nanotubes. In contrast with the metallic character of the infinite tubes, finite segments shorter than 10 nm are predicted to present a considerable bandgap, which vanishes as the length of the tube increases. Interestingly, the convergence to the infinite metallic system is non-monotonic, and pronounced threefold bandgap oscillations occur as the length of the tube is extended (see Fig. 10). These bandgap oscillations were associated with the periodic changes in the bonding characteristics of the HOMO (highest occupied molecular orbital) and LUMO (lowest unoccupied molecular orbital), which are a direct consequence of the quantum confinement of the π electrons along the tube axis.

As one may expect, the calculated bandgaps strongly depend on the specific computational method, where the HF and semiempirical approximations predict bandgap values which are four to six times larger than those obtained by the generalized gradient DFT and extended Huckel calculations. Nevertheless, the general characteristics of the bandgap behavior and the existence of the bandgap oscillations are predicted by all methods. Similar results have been obtained using the hybrid B3LYP functional for open-ended and capped finite nanotube sections (Li et al. 2002). Expanding the study to the case of zigzag and chiral nanotubes, Liu et al. (2001) have used extended Huckel calculations to show the dependence of the bandgap oscillations on the chirality of the finite nanotube segment. As shown in Fig. 11, as the chirality of the tube changes gradually from armchair to zigzag, the amplitude of the oscillations reduces, and almost vanishes for the case of (12,0) zigzag nanotube segments. This leads to the interesting conclusion that the metallic character of the infinite armchair nanotubes is replaced by HOMO–LUMO gap oscillations for finite armchair nanotube segments, while the oscillatory bandgap nature of infinite zigzag nanotubes is replaced by a vanishing HOMO–LUMO gap for the finite zigzag nanotube segments. An interesting interpretation of the behavior of the HOMO and LUMO levels of finite carbon nanotube segments as a function of their length was recently given using Clar sextet theory (Baldoni et al. 2007).

As discussed above, when an infinite graphene sheet is cut to form a quasi-one-dimensional graphene nanoribbon with a finite width and infinite length, the π -electrons wave function is confined along the direction perpendicular to the axis of the ribbon and is forced to vanish at large distances along this direction. These “particle in a box” like boundary conditions induce discretization of the

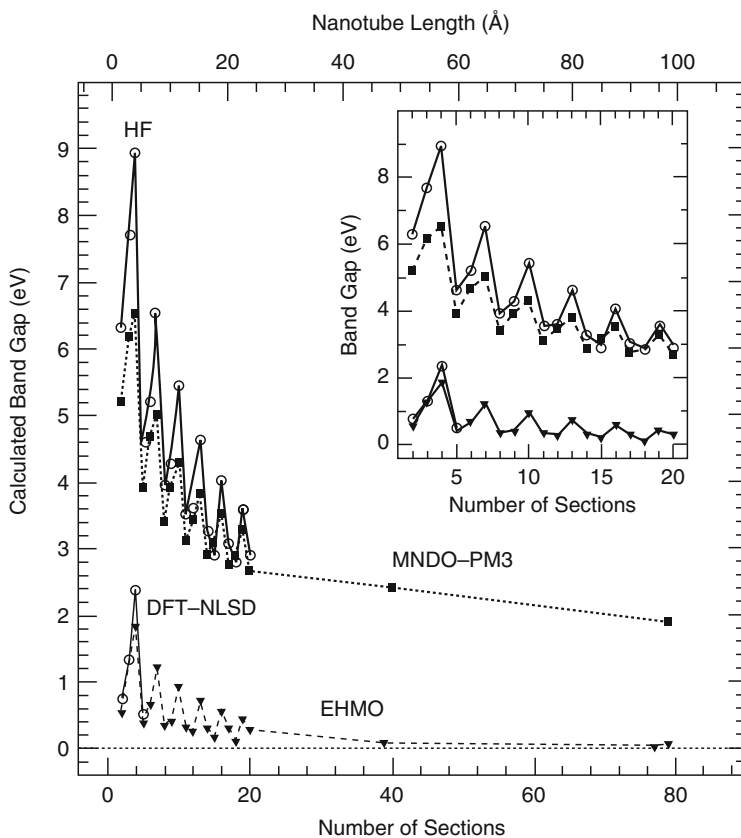

Fig. 10 Variation of the band gap of a (6,6) nanotube as a function of its length determined using different computational techniques (Reprinted (Adapted) with permission from Rochefort et al. (1999b). © (1999) American Chemical Society)

two-dimensional dispersion relation into a set of one-dimensional bands. This discretization induces bandgap dependence on the width of the obtained ribbons.

The dimensionality of these systems may be further reduced to form graphene nanodots, which can be viewed as molecular derivatives of graphene. This extra confinement has been recently shown to strongly impact the electronic structure of these systems (Hod et al. 2008; Shemella et al. 2007). Figure 12 presents the HOMO-LUMO gaps as a function of the length and width of a large number of graphene quantum dots calculated using the local density approximation (upper left panel), the PBE flavor of the generalized gradient correction (upper right panel), and the screened-exchange hybrid HSE functional (lower left panel). The studied graphene derivatives are rectangular in shape and denoted by $N \times M$ where N and M are the number of hydrogen atoms passivating the armchair and zigzag edge, respectively. As in the case of infinite armchair graphene nanoribbons, an oscillatory

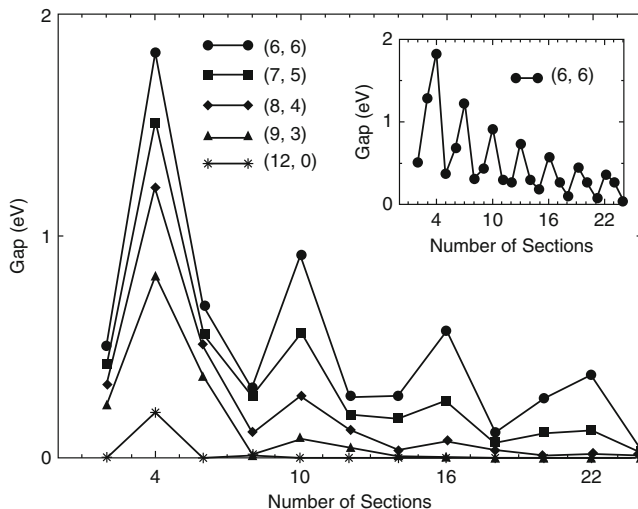

Fig. 11 The bandgap as a function of the (even) number of SWNTs sections (Reprinted with permission from Liu et al. (2001). © (2001) by the American Physical Society)

behavior of the energy gap as a function of the length of the ribbon is observed. The periodicity of these oscillations appears to be somewhat different than the threefold period obtained for the infinitely long counterparts. This, however, is a result of the fact that in order to prevent dangling carbon bonds, the width step taken for the finite systems is twice as large than the one taken in the infinitely long armchair ribbon calculations. The amplitude of the oscillations is found to be considerably damped due to the finite size of the ribbons. As expected, when the length of the armchair edge (N) is increased, the oscillation amplitude increases as well. It is interesting to note that, in general, the HOMO–LUMO gap is inversely proportional to the width (N) and the length (M) of the finite GNR in accordance with the semimetallic graphene sheet limit. Therefore, in order to obtain energy gap tailoring capability, one will have to consider GNRs with long armchair edges (large N values) and short zigzag edges (small M values). This will increase the amplitude of the energy gap oscillations while maintaining overall higher gap values.

Edge Effects in Graphitic Systems

The effects of localized edge states on the electronic properties of quasi-one-dimensional systems have been discussed in previous sections. The question arises of whether similar effects can be observed in quasi-zero-dimensional systems. It is well established that small molecular derivatives of graphene, such as different types of polyaromatic hydrocarbons, have a closed shell nonmagnetic ground state. On the other hand, infinite ZGNRs present a spin-polarized ground state. This suggests

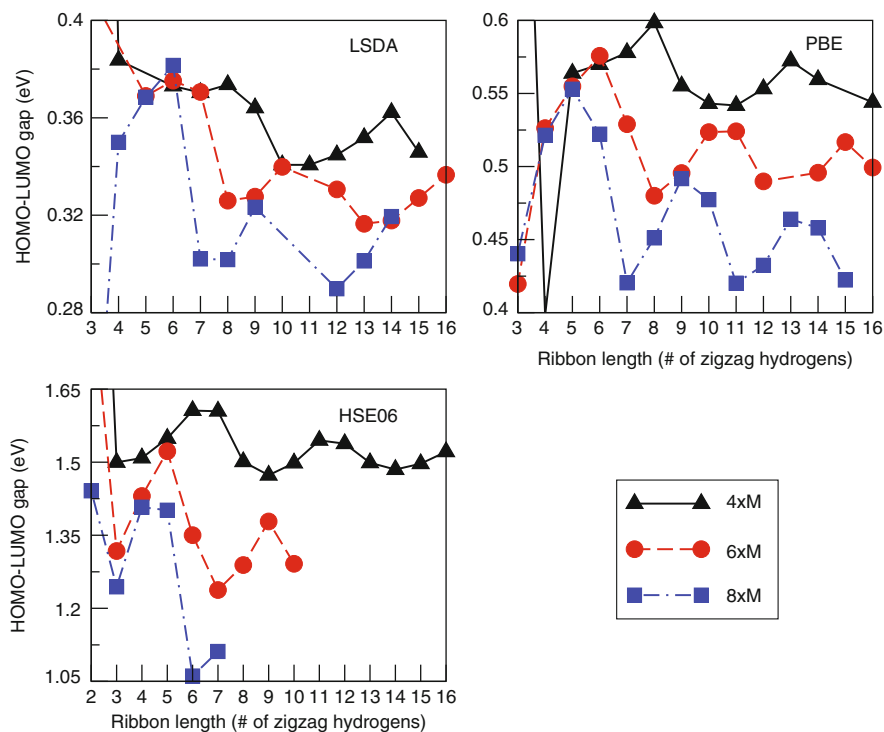

Fig. 12 HOMO–LUMO gap values for three sets of graphene nanodots, as calculated by the local spin density approximation (*upper left panel*), PBE functional (*upper right panel*), and the HSE06 functional (*lower left panel*) (Reprinted with permission from Hod et al. (2008). © (2008) by the American Physical Society)

that there exists a critical size at which molecular graphene derivatives become spin polarized. One of the earliest studies addressing this issue dates back to more than two decades ago (Stein and Brown 1987). Using Huckel theory it was found that finite graphene flakes exhibit electronic edge states along the zigzag edges. More recently, several studies, based on DFT calculations have investigated this question in detail. As a first step for obtaining quasi-zero-dimensional graphene derivatives, it is convenient to consider truncated graphene nanoribbons in the form of rectangular nanodots (Hod et al. 2008; Jiang et al. 2007; Kan et al. 2007; Rudberg et al. 2007; Shemella et al. 2007). Surprisingly, it was found that even molecular scale graphene derivatives, such as the bisanthrene (phenanthro[1,10,9,8-opqra]perylene) isomer of the $C_{28}H_{14}$ molecule and $C_{36}H_{16}$ (tetrabenzo[bc,ef,kl,no]coronene), are predicted to present a spin polarized ground state as shown in Fig. 13 (Hod et al. 2008; Jiang et al. 2007; Kan et al. 2007). For the smaller molecules, this was further verified using a complete active space self-consistent field many-body-wave function approach (Jiang et al. 2007). Furthermore, the application of an in-plane electric field perpendicular to the zigzag edge was found to turn the finite systems

Fig. 13 (a)–(e) Isosurface spin densities of the antiferromagnetic ground state of several molecular graphene derivatives as obtained using the HSE functional and the 6-31G** basis set. (f) and (g) represent diradical and hexaradical Clar structures of bisanthrene (Reprinted with permission from Hod et al. (2008). © (2008) by the American Physical Society)

into molecular scale half-metals (Hod et al. 2008; Kan et al. 2007), similar to the case of infinite ZGNRs.

When considering more complicated graphene derivatives such as triangular graphene flakes (Ezawa 2007; Fernandez-Rossier and Palacios 2007), the combination of the local antiferromagnetic spin ordering on adjacent carbon sites and the edge geometry of the triangular structure results in spin frustration. This leads to a metallic ground state with an overall ferromagnetic character and a finite magnetic moment. The results of tight-binding Ising model (Ezawa 2007) and Hubbard model (Fernandez-Rossier and Palacios 2007) Hamiltonians are consistent with the predictions of DFT (Fernandez-Rossier and Palacios 2007). These can be further rationalized by Lieb's theorem (Lieb 1989) regarding the total spin S of the exact ground state of the Hubbard model in bipartite lattices. The honeycomb lattice of graphene is formed by two triangular interpenetrating sublattices, A and B . Since triangular nanostructures have more atoms in one sublattice, $N_A > N_B$ the total spin S of the ground state is $2S = N_A - N_B > 0$. Here, the main contribution to the magnetic moment comes from edge states around the zigzag edges of

the triangular structure. Such molecular graphene derivatives were suggested to function as permanent magnets in future nanoscale memory devices.

Naturally, the effect of edge states reduces as the surface to edge ratio becomes larger. An interesting question to address is at what length would the effect of the edges disappear and the electronic structure of the system becomes essentially identical to that of the infinite system? In a recent study, this question was addressed using a divide-and-conquer (D&C) DFT approach, which enables the efficient and accurate calculation of the electronic properties and charge transport through finite elongated systems (Hod et al. 2006). Within this approach, the Hamiltonian \mathbf{H} is given in a localized basis set representation by a block-tridiagonal matrix, where the first and last diagonal blocks correspond to the two terminating units of the ribbon (see upper panel of Fig. 14). The remaining diagonal blocks correspond to the central part of the GNR which is composed of a replicated unit cell. The terminating units and the replicated central part unit cell are chosen to be long enough such that the block-tridiagonal representation of \mathbf{H} (and the overlap matrix \mathbf{S}) is valid.

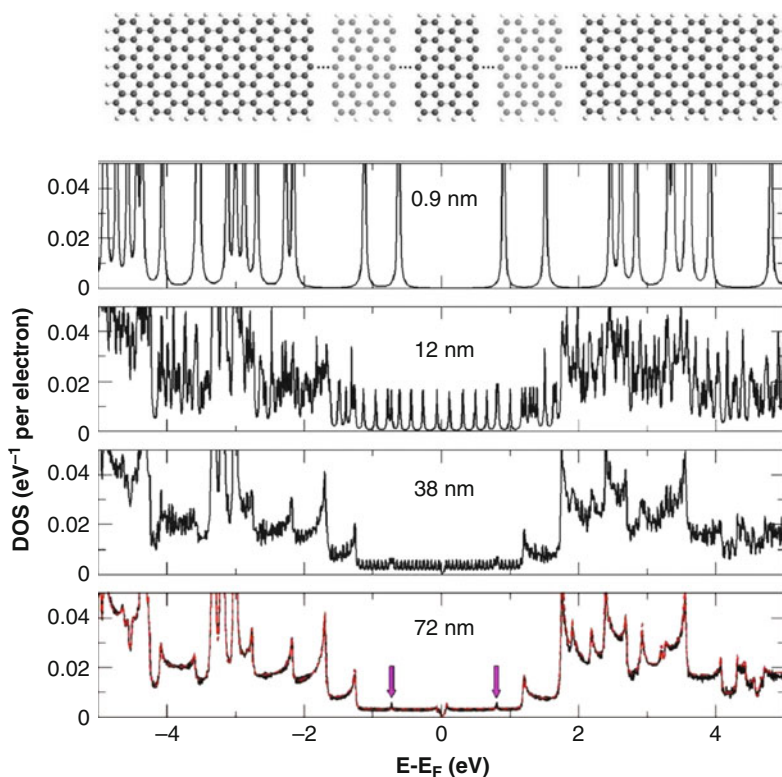

Fig. 14 *Upper panel:* A finite elongated graphene nanoribbon. *Lower panels:* DOS of the finite GNR at different lengths. The red curve in the lowermost panel is the DOS of the infinite system (Reprinted with permission from Hod et al. (2007b). © (2006) by the American Physical Society)

The terminating unit diagonal Hamiltonian blocks and their coupling to the central part are evaluated via a molecular calculation involving the two terminating units and one unit cell cut out of the central part. The replicated unit cell blocks of the central part and the coupling between two such adjacent blocks are approximated to be constant along the GNR and obtained from a periodic boundary conditions calculation. The resulting block-tridiagonal matrix $ES - \mathbf{H}$ is then partially inverted for each value of the energy E using an efficient algorithm, to obtain the relevant Green's function blocks needed for the DOS and transport calculations using the following formula

$$\rho(E) = -\frac{1}{\pi} \text{Im} \{ \text{Tr} [G^r(E)\mathbf{S}] \}, \quad (2)$$

where $G^r(E) = [ES - \mathbf{H}]^{-1}$. A detailed account of the D&C method can be found in Hod et al. (2006).

To study these edge effects in graphene, three graphene nanoribbons with consecutive widths were considered and their DOS as a function of the ribbons' length were calculated using this D&C approach (Hod et al. 2007b). As an example, Fig. 14 presents the DOS of a finite graphene nanoribbon of different lengths. It can be seen that for graphene nanodots up to 12 nm in length, the DOS resembles that of a finite molecular system characterized by a discrete set of energy levels. When the ribbon is further elongated to 38 nm, a constant DOS around the Fermi energy of the infinite system arises and typical Van Hove singularities start to build up. For this specific system, at a length of 72 nm most of the features that are related to the edge states disappear, and the DOS almost perfectly matches that of an infinite armchair graphene nanoribbon. The rate of convergence of the electronic properties of finite systems to those of the infinite counterparts will depend on the type of the system and the specific interactions that govern its electronic character. Therefore, the divide-and-conquer method allows the quantitative estimation of this rate based on state-of-the-art DFT approximations.

We now turn back to the case of carbon nanotubes. When a zigzag nanotube is cut into finite segments, the zigzag edges are exposed. We have shown in the previous section that quantum confinement effects may play an important role in determining the electronic character of such structures. Similar to the case of graphene nanoribbons, these effects are now accompanied by the formation of spin-polarized edge states which put their own fingerprints on the electronic structures of the system (see Fig. 15). There has been a debate in the literature regarding the energetic stability of these edge states, and whether they would appear for all finite zigzag nanotubes regardless of their diameter (Higuchi et al. 2004; Kim et al. 2003; Okada and Oshiyama 2003). It is now well accepted that all finite zigzag SWNT segments are expected to present a spin-polarized ground state (Hod and Scuseria 2008; Kim et al. 2003; Mananes et al. 2008). Furthermore, as for ZGNRs, the application of an axial electric field will drive the system into a half-metallic state, thus forming a perfect spin filter. If one now eliminates only one zigzag edge of the tube by capping it with a half-fullerene, spin frustration results in a

Fig. 15 Antiferromagnetic-type ground state spin density maps of the (7,0) (*upper left panel*), (8,0) (*upper right panel*), (9,0) (*lower left panel*), (10,0) (*lower right panel*) finite zigzag SWNT segments as obtained using the HSE functional with the 6-31G** basis set. spin-polarized ferromagnetic ground state (Kim et al. 2003), which resembles the case of triangular graphene derivatives discussed above and forms a molecular magnet bearing a permanent magnetic moment.

Two-dimensional graphene and its lower dimensional derivatives present a diversity of electronic behaviors, making them particularly attractive as building blocks for future nano-devices. Simplified model Hamiltonian approaches may give important insights on the general physical trends in these systems. Nevertheless, density functional theory in general, and the screen exchange hybrid functional approximation, in particular, seem to be excellent tools to quantitatively study the structure–function relations in these systems and the effects of external perturbations such as chemical substitutions and electric and magnetic fields.

Electromechanical Properties of One-Dimensional Graphitic Structures

Electromechanical devices are based on systems for which the mechanical properties can be controlled via the application of external electric potentials and/or the electronic properties may be altered via induced mechanical deformations. Such devices can be scaled down to form microelectromechanical systems (MEMS), which are small integrated devices or systems that combine electrical and mechanical components. Their dimensions may vary from the submicron level up to a few millimeters. By fabricating miniature mechanical elements such as beams, gears, diaphragms, and springs MEMS enabled the realization of diverse applications

including ink-jet-printer cartridges, accelerometers, miniature robots, microengines, locks, inertial sensors, microtransmissions, micromirrors, micro actuators, optical scanners, fluid pumps, transducers, and chemical, pressure, and flow sensors. Nanoelectromechanical (NEMS) systems present the ultimate miniaturization of such devices, scaling them further down to the molecular level. Apart from the reduced dimensions, these systems are characterized by lower energy consumption and increased sensitivity toward external perturbations. Furthermore, due to their quantum-mechanical nature, molecular-sized NEMS may present unique physical properties that cannot be obtained from their microscopic and macroscopic counterparts. The unique electronic and mechanical properties of carbon nanotubes have marked them as promising candidates for key components in NEMS. In recent years, several theoretical investigations as well as experimental realization of NEMS have been presented (Cao et al. 2003; Cohen-Karni et al. 2006; Fennimore et al. 2003; Gomez-Navarro et al. 2004; Hall et al. 2007; Maiti 2003; Minot et al. 2003; Nagapriya et al. 2008; Paulson et al. 1999; Rueckes et al. 2000; Sazonova et al. 2004; Semet et al. 2005; Stampfer et al. 2006; Tombler et al. 2000).

Carbon Nanotubes in NEMS Applications

The key components in most of the suggested setups are suspended carbon nanotubes bridging the gap between two conducting electrodes without making contact with the underlying surface (see Fig. 16). One may then induce mechanical deformations via manipulation of an external nanoscale tip while simultaneously measuring the changes in the conductance of the system. Strong reversible electromechanical response of carbon nanotubes under combined bending and stretching deformations have been recorded by several experimental groups (Cao et al. 2003; Maiti 2003; Minot et al. 2003; Semet et al. 2005; Stampfer et al. 2006; Tombler et al. 2000). In Fig. 17, the change in the SWNT's resistance as a function of the depression applied to the top cantilever (Fig. 16) is plotted. The resistance of the system increases by more than an order of magnitude over a depression range of less than 4 nm, suggesting that such setups may be used for highly sensitive and reliable displacement sensors. A similar setup, where a floating pedal is attached to a suspended

(2006). © (2006) American Chemical Society)

multi-walled nanotube, has enabled the investigation of the electromechanical response of single (Hall et al. 2007) and multi-walled (Cohen-Karni et al. 2006) nanotubes under the application of torsional deformations. In this setup, an atomic force microscope (AFM) tip presses down on the floating pedal. Since the SWNT is fixed at both edges to the conducting electrodes, the central section experiences torsion. This change in helicity of the system induces considerable variations in the electronic conductance. Interestingly, pronounced bandgap oscillations are observed as a function of the deflection angle of the pedal. The origin of these oscillations has been associated with the distortion of the first Brillouin zone (fBZ), which results in the shifting of the Dirac points (Cohen-Karni et al. 2006; Nagapriya et al. 2008). As the Dirac points shift within the fBZ they may approach an allowed electronic band thus increasing the conductance of the system. Once the Dirac point crosses the allowed band the conductance reaches a maximum value. Further deformation results in shifting the Dirac points away from the allowed band and thus a decrease in the conductance. This process is repeated anytime the Dirac point crosses one of the many parallel allowed bands. Other prototype devices such as nanotube actuators (Fennimore et al. 2003; Gomez-Navarro et al. 2004), and nonvolatile memory components based on SWNTs junctions (Rueckes et al. 2000) have been

successfully fabricated as well, demonstrating the potential of SWNTs as nanoscale electromechanical devices. Aiming to obtain a microscopic understanding of these experimental observations and to guide further experiments with carbon nanotubes under various mechanical deformation modes, many theoretical investigations have been performed (Maiti 2009). Due to the complexity of the deformed systems, most of the computational treatments were based on semiempirical or DFT-based TB calculations.

The effects of axial stretching (Heyd et al. 1997; Jiang et al. 2004; Kane and Mele 1997; Kleiner and Eggert 2001; Yang et al. 1999), bending (Kane and Mele 1997; Liu et al. 2000; Nardelli 1999; Nardelli and Bernholc 1999; Rochefort et al. 1998, 1999a; Yang and Han 2000), torsion (Jiang et al. 2004; Kleiner and Eggert 2001; Rochefort et al. 1999a; Yang and Han 2000; Yang et al. 1999; Zhang et al. 2009), and radial compression (Lammert et al. 2000; Lu et al. 2003; Peng and Cho 2002; Svizhenko et al. 2005) were studied extensively showing high sensitivity of the electronic properties and transport characteristics of the deformed nanotubes to the applied deformations.

Several DFT calculations were conducted to study the effect of axial strain (Guo et al. 2005), bending (Maiti 2001; Maiti et al. 2002), radial compression (Mehrez et al. 2005; Wu et al. 2004), and torsional deformations in carbon nanotubes (Nagapriya et al. 2008):

1. *Axialstrain*: While isolating the effect of axial stretching and compression is a challenging experimental task (Cao et al. 2003), pure axial deformations are easy to study using modern computational tools (Guo et al. 2005). Bandgap variations due to axial compression and stretching were studied using the local density approximation. As it can be seen in Fig. 18 for strains up to 3%, linear variations in the bandgap are predicted. The slope of the bandgap response depends on the tube type and on the sign of the axial deformation. For all systems studied, the relative changes in bandgap are of the order of 0.5 eV and are definitely measurable in experimental conditions.
2. *Bending*: The effect of pure bending and AFM tip-induced bending was studied using the Harris functional approximation (Maiti 2001; Maiti et al. 2002). It was shown that both pure bending and tip-induced compression maintain the hexagonal sp^2 lattice structure up to relatively high bending angles. Armchair tubes remain significantly conducting even at large deformations. However, metallic zigzag tubes display a dramatic drop in conductance, in particular under tip-induced deformations.
3. *Compression*: Radial compression was studied via a combined molecular dynamics and density functional theory-based nonequilibrium Green's function approach (Wu et al. 2004). Reversible pressure-induced metal-to-semiconductor transitions of armchair SWNTs were predicted suggesting that SWNTs may be used as miniature sensitive pressure detectors (Mehrez et al. 2005; Wu et al. 2004).
4. *Torsion*: While the torsional electromechanical response was successfully explained via the deformation of the Brillouin zone, another possible explanation

Fig. 18 Calculated bandgap variation of zigzag (9,0), (12,0), (15,0), and (27,0) SWNTs as a function of axial strain (Reprinted with permission from Guo et al. (2005). © (2005) American Institute of Physics)

for the bandgap oscillations may be the periodic formation of Moire patterns due to registry mismatch between the different walls of the multi-walled tubes, which have a different curvature. In order to rule out this possibility, DFT calculations within the LSDA were used to show that the interlayer coupling is weak and the electronic structure of the individual walls resembles that of single-walled nanotubes for different intertube orientations (Nagapriya et al. 2008).

As can be seen from all of the examples given above, the study of the physical properties of nanotubes in general and their electromechanical behavior in particular requires an intimate relation between theory and experiment, where the theoretical tools enable an atomic scale understanding of the experimental observations and provide guidelines for the design of new experiments. As we have seen above, when considering finite size effects and chemical functionalization, DFT presents new insights that are not captured within the simple TB approximations. When considering the electromechanical response of SWNTs to different mechanical deformations, TB calculations seem to give a reliable description. Nevertheless, calculations based on DFT are required for comparison and validation purposes.

Graphene Nanoribbons in NEMS Applications

Soon after the successful isolation of a single graphene sheet (Novoselov et al. 2004) the first experimental realization of an electromechanical device based on graphene nanoribbons was presented (Bunch et al. 2007). In this setup, atomic

thick layers of graphene were suspended above pre-designed trenches carved in the underlying silicon oxide surface while bridging the gap between gold electrodes. Both optical and electrical actuation procedures were demonstrated resulting in vibrational frequencies in the MHz regime. High charge sensitivities suggested the possibility of using similar devices as ultrasensitive mass and force detection (Bunch et al. 2007). Following this novel experimental fabrication and manipulation of graphene nanoribbons as nanoelectromechanical components, several other studies have explored the mechanical (Frank et al. 2007; Poot and van der Zant 2008) and electromechanical response of these systems (Milaninia et al. 2009). The effects of uniaxial strains in isolated graphene nanoribbons were recently studied in details using the generalized gradient approximation of the exchange correlation functional within the framework of DFT (Faccio et al. 2009; Sun et al. 2008). It was found that the electronic properties of zigzag GNRs are not sensitive to uniaxial strain, while the energy gap of armchair nanoribbons displays an oscillatory pattern as a function of the applied strain. By comparison to TB calculations, it was deduced that the nearest-neighbor hopping terms between atomic sites within the carbon hexagonal lattice are responsible for the observed electromechanical response. To simulate the effects of bending and torsional deformations in suspended graphene nanoribbons, DFT calculations utilizing the screened-exchange HSE density functional were performed (Hod and Scuseria 2009). A large set of short armchair graphene nanoribbons was considered, where narrow strips of atoms close to the zigzag edges of the ribbon were fixed to simulate a doubly clamped suspended nanoribbon (see Fig. 19).

The effect of a driven deformation due to an external tip were simulated by constraining a strip of hexagons at the central part of the ribbon to be either depressed or rotated with respect to the fixed edge atoms. Extreme mechanical deformations, way beyond the linear response regime, were applied to the full set of nanoribbons studied. Most of the nanoribbons considered stayed stable under depressions of 1 nm as well as torsional angles of 90° maintaining their spin-polarized ground state character. As it can be seen in Fig. 20, pronounced electromechanical responses for both bending and torsion (torsion not presented in Fig. 20) have been obtained including evidence of dimension-dependent bandgap oscillations similar to the case of SWNTs (Cohen-Karni et al. 2006; Nagapriya et al. 2008).

Different panels and *line colors* represent results for GNRs of different widths and lengths, respectively (Reprinted (Adapted) with permission from Hod and Scuseria (2009). © (2009) American Chemical Society)

Apart from indicating the promise that graphene nanoribbons hold from an electromechanical perspective, such calculations based on state-of-the-art density functional theory approaches, enhance the molecular scale understanding of the physical processes governing the behavior of these intriguing materials. Furthermore, theory and computations may guide future experiments to pursue promising scientific and technological routes toward which efforts and resources should be directed.

Concluding Remarks

In this chapter, we have given several examples of how theoretical investigations can be applied to elucidate the behavior of carbon nanostructures with emphasis on the understanding of the basic physical mechanisms that take place at the molecular level. In particular, we have shown that density functional theory is a powerful tool to this end, and we have provided several examples where density functional theory has been utilized to investigate electronic and structural properties of graphene

nanoribbons, carbon nanotubes, and other low-dimensional graphitic materials. We hope that this chapter will furnish the reader with an ample background on this growing field and that it will serve as a starting point for readers interested in pursuing research in this exciting field.

Abstract

Recent computer simulations have indicated that there is a linear relationship between the melting and the Curie temperatures for Ni_n ($n \leq 201$) clusters. In this chapter, it is argued that this result is a consequence of the fact that the surface and the core (bulk) contributions to the cluster properties vary with the cluster size in an analogous way. The universal aspect of this result is also discussed. Among the many interesting consequences resulting from this relationship is the intriguing possibility of the coexistence of melting and magnetization. As demonstrated, these conclusions have as their origin the major contribution coming from the melting/magnetization ratio arising from surface effects and

appear to overshadow all other contributions. As a result, this can be quantified with approximate methods which are suitable for describing any major surface contribution to a cluster property.

Introduction

As the cluster size increases, the cluster properties evolve toward their bulk counterparts. The understanding of this evolution is of fundamental importance not only from the perspective of basic science but also from the technological viewpoint. At a very approximate level, one can claim that the cluster properties can be described in terms of their surface and core (bulk) contributions and due to the fact that the surface to bulk ratio gets smaller as the cluster size increases. Consequently, it is natural to expect that the cluster properties will evolve to their corresponding bulk-phase ones for large cluster sizes.

As one particular example, we mention the melting temperature of large clusters. According to the proposed model, the following functional relationship for the variation of the melting temperature, $T_{\text{melt},N}^{\text{cl}}$, of a cluster as the number N of its atoms increases has been suggested:

$$T_{\text{melt},N}^{\text{cl}} = T_{\text{melt}}^{\text{bulk}} - \delta_{\text{melt}} N^{-1/3}, \quad (1)$$

where $T_{\text{melt}}^{\text{bulk}}$ is the melting temperature of the corresponding bulk phase and δ_{melt} is a constant that depends on N (Garcia-Rodeja et al. 1994; Gunes and Erkoc 2000; Lee et al. 2001; Nayak et al. 1998; Qi et al. 2001; Rey et al. 1993; Sun and Gong 1998). Correction terms in $N^{-2/3}$ and N^{-1} powers to the above expression have also been suggested (Doye and Calvo 2001). The term proportional to $N^{-1/3}$ in Eq. 1 reflects the surface to bulk contribution to the melting temperature.

Equation 1 was found to describe reasonably well the experimental findings in the large-size regime ($N > 500$). However, for clusters of smaller size, (especially for clusters with number of atoms $N \leq 50$), Eq. 1 does not ensure a quantitative description of the variation of $T_{\text{melt},N}^{\text{cl}}$ with the cluster size (see, e.g., Baletto and Ferrando 2005; Lee et al. 2001; Nayak et al. 1998; Qi et al. 2001). This is because for small clusters, (1) the surface-to-volume contribution to $T_{\text{melt},N}^{\text{cl}}$ is very large and (2) is very sensitive to the variations of the surface structure and the cluster geometry (symmetry), as both of these characteristics get altered as the cluster size changes.

Another property that has attracted much interest recently is the one pertaining to the evolution of the magnetic features of the magnetic clusters as the cluster size and temperature increase. This is mainly because of the potential applications of the magnetic grains in fabricating new materials for advanced magnetic storage devices and other applications (Bansman et al. 2005).

Recently, the results of our computer simulations led us to the conclusion that the Curie, $T_{C,N}^{\text{cl}}$, and the melting, $T_{\text{melt},N}^{\text{cl}}$, temperature of Ni_N clusters consisting of N atoms are linearly related over a large range of cluster sizes ($N \leq 201$), and this relationship is quantified by the following equation (Andriotis et al. 2007) :

$$T_{\text{melt},N}^{cl} = \alpha T_{C,N}^{cl} + \beta, \quad (2)$$

where α and β are constants. Least square fitting of our results leads to $\alpha = 0.5414$ and $\beta = 443.82^\circ\text{K}$. This relationship was suggested to be related to the ratio of the surface to bulk contributions to the cluster melting as well as to the average magnetic moment per cluster atom, $\bar{\mu}_{i,N}(T)$ $i = 1, \dots, N$. It was then claimed that this relationship could be justified within the mean field theory applied separately to the surface and core regions of the cluster (Andriotis et al. 2007).

A cursory thought seems to suggest that any type of direct relationship between $T_{\text{melt},N}^{cl}$ and $T_{C,N}^{cl}$ to be fortuitous since melting and magnetic order seem to reflect completely different aspects of the crystal potential. Therefore, Eq. 2 cannot be considered as one which reestablishes a valid physical relationship between these two cluster properties.

Furthermore, the variation of both $T_{\text{melt},N}^{cl}$ and $T_{C,N}^{cl}$ with the cluster size constitute separate distinct and complicated projects for both theory and experiment. This is because significant contributions to both of these physical quantities have their origin in surface as well as cluster-core (bulk) effects which, at first look, affect $T_{\text{melt},N}^{cl}$ and $T_{C,N}^{cl}$ differently. These contributions include: the effects of the cohesive energy, the shape (symmetry), the size, the surface to bulk ratio, the surface tension, the temperature of the cluster, etc.

In early reports, it was found that $T_{\text{melt},N}^{cl}$ is usually smaller than the corresponding bulk value. Of interest is the result applied for large enough spherical clusters of radius R :

$$T_{\text{melt},N}^{cl}/T_{\text{melt}}^{\text{bulk}} = 1 - k_m/R \quad (3)$$

where k_m is a material-dependent constant (see, e.g., Buffat and Borel 1976 and references therein). A similar expression describing the variation of the Curie temperature with the cluster size was also found within the phenomenological Landau–Ginsburg–Devonshire theory (Huang et al. 2000), i.e.,

$$T_{C,N}^{cl}/T_C^{\text{bulk}} = 1 - k_c/R \quad (4)$$

Use of Eqs. 3 and 4 gives the following values for α and β in Eq. 2:

$$\alpha = \frac{k_c}{k_m} \frac{T_C^{\text{bulk}}}{T_{\text{melt}}^{\text{bulk}}} \quad (5)$$

and

$$\beta = T_C^{\text{bulk}} - \alpha T_{\text{melt}}^{\text{bulk}} = \left(1 - \frac{k_c}{k_m}\right) T_C^{\text{bulk}}. \quad (6)$$

Diep and collaborators (1989) using Monte Carlo simulations studied the effect of the magnetic interactions on the melting temperature of a cluster. Although their

investigation was limited to very small clusters M_N , ($N \in [7, 17]$) of transition metals M, however, the conclusions they arrived at are very important. In particular, among others, they have found that the incorporation of the magnetic interactions leaves the cluster structure unchanged. However, magnetic interactions lead to sharper peaks in the specific heat (and, therefore, to more precise determination of melting and Curie temperatures), a slight increase in the melting temperature, and a slight cluster-volume contraction (magnetostriction). After examining more carefully the results of Diep et al. (1989) (included in their Fig. 12), we find that the relation of $T_{\text{melt},N}^{cl}$ and $T_{C,N}^{cl}$ is more or less linear with the exception of the data of the very small clusters, i.e., for $N \in [7, 8, 9]$. The linear relationship between $T_{\text{melt},N}^{cl}$ and $T_{C,N}^{cl}$ was also suggested recently on the basis of semiempirical and approximate phenomenological model descriptions (see Yang and Jiang 2005 and references therein).

All these descriptions support our findings (i.e., Eq. 2), which are based on a firm quantum mechanical model procedure as outlined in the following. In this work, we investigate the implications of such a relationship which seems to specify a universal aspect of the surface contribution to the cluster properties.

The Model

The investigation of clusters of medium and intermediate sizes consisting of transition metal atoms poses a severe challenge in terms of computer capacities and computer time. For this reason, approximate schemes have been employed with most pronounced being those based on empirical classical potentials. However, these models have limited applicability when there is a need to understand more about the electronic structure of these systems and follow its changes as the cluster size increases and approaches the bulk phase. It is thus necessary to use methods with firm ab initio footing while at the same time not sacrificing computational efficiency. One such method is based on the Tight-Binding approximation which we have adopted in our work.

In this section, we discuss briefly the implementation of this approach in order to model the temperature and magnetic features of transition metal clusters. We will firstly give a brief overview of our TB computational scheme that we used for systems at zero temperature. In the following sections, we will describe the generalization of our method enabling the inclusion of magnetic and temperature effects.

Tight-Binding Molecular Dynamics Methodology

The details of our Generalized Tight-Binding Molecular Dynamics (GTBMD) scheme can be found in Andriotis and Menon (1998) and Menon and Subbaswamy (1997). The GTBMD method makes explicit use of the nonorthogonality of the orbitals resulting in a transferable scheme that works well in the range all the way from a few atoms to the condensed solid. The scheme also includes d -electron

interactions enabling dynamic treatment of magnetic effects in transition metal systems. Here, we give a brief overview.

The total energy U is written in its general form as a sum of several terms (Andriotis and Menon 1998),

$$U = U_{\text{el}} + U_{\text{rep}} + U_0, \quad (7)$$

where U_{el} is the sum of the one-electron energies E_n for the occupied states:

$$U_{\text{el}} = \sum_n^{\text{occ}} E_n. \quad (8)$$

In the tight-binding scheme, E_n is obtained by solving the characteristic equation:

$$(\mathbf{H} - E_n \mathbf{S}) \mathbf{C}^n = 0, \quad (9)$$

where \mathbf{H} is the Hamiltonian of the system and \mathbf{S} the overlap matrix.

The Hellmann–Feynman theorem for obtaining the electronic part of the force is given by Menon and Subbaswamy (1997),

$$\frac{\partial E_n}{\partial x} = \frac{\mathbf{C}^{n\dagger} \left(\frac{\partial \mathbf{H}}{\partial x} - E_n \frac{\partial \mathbf{S}}{\partial x} \right) \mathbf{C}^n}{\mathbf{C}^{n\dagger} \mathbf{S} \mathbf{C}^n}. \quad (10)$$

The total energy expression also derives contributions from ion–ion repulsion interactions. This is approximated by a sum of pairwise repulsive terms and included in U_{rep} . This sum also contains the corrections arising from the double counting of electron–electron interactions in U_{el} (Andriotis and Menon 1998). U_0 is a constant that merely shifts the zero of energy. The contribution to the total force from U_{rep} is rather straightforward. One can then easily do molecular dynamics simulations by numerically solving Newton’s equation,

$$m \frac{d^2 x}{dt^2} = F_x = -\frac{\partial U}{\partial x} \quad (11)$$

to obtain x as a function of time.

Our TBMD scheme for a binary system consisting of elements A and B is based on a minimal set of five adjustable parameters for each pair (A,A), (B,B), and (A,B). These parameters are determined by fitting to experimental data for quantities such as the bond length, the vibrational frequency, and the binding energy of the dimers A_2 , B_2 , AB; the cohesive energy of the corresponding bulk states of the A, B, AB materials; and the energy level spacing of the lowest magnetic states of the dimer and trimer binary clusters consisting of atoms of A and B type. In the absence of experimental data, we fit to data of small clusters obtained using ab initio methods as described in the following subsection. It is apparent that only five parameters are required in the case of a single species system. The generalization to a system containing more than two kind of atoms is also plausible within this approach.

The fixed set of TB parameters are obtained from the universal scheme proposed by Harrison (1980) suitably scaled with respect to the interatomic distance (Andriotis and Menon 1998).

Collinear Magnetic Effects

In order to calculate the Curie temperature of a magnetic cluster, it is necessary to include non-collinear magnetic effects in our model description. These are introduced by extending our zero temperature (ZT) Tight-Binding Molecular Dynamics (TBMD) approach at the Hubbard-U level of approximation (Andriotis and Menon 1998) which we used to study magnetic clusters in the collinear magnetic approximation. According to this collinear model, an exchange-splitting parameter $s_0^{(i)}$ is introduced which is proportional to the intra-site Coulomb interaction U . This specifies the energy splitting between spin-up and spin-down electrons in the i th-atom in accordance with results obtained by ab initio methods. Thus, within this model, a site-diagonal spin-dependent Hamiltonian term $\mathbf{V}_{\text{spin}}^{(i)}$ is introduced which has the form:

$$\mathbf{V}_{\text{spin}}^{(i)} = \begin{pmatrix} s_0^{(i)} & 0 \\ 0 & -s_0^{(i)} \end{pmatrix} \quad (12)$$

In this model, it is assumed that all atomic magnetic moments (MMs) (of the cluster atoms) are collinear to the z-axis of a local xyz-system assigned to the i th cluster-atom.

The generalization of this model to include non-collinear effects is achieved in three steps. In the first step, we include the randomness in the directions of the atomic MMs. In the second, we include the spin-orbit interaction, and in the third, we include the temperature effects. For the sake of completeness, we briefly discuss this generalization in the following.

Step 1: Inclusion of Randomness in the Direction of the Atomic Magnetic Moments

In the first step, it is assumed that the deviation of the direction of the MM, μ_i , of the i th cluster-atom from the Z -axis of the global coordinate system XYZ is specified by the polar angles (θ_i, ϕ_i) defined with respect to this XYZ system. As a result, the potential $\mathbf{V}_{\text{spin}}^{(i)}$, originally defined in the local coordinate system xyz of the i th atom, is transformed to its expression $\mathbf{V}_{\text{spin}}^{(i),\text{global}}$ in the global system XYZ as follows (Anderson and Hasegawa 1955; Uhl et al. 1994):

$$\mathbf{V}_{\text{spin}}^{(i),\text{global}} = \Xi^\dagger(\theta_i, \phi_i) \mathbf{V}_{\text{spin}}^{(i)} \Xi(\theta_i, \phi_i), \quad (13)$$

where $\Xi(\theta_i, \phi_i)$ is the standard spin-1/2-rotation matrix :

$$\Xi(\theta_i, \phi_i) = \begin{pmatrix} e^{i\phi_i/2} \cos \theta_i/2 & e^{-i\phi_i/2} \sin \theta_i/2 \\ -e^{i\phi_i/2} \sin \theta_i/2 & e^{-i\phi_i/2} \cos \theta_i/2 \end{pmatrix} \quad (14)$$

It is assumed that the Z-axis of the global system can be arbitrarily chosen, and a usual choice is to take Z in alignment with the easy axis of the system.

Step 2: Inclusion of Spin-Orbit Interaction

In the second step, we introduce the Spin-Orbit (SO) interaction, $V_{SO}^{(i)}$, in the i th-atom within the \mathbf{L} - \mathbf{S} coupling scheme, i.e., $V_{SO}^{(i)} = -\lambda^{(i)} \mathbf{L}^{(i)} \cdot \mathbf{S}^{(i)}$ where, $\lambda^{(i)}$ is the spin-orbit coupling constant for the i th-atom, $\mathbf{L}^{(i)}$ its orbital angular momentum along the Z-axis, and $\mathbf{S}^{(i)}$ its total spin in the direction of μ_i .

Details of the implementation of the Spin-Orbit interaction within our TBMD method have been reported elsewhere (Andriotis and Menon 2004).

In the presence of a magnetic field, \mathbf{B} (assumed to be along the direction specified by the polar angles (θ_0, ϕ_0) with respect to XYZ-system), the atomic MMs of the cluster-atoms tend to become parallel to the direction of \mathbf{B} . The average projection of the MMs of the cluster-atoms, μ_{cl} , along the direction of \mathbf{B} (which is the experimentally measured quantity) is,

$$\mu_{cl} = \frac{1}{N_{cl}} \left| \sum_i^{N_{cl}} \mu_i \cos \gamma_i \right|, \quad (15)$$

where N_{cl} is the number of cluster-atoms and $\cos \gamma_i = \cos \theta_0 \cos \theta_i + \sin \theta_0 \sin \theta_i \cos(\phi_0 - \phi_i)$.

In a different formulation within the Hubbard-U model approximation to the e - e correlations, the spin-mixing interaction may be derived from a Coulomb-type Hamiltonian term of the form (Kato and Kokubo 1994; Ojeda et al. 1999): $\mathbf{V}_{\text{smix}} = -U \sum_{l\sigma} \rho_{l\sigma, l\bar{\sigma}} c_{l\bar{\sigma}}^\dagger c_{l\sigma}$, where $c_{l\sigma}^\dagger (c_{l\sigma})$ is the creation (annihilation) operator for an electron with spin σ at site l and $\rho_{l\bar{\sigma}, l\sigma}$ denote the electron density matrix elements, i.e., $\rho_{l\sigma, l\bar{\sigma}} = \langle c_{l\bar{\sigma}}^\dagger c_{l\sigma} \rangle$. It can be easily verified that the Hamiltonian term \mathbf{V}_{smix} is equivalent to that given by Eq. 13, i.e., $\mathbf{V}_{\text{spin}}^{(i), \text{global}}$.

Evaluation of the TB representation of the SO-interaction

In order to proceed with the evaluation of the TB matrix elements of the SO-interaction, we write the SO-term as

$$\mathbf{S} \cdot \mathbf{L} = L_x S_x + L_y S_y + L_z S_z \quad (16)$$

and compute the matrix elements with respect to the basis set. We are using a basis set of atomic orbitals $y_{ilm\sigma}(\mathbf{r})$, where the index i specifies the atom on which the atomic orbital (AO) is centered, l specifies the angular momentum, m is used to

count the various d -orbitals (i.e., d_{xy} , d_{xz} , d_{yz} , $d_{x^2-y^2}$, d_{z^2}), and σ denotes the spin. In terms of a linear superposition of these basis functions, the single electron wave functions take the form

$$\Psi_{i\sigma}(\mathbf{r}) = \sum_{l,m} C_{ilm\sigma} y_{ilm\sigma}(\mathbf{r}), \quad (17)$$

where $C_{ilm\sigma}$ denote the coefficients which are to be determined from the diagonalization of the Hamiltonian.

The spin operators of Eq. 16 refer to the global system and care has to be exercised as they act on the local spin states, the latter related with the former according to Eqs. 13 and 14. For example,

$$\langle \uparrow'_i | S_x | \downarrow'_i \rangle = \frac{1}{2} \cos \phi_i \sin \theta_i, \quad (18)$$

where the prime indicates the local functions and \uparrow , \downarrow indicate spin-up and spin-down states, respectively.

The matrix elements of the orbital angular momentum operators are obtained by operating on the angular part of the wave functions which, in our TBMD formalism are described by the Cubic harmonics. As an example, we write down the expression of the average value of the z -component of the orbital magnetic moment, L_z , in terms of its matrix elements:

$$\langle L_z \rangle = \sum_{i\sigma} \int d\mathbf{r} \Psi_{i\sigma}^*(\mathbf{r}) L_z \Psi_{i\sigma}(\mathbf{r}) \quad (19)$$

or

$$\langle L_z \rangle = \sum_{\sigma} \sum_i^{\text{occ}} \sum_{l,m} \sum_{l',m'} C_{ilm\sigma}^* C_{il'm'\sigma} \int d\mathbf{r} y_{ilm\sigma}^*(\mathbf{r}) L_z y_{il'm'\sigma}(\mathbf{r}) \quad (20)$$

Assuming orthogonality of AOs centered at different atoms, and orthonormal basis functions centered at one particular atom, we finally obtain the following expression for the d -orbital contribution to the orbital magnetic moment $\langle L_z^d \rangle$:

$$\langle L_z^d \rangle = \sum_{\sigma} \sum_i^{\text{occ}} \sum_{l=2} \sum_{mm'} \Delta_{mm'}^{il} C_{ilm\sigma}^* C_{il'm'\sigma} \quad (21)$$

where $\Delta_{mm'}^{il}$ are constants easily calculated by applying the relation:

$$L_z Y_{lm} = m Y_{lm} \quad (22)$$

where Y_{lm} are the spherical harmonics. For example, a straightforward calculation of the constants $\Delta_{mm'}^{il}$ shows that the only nonzero matrix elements of L_z are the following:

$$\langle d_{x^2-y^2} | L_z | d_{xy} \rangle = -2i \quad (23)$$

and

$$\langle yz | L_z | zx \rangle = -i \quad (24)$$

Combining the above, we construct the spin-dependent TB-representation of the SO-interaction term and add this to the other Hamiltonian terms.

Step 3: Inclusion of Temperature Effects

In the third step, our ZT-TBMD method has been extended by incorporating the *Nose*-bath (Nose 1984) and the Multiple Histogram approximations (Fanourgakis et al. 1997), so as to be applicable to cluster studies at finite temperatures in an efficient way (Andriotis et al. 2006, 2007; Fthenakis et al. 2003). This generalization allows one to calculate the caloric curve for the cluster and use this to study the effect of temperature on the structural, electronic, and magnetic properties of transition metal clusters and binary systems containing transition metal and semiconductor atoms. The method has been used to study the variation of structural and magnetic properties with temperature as well as to obtain the caloric curves of the Ni-clusters (Andriotis et al. 2006, 2007; Fthenakis et al. 2003).

Upon thermalization at temperature T , a cluster can be described by the canonical probability distribution function of total energy, $P_T(E)$, which specifies the probability that the system will be found in the energy interval $[E, E + \Delta E]$ at the specified temperature T . The distribution function corresponding to this temperature, within the canonical ensemble description, is (see Fanourgakis et al. 1997; Schmidt et al. 1997 and references therein):

$$P_T(E) = \frac{n_T(E)}{N_T} = \frac{[\Delta\Gamma(E)] e^{-E/k_B T}}{Z_T} \quad (25)$$

where $n_T(E)$ is the number of states in the energy interval $[E, E + \Delta E]$, N_T is the total number of accessible states, k_B is Boltzmann's constant, $\Delta\Gamma(E)$ the number of all the different states with energy in the interval $[E, E + \Delta E]$ (i.e., given by $Z_T = \sum_{E_i} \exp(-\beta E_i) = \sum_i \Delta\Gamma(E_i) \exp(-\beta E_i)$) and Z_T the partition function at temperature T .

A molecular dynamics (MD) simulation at a given temperature T provides numerical values for $n_T(E)$ at every accessible energy E . Having obtained these, we make use of the proposed Multiple Histogram Method (MHM) (Weerasinghe and Amar 1993), and obtain the partition functions Z_{T_j} for a finite set of temperatures T_j , $j = 1, \dots, M$ ($M \approx 200$) and the entropy terms $S(E_i) = k_B \ln[\Delta\Gamma(E_i)]$ (within an additive constant) for a much larger set of energy values E_i , $i = 1, \dots, N$ ($N \approx 6,000$) (Weerasinghe and Amar 1993).

Having obtained the quantities $n_T(E)$, $Z_T(E)$ and $S_T(E)$, we can then describe all the thermodynamic properties of the clusters and, in particular, the variation with temperature of their structural, electronic, and magnetic properties.

Computational Approach

The computation of the magnetic features of the clusters is performed within the above described non-collinear TBMD scheme as this allows for a full quantum MD relaxation of systems containing several hundred transition metal atoms while incorporating magnetic effects dynamically. More specifically, it includes: (1) e - e correlation effects at the Hubbard-U approximation (Andriotis and Menon 1998), (2) the spin-orbit interaction (in the $\mathbf{L} \cdot \mathbf{S}$ approximation), and (3) non-collinear magnetic effects (Andriotis and Menon 1998, 2004). Furthermore, the effect of temperature (Andriotis et al. 2006; Fthenakis et al. 2003) is included in the formalism while making use of the full s , p , d basis set and contains many unique features that make it ideally suited for the treatment of transition metal (TM) and semiconducting materials. For large-scale simulations we have developed a parallel algorithm that enables molecular dynamics simulations of systems containing atoms in excess of a thousand. This method is more accurate than the order- N methods that are being used at present to treat systems of these sizes. The successful application of our collinear TB scheme (see, e.g., Andriotis et al. 1998, 1999, 2000; Lathiotakis et al. 1996) guarantees similar success for the present generalization as well. Finally, we also mention that this approach has been suitably adapted in order for exclusive use in studying the transport properties (based on our computational codes as described in Andriotis and Menon 2001; Andriotis et al. 2002).

While the TBMD computational approach generalized in such a way is suitable for calculating the magnetic properties of the clusters (of a specific geometry), its use for relaxing the structure of particularly large clusters at nonzero temperatures has been found inefficient due to the extreme computational complexity. This is because the thermodynamic equilibration of a crystal requires sufficiently long MD relaxation time (of the order of 2–6 ns which is translated into 10–40 million MD steps with each step being of the order of a femtosecond).

In order to make our computations feasible, we firstly reach the thermodynamic equilibrium at each temperature using the classical Sutton–Chen interatomic potential (Sutton and Chen 1990) appropriately fitted to the TBMD results (Fthenakis et al. (unpublished)). It should be noted that for Ni, the classical Sutton–Chen potential (Sutton and Chen 1990) was found to give results closer in agreement with our TBMD method than any other classical potentials in use for Ni (Erkos 2001; Fthenakis et al. (unpublished)). While reaching the thermodynamic equilibrium, we apply our generalized TB formalism every 100 time-steps in order to calculate the MM of the cluster. In the MM calculation, the structure of the cluster is assumed frozen (as obtained within the classical potential approach at that particular time step), and the calculation of the MM of the cluster is repeated for a large number, $N_{\text{ran}}^{(i)}$, of atomic *spin configurations* taken randomly over the *ith-structural configuration* ($N_{\text{ran}}^{(i)} \approx 120 - 300$ for every i -time step in the present calculations).

In view of these results, Eq. 15 is generalized as follows:

$$\mu_{cl} = \frac{1}{KN_{cl}} \left| \sum_i^{N_{cl}} \sum_j^{N_{\text{ran}}^{(i)}} \mu_i^j \cos \gamma_i^j e^{-(E_i^j - E_0)/k_B T} \right|, \quad (26)$$

under the assumption that each spin configuration contributes to the magnetic state of the i th geometric configuration with probability $P_M(E_i^j) = \frac{1}{K} e^{-(E_i^j - E_0)/k_B T}$ where,

$$K = \sum_j N_{ran}^{(i)} e^{-(E_i^j - E_0)/k_B T}. \quad (27)$$

The index j in Eqs. 26 and 27 denotes quantities evaluated at the particular j th random atomic spin configuration of the i th structural configuration of the cluster. E_0 is taken to be the energy of the ferromagnetically aligned atomic-spin configuration. In this way, we take the average over the low-lying spin configurations of the cluster of a particular (frozen) geometric structure (i.e., as calculated at the specific time step). Finally, the thermodynamic average of μ_{cl} given by Eq. 26 over the various cluster geometric structures (i.e., time-steps) is obtained with the help of the probability $P_T(E)$ as given by Eq. 25.

Having obtained the temperature dependence of the average magnetic moment $\mu_{cl}(T)$ per cluster atom, we proceed with the calculation of the temperature dependence of the specific heat of each cluster by taking the derivative $d\{\mu_{cl}(T)\}^2/dT$ of the corresponding $\mu_{cl}(T)$ curves. Following Gerion et al. (2000), we obtain the Curie temperature $T_{C,N}^{cl}$ for each cluster by locating the maximum of the magnetic contribution to C_V . This is repeated for a number of clusters of various sizes.

Results and Discussion

In the present work, our focus is on the properties of the magnetic transition metal clusters and, in particular, on Ni clusters for which experimental data are available for comparison. Using the procedures discussed above, we have calculated the melting, $T_{melt,N}^{cl}$, and the Curie, $T_{C,N}^{cl}$, temperatures of the Ni_N clusters for $N \leq 201$. These results were discussed recently in Andriotis et al. (2007). The melting temperature $T_{melt,N}^{cl}$ has been derived on the basis of the Lindemann index using the caloric curve as obtained from the classical potential MD simulations. The Curie temperature $T_{C,N}^{cl}$ has been derived according to the quantum mechanical procedure discussed above. Both were found to increase with the cluster size tending to their corresponding bulk values as the size of the clusters increases, in good agreement with the existing experimental data (Andriotis et al. 2007).

The correlation between $T_{melt,N}^{cl}$ and $T_{C,N}^{cl}$ obtained from our results is shown in Fig. 1 by the black solid line. This demonstrates and supports the validity of Eq. 2. We discuss the universal aspect of this correlation and the conclusions that can be derived from in the following.

Firstly, it should be noted that the conclusions one can arrive at from the obtained relationship between melting and Curie temperatures of magnetic clusters depend crucially on the accuracy with which cluster melting temperatures are determined. This is a major issue as it has been extensively discussed in the literature (see, e.g., Baletto and Ferrando 2005; Qi et al. 2001; Sun and Gong 1998 and references

Fig. 1 Plot of $T_{\text{melt},N}^{\text{cl}}$ as a function of $T_{C,N}^{\text{cl}}$ for the Ni_N clusters studied in the present work, $N = 43, 80, 147, 177, 201$ (solid line). The dotted black line denoted Eq. 2 while and dashed black line describes Eq. 2 setting $\alpha = 1$ and $\beta = 0$. Points above (below) the dashed line have $T_{\text{melt}} > T_C$ ($T_{\text{melt}} < T_C$) respectively

therein). This is because surface melting of small particles occurs in a continuous manner over a broad temperature range in contradistinction to the melting of the solid-core (bulk-like) which occurs at a specific critical temperature (Garrigos et al. 1989). For this reason, it has been proposed that in order for $T_{\text{melt},N}^{\text{cl}}$ to be described quantitatively, the surface effects are usually treated separately from the core effects by introducing the *surface thickness*, t_0 , as a free parameter and calculate $T_{\text{melt},N}^{\text{cl}}$ by expressing firstly the heat of the cluster fusion in terms of t_0 and the cluster radius (see, e.g., Lai et al. 1996). A more commonly used approach for determining $T_{\text{melt},N}^{\text{cl}}$ is by employing the Lindemann's criterion, an approach followed in the present work (Fthenakis et al. 2003). Such a calculation is subject to the limitations and the accuracy of this method. In particular, the so derived melting temperatures depend strongly on the choice of the classical potential used (Andriotis et al. 2007; Fthenakis et al. 2003). This explains why the reported values for the melting temperature of Ni clusters cover a wide range. Nevertheless, the Sutton–Chen classical potential, employed in the present work for Ni, leads to accurate values for surface energies, vacancy energy, stacking fault energies, and bulk melting temperature in very good agreement with experiment (Qi et al. 2001).

The accuracy of Lindemann's criterion depends also on the steepness of its variation with temperature at phase transition and on the specification of its percentage increase which should be adequate to discriminate surface (partial) from

all-cluster melting. In the present case, we assign $T_{\text{melt},N}^{cl}$ to the temperature at which Lindemann's index starts increasing. This allows us to obtain the onset of cluster melting and to derive the melting temperature corresponding to a cluster phase in which unmolten parts with a possible magnetic order are still present.

Similarly, the determination of $T_{C,N}^{cl}$ depends crucially on the accurate location of the maximum of the heat capacity variation with temperature. This was demonstrated in our previous report (Andriotis et al. 2007) when discussing the $T_{\text{melt},N}^{cl}$ and $T_{C,N}^{cl}$ results of Ni_{43} and their deviation from the prediction of Eq. 2. Additionally, the surface energy contribution to the free energy of the cluster may be another reason that small cluster temperatures cannot be extrapolated to bulk phase values (Qi et al. 2001).

Following these clarifications, we next discuss some obvious and hidden consequences of Eq. 2. One of the first conclusion that can be deduced from these results is that the Curie temperature, $T_{C,N}^{cl}$, of a magnetic cluster has to follow a size-dependence relationship analogous to that of $T_{\text{melt},N}^{cl}$. That is, if $T_{\text{melt},N}^{cl}$ is given by Eq. 1, then $T_{C,N}^{cl}$ has to follow the following equation:

$$T_{C,N}^{cl} = T_C^{\text{bulk}} - \delta_C N^{-1/3}, \quad (28)$$

where δ_C is a constant that may have an N-dependence as δ_{melt} . In fact, assuming the validity of Eqs. 1 and 28 and taking the ratio between Eqs. 1 and 28 by parts, we obtain:

$$\frac{T_{C,N}^{cl} - T_C^{\text{bulk}}}{T_{\text{melt},N}^{cl} - T_{\text{melt}}^{\text{bulk}}} = \frac{\delta_C}{\delta_{\text{melt}}} = \delta_0, \quad (29)$$

where δ_0 is a constant which is expected to depend on N. It is apparent that Eq. 29 has exactly the form of our Eq. 2, suggesting that the N-dependence of the constant δ_0 is very weak.

It is worth noting that the numerical justification of Eq. 29 by our results as expressed by Eq. 2 cannot ensure that the trends described by Eqs. 1 and 28 and which are possibly valid for large clusters can be extrapolated to small clusters as well. The conclusion that comes from Eq. 2 is that whatever the functional relationship between the melting temperature of a cluster and its size (not necessarily limited to that of Eq. 1) is, the functional relationship followed by $T_{\text{melt},N}^{cl}$ should dictate the relationship between the Curie temperature with its size as well. This hypothesis is supported by the results of Diep and collaborators (Diep et al. 1989) who found that the incorporation of the magnetic interactions leaves the cluster structure unchanged, thereby justifying our computational procedure.

One may argue that the use of two noncomparable methods, i.e., that of a classical potential MD simulation for calculating the melting temperature and a quantum mechanical approximation for calculating the magnetic moments and the Curie temperature of a cluster, cannot lead to results that can be correlated. We addressed this issue by fitting the classical Sutton–Chen potential to the data for

small clusters in such a way that resulted in TBMD and fitted Sutton–Chen potential simulations giving the same structural properties for small Ni clusters. Obtaining similar structural results by both methods appears to confirm the validity of the classical potential MD simulations for our present purpose.

Furthermore, in order to resolve any reservations and ambiguities about the consistency of our conclusions derived from the use of mutually inconsistent methods in calculating the melting and Curie temperatures, it is demonstrated in the following that a calculation of the melting temperatures within our TBMD approximation is in excellent agreement with the results of the classical potential approximation used in the derivation of Eq. 2.

Following exactly the same procedure as the one we used to calculate the average magnetic moment per cluster atom (and from this the Curie temperature) (Andriotis et al. 2007), we calculate the average total energy, $\langle E_T \rangle$, of each cluster at its thermodynamic equilibrium at a series of temperatures T . An average over N_{ran} random spin configurations over the cluster atoms is taken at each k th time step for N_{cl} time steps (N_{ran} is taken approximately between 100 and 200). Finally, these spin-averaged values are averaged over time. That is,

$$\langle E_T \rangle = \frac{1}{N_{cl}} \sum_{k=1}^{N_{cl}} \frac{1}{N_{\text{ran}}} \frac{\sum_{i=1}^{N_{\text{ran}}} E_i^k e^{-(E_i^k - E_0)/k_B T}}{\sum_{i=1}^{N_{\text{ran}}} e^{-(E_i^k - E_0)/k_B T}}. \quad (30)$$

where E_0 is a reference energy (Andriotis et al. 2007). For completeness, it is recalled that

$$E_i^k = \sum_{j\sigma} \varepsilon_{j\sigma}^{i,k} + E_{\text{rep}}^{i,k} \quad (31)$$

where $\varepsilon_{j\sigma}^{i,k}$ denote the eigenvalues of the TB cluster Hamiltonian and $E_{\text{rep}}^{i,k}$, the sum of the repulsive interactions (Andriotis and Menon 1998) of the cluster at the i th random spin configuration and the k th time step. As in the case of the calculation of the Curie temperatures, the averaging process over time in Eq. 30 is performed while reaching the thermodynamic equilibrium every 100 time-steps.

In Figs. 2 and 3, we present our TB results for the variation with temperature of $\langle E_T \rangle$ for the Ni₁₄₇ and Ni₂₀₁ clusters. For Ni₁₄₇, it is observed that the onset of a phase change appears at ≈ 450 °K while the melting starts at ≈ 700 °K. For Ni₂₀₁, the melting takes place at ≈ 800 °K (taken to be the midpoint of the “parallel” shift of the two linear parts of the thermodynamic curve. The so obtained melting temperatures appear to be in excellent agreement with the results found using the classical potential method and the Lindemann criterion according to which $T_{\text{melt},N=147}^{cl} = 700$ °K and $T_{\text{melt},N=201}^{cl} = 780$ °K.

Further headway can be made if Eq. 2 is taken to be the zeroth-order approximation of a *piece-wise function of N* in analogy to similar findings (Gunes and Erkoç 2000; Qi et al. 2001) for the expression for $T_{\text{melt},N}^{cl}$ given by Eq. 1. In this view, the results of Diep et al. (1989) (see Fig. 12 of their work) in the extreme case of very small clusters ($N \in [7,17]$) can lend support to our results and conclusions.

Fig. 2 Numerical results obtained within the TBMD method for the variation with temperature of the average total energy of the Ni₁₄₇ cluster. Straight lines are least square fits to portions of the numerical data

Fig. 3 The same as in Fig. 2 but for the Ni₂₀₁ cluster

The appearance of the nonzero constant term at the right-hand side of Eq. 2 indicates that there is a possibility for $T_{C,N}^{cl}$ to be greater than $T_{melt,N}^{cl}$. In particular, Eq. 2 predicts that $T_{C,N}^{cl}$ could be greater than $T_{melt,N}^{cl}$ if

$$T_C^{bulk} > T_{C,N}^{cl} > \frac{\beta}{1 - \alpha}. \tag{32}$$

However, according to our results, the above inequality does not hold for the Ni clusters since $\beta / (1 - \alpha) \approx 968^\circ \text{K}$, a value much greater than $T_C^{\text{bulk}} = 631^\circ \text{K}$. This is demonstrated in Fig. 1 with the indicated crossing of the dotted and dashed black lines with the former describing Eq. 2 and the latter describing the same equation taking $\alpha = 1$ and $\beta = 0$ (i.e., corresponding to the $T_{C,N}^{cl} = T_{\text{melt},N}^{cl}$ case). This incompatibility can be taken as an indication that the functional forms dictated by Eqs. 1 and 28 are not valid for the entire range of the cluster sizes.

The nonzero value of the constant β has another consequence; it predicts that the ratio $\frac{T_{\text{melt},N}^{cl}}{T_{C,N}^{cl}}$ depends on the cluster size and, in fact, increases as the cluster size decreases. If the variation of $T_{\text{melt},N}^{cl}$ is assumed as given by Eq. 1, the predictions of Eq. 2 lead to the conclusion that $T_{C,N}^{cl}$ decreases at a slower rate than $T_{\text{melt},N}^{cl}$ as the cluster size decreases and, therefore, the “melting temperatures” of *partially molten clusters* can be found to be lower than the Curie temperatures as Eq. 2 implies. However, such a conclusion has to be taken with care as the validity of Eq. 1 over the entire range of cluster sizes is not valid.

Conclusion

We have presented results for the variation with the cluster size of the melting and Curie temperatures of Ni_n , $n \leq 201$, clusters. Two complimentary methods were used, i.e., the classical MD employing the Sutton–Chen potential and the TBMD for obtaining the melting and the Curie temperatures of the clusters. We have demonstrated that by fitting the classical potential to the results of the TB description in the case of small clusters, we can achieve excellent agreement between the results of the two methods referring to the structural properties and the estimation of the melting temperatures of the clusters.

Our results demonstrate without any ambiguity that the variation of the cluster properties with the cluster size exhibits strong dependence on the ratio of the surface to bulk (core) contributions, the latter appearing to have the same functional dependence on the cluster size for both $T_{C,N}^{cl}$ and $T_{\text{melt},N}^{cl}$.

In view of the established dependence of the melting temperature of a cluster on its surface to volume contribution (as, for example, Eq. 1), our conclusion can be interpreted as an indication of a universal aspect of the surface to volume contribution to the cluster properties. This justifies previous findings based on approximate and semiempirical approximations.

Abstract

Clusters contain more than just some few atoms but not so many that they can be considered as being infinite. By varying their size, their properties can often be varied in a more or less controllable way. Often, however, the precise relation between size and property is largely unknown: the sizes of the systems are below the thermodynamic limit so that simple scaling laws do not apply. Theoretical

studies of such systems can provide relevant information, although in many cases idealized systems have to be treated. The challenge of such calculations is the combination of the relatively large size of the systems together with an often unknown structure.

In this presentation, different theoretical methods for circumventing these problems shall be discussed. They shall be illustrated through applications on various types of clusters. These include isolated metal clusters with one or two types of atoms, metal clusters deposited on a surface, nanostructured HAIO, semiconductor nanoparticles, and metallocarbohedrenes. Special emphasis is put on the construction of descriptors that can be used in identifying general trends.

Introduction

Nanostructures are materials whose spatial extension in 1, 2, or 3 dimensions is roughly of the order of at most some 100 nm. Thereby material properties different from those of the macroscopic materials we know from our daily life emerge. According to the simplest description of the properties of some given material, we may apply scaling laws so that, e.g., the electrical resistance scales with the inverse cross section and linearly with the length of the system. With such scaling laws, it is indirectly assumed that the materials form some homogeneous continua and, accordingly, that the fact can be ignored that on the atomic length scale the materials are not at all homogeneous. However, since typical interatomic bond lengths are of the order of some tenths of a nm, a proper description of the material properties of nanostructures often cannot be based on the above assumption that the materials are homogeneous. Thus, for nanomaterials, one can no longer apply the abovementioned scaling laws, i.e., the systems of interest have sizes far from the thermodynamic limit and one has left the scaling regime so that “every single atom counts.” Indeed, the fact that the material properties depend, in some cases even strongly, on the size of the system for nanostructures is the reason for the large interest in such systems. Here, both the prospects related to possible practical applications of these materials as well as the wish to understand in detail the size–property relations are motivations behind this interest.

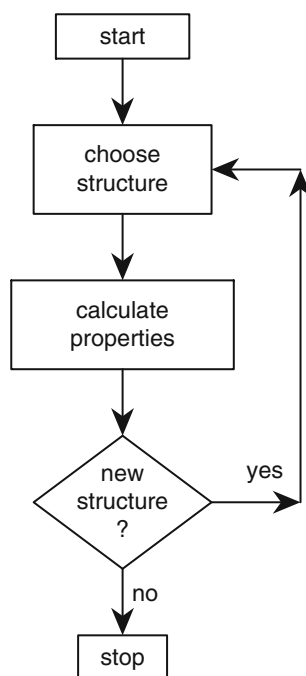

The present chapter is devoted to the results of our theoretical studies of clusters, i.e., nanostructures that are finite in all three spatial dimensions. Therefore, their number of surface atoms relative to their total number of atoms is large, and of the same reason, finite-size effects show up. In addition, they most often contain just one or, at most, some few types of atoms, with the possible existence of surfactants as an exception. The surfactants are radicals that are used in saturating dangling bonds at the surfaces and, thus, in stabilizing the materials. For theoretical studies, it is important to notice that these systems are fairly large, but not so large that they can be considered as being infinite and periodic and that, consequently, they may have a quite low symmetry so that in a theoretical calculation chemically identical atoms may have to be treated as being different since they have different surroundings.

In experimental studies, such clusters/colloids are often produced and studied in a solution or on the surface of some substrate. Moreover, as mentioned above, they are often stabilized through ligands. In total, this means that the systems often are interacting with other systems, this being the solvent, the substrate, or the ligands. This is contrasted by theoretical studies that often consider isolated nanoparticles in gas phase that, in addition, often are naked (i.e., without ligands). Another difference between experiment and theory is that the precise size of the experimentally studied systems often is only approximately known, whereas, per construction, theoretical studies consider well-defined systems, although for those one often assumes a certain structure that may or may not be realistic. Thus, experimental and theoretical studies are rarely competing but instead complementing each other.

When attempting to use electronic-structure methods in studying the properties of clusters, in particular the size dependence of those where one, accordingly, will consider a larger range of sizes, one very fast encounters some fundamental properties related to theoretical calculations. We shall here briefly outline those.

In a typical electronic-structure calculation, the number and types of the atoms for the system that shall be studied are known. Then (cf. Fig. 1), some initial structure is chosen and various properties for this structure are calculated. These properties are first of all the total energy but may also be others like the forces acting on the nuclei (i.e., the derivatives of the total energy with respect to the nuclear

Fig. 1 A flowchart for a typical electronic-structure calculation

coordinates). Also available experimental information may be sought calculated. Subsequently, one may ask whether a new structure shall be studied. The reasons for doing so could be that the calculated forces are not approximately vanishing, that the calculated properties differ significantly from those obtained in experiment, or that one simply wants to explore further parts of the structure space.

For larger systems, this approach is related with two serious problems. First, if the system of interest contains N nuclei and M electrons, the computational costs for calculating the properties for one single structure scale as the size of the system to some power, i.e., like M^k or N^k , where k is some power from 2 and upward. For some of the most popular approaches, like density-functional and Hartree–Fock methods (see, e.g., Springborg 2000), k is typically 3, but for more advanced methods, k may be larger than 7. Thus, in this case, it should be obvious that for just intermediately large systems, the calculation of the properties for just one single geometry may become computationally very costly.

Independently of the scaling of the computational needs as a function of the size of the system, another complementary problem causes additional complications. This problem is related to the fact that the number of nonequivalent minima on the total-energy surface as a function of structure grows very fast with the size of the system. In fact, it has been shown (Wille and Vennik 1985) that the number of local total-energy minima grows faster than any polynomial in N or, alternatively expressed, that the determination of the global total-energy minimum is a so-called NP-hard problem.

A model system that is so simple that detailed studies can be performed is that of a cluster of identical atoms for which it is assumed that the total energy can be written as a sum of pair potentials, each one being a simple Lennard–Jones potential. This system was studied by Tsai and Jordan (1993), who found a rapidly increasing number of nonequivalent metastable structures as a function of size. In Fig. 2 their

Fig. 2 A schematic representation of the number of nonequivalent local total-energy minima for Lennard–Jones clusters (the *black circles*) together with a fit with an exponential (the *full curve*)

results have been fitted with an exponential, $a \cdot \exp(bN)$, and it is seen that the fit follows the calculated results fairly close. The fit gave $a = 0.00341$ and $b = 0.983$, which in turn means that for $N = 55$ the fit predicts that of the order of 10^{21} nonequivalent minima exist.

This result points directly to a central issue of this presentation, i.e., how can we determine the structure for a system with at least some 10s of atoms and for which no, or only very limited, information on the structure can be used.

The ground-state *structure* is obtained by minimizing the total energy. Employing the Born–Oppenheimer approximation, the nuclei are treated as classical and not quantum particles, and there is no variational principle that can be used in systematically getting arbitrarily close to the true ground-state structure, even when assuming that the total energy can be calculated accurately for any structure. Instead, most often one has to change the structure “by hand” until one feels confident that the structure of the lowest total energy has been identified. But it shall be stressed that there is absolutely no approach that with absolute certainty can guarantee that precisely that structure has been found. Trying to prove so would require complete knowledge about the total-energy surface as a function of all internal degrees of freedom. This information is beyond whatever will be available, even if the computers keep on becoming more and more powerful and the programs more and more efficient.

That this information will never become available can be seen by, e.g., considering the largest possible computer, i.e., the complete universe. Lloyd (2002) estimated that the complete universe, viewed as an enormous quantum computer that has been operating since the Big Bang, could have performed of the order of 10^{120} binary operations. Although this number is very large, it is also finite. Therefore, it means that considering, e.g., a system of 42 atoms, assuming that a total-energy calculation for this system and a given structure is just one single binary operation, and considering just 10 different values for each internal structural degree of freedom, exactly 10^{120} calculations are needed for obtaining this, relatively crude, total-energy hypersurface. Thus, the calculations would have required the use of the complete universe since the Big Bang!

In total, it is obvious that for any but the absolutely smallest systems it is not possible to explore anything but very limited parts of the total-energy hypersurface and, moreover, that it is never possible to be absolutely sure that the true global total-energy minimum has been found. Any total-energy minimum may provide a total energy that is close to that of the global minimum, although the structures of the two may be markedly different, simply due to the very large number of local total-energy minima. It is also obvious that any attempt to identify the global total-energy minimum has to be based on some kind of qualified search in the multidimensional structure space.

It is one of the purposes of this presentation to discuss some of the approaches that we are using in searching for the global total-energy minimum in the structure space. Another purpose is to present various descriptors/tools that we have derived in order to extract chemical or physical information from the calculated properties.

We emphasize that we shall concentrate on the results of our own studies. For more general reviews the reader is referred to, e.g., Baletto and Ferrando (2005), Ferrando et al. (2008), and Springborg (2009).

Basics

In the most general case, our goal is to calculate the properties of a system containing N nuclei and M electrons. We shall denote the nuclear positions $\mathbf{R}_1, \mathbf{R}_2, \dots, \mathbf{R}_N$ and those of the electrons $\mathbf{r}_1, \mathbf{r}_2, \dots, \mathbf{r}_M$. Moreover, we use Hartree atomic units and set accordingly $m_e = |e| = 4\pi\epsilon_0 = \hbar \equiv 1$. The mass and charge of the k th nucleus is then M_k and Z_k , respectively. The combined coordinate \mathbf{x}_i denotes the position and spin coordinate of the i th electron. In the absence of external interactions and relativistic effects, the Hamilton operator for this system can then be written as a sum of five terms,

$$\hat{H} = \hat{H}_{kn} + \hat{H}_{ke} + \hat{H}_{nn} + \hat{H}_{ee} + \hat{H}_{en}, \quad (1)$$

with

$$\begin{aligned} \hat{H}_{kn} &= - \sum_{k=1}^N \frac{1}{2M_k} \nabla_{\mathbf{R}_k}^2 \\ \hat{H}_{ke} &= - \sum_{i=1}^M \frac{1}{2} \nabla_{\mathbf{r}_i}^2 \\ \hat{H}_{nn} &= \frac{1}{2} \sum_{k \neq l=1}^N \frac{Z_k Z_l}{|\mathbf{R}_k - \mathbf{R}_l|} \\ \hat{H}_{ee} &= \frac{1}{2} \sum_{i \neq j=1}^M \frac{1}{|\mathbf{r}_i - \mathbf{r}_j|} \\ \hat{H}_{en} &= - \sum_{k=1}^N \sum_{i=1}^M \frac{Z_k}{|\mathbf{R}_k - \mathbf{r}_i|}, \end{aligned} \quad (2)$$

i.e., the kinetic energy operator for the nuclei, that for the electrons, and the three potential energy operators for the nucleus–nucleus, the electron–electron, and the electron–nucleus interactions, respectively.

The time-independent Schrödinger equation becomes then

$$\hat{H}\Psi(\mathbf{x}_1, \mathbf{x}_2, \dots, \mathbf{x}_M, \mathbf{R}_1, \mathbf{R}_2, \dots, \mathbf{R}_N) = E \cdot \Psi(\mathbf{x}_1, \mathbf{x}_2, \dots, \mathbf{x}_M, \mathbf{R}_1, \mathbf{R}_2, \dots, \mathbf{R}_N). \quad (3)$$

As indicated above, we shall assume that the Born–Oppenheimer approximation is accurate. Then, \hat{H}_{kn} is ignored, and furthermore, the wave function Ψ that depends

functionally on both electronic and nuclear coordinates is written as a product of two functions,

$$\begin{aligned} \Psi(\mathbf{x}_1, \mathbf{x}_2, \dots, \mathbf{x}_M, \mathbf{R}_1, \mathbf{R}_2, \dots, \mathbf{R}_N) \\ = \Psi_n(\mathbf{R}_1, \mathbf{R}_2, \dots, \mathbf{R}_N) \cdot \Psi_e(\mathbf{R}_1, \mathbf{R}_2, \dots, \mathbf{R}_N; \mathbf{x}_1, \mathbf{x}_2, \dots, \mathbf{x}_M). \end{aligned} \quad (4)$$

Here, Ψ_n is the wave function for the nuclei (which for the present study is irrelevant) and Ψ_e is the electronic wave function. Ψ_e depends functionally on the electronic coordinates but also parametrically on the nuclear coordinates (implying that different structures have different electronic wave functions). Ψ_e is calculated from the electronic Schrödinger equation

$$\hat{H}_e \Psi_e = E_e \Psi_e \quad (5)$$

with

$$\hat{H}_e = \hat{H}_{ke} + \hat{H}_{ee} + \hat{H}_{en}. \quad (6)$$

Moreover, the total energy is

$$E = E_e + \hat{H}_{nn} = E(\mathbf{R}_1, \mathbf{R}_2, \dots, \mathbf{R}_N), \quad (7)$$

i.e., a function of the structure of the system.

Although the Born–Oppenheimer approximation does lead to some computational simplifications, solving the resulting equations is still computational demanding, so that when aiming at studying *many* structures for *larger* systems (as is the goal of the present work), it can easily become necessary to invoke additional approximations. Then, the type of approximation will depend on the system and scientific issue at hand, as we shall illustrate below.

Only Nuclei

Methods

Ultimately, the goal is to study the total energy, E , as a function of structure, i.e., $E(\mathbf{R}_1, \mathbf{R}_2, \dots, \mathbf{R}_N)$. The determination of the electronic orbitals, their energies, and the total electronic energy, E_e , provides thereby additional information that may be highly relevant for other purposes, but may also be considered as a complication that might be circumvented. The use of approximate expressions (i.e., force fields) of the form

$$\begin{aligned} E(\mathbf{R}_1, \mathbf{R}_2, \dots, \mathbf{R}_N) \simeq \sum_i E_{t(i)}^{(1)} + \sum_{ij} E_{t(i),t(j)}^{(2)}(\mathbf{R}_i, \mathbf{R}_j) \\ + \sum_{ijk} E_{t(i),t(j),t(k)}^{(3)}(\mathbf{R}_i, \mathbf{R}_j, \mathbf{R}_k) + \dots \end{aligned} \quad (8)$$

represents one possibility. Here, $t(i)$ is the atom type of the i th atom, and the total energy has been split into atomic parts as well as 2-, 3-, ... body interactions. The various functions $E^{(i)}$ are then represented in some approximate, analytical, or numerical form.

Such approximations are very useful for the study of the structural properties of a larger number of larger systems, but may, of course, suffer from inaccuracies due to the approximate nature of the total-energy expression. The Lennard–Jones clusters discussed above represents one such expression, where only 1- and 2-body terms are included. Some further examples are discussed in Springborg (2006).

When applying such approaches to clusters, it is important to choose the method according to the chemical bonding of the system of interest. In metallic systems, the electrons are considered as being delocalized and packing effects are often the main driving force for the structure. On the other hand, for many semiconductors and insulators, the bonds between the atoms are partly covalent and partly ionic, so that directional bonding and electron transfers are important, i.e., a precise description of the electronic degrees of freedom is important. Yet other types of systems include, e.g., molecular crystals with weak interactions between the molecules, but here we are concerned with the first two types of systems.

One approach that we have been using for clusters of metal atoms is based on the embedded-atom method (EAM) of Daw, Baskes, and Foiles (Daw and Baskes 1983, 1984; Daw et al. 1993; Foiles et al. 1986). According to this method, the total energy of the system is written as a sum over atomic energies,

$$E_{\text{tot}} = \sum_{i=1}^N E_i \quad (9)$$

with

$$E_i = F_i(\rho_i^h) + \frac{1}{2} \sum_{i \neq j=1}^N \phi_{ij}(|\mathbf{R}_i - \mathbf{R}_j|) \quad (10)$$

being the energy of the i th atom.

In Eq. (10) the first term is the so-called embedding energy, which is obtained by considering each atom as an impurity embedded into a host provided by the rest of the atoms. The second term describes electron–electron interactions and is represented in terms of short-range pair potentials. The local density at site i is assumed being a superposition of atomic electron densities,

$$\rho_i^h = \sum_{j (\neq i)} \rho_j^a(|\mathbf{R}_i - \mathbf{R}_j|) \quad (11)$$

where $\rho_j^a(r)$ is the spherically averaged atomic electron density provided by atom j at the distance r .

With the EAM, the total-energy expression of Eq. (8) contains also contributions from P -body interactions with P being the number of nearest neighbors of the atoms of the system of interest. Other potentials that also include many-body interactions are the Gupta, Murrell–Mottram, Sutton–Chen, and Cleri–Rosato potentials among others. Since we have used the Gupta, Sutton–Chen, and Cleri–Rosato potentials in some studies, we shall here discuss these briefly.

With the Gupta potential (Gupta 1981), the total energy is written in terms of repulsive and attractive many-body terms,

$$E_{\text{tot}} = \sum_{i=1}^N [V^r(i) - V^m(i)] \quad (12)$$

where

$$V^r(i) = \sum_{j=1(\neq i)}^N A(a, b) \exp \left[-p(a, b) \left(\frac{|\mathbf{R}_i - \mathbf{R}_j|}{r_0(a, b)} - 1 \right) \right] \quad (13)$$

and

$$V^m(i) = \left\{ \sum_{j=1(\neq i)}^N \zeta^2(a, b) \exp \left[-2q(a, b) \left(\frac{|\mathbf{R}_i - \mathbf{R}_j|}{r_0(a, b)} - 1 \right) \right] \right\}^{\frac{1}{2}}. \quad (14)$$

The summations run over all (N) atoms of the system of interest. Furthermore, A , r_0 , ζ , p , and q are fitted to experimental values of the cohesive energy, lattice parameters, and elastic constants for the crystal at 0 K.

The Sutton–Chen potentials are based on the empirical N -body potentials that have been developed by Finnis and Sinclair (1984) for the description of cohesion in metals. With these potentials, the total internal energy is represented by a cohesive functional of pair interactions and a predominantly repulsive pair potential. The main difference of such a potential to a pair potential is that using only pair potentials, the calculated force exerted by one atom on another depends on the interatomic distance only, whereas in the present case it depends on all neighbors of both atoms. Finnis–Sinclair potentials are of relatively short range and extend only to third neighbors in fcc crystals. The long-range modification constitutes the Sutton–Chen potential. This potential has an extra $\frac{1}{r^6}$ van der Waals tail and, accordingly, the following form

$$E = \epsilon \left[\frac{1}{2} \sum_i \sum_{j \neq i} V(|\mathbf{R}_i - \mathbf{R}_j|) - c \sum_i \sqrt{\rho_i} \right] \quad (15)$$

with

$$V(|\mathbf{R}_i - \mathbf{R}_j|) = \left(\frac{a}{|\mathbf{R}_i - \mathbf{R}_j|} \right)^n$$

$$\rho_i = \sum_{j \neq i} \left(\frac{a}{|\mathbf{R}_i - \mathbf{R}_j|} \right)^m. \quad (16)$$

With the empirical many-body potential given by Cleri and Rosato (1993), the cohesive energy of the system is written as

$$E_c = \sum_i (E_R^i + E_B^i), \quad (17)$$

where

$$E_R^i = \sum_j A e^{-p \left(\frac{|\mathbf{R}_i - \mathbf{R}_j|}{r_0} - 1 \right)}$$

$$E_B^i = - \left\{ \sum_j \xi^2 e^{-2q \left(\frac{|\mathbf{R}_i - \mathbf{R}_j|}{r_0} - 1 \right)} \right\}^{\frac{1}{2}}. \quad (18)$$

As for the Gupta potential, the values of the parameters that enter the Sutton–Chen and Cleri–Rosato potentials are determined from experimental information.

In a series of studies, we have studied the properties of various metal clusters for which the total energy was approximated using one of those methods just mentioned. These include Ni (Grigoryan and Springborg 2001, 2003, 2004; Grigoryan et al. 2006), Al (Joswig and Springborg 2003), Ti (Joswig and Springborg 2007), Cu (Grigoryan et al. 2006), Au (Grigoryan et al. 2006; Alamanova et al. 2006), Ag (Alamanova et al. 2007), Ni–Cu (Hristova et al. 2008b), and K–Cs and Rb–Cs (Hristova et al. 2008a, 2009a) clusters.

In all cases, the total-energy methods were combined with unbiased global optimization methods. For the studies we shall report below in this section, we used the Aufbau/Abbau method that was developed earlier by us (Grigoryan and Springborg 2003, 2004) and which consists of the following steps:

1. We assume that we have obtained the structures of the global total-energy minima for the clusters with up to N atoms.
2. In addition, we consider clusters with $N + K$ atoms with $K \simeq 5 - 10$. For each of those sizes (i.e., N and $N + K$), we randomly generate and relax a large set of structures, from which the one of the lowest total energy is selected.
3. This leaves us with two “source” clusters with N and $N + K$ atoms. For the cluster with N atoms, we add at a random position a single atom and the structure

is relaxed. This is repeated many hundred times. In parallel, we consider the $N + K$ structures of $N + K - 1$ atoms that can be obtained by removing one of the atoms from the cluster with $N + K$ atoms and relaxing the structure. The structure of the lowest total energy is kept.

4. The procedure of step (3) is repeated $K - 1$ times until we have obtained two sequences of cluster structures with $N, N + 1, \dots, N + K - 1$, and $N + K$ atoms. From these two sets, the structures of the lowest total energies are chosen.
5. The steps (3) and (4) are repeated with the new sets of structures, until no lower total energies are found. Then it is assumed that the global total-energy minima for this size range have been identified, and we proceed to the next set of sizes.

By keeping track of not only the single energetically lowest isomer but more of those, we also obtain information about the energetic distribution of different isomers of the same cluster sizes.

In some studies, we used instead the basin-hopping method (Li and Scheraga 1987; Wales and Doey 1997) to determine the structures of total-energy minima. This method is closely related to Monte Carlo methods, but considers a transformed total-energy surface. Thus, for each structure, $\mathbf{R} \equiv (\mathbf{R}_1, \mathbf{R}_2, \dots, \mathbf{R}_N)$, instead of considering the true total energy E at that structure, one considers the total energy \tilde{E} that the structure would have after having relaxed to its closest total-energy minimum,

$$\tilde{E}(\mathbf{R}) = \min\{E(\mathbf{R})\}, \quad (19)$$

where it is indicated that $\tilde{E}(\mathbf{R})$ is the lowest total energy that is obtained when starting from the structure \mathbf{R} but letting it locally relax. Ultimately, this leads to a transformed total-energy surface. The transformed energy surface \tilde{E} is much less structured than E , although the energies at the global and local total-energy minima are identical. The simpler shape of the transformed structure makes it significantly easier to identify the global total-energy minimum, without biasing the calculation in any way. In a practical calculation, instead of changing the structure according to the Monte Carlo steps directly, the structure is first locally relaxed using standard methods.

Ni Clusters

As a first example of isolated monatomic metal clusters, we shall in this subsection discuss some of our results for isolated Ni_N clusters (Grigoryan and Springborg 2001, 2003, 2004; Grigoryan et al. 2006).

The calculations outlined in the previous subsection give essentially nothing but a listing of the total energies and the nuclear coordinates for a set of clusters. Thus, in our study on the Ni_N clusters, we considered the four energetically lowest isomers up to $N = 150$ and obtained, accordingly, roughly 45,000 numbers. A large

Fig. 3 The binding energy per atom for the energetically two lowest isomers (*upper part*), the stability function (*middle part*), and the total-energy difference for the two energetically lowest isomers (*lowest part*) for Ni_N clusters as functions of N . All energies are given in eV

challenge is, consequently, to extract physical and chemical information from this information.

In Fig. 3 we show in the upper panel the binding energy per atom. A careful inspection of the figure reveals that there are two curves very close in energy, since the results are given for the two energetically lowest isomers. Nevertheless, the curves are rather structureless which is a result of the fact that any cluster Ni_N cluster is stabler than any two noninteracting subparts Ni_{N-K} and Ni_K for all $K > 0$.

More information can be obtained from the so-called stability function

$$\Delta_2 E(N) = E_{\text{tot}}(N-1, 1) + E_{\text{tot}}(N+1, 1) - 2E_{\text{tot}}(N, 1) \quad (20)$$

with $E_{\text{tot}}(N, j)$ being the total energy for the energetically j th lowest isomer of the Ni_N cluster. $\Delta_2 E(N)$ possesses peaks for clusters that are particularly stable compared to those with one atom more or less. As seen in the middle panel in Fig. 3,

Fig. 4 The structures of the Ni_N clusters with (top, left) $N = 13$, (top, right) 19, (bottom, left) 55, and (bottom, right) 78

this is the case for clusters with $N = 13, 19, 23, 55$, and 147. These, so-called magic numbers, correspond to clusters with a particularly high-symmetric structure as can be seen from a more careful inspection of the structures. As examples we show in Fig. 4 the structures of the Ni_N clusters with $N = 13, 19, 55$, and 78.

Alternatively, one may compare the total energies for the energetically two lowest isomers of the same cluster size, i.e., $E_{\text{tot}}(N, 2) - E_{\text{tot}}(N, 1)$. This has peaks for clusters that are particularly stable compared to the next isomer of the same cluster size. As seen in Fig. 3, many of the magic-numbered clusters are also particularly stable according to this second criterion. This suggests that the characterization of certain clusters to be particularly stable is very robust.

In order to obtain information about the overall shape of the clusters, we consider the 3×3 matrix containing the elements

$$I_{st} = \frac{1}{u_l^2} \sum_{n=1}^N (R_{n,s} - R_{0,s})(R_{n,t} - R_{0,t}) \quad (21)$$

with $u_l = 1 \text{ \AA}$ being a length unit; s and t being x, y , or z , and

$$\mathbf{R}_0 = \frac{1}{N} \sum_{n=1}^N \mathbf{R}_n \quad (22)$$

being the center of the cluster; and R_n being the position of the n th atom. The three eigenvalues of this matrix, $I_{\alpha\alpha}$, can be used in separating the clusters into

Fig. 5 The normalized eigenvalues of the matrix containing the elements of Eq. (21) as functions of N . The three *solid curves* give the eigenvalues and the *dashed curve* their average. In the *upper part* of the figure, a simple estimate of the overall shape of the clusters is given: either being spherical (marked with points in the lowest row), cigar shaped (points in the middle row), or lens shaped (points in the uppermost row)

being overall spherical (all eigenvalues are identical), more cigar-like shaped (one eigenvalue is large, the other two are small), or more lens shaped (two large and one small eigenvalue). Moreover, the average of the three eigenvalues, $\langle I_{\alpha\alpha} \rangle$, is a measure of the overall extension of the cluster. Finally, the sum of any two of those three eigenvalues gives a moment of inertia that is relevant for rotational properties of the clusters.

For a homogeneous, spherical cluster with N atoms, the eigenvalues are proportional to $N^{5/3}$. Therefore, in Fig. 5 we scale the eigenvalues by $N^{-5/3}$. This figure shows that the overall shape changes many times for clusters with N up to somewhat above 50. After that, the shape is more constant, with some few exceptions that in some cases are due to the fact that the three eigenvalues all are very close so that only small atomic displacements would change the shape classification.

In order to obtain further information on the structure of the clusters, we introduce the concept of radial distances. For each atom, its radial distance is defined as

$$r_n = |\mathbf{R}_n - \mathbf{R}_0|. \quad (23)$$

By plotting various properties as functions of the radial distances, we can obtain further insight into the cluster properties. At first we show the radial distances themselves; cf. Fig. 6. This figure shows that the overall size of the cluster (using the largest radial distance as a measure) in general increases with size of the cluster, although not monotonically. Moreover, for certain size ranges, like slightly above 50 and 140 atoms, the radial distances tend to form different groups. This implies that those clusters have an onion-like structure with different, essentially concentric, shells of atoms. For other sizes, the clusters tend to have a much more irregular structure.

Fig. 6 The radial distances (in Å) as a function of cluster size, i.e., each small line represents (at least) one atom with that radial distance

Riley and coworkers (Parks et al. 1997, 1998, 2001) have presented experimental results of so-called chemical probe experiments on Ni_N clusters. By measuring the mass of the clusters before and after exposure to (in this case) an N_2 atmosphere, the number of N_2 molecules that are adsorbed on the surface of the cluster can be determined, which in turn gives information on the surface of the cluster. Thereby, Riley et al. make use of some simple empirical rules for the adsorption: Nickel atoms with a coordination of 4 or less will bind two molecules; for a coordination between 5 and 8, they will bind one molecule; for a coordination of 9, there may be one molecule bonded; and for larger coordination, there will be no molecule bonded. Using the same rules, we calculated the number of N_2 molecules that could be adsorbed on the structures we have determined for the four energetically lowest isomers and show the results, in comparison with experiment, in Fig. 7. It is here remarkable that there is a very good agreement between theory and experiment and, moreover, that the overall shape of the size dependence of this number appears to change slope for clusters with some 60–70 atoms. Unfortunately, the experimental studies do not allow for analyzing this prediction.

For the study of growth processes as well as for analyzing the size for which the clusters obtain structures that resemble small parts of the macroscopic crystalline material, we have found the concept of similarity functions useful. In order to compare two structures consisting of N_1 and N_2 atoms, we shall, for each, calculate either the interatomic distances or the radial distances, subsequently sort these, and, finally, define a so-called similarity function through

$$S = \left\{ 1 + \left[\frac{1}{M} \sum_{i=1}^M (d_i - d'_i)^2 \right]^{1/2} / u_l \right\}^{-1}. \quad (24)$$

Fig. 7 The (*open circles*) experimentally determined number of N_2 binding sites for Ni_N clusters as function of N in comparison with theoretical calculated numbers (*closed circles*)

Here, $u_l = 1 \text{ \AA}$. Moreover $\{d_i\}$ and $\{d'_i\}$ are the sorted radial or interatomic distances for the two structures, and M is their total number [being either N or $N(N - 1)/2$ with N the smallest of N_1 and N_2]. The two structures are very similar (different) if S approaches 1 (0). We add that our experience has shown that qualitatively the same results are obtained independently of whether the radial or the interatomic distances are used. Another result of our experience is that S below roughly 0.7–0.8 usually indicates that the structures are quite different.

At first, we shall use the similarity functions in studying whether the structure with N atoms can be considered similar to the one with $N - 1$ atoms plus an extra atom. To this end, we consider each of the N structures that can be obtained by removing one of the atoms from the N atom cluster and keeping the positions of the remaining $N - 1$ atoms. Then, we compare this $N - 1$ atom fragment with the cluster with $N - 1$ atoms, using the similarity function. Ultimately, the largest of these N values for S is used. Figure 8a shows the results when comparing the energetically lowest isomers of the two clusters with $N - 1$ and N atoms. Also for this property we see many dips in the function for cluster sizes up to around 50 atoms after which S gets much more regular. This effect becomes even more pronounced when comparing the Ni_N cluster of the lowest energy with the four energetically lowest isomers with $N - 1$ atoms. Then [cf. Fig. 8b], S approaches 1 for almost all $N > 50$, suggesting that more different isomers are active in the growth processes: the most stable Ni_N cluster has a structure that may be derived from that of an energetically higher structure of the Ni_{N-1} cluster.

Finally, we show in Fig. 8 also the similarity function that is obtained when comparing the cluster structures with fragments of the crystal or with an icosahedron. In this case, the similarity function is based on the radial distances, and for the crystal we have considered three different spherical fragments with different definitions of the center. It is immediately seen that for some ranges of N (e.g., N around 75), the structures resemble fragments of the fcc crystal, but also that for even larger sizes

Fig. 8 The similarity functions for comparing the structure of the Ni_N cluster with (a) the energetically lowest cluster with $N - 1$ atoms, (b) the four energetically lowest clusters with $N - 1$ atoms, (c) a fragment of the fcc crystal, and (d) an icosahedron. For details, see the text

(around 145 atoms) as well as for $N \simeq 55$, there is considerably larger structural similarity with an icosahedron. Thus, even clusters with around 150 atoms are too small to approach the macroscopic crystalline limit.

Thermodynamic Properties

From the optimized structures as discussed in the preceding subsection, we may proceed to calculate thermodynamic properties as a function of temperature for at least not too elevated temperatures. Using a harmonic approximation, we expand the total energy as a function of nuclear coordinates up to second order,

$$\begin{aligned}
 E(\mathbf{R}_1, \mathbf{R}_2, \dots, \mathbf{R}_N) &\simeq E(\mathbf{R}_1^e, \mathbf{R}_2^e, \dots, \mathbf{R}_N^e) \\
 &+ \frac{1}{2} \sum_{k_1, k_2=1}^N \sum_{\alpha_1, \alpha_2=x, y, z} \frac{\partial^2 E}{\partial R_{k_1, \alpha_1} \partial R_{k_2, \alpha_2}} (R_{k_1, \alpha_1} - R_{k_1, \alpha_1}^e) (R_{k_2, \alpha_2} - R_{k_2, \alpha_2}^e),
 \end{aligned}
 \tag{25}$$

where the upper indices e mark the values at the total-energy minimum. This approximation can subsequently be used in calculating the N_v vibrational frequencies of the cluster of interest, whereby $N_v = 3N - 6$ except for linear systems where $i N_v = 3N - 5$. Subsequently, we can calculate the vibrational contributions to the thermodynamic properties, i.e.,

$$\begin{aligned}
 Z &= \sum_n e^{-E_n/k_B T} = e^{-E_0/k_B T} \prod_{i=1}^{N_v} [2 \sinh(\alpha_i/2)]^{-1} \\
 F &= -k_B T \ln Z = E_0 + k_B T \sum_{i=1}^{N_v} [\alpha_i/2 + \ln(1 - e^{-\alpha_i})] \\
 S &= -\partial F/\partial T = k_B \sum_{i=1}^{N_v} [\alpha_i/(e^{\alpha_i} - 1) - \ln(1 - e^{-\alpha_i})] \\
 E &= F + TS = (E_0 + \sum_{i=1}^{N_v} \hbar\omega_i/2) + \sum_{i=1}^{N_v} \hbar\omega_i/(e^{\alpha_i} - 1) \\
 C &= \partial E/\partial(k_B T) = \sum_{i=1}^{N_v} [\alpha_i^2 e^{\alpha_i}/(e^{\alpha_i} - 1)^2]. \tag{26}
 \end{aligned}$$

In these equations, Z , F , S , E , and C are the vibrational partition function, Helmholtz free enthalpy, entropy, internal energy, and heat capacity, respectively. Moreover, k_B is the Boltzmann constant and E_0 is the optimized total energy of the cluster at $T = 0$. Different $E_n = E_0 + \sum_{i=1}^{N_v} \hbar\omega_i(n_i + 1/2)$ with $n = \{n_1, n_2, \dots, n_{N_v}\}$ are the different vibrational energy levels of the cluster. Moreover, $\alpha_i = \hbar\omega_i/k_B T$. The formulas above include the zero-point contributions. Finally, the heat capacity is given in units of k_B . At sufficiently elevated temperatures, $k_B T \gg \hbar\omega_i$, C approaches the classical value of N_v , whereas for very low temperatures, $k_B T \ll \hbar\omega_i$, C approaches $(\hbar\omega_1/k_B T)^2 \exp(-\hbar\omega_1/k_B T)$ which differs markedly from the bulk T^3 (Debye) temperature dependence. Thus, with decreasing temperature, the vibrational heat capacity in clusters approaches zero faster than in bulk.

We used this approach for pure nickel and pure copper clusters (Grigoryan and Springborg 2010). From the obtained vibrational frequencies, we observed an interest aspect: for almost all cluster sizes, the highest vibrational frequency was higher than that of the corresponding crystalline system with the most important exception being for clusters for which the structure resembles a fragment of the crystal.

Figure 9 shows the resulting average heat capacity per vibrational mode, $C_{VM} = C/N_v$ for different temperatures. For the lowest temperatures, we see a very strong dependence on cluster size. Thus, Ni clusters with, for instance, 33, 37, and, less pronounced, 83 and 86 atoms and Cu clusters with $N = 16, 30, 44, 74, 95$, and 111 (clusters with either low-symmetrical structures with incomplete geometrical shells

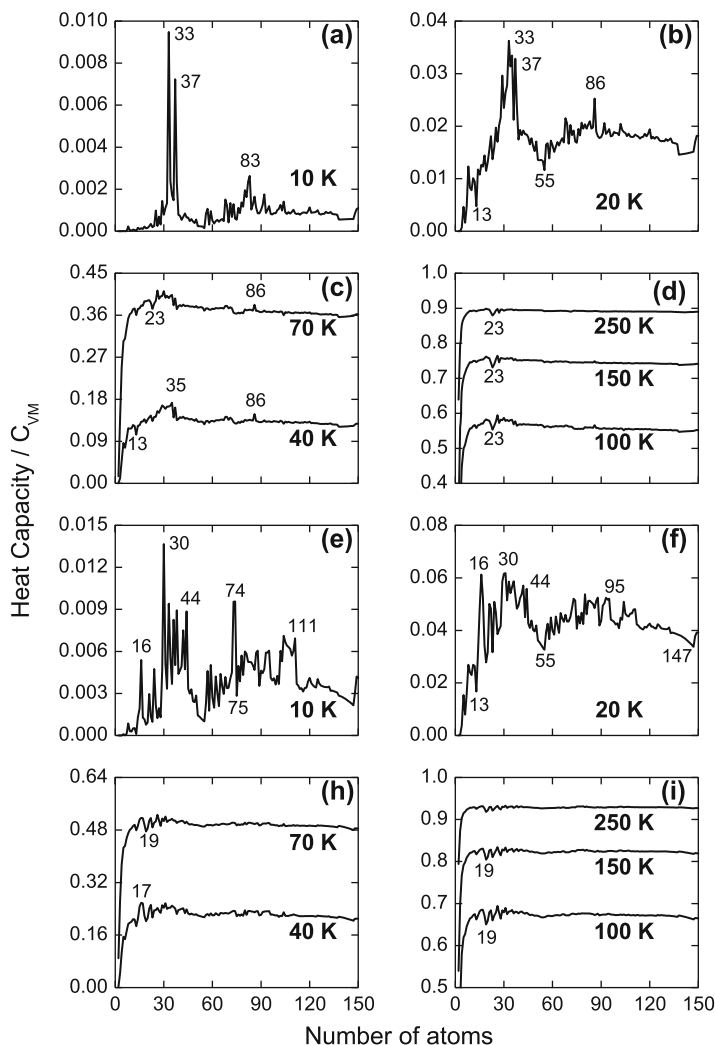

Fig. 9 Heat capacity of Ni [(a)–(d)] and Cu [(e)–(f)] clusters as a function of cluster size for different temperatures: (a) and (e) $T = 10$ K, (b) and (f) $T = 20$ K, (c) $T = 40$ and 70 K, and (d, i) $T = 100, 150,$ and 250 K

or decahedral/fcc structures) have large values for the vibrational heat capacities, whereas the particularly stable, i.e., magic-numbered, icosahedral clusters with $N = 13, 23, 55,$ and 147 show the most pronounced minima at low temperatures. As Fig. 9 suggests, the size dependence of C_{VM} becomes less pronounced with increasing temperature with clusters with less than roughly 30 atoms forming an exception. On the average, the heat capacities for copper clusters show stronger oscillations and larger values than those for Ni clusters.

Since we in the structure optimization calculations determined not only the energetically lowest structure but also the second and third lowest ones, we can use the vibrational spectra of those to study, for instance, a solid–solid transition temperature within a two-minima model. Two minima, “1” and “2,” with $E_0^{(1)} < E_0^{(2)}$ can represent two competing structural types as a decahedron and an icosahedron or a truncated octahedron and an icosahedron. According to the superposition approximation (Wales 2003), at the transition temperature, $T_{ss}(1 \leftrightarrow 2)$, the two probabilities P_1 and P_2 to find cluster structures “1” and “2” are identical. The corresponding equation for the transition temperature of the structural change from “1” to “2” is given by $P_1[T_{ss}(1 \leftrightarrow 2)] = P_2[T_{ss}(1 \leftrightarrow 2)]$ or $n_1 Z_1[T_{ss}(1 \leftrightarrow 2)] = n_2 Z_2[T_{ss}(1 \leftrightarrow 2)]$. Here, n_j is a degeneracy factor that takes into account the identical contributions from all the $2N!/o_j$ permutation–inversion isomers of structure j with o_j being the order of the point group, which is, for example, 114 for an icosahedron (I_h), 48 for a fcc structure (O_h), and 20 for a decahedron (D_{5h}).

Using this expression and the lowest-energy structures of Ni and Cu clusters together with their vibrational spectra, we have studied the structural changes from fcc to icosahedral structure in 38-atomic Ni and Cu clusters as well as from decahedral (Ni_{79}) to fcc (Ni_{79}) and from fcc (Cu_{79}) to decahedral (Cu_{79}) structures. As transition temperatures, we found 482 K for Ni_{38} , 587 K for Cu_{38} , and 87 K for Cu_{79} . Furthermore, we found that, despite the small total-energy difference of 0.04 eV between the two lowest isomers of Ni_{79} , the structural transition between them will not take place up to temperatures of at least 800 K.

Bimetallic Clusters

For binary clusters (i.e., clusters with two types of atoms), the additional existence of so-called homotops (Lloyd et al. 2004; Jellinek and Krissinel 1996) increases the computational demands enormously. Homotops for, e.g., $A_p B_q$ clusters, are defined as clusters with the same size, composition, and geometric arrangement but differing in the way in which A- and B-type atoms are arranged. Their number for the $A_p B_q$ cluster equals $\frac{(p+q)!}{p!q!}$.

As a first example, we shall here discuss the results of our study on bimetallic $\text{Ni}_n \text{Cu}_m$ clusters (Hristova et al. 2008a). In this case we used the basin-hopping method for optimizing the structure in combination with the EAM for the calculation of the total energy of a given structure. The EAM (as many other methods that do not include electronic/orbital degrees of freedom explicitly) has a preference for closed-packed structures so that in many cases the EAM method predicts very similar structures for pure clusters with just one element. Therefore, often only one or two types of structures were found for different $\text{Ni}_n \text{Cu}_m$ clusters with the same total number of atoms, $N = n + m$. The less obvious issue is accordingly how the two types of atoms are distributed within the cluster and if more than one overall structure exists, which structure is found for which stoichiometry.

For the $\text{Ni}_n \text{Cu}_m$ clusters, we found only three different types of scenarios. Either all clusters for a given $N = n + m$ have the same structure, which is the case

Fig. 10 The structures of Ni_nCu_m clusters for a fixed value of $N = n + m = 23$ and different values of (n, m) . The dark atoms mark the Ni atoms

for $N = 13$ and 23 , for instance. Figure 10 shows the results for $N = 23$. For $N = 38$, on the other hand, the two pure clusters have the same structure, whereas for $n = 5 - 25$, another structure is found as shown in Fig. 11. Finally, for $N = 15$ the two pure clusters have different structures, and the transition from the structure of the pure Cu cluster to that of the pure Ni cluster takes place for just 2 Ni atoms (cf. Fig. 12). In all cases, the Ni atoms tend to occupy inner positions, whereas the Cu atoms more often are found on the surface. This difference can be understood when comparing the cohesive energy of the two metals: the larger value for Ni suggests that this type of atom has a stronger preference for high coordination than Cu has.

In a very exhaustive study (Molayem et al. 2011a, b), we considered all Ni_mAg_n and Cu_mAg_n nanoalloys with $n + m$ up to 60. We shall here briefly discuss some few of the key results.

For the monometallic clusters like the Ni_n clusters of the preceding subsections, we identified particularly stable clusters (i.e., magic clusters) by comparing the total energy of the Ni_n cluster with those of the Ni_{n-1} and Ni_{n+1} clusters. For the nanoalloys, it is less obvious how a similar definition can be used in identifying particularly stable stoichiometries. Thus, we may, e.g., compare the total energy of the Ni_mAg_n system with those of the $\text{Ni}_{m-1}\text{Ag}_n$ and $\text{Ni}_{m+1}\text{Ag}_n$ systems, or with those of the $\text{Ni}_m\text{Ag}_{n-1}$ and $\text{Ni}_m\text{Ag}_{n+1}$ systems, or with those of the $\text{Ni}_{m-1}\text{Ag}_{n+1}$ and $\text{Ni}_{m+1}\text{Ag}_{n-1}$ systems, or with those of the $\text{Ni}_{m-1}\text{Ag}_{n-1}$ and $\text{Ni}_{m+1}\text{Ag}_{n+1}$ systems to mention just some possibilities.

The results for different definitions of the stability function related to the discussion above demonstrated, both for Ni_mAg_n and for Cu_mAg_n clusters, that with very few exceptions the different definitions would identify different clusters as

Fig. 11 The structures of Ni_nCu_m clusters for a fixed value of $N = n + m = 38$ and different values of (n, m) . The dark atoms mark the Ni atoms

Fig. 12 The structures of Ni_nCu_m clusters for a fixed value of $N = n + m = 15$ and different values of (n, m) . The dark atoms mark the Ni atoms

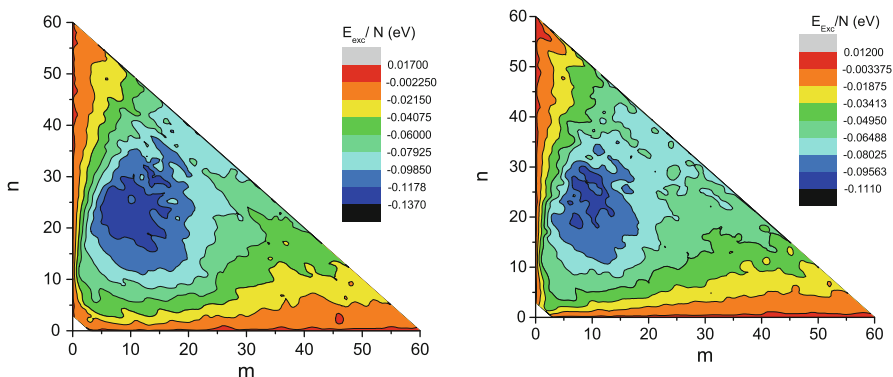

Fig. 13 The excess energy per atom for (left part) Ni_mAg_n and (right part) Cu_mAg_n clusters as a function of (m, n) for $N = m + n$ from 2 to 60

being particularly stable. Alternatively, we may consider an excess energy defined through

$$E_{\text{exc}} = E(m, n) - m \frac{E(m+n, 0)}{m+n} - n \frac{E(0, m+n)}{m+n} \quad (27)$$

Here, $E(m, n)$ is the energy for the Ni_mAg_n or Cu_mAg_n clusters. However, also this definition suffered from being biased: if the pure clusters with $m + n$ atoms are particularly stable (unstable), the excess energy would be particularly high (low). Thus, we have to conclude that it is hardly possible to identify uniquely particularly stable stoichiometries.

In Fig. 13 we show E_{exc}/N with $N = m + n$ for the two types of clusters of this study. As can be seen in the figure, E_{exc}/N is negative for almost all sizes and stoichiometries, which indicates that mixing is favorable. It is moreover interesting to notice that there is a certain size range, i.e., $m \simeq 10$ and $n \simeq 22$ for the Ni_mAg_n clusters and m between $m \simeq 6$ – 15 and n between $n \simeq 17$ – 30 for the Cu_mAg_n clusters, for which E_{exc}/N is particularly negative, suggesting that these clusters are the most stable ones. Another possible explanation, i.e., that the corresponding pure Ag, Cu, and Ni clusters are particularly unstable, does not hold here. A comparison between the two systems in Fig. 13 demonstrates that the energetic properties of the Ni_mAg_n or Cu_mAg_n clusters differ somewhat. This is much less the case for the structural properties, and therefore, we shall discuss the latter for only the Ni_mAg_n clusters.

The fact that mixing in general is preferred can be studied further via structural information. Thus, mixing vs. segregation of the nanoalloys can be studied through the bond order parameter σ (Pittaway et al. 2009). For an A_mB_n nanoalloy, it is defined as

$$\sigma = \frac{N_{A-A} + N_{B-B} - N_{A-B}}{N_{A-A} + N_{B-B} + N_{A-B}} \quad (28)$$

Fig. 14 Bond order parameter as a function of composition (number of Ni atoms, m) for the global minima of four sizes of interest ($N = 34, 38, 55,$ and 60). The inserts show the number of the three possible types of bonds versus m . *Solid triangles* and *squares* refer to the numbers of Ni–Ni and Ag–Ag bonds, respectively, whereas *open circles* are for Ni–Ag bonds

with N_{i-j} ($i, j = A, B$) being the number of nearest-neighbor bonds between atoms of type i and j . σ is positive for segregated, almost zero for disorderly mixed, and negative for mixed and onion-like phases of nanoalloys.

Figure 14 shows the bond order parameter versus number of Ni atoms for all the compositions of four selected sizes, $N = 34, 38, 55,$ and 60 . In addition, in each case, we also show the corresponding number of Ni–Ni, Ag–Ag, and Ni–Ag bonds. Having only positive values of σ implies some degree of segregation, and as we shall argue below, this segregation is mainly due to the formation of core–shell-like structures. For the clusters with comparable numbers of Ni and Ag atoms, there is a relatively large number of Ni–Ag bonds so that σ obtains lower values. Thus, the lowest value of σ for $N = 34$ is found for the (16, 18) and (17, 17) clusters. On the other hand, for $N = 38, 55,$ and 60 , the lowest values of the bond order parameter are found for more asymmetric clusters, i.e., $(m, n) = (16, 22), (23, 32),$ and $(34, 26)$, respectively.

A possible spatial separation of the Ni and Ag atoms can be (partly) identified through the radial distances of Eq. (23) when considering these individually for the two types of atoms. We show in Fig. 15 the ratio of average radial distances of Ni and

Fig. 15 The ratio of the average radial distances of the Ni atoms to that of the Ag atoms in $Ni_m Ag_n$ clusters as a function of (m, n) for $N = m + n$ from 2 to 60

Ag atoms for all of the considered clusters. A segregation of the Ag atoms toward sites with larger distances from the center of the clusters is clearly recognized as the ratio of distances is mostly less than 1 and is only for Ni-rich clusters close to 1. This suggests a partial formation of core-shell structures, although the segregation is not complete.

Clusters on Surfaces

As mentioned in the introduction, section “Introduction,” experimental studies of clusters often consider clusters on some surface. Both clusters that have been deposited on the surfaces and clusters that are grown directly on the surfaces have been studied. Since theoretical studies often consider clusters in the gas phase, a highly relevant question is whether the latter have anything to do with clusters on a surface. In some few studies, we have addressed this issue.

Using molecular-dynamics simulations and the EAM, we studied the deposition of the particularly stable Ni_{13} and Cu_{13} clusters (cf. section “Ni Clusters”) on the (111) surfaces of crystalline Ni and Cu (Kasabova et al. 2007) as well as more different Cu clusters deposited on the Cu(111) surface (Alamanova et al. 2008). The deposition energies, 0–1 eV/atom, imply according to experimental classifications that the depositions are to be considered as being soft. Nevertheless, the depositions

Fig. 16 Top view of the final structures obtained when depositing A_{13} clusters on the B(111) surface with 0 eV/atom deposition energy. A and B are (top, left) Ni and Cu, (top, right) Cu and Ni, (bottom, left) Cu and Cu, and (bottom, right) Ni and Ni. The dark atoms are those of the clusters. The deposition energy equals in all cases 0 eV/atom

even at the smallest possible deposition energies (cf. Fig. 16) led to clusters that were highly deformed compared to the gas-phase structures. To some extent, Ni clusters deposited on the Cu surface were partly intact, which may be understood through the higher cohesive energy and bulk modulus of Ni compared with Cu. Thus, in this respect, Ni and Cu can be classified as being hard and soft, respectively.

Alternatively, one may suggest that when clusters and surfaces are made of the same metal, the cluster atoms will lead to an epitaxial growth of the substrate. To quantify this suggestion, we introduced a so-called index of epitaxy (Alamanova et al. 2008), I , through

$$q = \sum_i^N |\mathbf{R}_i - \mathbf{R}_c|^2$$

$$I = \frac{1}{1 + q/u_i^2}, \quad (29)$$

where $|\mathbf{R}_i - \mathbf{R}_c|$ is the distance between the positions of the i th atom and the closest-lying fictitious atom in the infinite, periodic crystal that is obtained by continuing

the structure of the substrate periodically. $I = 1$ if perfect epitaxy is obtained. Our calculations indicated, however, very little epitaxy.

In another study, we consider the structures that result when a cluster is grown directly on the substrate (Hristova et al. 2009b). We considered Ag_N clusters grown on Ag(111) and Ni(111) surfaces. Since the (111) surfaces are closed packed and since the EAM (as mentioned above) has a strong (and, for the present systems, realistic) preference for structures with high-coordinated atoms, the growth of Ag clusters on the Ag(111) surface led to planar structures that moreover were roughly spherical. Thereby, the highest coordination for the cluster atoms could be obtained, and since substrate and cluster are of the same material, there is no strain involved.

This is different for Ag clusters on the Ni(111) surface. In this case, the lattice mismatch between Ag and Ni leads to some strain in the clusters grown epitaxially on the surface, and accordingly, the Ag clusters tend to get a somewhat elongated structure.

Only Electrons

The approaches we have discussed in the preceding section were based on the rationale that for metal clusters, there is no directional bonding, and instead, the electrons are delocalized over the complete system. Thereby, particularly stable clusters (i.e., magic numbers) occur for clusters for which the atoms can form a particularly compact, closed-packed geometrical structure. The electronic effects were at most indirectly included so that, e.g., stability due to electronic shell effects is not taken into account.

This is, on the other hand, the main effect that is included in the jellium model. Within the jellium model, it is assumed that the system of interest forms a compact, closed-packed structure and that the valence electrons are delocalized over the complete system. Due to the delocalization of the electrons, they do hardly feel the precise arrangement of the nuclei and core electrons so that the effects of those can be approximated as being those of a homogeneous charge density with the same average density as for the true system. The valence electrons move then in the electrostatic potential created by this jellium.

The jellium model has been used intensively for the studies of clusters of metals; see, e.g., de Heer (1993) and Brack (1993). In fact, one of the first papers in more recent times that treated the special properties of clusters was a combined experimental and theoretical study on Na_N clusters (Knight et al. 1984). Sodium can be considered the prototype of metal clusters for which the unidirectional bonding due to the $3s$ valence electrons suggests that the arguments above provide a good starting point for rationalizing the properties of Na clusters. Thus, packing effects that can be modeled accurately with a simple potential that does not include electronic orbitals will be responsible for the (essentially spherical) structures, and the particularly stable structures can be identified with a jellium model for delocalized electrons. In their study, Knight et al. assumed that the jellium was spherical and calculated, subsequently, the orbitals for the electrons moving in

this jellium and under the influence of each other. Comparing with experimental mass abundance spectra, they could explain the experimental observation of certain cluster sizes that showed up particularly often as related to these clusters' high stability. The latter was, in turn, due to the closing of shells of electronic orbitals, equivalent to what explains the inertness of the inert gases He, Ne, etc. in the periodic table.

In some more recent studies, we have used the spherical jellium model to analyze the properties of Cs_N clusters (Springborg 1999) and of a C_{60} molecule coated with alkali metals (Springborg et al. 1996). We shall here, however, not discuss these studies further but below address the accuracy of this jellium model.

Both Nuclei and Electrons

Methods

When including both electrons and nuclei in the calculations, the calculations may become so demanding that the number of structures and/or the size of the systems has to be limited. It is then often very useful to augment calculations based on less accurate methods with more accurate ones on selected structures in order to access the accuracy of the approximate methods. In some case we have done so, too, using density-functional methods (see, e.g., Springborg 2000 for a description of such methods).

As a compromise between accuracy and computational demands, we have often used the so-called DFTB (density-functional tight-binding) method of Seifert and coworkers (Seifert and Schmidt 1992; Porezag et al. 1995; Seifert et al. 1996). The DFTB method is based on the density-functional theory (DFT) of Hohenberg and Kohn (1964) in the formulation of Kohn and Sham (1965). For more details, we refer the reader to the original works or to Springborg (2000). Within the DFTB approach, the total energy relative to the noninteracting atoms is given as

$$E_{\text{tot}} \simeq \sum_i^{\text{occ}} \epsilon_i - \sum_j \sum_m \epsilon_{jm} + \frac{1}{2} \sum_{j \neq k} U_{jk}(|\mathbf{R}_j - \mathbf{R}_k|), \quad (30)$$

where ϵ_i is the energy of the i th orbital for the system of interest and ϵ_{jm} is the energy of the j th orbital for the isolated m th atom. Moreover, U_{jk} is a short-range pair potential between atoms j and k that is adjusted so that results from parameter-free density-functional calculations on two-atomic systems as a function of the interatomic distance are accurately reproduced. Finally, only the valence electrons are explicitly included in the calculations, whereas the other orbitals are treated within a frozen-core approximation.

The elements of the Hamilton and overlap matrices, i.e., $\langle \chi_{m_1 n_1} | \hat{H} | \chi_{m_2 n_2} \rangle$ and $\langle \chi_{m_1 n_1} | \chi_{m_2 n_2} \rangle$ with χ_{mn} being the n th atomic orbital of the m th atom, are obtained

from calculations on diatomic molecules. The Hamilton operator contains the kinetic energy operator as well as the potential. The latter is approximated as a superposition of the potentials of the isolated atoms,

$$V(\mathbf{r}) = \sum_m V_m(|\mathbf{r} - \mathbf{R}_m|), \quad (31)$$

and we assume that the matrix element $\langle \chi_{m_1 n_1} | V_m | \chi_{m_2 n_2} \rangle$ vanishes unless at least one of the atoms m_1 and m_2 equals m .

Thus, within this approach, all information that enters the calculations are extracted from the properties of diatomic molecules. These can, in turn, be determined from accurate, density-functional calculations. In order to access the accuracy of the approach, we perform additional calculations on the infinite, periodic systems. If these provide accurate results, we assume that also for the intermediate, finite clusters, the results are accurate.

For an unbiased structure determination, we combine the DFTB method with genetic algorithms. The genetic algorithms are based on the principles of natural evolution and are, therefore, also called evolutionary algorithms (Holland 1975; Goldberg 1989) and have been found to provide an efficient tool for global geometry optimizations. One version of the genetic algorithms that we are using is as follows.

A population of P initial structures is chosen randomly (these clusters are called parents), and each structure is relaxed to its nearest total-energy minimum. By cutting each parent randomly into two parts, a next set of P structures is obtained by interchanging (“mating”) these two parts and allowing the resulting “children” to relax, too. Comparing the energies of the $2P$ clusters of both sets, those P with the lowest total energies are chosen to form the set of parents for the next generation. This procedure is repeated for many hundred generations until the lowest total energy is unchanged for a large number of generations.

Alternatively, this “two-parent” method may be replaced by a “single-parent” method where the two parts of one cluster simply are interchanged. The advantage of this latter approach is that for systems with more than one type of atoms, stoichiometry is automatically conserved. Moreover, in some cases, we found that the latter is faster than the former.

Na and Au Clusters

As discussed in section “Only Electrons,” Na clusters may be considered as being the prototype for which the jellium model provides a good starting point. Therefore, it seems to be highly appropriate to start our discussion with considering this system but applying other theoretical approaches. Accordingly, we have studied the properties of Na_N clusters both using the EAM method of section “Only Nuclei” and the DFTB method. In both cases, the total-energy methods were combined with unbiased structure optimization methods (Tevekelyska et al. 2010).

Fig. 17 Stability function (in eV) as function of the size of the clusters from the DFTB (*upper part*) and the EAM (*lower part*) calculations

In Fig. 17 we show the resulting stability function and in Fig. 18 the radial distances of the atoms. The stability functions show only a marginal similarity, and only the DFTB calculations find particularly stably clusters for sizes that agree with those of the mass abundance experiments and the jellium calculations (2, 8, 18, 20, 34, 40, 58, ...) (Knight et al. 1984). On the other hand, the radial distances indicate that the structures found in the EAM calculations are somewhat more symmetric than are those of the DFTB calculations. In fact, based on a shape analysis (not shown), we find that none of the DFTB structures can be considered as being roughly spherical, in marked contrast to the inherent assumptions behind the jellium calculations.

Although gold often is considered as being a normal metal, it has remarkable bonding properties that manifest themselves clearly in nanosystems (see, e.g., Springborg 2009). Thus, gold is often found in situations with low coordinations. This is attributed to effects related to the electronic orbitals (although the precise role of various effects like *sd* hybridization, relativistic effects, the range of the atomic potential, etc. has not yet been clarified unambiguously) that are absent in the EAM. Therefore, that EAM calculations for gold clusters (Alamanova et al. 2006) led to too compact structures may not surprise.

Fig. 18 Radial distances (in Å) for sodium clusters obtained with DFTB (*lower part*) and EAM (*upper part*) as a function of the number of atoms N . In each panel, a *small horizontal line* for a given N marks that at least one atom has that distance to the center of the cluster

Instead, we used the DFTB method in combination with the genetic algorithms to study the properties of Au_N clusters with N up to 58 (Dong and Springborg 2007). The main findings are reproduced in Fig. 19. The total energy per atom is seen to fall steeply until around 20 atoms after which it depends much weaker on the cluster size. It is known that small, neutral Au_N clusters are planar up to N somewhat above 10 (see, e.g., the discussion in Dong and Springborg 2007), although this is not found in the present calculations. On the other hand, as seen in the figure, the difference in the total energy between the planar and our nonplanar structures is small. This difference can be taken as an estimate of the accuracy of the present DFTB approach. Moreover, also the experimentally observed tetragonal Au_{20} structure is not found in our calculations, although it has a total energy that is very close to that of our optimized structure. On the other hand, as all other electronic-structure studies on Au_{13} , our calculations do not find the icosahedron to be the most stable structure.

From the radial distances of the Au_N clusters, we see that they all are low symmetric. This can also be seen when comparing the (high-symmetric) structures of Ni_N clusters with those of Au_N clusters with the same number of atoms, i.e.,

Fig. 19 The upper part shows the variation in the total energy per atom (relative to that of the isolated atom) for the optimized Au_N clusters (*solid curve*) together with those of planar structures (*dark circles*) and those of icosahedral Au_{13} and tetragonal Au_{20} clusters (*dark triangles*). The *lower part* shows the radial distances as a function of cluster size, i.e., each small line represents (at least) one atom with that radial distance. The curve shows the radius of the spherical jellium with a density as in the crystal

when comparing Figs. 4 and 20. Moreover, for $10 \leq N \leq 20$, no atom has a small value for its radial distance, implying that these structures are shell-like (see also Fig. 20). Indeed the finding of such “golden cages” is in agreement with other studies (Bulusu et al. 2006). Finally, we add that when analyzing the coordination of the individual atoms, we found that no atom has a coordination larger than 11, i.e., the value of 12 of crystalline fcc gold is not found even for the fairly large clusters of this study. This may be considered a further confirmation of the ability of gold atoms to exist in low-coordinated situations.

In a more recent study (Dong et al. 2013b), we augmented this study on the gold clusters with an analysis of the vibrational properties and the size and temperature dependence of the heat capacity. We used thereby an approach as given in Eqs. (25) and (26) with the only difference being in the way the total energy as a function

Fig. 20 The structures of the Au_N clusters with (from left to right) $N = 13, 19,$ and 55

of structure is calculated. For the second-order derivatives of the total energy with respect to structural coordinates, it turned out to be most accurate to use a finite-difference approximation

$$\begin{aligned}
 f_{ij} &= \frac{\partial}{\partial q_i} \frac{\partial E}{\partial q_j} = \frac{\partial}{\partial q_j} \frac{\partial E}{\partial q_i} = \frac{1}{2} \left(\frac{\partial}{\partial q_i} \frac{\partial E}{\partial q_j} + \frac{\partial}{\partial q_j} \frac{\partial E}{\partial q_i} \right) = \frac{-1}{2} \left(\frac{\partial F_i}{\partial q_j} + \frac{\partial F_j}{\partial q_i} \right) \\
 &\simeq \frac{-1}{4\Delta s} [F_i(q_j + \Delta s) - F_i(q_j - \Delta s) + F_j(q_i + \Delta s) - F_j(q_i - \Delta s)]
 \end{aligned}
 \tag{32}$$

where Δs is a small but finite change in the coordinates, and $F_m(q_n \pm \Delta s)$ denotes the m th force component for the structure where the n th coordinate has been changed by $\pm \Delta s$. From test calculations, we found that $\Delta s = 0.01$ a.u. results in numerically stable results. It turned out to be useful to introduce a characteristic temperature for each vibration through

$$\alpha_i = \frac{\hbar\omega_i}{k_B T} \equiv \frac{T_i}{T}.
 \tag{33}$$

For each mode, its contribution to the vibrational heat capacity is a monotonously increasing function of temperature, and the temperature $T \simeq 2.35T_i$ is the one at which the contribution of the given mode changes most rapidly as a function of temperature. At $T \simeq 2.35T_i$ the contribution of the i th mode equals roughly 64 % of its maximal contribution (at $T \rightarrow \infty$).

In Fig. 21 we show the heat capacity per atom of the Au_N clusters for temperatures of 70, 298.25, 500, 700, and 1200 K. We observe a strong size dependence of the vibrational heat capacity per atom in particular for the smallest clusters and lowest temperatures. That this is so can be understood from Eq. (26). Thus, for the highest temperatures, the vibrational heat capacity per atom approaches $(3 - \frac{6}{N})k_B$ for nonlinear clusters, which is smooth and monotonically increasing as a function of N and converges to $3k_B$ for $N \rightarrow \infty$. On the other hand, for a low temperature, T , only those clusters for which there exist one or more vibrational modes with characteristic temperatures $T_i < T$ will have significant heat capacities.

Fig. 21 The vibrational contribution to the heat capacity per atom for different temperatures (given in the *upper panel*) as function of the size of the clusters. The *lower panel* shows an expanded version of the results for 70 K

An interesting issue is whether a correlation between stability and heat capacity exists. One may speculate that clusters that are particularly stable (unstable) also are particularly rigid (soft), i.e., have particularly high (low) vibrational frequencies. That would imply that the heat capacity then has a minimum (maximum) for those clusters. However, by comparing the heat capacity per atom with the stability function (not shown), it is clear that there is no correlation between stability and heat capacity. Thus, the largest values for the heat capacity are found for $N = 5$ and 6, for which, however, the stability function does not show any pronounced minima. On the other hand, the most stable clusters are found for $N = 42$ and 51, for which the heat capacity has average values.

By plotting the characteristic temperatures as a function of cluster size (this is done in Fig. 22), we can identify those clusters that have a particularly large heat capacity at low temperatures as those that have modes with particularly low characteristic temperatures. As seen in the figure, this is the case for $N = 5, 12, 22, 25, 32, 35, 38, 39, 40, 45, 50, 51,$ and 53. The reason that some of the vibrational modes for certain cluster sizes have particularly low characteristic frequencies is often due to, e.g., wagging of some low-coordinated atoms. This is, for instance, seen for planar clusters.

Fig. 22 The characteristic temperatures for the different vibrational modes as function of the size, N , of the clusters. For a given N , each *line* marks that at least one mode has that characteristic temperature

HAIO Clusters

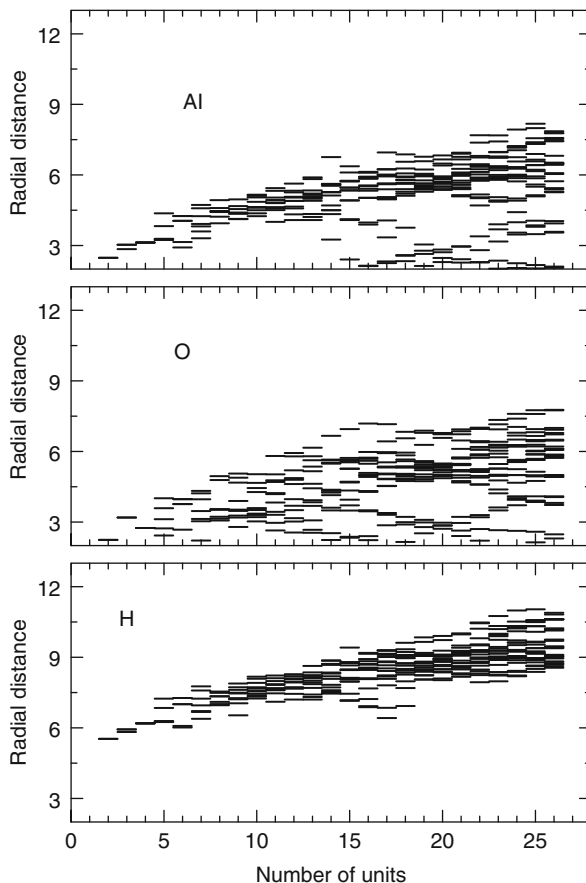

HAIO is a nanostructured material that can be used as substrate for deposition of other materials. However, little is known about the material itself, except that it is stoichiometric (i.e., it contains 1:1:1 mole fractions of H, Al, and O). From nuclear resonance and vibrational spectroscopy experiment, some information can be obtained about the short-range arrangements of the atoms.

In a collaboration with members of one of the groups that synthesize this material, we studied its properties using different theoretical methods (Dong et al. 2005). Genetic algorithms together with the DFTB method were used in an unbiased determination of isolated $(\text{HAIO})_n$ clusters with $n \leq 26$. Moreover, since the material is macroscopic and contains interacting nanostructures, we also studied the interactions between two of those optimized clusters using the DFTB approach. Finally, the predictions of the calculations were supported by parameter-free density-functional calculations on selected structures for clusters with $n \leq 6$.

At first, we show in Fig. 23 the radial distances for each atom type as a function of n . It is evident from this figure that the clusters consist of a core of aluminum and oxygen atoms covered by a shell of hydrogen atoms. A more careful inspection of the structures (not shown) reveals that for the Al–O core, only heteroatomic (i.e., Al–O) and not homoatomic (Al–Al or O–O) bonds exist.

The results of the parameter-free density-functional calculations are in support for these structural findings. We considered in total 50 isomers of $(\text{HAIO})_n$ with $n = 1, 2, 3, 4,$ and 6 . When analyzing the structures of those, we found that none possessed O–O or H–H nearest neighbors and that it was relatively easy to identify Al–H, Al–O, and O–H bonds as being pairs with an interatomic distance smaller than 2.2, 2.5, and 1.5 Å, respectively. The Al–Al interatomic distances, on the other hand, showed a large spread, and it was not possible readily to identify a cutoff distance below which the Al atoms could be considered as being bonded. In the subsequent analysis, we therefore considered two extreme values, 2.5 and 4.1 Å.

Fig. 23 The radial distances (in a.u.) for Al, O, and H atoms, separately, as a function of the size of the cluster n for $(\text{HAIO})_n$ clusters. In each panel, a *small horizontal line* shows that at least one atom of the corresponding type has that distance to the center of the cluster for a given value of n

Next we studied the total energy per unit as a function of number of A–B bonds per unit, with A and B being H, Al, and O. The results are shown in Fig. 24. The results are very scattered, but it is possible to identify certain trends. First, the total energy decreases as the number of Al–O bonds increases. Second, a similar, but much weaker, trend can be identified for the number of Al–Al bonds (here we have used 4.1 Å as our cutoff value, but 2.5 Å gives very similar results). Third, there is a clear preference for structures with one Al–H bond per unit. These observations can be quantified by approximating the total energy of the various $(\text{HAIO})_n$ isomers as

$$E_{\text{tot}} \simeq n \cdot E_0 + n_{\text{AlAl}} \cdot E_{\text{AlAl}} + n_{\text{AlO}} \cdot E_{\text{AlO}} + n_{\text{AlH}} \cdot E_{\text{AlH}} + n_{\text{OH}} \cdot E_{\text{OH}}. \quad (34)$$

A least-squares fit gave $E_{\text{AlAl}} = -0.175 \text{ eV}$ (-0.122 eV), $E_{\text{AlO}} = -1.000 \text{ eV}$ (-1.170 eV), $E_{\text{AlH}} = 0.750 \text{ eV}$ (0.678 eV), and $E_{\text{OH}} = 1.119 \text{ eV}$ (0.798 eV), when using 4.1 Å (2.5 Å) as cutoff distance for Al–Al bonds. These numbers show that Al–O bonds are strongly preferred and that when choosing between adding H to either Al or O, it is energetically preferred to create Al–H bonds.

Fig. 24 Variation in the total energy per unit as function of the number of A–B bonds per unit. The results are from the parameter-free density-functional calculations for the $(\text{HAIO})_n$ clusters with $n = 1, 2, 3, 4, 6$, and the meaning of A and B is given in the panels

Our theoretical findings that the H atoms prefer to stay outside an AIO core, which for larger clusters becomes increasingly difficult when requiring that the material is stoichiometric, suggest that stable structures of HAIO may occur for layers of HAIO. In order to study this proposal further, we considered theoretically extended HAIO systems consisting of either one or two layers of HAIO. We add that these calculations ignore interlayer interactions that can be very important and that, therefore, may modify our conclusions significantly, when included. For a single layer of HAIO, one can imagine two highly symmetric cases, i.e., one where all H atoms are on the one side of the layer and one where every second H atom is above and every second H atom below the AIO layer. For the case that all H atoms are on the same side of the layer, the Al and O atoms form a layer with bond lengths of $3.33 \text{ a.u.} = 1.76 \text{ \AA}$ and $3.34 \text{ a.u.} = 1.77 \text{ \AA}$. Moreover, the hydrogen atoms are sitting on the outside of the layer bonded to the Al atoms with Al–H bond lengths of $3.21 \text{ a.u.} = 1.70 \text{ \AA}$. The Al–O–Al bond angles are $85^\circ\text{--}86^\circ$ and $147^\circ\text{--}152^\circ$. Remarkably different things occur when the H atoms are sitting alternating on the two sides of the single AIO layer. Then we found that the layer split into several small parts all with the same kind of structure, i.e., the H atoms are binding to the Al atoms with

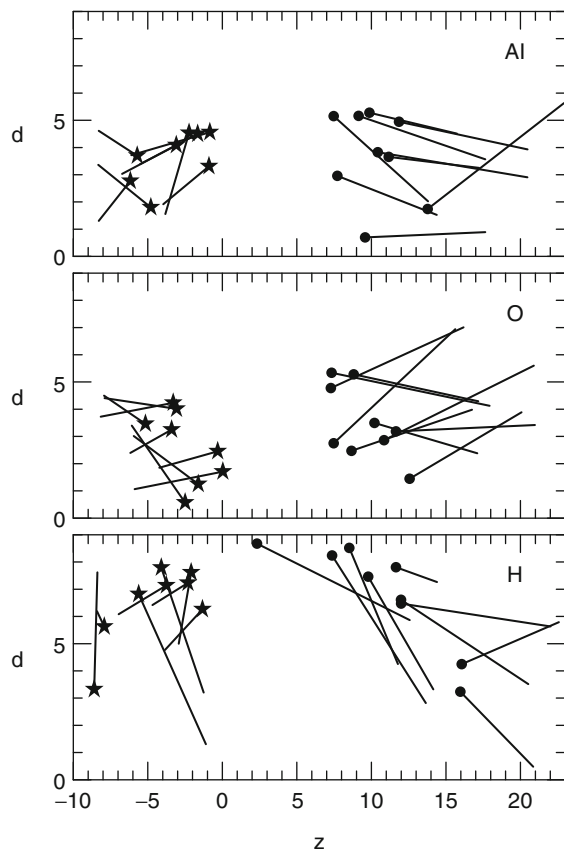

Fig. 25 Variation in energy per unit for isolated clusters and for the layers of HAIO. The results for the layers are shown to the right with the one-layer results marked with *stars* (here, the lowest total energy is for the case that the H atoms are on the same side, whereas they are alternating on the two different sides in the other case) and the two-layer results marked with *circles* (here, the lowest total energy is for the case that Al–O bonds form the bonds between the layers). The energy is given in Hartrees (1 Hartree \simeq 27.21 eV)

Al–H bond lengths around 3.08 a.u. = 1.63 Å, whereas the Al–O bond lengths are around 3.40 a.u. = 1.80 Å. For the case of two layers of HAIO, we studied two cases, i.e., either the Al atoms of one layer were placed on top of the O atoms of the other layer, or they were placed on top of the Al atoms of the other layer. It turned out that the first situation was much more stable than the second one, which may not surprise, and in the second case, we find that the system breaks into small parts.

Finally, in Fig. 25 we show the energy per unit for the finite clusters in comparison with that for the layers. It is remarkable that the two-layer structure is not significantly more stable than the finite clusters. We believe that the systems prefer to have H atoms on some surface. However, since the surface area scales as $n^{2/3}$, the available area per H atom scales like $n^{-1/3}$, meaning that above a certain critical size, the finite (HAIO) $_n$ clusters will be less stable simply due to too little space for the H atoms on the surface. This effect is not found for the layers that per construction are infinite. But it suggests that there is a competition between clusters of HAIO and layers of HAIO, which may explain why different synthesis routes lead to different materials. It is not possible to determine directly the critical size of the finite (HAIO) $_n$ clusters above which they become unstable, but our results suggest that this size may be comparable to the largest clusters of the present study.

As mentioned above, HAIO is a nanostructured material, so that the individual clusters may interact with each other. In this context it is an interesting issue whether the H atoms will try to remain outside a central part, as we have observed for the individual, isolated clusters. We decided, therefore, to study the interaction between two clusters by putting two of the previously optimized clusters together. This was done as follows. We placed two clusters of n_1 and n_2 units so close to each other that they would interact. The initial structures were those of the isolated (HAIO) $_{n_1}$

Fig. 26 A graphical illustration of the structural relaxations of bringing the $n_1 = 8$ (left part) and $n_2 = 9$ (right part) HAIO clusters together. Shown are the relaxations in a cylindrical coordinate system with z and d being the position along the cylindrical axis and distance from it, respectively, both in a.u. The three panels show the displacements of the Al, O, and H atoms, individually. For details about the presentation, see the text

and $(\text{HAIO})_{n_2}$ clusters, and we considered very many relative orientations of the two clusters, out of which we chose the one that led to the lowest total energy after structural relaxation. For the case that the two clusters were brought so close that they interact, before the combined cluster was relaxed, it was found that the hydrogen atoms are placed between the two cores of AIO, but after the combined cluster was relaxed, the hydrogen atoms are only sitting on the surface of the combined cluster. This supports our consensus that clusters with hydrogen sitting on the surface of the clusters are most stable.

This is illustrated in Fig. 26 that has been obtained as follows. We consider the case of $n_1 = 8$ and $n_2 = 9$ units before and after relaxation. In each case (i.e., before and after relaxation), we calculate the center of the two parts according to Eq. (22). The line joining these two centers defines the z axis in a cylindrical coordinate system with $z = 0$ being the midpoint between the two centers. Subsequently, we superpose the two coordinate systems in one figure and show the initial and final values of z and the distance to the z axis (denoted d) for each atom separately by joining these points with a straight line. Finally, we depict these lines for each type of atom individually. The stars mark the final positions of the $n_1 = 8$ system, whereas

the closed circles mark the final positions of the $n_2 = 9$ system. In particular the H atoms tend to increase d upon relaxation, i.e., to move away from the region between the two clusters. On the other hand, first of all the O atoms but also to a lesser extent the Al atoms are seeking to fill out the space between the two clusters when they are combined.

AB Semiconductor Clusters

Semiconductors are interesting materials first of all because of their electronic properties. By modifying the material, it is partly possible to vary these properties in a controllable way, and further possibilities are obtained by considering semiconductor nanoparticles. When the spatial extension of the clusters becomes comparable with that of an exciton, the electronic and optical properties of the semiconductor will depend markedly on the cluster size.

An important class of semiconductors is the II–VI and III–V semiconductors. For those an additional, relevant (and interesting) issue is that the macroscopic, crystalline material may exist in (at least) two structures that are energetically very close, i.e., the zinc blende and the wurtzite structure (Yeh et al. 1992a, b). Accordingly, it is likely that for the finite-sized clusters, the energetic ordering of those two structures may change. To access this issue, we have studied finite clusters of a larger range of II–VI and III–V semiconductor nanoparticles (Joswig et al. 2000, 2002, 2003; Roy and Springborg 2003, 2005; Sarkar and Springborg 2003; Sarkar et al. 2005; Goswami et al. 2006; Asaduzzaman and Springborg 2006; ur Rehman et al. 2011). We have used the DFTB method that includes electronic degrees of freedom and not attempted to optimize the structure completely. Instead, starting from the infinite, periodic crystals, we have cut out a spherical part that subsequently was allowed to relax to the structure of the closest local total-energy minimum. In most cases we considered stoichiometric clusters that were obtained by placing the center of the abovementioned sphere on the midpoint of a nearest-neighbor bond.

In Fig. 27 we show representative examples for the relative total energy of clusters derived from the two different crystal structures. It is clear that the relative total energy depends critically both on size and on material of the clusters. This is in agreement with experimental observations for nanoparticles of the same material but different sizes (see, e.g., Weller and Eychmüller 1996). Moreover, although the total energy does show an overall decreasing behavior as a function of size of the cluster, it is also structured.

There is an interesting correlation between the variation of the total energy and the energy gap between the highest occupied (HOMO) and lowest unoccupied (LUMO) molecular orbital. In Fig. 28 we illustrate this for a single example, i.e., CdS clusters. Similar results are obtained for the other systems. The figure demonstrates that high stability coincides with a high energy gap, which may be interpreted in terms of the so-called hard and soft acids and bases (HSAB) principle (Pearson 1997). Moreover, a more detailed analysis of the frontier orbitals gives that for the less stable structures, i.e., the ones with a small HOMO–LUMO gap,

Fig. 27 The variation in total energy per atom pair for stoichiometric (a) CdS and (b) CdSe clusters for (*thick curves*) zincblende- and (*thin curves*) wurtzite-derived clusters

Fig. 28 Variation in the total energy per atom pair (*thick curves*) and band gap (*thin curves*) for CdS clusters with (a) zinc blende- and (b) wurtzite-derived structures as a function of the total number of atoms in the cluster

and at least one of the HOMO and LUMO orbitals is localized to the surface region. Because of these surface states, less stable clusters are particularly reactive.

From these results, we obtain also an example of how strongly and irregularly the properties can depend on the size of the clusters. For Cd_nS_n clusters, we find a HOMO–LUMO gap of around 1.6 eV for $n = 16$, which increases to 3.2 eV for $n = 17$ (Joswig et al. 2003). When analyzing the structures of those two, this difference can be explained: for $n = 16$ the cluster contains a number of single-coordinated atoms, making it less stable, whereas no such atoms are found for $n = 17$.

Finally, the fact that at least one of the frontier orbitals is localized to the surface is in agreement with experimental studies of the recombination of holes and electrons in such clusters (Lifshitz et al. 1998).

Fig. 29 Schematic presentation of the variation in the total energy per atom (*solid curve*) as a function of size of the cluster together with the size distribution (*dashed curve*) (a) as it usually is assumed together with (b) a modification as it may be in reality. The *solid curve* may also represent the optical absorption threshold as a function of cluster size

The results above have two important implications. First, in experimental studies, it is often assumed (cf. Fig. 29) that one obtains a more or less narrow size distribution that is very regular as a function of size. Moreover, the size of the clusters is often estimated through the energy of the optical transition for which it is assumed that is a monotonous function of size. However, our results give that the total energy is structured as a function of size, suggesting that the size distribution also will be structured, and also that the energy for optical transitions is less regular as a function of cluster size, although a general decrease as a function of increasing cluster size can be identified.

Second, since the stability of the clusters is strongly dependent on the presence/absence of low-coordinated atoms on the surface, it should be possible to stabilize the clusters through properly chosen surfactants or by modifying the surface in other ways (Frenzel et al. 2005). For our stoichiometric AB clusters, the outermost atoms are formed to equal parts by A and by B atoms. Considering nonstoichiometric clusters constructed, e.g., as a spherical cutout of the crystal with the center at an atomic position, the surface will contain exclusively one type of atoms. In one study, on InP clusters (Roy and Springborg 2003), we considered this case and did indeed observe a strong dependence of the properties on the surface, although the properties did not only depend on the type of the outermost atoms. A further study (Roy and Springborg 2005) demonstrated that surfactants could modify the electronic properties of the clusters, leading in most, but not all, cases to a larger HOMO–LUMO gap.

Alternatively, one may obtain more stable structures by considering the so-called core/shell nanoparticles, which are systems containing a core of one material coated by a shell of another. We studied such systems with the two materials being either CdS and CdSe or Si and Ge (Sarkar et al. 2005; Asaduzzaman and Springborg 2006) and found, besides a saturation of dangling bonds on the core part of the

Fig. 30 The optimized structures of the Si_n clusters for $n = 7, 16, 34,$ and 38 (from left to right)

nanoparticle, that new properties may emerge from such systems. This includes that in some few cases, the HOMO and LUMO are localized to the two different materials, making a charge separation upon optical excitation possible. Furthermore, the more stable systems were obtained when the shell material was the one with the lowest surface energy.

The results that we have discussed here were all obtained by assuming that the structure of the clusters resembles that of a finite part of the crystals. This may be the case for larger clusters and clusters protected through ligands on the surface, but for smaller ones, deviations from this may occur. To study whether this assumption is realistic, we have used the genetic algorithm approach in obtaining the stablest structures for Si_n , Ge_n , and Si_nGe_n clusters with n up to 44 for the pure clusters and up to 22 for the mixed ones (ur Rehman et al. 2011).

According to the results, there is a tendency for the Ge clusters to be more open and have lower-coordinated atoms than what is found for the other two systems. For the larger clusters, particularly stable sizes are found for $n = 16, 34, 28,$ and 42 for Si_n clusters; $n = 16, 26, 39,$ and 43 for Ge_n clusters; and $n = 7, 12, 14,$ and 18 for Si_nGe_n clusters. The structures of some of those Si_n clusters are shown in Fig. 30. It is clear that the structures have a low symmetry. Moreover, the larger structures consist of compact parts, each often containing around roughly 10 atoms but sometimes being smaller. These parts are less strongly bonded with each other. This finding is consistent with the dissociation pattern where we found that it is energetically cheapest to dissociate a cluster into two parts that are of comparable size. This is in fact contrasted by the results for the Ni_n clusters discussed earlier in this review and where we found that the Ni_n clusters tend to split off just 1–3 atoms even for clusters with up to 150 atoms in total. Furthermore, for the smaller Si, Ge, or mixed clusters, the overall structure is that of an elongated, cigar-shaped, oblate object, whereas the larger clusters are more spherical.

A more careful analysis of the results reveals that the structures for the different types of clusters are not at all similar. Thus, Si atoms tend to be higher coordinated than what is found for the Ge atoms. In order to study this in more detail, we first identify an interatomic distance, d^0 , which separates bonded pairs of atoms (their mutual distance is less than d^0) from nonbonded pairs. For this purpose, we define a pair correlation function

$$g(r) = \sum_n \sum_{i \neq j} f(r - r_{nij}). \quad (35)$$

Here, the n summation is over all clusters of a given type, whereas the i and j summations are over all atoms of a given clusters. r_{nij} is the distance between the i th and j th atom of the n th cluster. Finally, $f(s)$ is a narrow, normalized Gaussian for which we chose a full width at half maximum of 0.01 a.u. The resulting function (not shown) for each of the three types of interatomic distances (i.e., Si–Si, Ge–Ge, and Si–Ge) has a fairly narrow maximum for small r . For the Si_n clusters, we found for larger r essentially only a broad feature, whereas for the Ge containing clusters, a second maximum for a slightly larger r was observed. The first maximum corresponds to the typical nearest-neighbor distance in the three different types of clusters, i.e., 5.03 a.u. for Si_n clusters, 6.73 a.u. for Ge_n clusters, and 5.02 a.u. for Si_nGe_n clusters. Above the first maximum, there is a range for which $g(r)$ becomes very close or identical to 0. We shall use the midpoint of this range in defining d^0 which, thus, becomes

$$\begin{aligned} d_{\text{Si}}^0 &= 5.35 \text{ a.u.} \\ d_{\text{Ge}}^0 &= 5.85 \text{ a.u.} \\ d_{\text{SiGe}}^0 &= 5.85 \text{ a.u.} \end{aligned} \quad (36)$$

However, only for the Ge_n clusters, $g(d^0) = 0$.

Using these values, we can next calculate the relative occurrence of different coordinations for the atoms of the clusters, i.e., $o(n_{\text{AB}})$. Thereby, n_{AB} is the number of B atoms around an atom of type A. The results are shown in Fig. 31 where we have used three different values for d^0 , i.e., those of Eq. (36) as well as those multiplied by either 0.95 or by 1.05. Some smaller differences from these different values are observed, but the main trends remain. Hence, even for the pure clusters, Ge atoms tend to be lower coordinated (hardly above fourfold coordinated) than Si atoms. This difference between Si and Ge can also explain why the Si_n clusters are more compact than the Ge_n clusters. Also for the Si–Ge clusters, there are only few Ge–Ge bonds, whereas most often heteroatomic Si–Ge bonds are found, but also some Si–Si bonds exist.

The fact that the structures are fairly open although still consisting of compact subparts makes it difficult to quantify structural similarity using the approaches we have discussed earlier in this presentation. Nevertheless, in a first study (ur Rehman et al. 2011), we used the interatomic distances in discussing structural similarity between different clusters. First we compare two clusters with the same number of atoms, N . For each of those, we calculate all $\frac{N(N-1)}{2}$ interatomic distances that subsequently are sorted. Then, we calculate

$$q = \left[\frac{2}{N(N-1)} \sum_{i=1}^{N(N-1)/2} \left(\frac{d_{\text{A},i}}{d_{\text{A}}^0} - \frac{d_{\text{B},i}}{d_{\text{B}}^0} \right)^2 \right]^{1/2}, \quad (37)$$

Fig. 31 The function $o(n_{AB})$ that describes how many B neighbors an A atom has in the different types of structures. In the panels, the notation “B to A in C” represents the B and A atoms in C clusters. The three different curves in each panel are obtained by using three slightly different values for determining whether two atoms are bonded

where A and B equal Si, Ge, or SiGe, and the interatomic distances have been scaled by the lengths of Eq. (36). From this, we define a similarity function according to

$$S = \frac{1}{1 + q}, \tag{38}$$

that approaches 1 (0) if the two structures are structurally very similar (different). For the Si–Ge clusters, we do not distinguish between atom types. Alternatively, we may replace the $\frac{N(N-1)}{2}$ interatomic distances with the N radial distances or the N reciprocal radial distances.

In a more recent work for quantifying structural similarity (Dong et al. 2013a), we were motivated by what you do in your mind when examining whether two systems are similar. Thus, at first each of the two structures is scaled, and subsequently one of the two is rotated and translated so that it maximally overlap with the other structure.

In describing our new approach, we will let B be the larger system with M atoms and A be the smaller one with N atoms. Also in the special case that $M = N$, we will use this notation. In detail, our approach consists then of the following steps:

1. For each of the two systems, we use scaled relative coordinates, i.e.,

$$\begin{aligned} \mathbf{s}_{A,i} &= \mathbf{r}_{A,i}, & i &= 1, 2, \dots, N \\ \mathbf{s}_{B,i} &= \mathbf{r}_{B,i}, & i &= 1, 2, \dots, M. \end{aligned} \quad (39)$$

2. Subsequently, we apply an initial rotation and translation to system A. By repeating this and the following steps for different initial rotations and translations, we hope to be able to find the optimal way of placing structure A on structure B.

$$\mathbf{s}_{A,i} \rightarrow \mathbf{s}_{A,i}' = \underline{\underline{R}}_0 \mathbf{s}_{A,i} + \mathbf{t}_0. \quad (40)$$

$\underline{\underline{R}}_0$ is the rotational matrix expressed in terms of a set of Euler angles and \mathbf{t}_0 is the translation vector.

3. For each atom, i , of system A, we identify that atom in system B, $n_{BA}(i)$, that is closest to the atom i of system A, i.e., the partner of atom i . $n_{BA}(i)$ is that atom of system B that makes

$$q_i = |\mathbf{s}_{A,i}' - \mathbf{s}_{B,n_{BA}(i)}|^2 \quad (41)$$

as small as possible. It may happen that two (or more) atoms of system A, i_1 and i_2 , have the same partner, i.e., $n_{BA}(i_1) = n_{BA}(i_2)$. In that case, $n_{BA}(i_1)$ ($n_{BA}(i_2)$) is kept if the corresponding value of q_{i_1} is smaller (larger) than the equivalent value of q_{i_2} , and for the i_2 th (i_1 th) atom of system A, another partner of system B is found. Thus, no two atoms of system A will have the same partners.

4. We apply a rotation and a translation to the complete system A. This changes the positions of the atoms in system A according to

$$\mathbf{s}_{A,i}' \rightarrow \mathbf{s}_{A,i}'' = \underline{\underline{R}} \mathbf{s}_{A,i}' + \mathbf{t}. \quad (42)$$

Here, $\underline{\underline{R}}$ is a rotation matrix, described through three Euler angles α , β , and γ . Moreover, \mathbf{t} is a translation containing the three parameters x , y , and z . Thus, in total, 6 parameters, α , β , γ , x , y , and z , define the displacement of system A.

5. These 6 parameters are optimized so that

$$Q(\alpha, \beta, \gamma, x, y, z) = \frac{1}{N} \sum_{i=1}^N |\mathbf{s}_{A,i}'' - \mathbf{s}_{B,n_{BA}(i)}|^2 \quad (43)$$

is minimized.

6. It cannot be excluded that through the transformation of Eq. (42), the atoms of system A will be closer to other atoms than its original partners. Therefore, we repeat step 3 and identify a new set of partners for the atoms of system A. For this new set, we calculate Q of Eq. (43) for the special case that $\alpha = \beta = \gamma = 0$ and $\mathbf{t} = \mathbf{0}$ (i.e., the rotation and translation are not optimized). If this new value of Q is lower than the one we have optimized in the previous step, we go back to step 4 for this new set of partners.
7. Otherwise, we may return to step 2 for a new set of initial rotations and translations.
8. Finally, in order to check whether system A is the mirror image of system B, the whole procedure is repeated by replacing, e.g., all z coordinates of the atoms of system A by their negative values (or, in the special case, that they all vanish, then the x or y values).

From the smallest value of Q_R , we define finally the similarity function as

$$S = \frac{1}{1 + Q_R^{1/2}}. \quad (44)$$

This new approach and the earlier one, given through Eqs. (37) and (38), were applied for comparing Si_n with Ge_n , Si_{2n} with Si_nGe_n , Ge_{2n} with Si_nGe_n , Si_n with Si_{n-1} , Ge_n with Ge_{n-1} , Si_nGe_n with $\text{Si}_{n-1}\text{Ge}_{n-1}$, and Si_n , Ge_n , and Si_nGe_n with the diamond crystal structure. For the diamond crystal structure, we constructed a cubic cutout of the crystal containing $5 \times 5 \times 5$ units of each 8 atoms. These 8 atoms were placed at $(0, 0, 0)$, $(\frac{1}{4}, \frac{1}{4}, \frac{1}{4})$, $(\frac{1}{2}, \frac{1}{2}, 0)$, $(\frac{3}{4}, \frac{3}{4}, \frac{1}{4})$, $(0, \frac{1}{2}, \frac{1}{2})$, $(\frac{1}{4}, \frac{3}{4}, \frac{3}{4})$, $(\frac{3}{4}, \frac{1}{4}, \frac{3}{4})$, and $(\frac{1}{2}, 0, \frac{1}{2})$, and the three lattice vectors are $(0, 0, 1)$, $(0, 1, 0)$, and $(1, 0, 0)$.

We considered two different ways of choosing the scaling parameters of Eq. (39). In one set of calculations, we set these for all Si clusters equal to 5.35 a.u., whereas we for all Ge and all SiGe clusters used a value of 5.85 a.u. Alternatively, we used the average value for the nearest- and next-nearest-neighbor distance of the crystalline material. For the mixed clusters, we chose the average of the values for the pure clusters.

Figure 32 shows the similarity function as calculated in our previous study together with the similarity functions based on either the radial distances, the inverse radial distances, the interatomic distances, and the inverse interatomic distances. In each case, $S \simeq 1$ suggests that the two structures that are being compared are very similar. Thus, any drop in a similarity function in the left panels in Fig. 32 suggests that a structural change has taken place at that size. If S remains low, each cluster has a structure different from that of the cluster of the neighboring, lower size, whereas

Fig. 32 The *thick curves* show the similarity functions of our new approach, whereas the *thin curves* show those of our earlier approach. N is the total number of atoms in the clusters, i.e., n for the pure Si_n and Ge_n clusters and $2n$ for the Si_nGe_n clusters. With the new approach, the *solid curves* mark the results based on setting the scaling parameters for Si_n , Ge_n , and Si_nGe_n equal to 5.35, 5.85, and 5.85 a.u., respectively, whereas they were set equal to 5.851, 6.095, and 5.973 a.u., respectively, for the results of the *dashed curves*. With the old approach, only the former set of scaling parameters was used. Moreover, then the *solid curves* show the results based on the radial distances, the *dashed curves* the results based on the inverse radial distances, the *dash-dotted curves* those based on the interatomic distances, and the *dotted curves* those based on the inverse interatomic distances. In the last case, q of Eq. (37) has been multiplied by 10

if S after a jump to a low value becomes close to 1, then a new structural motif has emerged that is kept for more cluster sizes.

In Fig. 32 we first notice that the two sets of results with the new approach for different scaling parameters lie almost on top of each other, implying that this approach is not very sensitive to the value of these scaling parameters, as long as these are chosen reasonably. Second, we see that S based on the inverse interatomic

distances possesses very little structure even after multiplying q of Eq. (37) by 10 (so that S in this case covers essentially the same range as in the other cases). Accordingly, this choice does not provide very much information. Third, for S based on the inverse radial distances, we see very low values for certain cluster sizes, which is due to the fact that one atom happens to sit very close to the center of the cluster.

Figure 32 shows also that the structures of neighboring sizes of the same types of systems (i.e., Si clusters, Ge clusters, or SiGe clusters) are much more similar than are the structures of the same sizes but different types of systems. In fact, the latter appear to become increasingly different with increasing size. These findings match actually what a simple inspection of the structures intuitively gives.

Next, we compare the structures of the clusters with the diamond crystal structure. The results of this comparison are shown in Fig. 33. It is interesting to notice that also in this case the results are independent of the precise values of the scaling parameters. Thus, although the comparison of two larger, identical cutouts of a crystal structure with slightly different scaling parameters will yield a similarity function below 1, the relative low values in Fig. 33 even for the largest clusters are not a result of inadequately chosen scaling parameters but indeed imply that the structures of the clusters are quite different from fragments of the diamond structure.

Metcars

With the last example of this presentation, we shall discuss the systems that initially led us to start the theoretical work on unbiased structure optimization for nanoparticles.

In the beginning of the 1990s, the group around Castleman in Pennsylvania produced metal-containing carbon clusters M_mC_n . In mass abundance spectra with M being Ti, they observed a peak for $(m, n) = (8, 12)$ (Guo et al. 1992), suggesting that this cluster was particularly stable. They proposed a cage-like structure of cubic T_h symmetry with 12 five-membered rings, each containing two metal and three carbon atoms. Thus, the topology is as that of the smallest possible fullerene molecule C_{20} but containing metal atoms. An alternative description of the structure is to consider it as formed by a cube of the eight metal atoms. The 12 carbon atoms form six C_2 units that are placed symmetrically above the sides of the cube with the C–C bonds parallel to the edges. Later, theoretical studies – first of all by Dance (1992) – suggested that the structure instead had tetragonal T_d symmetry. Compared with the T_h symmetry, the C_2 dimers are for the T_d symmetry lying parallel to the diagonals of the six sides of the cube of the eight metal atoms, and in addition, the cube becomes somewhat distorted. First recently, theoretical and experimental studies agree that the tetragonal structure is the correct one (see, e.g., Rohmer et al. 2000). In the meantime it has been found that also for

Fig. 33 The similarity function for the comparison of the structures of the Si_n , Ge_n , and Si_nGe_n clusters with a fragment of the diamond crystal. N is the total number of atoms in the clusters, i.e., n for the pure Si_n and Ge_n clusters and $2n$ for the Si_nGe_n clusters. The *solid curves* mark the results based on setting the scaling parameters for Si_n , Ge_n , and Si_nGe_n equal to 5.35, 5.85, and 5.85 a.u., respectively, whereas they were set equal to 5.851, 6.095, and 5.973 a.u., respectively, for the results of the *dashed curves*

other metals (e.g., Hf, Zr, V), those so-called metallocarbohedrenes or metcars can be formed, and even metcars with more different types of metals have been produced. However, whether they occur in significant amounts depends strongly on the experimental conditions, suggesting that kinetic effects play a significant role in their production.

In order to study the properties of these Ti-based clusters further, the group around Ganteför in Konstanz, Germany, decided to study a whole class of Ti_mC_n clusters with different values of (m, n) centered around $(m, n) = (8, 12)$ (Blessing 1998). Using two different sources, Ti and C atoms were produced that subsequently were allowed to form the clusters mentioned above. After ionization, a magnetic field could be used to mass-separate the clusters, and finally, photoelectron spectra

could be recorded for these mass-selected clusters. Accompanying theoretical studies would then be very useful as a support for the interpretation of the experimental results.

As one of the clusters of the experiments, let us choose Ti_6C_{10} , i.e., $(m, n) = (6, 10)$, whose structure is absolutely unknown. One suggestion could be to assume that it has a structure that can be formed by removing two carbon and two titanium atoms from the larger $(m, n) = (8, 12)$ cluster, but the first question is then: which four atoms shall be removed? Starting with the two proposed structures (i.e., those of T_h and T_d symmetry) for the $(m, n) = (8, 12)$ cluster mentioned above, we tried this strategy but obtained a new structure in each attempt. The simplest approach would then be to choose the structure of the lowest total energy. However, it has to be remembered that the experiment is performed in a completely different way: instead of starting with the larger $(m, n) = (8, 12)$ cluster and from that removing some atoms, the $(m, n) = (6, 10)$ cluster is formed from essentially isolated atoms, and therefore, it is not at all given that its structure has any resemblance to that of the $(m, n) = (8, 12)$ cluster.

Therefore, in order to obtain unbiased information on the structures of the different Ti_mC_n clusters, we started applying the genetic algorithms that were discussed earlier in this section together with the DFTB method and applied the approach to the metcars (Joswig et al. 2001; Joswig and Springborg 2008). In Fig. 34 some of the results are summarized. This figure shows the total energies for two series of Ti_mC_n metcars, i.e., with $m = 7, 8$ and $n = 10\text{--}14$. We have defined an energy gain, for clusters with same m , as the difference in the total energy of $\text{Ti}_m\text{C}_{n-1}$ and Ti_mC_n . For $m = 8$, experiments found the Ti_8C_{12} metcar to be a particularly stable cluster. However, our calculations do not find a specially high energy gain for this cluster, although they do for the Ti_7C_{12} cluster. Also the HOMO–LUMO gap does not indicate a high stability for the Ti_8C_{12} metcar. Actually, it has the smallest gap in the $m = 8$ series [cf. Fig. 34f]. Furthermore, there is no evidence that the number of bonds is related to the stability of the clusters, as also indicated by the results in Fig. 34. In total, the structural properties give no hints to the experimentally observed special stability of the Ti_8C_{12} metcar.

Instead, one may suggest that effects (for instance, kinetic effects) that are beyond the calculational approach are important. An experimental support for this suggestion can be found in the work of van Heijnsbergen et al. (1999). These authors found that the mass abundance spectra depend critically on experimental parameters so that in one experiment the Ti_8C_{12} metcar showed a large abundance, whereas in another it hardly occurred and a $\text{Ti}_{14}\text{C}_{13}$ cluster (which has a structure similar to a part of the rocksalt crystal; cf. Joswig and Springborg 2008) was found in large abundance.

Finally, we mention that exactly the Ti_6C_{10} metcar that we discussed above was found in our calculation to be particularly stable and of special high symmetry; see Fig. 35. However, so far it has not been discussed in detail in connection with experimental studies.

Conclusions

In this overview we have presented various, typical results from our theoretical studies on structural and electronic properties of clusters and colloids. We have put the main emphasis on presenting the principles behind our approaches and less on the discussion of the different systems, separately. It shall be added that there are many other, related studies by others, but that we have here chosen to focus on our own work.

The major challenge related to studies as those we have presented here is the complexity of the calculations due to the fairly large size combined with an often low symmetry. In addition, when aiming at extracting trends, as we have been, one needs to study not only one cluster size of a given material but a whole range, adding to the computational demands.

Moreover, the fact that there is no standard method that can be used in identifying unambiguously the structure of the lowest total energy for a given system means that one has to apply more or less intelligent methods in the structure optimization and, furthermore, that there never will be any guarantee that the structure of the lowest total energy indeed is identified. Experience has shown that specially developed methods for unbiased structure optimization are the most efficient ones, whereas others like molecular-dynamics simulations and random searches often perform considerably worse. In this overview we have presented some few intelligent methods, including genetic algorithms, basin-hopping methods, and our own Aufbau/Abbau method. Alternatively, one may also consider only certain types of structures when aiming at studying special effects. The latter we illustrated through our study on AB semiconductor particles for which an interesting issue is the relative stability of cluster structures that can be derived from two different crystal structures (in this case, the zinc blende and wurtzite structures).

But even when applying such intelligent structure optimization methods, one often has to perform maybe even several 10^6 s of total-energy calculations for a given cluster. Therefore, it is often necessary to use approximate total-energy methods that then shall be chosen carefully according to the properties of the system of interest. In this presentation, we have discussed embedded-atom methods and Gupta potentials and similar approaches as useful methods for metallic systems with delocalized electrons, the DFTB method for systems with directional, covalent bonds, and the jellium model, also for metallic systems with delocalized electrons. Due to the approximations inherent in such approaches, it is always important to assess their accuracy through comparison with results of more accurate calculations or with other studies on similar systems.

Finally, we placed much emphasis in presenting various descriptors that we have developed in order to be able to extract general chemical or physical information from the, often enormous amount of, information from the calculations. This included descriptors for analyzing stability, shape, spatial distribution of atoms and orbitals, and structural similarity.

Acknowledgements The work that has been presented in this overview would not have been possible without the active participation of a number of persons, including (in alphabetic order) Abu Asaduzzaman, Markus Burkhard, Yi Dong, Valeri G. Grigoryan, Elisaveta Hristova (née Kasabova), Jan-Ole Joswig, Mohammad Molayem, Francisco Morales Morillon, Yong Pang, Sudip Roy, Pranab Sarkar, Sashi Satpathy, Gotthard Seifert, Violina Spurk (née Tevekeliyska), Michael Veith, and Ingolf Warnke. Moreover, we have benefited from financial support through the German Research Council (DFG).

Abstract

We present an overview of our understanding of how extended materials exposed to an electrostatic field can be treated theoretically. We concentrate on materials that are regular so that they can be approximated as being infinite and periodic. We show how expressions for the dipole moment per unit that were suggested previously within the so-called modern theory of polarization can be obtained. Subsequently, we present the single-particle equations that describe how the electrons respond to an external, electrostatic field and present a numerically efficient method of solution. We also discuss how structural responses in the presence of an electrostatic field can be calculated automatically. We demonstrate that bulk properties of macroscopic systems will depend upon the surfaces and demonstrate how these properties may be evaluated from calculations on the infinite and periodic system even though the latter does not contain surfaces. As one example, we show how the surfaces will contribute to the so-called converse piezoelectric effect. In addition, the polarizabilities induced by the structural response may be larger than the corresponding electronic polarizabilities. Finally, problems related to the description of the responses within density-functional theory are briefly discussed.

Introduction

The response to external electric and magnetic fields provides a fundamental tool for studying and altering the properties of chemical systems with numerous attendant applications. An indispensable ingredient for effectively utilizing this tool is the ability to relate the properties to electronic structure through chemical computations. Such computations depend, of course, on having an appropriate theoretical basis along with suitable algorithms for implementing the theory. In the case of atoms and molecules much has been achieved in this regard and many aspects are very well established. On the other hand, for infinite periodic systems (or systems that, in first approximation, may be regarded as such), developments are in a much more primitive state. In the case of uniform electric fields, one can relate this issue to the properties of the scalar electronic interaction potential, which is usually employed in atomic and molecular calculations. This potential is proportional to the quantum-mechanical operator \mathbf{r} (i.e., the electronic position) and is, therefore, nonperiodic and unbounded from below.

This situation is illustrated in Fig. 1 where we show the potential for an atom, a small molecule, and a long-chain compound both in the absence and in the presence of an external electrostatic field. For the atom, the electrostatic field leads to a situation where the lowest point on the potential curve is found infinitely far from the nucleus so that the bound states are changed into resonances. In the case of the small

Fig. 1 Schematic representation of the potential for (*top row*) a single atom, (*middle row*) a three-atomic molecule, and (*bottom row*) a very large-chain compound. In each row, the leftmost panel shows the situation without an external electrostatic field, whereas a such is switched on in the other panels. The *short lines* symbolize electronic levels, and the *dark circles* their occupancies

molecule, a sufficiently strong field will cause the electrons to tunnel from one end to the other (Zener tunneling). Both these situations can be avoided in theoretical calculations by applying basis sets with functions that are localized to the system of interest and by applying sufficiently weak, external electrostatic fields. But neither of these methods seems able to allow for the treatment of the long-chain compound when it is exposed to an electrostatic field.

The systems that we shall study contain a large sequence of identical, regularly placed units for which deviations of this regularity only may occur near their boundaries. In that case, an alternative to the large, finite systems is to consider them as being infinite and periodic. Ultimately, any true system is finite, and, therefore, when treating it as being infinite and periodic, it is important to assure that the results are identical to those found for the large, finite system. In this presentation, we shall focus on the responses of such systems to electrostatic field and have, accordingly, a situation like that of the third example in Fig. 1 when treating them as being large and finite. As we shall see, for the infinite, periodic system the situation is much less obvious than what may intuitively have been imagined. Therefore, a close comparison between the results for large, finite systems and those for infinite, periodic ones becomes of ultimate importance.

A number of different methods have been suggested for dealing with the problems presented by the scalar interaction potential as applied to infinite periodic

Fig. 2 Different proposals for how to approximate the potential from an electrostatic field. (a) shows the true potential, whereas in (b) and (c), approximations are shown that keep (b) the lattice or (c) BvK periodicity

systems. The most straightforward is to study finite clusters of increasing size and, then, extrapolate to the infinite size limit. At the first-principles level, this approach is prohibitively CPU demanding for 3D solids but can be manageable for quasilinear polymers (see, e.g., Champagne et al. (1997) for an early example of such studies). Often a key issue in such cases is how to extrapolate when the functional dependence of the property on chain length is unknown (Weniger and Kirtman 2003; Kudin et al. 2005; Berger et al. 2005).

A different approach, standard in solid-state physics, is to adopt Born-von Kármán (BvK) periodic boundary conditions in order to describe the infinite-system limit. Then, by construction, the system does not possess any surfaces, and any computed property is, by definition, “bulk.” At the same time, the electron position, \mathbf{r} , may be approximated as a sawtooth function with the periodicity of the BvK zone (Kunc and Resta 1983; Schmidt and Springborg 1999; Sebastiani and Parrinello 2003; Darrigan et al. 2003) (see Fig. 2). Despite some successes, we have shown (Springborg et al. 2004) (as discussed in further detail later on) that an ordinary sawtooth cannot fully account for the polarization. It is missing a contribution that may be expressed as being due to a flow of electronic charge throughout the system. This charge flow term is especially important when there is substantial electron delocalization. Recently, we have revisited the sawtooth potential and shown how it may be modified to yield polarization properties other than the dipole moment for the response to a finite field (Kirtman et al. 2009). In addition to these important exceptions, the convergence behavior of the modified potentials is poor, i.e., quite large systems need to be treated before the infinite-system limit can be identified.

Within the past 10–20 years, a “modern theory of polarization” (MTP) has become popular (King-Smith and Vanderbilt 1993; Resta 1994, 1998) in the physics community. The MTP is based on a discretized Berry-phase treatment and has been applied to calculate the static polarization (dipole moment) and linear polarizability of many 3D materials, most notably piezoelectrics and ferroelectrics. It does not include frequency-dependence and, until quite recently, was limited to infinitesimal

fields, i.e., fields small enough so that they can be treated by perturbation theory (de Gironcoli et al. 1989; Baroni et al. 2001; van Gisbergen et al. 1998; Nunes and Gonze 2001).

An alternative approach has been developed by Kirtman and coworkers (Kirtman et al. 2000; Bishop et al. 2001). Instead of dealing with the scalar potential or (explicitly) with the Berry phase, these authors have developed a time-dependent vector potential approach (VPA) based on a suggestion made originally by Genkin and Mednis (1968) (GM). Taken together with the prescription for the polarization operator given by GM, as well as Blount (1962), this approach has the virtue of immediately satisfying the periodicity requirement and of introducing frequency-dependence in a straightforward manner. Through a detailed comparison between the VPA and MTP for static fields, it has been shown that the two approaches are closely related (Springborg and Kirtman 2008).

In this contribution, we shall review our own work that is closely related to the MTP and VPA methodologies. We shall start with the large, finite system that will act as a reference for the approaches where the system is treated as being infinite and periodic. By requiring that a thermodynamic limit exists for the former, we obtain information on the responses of the system of interest to electrostatic fields. In particular, we shall see that surfaces and shapes are relevant. Nevertheless, we shall subsequently see that when treating the systems as being infinite and periodic, the effects of the surfaces are included.

The single-particle (Hartree-Fock or Kohn-Sham) equations for the infinite periodic system exposed to an electrostatic field have a nonstandard form. We shall therefore discuss how they can be solved. Finally, we give a few exemplary applications of our theory.

The Gauge

For an electron in an external electromagnetic field, the time-dependent (Hartree-Fock or Kohn-Sham) single-particle equation takes the form

$$\left\{ \frac{1}{2m} \left[-i\hbar\nabla + \frac{e}{c} \mathbf{A}_{\text{ext,E}}(\mathbf{r}, t) \right]^2 + V_{\text{ext,n}}(\mathbf{r}) + V_J(\mathbf{r}) + \hat{V}_{\text{xc}}(\mathbf{r}, t) + V_{\text{ext,E}}(\mathbf{r}, t) \right\} \psi_i(\mathbf{x}, t) = i\hbar \frac{\partial}{\partial t} \psi_i(\mathbf{x}, t). \quad (1)$$

Here, m is the mass of the electron and c is the speed of light. V_J is the coulombic potential due to electron-electron repulsion including self-interaction. Within density-functional theory, exchange and correlation effects are contained in \hat{V}_{xc} , which is a functional of the (time-dependent) electron density, whereas only exchange interactions are included in the Hartree-Fock approximation. In that case, \hat{V}_{xc} becomes an operator that depends on the occupied orbitals. $V_{\text{ext,n}}$ describes the electrostatic nuclear-electron attraction. The effects of the electric field are described

via the vector potential $\mathbf{A}_{\text{ext,E}}$ and the scalar potential $V_{\text{ext,E}}$. In the general case, an electric field, \mathbf{E} , and a magnetic field, \mathbf{B} , are given through

$$\begin{aligned}\mathbf{E}(\mathbf{r}, t) &= -\nabla V_{\text{ext,E}}(\mathbf{r}, t) - \frac{1}{c} \frac{\partial}{\partial t} \mathbf{A}_{\text{ext,E}}(\mathbf{r}, t) \\ \mathbf{B}(\mathbf{r}, t) &= \nabla \times \mathbf{A}_{\text{ext,E}}(\mathbf{r}, t).\end{aligned}\quad (2)$$

In the present discussion, we shall not be concerned with magnetic fields, so that $\mathbf{B} = \mathbf{0}$, which can be satisfied by taking

$$\mathbf{A}_{\text{ext,E}}(\mathbf{r}, t) = \nabla f_{\text{ext}}(\mathbf{r}, t), \quad (3)$$

where $f_{\text{ext}}(\mathbf{r}, t)$ is some function. Even then, however, the separation of \mathbf{E} into scalar and vector potential contributions is not unique: different choices define different gauges.

An example that we shall discuss below in some detail is that of a homogeneous, electrostatic field given by a constant \mathbf{E} everywhere in space. This can be described, for example, through a pure scalar potential,

$$\begin{aligned}V_{\text{ext,E}}(\mathbf{r}, t) &= -\mathbf{E} \cdot \mathbf{r} \\ \mathbf{A}_{\text{ext,E}}(\mathbf{r}, t) &= \mathbf{0},\end{aligned}\quad (4)$$

or, equivalently, through a pure vector potential,

$$\begin{aligned}V_{\text{ext,E}}(\mathbf{r}, t) &= 0 \\ \mathbf{A}_{\text{ext,E}}(\mathbf{r}, t) &= -c\mathbf{E} \cdot t.\end{aligned}\quad (5)$$

Linear combinations of the two cases are possible, too, but here we shall only be concerned with these two choices. Equation (1) depends on which of the two forms in Eqs. (4) and (5) is used, but, of course, physical observables must be independent of that choice. Below we shall exploit both possibilities.

The Dipole Moment for the Finite System

For any finite system exposed to a homogeneous, electrostatic field, the Hamilton operator changes according to

$$\hat{H} \rightarrow \hat{H} - \hat{\boldsymbol{\mu}} \cdot \mathbf{E}. \quad (6)$$

Here, \hat{H} is the Hamilton operator in the absence of the field, and we have used the scalar interaction potential with \mathbf{E} as the electrostatic field. Finally, $\hat{\boldsymbol{\mu}}$ is the dipole moment operator for the system of interest.

The dipole moment property (i.e., the expectation value of the operator) can be written as a sum of a contribution from the nuclei and one from the electrons,

$$\boldsymbol{\mu} = \sum_p Z_p \mathbf{R}_p - \int \rho(\mathbf{r}) \mathbf{r} d\mathbf{r}. \quad (7)$$

As everywhere else in this contribution going forward, we have used atomic units, in which case $|e| = 1$. Moreover, Z_p and \mathbf{R}_p are the charge and position of the p th nucleus, whereas $\rho(\mathbf{r})$ is the electron density.

As mentioned above, in the present study, we shall focus on systems that, besides being very large, are regular in the sense that they contain a very large number of identical units and only in the surface regions may one observe deviations from regularity. In that event, the thermodynamic limit has been reached. It is customary to approximate such systems as if they were infinite and periodic.

Quasi-One-Dimensional Systems

For the sake of simplicity, we shall start with a discussion of quasi-one-dimensional systems (chains) that are assumed to lie along the z axis. Then, the (intensive) property per unit corresponding to the extensive property $\xi(N)$, in which N is the number of units, may be determined as

$$\bar{\xi} = \lim_{N \rightarrow \infty} \frac{\xi(N)}{N} = \lim_{N \rightarrow \infty} \frac{1}{\Delta N} [\xi(N + \Delta N) - \xi(N)]. \quad (8)$$

Figure 3 shows a schematic representation of a long, regular chain. We see that the chain consists of a number of repeated units in the so-called central region marked by vertical blue lines). In this region, the presence of the boundaries/terminations is not felt. That is different for the terminal regions. The separation into a central region and terminations is not unique as can be seen by comparing the two topmost panels in Fig. 3. Nevertheless, the units of the central region are neutral regardless of the precise definition of those units. That this is so can be understood as follows. Imagine that these cells were not neutral but each carries some charge, q . When increasing the size of the system, the central units will, per construction, remain unchanged. Moreover, the charges in the terminal regions are required to stay unchanged when the system is sufficiently large. Then the total charge of the system would increase, which is in contrast to the assumption that we have reached the thermodynamic limit. Thus, in the thermodynamic limit $q = 0$.

If, in addition, the chain is neutral, then, the charges accumulated at the right and the left terminal regions must add to zero,

$$q_L = -q_R. \quad (9)$$

Fig. 3 Schematic representation of a long, regular chain. The two topmost panels differ in the way the repeated unit is defined (marked through the vertical lines), whereas the two bottommost panels differ in the length of the chain

We shall now discuss the dipole moment for the large chain with the ultimate goal of obtaining expressions for the dipole moment per unit using the last identity in Eq. (8). The total dipole moment of the system in the middle panel of Fig. 3 can be written as

$$\begin{aligned} \boldsymbol{\mu} &= \int \rho_{\text{tot}}(\mathbf{r})\mathbf{r}d\mathbf{r} = \int_C \rho_{\text{tot}}(\mathbf{r})\mathbf{r}d\mathbf{r} + \int_L \rho_{\text{tot}}(\mathbf{r})\mathbf{r}d\mathbf{r} + \int_R \rho_{\text{tot}}(\mathbf{r})\mathbf{r}d\mathbf{r} \\ &= K_C \boldsymbol{\mu}_C + (\mathbf{R}_R - \mathbf{R}_L) \int_R \rho_{\text{tot}}(\mathbf{r})d\mathbf{r} + \int_L \rho_{\text{tot}}(\mathbf{r})(\mathbf{r} - \mathbf{R}_L)d\mathbf{r} + \int_R \rho_{\text{tot}}(\mathbf{r})(\mathbf{r} - \mathbf{R}_R)d\mathbf{r}, \end{aligned} \quad (10)$$

where we have made explicit use of the spatial separation into right (R), left (L), and central (C) regions and used the neutrality of the central units as well as the overall neutrality. In Eq. (10), $\rho_{\text{tot}}(\mathbf{r})$ is the total charge density; \mathbf{R}_R and \mathbf{R}_L are typical positions within the right and left regions, respectively; and K_C is the number of units in C . Combining this relation with the second definition of Eq. (8) gives immediately (cf. the two lowest panels in Fig. 3)

$$\bar{\boldsymbol{\mu}} = \boldsymbol{\mu}_C + q_R \cdot \mathbf{a}, \quad (11)$$

in which q_R is the total charge of R , $\boldsymbol{\mu}_C$ is the dipole moment of one of the C units, and \mathbf{a} is the lattice constant of C . That is to say, upon increasing the size of the system, one contribution to the dipole moment per unit comes from the increased number of central units and another from the increased distance between the charges at the terminations.

It is clear that $\bar{\boldsymbol{\mu}}$ depends on the charge accumulated at the terminations. Thus, it might be thought that upon chemical substitution at the terminations, q_R can be varied essentially arbitrarily (within chemical limits), thereby making all values of $\bar{\boldsymbol{\mu}}$

possible. However, that is not the case as may be seen from the following argument (Vanderbilt and King-Smith 1993; Kudin et al. 2007).

The first step is to transform the occupied orbitals into a set of maximally localized orthogonal functions, $\{w_{np}(\mathbf{r})\}$, which in C will approach Wannier functions as the system becomes larger. Here, w_{np} is the p th function localized primarily to the n th cell (in the terminal regions, the division into cells is arbitrary) which, however, may have tails sticking out into other cells. We can, then, write $\underline{\mu}$ as

$$\begin{aligned}
 \mu &= \sum_n \left[-\sum_p \int |w_{np}(\mathbf{r})|^2 \mathbf{r} d\mathbf{r} + \sum_m \mathbf{R}_{nm} Z_m \right] \\
 &= \sum_{n \in C} \left[-\sum_p \int |w_{np}(\mathbf{r})|^2 \mathbf{r} d\mathbf{r} + \sum_m \mathbf{R}_{nm} Z_m \right] \\
 &\quad + \mathbf{R}_L \sum_{n \in L} \left[-\sum_p \int |w_{np}(\mathbf{r})|^2 d\mathbf{r} + \sum_m Z_m \right] \\
 &\quad + \sum_{n \in L} \left[-\sum_p \int |w_{np}(\mathbf{r})|^2 (\mathbf{r} - \mathbf{R}_L) d\mathbf{r} + \sum_m Z_m (\mathbf{R}_{nm} - \mathbf{R}_L) \right] \\
 &\quad + \mathbf{R}_R \sum_{n \in R} \left[-\sum_p \int |w_{np}(\mathbf{r})|^2 d\mathbf{r} + \sum_m Z_m \right] \\
 &\quad + \sum_{n \in R} \left[-\sum_p \int |w_{np}(\mathbf{r})|^2 (\mathbf{r} - \mathbf{R}_R) d\mathbf{r} + \sum_m Z_m (\mathbf{R}_{nm} - \mathbf{R}_R) \right] \quad (12)
 \end{aligned}$$

where Z_m is the charge of the m th nucleus (independent of n) and \mathbf{R}_{nm} is the position of the m th nucleus in the n th cell. In Eq. (12), all integrals are over the complete space, but the orbital densities are localized to different regions, whereas in Eq. (10), the integrals are over different regions, but the (electron) densities are completely delocalized. In the last identity in Eq. (12), only the first, second, and fourth terms depend (linearly) on the size of the system, and therefore only these terms will contribute to the long-chain limit of the dipole moment per unit.

Using the w functions, the density matrix for the occupied orbitals can be written in block form,

$$\underline{\underline{D}} = \begin{pmatrix} \underline{\underline{D}}_L & \underline{\underline{0}} & \underline{\underline{0}} \\ \underline{\underline{0}} & \underline{\underline{D}}_C & \underline{\underline{0}} \\ \underline{\underline{0}} & \underline{\underline{0}} & \underline{\underline{D}}_R \end{pmatrix} \quad (13)$$

where each block $\underline{\underline{D}}_X$ is the density matrix for the region X and the submatrices $\underline{\underline{0}}$ contain elements that are exponentially vanishing as a function of the distance from

the boundary between the regions. As the w functions become closer to Wannier functions in C , \underline{D}_C will approach a diagonal matrix. This density matrix for the occupied orbitals, \underline{D} , is idempotent, so that each block \underline{D}_X is idempotent as well. Therefore, in the formulation of Eq. (12), the w functions centered in the terminal regions are associated with an integral number of electrons.

We, finally, add that the separation of the dipole moment per unit into a bulk part and a contribution from the terminations, Eq. (11), is not unique. The two uppermost panels in Fig. 3 show the same system but with different definitions of the unit cells in the central region. Thereby, different values for μ_C result. However, also the precise definition of the terminations is affected by the definition of the bulk unit cells, and, accordingly, the charge we associate with those, q_R , changes, too. Ultimately, the total dipole moment per unit, $\bar{\mu}$, is unchanged but the individual components are not.

Higher Dimensions

For quasi-two-dimensional and three-dimensional systems, we can use an approach very similar to that presented above with, however, a couple of important modifications.

In Fig. 4 we show a schematic representation of a two-dimensional system with a rectangular shape. We have split the system into a central region, side regions, and corner regions. The unit cells of each of the side regions will all be equivalent but in most cases larger than those of the central region. This can happen because of surface reconstructions [which can make the surface units larger both in direction(s) parallel to the surface and in the direction perpendicular to the surface] as well as

Fig. 4 Schematic representation of a two-dimensional system

the vacuum discontinuity (which will make the surface units larger/thicker in the direction perpendicular to the surface).

As above, the units of the central region are per construction neutral. This is not the case for either the side or the corner units, although each unit carries the same charge. With N_r being the number of surface units on the r th side and q_r being the charge of each of those units, charge neutrality gives that

$$\sum_r N_r q_r = 0, \tag{14}$$

where the r summation runs over all surfaces. This condition has the interesting consequence that two equivalent surfaces of two systems of the same material but differing in the shape may have different q_r values, i.e., the overall shape of the system dictates the possible surface charges on the individual sides.

In order to calculate the dipole moment per (bulk-size) unit, we proceed as in the previous subsection by studying the change in the dipole moment as the size of the system is increased. A general situation for a (quasi)-two-dimensional system is shown in Fig. 5. When the system is made larger, the r th surface is displaced the fraction f_r along the vector shown in the figure. This vector can be written as

$$\Delta \mathbf{R}_r = n_{ra} \cdot \mathbf{a} + n_{rb} \cdot \mathbf{b} \tag{15}$$

with \mathbf{a} and \mathbf{b} being the (bulk) lattice vectors and n_{ra} and n_{rb} being integers that describe the orientation of the r th side. The factors f_r are chosen so that the overall shape of the system remains unchanged. Through the displacement,

$$\Delta N_r = f_r N_r (n_{ra}^2 + n_{rb}^2) \tag{16}$$

Fig. 5 Schematic representation of the surface of a two-dimensional system. The two different panels differ in the definition of the bulk unit cell

Fig. 6 A detailed illustration of how the number of unit cells in a two-dimensional system changes when the surface is displaced. The surface is characterized by $(n_{sa}, n_{sb}) = (3, 2)$. This vector is shown in red in the upper, left panel. In this panel, we also show (in grey) the ΔN_s unit cells that are added when the surface is displaced. In the upper, right panel, we have marked with different grey tones different parts that are replaced in order to facilitate the determination of ΔN_s as demonstrated in the lower panel

bulk units have been added to the system. In Fig. 6, we illustrate this through an example for which $f_r = 1$. Similarly, the total dipole moment has changed by

$$\Delta \boldsymbol{\mu}_r = f_r N_r q_r \quad \Delta \mathbf{R}_r = f_r N_r q_r (n_{ra} \mathbf{a} + n_{rb} \mathbf{b}). \tag{17}$$

The contribution to the dipole moment per unit from all surfaces is found by summing this expression over all surfaces, and dividing this by the total number of additional units, i.e., the sum of the terms in Eq. (16) and by also including the dipole moment for a single central unit, we have the total dipole moment per unit,

$$\bar{\boldsymbol{\mu}} = \boldsymbol{\mu}_C + \frac{\sum_r f_r N_r q_r (n_{ra} \mathbf{a} + n_{rb} \mathbf{b})}{\sum_r f_r N_r (n_{ra}^2 + n_{rb}^2)}. \tag{18}$$

For three-dimensional systems, the arguments above can be repeated with only minor modifications. Thus, the system will be split into a central region as well as surface, edge, and corner regions (see Fig. 7). Of those, only the central region (whose units are neutral) as well as the charges on the surfaces will contribute to the dipole moment per unit,

$$\bar{\boldsymbol{\mu}} = \boldsymbol{\mu}_C + \frac{\sum_r f_r N_r q_r (n_{ra} \mathbf{a} + n_{rb} \mathbf{b} + n_{rc} \mathbf{c})}{\sum_r f_r N_r (n_{ra}^2 + n_{rb}^2 + n_{rc}^2)}, \tag{19}$$

where now three integers are needed to describe the orientation of each surface. In this case as well, the charges q_r can take any value as long as Eq. (14) is satisfied.

Fig. 7 The separation of a 3D rectangular sample into surface (*S*), edge (*E*), and corner (*C*) regions. The central region is not shown

The Dipole Moment for the Periodic Case

Despite some obvious difficulties, it is of interest to consider whether the systems discussed above can be approximated as being infinite and periodic when subject to an external electrostatic field. Per construction, such systems do not possess any surfaces. However, as we have seen, the dipole moment contains a non-negligible contribution from the surfaces. Moreover, such fields destroy the translational invariance making it even more questionable whether the translational symmetry can be of any use.

We shall, however, see that it indeed is possible to reintroduce the translational invariance and that the effects of the surfaces are included in the calculations. The approach we shall use is not trivial and shall accordingly be discussed in some detail.

In the absence of any field, the translational symmetry can be used in classifying the single-particle orbitals according to their symmetry properties upon translation, i.e., to write them as Bloch functions,

$$\psi_j(\mathbf{r}) = \psi_j(\mathbf{k}, \mathbf{r}) = e^{i\mathbf{k}\cdot\mathbf{r}} u_j(\mathbf{k}, \mathbf{r}), \tag{20}$$

where $u_j(\mathbf{k}, \mathbf{r})$ is a lattice-periodic function and where j is used in distinguishing different functions of the same \mathbf{k} . \mathbf{k} lies in the first Brillouin zone, but in a practical calculation one considers only a finite, discrete set of K \mathbf{k} values including $\mathbf{k} = \mathbf{0}$. K unit cells form the Born-von Kármán zone.

Often the orbitals of Eq. (20) are expanded in a set of atom-centered functions,

$$\begin{aligned} \psi_j(\mathbf{k}, \mathbf{r}) &= \sum_l c_{lj}(\mathbf{k}) \chi_l(\mathbf{k}, \mathbf{r}) \\ \chi_l(\mathbf{k}, \mathbf{r}) &= \lim_{N \rightarrow \infty} \frac{1}{\sqrt{N}} \sum_{\mathbf{n}} e^{i\mathbf{k}\cdot\mathbf{R}_n} \chi_{l,\mathbf{n}}(\mathbf{r}). \end{aligned} \tag{21}$$

Here, $\chi_{l,\mathbf{n}}(\mathbf{r})$ is the l th atom-centered function of the unit cell at lattice point $\mathbf{R}_{\mathbf{n}}$, and N is the number of lattice points in the \mathbf{n} summation.

The Single-Electron Case

In order to obtain an expression for the position operator, we start with a single electron occupying an orbital of the form of Eq. (20). As observed by Blount (1962), the effect of the position operator acting on this orbital may be represented through the relation

$$\mathbf{r} [e^{i\mathbf{k}\cdot\mathbf{r}} u_j(\mathbf{k}, \mathbf{r})] = [i e^{i\mathbf{k}\cdot\mathbf{r}} \nabla_{\mathbf{k}} e^{-i\mathbf{k}\cdot\mathbf{r}} - i \nabla_{\mathbf{k}}] [e^{i\mathbf{k}\cdot\mathbf{r}} u_j(\mathbf{k}, \mathbf{r})], \quad (22)$$

where $\nabla_{\mathbf{k}}$ is the gradient operator in \mathbf{k} space. However, in a practical calculation, we have only a discrete set of \mathbf{k} vectors at our disposal and will accordingly replace the \mathbf{k} derivatives with finite-difference approximations. Moreover, we shall consider a general function that is expanded in terms of the Bloch functions [ignoring an index j as in Eq. (21)],

$$\psi(\mathbf{r}) = \sum_l \sum_{\mathbf{k}} c_l(\mathbf{k}) \chi_l(\mathbf{k}, \mathbf{r}), \quad (23)$$

which corresponds to the Crystal Momentum Representation of Blount (1962). As Blount notes, the effect of using Eq. (23) for the position operator acting on a general ψ is given by

$$\begin{aligned} \mathbf{r}\psi(\mathbf{r}) &= \frac{1}{(2\pi)^3} \int e^{i\mathbf{k}\cdot\mathbf{r}} \mathbf{r} \sum_l c_l(\mathbf{k}) u_l(\mathbf{k}, \mathbf{r}) d\mathbf{k} \\ &= \frac{1}{(2\pi)^3} \int (-i) \sum_l \nabla_{\mathbf{k}} [c_l(\mathbf{k}) \psi_l(\mathbf{k}, \mathbf{r})] d\mathbf{k} \\ &\quad + \frac{1}{(2\pi)^3} \int i e^{i\mathbf{k}\cdot\mathbf{r}} \sum_l \nabla_{\mathbf{k}} [c_l(\mathbf{k}) u_l(\mathbf{k}, \mathbf{r})] d\mathbf{k}. \end{aligned} \quad (24)$$

It is convenient to take components along crystallographic axes. These may readily be transformed when necessary to obtain components along orthogonal directions. Then, if \hat{s}_1 refers to the finite-difference expression for the $i \nabla_{\mathbf{k}}$ term, we have

$$\begin{aligned} \hat{s}_1 \psi(\mathbf{r}) &= \hat{s}_1 \left[\sum_l \sum_{\mathbf{k}} c_l(\mathbf{k}) \chi_l(\mathbf{k}, \mathbf{r}) \right] = \sum_l \sum_{\mathbf{k}} \hat{s}_1 [c_l(\mathbf{k}) \chi_l(\mathbf{k}, \mathbf{r})] \\ &= i \sum_l \sum_{\mathbf{k}} \frac{c_l(\mathbf{k} + \Delta\mathbf{k}_s) \chi_l(\mathbf{k} + \Delta\mathbf{k}_s, \mathbf{r}) - c_l(\mathbf{k}) \chi_l(\mathbf{k}, \mathbf{r})}{\Delta k_s} \end{aligned} \quad (25)$$

where

$$\Delta k_s = \frac{2\pi}{a_s K_s} \quad (26)$$

is the spacing in \mathbf{k} space, the subscript s refers to the crystallographic direction, and a_s is the length of the lattice vector in direct space.

The finite-difference expression for the remaining gradient term may be written as

$$\begin{aligned} \hat{s}_2 \psi(\mathbf{r}) &= \hat{s}_2 \left[\sum_l \sum_{\mathbf{k}} c_l(\mathbf{k}) \chi_l(\mathbf{k}, \mathbf{r}) \right] = \sum_l \sum_{\mathbf{k}} \hat{s}_2 [c_l(\mathbf{k}) \chi_l(\mathbf{k}, \mathbf{r})] \\ &= i \sum_l \sum_{\mathbf{k}} e^{i\mathbf{k}\cdot\mathbf{r}} \frac{e^{-i(\mathbf{k}+\Delta\mathbf{k}_s)\cdot\mathbf{r}} c_l(\mathbf{k}+\Delta\mathbf{k}_s) \chi_l(\mathbf{k}+\Delta\mathbf{k}_s, \mathbf{r}) - e^{-i\mathbf{k}\cdot\mathbf{r}} c_l(\mathbf{k}) \chi_l(\mathbf{k}, \mathbf{r})}{\Delta k_s}. \end{aligned} \quad (27)$$

It is now easy to show that

$$\begin{aligned} \hat{s}_1 \psi(\mathbf{r}) &= i \sum_l \sum_{\mathbf{k}} \frac{c_l(\mathbf{k} + \Delta\mathbf{k}_s) \chi_l(\mathbf{k} + \Delta\mathbf{k}_s, \mathbf{r}) - c_l(\mathbf{k}) \chi_l(\mathbf{k}, \mathbf{r})}{\Delta k_s} \\ &= i \frac{1}{\Delta k_s} \left[\sum_l \sum_{\mathbf{k}} c_l(\mathbf{k} + \Delta\mathbf{k}_s) \chi_l(\mathbf{k} + \Delta\mathbf{k}_s, \mathbf{r}) - \sum_l \sum_{\mathbf{k}} c_l(\mathbf{k}) \chi_l(\mathbf{k}, \mathbf{r}) \right] \\ &= i \frac{1}{\Delta k_s} \left[\sum_l \sum_{\mathbf{k}'} c_l(\mathbf{k}') \chi_l(\mathbf{k}', \mathbf{r}) - \sum_l \sum_{\mathbf{k}} c_l(\mathbf{k}) \chi_l(\mathbf{k}, \mathbf{r}) \right] \\ &= 0 \end{aligned} \quad (28)$$

since the \mathbf{k} and \mathbf{k}' summations go over all \mathbf{k} in the first Brillouin zone and we have cyclic boundary conditions in \mathbf{k} space. Similarly,

$$\begin{aligned} \hat{s}_2 \psi(\mathbf{r}) &= i \sum_l \sum_{\mathbf{k}} e^{i\mathbf{k}\cdot\mathbf{r}} \frac{e^{-i(\mathbf{k}+\Delta\mathbf{k}_s)\cdot\mathbf{r}} c_l(\mathbf{k}+\Delta\mathbf{k}_s) \chi_l(\mathbf{k}+\Delta\mathbf{k}_s, \mathbf{r}) - e^{-i\mathbf{k}\cdot\mathbf{r}} c_l(\mathbf{k}) \chi_l(\mathbf{k}, \mathbf{r})}{\Delta k_s} \\ &= i \frac{1}{\Delta k_s} \left[\sum_l \sum_{\mathbf{k}} e^{-i\Delta\mathbf{k}_s\cdot\mathbf{r}} c_l(\mathbf{k}+\Delta\mathbf{k}_s) \chi_l(\mathbf{k}+\Delta\mathbf{k}_s, \mathbf{r}) - \sum_l \sum_{\mathbf{k}} c_l(\mathbf{k}) \chi_l(\mathbf{k}, \mathbf{r}) \right] \\ &= i \frac{1}{\Delta k_s} \left[e^{-i\Delta\mathbf{k}_s\cdot\mathbf{r}} \sum_l \sum_{\mathbf{k}} c_l(\mathbf{k}+\Delta\mathbf{k}_s) \chi_l(\mathbf{k}+\Delta\mathbf{k}_s, \mathbf{r}) - \sum_l \sum_{\mathbf{k}} c_l(\mathbf{k}) \chi_l(\mathbf{k}, \mathbf{r}) \right] \end{aligned}$$

$$\begin{aligned}
&= i \frac{1}{\Delta k_s} \left[e^{-i\Delta\mathbf{k}_s \cdot \mathbf{r}} \sum_l \sum_{\mathbf{k}'} c_l(\mathbf{k}') \chi_l(\mathbf{k}', \mathbf{r}) - \sum_l \sum_{\mathbf{k}} c_l(\mathbf{k}) \chi_l(\mathbf{k}, \mathbf{r}) \right] \\
&= i \frac{1}{\Delta k_s} [e^{-i\Delta\mathbf{k}_s \cdot \mathbf{r}} - 1] \sum_l \sum_{\mathbf{k}} c_l(\mathbf{k}) \chi_l(\mathbf{k}, \mathbf{r}) \\
&= \frac{i}{\Delta k_s} [e^{-i\Delta\mathbf{k}_s \cdot \mathbf{r}} - 1] \psi(\mathbf{r}). \tag{29}
\end{aligned}$$

The Many-Electron Case

We consider a system with

$$N = K \cdot N_e \tag{30}$$

electrons per Born-von Kármán (BvK) zone. Here, K is the number of unit cells per BvK zone, and N_e is the number of electrons per unit cell. The N -electron wave function is written as a single Slater determinant

$$\begin{aligned}
\Psi(\mathbf{x}_1, \mathbf{x}_2, \dots, \mathbf{x}_N) &= \frac{1}{\sqrt{N!}} \begin{vmatrix} \psi_1(\mathbf{x}_1) & \psi_2(\mathbf{x}_1) & \dots & \psi_N(\mathbf{x}_1) \\ \psi_1(\mathbf{x}_2) & \psi_2(\mathbf{x}_2) & \dots & \psi_N(\mathbf{x}_2) \\ \vdots & \vdots & \ddots & \vdots \\ \psi_1(\mathbf{x}_N) & \psi_2(\mathbf{x}_N) & \dots & \psi_N(\mathbf{x}_N) \end{vmatrix} \\
&= \frac{1}{\sqrt{N!}} \sum_P (-1)^P \psi_{l_1}(\mathbf{x}_1) \psi_{l_2}(\mathbf{x}_2) \dots \psi_{l_N}(\mathbf{x}_N) \\
&\equiv \hat{\mathcal{A}} [\psi_1(\mathbf{x}_1) \psi_2(\mathbf{x}_2) \dots \psi_N(\mathbf{x}_N)], \tag{31}
\end{aligned}$$

where \mathbf{x}_i is the usual combined position and spin coordinate and $\hat{\mathcal{A}}$ is the antisymmetrizing operator. Finally, the summation is over all permutations of the N indices of the single-particle orbitals, and P is the order of the permutation (either even or odd).

Each of the orbitals $\psi_j(\mathbf{x})$ is expanded in the Bloch functions,

$$\psi_j(\mathbf{x}) = \sum_l \sum_{\mathbf{k}} c_{lj}(\mathbf{k}) \chi_l(\mathbf{k}, \mathbf{x}). \tag{32}$$

Then, the terms in Eq. (31) can be written as

$$\begin{aligned}
\psi_{j_1}(\mathbf{x}_1) \psi_{j_2}(\mathbf{x}_2) \dots \psi_{j_N}(\mathbf{x}_N) &= \prod_n \psi_{j_n}(\mathbf{x}_n) \\
&= \prod_n \sum_{l_n} \sum_{\mathbf{k}_n} c_{l_n j_n}(\mathbf{k}_n) \chi_{l_n}(\mathbf{k}_n, \mathbf{x}_n). \tag{33}
\end{aligned}$$

Based on the same arguments as in the previous subsection, we define the N -electron operators \hat{S}_1 and \hat{S}_2 through

$$\begin{aligned} \hat{S}_1[\psi_{j_1}(\mathbf{x}_1)\psi_{j_2}(\mathbf{x}_2)\cdots\psi_{j_N}(\mathbf{x}_N)] &= \frac{i}{\Delta k_s} \left[\prod_n \sum_{l_n} \sum_{\mathbf{k}_n} c_{l_n j_n}(\mathbf{k}_n + \Delta \mathbf{k}_s) \chi_{l_n}(\mathbf{k}_n + \Delta \mathbf{k}_s, \mathbf{x}_n) \right. \\ &\quad \left. - i \prod_n \sum_{l_n} \sum_{\mathbf{k}_n} c_{l_n j_n}(\mathbf{k}_n) \chi_{l_n}(\mathbf{k}_n, \mathbf{x}_n) \right] = 0 \end{aligned} \quad (34)$$

and

$$\begin{aligned} &\hat{S}_2[\psi_{j_1}(\mathbf{x}_1)\psi_{j_2}(\mathbf{x}_2)\cdots\psi_{j_N}(\mathbf{x}_N)] \\ &= \frac{i}{\Delta k_s} \left[\exp\left(i \sum_n \mathbf{k}_n \cdot \mathbf{r}_n\right) \prod_n \sum_{l_n} \sum_{\mathbf{k}_n} \exp\left(-i \sum_n (\mathbf{k}_n + \Delta \mathbf{k}_s) \cdot \mathbf{r}_n\right) \right. \\ &\quad \left. \times c_{l_n j_n}(\mathbf{k}_n + \Delta \mathbf{k}_s) \chi_{l_n}(\mathbf{k}_n + \Delta \mathbf{k}_s, \mathbf{x}_n) \right. \\ &\quad \left. - i \exp\left(i \sum_n \mathbf{k}_n \cdot \mathbf{r}_n\right) \prod_n \sum_{l_n} \sum_{\mathbf{k}_n} \exp\left(-i \sum_n \mathbf{k}_n \cdot \mathbf{r}_n\right) c_{l_n j_n}(\mathbf{k}_n) \chi_{l_n}(\mathbf{k}_n, \mathbf{x}_n) \right] \\ &= \frac{i}{\Delta k_s} \left[\exp\left(-i \Delta \mathbf{k}_s \cdot \sum_n \mathbf{r}_n\right) - 1 \right] [\psi_{j_1}(\mathbf{x}_1)\psi_{j_2}(\mathbf{x}_2)\cdots\psi_{j_N}(\mathbf{x}_N)]. \end{aligned} \quad (35)$$

Thus,

$$\hat{S}_2\Psi(\mathbf{x}_1, \mathbf{x}_2, \dots, \mathbf{x}_N) = \frac{i}{\Delta k_s} \left[\exp\left(-i \Delta \mathbf{k}_s \cdot \sum_n \mathbf{r}_n\right) - 1 \right] \Psi(\mathbf{x}_1, \mathbf{x}_2, \dots, \mathbf{x}_N), \quad (36)$$

which means that

$$\begin{aligned} &\langle \Psi(\mathbf{x}_1, \mathbf{x}_2, \dots, \mathbf{x}_N) | \hat{S}_2 | \Psi(\mathbf{x}_1, \mathbf{x}_2, \dots, \mathbf{x}_N) \rangle \\ &= \frac{1}{N!} \frac{i}{\Delta k_s} \sum_{P_1, P_2} (-1)^{P_1+P_2} \langle \psi_{m_1}(\mathbf{x}_1) | e^{-i \Delta \mathbf{k}_s \cdot \mathbf{r}_1} | \psi_{j_1}(\mathbf{x}_1) \rangle \langle \psi_{m_2}(\mathbf{x}_2) | e^{-i \Delta \mathbf{k}_s \cdot \mathbf{r}_2} | \psi_{j_2}(\mathbf{x}_2) \rangle \\ &\quad \cdots \langle \psi_{m_N}(\mathbf{x}_N) | e^{-i \Delta \mathbf{k}_s \cdot \mathbf{r}_N} | \psi_{j_N}(\mathbf{x}_N) \rangle - \frac{i}{\Delta k_s} \\ &= \frac{i}{\Delta k_s} \sum_P (-1)^P \langle \psi_1(\mathbf{x}_1) | e^{-i \Delta \mathbf{k}_s \cdot \mathbf{r}_1} | \psi_{j_1}(\mathbf{x}_1) \rangle \langle \psi_2(\mathbf{x}_2) | e^{-i \Delta \mathbf{k}_s \cdot \mathbf{r}_2} | \psi_{j_2}(\mathbf{x}_2) \rangle \\ &\quad \cdots \langle \psi_N(\mathbf{x}_N) | e^{-i \Delta \mathbf{k}_s \cdot \mathbf{r}_N} | \psi_{j_N}(\mathbf{x}_N) \rangle - \frac{i}{\Delta k_s} \end{aligned}$$

$$\begin{aligned}
 &= \frac{i}{\Delta k_s} \begin{vmatrix} \langle \psi_1 | e^{-i \Delta \mathbf{k}_s \cdot \mathbf{r}} | \psi_1 \rangle & \langle \psi_1 | e^{-i \Delta \mathbf{k}_s \cdot \mathbf{r}} | \psi_2 \rangle & \dots & \langle \psi_1 | e^{-i \Delta \mathbf{k}_s \cdot \mathbf{r}} | \psi_N \rangle \\ \langle \psi_2 | e^{-i \Delta \mathbf{k}_s \cdot \mathbf{r}} | \psi_1 \rangle & \langle \psi_2 | e^{-i \Delta \mathbf{k}_s \cdot \mathbf{r}} | \psi_2 \rangle & \dots & \langle \psi_2 | e^{-i \Delta \mathbf{k}_s \cdot \mathbf{r}} | \psi_N \rangle \\ \vdots & \vdots & \ddots & \vdots \\ \langle \psi_N | e^{-i \Delta \mathbf{k}_s \cdot \mathbf{r}} | \psi_1 \rangle & \langle \psi_N | e^{-i \Delta \mathbf{k}_s \cdot \mathbf{r}} | \psi_2 \rangle & \dots & \langle \psi_N | e^{-i \Delta \mathbf{k}_s \cdot \mathbf{r}} | \psi_N \rangle \end{vmatrix} - \frac{i}{\Delta k_s} \\
 &\equiv \frac{i}{\Delta k_s} \left[\det \underline{S}_s^- - 1 \right]. \tag{37}
 \end{aligned}$$

The index s on \underline{S}_s^- specifies the direction in \mathbf{k} space so that \underline{S}_s^- can be interpreted as one of the components of a vector in three-dimensional space. Moreover, in the second identity, we have used the fact that one of the two summations P_1 and P_2 corresponds to interchanging the $\{\psi_{m_i}\}$ orbitals which is equivalent to interchanging the $\{x_i\}$ arguments of the orbitals. However, since these are “dummy” integration variables, the different permutations give the same contributions, and we can, accordingly, remove one of the summations when we simultaneously multiply with the number of such permutations, $N!$

We now make the approximation (Springborg et al. 2004) which is good in the limit $\Delta k_s \rightarrow 0$,

$$\begin{aligned}
 \frac{i}{\Delta k_s} \det \underline{S}_s^- &= \langle \Psi(\mathbf{x}_1, \mathbf{x}_2, \dots, \mathbf{x}_N) | \frac{i}{\Delta k_s} \exp \left(-i \Delta \mathbf{k}_s \cdot \sum_n \mathbf{r}_n \right) | \Psi(\mathbf{x}_1, \mathbf{x}_2, \dots, \mathbf{x}_N) \rangle \\
 &\simeq \frac{i}{\Delta k_s} \exp \left(\langle \Psi(\mathbf{x}_1, \mathbf{x}_2, \dots, \mathbf{x}_N) | -i \Delta \mathbf{k}_s \cdot \sum_n \mathbf{r}_n | \Psi(\mathbf{x}_1, \mathbf{x}_2, \dots, \mathbf{x}_N) \rangle \right), \tag{38}
 \end{aligned}$$

so that for the position operator per cell, we find

$$\begin{aligned}
 \frac{1}{K} \langle \Psi(\mathbf{x}_1, \mathbf{x}_2, \dots, \mathbf{x}_N) | \frac{\Delta \mathbf{k}_s}{\Delta k_s} \cdot \sum_n \mathbf{r}_n | \Psi(\mathbf{x}_1, \mathbf{x}_2, \dots, \mathbf{x}_N) \rangle &\simeq \frac{i}{K \Delta k_s} \ln \det \underline{S}_s^- \\
 &= -\frac{1}{K \Delta k_s} \text{Im} \ln \det \underline{S}_s^-, \tag{39}
 \end{aligned}$$

since the expression on the left-hand side must be real.

A special case arises when the single-particle orbitals are Bloch functions with a unique \mathbf{k} , cf. Eq. (20), whereby

$$\begin{aligned}
 \langle \psi_{j_1}(\mathbf{k}_1, \mathbf{x}) | e^{-i \Delta \mathbf{k}_s \cdot \mathbf{r}} | \psi_{j_2}(\mathbf{k}_2, \mathbf{x}) \rangle &= \delta_{\mathbf{k}_1, \mathbf{k}_2 - \Delta \mathbf{k}_s} \langle u_{j_1}(\mathbf{k}_1, \mathbf{x}) | u_{j_2}(\mathbf{k}_2, \mathbf{x}) \rangle \\
 &\simeq \langle u_{j_1}(\mathbf{k}_1, \mathbf{x}) | u_{j_2}(\mathbf{k}_1, \mathbf{x}) \rangle + \Delta \mathbf{k}_s \cdot \nabla_k u_{j_2}(\mathbf{k}_1, \mathbf{x}) \\
 &= \delta_{j_1, j_2} + \langle u_{j_1}(\mathbf{k}_1, \mathbf{x}) | \Delta \mathbf{k}_s \cdot \nabla_k u_{j_2}(\mathbf{k}_1, \mathbf{x}) \rangle. \tag{40}
 \end{aligned}$$

Here, we have kept only the lowest-order terms in Δk_s and used the orthonormality of the Bloch waves.

We now insert the approximation of Eq. (40) into the expression for $\det \underline{S}_s^-$. Then, when evaluating $\det \underline{S}_s^-$, one obtains a sum of $N!$ terms, each involving the product of N factors of the type of Eq. (40). Upon keeping only terms that are at most linear in Δk_s , we see that only the product of diagonal terms survives. Then,

$$\det \underline{S}_s^- \simeq 1 + \sum_j \sum_{\mathbf{k}} \Delta \mathbf{k}_s \cdot \langle u_j(\mathbf{k}, \mathbf{x}) | \nabla_{\mathbf{k}} u_j(\mathbf{k}, \mathbf{x}) \rangle, \quad (41)$$

so that

$$\begin{aligned} & \frac{1}{K} \langle \Psi(\mathbf{x}_1, \mathbf{x}_2, \dots, \mathbf{x}_N) | \frac{\Delta \mathbf{k}_s}{\Delta k_s} \cdot \sum_n \mathbf{r}_n | \Psi(\mathbf{x}_1, \mathbf{x}_2, \dots, \mathbf{x}_N) \rangle \\ & \simeq -\frac{1}{K \Delta k_s} \text{Im} \ln \det \underline{S}_s^- \\ & \simeq \frac{i}{K \Delta k_s} \ln \left[1 + \sum_j \sum_{\mathbf{k}} \Delta \mathbf{k}_s \cdot \langle u_j(\mathbf{k}, \mathbf{x}) | \nabla_{\mathbf{k}} u_j(\mathbf{k}, \mathbf{x}) \rangle \right] \\ & \simeq \frac{i}{K \Delta k_s} \sum_j \sum_{\mathbf{k}} \Delta \mathbf{k}_s \cdot \langle u_j(\mathbf{k}, \mathbf{x}) | \nabla_{\mathbf{k}} u_j(\mathbf{k}, \mathbf{x}) \rangle \\ & = \frac{i}{K} \sum_j \sum_{\mathbf{k}} \frac{\Delta \mathbf{k}_s}{\Delta k_s} \cdot \langle u_j(\mathbf{k}, \mathbf{x}) | \nabla_{\mathbf{k}} u_j(\mathbf{k}, \mathbf{x}) \rangle. \end{aligned} \quad (42)$$

This last expression can also be used in obtaining the energy due to an electrostatic field,

$$\begin{aligned} & \frac{1}{K} \langle \Psi(\mathbf{x}_1, \mathbf{x}_2, \dots, \mathbf{x}_N) | \mathbf{E} \cdot \sum_n \mathbf{r}_n | \Psi(\mathbf{x}_1, \mathbf{x}_2, \dots, \mathbf{x}_N) \rangle \\ & = \frac{i}{K} \sum_j \sum_{\mathbf{k}} \mathbf{E} \cdot \langle u_j(\mathbf{k}, \mathbf{x}) | \nabla_{\mathbf{k}} u_j(\mathbf{k}, \mathbf{x}) \rangle. \end{aligned} \quad (43)$$

The expression of Eq. (39) was originally proposed by Resta (1994), whereas that of Eq. (42) was proposed by Vanderbilt and King-Smith (1993) (King-Smith and Vanderbilt 1993). These expressions, which are at the roots of the so-called modern theory of polarization, were originally given without derivation. More recently, we have presented the mathematical derivations outlined above (Springborg et al. 2004).

Quasi-One-Dimensional Systems

It is useful to illustrate the findings above on quasi-one-dimensional systems, i.e., chains. However, as we shall see, there is an important difference between quasi-one-dimensional and higher-dimensional systems. We assume that the chain is

placed along the z axis and consider accordingly the z component of the dipole moment per unit. This is separated into an electronic and a nuclear contribution,

$$\bar{\mu}_z = \bar{\mu}_{zn} + \bar{\mu}_{ze}. \quad (44)$$

As demonstrated above, within a single-particle (Hartree-Fock or Kohn-Sham) picture, the electronic contribution can be written either as (Resta 1994)

$$\bar{\mu}_{ze} = \bar{\mu}_R \equiv -\frac{a}{2\pi} \text{Im} \ln \det \underline{\underline{S}}^+ = \frac{a}{2\pi} \text{Im} \ln \det \underline{\underline{S}}^- \quad (45)$$

or as (King-Smith and Vanderbilt 1993; Vanderbilt and King-Smith 1993)

$$\begin{aligned} \bar{\mu}_{ze} = \bar{\mu}_{\text{KSV}} &\equiv -\frac{i}{K} \sum_{k=1}^K \sum_{j=1}^B \langle u_j(k, \mathbf{r}) | \frac{\partial}{\partial k} u_j(k, \mathbf{r}) \rangle \\ &= -\frac{i}{K} \sum_{k=1}^K \sum_{j=1}^B \langle e^{-ikz} \psi_j(k, \mathbf{r}) | \frac{\partial}{\partial k} e^{-ikz} \psi_j(k, \mathbf{r}) \rangle, \end{aligned} \quad (46)$$

where B is the number of occupied bands and spin degeneracy is not assumed [notice the difference in the sign compared to Eq. (42) which is due to the negative electronic charge]. These expressions are valid only for systems with an energy gap between occupied and unoccupied orbitals, i.e., semiconductors and insulators.

In Eq. (45), we have two different, but equivalent, expressions that can both be derived using the approach of the previous subsection. In this equation, the dimension of the matrices $\underline{\underline{S}}^\pm$ is equal to the number of electrons per BvK zone (i.e., KB), and the elements when expressed in terms of the Bloch functions of Eq. (20) become

$$\begin{aligned} [S_{j_1 j_2}(k_1 k_2)]^\pm &= \langle \psi_{j_1}(k_1, \mathbf{r}) | e^{\pm i \Delta k z} | \psi_{j_2}(k_2, \mathbf{r}) \rangle \\ &= \delta_{k_1, k_2 \pm \Delta k} \langle \psi_{j_1}(k_1, \mathbf{r}) | e^{\pm i \Delta k z} | \psi_{j_2}(k_2, \mathbf{r}) \rangle \\ &= \delta_{k_1, k_2 \pm \Delta k} \langle u_{j_1}(k_1, \mathbf{r}) | u_{j_2}(k_2, \mathbf{r}) \rangle, \end{aligned} \quad (47)$$

where $\Delta k = \frac{2\pi}{Ka}$ is the spacing between the k points. Upon organizing the occupied Bloch waves in order of increasing k , the $\underline{\underline{S}}^\pm$ matrices have the simple structure shown in Fig. 8 with square blocks above and below the $k_1 = k_2$ diagonal (except at the corners). Thus, when using expression (45), the dipole moment per unit couples neighboring k points. Accordingly, when including an external electrostatic field according to Eq. (6), lattice periodicity is destroyed and, instead, one has to deal with the complete BvK zone. This may be contrasted with the expression of Eq. (46) that does not destroy lattice periodicity.

Fig. 8 Schematic presentation of the structure of the \underline{S}^\pm matrices when using Bloch functions as the basis. Only the elements inside the *shaded blocks* can be nonzero

Fig. 9 Schematic presentation of one set of equivalent Wannier functions for a quasi-one-dimensional system. The different functions are centered at different cells but otherwise equivalent. In the general case, there will be more sets of equivalent Wannier functions

In order to complete the picture, the nuclear contribution to the dipole moment per unit cell may be obtained simply as

$$\bar{\mu}_{zn} = \sum_m (Z_{mp} - pa) Q_m. \tag{48}$$

Here, Z_{mp} is the z component of the position of the m th nucleus in the p th unit cell, and Q_m is the nuclear charge. $\bar{\mu}_{zn}$ is independent of p .

It is useful to transform the set of K delocalized Bloch functions in Eq. (20) to a set of localized Wannier functions (see Fig. 9), i.e.,

$$w_{j,p}(\mathbf{r}) = \frac{1}{\sqrt{K}} \sum_{k=1}^K \psi_j(k, \mathbf{r}) e^{-ikap}$$

$$\psi_j(k, \mathbf{r}) = \frac{1}{\sqrt{K}} \sum_{p=1}^K w_{j,p}(\mathbf{r}) e^{ikap}. \tag{49}$$

Here, the Wannier function $w_{j,p}$ of the j th band is more or less localized to the p th unit inside the BvK zone. In terms of these functions, one can easily obtain

$$\begin{aligned}
 \bar{\mu}_{\text{KSV}} &= -\frac{i}{K} \sum_j \sum_k \langle u_j(k) | \frac{d}{dk} u_j(k) \rangle \\
 &= -\frac{i}{K^2} \sum_j \sum_{p_1, p_2} \sum_k e^{ika(p_2-p_1)} \langle w_{jp_1} | -i(z - ap_2) | w_{jp_2} \rangle \\
 &= -\frac{1}{K} \sum_j \sum_{p_1, p_2} \delta_{p_1, p_2} \langle w_{jp_1} | z - ap_2 | w_{jp_2} \rangle \\
 &= -\sum_{j=1}^B \langle w_{j,0}(\mathbf{r}) | z | w_{j,0}(\mathbf{r}) \rangle. \tag{50}
 \end{aligned}$$

(Notice the minus sign that originates from the negative charge of the electrons).

Alternatively, we may consider the LCAO approach of Eq. (21). Then

$$\begin{aligned}
 \bar{\mu}_{ze} &= \bar{\mu}_{\text{KSV}} \\
 &= -\frac{i}{K} \sum_j \sum_k \langle u_j(k, \mathbf{r}) | \frac{\partial}{\partial k} u_j(k, \mathbf{r}) \rangle \\
 &= -\frac{1}{K} \sum_{jm} \sum_k e^{ikma} \sum_{pq} c_{qj}^*(k) \left(\underbrace{\langle \chi_{q0} | z - ma | \chi_{pm} \rangle}_{\text{charge}} + i \underbrace{\langle \chi_{q0} | \chi_{pm} \rangle \frac{d}{dk}}_{\text{current}} \right) c_{pj}(k). \tag{51}
 \end{aligned}$$

Thereby we have split $\bar{\mu}_{ze}$ into so-called charge and current contributions. This separation can also be carried out including the nuclear part, which only affects the charge contribution, to give

$$\bar{\mu} = \bar{\mu}_{\text{charge}} + \bar{\mu}_{\text{current}}. \tag{52}$$

It can be shown analytically (Springborg and Kirtman 2011) that, for a large finite system, the charge contribution corresponds to that part of the dipole moment per unit that is associated with a central unit, i.e., μ_C of Eq. (11). Thus, the current contribution to the dipole moment per unit of the finite chain is due to the charge transfer between the termination regions, i.e., $q_R \cdot \mathbf{a}$ of Eq. (11), a proposition that has been verified numerically (Springborg and Kirtman 2008). This relation between the current term for the infinite, periodic system and the termination charges for the large, finite system leads to the interesting conclusion that covalently bonded systems with large band widths and delocalized electrons are those for which the largest surface charges can be found.

For our arguments, it is important to notice that each expression for the dipole moment per unit contains an unknown integer multiple of the lattice constant. In the expression of Eq. (45), $\text{Im} \ln \det \underline{S}^\pm$ is simply the phase of the complex number $\det \underline{S}^\pm$, which contains an unknown integer multiple of 2π . Thus, $\bar{\mu}_R$ is only

determined up to an integer times the lattice constant. Equivalently, in evaluating $\bar{\mu}_{\text{KSV}}$ of Eq. (46), we may modify each electronic orbital by a phase factor

$$\psi_j(k, \mathbf{r}) \rightarrow \psi_j(k, \mathbf{r})e^{i\phi_j(k)}. \quad (53)$$

The phases $\{\phi_j(k)\}$ are arbitrary except for satisfying

$$e^{i\phi_j(\pi/a)} = e^{i\phi_j(-\pi/a)} \quad (54)$$

or, equivalently,

$$\phi_j(\pi/a) = \phi_j(-\pi/a) + \tilde{n}_j \cdot 2\pi. \quad (55)$$

\tilde{n}_j is some integer. As a result, the dipole moment per unit is changed by an amount

$$-\tilde{n} \cdot a = -\sum_{j=1}^B \tilde{n}_j \cdot a. \quad (56)$$

This change arises entirely from the current term.

Finally, the expression for the dipole moment based on the Wannier functions in Eq. (49) also contains an equivalent additive integer. The reason is that the assignment of the localized functions to individual units is nonunique (see Fig. 9).

Higher Dimensions

In higher dimensions, we may use approaches similar to those above for each of the components of the dipole moment. Then, we will write

$$\mathbf{E} \cdot \bar{\boldsymbol{\mu}} = \sum_s E_s \bar{\mu}_s. \quad (57)$$

One possibility is to use expressions based on the $\underline{\underline{S}}_s^\pm$ matrices,

$$\bar{\mu}_s = \frac{\pm 1}{K \Delta k_s} \text{Im} \ln \det \underline{\underline{S}}_s^\pm. \quad (58)$$

In the d -dimensional case,

$$\Delta k_s \propto K^{-1/d}. \quad (59)$$

Therefore, the fact that $\text{Im} \ln \det \underline{\underline{S}}_s^\pm$ contains an undefined additive multiple of 2π means that $\bar{\mu}_s$ contains an undefined additive constant that only in the quasi-one-dimensional case ($d = 1$) becomes an additive multiple of the lattice constant.

Not surprising, this is also the case when using an expression like Eq. (46). We consider a substitution like that of Eq. (53) and replace the summation over all \mathbf{k} through an integration over the first Brillouin zone,

$$\begin{aligned}
 \mathbf{E} \cdot \bar{\boldsymbol{\mu}}_e &= -\frac{i}{K} \sum_{\mathbf{k}} \sum_{j=1}^B \langle e^{-i\mathbf{k}\cdot\mathbf{r}} \psi_j(\mathbf{k}, \mathbf{r}) | \mathbf{E} \cdot \nabla_{\mathbf{k}} e^{-i\mathbf{k}\cdot\mathbf{r}} \psi_j(\mathbf{k}, \mathbf{r}) \rangle \\
 &\rightarrow -\frac{i}{K} \sum_{\mathbf{k}} \sum_{j=1}^B \left[\langle e^{-i\mathbf{k}\cdot\mathbf{r}} \psi_j(\mathbf{k}, \mathbf{r}) | \mathbf{E} \cdot \nabla_{\mathbf{k}} e^{-i\mathbf{k}\cdot\mathbf{r}} \psi_j(\mathbf{k}, \mathbf{r}) \rangle \right. \\
 &\quad \left. + i \mathbf{E} \cdot \nabla_{\mathbf{k}} \phi_j(\mathbf{k}) \langle \psi_j(\mathbf{k}, \mathbf{r}) | \psi_j(\mathbf{k}, \mathbf{r}) \rangle \right] \\
 &= \mathbf{E} \cdot \bar{\boldsymbol{\mu}}_{e0} + \frac{1}{K} \sum_{\mathbf{k}} \sum_{j=1}^B \mathbf{E} \cdot \nabla_{\mathbf{k}} \phi_j(\mathbf{k}) \\
 &\rightarrow \mathbf{E} \cdot \bar{\boldsymbol{\mu}}_{e0} + \frac{1}{V_{\text{BZ}}} \sum_{j=1}^B \int_{1\text{BZ}} \mathbf{E} \cdot \nabla_{\mathbf{k}} \phi_j(\mathbf{k}) d\mathbf{k} \\
 &= \mathbf{E} \cdot \bar{\boldsymbol{\mu}}_{e0} + \frac{1}{V_{\text{BZ}}} \sum_{j=1}^B \int_{1\text{BZ}} \nabla_{\mathbf{k}} \cdot [\mathbf{E} \phi_j(\mathbf{k})] d\mathbf{k} \\
 &= \mathbf{E} \cdot \bar{\boldsymbol{\mu}}_{e0} + \frac{1}{V_{\text{BZ}}} \sum_{j=1}^B \int_{\delta 1\text{BZ}} \mathbf{1}_k \cdot [\mathbf{E} \phi_j(\mathbf{k})] d\mathbf{k} \\
 &= \mathbf{E} \cdot \bar{\boldsymbol{\mu}}_{e0} + \frac{1}{V_{\text{BZ}}} \sum_{j=1}^B \int_{\frac{1}{2}\delta 1\text{BZ}} \mathbf{1}_k \cdot \mathbf{E} [\phi_j(\mathbf{k}) - \phi_j(-\mathbf{k})] d\mathbf{k}. \quad (60)
 \end{aligned}$$

Here, $\bar{\boldsymbol{\mu}}_{e0}$ is the reference value before the substitution of Eq. (53), V_{BZ} is the volume of the first Brillouin zone, and we have used Gauss' theorem (the divergence theorem) to change the volume integral (labelled "1BZ") into an integral over the surface of the first Brillouin zone (labelled " $\delta 1\text{BZ}$ ") with $\mathbf{1}_k$ being an outwards pointing normal. We also utilize the fact that the integral over the complete surface of the first Brillouin zone can be written as a sum of two integrals, each over one half of the first Brillouin zone (labelled " $\frac{1}{2}\delta 1\text{BZ}$ "). Finally, based on the continuity in \mathbf{k} space,

$$\psi_j(\mathbf{k}, \mathbf{r}) = \psi_j(\mathbf{G} + \mathbf{k}, \mathbf{r}) \quad (61)$$

(with \mathbf{G} a lattice vector in reciprocal space), we define the integers

$$\phi_j(\mathbf{k}) - \phi_j(-\mathbf{k}) = 2\pi n_j(\mathbf{k}) \quad (62)$$

for \mathbf{k} on the boundary of the first Brillouin zone. Then, Eq. (60) becomes

$$\mathbf{E} \cdot \bar{\boldsymbol{\mu}}_e \rightarrow \mathbf{E} \cdot \bar{\boldsymbol{\mu}}_{e0} + \frac{2\pi}{V_{\text{BZ}}} \sum_{j=1}^B \int_{\frac{1}{2}\delta\text{1BZ}} \mathbf{1}_k \cdot \mathbf{E} n_j(\mathbf{k}) d\mathbf{k}. \quad (63)$$

As above, this expression also demonstrates that the dipole moment contains an additive constant that can take any value.

The Single-Particle Equations in the Periodic Case

For any large, finite, molecular system in the presence of a uniform electrostatic field, the electronic energy may be written, within the Born-Oppenheimer approximation, as $\langle \Psi | \hat{H}_e | \Psi \rangle - \langle \Psi | \mathbf{E} \cdot \hat{\boldsymbol{\mu}}_e | \Psi \rangle$. Here \hat{H}_e and $\hat{\boldsymbol{\mu}}_e$ are the usual field-free electronic Hamilton operator and the operator for the electronic part of the dipole moment, respectively. We use a single-particle (Hartree-Fock or Kohn-Sham) approach so that Ψ is the Slater determinant containing all the occupied single-particle orbitals. The latter are, then, expanded in a set of basis functions,

$$\psi_j(\mathbf{x}) = \sum_l c_{lj} \chi_l(\mathbf{x}). \quad (64)$$

As is standard, the expansion coefficients are determined by requiring that

$$\frac{\partial}{\partial c_{mp}^*} \left[\langle \Psi | \hat{H}_e | \Psi \rangle - \langle \Psi | \mathbf{E} \cdot \hat{\boldsymbol{\mu}}_e | \Psi \rangle - \sum_{mn} \lambda_{mn} (\langle \psi_m | \psi_n \rangle - \delta_{m,n}) \right] = 0. \quad (65)$$

For the infinite, periodic system, $\langle \Psi | \mathbf{E} \cdot \hat{\boldsymbol{\mu}}_e | \Psi \rangle$ becomes a nontrivial expression. We may choose between using expressions based either on the S_{\pm}^{\pm} matrices or on the ∇_k operators. In the former case, \mathbf{k} is no longer a good quantum number, and the secular equation becomes an eigenvalue equation with the dimension of the BvK zone (Springborg and Kirtman 2008). Moreover, the resulting single-particle equations become highly nonlinear in the orbital expansion coefficients. Therefore, we do not follow this approach but consider instead

$$\langle \Psi | \mathbf{E} \cdot \bar{\boldsymbol{\mu}}_e | \Psi \rangle = -\frac{i}{K} \sum_{\mathbf{k}} \sum_{j=1}^B \langle e^{-i\mathbf{k}\cdot\mathbf{r}} \psi_j(\mathbf{k}, \mathbf{r}) | \mathbf{E} \cdot \nabla_k | e^{-i\mathbf{k}\cdot\mathbf{r}} \psi_j(\mathbf{k}, \mathbf{r}) \rangle. \quad (66)$$

The Dipole Moment Operator

The expression of Eq. (66) corresponds to a single-particle, dipole moment operator for the electrons of the form

$$\hat{\boldsymbol{\mu}}_e = i e^{i\mathbf{k}\cdot\mathbf{r}} \nabla_k e^{-i\mathbf{k}\cdot\mathbf{r}}. \quad (67)$$

It is worthwhile to discuss the properties of this operator. In this connection, we consider two operators, namely,

$$\begin{aligned}\hat{S}_1 &= i \nabla_k \\ \hat{S}_2 &= i e^{i\mathbf{k}\cdot\mathbf{r}} \nabla_k e^{-i\mathbf{k}\cdot\mathbf{r}}\end{aligned}\quad (68)$$

and let them act on the functions

$$f_m(\mathbf{k}, \mathbf{r}) = e^{i\mathbf{k}\cdot\mathbf{r}} u_m(\mathbf{k}, \mathbf{r}) \quad (69)$$

with $u_m(\mathbf{k}, \mathbf{r})$ being lattice periodic. We also define

$$\begin{aligned}S_{mn}(\mathbf{k}) &= \langle f_m(\mathbf{k}, \mathbf{r}) | f_n(\mathbf{k}, \mathbf{r}) \rangle \\ &= \langle e^{i\mathbf{k}\cdot\mathbf{r}} u_m(\mathbf{k}, \mathbf{r}) | e^{i\mathbf{k}\cdot\mathbf{r}} u_n(\mathbf{k}, \mathbf{r}) \rangle \\ &= \langle u_m(\mathbf{k}, \mathbf{r}) | u_n(\mathbf{k}, \mathbf{r}) \rangle.\end{aligned}\quad (70)$$

Then, we may obtain two alternative expressions for $i \nabla_k S_{mn}(\mathbf{k})$, i.e.,

$$\begin{aligned}i \nabla_k S_{mn}(\mathbf{k}) &= \langle -i \nabla_k f_m(\mathbf{k}, \mathbf{r}) | f_n(\mathbf{k}, \mathbf{r}) \rangle + \langle f_m(\mathbf{k}, \mathbf{r}) | i \nabla_k f_n(\mathbf{k}, \mathbf{r}) \rangle \\ &= -\langle f_n(\mathbf{k}, \mathbf{r}) | i \nabla_k f_m(\mathbf{k}, \mathbf{r}) \rangle^* + \langle f_m(\mathbf{k}, \mathbf{r}) | i \nabla_k f_n(\mathbf{k}, \mathbf{r}) \rangle \\ &= -\langle f_n(\mathbf{k}, \mathbf{r}) | i \nabla_k | f_m(\mathbf{k}, \mathbf{r}) \rangle^* + \langle f_m(\mathbf{k}, \mathbf{r}) | i \nabla_k | f_n(\mathbf{k}, \mathbf{r}) \rangle \\ &= -\langle f_n(\mathbf{k}, \mathbf{r}) | \hat{S}_1 | f_m(\mathbf{k}, \mathbf{r}) \rangle^* + \langle f_m(\mathbf{k}, \mathbf{r}) | \hat{S}_1 | f_n(\mathbf{k}, \mathbf{r}) \rangle\end{aligned}\quad (71)$$

as well as

$$\begin{aligned}i \nabla_k S_{mn}(\mathbf{k}) &= \langle -i \nabla_k u_m(\mathbf{k}, \mathbf{r}) | u_n(\mathbf{k}, \mathbf{r}) \rangle + \langle u_m(\mathbf{k}, \mathbf{r}) | i \nabla_k u_n(\mathbf{k}, \mathbf{r}) \rangle \\ &= -\langle u_n(\mathbf{k}, \mathbf{r}) | i \nabla_k u_m(\mathbf{k}, \mathbf{r}) \rangle^* + \langle u_m(\mathbf{k}, \mathbf{r}) | i \nabla_k u_n(\mathbf{k}, \mathbf{r}) \rangle \\ &= -\langle e^{-i\mathbf{k}\cdot\mathbf{r}} f_n(\mathbf{k}, \mathbf{r}) | i \nabla_k e^{-i\mathbf{k}\cdot\mathbf{r}} f_m(\mathbf{k}, \mathbf{r}) \rangle^* \\ &\quad + \langle e^{-i\mathbf{k}\cdot\mathbf{r}} f_m(\mathbf{k}, \mathbf{r}) | i \nabla_k e^{-i\mathbf{k}\cdot\mathbf{r}} f_n(\mathbf{k}, \mathbf{r}) \rangle \\ &= -\langle f_n(\mathbf{k}, \mathbf{r}) | i e^{i\mathbf{k}\cdot\mathbf{r}} \nabla_k e^{-i\mathbf{k}\cdot\mathbf{r}} | f_m(\mathbf{k}, \mathbf{r}) \rangle^* \\ &\quad + \langle f_m(\mathbf{k}, \mathbf{r}) | e^{i\mathbf{k}\cdot\mathbf{r}} i \nabla_k e^{-i\mathbf{k}\cdot\mathbf{r}} | f_n(\mathbf{k}, \mathbf{r}) \rangle \\ &= -\langle f_n(\mathbf{k}, \mathbf{r}) | \hat{S}_2 | f_m(\mathbf{k}, \mathbf{r}) \rangle^* + \langle f_m(\mathbf{k}, \mathbf{r}) | \hat{S}_2 | f_n(\mathbf{k}, \mathbf{r}) \rangle.\end{aligned}\quad (72)$$

Thus, only for functions satisfying

$$\nabla_k S_{mn}(\mathbf{k}) = \mathbf{0}, \quad (73)$$

can we say that the operators \hat{s}_1 and \hat{s}_2 are hermitian. That is true, for example, in the case of the orthonormal band orbitals. On the other hand,

$$\hat{s}_2 - \hat{s}_1 = \mathbf{r} \quad (74)$$

is always hermitian.

However, in a practical calculation, we ignore \hat{s}_1 of the reasons discussed in section “The Single-Electron Case” and let \hat{s}_2 act on Bloch functions formed from atom-centered orbitals, and as a result, Eq. (73) is not necessarily satisfied. Therefore, we make the replacement

$$\hat{s}_2 \rightarrow \frac{1}{2} (\hat{s}_2^\dagger + \hat{s}_2). \quad (75)$$

If the single-particle orbitals, $\{\psi_j\}$, are written as a linear combination of Bloch functions of atomic orbitals:

$$\psi_j(\mathbf{x}) = \psi_j(\mathbf{k}, \mathbf{x}) = \sum_l c_{lj}(\mathbf{k}) \chi_l(\mathbf{k}, \mathbf{x}) = \lim_{N \rightarrow \infty} \sum_l c_{lj}(\mathbf{k}) \frac{1}{\sqrt{N}} \sum_{\mathbf{n}} e^{i\mathbf{k} \cdot \mathbf{R}_n} \chi_{l,\mathbf{n}}(\mathbf{r}), \quad (76)$$

then

$$\begin{aligned} & \langle \Psi | \mathbf{E} \cdot \bar{\boldsymbol{\mu}}_e | \Psi \rangle \\ &= -\frac{i}{K} \sum_{\mathbf{k}} \sum_{j=1}^B \langle \psi_j(\mathbf{k}, \mathbf{r}) | \mathbf{E} \cdot \frac{1}{2} (\hat{s}_2^\dagger + \hat{s}_2) | \psi_j(\mathbf{k}, \mathbf{r}) \rangle \\ &= \lim_{N \rightarrow \infty} \frac{1}{2N} \sum_{\mathbf{k}} \sum_{j=1}^B \sum_{l_1, l_2} \sum_{\mathbf{n}_1, \mathbf{n}_2} e^{i\mathbf{k} \cdot (\mathbf{R}_{\mathbf{n}_2} - \mathbf{R}_{\mathbf{n}_1})} \\ & \quad \times \left\{ c_{l_1 j}^*(\mathbf{k}) c_{l_2 j}(\mathbf{k}) \left[\langle \chi_{l_1, \mathbf{n}_1} | \mathbf{E} \cdot (\mathbf{r} - \mathbf{R}_{\mathbf{n}_2}) | \chi_{l_2, \mathbf{n}_2} \rangle + \langle \chi_{l_1, \mathbf{n}_1} | \mathbf{E} \cdot (\mathbf{r} - \mathbf{R}_{\mathbf{n}_1}) | \chi_{l_2, \mathbf{n}_2} \rangle \right] \right. \\ & \quad \left. + i \left[-\mathbf{E} \cdot (\nabla_{\mathbf{k}} c_{l_1 j}^*(\mathbf{k})) c_{l_2 j}(\mathbf{k}) + c_{l_1 j}^*(\mathbf{k}) \mathbf{E} \cdot \nabla_{\mathbf{k}} c_{l_2 j}(\mathbf{k}) \right] \langle \chi_{l_1, \mathbf{n}_1} | \chi_{l_2, \mathbf{n}_2} \rangle \right\}. \quad (77) \end{aligned}$$

It is convenient to introduce the dipole matrix elements

$$\begin{aligned} \mathbf{M}_{l_1, l_2}(\mathbf{k}) &= \lim_{N \rightarrow \infty} \sum_{\mathbf{n}} e^{i\mathbf{k} \cdot \mathbf{R}_n} \langle \chi_{l_1, \mathbf{0}} | \mathbf{r} - \mathbf{R}_n | \chi_{l_2, \mathbf{n}} \rangle \\ &= \lim_{N \rightarrow \infty} \sum_{\mathbf{n}} e^{-i\mathbf{k} \cdot \mathbf{R}_n} \langle \chi_{l_1, \mathbf{n}} | \mathbf{r} | \chi_{l_2, \mathbf{0}} \rangle \quad (78) \end{aligned}$$

as well as the overlap matrix elements

$$\begin{aligned} S_{l_1, l_2}(\mathbf{k}) &= \lim_{N \rightarrow \infty} \sum_{\mathbf{n}} e^{i\mathbf{k} \cdot \mathbf{R}_n} \langle \chi_{l_1, \mathbf{0}} | \chi_{l_2, \mathbf{n}} \rangle \\ &= \lim_{N \rightarrow \infty} \sum_{\mathbf{n}} e^{-i\mathbf{k} \cdot \mathbf{R}_n} \langle \chi_{l_1, \mathbf{n}} | \chi_{l_2, \mathbf{0}} \rangle. \end{aligned} \quad (79)$$

In terms of these matrix elements, Eq. (77) becomes

$$\begin{aligned} &\langle \Psi | \mathbf{E} \cdot \bar{\boldsymbol{\mu}}_e | \Psi \rangle \\ &= \frac{1}{2} \sum_{\mathbf{k}} \sum_{j=1}^B \sum_{l_1, l_2} \left\{ c_{l_1 j}^*(\mathbf{k}) c_{l_2 j}(\mathbf{k}) \mathbf{E} \cdot [\mathbf{M}_{l_1, l_2}(\mathbf{k}) + \mathbf{M}_{l_2, l_1}^*(\mathbf{k})] \right. \\ &\quad \left. + i \left[-\mathbf{E} \cdot (\nabla_{\mathbf{k}} c_{l_1 j}^*(\mathbf{k})) c_{l_2 j}(\mathbf{k}) + c_{l_1 j}^*(\mathbf{k}) \mathbf{E} \cdot \nabla_{\mathbf{k}} c_{l_2 j}(\mathbf{k}) \right] S_{l_1, l_2}(\mathbf{k}) \right\}. \end{aligned} \quad (80)$$

The Secular Equation

The secular equation is obtained by taking the derivative of the total electronic energy with respect to an orbital expansion coefficient, $c_{l_p j_p}^*(\mathbf{k}_p)$, similar to what was done for the finite system in Eq. (65). Except for the term that depends explicitly on the electrostatic field, the “standard” approach may be followed. It is more difficult, however, to treat the electrostatic field term given in Eq. (80). For the sake of simplicity that is done below for the quasi-one-dimensional case:

$$\begin{aligned} &\langle \Psi | E \bar{\mu}_{ez} | \Psi \rangle \\ &= \frac{1}{2} \sum_k \sum_{j=1}^B \sum_{l_1, l_2} \left\{ c_{l_1 j}^*(k) c_{l_2 j}(k) E \cdot [M_{l_1, l_2}(k) + M_{l_2, l_1}^*(k)] \right. \\ &\quad \left. + i \left[-E \cdot \frac{d}{dk} c_{l_1 j}^*(k) c_{l_2 j}(k) + c_{l_1 j}^*(k) E \cdot \frac{d}{dk} c_{l_2 j}(k) \right] S_{l_1, l_2}(k) \right\}. \end{aligned} \quad (81)$$

If we use

$$\begin{aligned} &\frac{\partial}{\partial c_{l_p j_p}^*(k_p)} \sum_k \sum_{j=1}^B \sum_{l_1, l_2} i E \cdot \frac{d}{dk} c_{l_1 j}^*(k) c_{l_2 j}(k) S_{l_1, l_2}(k) \\ &\simeq \frac{\partial}{\partial c_{l_p j_p}^*(k_p)} \sum_k \sum_{j=1}^B \sum_{l_1, l_2} i E \cdot \frac{c_{l_1 j}^*(k + \Delta k) - c_{l_1 j}^*(k)}{\Delta k} c_{l_2 j}(k) S_{l_1, l_2}(k) \end{aligned}$$

$$\begin{aligned}
&= \sum_{l_2} iE \cdot \frac{c_{l_2 j_p}(k_p - \Delta k) S_{l_p, l_2}(k_p - \Delta k) - c_{l_2 j_p}(k_p) S_{l_p, l_2}(k_p)}{\Delta k} \\
&\simeq - \sum_{l_2} iE \cdot \frac{d}{dk} [c_{l_2 j_p}(k_p) S_{l_p, l_2}(k_p)]. \tag{82}
\end{aligned}$$

then

$$\begin{aligned}
&\frac{\partial}{\partial c_{l_p j_p}^*(k_p)} \langle \Psi | E \bar{\mu}_{ez} | \Psi \rangle \\
&= \frac{1}{2} \sum_{l_2} \left\{ c_{l_2 j_p}(k_p) E \cdot \left[M_{l_p, l_2}(k_p) + M_{l_2, l_p}^*(k_p) + i \frac{d}{dk} S_{l_p, l_2}(k_p) \right] \right. \\
&\quad \left. + iE [S_{l_p, l_2}(k_p) + S_{l_p, l_2}(k_p)] \frac{dc_{l_2 j_p}(k_p)}{dk} \right\}. \tag{83}
\end{aligned}$$

We have

$$M_{l_p, l_2}(k_p) + M_{l_2, l_p}^*(k_p) + i \frac{d}{dk} S_{l_p, l_2}(k_p) = 2M_{l_p, l_2}(k_p) \tag{84}$$

so that in the general one-, two-, or three-dimensional case, we have the following contribution to the secular equation from the electrostatic field

$$\sum_{l_2} \left[\mathbf{E} \cdot \mathbf{M}_{l_p, l_2}(\mathbf{k}_p) c_{l_2 j_p}(\mathbf{k}_p) + i S_{l_p, l_2}(\mathbf{k}_p) \mathbf{E} \cdot \nabla_{\mathbf{k}} c_{l_2 j_p}(\mathbf{k}_p) \right]. \tag{85}$$

This expression is actually the one we would obtain when using \hat{s}_2 directly without making the substitution of Eq. (75).

With this, the single-particle equations become

$$\left(\underline{\underline{F}}(\mathbf{k}) + \mathbf{E} \cdot \left[\underline{\underline{M}}(\mathbf{k}) + i \underline{\underline{S}}(\mathbf{k}) \nabla_{\mathbf{k}} \right] \right) \cdot \underline{\underline{c}}_j(\mathbf{k}) = \epsilon_j(\mathbf{k}) \cdot \underline{\underline{S}}(\mathbf{k}) \cdot \underline{\underline{c}}_j(\mathbf{k}). \tag{86}$$

Here, $\underline{\underline{F}}$ is the “standard” Fock (or Kohn-Sham) matrix although evaluated using the field-containing orbitals.

The Vector Potential Approach

Originally (Kirtman et al. 2000), Eq. (86) was derived using a vector potential approach in describing the effects of the external electric field (see section The Gauge). This approach allows for a simple treatment of dynamic, in addition to static, electric fields and shall therefore be briefly described here.

For the infinite, periodic system exposed to a time-dependent vector potential, the time-dependent single-particle equations are

$$\left(\hat{F} - i \frac{\partial}{\partial t}\right) \psi_{j_1}(\mathbf{k}, \mathbf{r}, t) = \sum_{j_2} \epsilon_{j_2 j_1}(k, t) \psi_{j_2}(\mathbf{k}, \mathbf{r}, t) \quad (87)$$

and, using the LCAO expansion of Eq. (64),

$$\begin{aligned} \underline{\underline{F}}(\mathbf{k}, t) \cdot \underline{\underline{c}}(\mathbf{k}, t) - \mathbf{E}(t) \cdot \left[\underline{\underline{M}}(\mathbf{k}) \cdot \underline{\underline{c}}(\mathbf{k}, t) + i \underline{\underline{S}}(\mathbf{k}) \nabla_k \underline{\underline{c}}(\mathbf{k}, t) \right] - i \underline{\underline{S}}(\mathbf{k}) \frac{\partial}{\partial t} \underline{\underline{c}}(\mathbf{k}, t) \\ = \underline{\underline{S}}(\mathbf{k}) \cdot \underline{\underline{c}}(\mathbf{k}, t) \cdot \underline{\underline{c}}(\mathbf{k}, t). \end{aligned} \quad (88)$$

Here, $\mathbf{E}(t)$ is the electric field obtained by taking the time derivative of the vector potential. As will be discussed in a later section, Eq. (88) offers an approach wherein the response to dynamic electric fields may be treated using perturbation theory. It is also valid in the limit of a static field, i.e., $\mathbf{E}(t)$ is time-independent. In that case, one arrives at Eq. (86). By solving for the linear and quadratic response to such fields, the linear and nonlinear static hyperpolarizabilities may be calculated. In addition, the same calculations determine infrared (Maschio et al. 2012, 2013) and Raman (Maschio et al. 2013) vibrational intensities. It should be noted that the latter are found by taking advantage of interchange-type relations that avoid having to solve equations for the response to the various vibrational displacements. This leads to a very efficient, fully analytical, procedure.

Solving the Secular Equation

We shall now return to the electrostatic field case. Because of the ∇_k term, Eq. (86) is not a standard matrix-eigenvalue problem. However, by using the normalization condition

$$\underline{\underline{1}} = \underline{\underline{c}}^\dagger(\mathbf{k}) \cdot \underline{\underline{S}}(\mathbf{k}) \cdot \underline{\underline{c}}(\mathbf{k}), \quad (89)$$

one can obtain

$$\underline{\underline{S}}(\mathbf{k}) \nabla_k \underline{\underline{c}}(\mathbf{k}) = \left\{ \underline{\underline{S}}(\mathbf{k}) \left[\nabla_k \underline{\underline{c}}(\mathbf{k}) \right] \underline{\underline{c}}^\dagger(\mathbf{k}) \underline{\underline{S}}(\mathbf{k}) \right\} \underline{\underline{c}}(\mathbf{k}), \quad (90)$$

whereby Eq. (86) can be cast into the standard form. In that case, the term in the curly brackets in Eq. (90) (as well as the Fock matrix) has to be treated self-consistently.

Even after the reformulation of Eq. (90), the \mathbf{k} derivatives of the orbital expansion coefficients are needed. As indicated, Eq. (86) conforms with the lattice periodicity so that \mathbf{k} is a good quantum number. Thus, in a practical calculation, one will solve

Eq. (86) [with the modification of Eq. (90)] for each \mathbf{k} point separately. Ultimately, this means that the orbital expansion coefficients may contain essentially arbitrary phase factors and, for \mathbf{k} where bands are crossing, more or less random linear combinations of the degenerate orbitals are determined. When calculating the \mathbf{k} derivatives of the orbital coefficients numerically (which is the way we shall do it), the phase factor and band-crossing issues can make the numerical derivatives highly inaccurate.

In order to circumvent the above problems, we have developed a smoothing technique (Springborg and Kirtman 2008) with which band-crossings and degeneracies are treated. Subsequently, the orbital expansion coefficients are modified according to

$$c_{lj}(\mathbf{k}) \rightarrow c_{lj}(\mathbf{k})e^{i\phi_j(\mathbf{k})} \quad (91)$$

so that the coefficients of neighboring \mathbf{k} points become maximally similar. This smoothing is a multistep procedure that will not be described in detail here.

In a practical calculation, we have an equidistant set of \mathbf{k} points in the three directions of \mathbf{k} space. Then, a derivative can be obtained as

$$\frac{\partial f(\mathbf{k})}{\partial k_s} \simeq \frac{1}{2\Delta k_s} \sum_{n=1}^{N_k} w_{n,N_k}^{(1)} [f(\mathbf{k} + n \cdot \Delta \mathbf{k}_s) - f(\mathbf{k} - n \cdot \Delta \mathbf{k}_s)]. \quad (92)$$

Here, s defines the direction in \mathbf{k} space and $\Delta \mathbf{k}_s$ is the spacing in that direction with the length Δk_s . A set of weight coefficients $\{w_{n,N_k}^{(1)}\}$ has been given by Dvornikov (2007) and by Khan and Ohba (2000),

$$w_{n,N_k}^{(1)} = \frac{1}{n\pi_n(N_k)} \quad (93)$$

with

$$\pi_n(N_k) = \prod_{k=1, k \neq n}^{N_k} \left(1 - \frac{n^2}{k^2}\right). \quad (94)$$

Alternative expressions (differing in the values of the weight factors $w_{n,N_k}^{(1)}$) were given later by Li (2005). Both formulas are based on expanding the function of interest $f(\mathbf{k})$ in some power or polynomial series about the point of interest at which the derivative(s) are calculated and, subsequently, differentiating the fitting function. However, as pointed out by Press et al. (1992), even if the function $f(\mathbf{k})$ is well behaved for real values of \mathbf{k} and we are only interested in such values, the existence of poles for complex \mathbf{k} can make such an approach unreliable. In fact, model calculations for a two-band system with an avoided band-crossing (in which all quantities are determined analytically) demonstrate that the treatments of Dvornikov, Khan and Ohba, and Li are inaccurate exactly at those \mathbf{k} that are

in the neighborhood of the avoided band-crossing where the derivatives $\frac{\partial f(\mathbf{k})}{\partial k_s}$ are numerically largest. So we use, instead, a rational approximation

$$f(\mathbf{k} + \Delta\mathbf{k}) \simeq \frac{a_0 + a_1|\Delta\mathbf{k}| + a_2|\Delta\mathbf{k}|^2 + \dots + a_N|\Delta\mathbf{k}|^N}{1 + b_1|\Delta\mathbf{k}| + b_2|\Delta\mathbf{k}|^2 + \dots + b_N|\Delta\mathbf{k}|^N}. \tag{95}$$

That the polynomials in the numerator and denominator are of the same order is not a necessity but we have made that choice. The $2N + 1$ unknown coefficients $a_0, a_1, a_2, \dots, a_N$ and b_1, b_2, \dots, b_N are determined by requiring that Eq. (95) is exactly satisfied for

$$\Delta\mathbf{k} = n\Delta\mathbf{k}_s, \quad n = -N, -N + 1, \dots, N - 1, N \tag{96}$$

for which we have the exact values of $f(\mathbf{k} + \Delta\mathbf{k})$. This condition can be written as a set of linear equations,

$$\sum_{j=0}^N a_j |n\Delta\mathbf{k}_s|^j - \sum_{j=1}^N b_j |n\Delta\mathbf{k}_s|^j f(\mathbf{k} + n\Delta\mathbf{k}_s) = f(\mathbf{k} + n\Delta\mathbf{k}_s), \tag{97}$$

that are solved using a singular value decomposition approach. These equations have to be set up and solved for each \mathbf{k} separately. From the approximate expression in Eq. (95), we can calculate the derivatives directly,

$$\frac{\partial f(\mathbf{k})}{\partial k_s} \simeq a_1 - b_1 a_0. \tag{98}$$

Finally, we mention an alternative suggestion (Kirtman et al. 2000), i.e., to write

$$\nabla_k \underline{\underline{c}}(\mathbf{k}) = \underline{\underline{c}}(\mathbf{k}) \cdot \underline{\underline{Q}}(\mathbf{k}). \tag{99}$$

Here, all matrix elements of $\underline{\underline{Q}}(\mathbf{k})$ can be determined analytically with a single exception: the imaginary part of the diagonal elements. This exception is due to the fact that the orbital expansion coefficients can be modified by arbitrary phase factors as shown, e.g., in Eq. (91).

For the one-dimensional case, $\frac{dc_{pj}(k)}{dk}$ in Eq. (51) is expressed in terms of the k dependent $\underline{\underline{Q}}$ matrix defined by

$$\frac{dc_{pj}(k)}{dk} = \sum_{j'} c_{pj'}(k) Q_{j'j}(k). \tag{100}$$

Then, using the orthonormality of the crystal orbitals

$$\sum_m e^{ikam} \sum_{pq} c_{qj'}^*(k) \langle \chi_{q0} | \chi_{pm} \rangle c_{pj}(k) = \sum_{pq} c_{qj'}^*(k) S_{qp}(k) c_{pj}(k) = \delta_{jj'}, \tag{101}$$

the current term in Eq. (51) becomes simply

$$\bar{\mu}_{\text{current}} = -\frac{i}{K} \sum_j Q_{jj}(k). \quad (102)$$

From the $\frac{d}{dk}$ derivative of the orthonormality condition in Eq. (101), it follows that

$$Q_{jj}(k) + Q_{jj}^*(k) = -\sum_{pq} c_{qj}^*(k) \frac{dS_{qp}(k)}{dk} c_{pj}(k). \quad (103)$$

This relation yields the real part of the diagonal elements of $Q_{jj}(k)$ but leaves the imaginary part unknown. In fact, the integers \tilde{n}_j of Eq. (55) are determined by the imaginary part of $Q_{jj}(k)$.

Applications

The approach we have sketched above has not yet been applied to a large number of systems or properties. However, some results have been obtained that will be discussed here briefly.

Structure

For the large finite system exposed to an electrostatic field, it is relatively easy to obtain analytical expressions for the forces acting on the nuclei, i.e.,

$$\mathbf{F}_p = -\nabla_p \left[\langle \Psi | \hat{H} - \hat{\mu}_e \cdot \mathbf{E} | \Psi \rangle + \frac{1}{2} \sum_{p_1 \neq p_2} \frac{Z_{p_1} Z_{p_2}}{|\mathbf{R}_{p_1} - \mathbf{R}_{p_2}|} + \sum_p Z_p \mathbf{R}_p \cdot \mathbf{E} \right] \quad (104)$$

with Z_p being the charge of the p th nucleus placed at \mathbf{R}_p and with ∇_p being the gradient operator with respect to the coordinates of the p th nucleus. The last two terms in the square brackets are the contribution of the nuclei to the total energy due to the nuclear-nuclear repulsion and to the electrostatic field, respectively.

For the infinite, periodic system, the electronic dipole moment operator becomes more complicated involving derivatives with respect to \mathbf{k} . Nevertheless, it has become possible to derive analytical expressions for the forces also in this case (Springborg and Kirtman 2008). Thereby, the changes in the structural parameters of a given system due to the electrostatic field can be calculated automatically.

A crucial test of the approach for the infinite, periodic system is to verify that electronic and structural responses of a very large system can be calculated using the infinite-system approach. To that end, we considered the quasi-one-dimensional system of Fig. 10 using a model Hamiltonian. The system contains repeated units of

Fig. 10 Schematic presentation of a linear chain with alternating atoms and bond lengths

Fig. 11 Structural parameters obtained from a set of representative calculations for the model. The *open* and *filled circles* represent values for finite chains with 40/41 units. All other results are for periodic chains with $K = 80$. The finite chain calculations differ from one another by an end-to-end transfer of two electrons. For the periodic chains, \times , *triangles*, *squares*, *stars*, and $+$ mark results for the integer \tilde{n} being equal to 0, 2, -2 , 4, and -4 , respectively. The *straight*, *dashed lines* are linear approximations to the infinite periodic chain values

two different atoms with alternating nearest-neighbor bond lengths. We used a basis set of two functions per atom and parameterized the field-free Fock matrix. Through this approach, it became possible to treat fairly large, finite systems accurately as well as to remove problems due to summations in direct or reciprocal space.

We considered first, for fixed structure, the increment in the total energy of a large finite system upon adding one more diatomic unit:

$$\bar{\mathcal{E}}_{\text{tot}}(E) = \lim_{N \rightarrow \infty} [\mathcal{E}_{\text{tot}}(E, N + 1) - \mathcal{E}_{\text{tot}}(E, N)], \quad (105)$$

Here $\mathcal{E}_{\text{tot}}(E, N)$ is the total energy of the chain containing N units and exposed to an electrostatic field E . As required, the value of this increment was identical to the total energy per cell for the infinite, periodic system.

Of particular interest are the results of Fig. 11 where we show the optimized structures for the large, finite chains and for the infinite, periodic chain as a function of E . For the former, we use the structure of the unit cells in the middle of a chain that is made so large that a regular structure in the middle can be identified.

The figure demonstrates clearly that the two set of calculations lead to identical structural responses. Moreover, by modifying the charge at the terminations for the large finite system, different responses are obtained, a fact that we shall discuss

Fig. 12 Optimized values of the lattice constant, a , and bond-length alternation parameter, u_0 , for the infinite periodic chain as a function of the field, E . The different symbols mark results for different values of \tilde{n}

further in the next subsection. It is most noteworthy that the different periodic chain results can be modeled simply by varying the integer \tilde{n} of Eq. (56). This integer, which at first appears to be related solely to the mathematical formulation is, thereby, given a physical interpretation as well.

In Fig. 12, we show results from another set of model calculations whereby only the periodic system case is treated. In that figure, we can identify higher-order responses to the electrostatic field. Ultimately, the variation in the dipole moment or total energy per unit as a function of field strength can be fit by a power series in E . The coefficients yield the polarizabilities and hyperpolarizabilities, e.g., for the quasi-one-dimensional system, we may write

$$\bar{\mu} = \bar{\mu}^{(0)} + \bar{\alpha}E + \frac{1}{2}\bar{\beta}E^2 + \frac{1}{6}\bar{\gamma}E^3 + \dots, \quad (106)$$

where only the components parallel to the chain have been considered.

One may now distinguish between the electronic and the structural responses which, for instance, can be done theoretically by determining α , β , and γ for the field-free structure (thus giving an estimate for the electronic responses) and by allowing the structure to relax in the presence of the electrostatic field (thus giving the sum of electronic and structural responses).

From the model calculations, we found that the responses were largest for covalently bonded systems with large hopping integrals between neighboring atoms. These systems are also those for which the termination effects (quantified through \tilde{n}) are the largest. Moreover, for the higher-order responses (e.g., β and γ), the structural responses are dominant; they can easily account for 90% of the total.

Finally, we mention that a comparison of computation times for the finite system calculations with those for the periodic system (to obtain the results presented in Fig. 11) reveals that the latter are many (typically, 10) orders faster. From that point of view, then, the use of the infinite periodic system approach is highly recommended.

Converse Piezoelectricity

Piezoelectricity describes the ability of materials (most often, crystals) to produce an electric potential under the influence of an externally applied mechanical stress. For a material that is not short-circuited, the mechanical stress will lead to a separation of opposite electrical charges at opposite crystal surfaces which results in an electric voltage across the material. This effect is reversible in the sense that materials exhibiting the so-called direct piezoelectric effect, i.e., the production of electricity when a stress is applied, also exhibit the converse piezoelectric effect, i.e., the production of stress and/or strain when an electric field is applied. Thus, the results of Figs. 11 and 12 can be considered as manifestations of the converse piezoelectric effect for the systems of interest: upon applying an electrostatic field, the spatial dimension of the system changes. The fact that the figures show several different curves demonstrates that the converse piezoelectric effect depends on the terminations (or, for higher-dimensional systems, on the surfaces) of the system. We shall now discuss this in more detail.

Let us consider the model system of Fig. 10. The total energy per cell relative to that of the optimized structure in the absence of the electrostatic field (i.e., a_0 and u_0) may be approximated via a second-order Taylor expansion in $a - a_0$ and $u - u_0$ and a parameter that describes the external field, λ (λ will later be the field strength itself or the voltage)

$$\begin{aligned} \bar{\mathcal{E}}_{\text{tot}} \simeq & (a - a_0) \frac{\partial \bar{\mathcal{E}}_{\text{tot}}}{\partial a} + (u - u_0) \frac{\partial \bar{\mathcal{E}}_{\text{tot}}}{\partial u} + \lambda \frac{\partial \bar{\mathcal{E}}_{\text{tot}}}{\partial \lambda} + \frac{1}{2} (a - a_0)^2 \frac{\partial^2 \bar{\mathcal{E}}_{\text{tot}}}{\partial a^2} \\ & + \frac{1}{2} (u - u_0)^2 \frac{\partial^2 \bar{\mathcal{E}}_{\text{tot}}}{\partial u^2} + (u - u_0)(a - a_0) \frac{\partial^2 \bar{\mathcal{E}}_{\text{tot}}}{\partial u \partial a} + \frac{1}{2} \lambda^2 \frac{\partial^2 \bar{\mathcal{E}}_{\text{tot}}}{\partial \lambda^2} \\ & + \lambda (a - a_0) \frac{\partial^2 \bar{\mathcal{E}}_{\text{tot}}}{\partial \lambda \partial a} + \lambda (u - u_0) \frac{\partial^2 \bar{\mathcal{E}}_{\text{tot}}}{\partial \lambda \partial u}. \end{aligned} \quad (107)$$

We use the fact that

$$\frac{\partial \bar{\mathcal{E}}_{\text{tot}}}{\partial a} = \frac{\partial \bar{\mathcal{E}}_{\text{tot}}}{\partial u} = 0 \quad (108)$$

at the equilibrium structure in the field-free case and the same conditions for $\lambda \neq 0$ to find the optimized structure in the presence of a DC field. This yields

$$\begin{aligned} (a - a_0) \frac{\partial^2 \bar{\mathcal{E}}_{\text{tot}}}{\partial a^2} + \lambda \frac{\partial^2 \bar{\mathcal{E}}_{\text{tot}}}{\partial \lambda \partial a} + (u - u_0) \frac{\partial^2 \bar{\mathcal{E}}_{\text{tot}}}{\partial u \partial a} &= 0 \\ \lambda \frac{\partial^2 \bar{\mathcal{E}}_{\text{tot}}}{\partial \lambda \partial u} + (a - a_0) \frac{\partial^2 \bar{\mathcal{E}}_{\text{tot}}}{\partial u \partial a} + (u - u_0) \frac{\partial^2 \bar{\mathcal{E}}_{\text{tot}}}{\partial u^2} &= 0 \end{aligned} \quad (109)$$

where all derivatives are taken at $u = u_0$, $a = a_0$, and $\lambda = 0$.

The solution of the linear simultaneous equations in Eq. (109) leads to expressions for a macroscopic, converse piezoelectric coefficient,

$$\eta = \left. \frac{da}{d\lambda} \right|_{\lambda=0} \quad (110)$$

as well as an “internal” converse piezoelectric coefficient for the internal degree of freedom,

$$\zeta = \left. \frac{du}{d\lambda} \right|_{\lambda=0}. \quad (111)$$

The result is

$$\begin{aligned} \eta &= \left[\frac{\partial^2 \bar{\mathcal{E}}_{\text{tot}}}{\partial \lambda \partial u} \frac{\partial^2 \bar{\mathcal{E}}_{\text{tot}}}{\partial u \partial a} - \frac{\partial^2 \bar{\mathcal{E}}_{\text{tot}}}{\partial \lambda \partial a} \frac{\partial^2 \bar{\mathcal{E}}_{\text{tot}}}{\partial u^2} \right] \cdot \left[\frac{\partial^2 \bar{\mathcal{E}}_{\text{tot}}}{\partial a^2} \frac{\partial^2 \bar{\mathcal{E}}_{\text{tot}}}{\partial u^2} - \left(\frac{\partial^2 \bar{\mathcal{E}}_{\text{tot}}}{\partial u \partial a} \right)^2 \right]^{-1} \\ \zeta &= \left[\frac{\partial^2 \bar{\mathcal{E}}_{\text{tot}}}{\partial \lambda \partial a} \frac{\partial^2 \bar{\mathcal{E}}_{\text{tot}}}{\partial u \partial a} - \frac{\partial^2 \bar{\mathcal{E}}_{\text{tot}}}{\partial a^2} \frac{\partial^2 \bar{\mathcal{E}}_{\text{tot}}}{\partial \lambda \partial u} \right] \cdot \left[\frac{\partial^2 \bar{\mathcal{E}}_{\text{tot}}}{\partial a^2} \frac{\partial^2 \bar{\mathcal{E}}_{\text{tot}}}{\partial u^2} - \left(\frac{\partial^2 \bar{\mathcal{E}}_{\text{tot}}}{\partial u \partial a} \right)^2 \right]^{-1}. \quad (112) \end{aligned}$$

We are interested in separating the contributions to η and ζ that arise from the charges at the terminations, cf. Eq. (11) from those that do not. To that end, the dipole moment per unit for the infinite, periodic system may be written as

$$\bar{\mu}_z = \bar{\mu}_{z0} + \tilde{n}a. \quad (113)$$

Thus, the first-order (linear in E) contribution to the total energy per unit for the infinite, periodic system exposed to an electrostatic field becomes

$$\bar{\mathcal{E}}_{\text{DC}} = E\bar{\mu}_{z0} + E\tilde{n}a. \quad (114)$$

At this point, we take

$$\lambda = E. \quad (115)$$

Then, in Eq. (112), all quantities except for

$$\frac{\partial^2 \bar{\mathcal{E}}_{\text{tot}}}{\partial \lambda \partial a} = \frac{\partial^2 \bar{\mathcal{E}}_{\text{tot}}}{\partial E \partial a} = \frac{\partial \bar{\mu}_{z0}}{\partial a} + \tilde{n} \quad (116)$$

are independent of the charges at the termination. In that case, the coefficients in Eq. (112) may be separated into terms that depend on \tilde{n} and terms that do not,

$$\begin{aligned} \eta &= \eta_0 + \tilde{n}\eta_1 \\ \zeta &= \zeta_0 + \tilde{n}\zeta_1 \end{aligned} \tag{117}$$

where

$$\begin{aligned} \eta_0 &= \left[-a \frac{\partial P_0}{\partial u} \frac{\partial^2 \bar{\mathcal{E}}_{\text{tot}}}{\partial u \partial a} + \left(P_0 + a \frac{\partial P_0}{\partial a} \right) \frac{\partial^2 \bar{\mathcal{E}}_{\text{tot}}}{\partial u^2} \right] \cdot \left[\frac{\partial^2 \bar{\mathcal{E}}_{\text{tot}}}{\partial a^2} \frac{\partial^2 \bar{\mathcal{E}}_{\text{tot}}}{\partial u^2} - \left(\frac{\partial^2 \bar{\mathcal{E}}_{\text{tot}}}{\partial u \partial a} \right)^2 \right]^{-1} \\ \zeta_0 &= \left[- \left(P_0 + a \frac{\partial P_0}{\partial a} \right) \frac{\partial^2 \bar{\mathcal{E}}_{\text{tot}}}{\partial u \partial a} + \frac{\partial^2 \bar{\mathcal{E}}_{\text{tot}}}{\partial a^2} a \frac{\partial P_0}{\partial u} \right] \cdot \left[\frac{\partial^2 \bar{\mathcal{E}}_{\text{tot}}}{\partial a^2} \frac{\partial^2 \bar{\mathcal{E}}_{\text{tot}}}{\partial u^2} - \left(\frac{\partial^2 \bar{\mathcal{E}}_{\text{tot}}}{\partial u \partial a} \right)^2 \right]^{-1} \\ \eta_1 &= \frac{\partial^2 \bar{\mathcal{E}}_{\text{tot}}}{\partial u^2} \cdot \left[\frac{\partial^2 \bar{\mathcal{E}}_{\text{tot}}}{\partial a^2} \frac{\partial^2 \bar{\mathcal{E}}_{\text{tot}}}{\partial u^2} - \left(\frac{\partial^2 \bar{\mathcal{E}}_{\text{tot}}}{\partial u \partial a} \right)^2 \right]^{-1} \\ \zeta_1 &= - \frac{\partial^2 \bar{\mathcal{E}}_{\text{tot}}}{\partial u \partial a} \cdot \left[\frac{\partial^2 \bar{\mathcal{E}}_{\text{tot}}}{\partial a^2} \frac{\partial^2 \bar{\mathcal{E}}_{\text{tot}}}{\partial u^2} - \left(\frac{\partial^2 \bar{\mathcal{E}}_{\text{tot}}}{\partial u \partial a} \right)^2 \right]^{-1} \end{aligned} \tag{118}$$

with

$$P_0 = \frac{\bar{\mu}}{a} \tag{119}$$

being the polarization, i.e., dipole moment per length (in three dimension, dipole moment per volume).

Alternatively, one may let λ be the potential drop over one unit cell,

$$\lambda = V = Ea, \tag{120}$$

whereby

$$\begin{aligned} \frac{\partial^2 \bar{\mathcal{E}}_{\text{tot}}}{\partial \lambda \partial a} &= \frac{\partial^2 \bar{\mathcal{E}}_{\text{tot}}}{\partial (aE) \partial a} \\ &= \frac{\partial}{\partial a} \left[\frac{-\bar{\mu}_z}{a} + \frac{1}{E} \frac{\partial \bar{\mathcal{E}}_{\text{tot}}}{\partial a} \right] \\ &= \frac{\bar{\mu}_{z0}}{a^2} - \frac{1}{a} \frac{\partial \bar{\mu}_{z0}}{\partial a} + \frac{1}{E} \frac{\partial^2 \bar{\mathcal{E}}_{\text{tot}}}{\partial a^2}, \end{aligned} \tag{121}$$

which is independent of \tilde{n} . Thus, in this case, the converse piezoelectric coefficient is independent of surface charges. Finally, we add that the straight, dashed lines in Fig. 11 were obtained using the expressions of Eqs. (110), (111), and (112).

The results of the model calculations suggest that the converse piezoelectric effect contains a non-negligible contribution from the surface charges. However, the model was not designed to represent any real system, and, accordingly, it is possible that this contribution is overestimated. It is, therefore, relevant to study a real material.

For that purpose, the so-called layered perovskites $R_2Ti_2O_7$ with R being Sm or Gd (Sayede et al. 2012) were considered. Although these systems possess many structural parameters, we reduced these to the two that are closely related to the spontaneous polarization (i.e., the permanent dipole moment per unit volume) that these materials possess. One of the two parameters is the lattice constant, a , in the direction of the spontaneous polarization, and the other, u , describes the distortion from the centrosymmetric structure at which the spontaneous polarization would vanish. All other structural parameters were relaxed to the optimized field-free value for a given a and u . For further details of the calculations, please consult Sayede et al. (2012).

Assuming that the second-order expansion on the right-hand side of Eq. (107) is sufficiently accurate in this case as well, one can calculate all required quantities approximately from the total energy and dipole moment per cell as functions of a and u using finite-difference approximations (see Sayede et al. 2012). The results for the (converse) piezoelectric parameters in Eq. (117) are $\eta_0 = 9.9$ (7.9) 10^{-10} (V/cm) $^{-1}$ and $\eta_1 = -7.5$ (-7.0) 10^{-11} [V/cm/(surface cell)] $^{-1}$ for R = Sm (R = Gd). Even if these numbers should be taken with some caution due to the finite-difference approximations involved in their determination, they do indicate a non-negligible effect of the surfaces. In practice, η_1 must be multiplied by the number of electrons per surface unit cell that are transferred from one surface to its opposite due, for example, to chemical modifications. For a transfer of ± 2 electrons/(surface cell), these results correspond to a change in the converse piezoelectric coefficient of about 20 % which is an effect that should be detectable experimentally.

Our treatment above can easily be generalized to the higher-dimensional case with several structural degrees of freedom. We shall assume that the number of atoms of the periodically repeated unit remains unchanged in the presence of the external field, although both the lattice vectors and the internal structural parameters may vary. The DC field vector is described by (E_1, E_2, E_3) . Let us assume that we have optimized the field-free structure. The lattice vectors for this structure can be described through six parameters $\{a_{i0}\}$, and the values of the internal structural degrees of freedom are $\{u_{n0}\}$. As before, we expand the total field-dependent energy, \mathcal{E} , around the field-free optimized structure (and zero field) as a function of geometry and field keeping terms only through second order,

$$\begin{aligned}
\bar{\mathcal{E}}_{\text{tot}} \simeq & \sum_i (a_i - a_{i0}) \frac{\partial \bar{\mathcal{E}}_{\text{tot}}}{\partial a_i} + \sum_n (u_n - u_{n0}) \frac{\partial \bar{\mathcal{E}}_{\text{tot}}}{\partial u_n} + \sum_k E_k \frac{\partial \bar{\mathcal{E}}_{\text{tot}}}{\partial E_k} \\
& + \frac{1}{2} \sum_{ij} (a_i - a_{i0})(a_j - a_{j0}) \frac{\partial^2 \bar{\mathcal{E}}_{\text{tot}}}{\partial a_i \partial a_j} + \frac{1}{2} \sum_{nm} (u_n - u_{n0})(u_m - u_{m0}) \frac{\partial^2 \bar{\mathcal{E}}_{\text{tot}}}{\partial u_n \partial u_m} \\
& + \sum_i \sum_n (u_n - u_{n0})(a_i - a_{i0}) \frac{\partial^2 \bar{\mathcal{E}}_{\text{tot}}}{\partial u_n \partial a_i} + \frac{1}{2} \sum_{kl} E_k E_l \frac{\partial^2 \bar{\mathcal{E}}_{\text{tot}}}{\partial E_k \partial E_l} \\
& + \sum_k \sum_i E_k (a_i - a_{i0}) \frac{\partial^2 \bar{\mathcal{E}}_{\text{tot}}}{\partial E_k \partial a_i} + \sum_k \sum_n E_k (u_n - u_{n0}) \frac{\partial^2 \bar{\mathcal{E}}_{\text{tot}}}{\partial E_k \partial u_n}. \quad (122)
\end{aligned}$$

In this case, the quantities $\frac{\partial^2 \bar{\mathcal{E}}_{\text{tot}}}{\partial E_k \partial a_i}$ will depend on the surface charges. However, for the higher-dimensional systems, this dependence is not through an additive lattice vector, but the additional contribution to the dipole moment per cell can take any value (cf. section ‘‘Higher Dimensions’’). Thereby, it becomes very difficult to compare calculated and measured values.

The Vector Potential and Time-(In)dependent Fields

As discussed in section ‘‘The Vector Potential Approach’’, it is also possible to use the vector potential approach, Eq. (86), for the effects of a homogeneous electrostatic field. With that approach, there is the added advantage that homogeneous, dynamic electric fields fall under the same rubric. Kirtman and coworkers have, in fact, presented a treatment for the linear and nonlinear frequency-dependent electronic responses of quasi-1D systems (Kirtman et al. 2000) based on the coupled perturbed Hartree-Fock method (CPHF). The extension to 2D and 3D systems, as well as to coupled perturbed Kohn-Sham (CPKS) time-dependent DFT, can readily be accomplished in the same way as it has already been done for the static responses (Ferrero et al. 2009; Orlando et al. 2010a, b). Indeed, an implementation in the CRYSTAL computer code (Dovesi et al. 2014) is currently well underway.

DFT Catastrophe

Finally, we shall discuss briefly an issue where the approach outlined here has given additional information. When carrying through a parameter-free electronic structure calculation, one may use either a wave function (e.g., Hartree-Fock, Møller-Plesset, CI, etc.) or density-based (Kohn-Sham) approach. In the latter case, one has to apply some approximate functional of the electron density to describe exchange and correlation effects.

It turns out that when calculating the linear and nonlinear responses to electrostatic fields [i.e., $\bar{\alpha}$, $\bar{\beta}$, $\bar{\gamma}$, ... of Eq. (106)] for large, finite, oligomers, the values obtained are much larger when applying density-functional methods with present commonly used functionals than what is found when using Hartree-Fock and beyond wave function approaches (Champagne et al. 1998, 2000). Moreover, this overestimate increases dramatically with increasing chain length, occurs for higher-dimensional systems as well, and is larger for the higher-order responses. These problems of the density-functional calculations have been called the “DFT catastrophe.”

If one is interested in obtaining the thermodynamic limit, it is essential that sufficiently large systems are considered so that the systems contain a central region of identical, neutral unit cells. As we have found in our model calculations, this requirement often implies that finite chains of some 50 units are treated. For higher-dimensional systems, this number becomes correspondingly larger.

By having an approach for treating the infinite, periodic system exposed to an electrostatic field, it is possible to treat the thermodynamic limit directly. Moreover, the formulation of the responses to the field is different for the infinite, periodic system than for the large, finite system, although, of course, the same numerical values must be obtained in the two cases.

Using a simple model system, we were able to study both the large, finite system and the infinite, periodic system both with Hartree-Fock and with density-functional calculations (Vargas et al. 2014). The approach allowed us also to decompose the responses into cell contributions, whereby it could be seen that the higher-order responses were more delocalized. Moreover, the results suggested that so-called range-separated density-functional methods, despite a large sensitivity to the range separation parameter, could be those that will be able to remove (the largest parts of) the DFT catastrophe. However, further improvements are necessary considering some of the weaknesses that have already been identified (Bulik et al. 2013; Kirtman et al. 2008).

Conclusions

In this overview, we have described our current understanding of how to treat large, regular systems that are exposed to electrostatic fields. Such systems are best treated as being infinite and periodic, and we demonstrated that, even when the electrostatic fields are included, it is possible to derive a formulation where the translational symmetry is retained. However, the formulation is not trivial and involves operators that contain derivatives with respect to the k -vector. Consequently, special techniques had to be developed in order to calculate directly the responses – particularly, the dipole moment and related properties – to electrostatic fields.

An interesting feature is that the responses of the large, finite systems depend on the surfaces/terminations. Although these are not explicitly included in the infinite, periodic systems, their effects are nevertheless accessible in periodic system calculations. Here, however, an open issue remains: it is possible to understand that

different, periodic systems correspond to modeling samples of different shape, but it is not (yet) possible to describe precisely how a given shape can be described within the infinite, periodic system treatment.

Although our work has revealed a number of interesting, fundamental aspects, it is also highly relevant to apply our approach to real materials in order to determine their linear and nonlinear, electronic, and structural responses to electrostatic fields. Therefore, we are planning to implement our approach in established computer programs so that it can be broadly applied.

Acknowledgements The work has benefited from financial support through the German Research Council (DFG). Moreover, one of the authors (MS) is very grateful to the International Center for Materials Research, University of California, Santa Barbara, for generous hospitality. Finally, this work has benefited from collaborations with Emilie Bruyer, Yi Dong, Mauro Ferrero, Michel Rérat, Adlane Sayede, Violina Spurk (née Tevekeliyska), Jorge Vargas, Lorenzo Maschio, Roberto Orlando, and Roberto Dovesi.

Abstract

Materials properties show a dependence on the dimensionality of the systems studied. Due to the increased importance of surfaces and edges, lower-dimensional systems display behavior that may be widely different from their bulk counterparts. As a means to complement the newly developed experimental methods to study these reduced dimensional systems, a large fraction of

the theoretical effort in the field continues to be channeled toward computer simulations. This chapter reviews briefly the computational methods used for the low-dimensional materials and presents how the materials properties change with dimensionality. Low-dimensional systems investigated are classified into a few broad classes: 0D nanoparticles, 1D nanotubes, nanowires, nanorods, and 2D graphene and derivatives. A comprehensive literature will guide the readers' interest in computational materials sciences.

Introduction

Hierarchy of Methods

Methods for materials modeling are based on the particular length and time scales used for the investigation of various materials properties that operate only over those scales. This has led to basically four independent methodological streams, which may be categorized as ab initio density functional theory, molecular dynamics, statistical methods based on Monte Carlo algorithms, and continuum mechanics (see Fig. 1 for the ranges of them). Each of these is computationally intensive within its own range. However, the expanding capabilities of computational methods due to the increasing power of computers and continuing development of efficient algorithms, together with advances in the synthesis, analysis, and visualization of

Fig. 1 Ranges of scales used for different methods in materials properties (Adapted from Vvedensky 2004)

materials at increasingly finer spatial and temporal resolutions, have spawned a huge effort in the modeling of materials phenomena.

Since the materials properties are directly related with the dimensionality of materials, particularly at the nanoscale, it would be better to classify the methods of modeling of nanostructures with respect to the dimensionality, such as zero-dimensional (0D), one-dimensional (1D), two-dimensional (2D), and three-dimensional (3D) materials. At the nanoscale the first three dimensionalities (0D, 1D, 2D) are commonly used, but the 3D materials are usually considered as macroscopic systems; therefore those materials are not the subject of this chapter.

0D Structures: Nanoparticles

The class of nanomaterials that may be termed *zero-dimensional* comprises systems that are confined within up to several hundreds of nanometers in all three dimensions. Although there exists no clear-cut size threshold at which a system switches from a zero-dimensional system to bulk, there is a rather well-defined class of systems that fit the above definition with unique and intriguing properties. The most commonly studied zero-dimensional systems are *quantum dots*, *nanoparticles* (or *clusters*), and *cage-like structures*. In this section, we shall begin with an overview of methods used to study such materials.

After the 1980s, the field of nanoparticles/Clusters has seen increasing activity. The results of these studies and their applications have been collected in several reviews (Balasubramanian 1990; Baletto and Ferrando 2005; Bonacic-Koutecky et al. 1991; Brack 1993; de Heer 1993; Halicioglu and Bauschlicher 1988; Morse 1986; Ustunel and Erkoc 2007; Weltner and Van Zee 1984; Oymak and Erkoc 2012). Studies on clusters have been concentrated on such diverse applications as catalysis, chemisorption and substrate adsorption, laser applications, magnetism, nucleation, photographic processes, and reactivity.

The term *cluster* may, in the broadest sense, be defined as an aggregate of atoms or molecules that form a size regime between molecules and bulk materials. It is far from a straightforward task to define the range of number of atoms which constitute a cluster. In contrast to their bulk counterparts, structural and electronic properties of clusters display a rather strong dependence on size and geometric configuration due to their large surface-to-volume ratio. Thus in order to understand the properties of clusters, a careful determination of the equilibrium structure is crucial. In general, the equilibrium geometry is determined by locating the global minimum of the *potential energy surface* (PES) of a cluster, which in principle can be mapped out by calculating the total energy as a function of all possible locations of the atoms. Unfortunately even the smallest clusters often have extremely complicated potential energy surfaces with practically countless local minima. This requires a thorough search over the entire PES for a realistic determination of the equilibrium structure (Farrow et al. 2014).

An added complication to the difficulty of determining the global minima is that clusters with different but similar sizes of the same material may present PESs that

are entirely different. It is likely then that the equilibrium shape of a cluster of a given material and size is significantly different from a different size cluster of the same material. Fortunately, some similarities may be found in the vast number of possible structures. Mass spectroscopy of clusters reveals that certain sizes of clusters are preferred over others, indicated by the high abundance detected (Martin 1996). The number of atoms or molecules in a preferred cluster is commonly referred to as a *magic number*. The origin of a magic number may be the completion of a *geometric* or an *electronic* shell of the cluster. The particular geometric or electronic shell being completed obviously depends upon the constituents of the clusters and the bonding between them. For instance, noble gases are found in polyhedral form, whereas metallic clusters prefer cubic or prolate structures (Johnston 2002). The search for magic numbers has been the subject of a very large number of works (Anagnostatos 1987; Balasubramanian 1990; Bonacic-Koutecky et al. 1991; Haberland 1994; Jarrold and Constant 1991; Moraga 1993; Yang et al. 2006).

In order to map out the energy landscape of nanoparticles, an adequate model for the interatomic interactions within the cluster needs to be employed. Empirical potentials, the tight-binding approximation, and density functional theory whose brief description has been given in previous sections are the most commonly used methods in literature. While empirical potentials (Erkoc 1997, 2001a) offer an efficient means of exploring the PES and determining the equilibrium structure of large clusters, calculations based on the tight-binding approximation and density functional theory are preferred for more accurate and detailed description of geometrical and electronic properties of small- to medium-sized clusters.

Once the method of choice is determined for interatomic interactions, the corresponding potential energy surface may be explored using *global search algorithms* to determine the lowest lying minima. A concise review of global optimization methods is given in the reviews (Baletto and Ferrando 2005; Dugan and Erkoc 2009; Wales and Doye 1997; Erkoc et al. 2003; Catlow et al. 2010). Here, we shall briefly describe a few of them.

The *basin-hopping algorithm* (Wales and Doye 1997) belongs to a class of optimization methods called *hypersurface deformation methods*. These methods aim to simplify the PES by applying a map that smooths it out. The global minimum of the simplified PES is then mapped back to that of the real PES assuming that it leads back to the global minimum of the real PES. In the basin-hopping algorithm, the original, complicated PES, $U(\vec{r})$, is transformed onto a steplike function $\tilde{U}(\vec{r})$ according to the rule (Baletto and Ferrando 2005; Wales and Doye 1997).

$$\tilde{U}(\vec{r}) = \min [U(\vec{r})], \quad (1)$$

where the min function implies that a local minimization is to be applied such as the conjugate gradients algorithm (Hestenes and Stiefel 1952).

In many of the cluster applications using basin hopping (Bromley and Flikkema 2005; Doye and Wales 1999; Hsu and Lai 2006; Wales and Doye 1997), this transformed PES is sampled with a Monte Carlo algorithm, sometimes with a fixed acceptance (Wales and Doye 1997).

The second method we shall mention is *the simulated annealing method* (Kirkpatrick et al. 1983), in which the system is evolved at high temperature and then gradually cooled down. Assuming that the system does not get trapped in a basin of attraction which is not the minimum, it reaches the state of lowest energy during the cooling process. Attempts to use simulated annealing to find the global energy minimum in larger systems are frustrated by high-energy barriers that trap the system in metastable configurations (Ma and Wang 2006).

Finally, we briefly describe a class of algorithms that has recently gained popularity, namely, *genetic algorithms*. Genetic algorithms (GAs) are based on ideas borrowed from natural evolution. As explained in Darby and coworkers (2002), they employ operators that are analogues of the evolutionary processes of genetic crossover, mutation, and natural selection. A GA can be applied to any problem where the variables to be optimized can be encoded to form a string, each string representing a trial solution to the system. In cluster terminology each *string* is a list of coordinates of a cluster. An initial number of clusters are chosen according to some generation scheme (usually random) and locally minimized.

After the creation of the initial generation of strings, each member of this generation is assigned a *fitness parameter* based on a fitness function. In Darby and coworkers (2002), for example, this function was chosen to be the negative exponent of the deviation of the total energy of each cluster from the cluster with minimum energy.

Once a fitness parameter is assigned to each member of the population, a new generation is created: Two *parents* are chosen from members with high fitness parameter for each *offspring* (member of the new generation) and then subjected to the *crossover* operation. A crossover operation for clusters consists of a particular rearrangement and combination of the atomic coordinates in the parent clusters. For an example, see Darby and coworkers (2002). After each new cluster is generated, a local minimization is performed. Mating continues in this way until the desired number of offsprings are generated. New fitness parameters are assigned to each offspring. In order to maintain diversity, new genetic material is introduced into the population by means of the *mutation* operator. After mutation in a cluster population, clusters are once again locally minimized.

Finally the next generation is completed by applying *natural selection*. The previous generation and the new generation are ranked in order of fitness and the best N individuals (clusters) are chosen, where N is the population of the original population. These N individuals constitute the new generation, and mating is performed again.

The process of mating, mutation, and selection is repeated for a predetermined number of generations or until a given criterion is reached. This criterion could be, for example, the convergence of the highest fitness to a plateau so that consecutive generations do not produce better results.

Other global search algorithms include parallel random tunneling, conformational space annealing, greedy search method, simulated annealing, quantum annealing, smoothing and hypersurface deformation techniques, lattice methods, growth sequence analysis, and replica exchange method (Oymak and Erkoc 2004).

Global Optimization with Empirical Potentials

In spite of the wealth of information they provide, global search algorithms ordinarily fail to identify all the minima of a given cluster. The best explored potential surface for clusters belongs to possibly the simplest empirical potential, namely, the Lennard-Jones potential. The Lennard-Jones potential is a simple model that captures the long- and short-range behavior of atoms and molecules. It was proposed in 1931 by Lennard-Jones (1931) and has been used in innumerable studies ever since. It has the following simple form

$$V(r) = 4\epsilon \left[\left(\frac{\sigma}{r} \right)^{12} - \left(\frac{\sigma}{r} \right)^6 \right] \quad (2)$$

where ϵ and σ are parameters that determine the depth and the width of the potential well, respectively, and r is the interatomic distance between atom pairs.

The four known structural forms for the LJ potential are (Hartke 2002) as seen in Fig. 2:

1. Icosahedral: formed by starting from the pentagonal bipyramid and adding a further layer of atoms

Fig. 2 The four basic structures of Lennard-Jones clusters (Reprinted with permission from Hartke (2002). © (2002) by Wiley-VCH Verlag GmbH & Co. KGaA)

2. Decahedral: icosahedral core surrounded by fcc stacks
3. Tetrahedral: tetrahedron of atoms in the innermost core
4. Face-centered cubic: sections of the fcc bulk structure

For $N < 1,000$, Lennard-Jones clusters follow an icosahedral pattern growth with magic numbers corresponding to *Mackay icosahedra* (Mackay 1962) for $N = 13, 55, 147, 309$, etc. In between these magic numbers, most of the structures are Mackay-like with incomplete outer layers. Exceptions occur when there are alternative structures with complete shells. These are mostly Marks decahedra (Doye 2003), but there are instances of an fcc truncated octahedron and a Leary tetrahedron (Noya and Doye 2006). The preference for icosahedral structures of Lennard-Jones clusters at small sizes is thought to be due to a trade-off between optimal bond distance and strain (Hartke 2002; Krainyukova 2006).

In spite of its simplicity, the Lennard-Jones potential may not be used for accurate description of cluster properties with the possible exception of noble gas clusters. Often empirical potentials that involve a larger number of parameters than the two-parameter Lennard-Jones potential are employed for structural determination (Farrow et al. 2014).

To understand their behavior at finite temperature, Wu and coworkers studied Zn clusters using the Gupta potential by means of molecular dynamics (Wu et al. 2005). Zn clusters are found to display peculiar structures that are very different from other sp-type metal clusters. The $N = 13$ cluster, for instance, has a disordered structure instead of the icosahedral structure found in most metals of the same size. The C_v curve also differs in that it has a double peak structure, whereas icosahedral structures display a single peak. The ΔE_2 study in Wu et al. (2005) reveals that magic structures are found at $N = 6, 13, 29, 33, 36, 42, 49$, and 53.

In a study by Rey and coworkers (1993), several transition metal clusters (Ni, Pd, Au, and Ag) were studied using different model potentials. Three different *embedded atom models* (EAM) and two different parameterizations of an N-body analytical potential were considered. For Ni clusters, although the binding energies provided by the various models showed differences, the peak stability was obtained for all the models at $N = 13$ (icosahedron) and $N = 19$ (double icosahedron). In this work (Rey et al. 1993), earlier experiments on large Ni clusters ($N = 49$ –2300) are also quoted where icosahedral growth was observed. For Ni the EAM that was fitted to bulk values (EAM1) gave poorer results than the one fitted to diatomic values. For Pd, Au, and Ag, only EAM1 and one of parameterizations of the analytical potential (TBM1) were compared. EAM1 failed to yield enhanced stability for $N = 13$ and $N = 19$, while TBM1 mostly gave icosahedral structures for both sizes. This shows the importance of parameterization for the accuracy of the model potentials.

In a recent study by Doye (2006), results for Pb clusters were calculated and compared for the Gupta potential and a glue potential in combination with a basin-hopping algorithm. Within the Gupta potential framework, Pb clusters, in contrast to Si, Ge, and Sn, do not show any tendency to form prolate or oblate structures. Their structures are mostly spherical with decahedra being the most favored structure

followed by close packed. This study also presents an interesting comparison between the Gupta potential and the glue potential, which reveals that there is virtually no agreement between the two potentials neither in the magic numbers nor in the resulting structures. This sharp discrepancy demonstrates that one should be very careful while comparing results from different methods. More disordered structures are favored for the glue potential than the Gupta potential because the embedding term dominates for the latter.

An interesting result from the work of Doye (2006) is that for the Gupta potential, the uncentered Mackay icosahedron with $N = 54$ is more stable than the complete $N = 55$ Mackay icosahedron. This is because of the strain applied by the external atoms on the center, making it unfavorable to be occupied.

As a final remark on empirical potentials, we note that the particular parameterization of the potential plays a crucial role in correctly identifying structural properties, and caution should therefore be used in interpreting results for empirical potentials. For instance, according to Michaelian et al. (1999), the global minima of Au clusters are difficult to localize because of the short range of the Au potential. As the range of a potential decreases, the number of global minima associated with the potential increases. As a result of this, different studies have identified different global minima for Au clusters. In addition different potential models for the metal yield different ordering of the lowest lying minima.

Local Optimization with Higher Accuracy Methods

Outside of the domain of simple empirical potentials, identifying the global minima of cluster PESs becomes a prohibitively demanding task. Therefore, most studies on the theoretical determination of cluster minima employ methods that either focus on local minima obtained through an adequate initial guess or a mixture of global search algorithms with simple potentials to reduce the number of minima followed by local minimization techniques that are more accurate.

The majority of elements, regardless of whether they prefer atomic shells or electronic shells, form clusters that are more or less spherical. The only elements that deviate from this behavior are the group IVA elements. This is especially remarkable in carbon, which goes from linear chains all the way to fullerenes. Clusters of Si and Ge first grow in one dimension and then abruptly change to form spherical clusters (Shvartsburg and Jarrold 1999). Some similarities exist between the growth patterns of Si and Ge cluster but major differences also occur especially concerning the size at which transition to bulk-like structures takes place (Shvartsburg and Jarrold 1999).
